Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Lloyd Hollingsworth (Holly) Smith, Jr., MD Fred Plum, MD (Deceased)

This ninth edition of Andreoli and Carpenter's Cecil Essentials of Medicine had as its progenitor Cecil Essentials of Medicine. The idea for Essentials was originally conceived in the mid-1980s by Holly Smith and by Fred Plum. At the time, Charles C.J. (Chuck) Carpenter and I were Consulting Editors for The Cecil Textbook of Medicine for Infectious Diseases and Nephrology, respectively. Holly and Fred entrained the two of us into participating in a new venture that, happily, has become a successful force in Internal Medicine. The entire idea was to make Internal Medicine accessible in a compact but critical format to medical students, residents, and other practitioners of medicine. It is a privilege to pay tribute to Holly and Fred by dedicating this ninth edition of Essentials to them.

Lloyd H. Smith, Jr., MD

Dr. Smith, universally known as Holly Smith, is one of the true giants of academic medicine. A thoroughly engaging and courtly Southern gentleman, Holly was educated at Washington and Lee University, where he received a bachelor's degree, summa cum laude, in 1944. He then went north to Harvard Medical School where, in 1948, he received his MD, magna cum laude.

Following his residency in internal medicine at the Massachusetts General Hospital, Holly joined the Army Medical Corps where he provided, among other clinical activities, early dialysis in soldiers afflicted with epidemic hemorrhagic fever in the Korean Conflict. Investigatively, Holly's work was an exemplar for the early beginnings of molecular biology. In particular, he found that there was a double enzyme defect in a rare genetic disorder, orotic aciduria. Subsequently, working with Hibbard Williams, he discovered the enzyme defects of two distinct forms of primary hyperoxaluria.

One can see from the above narrative that Holly excelled in clinical medicine and in research. But perhaps his most powerful impact on internal medicine was his acceptance of the position as chair of internal medicine at the University of California, San Francisco, which he held from 1964 through 1985. He is now a professor of medicine and associate dean emeritus at UCSF. Holly's contribution as chair of internal medicine at UCSF was, in a word, dazzling. He developed a faculty that is peerless among departments of internal medicine in the United States. Following his tenure as chair of internal medicine at UCSF, Holly became associate dean, a position he held between 1985 and 2000, where his exceptional administrative talents provided a major impetus to the further expansion of UCSF.

For his contributions, Holly has been recognized as the president of virtually all the major societies in internal medicine, including the American Society for Clinical Investigation (1969), the Association of American Physicians (1975), and the Association of Professors of Medicine (1978). He has received the George M. Kober Medal from the Association of American Physicians, as well as membership in the American Academy of Arts and Sciences and the Institute of Medicine of the National Academy of Sciences.

Fred Plum, MD (Deceased)

Fred Plum, attending neurologist at New York Presbyterian Hospital and university professor at Weill Medical College of Cornell University, was, together with Holly Smith, one of the two progenitors of Essentials. Fred was a truly remarkable individual who had an exceptional mastery of the neurologic sciences, both basic and clinical. One could hardly imagine two more different personalities than Holly and Fred. As I mentioned above, Holly is a classic Southern gentleman. Fred was born and raised in Atlantic City, New Jersey, and carried with him the charming but demanding characteristics of a resident of that city.

Fred trained in medicine and neurology at New York Hospital and at the neurologic division of Bellevue Hospital. Subsequently, he became an instructor in medicine at Cornell University Medical College, then an assistant professor, associate professor, and professor of medicine (neurology) at the University of Washington School of Medicine, all between 1953 and 1963. In 1963, Fred became the Anne Parrish Titzell Professor and Chair of the Department of Neurology at Cornell University Medical College, a position he held for 31 years. After stepping down as chairman of neurology, he was recognized for his remarkable accomplishments by having been made a university professor at Weill Medical College of Cornell University in 1998.

Fred was a member of virtually all distinguished societies in internal medicine and in neurology. He held honorary doctorates from at least two medical schools, including the Karolinska Institute in Stockholm.

Fred was not only a spectacular clinician but an extraordinary teacher. His textbook, Diagnosis of Stupor and Coma, written together with J.B. Posner, is one of the classics of its field.

Fred, like Holly, recognized in the mid-1980s the need for providing a textbook which was sufficiently concise yet comprehensive to be usable by students, house staff, young physicians, and physicians outside his own discipline of neurology. I remember particularly well the editorial meetings in the early years of Essentials, involving Fred, Holly Smith, Chuck Carpenter, and myself. Fred's exceptional analytic reasoning, coupled with remarkable flexibility, was clearly a tutorial in how one deals with a pleomorphic group such as the four editors: flexibility on the one hand and an insistence on excellence on the other.

Holly and Fred were the two prime movers in the development of what was originally Cecil Essentials of Medicine and is now titled Andreoli and Carpenter's Cecil Essentials of Medicine. Medical students, residents in internal medicine, young physicians, and others interested in internal medicine owe a great deal to Holly and Fred for their vision in generating the notion of Essentials.

And the other editors of Essentials owe Holly and Fred a great debt for tutoring us in how one assembles a textbook of internal medicine.

Thomas E. Andreoli, MD (Deceased)

Kevin M. Biglan, MD, MPH

Associate Chair of Clinical Research, Associate Professor of Neurology, Director, National Parkinson Foundation Center of Excellence; Director, Huntington Disease Society of America Center of Excellence, University of Rochester School of Medicine and Dentistry, Strong Memorial Hospital, Rochester, New York

Bryan J. Bonder, MD

Department of Neurology, University Hospitals Case Medical Center, Cleveland, Ohio

William P. Cheshire, Jr., MD

Professor of Neurology, Mayo Clinic, Jacksonville, Florida

Mohamad Chmayssani, MD

Clinical Instructor, Department of Neurosurgery, David Geffen School of Medicine at UCLA, Los Angeles, California

Emma Ciafaloni, MD

Professor of Neurology and Pediatrics, Department of Neurology, University of Rochester, Rochester, New York

Timothy J. Counihan, MD, FRCPI

Honorary Senior Clinical Lecturer in Medicine, School of Medicine, National University of Ireland Galway, Galway, Ireland

Anne Haney Cross, MD

Professor of Neurology, Washington University School of Medicine, Saint Louis, Missouri

Mitchell S.V. Elkind, MD, MS

Professor of Neurology and Epidemiology, Fellowships Director, Head, Division of Neurology Clinical Outcomes Research and Population Sciences, Department of Neurology and Sergievsky Center, Columbia University, New York, New York

Robert C. Griggs, MD, FACP, FAAN

Professor of Neurology, Medicine, Pathology and Laboratory Medicine, Pediatrics, Center for Human Experimental Therapeutics, University of Rochester School of Medicine and Dentistry, Rochester, New York

Carlayne E. Jackson, MD

Professor of Neurology, University of Texas Health Science Center, San Antonio, Texas

Kevin A. Kerber, MD, MS

Associate Professor, Department of Neurology, University of Michigan Health System, Ann Arbor, Michigan

Jennifer M. Kwon, MD

Associate Professor, Departments of Neurology and Pediatrics, University of Rochester Medical Center, Rochester, New York

Geoffrey S.F. Ling, MD, PhD

Professor of Neurology, Uniformed Services University of the Health Sciences, Bethesda, Maryland; Attending Physician in Neuro Critical Care Medicine, Johns Hopkins Medical Institutions, Baltimore, Maryland

Jeffrey M. Lyness, MD

Senior Associate Dean for Academic Affairs, Professor of Psychiatry and Neurology, University of Rochester School of Medicine and Dentistry, Rochester, New York

Frederick J. Marshall, MD

Associate Professor, Department of Neurology, University of Rochester, Rochester, New York

Eavan McGovern, MD

Department of Neurology, St. Vincent's University Hospital, Dublin, Ireland

Sinéad M. Murphy, MB, MD, FRCPI

Consultant Neurologist, The Adelaide and Meath Hospitals incorporating the National Children's Hospital, Tallaght, Dublin; Senior Lecturer, Department Medicine, Trinity College Dublin, Dublin, Ireland

Lisa R. Rogers, DO

Medical Director, Neuro-oncology Program, Brain Tumor and Neuro-oncology Center, The Neurological Institute, Cleveland, Ohio

Maxwell H. Sims

Halterman Research Lab, Center for Neural Development and Disease, University of Rochester, Rochester, New York

Jeffrey M. Statland, MD

Assistant Professor of Neurology, University of Kansas Medical Center, Kansas City, Kansas

Paul M. Vespa, MD, FCCM, FAAN, FNCS

Professor, Departments of Neurology and Neurosurgery, David Geffen School of Medicine at UCLA, Los Angeles, California

XVII Geriatrics**Contributors****Harvey Jay Cohen, MD**

Walter Kempner Professor of Medicine and Director, Center for the Study of Aging and Human Development, Duke University School of Medicine, Durham, North Carolina

Mitchell T. Heflin, MD, MHS

Associate Professor, Department of Medicine, Duke University School of Medicine, Durham, North Carolina

XVIII Palliative Care**Contributors****Robert G. Holloway, MD, MPH**

Professor of Neurology, Chairman, Department of Neurology, Palliative Care Program, University of Rochester Medical Center, Rochester, New York

Timothy E. Quill, MD

Professor of Medicine, Psychiatry and Medical Humanities, Palliative Care Program, University of Rochester Medical Center, Rochester, New York

XIX Alcohol and Substance Abuse**Contributors****L. David Hillis, MD**

Professor and Chair, Department of Internal Medicine, University of Texas Health Science Center, San Antonio, Texas

Preface

This is the ninth edition of *Andreoli and Carpenter's Cecil Essentials of Medicine*. *Essentials IX*, like its predecessors, is intended to be comprehensive but concise. *Essentials IX*, therefore, provides an exacting and thoroughly updated treatise on internal medicine, without excessive length, for students of medicine at all levels of their careers.

We welcome with enthusiasm a new editor, J. Gregory Fitz, MD, provost and dean of medicine at the University of Texas Southwestern Medical Center at Dallas.

Essentials IX has maintained its three cardinal components and added a fourth. First, at the beginning of each section—kidney, for example—we provide a brief but rigorous summary of the fundamental biology of the kidney and/or the cardinal signs and symptoms of diseases of the kidney. The same format has been used in all the sections of the book. Second, the main body of each section contains a detailed but, again, concise description of the diseases of the various organ systems together with their pathophysiology and their treatment.

Essentials IX relies heavily on the internet. Along with the print publication, *Essentials IX* is published in its entirety online. In the online version of *Essentials IX*, we provide a substantial amount of supplemental material, indicated in the hard copy text by various icons in the margins of the pages. These icons are present throughout the hard copy of the book as well as in the Internet version and direct the reader to a series of illustrations, tables, or videos in the online version of *Essentials*. This material is clearly

crucial to understanding modern medicine, but we hope that, in this manner, the supplemental material will enrich *Essentials IX* without having enlarged the book significantly.

Finally, *Essentials IX* is being published simultaneously with *Goldman-Cecil Medicine*, 25th Edition, which is edited by Lee Goldman, MD, and Andrew I. Schafer, MD. Accordingly, the student has both the depth and breadth of two complementary textbooks, which were written and edited by contributors who number among the most recognized and respected authorities in the field. We feel that such integration and partnership expose students at all levels to the latest developments in biology with current evidence-based diagnosis, therapy, and practices.

As in prior editions, we make abundant use of four-color illustrations and each section has been reviewed first by one or another of the editors and finally by the editor-in-chief.

We thank James T. Merritt, senior acquisitions editor, medical education, of Elsevier, Inc., and especially Taylor Ball, content development manager, Elsevier, Inc. Both Jim Merritt and Taylor Ball contributed heartily to the preparation of this ninth edition of *Essentials*. Lastly, we thank our very able secretarial staff, Ms. Deborah Lamontange and Rachel Trower (Milwaukee), Ms. Patricia Hopkins (Rochester), Ms. Diane DiLolle (Dallas), and Ms. Carrie Gridelli and Ms. Lola Wright (Providence).

Contents

I Introduction to Molecular Medicine

- 1 Molecular Basis of Human Disease** 2
Ivor J. Benjamin

II Cardiovascular Disease

- 2 Structure and Function of the Normal Heart and Blood Vessels** 16
Nicole L. Lohr and Ivor J. Benjamin
- 3 Evaluation of the Patient with Cardiovascular Disease** 22
James Kleczka and Ivor J. Benjamin
- 4 Diagnostic Tests and Procedures in the Patient with Cardiovascular Disease** 37
Ivor J. Benjamin
- 5 Heart Failure and Cardiomyopathy** 55
Nunzio A. Gaglianello, Claudius Mahr, and Ivor J. Benjamin
- 6 Congenital Heart Disease** 67
Scott Cohen and Michael G. Earing
- 7 Valvular Heart Disease** 76
Timothy D. Woods
- 8 Coronary Heart Disease** 87
Michael P. Cinquegrani
- 9 Cardiac Arrhythmias** 110
Marcie G. Berger, Jason C. Rubenstein, and James A. Roth
- 10 Pericardial and Myocardial Disease** 136
Jennifer L. Strande, Panayotis Fasseas, and Ivor J. Benjamin
- 11 Other Cardiac Topics** 145
Mohamed F. Algahim, Robert B. Love, and Ivor J. Benjamin
- 12 Vascular Diseases and Hypertension** 159
Wanpen Vongpatanasin and Ronald G. Victor

III Pulmonary and Critical Care Medicine

- 13 Lung in Health and Disease** 182
Sharon Rounds and Matthew D. Jankowich
- 14 General Approach to Patients with Respiratory Disorders** 185
Rizwan Aziz and Brian Casserly
- 15 Evaluating Lung Structure and Function** 190
Jigme M. Sethi and F. Dennis McCool
- 16 Obstructive Lung Diseases** 207
Matthew D. Jankowich
- 17 Interstitial Lung Diseases** 222
Matthew D. Jankowich
- 18 Pulmonary Vascular Diseases** 240
Sharon Rounds and Matthew D. Jankowich
- 19 Disorders of Respiratory Control** 245
Sharon Rounds and Matthew D. Jankowich
- 20 Disorders of the Pleura, Mediastinum, and Chest Wall** 248
Eric J. Gartman and F. Dennis McCool
- 21 Infectious Diseases of the Lung** 254
Narendran Selvakumar, Brian Casserly, and Sharon Rounds
- 22 Essentials in Critical Care Medicine** 259
Narendran Selvakumar, Brian Casserly, and Sharon Rounds
- 23 Neoplastic Disorders of the Lung** 266
Lauren M. Catalano and Jason M. Aliotta

IV Preoperative and Postoperative Care

- 24 Preoperative and Postoperative Care** 272
Prashant Vaishnava and Kim A. Eagle

V Renal Disease

- 25 Renal Structure and Function 282**
Orson W. Moe and Javier A. Neyra
- 26 Approach to the Patient with Renal Disease 289**
Rajiv Agarwal
- 27 Fluid and Electrolyte Disorders 299**
Biff F. Palmer
- 28 Glomerular Diseases 314**
Sanjeev Sethi, An De Vriese, and Fernando C. Fervenza
- 29 Major Nonglomerular Disorders of the Kidney 329**
Nilum Rajora, Shani Shastri, and Ramesh Saxena
- 30 Vascular Disorders of the Kidney 341**
Jeffrey S. Berns
- 31 Acute Kidney Injury 352**
Mark A. Perazella and Jeffrey M. Turner
- 32 Chronic Kidney Disease 363**
Kerri L. Cavanaugh and T. Alp Ikizler

VI Gastrointestinal Disease

- 33 Common Clinical Manifestations of Gastrointestinal Disease 372**
M. Michael Wolfe
- A Abdominal Pain 372**
Charles M. Bliss, Jr. and M. Michael Wolfe
- B Gastrointestinal Hemorrhage 375**
D. Roy Ferguson and M. Michael Wolfe
- C Malabsorption 378**
Sharheel K. Wasan, Elihu M. Schimmel, and M. Michael Wolfe
- D Diarrhea 384**
John S. Maxwell and M. Michael Wolfe
- 34 Endoscopic and Imaging Procedures 389**
Christopher S. Huang and M. Michael Wolfe
- 35 Esophageal Disorders 396**
Carla Maradey-Romero, Ronnie Fass, and M. Michael Wolfe

- 36 Diseases of the Stomach and Duodenum 402**
Robert C. Lowe and M. Michael Wolfe
- 37 Inflammatory Bowel Disease 417**
Hannah L. Miller and Francis A. Farraye
- 38 Diseases of the Pancreas 425**
David R. Lichtenstein

VII Diseases of the Liver and Biliary System

- 39 Laboratory Tests in Liver Disease 440**
Shaheryar A. Siddiqui and Michael B. Fallon
- 40 Jaundice 444**
Klaus Mönkemüller, Helmut Neumann, and Michael B. Fallon
- 41 Acute and Chronic Hepatitis 449**
Jen-Jung Pan and Michael B. Fallon
- 42 Acute Liver Failure 456**
Brendan M. McGuire and Michael B. Fallon
- 43 Cirrhosis of the Liver and Its Complications 458**
Shaheryar A. Siddiqui and Michael B. Fallon
- 44 Disorders of the Gallbladder and Biliary Tract 469**
Matthew P. Spinn and Michael B. Fallon

VIII Hematologic Disease

- 45 Hematopoiesis and Hematopoietic Failure 478**
Eunice S. Wang and Nancy Berliner
- 46 Clonal Disorders of the Hematopoietic Stem Cell 489**
Eunice S. Wang and Nancy Berliner
- 47 Disorders of Red Blood Cells 502**
Michal G. Rose and Nancy Berliner
- 48 Clinical Disorders of Neutrophils 515**
Michal G. Rose and Nancy Berliner
- 49 Disorders of Lymphocytes 520**
Jill Lacy and Stuart Seropian

- 50 Normal Hemostasis 534**
Alexa J. Siddon, Henry M. Rinder, and
Christopher A. Tormey
- 51 Disorders of Hemostasis:
Bleeding 544**
Christopher A. Tormey and Henry M. Rinder
- 52 Disorders of Hemostasis:
Thrombosis 564**
Richard Torres and Henry M. Rinder
- IX Oncologic Disease**
- 53 Cancer Biology 576**
Aram F. Hezel
- 54 Cancer Epidemiology 579**
Gary H. Lyman and Nicole M. Kuderer
- 55 Principles of Cancer Therapy 585**
Davendra P.S. Sohal and Alok A. Khorana
- 56 Lung Cancer 592**
Patrick C. Ma
- 57 Gastrointestinal Cancers 598**
Davendra P.S. Sohal and Alok A. Khorana
- 58 Genitourinary Cancers 604**
Robert Dreicer, Jorge Garcia, Timothy Gilligan,
and Brian Rini
- 59 Breast Cancer 610**
Nicole M. Kuderer and Gary H. Lyman
- 60 Other Solid Tumors 613**
Michael J. McNamara
- 61 Complications of Cancer and Cancer
Treatment 618**
Bassam Estfan and Alok A. Khorana
- X Endocrine Disease and Metabolic
Disease**
- 62 Hypothalamic-Pituitary Axis 624**
Kawaljeet Kaur and Diana Maas
- 63 Thyroid Gland 633**
Theodore C. Friedman
- 64 Adrenal Gland 642**
Theodore C. Friedman
- 65 Male Reproductive Endocrinology 652**
Glenn D. Braunstein
- 66 Diabetes Mellitus, Hypoglycemia 657**
Robert J. Smith
- 67 Obesity 675**
Osama Hamdy
- 68 Malnutrition, Nutritional Assessment,
and Nutritional Support in Hospitalized
Adults 683**
Thomas R. Ziegler
- 69 Disorders of Lipid Metabolism 689**
Geetha Gopalakrishnan and Robert J. Smith
- XI Women's Health**
- 70 Women's Health Topics 698**
Kelly McGarry, Kimberly Babb, Laura Edmonds,
Christine Duffy, Michelle Anvar, and
Jennifer Jeremiah
- XII Men's Health**
- 71 Men's Health Topics 714**
David James Osborn, Douglas F. Milam, and
Joseph A. Smith, Jr.
- XIII Diseases of Bone and Bone Mineral
Metabolism**
- 72 Normal Physiology of Bone and Mineral
Homeostasis 732**
Andrew F. Stewart
- 73 Disorders of Serum Minerals 741**
Steven P. Hodak and Andrew F. Stewart
- 74 Metabolic Bone Diseases 750**
Mara J. Horwitz and Andrew F. Stewart
- 75 Osteoporosis 757**
Susan L. Greenspan
- XIV Musculoskeletal and Connective
Tissue Disease**
- 76 Approach to the Patient with Rheumatic
Disease 766**
Niveditha Mohan

- 77 Rheumatoid Arthritis 770**
Rayford R. June and Larry W. Moreland
- 78 Spondyloarthritis 775**
Douglas W. Lienesch
- 79 Systemic Lupus Erythematosus 780**
Amy H. Kao and Susan Manzi
- 80 Systemic Sclerosis 787**
Robyn T. Domsic
- 81 Systemic Vasculitis 793**
Kimberly P. Liang
- 82 Crystal Arthropathies 799**

- 96 Infectious Diarrhea 899**
Awewura Kwara
- 97 Infections Involving Bones and Joints 905**
Jerome Larkin
- 98 Urinary Tract Infections 909**
Joao Tavares and Steven M. Opal
- 99 Health Care–Associated Infections 912**
Steven “Shaefer” Spires and Thomas R. Talbot
- 100 Sexually Transmitted Infections 918**
Philip A. Chan and Susan Cu-uvin
- 101 Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome 927**
Brian T. Montague, Aadia I. Rana, Edward J. Wing, and Timothy P. Flanigan
- 102 Infections in the Immunocompromised Host 943**
Staci A. Fischer
- 103 Infectious Diseases of Travelers: Protozoal and Helminthic Infections 951**
Rebecca Reece, Aadia I. Rana, and Erna Milunka Kojic

XVI Neurologic Disease

- 104 Neurologic Evaluation of the Patient 960**
Frederick J. Marshall
- 105 Disorders of Consciousness 965**
Mohamad Chmayssani and Paul M. Vespa
- 106 Disorders of Sleep 971**
Selim R. Benbadis
- 107 Cortical Syndromes 976**
Sinéad M. Murphy and Timothy J. Coughlin
- 108 Dementia and Memory Disturbances 980**
Frederick J. Marshall

- 109 Major Disorders of Mood, Thoughts, and Behavior 985**
Jeffrey M. Lyness
- 110 Autonomic Nervous System Disorders 990**
William P. Cheshire, Jr.
- 111 Headache, Neck and Back Pain, and Cranial Neuralgias 994**
Timothy J. Counihan
- 112 Disorders of Vision and Hearing 1002**
Eavan McGovern and Timothy J. Counihan
- 113 Dizziness and Vertigo 1010**
Kevin A. Kerber
- 114 Disorders of the Motor System 1013**
Kevin M. Biglan
- 115 Congenital, Developmental, and Neurocutaneous Disorders 1024**
Maxwell H. Sims and Jennifer M. Kwon
- 116 Cerebrovascular Disease 1033**
Mitchell S.V. Elkind
- 117 Traumatic Brain Injury and Spinal Cord Injury 1046**
Geoffrey S.F. Ling
- 118 Epilepsy 1051**
Michel J. Berg
- 119 Central Nervous System Tumors 1064**
Bryan J. Bonder and Lisa R. Rogers
- 120 Demyelinating and Inflammatory Disorders 1069**
Anne Haney Cross

Introduction to Molecular Medicine

1 Molecular Basis of Human Disease

Ivor J. Benjamin

Molecular Basis of Human Disease

Ivor J. Benjamin

INTRODUCTION

Medicine has evolved dramatically during the past century—from a healing art in which standards of practice were established on the basis of personal experience passed on from one practitioner to the next to a rigorous intellectual discipline reliably steeped in the scientific method. This process tests the validity of a hypothesis or prediction through experimentation, the foundation of current advances in the fields of physiology, microbiology, biochemistry, and pharmacology.

These advances have served as the basis for new diagnostic and therapeutic approaches to illness and disease while challenging providers and practitioners to adopt their use at an accelerated pace in 21st century. Since the 1980s, for example, understanding of the molecular basis of genetics has expanded dramatically, and advances in this field have identified new and exciting dimensions for defining the basis of conventional genetic diseases (e.g., sickle cell disease) and complex genetic traits (e.g., hypertension). Insights into the interactions between genes and environment that independently influence the noncoding genome laid the foundation for the field of epigenetics.

Armed with a variety of sensitive and specific molecular techniques, contemporary medicinal practice seeks to provide the molecular underpinning of complex pathobiologic processes and identify individuals at risk for common diseases. To fully exploit modern medicine, clinical teams are increasingly relying on a detailed understanding of cellular mechanisms and on precision drugs that disrupt the fine-structural targets underlying the molecular basis of disease. The outcomes of large clinical trials that yield mean responses to therapy will likely evolve into personalized medicine, defining more effective treatments for specific patient subpopulations. This introductory chapter offers an overview of these complex and rapidly evolving topics and summarizes the principles of molecular medicine that are highlighted in specific sections throughout this text.

DEOXYRIBONUCLEIC ACID AND THE GENOME

All organisms possess a scheme to transmit the essential information containing the genetic makeup of the species through successive generations. Human cells have 23 pairs of chromosomes, and each pair contains a unique sequence of genetic information. In the human genome, about 6×10^9 nucleotides, or 3×10^9 pairs of nucleotides, associate in the double helix. The specificity of DNA is determined by the base sequence that is stored in

complementary form in the double-helical structure. It facilitates correction of sequence errors and provides a mechanistic basis for replication of information during cell division. Each DNA strand provides a template for replication, which is accomplished by the action of DNA-dependent polymerases that unwind the double-helical DNA and copy each single strand with remarkable fidelity.

Except for gametocytes, all cells contain the duplicate, diploid number of genetic units, one half of which is referred to as the *haploid number*. The genetic information contained in chromosomes is separated into discrete functional elements known as *genes*. A gene is a unit of base sequences that (with rare exception) encodes a specific polypeptide sequence. New evidence suggests that small, noncoding RNAs play critical roles in the expression of this essential information. An estimated 30,000 genes constitute the human haploid genome, and they are interspersed among sequence regions that do not code for protein and whose function is as yet unknown. For example, noncoding RNAs (e.g., transfer RNAs [tRNAs], ribosomal RNAs [rRNAs], other small RNAs) are components of enzyme complexes such as the ribosome and spliceosome. The average chromosome contains 3000 to 5000 genes, which range in size from about 1 kilobase (kb) to 2 megabases (Mb).

RIBONUCLEIC ACID SYNTHESIS

Transcription, or RNA synthesis, is the process of transferring information contained in nuclear DNA to an intermediate molecular species known as messenger RNA (mRNA). Two biochemical differences distinguish RNA from DNA. The polymeric backbone is made up of ribose rather than deoxyribose sugars linked by phosphodiester bonds, and the base composition is different in that uracil is substituted for thymine.

RNA synthesis from a DNA template is performed by three types of DNA-dependent RNA polymerases, each a multisubunit complex with distinct nuclear location and substrate specificity. RNA polymerase I, located in the nucleolus, directs the transcription of genes encoding the 18S, 5.8S, and 28S ribosomal RNAs, forming a molecular scaffold with catalytic and structural functions within the ribosome. RNA polymerase II, which is located in the nucleoplasm instead of the nucleoli, primarily transcribes precursor mRNA transcripts and small RNA molecules. The carboxyl terminus of RNA polymerase II is uniquely modified with a 220-kD protein domain, which is the site of enzymatic regulation by protein phosphorylation of critical serine and threonine

FIGURE 1-1 Transcription. Genomic DNA is shown with enhancer and silencer sites located 5' upstream of the promoter region, to which RNA polymerase is bound. The transcription start site is shown downstream of the promoter region, and this site is followed by exonic sequences interrupted by intronic sequences. The former sequences are transcribed one after another (ad seriatim) by the RNA polymerase.

residues. All tRNA precursors and other rRNA molecules are synthesized by RNA polymerase III in the nucleoplasm.

RNA polymerases are synthesized from precursor transcripts that must be cleaved into subunits before further processing and assembling with ribosomal proteins into macromolecular complexes. Ribosomal architectural and structural integrity are derived from the secondary and tertiary structures of rRNA, which assume a series of folding patterns containing short duplex regions. Precursors of tRNA in the nucleus undergo the removal of the 5' leader region, splicing of an internal intron sequences, and modification of terminal residues.

Precursors of mRNA are produced in the nucleus by the action of DNA-dependent RNA polymerase II, which copies the *anti-sense* strand of the DNA double helix to synthesize a single strand of mRNA that is identical to the *sense* strand of the DNA double helix in a process called *transcription* (Fig. 1-1). The initial, immature mRNA first undergoes modification at the 5' and 3' ends. A special nucleotide structure called the *cap* is added to the 5' end, which increases binding to the ribosome and enhances translational efficiency. The 3' end undergoes modification by nuclease cleavage of about 20 nucleotides, followed by the addition of a length of polynucleotide sequence containing a uniform stretch of adenine bases, the so-called poly-A tail that stabilizes the mRNA.

In addition to these changes that occur uniformly in all mRNAs, more selective modifications can occur. Because each gene contains exonic and intronic sequences and the precursor mRNA is transcribed without regard for exon-intron boundaries, this immature message must be edited so that all exons are spliced together in an appropriate sequence. The process of splicing, or removing intronic sequences to produce the mature mRNA, is an exquisitely choreographed event that involves the intermediate formation of a spliceosome, which is a large complex consisting of small nuclear RNAs and specific proteins that contains a loop or lariat-like structure that includes the intron targeted for removal. Only after splicing, a catalytic process requiring adenosine triphosphate hydrolysis, has concluded is the mature mRNA able to transit from the nucleus into the cytoplasm, where the encoded information is translated into protein.

Alternative splicing is a process for efficiently generating multiple gene products that often are dictated by tissue specificity, developmental expression, and pathologic state. Gene splicing allows the expression of multiple isoforms by expanding the repertoire for molecular diversity. An estimated 30% of genetic

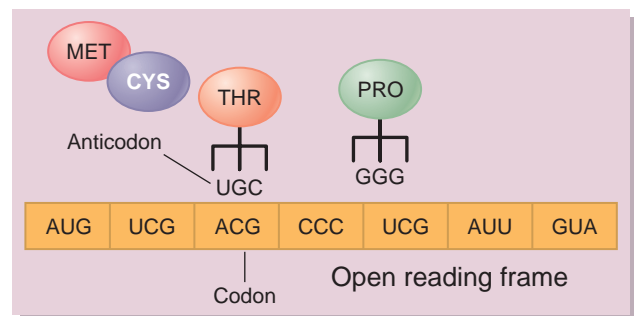

FIGURE 1-2 Translation. The open reading frame of a mature messenger RNA is shown with its series of codons. Transfer RNA molecules are shown with their corresponding anticodons, charged with their specific amino acid. A short, growing polypeptide chain is depicted. A, Adenine; C, cytosine; CYS, cysteine; G, guanine; MET, methionine; PRO, proline; THR, threonine; U, uracil.

diseases in humans arise from defects in splicing. The resulting mature mRNA then exits the nucleus to begin the process of *translation* or conversion of the base code to polypeptide (Fig. 1-2). Alternative splicing pathways (i.e., alternative exonic assembly pathways) for specific genes also serve at the level of transcriptional regulation. The discovery of catalytic RNA, which enables self-directed internal excision and repair, has advanced the view that RNA serves as a template for translation of the genetic code and simultaneously as an enzyme (see [Transcriptional Regulation](#)).

Protein synthesis, or translation of the mRNA code, occurs on ribosomes, which are macromolecular complexes of proteins and rRNA located in the cytoplasm. Translation involves the conversion of the linear code of a triplet of bases (i.e., codon) into the corresponding amino acid. A four-base code generates 64 possible triplet combinations ($4 \times 4 \times 4$), and they correspond to 20 different amino acids, many of which are encoded by more than one base triplet. To decode mRNA, an adapter molecule (tRNA) recognizes the codon in mRNA through complementary base pairing with a three-base anticodon that it bears; each tRNA is charged with a unique amino acid that corresponds to the anticodon (Fig. 1-3).

Translation on the mRNA template proceeds without punctuation of the non-overlapping code with the aid of rRNA on an assembly machine called a *ribosome*—essentially a polypeptide polymerase. At least one tRNA molecule exists for each of the 20 amino acids, although degeneracy in the code expands the

FIGURE 1-3 Secondary structure of transfer RNA (tRNA). The structure of each tRNA serves as an adapter molecule that recognizes a specific codon for the amino acid to be added to the polypeptide chain. About one half the hydrogen-bonded bases of the single chain of ribonucleotides are shown paired in double helices like a cloverleaf. The 5' terminus is phosphorylated, and the 3' terminus contains the hydroxyl group on an attached amino acid. The anticodon loop is typically located in the middle of the tRNA molecule. C, Cytocidine; DHU, dihydroxyuridine; G, guanine; UH₂, dihydrouridine; ψ, pseudouridine; T, ribothymidine; U, uracil. (Data from Berg JM, Tymoczko JL, Strayer JL: Berg, Tymoczko, and Strayer's biochemistry, ed 5, New York, 2006, WH Freeman.)

number of available tRNA molecules, mitigates the chances of premature chain termination, and ameliorates the potential deleterious consequences of single-base mutations. The enzymatic activity of the ribosome then links amino acids through the synthesis of a peptide bond, releasing the tRNA in the process.

Consecutive linkage of amino acids in the growing polypeptide chain represents the terminal event in the conversion of information contained within the nuclear DNA sequence into mature protein (DNA → RNA → protein). Proteins are directly responsible for the form and function of an organism. Abnormalities in protein structure or function brought about by changes in primary amino acid sequence are the immediate precedent cause of changes in phenotype, adverse forms of which define a disease state.

Inhibition of RNA synthesis is a well-recognized mechanism of specific toxins and antibiotics. Toxicity from the ingestion of the poisonous mushroom (*Amanita phalloides*), for example, leads to the release of the toxin α-amanitin, a cyclic octapeptide that inhibits the RNA polymerase II and blocks elongation of RNA synthesis. The antibiotic actinomycin D binds with high affinity to double-helical DNA and intercalates between base

pairs, precluding access of DNA-dependent RNA polymerases and the selective inhibition of transcription. Several major antibiotics inhibit translation. For example, the aminoglycoside antibiotics disrupt the mRNA-tRNA codon-anticodon interaction, whereas erythromycin and chloramphenicol inhibit peptide bond formation.

CONTROL OF GENE EXPRESSION

Overview

The timing, duration, localization, and magnitude of gene expression are all important elements in the complex tapestry of cell form and function governed by the genome. Gene expression represents the flow of information from the DNA template into mRNA transcripts and the process of translation into mature protein.

Four levels of organization involving transcription factors, RNAs, chromatin structure, and epigenetic factors orchestrate gene expression in the mammalian genome. Transcriptional regulators bind to specific DNA motifs that positively or negatively control the expression of neighboring genes. The information contained in the genome must be transformed into functional units of RNA or protein products. How DNA is packed and modified represents additional modes of gene regulation by disrupting the access of transcription factors from DNA-binding motifs.

In the postgenomic era, the challenge is to understand the architecture by which the genome is organized, controlled, and modulated. Transcription factors, chromatin architecture, and modifications of nucleosomal organization make up the major mechanisms of gene regulation in the genome.

Transcriptional Regulation

The principal regulatory step in gene expression occurs at the level of gene transcription. A specific DNA-dependent RNA polymerase performs the transcription of information contained in genomic DNA into mRNA transcripts. Transcription begins at a proximal (i.e., toward the 5' end of the gene) transcription start site containing nucleotide sequences that influence the rate and extent of the process (see Fig. 1-1). This *promoter region* of the gene often includes a sequence rich in adenine and thymine (i.e., TATA box) along with other sequence motifs within about 100 bases of the start site. These regions of DNA that regulate transcription are known as *cis*-acting regulatory elements. Some of these regulatory regions of promoter sequence bind proteins known as *trans*-acting factors (i.e., transcription factors), which are themselves encoded by other genes. The *cis*-acting regulatory sequences to which transcription factors bind are often referred to as *response elements*. Families of transcription factors have been identified and are often described by unique aspects of their predicted secondary protein structure, including helix-turn-helix motifs, zinc finger motifs, and leucine zipper motifs. Transcription factors make up an estimated 3% to 5% of the protein-coding products of the genome.

In addition to gene-promoter regions, enhancer sites are distinct from promoter sites in that they can exist at distances quite remote from the start site, either upstream or downstream (i.e., beyond the 3' end of the gene), and without clear orientation

requirements. *Trans*-acting factors bind to these enhancer sites and are thought to alter the tertiary structure or conformation of the DNA in a manner that facilitates the binding and assembly of the transcription-initiation complex at the promoter region, perhaps in some cases by forming a broad loop of DNA in the process. Biochemical modification of select promoter or enhancer sequences, such as methylation of cytosine-phosphate-guanine (CpG)-rich sequences, can also modulate transcription; methylation typically suppresses transcription. The terms *silencer* and *suppressor* elements refer to *cis*-acting nucleotide sequences that reduce or shut off gene transcription and do so through association with *trans*-acting factors that recognize these specific sequences.

Regulation of transcription is a complex process that occurs at several levels. The expression of many genes is regulated to maintain high basal levels; they are known as *housekeeping* or *constitutively expressed* genes. They typically yield protein products that are essential for normal cell function or survival and must be maintained at a specific steady-state concentration in all circumstances. Many other genes are not expressed or are only modestly expressed under basal conditions; however, with the imposition of some stress or exposure of the cell to an agonist that elicits a cellular response distinct from that of the basal state, expression of these genes is induced or enhanced. For example, the heat shock protein genes encoding *stress proteins* are rapidly induced in response to diverse pathophysiologic stimuli (e.g., oxidative stress, heavy metals, inflammation) in most cells and organisms. Increased heat shock protein expression is complementary to the basal level of heat shock proteins, which are molecular chaperones that play key roles during protein synthesis to prevent protein misfolding, increase protein translocation, and accelerate protein degradation. These adaptive responses often mediate changes in phenotype that are homeostatically protective to the cell or organism.

Micro-RNAs and Gene Regulation

Less is known about the determinants of translational regulation than is known about transcriptional regulation. The recent discovery and identification of small RNAs (21-mer to 24-mer clusters), called *micro-RNAs* (miRNAs), adds further complexity to the regulation of gene expression in the eukaryotic genome. First discovered in worms more than 15 years ago, miRNAs are conserved noncoding strands of RNA that bind by Watson-Crick base pairing to the 3'-untranslated regions of target mRNAs, enabling gene silencing of protein expression at the translational level. Gene-encoding miRNAs exhibit tissue-specific expression and are interspersed in regions of the genome unrelated to known genes.

Transcription of miRNAs proceeds in multiple steps from sites under the control of an mRNA promoter. RNA polymerase II transcribes the precursor miRNA, called *primary miRNA* (pri-miRNA), containing 5' caps and 3' poly-A tails. In the nucleus, the larger pri-miRNAs of 70 nucleotides form an internal hairpin loop, embedding the miRNA portion that undergoes recognition and subsequent excision by a double-stranded RNA-specific ribonuclease called *Drosha*. Gene expression is silenced by the effect of miRNA on nascent RNA molecules targeted for degradation.

Because translation occurs at a fairly invariant rate among all mRNA species, the stability or half-life of a specific mRNA also serves as another checkpoint for the regulation of gene expression. The 3'-untranslated region of mRNAs contains regions of sequence that dictate the susceptibility of the message to nuclease cleavage and degradation. Stability appears to be sequence specific, and in some cases, it depends on *trans*-acting factors that bind to the mRNA. The mature mRNA contains elements of untranslated sequence at the 5' and 3' ends that can regulate translation.

Beginning in the organism's early development, miRNAs may facilitate much more intricate ways for the regulation of gene expression, as have been shown for germline production, cell differentiation, proliferation, and organogenesis. Because studies have implicated the expression of miRNAs in brain development, cardiac organogenesis, skeletal muscle regeneration, colonic adenocarcinoma, and viral replication, this novel mechanism for gene silencing has potential therapeutic roles for congenital heart defects, viral disease, neurodegeneration, regenerative medicine, and cancer.

Chromatin Remodeling and Gene Regulation

The size and complexity of the human genome with 23 chromosomes ranging in size between 50 and 250 Mb pose formidable challenges for transcription factors to exert the specificity of DNA-binding properties in gene regulation. Control of gene expression takes place in diverse types of cells, often with exquisite temporal and spatial specificity throughout the lifespan of the organism. In eukaryotic cells, the genome is highly organized into densely packed nucleic acid DNA- and RNA-protein structures, called *chromatin*. The building blocks of chromatin are called *histones*, a family of small basic proteins that occupy one half of the mass of the chromosome. Histones derive their basic properties from the high content of basic amino acids, arginine, and lysine. Five major types of histones—H1, H2A, H2B, H3, and H4—have evolved to form complexes with genomic DNA. Two pairs each of the four types of histones form a protein core, the histone octamer, which is wrapped by 200 base pairs of DNA to form the nucleosome (Fig. 1-4). The core proteins within the nucleosomes have protruding amino-terminal ends, exposing critical lysine and arginine residues for covalent modification. Further DNA condensation is achieved as higher-order structure is imposed on the chromosomes. The nucleosomes are further compacted in layered stacks with a left-handed superhelix resulting in negative supercoils that provide the energy for DNA strand separation during replication.

Condensation of DNA in chromatin precludes the access of regulatory molecules such as transcription factors. Reversal of chromatin condensation typically occurs in response to environmental and other developmental signals in a tissue-dependent manner. Promoter sites undergoing active transcription and relaxation of chromatin structure that become susceptible to enzymatic cleavage by nonspecific DNAase I are called *hypersensitive sites*. Transcription factors on promoter sites may gain access by protein-protein interactions to enhancer elements containing tissue-specific proteins at remote sites (several thousand bases away), resulting in transcription activation or repression.

FIGURE 1-4 Schematic representation of a nucleosome. Rectangular blocks represent the DNA strand wrapped around the core that consists of eight histone proteins. Each histone has a protruding tail that can be modified to repress or activate transcription.

Epigenetic Control of Gene Expression

Complex regulatory networks revolve around transcription factors, nucleosomes, chromatin structure, and epigenetic markings. *Epigenetics* refers to heritable changes in gene expression without changes in the DNA sequence. Examples include DNA methylation, gene silencing, chromatin remodeling, and X-chromosome inactivation. This form of inheritance involves alterations in gene function without changes in DNA sequence. The chemical marking of DNA methylation is cell specific and developmentally regulated. Methylation of the 5'-CpG dinucleotide by specific methyl transferases, which occurs in 70% of the mammalian genome, is another mechanism of gene regulation. Steric hindrance from the bulky methyl group of 5'-methylcytosine precludes occupancy by transcription factors that stimulate or attenuate gene expression. Most genes are found in CpG islands, reflecting sites of gene activity across the genome.

In an analogous manner, modifications of histone by phosphorylation, methylation, ubiquitination, and acetylation are transmitted and reestablished in an inheritable manner. It is conceivable that other epigenetic mechanisms do not involve genomic modifications of DNA. For example, modification of the gene encoding the estrogen receptor- α has been implicated in gene silencing at 5-methylcytosine (^5mC) sites of multiple downstream targets in breast cancer cells. Powerful approaches are being developed to examine feedback and feed-forward loops in the transmission of epigenetic markings.

The concept that dynamic modifications (i.e., DNA methylation and acetylation) of histones or epigenesis contribute in part to tumorigenic potential for progression has already been translated into therapies. Histone acetyltransferases (HATs) and histone deacetyltransferases (HDACs) play antagonistic roles in the addition and removal of acetylation in the genome. Genome-wide analysis of HATs and HDACs is beginning to provide important insights into complex modes of gene regulation. Several inhibitors of histone deacetylases with a range of

biochemical and biologic activities are being developed and tested as anticancer agents in clinical trial. Results of phase I clinical trials have suggested that these drugs are well tolerated. Inhibition of deacetylase remodels chromatin assembly and reactivates transcription of the genome. Because the mechanisms of actions of HDACs extend to apoptosis, cell cycle control, and cellular differentiation, current clinical trials are seeking to determine the efficacy of these novel reagents in the drug compendium for human cancers.

GENETIC SEQUENCE VARIATION, POPULATION DIVERSITY, AND GENETIC POLYMORPHISMS

A stable, heritable change in DNA is defined as a *mutation*. This strict contemporary definition does not depend on the functional relevance of the sequence alteration and implicates a change in the primary DNA sequence. Considered in a historical context, mutations were first defined on the basis of identifiable changes in the heritable phenotype of an organism. As biochemical phenotyping became more precise in the mid-20th century, investigators demonstrated that many proteins exist in more than one form in a population, and these forms were viewed as a consequence of variations in the gene coding for that protein (i.e., allelic variation). With advances in DNA-sequencing methods, the concept of mutation evolved from one that could be appreciated only by identifying differences in phenotype to one that could precisely be defined at the level of changes in the structure of DNA. Although most mutations are stably transmitted from parents to offspring, some are genetically lethal and cannot be passed on. The discovery of regions of the genome that contain sequences that repeat in tandem a highly variable number of times (i.e., tandem repeats) suggests that some mutations are less stable than others. These tandem repeats are further described later.

The molecular nature of mutations is varied (Table 1-1). A mutation can involve the deletion, insertion, or substitution of a single base, all of which are referred to as *point mutations*. Substitutions can be further classified as *silent* when the amino acid encoded by the mutated triplet does not change, as *missense* when the amino acid encoded by the mutated triplet changes, and as *nonsense* when the mutation leads to premature termination of translation (i.e., stop codon). Occasionally, point mutations can alter the processing of precursor mRNA by producing alternate splice sites or eliminating a splice site. When a single- or double-base deletion or insertion occurs in an exon, a frameshift mutation results, usually leading to premature termination of translation at a now in-frame stop codon. The other end of the spectrum of mutations includes large deletions of an entire gene or a set of contiguous genes; deletion, duplication, and translocation of a segment of one chromosome to another; or duplication or deletion of an entire chromosome. These chromosomal mutations play a large role in the development of many cancers.

Each individual possesses two alleles, one from each parent, for any given gene locus. Identical alleles define homozygosity and nonidentical alleles define heterozygosity for any gene locus. The heritability of these alleles follows typical mendelian rules. With a clearer understanding of the molecular basis of mutations and of allelic variation, their distribution in populations can be analyzed precisely by following specific DNA sequences.

TABLE 1-1 MOLECULAR BASIS OF MUTATIONS

TYPE	EXAMPLES
POINT MUTATIONS	
Deletion	α -Thalassemia, polycystic kidney disease
SUBSTITUTIONS	
Silent	Cystic fibrosis
Missense	Sickle cell anemia, polycystic kidney disease, congenital long QT syndrome
Nonsense	Cystic fibrosis, polycystic kidney disease
LARGE MUTATIONS (GENE OR GENE CLUSTER)	
Deletion	Duchenne's muscular dystrophy
Insertion	Factor VIII deficiency (hemophilia A)
Duplication	Duchenne's muscular dystrophy
Inversion	Factor VIII deficiency
Expanding triplet	Huntington's disease
VERY LARGE MUTATIONS (CHROMOSOMAL SEGMENT OR CHROMOSOME)	
Deletion	Turner's syndrome (45,X)
Duplication	Trisomy 21
Translocation	XX male [46,X; t(X;Y)]*

*Translocation onto an X chromosome of a segment of a Y chromosome that bears the locus for testicular differentiation.

Differences in DNA sequences studied within the context of a population are referred to as *genetic polymorphisms*, and these polymorphisms underlie the diversity observed within a given species and among species.

Despite the high prevalence of benign polymorphisms in a population, the occurrence of harmful mutations is rare because of selective pressures that eliminate the most harmful mutations from the population (i.e., lethality) and the variability within the genomic sequence in response to polymorphic change. Some portions of the genome are remarkably stable and free of polymorphic variation, whereas other portions are highly polymorphic, the persistence of variation within which is a consequence of the functional benignity of the sequence change. In other words, polymorphic differences in DNA sequence between individuals can be categorized as those producing no effect on phenotype, those causing benign differences in phenotype (i.e., normal genetic variation), and those producing adverse consequences in phenotype (i.e., mutations). The latter group can be further subdivided into the polymorphic mutations that alone are able to produce a functionally abnormal phenotype such as monogenic disease (e.g., sickle cell anemia) and those that alone are unable to do so but in conjunction with other mutations can produce a functionally abnormal phenotype (i.e., complex disease traits such as essential hypertension).

Polymorphisms are more common in noncoding regions of the genome than they are in coding regions, and one common type involves the tandem repetition of short DNA sequences a variable number of times. If these tandem repeats are long, they are called *variable number tandem repeats* (VNTRs); if the repeats are short, they are called *short tandem repeats* (STRs). During mitosis, the number of tandem repeats can change, and the frequency of this kind of replication error is high enough to make alternative lengths of the tandem repeats common in a population. However,

the rate of change in length of the tandem repeats is low enough to make the size of the polymorphism useful as a stable genotypic trait in families, and polymorphic tandem repeats are useful in determining the familial heritability of specific genomic loci.

Polymorphic tandem repeats are sufficiently prevalent along the entire genomic sequence, enabling them to serve as genetic markers for specific genes of interest by analysis of their linkage to those genes during crossover and recombination events. Analyses of multiple genetic polymorphisms in the human genome (i.e., genotyping) reveal that a remarkable variation exists among individuals at the level of the sequence of genomic DNA. A single-nucleotide polymorphism (SNP), the most common variant, differs by a single base between chromosomes on a given stretch of DNA sequence (Fig. 1-5). From genotyping of the world's representative population, 10 million variants (i.e., one site per 300 bases) are estimated to make up 90% of the common SNP variants in the population, with the rare variants making up the remaining 10%. With each generation of a species, the frequency of polymorphic changes in a gene is 10^{-4} to 10^{-7} . In view of the number of genes in the human genome, between 0.5% and 1.0% of the base sequence of the human genome is polymorphic. In this context, the new variant can be traced historically to the surrounding alleles on the chromosomal background present at the time of the mutational event.

A haplotype is a specific set or combination of alleles on a chromosome or part of a chromosome (see Fig. 1-5). When parental chromosomes undergo crossover, new *mosaic* haplotypes that contain additional mutations are created from the recombination. SNP alleles within haplotypes can be co-inherited with other alleles in the population, a mechanism called *linkage disequilibrium* (LD). The association between two SNPs declines with increasing distance, enabling patterns of LD to be identified from the proximity of nearby SNPs. Conversely, a few well-selected SNPs are often sufficient to predict the location of other common variants in the region.

Haplotypes associated with a mutation are expected to become common by recombination in the general population over thousands of generations. In contrast, genetic mapping with LD departs from traditional mendelian genetics by using the entire human population as a large family tree without an established pedigree. Of the possible 10 million variants, the International HapMap Project and the Perlegen private venture have deposited more than 8 million variants comprising the public human SNP map from more than 341 people representing different population samples. The SNPs distributed across the genome of unrelated individuals provide a sufficiently robust sample set for statistical associations to be drawn between genotypes and modest phenotypes. A mutation is now defined as a specific type of allelic polymorphism that causes a functional defect in a cell or organism.

The causal relationship between monogenic diseases with well-defined phenotypes that co-segregate with the disease requires only a small number of affected individuals compared with unaffected control individuals. In contrast, complex disorders (e.g., diabetes, hypertension, cancer) necessitate the combinatorial effects of environmental factors and genes with subtle effects. Only by searching for variations in genetic frequency between patients and the general population can the causation of

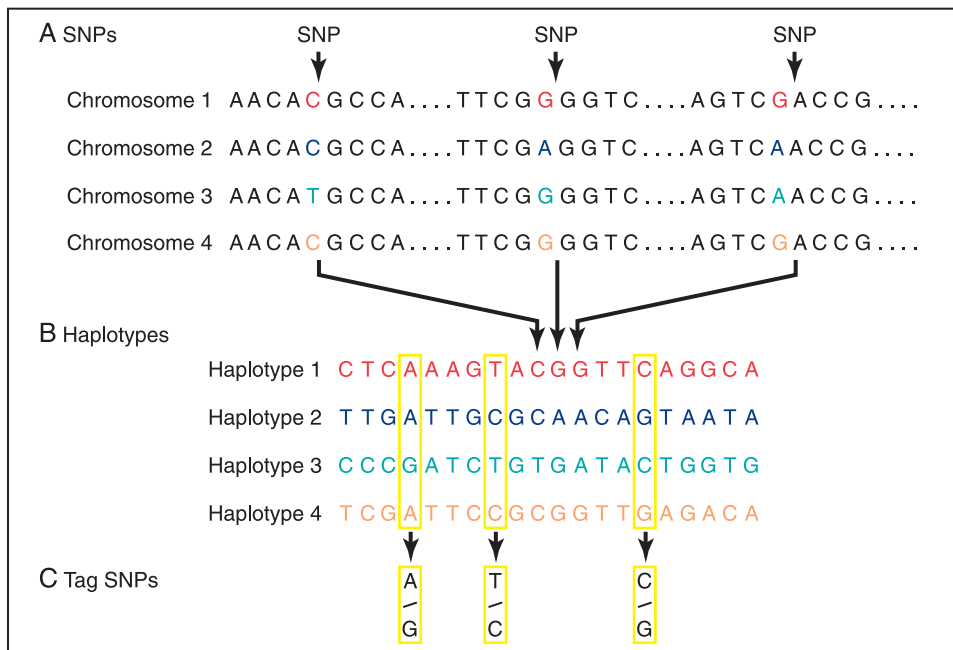

FIGURE 1-5 Single nucleotide polymorphisms (SNPs), haplotypes, and tag SNPs. Stretches of mostly identical DNA on the same chromosome are shown for four individuals. SNP refers to the variation of the three bases shown in a DNA region. The combination of nearby SNPs (A) defines a haplotype. Tag SNPs (C) are useful tools for genotyping four unique haplotypes from the 20 haplotypes (B). (Modified from International HapMap Consortium: The International HapMap Project, *Nature* 426:789–796, 2003.)

disease be discerned. In the postgenomic era, gene mapping entails the statistical association with the use of LD and high-density genetic maps that span thousands to 100,000 base pairs. To enable comprehensive association studies to become routine in clinical practice, inexpensive genotyping assays and denser maps with all common polymorphisms must be linked to all possible manifestations of the disease. Longitudinal studies of the HapMap and Perlegen cohorts can determine the effects of diet, exercise, environmental factors, and family history on future clinical events. Without similar approaches to securing adequate sample sizes and datasets, the promise of genetic population theory will not overcome the inherent limitations of linking human sequence variation with complex disease traits.

GENE MAPPING AND THE HUMAN GENOME PROJECT

The process of gene mapping involves identifying the relative order and distance of specific loci along the genome. Maps can be of two types: genetic and physical. Genetic maps identify the genomic location of specific genetic loci by a statistical analysis based on the frequency of recombination events of the locus of interest with other known loci. Physical maps identify the genomic location of specific genetic loci by direct measurement of the distance along the genome at which the locus of interest is located in relation to one or more defined markers. The precise location of genes on a chromosome is important for defining the likelihood that a portion of one chromosome will interchange, or cross over, with the corresponding portion of its complementary chromosome when genetic recombination occurs during meiosis (Fig. 1-6).

During meiotic recombination, genetic loci or alleles that have been acquired from one parent interchange with those acquired from the other parent to produce new combinations of alleles,

and the likelihood that alleles will recombine during meiosis varies as a function of their linear distance from one another in the chromosomal sequence. This recombination probability (i.e., distance) is commonly quantitated in centimorgan (cM) units; 1 cM is the chromosomal distance over which there is a 1% chance that two alleles will undergo a crossover event during meiosis. Crossover events serve as the basis for mixing parental base sequences during development, promoting genetic diversity among offspring. Analysis of the tendency for specific alleles to be inherited together indicates that the recombination distance in the human genome is about 3000 cM.

Identifying the gene or genes responsible for a specific polygenic disease phenotype requires an understanding of the topographic anatomy of the human genome, which is inextricably linked to interactions with the environment. The Human Genome Project, first proposed in 1985, represented an international effort to determine the complete nucleotide sequence of the human genome, including the construction of its detailed genetic, physical, and transcript maps, with identification and characterization of all genes. This foray into large-scale biology was championed by Nobel Laureate James Watson as the defining moment in his lifetime for witnessing the path from the double helix to the sequencing of 3 billion bases of the human genome, paving the way for understanding human evolution and harnessing the benefits for human health.

Among the earliest achievements of the Human Genome Project was the development of 1-cM resolution maps, each containing 3000 markers, and the identification of 52,000 sequenced tagged sites. For functional analysis on a genome-wide scale, major technologic advances were made, including as high-throughput oligonucleotide synthesis, normalized and subtracted complementary DNA (cDNA) libraries, and DNA microarrays.

FIGURE 1-6 Crossing over and recombination. **A**, Two haploid chromosomes are shown, one from each parent (*red* and *blue*) with two genomic loci denoted by the *circles* and *squares*. **B**, Crossing over of one haploid chromosome from each parent. **C**, Resulting recombination of chromosomal segments redistributes one haploid locus (*squares*) from one diploid pair to another.

In 1998, the Celera private venture proposed a goal similar to that of the Human Genome Project using a revolutionary approach, called *shotgun sequencing*, to determine the sequence of the human genome (<http://www.dnai.org/c/index.html>). The shotgun sequencing method was designed for random, large-scale sequencing and subsequent alignment of sequenced segments using computational and mathematic modeling. In the end, the Human Genome Project in collaboration with the Celera private venture produced a refined map of the entire human genome in 2001.

Because of the differences in genomic sequence that arise as a consequence of normal biologic variations or sequence polymorphisms, the resulting restriction fragment length polymorphisms (RFLPs) differ among individuals and are inherited according to mendelian principles. These polymorphisms can serve as genetic markers for specific loci in the genome. One of the most useful types of RFLP for localization of genetic loci in the genome is that produced by tandem repeats of sequence. Tandem repeats arise through *slippage* or stuttering of the DNA polymerase during replication in the case of STRs; longer variations arise through unequal crossover events. STRs are distributed throughout the genome and are highly polymorphic. These markers have

FIGURE 1-7 Linkage analysis. Analysis of the association (i.e., genomic contiguity) of a mutation (*M*) and a polymorphic allelic marker (*A*) shows close linkage in that the mutation segregates with the *A* allele, whereas the wild-type gene locus (*WT*) associates with the *B* allele.

two different alleles at each locus that are derived from each parent; the origins of the two chromosomes can be discerned through this analysis.

The use of highly polymorphic tandem repeats that occur throughout the genome as genomic markers has provided a basis for mapping specific gene loci by establishing the association or linkage with select markers. Linkage analysis is predicated on a simple principle: the likelihood that a crossover event will occur during meiosis decreases the closer the locus of interest is to a given marker. The extent of genetic linkage can be ascertained for any group of loci, one of which may contain a disease-producing mutation (Fig. 1-7).

IDENTIFYING MUTANT GENES

Deducing the identity of a specific gene sequence thought to cause a specific human disease requires identification of mutations in the gene of interest. If the gene suspected to be responsible for the disease phenotype is known, its sequence can be determined by conventional cloning and sequencing strategies, and the mutation can be identified. A variety of techniques are available for detecting mutations. Mutations that involve insertion or deletion of large segments of DNA can be detected by Southern blot, in which the isolated DNA is annealed to a radioactively labeled fragment of a cDNA sequence. Prior incubation of the DNA with a specific restriction endonuclease cleaves the DNA sequence of interest at specific sites to produce smaller fragments that can be monitored by agarose gel electrophoresis. Shifts in mobility on the gel in comparison with wild-type sequence become apparent as a function of changes in the molecular size of the fragment. Alternatively, the polymerase chain reaction (PCR) can be used to identify mutations.

In the PCR approach, small oligonucleotides (20 to 40 bases long), which are complementary to regions of DNA that bracket the sequence of interest and are complementary to each strand of the double-stranded DNA, are synthesized and used as primers for the amplification of the DNA sequence of interest. These

primers are added to the DNA solution. The temperature of the solution is increased to dissociate the individual DNA strands and is then reduced to permit annealing of the primers to their complementary template target sites. A thermostable DNA polymerase is included in the reaction to synthesize new DNA in the 5' to 3' direction from the primer annealing sites. The temperature is then increased to dissociate duplex structures, after which it is reduced, enabling another cycle of DNA synthesis to occur. Several temperature cycles (usually up to 40) are used to amplify progressively the concentration of the sequence of interest, which can be identified as a PCR product by agarose gel electrophoresis with a fluorescent dye. The product can be isolated and sequenced to identify the suggested mutation.

If the gene is large and the site of the mutation is unknown (especially if it is a point mutation), other methods can be used to identify the likely mutated site in the exonic sequence. A common approach involves scanning the gene sequence for mutations that alter the structural conformation of short complexes between parent DNA and PCR products, leading to a shift in mobility on a nondenaturing agarose gel (i.e., single-strand conformational polymorphism). A single-base substitution or deletion can change the conformation of the complex compared with wild-type complexes and yield a shift in mobility. Sequencing this comparatively small region of the gene facilitates precise identification of the mutation.

When the gene thought to cause the disease phenotype is unknown, when its likely position on the genome has not been identified, or when only limited mapping information is available, a candidate gene approach can be used to identify the mutated gene. In this strategy, potential candidate genes are identified on the basis of analogy to animal models or by analysis of known genes that map to the region of the genome for which limited information is available. The candidate gene is then analyzed for potential mutations. Regardless of the approach used, mutations identified in candidate genes should always be correlated with functional changes in the gene product because some mutations may be functionally silent, representing a polymorphism without phenotypic consequences. Functional changes in the gene product can be evaluated through the use of cell culture systems to assess protein function by expressing the mutant protein through transiently transfecting the cells with a vector that carries the cDNA coding for the gene of interest and incorporating the mutation of interest. Alternatively, unique animal models can be developed in which the mutant gene is incorporated in the male pronucleus of oocytes taken from a superovulating, impregnated female. This union produces an animal that overexpresses the mutant gene; it produces a transgenic animal, an animal with more than the usual number of copies of a given gene, or an animal in which the gene of interest is disrupted and the gene product is not synthesized (i.e., a gene *knockout* animal or an animal with one half [heterozygote] or none [homozygote] of the usual number of a given gene).

Molecular Diagnostics

The power of molecular techniques extends beyond their use in defining the precise molecular basis of an inherited disease. By exploiting the exquisite sensitivity of PCR to amplify rare nucleic acid sequences, it is possible to diagnose rapidly a range of

infectious diseases for which unique sequences are available. In particular, infections caused by fastidious or slow-growing organisms can be rapidly diagnosed, similar to the case for *Mycobacterium tuberculosis*. The presence of genes conferring resistance to specific antibiotics in microorganisms can also be verified by PCR techniques. Sequencing of the entire genome of organisms such as *Escherichia coli*, *M. tuberculosis*, and *Treponema pallidum* offers unparalleled opportunities to monitor the epidemiologic structures of infections, follow the course of acquired mutations, tailor antibiotic therapies, and develop unique gene-based therapies (discussed later) for infectious agents for which conventional antibiotic therapies are ineffective or marginally effective.

The application of molecular methods to human genetics has revolutionized the field. Through the use of approaches that incorporate linkage analysis and PCR, point mutations can be precisely localized and characterized. At the other end of the spectrum of genetic changes that underlie disease, chromosomal translocations, deletions, or duplications can be identified by conventional cytogenetic methods. Large deletions that can incorporate many kilobase pairs and many genes can be visualized with fluorescence in situ hybridization (FISH), a technique in which a segment of cloned DNA is labeled with a fluorescent tag and hybridized to chromosomal DNA. With the deletion of the segment of interest from the genome, the chromosomal DNA fails to fluoresce in the corresponding chromosomal location.

Advances in molecular medicine have elucidated the mechanisms of carcinogenesis and revolutionized the diagnosis and treatment of neoplastic diseases. According to current views, a neoplasm arises from the clonal proliferation of a single cell that is transformed from a regulated, quiescent state into an unregulated growth phase. DNA damage accumulates in the parental tumor cell as a result of exogenous factors (e.g., radiation exposure) or heritable determinants. In early phases of carcinogenesis, certain genomic changes may impart intrinsic genetic instability that increases the likelihood of additional damage. One class of genes that becomes activated during carcinogenesis is oncogenes, which are primordial genes that normally exist in the mammalian genome in an inactive (proto-oncogene) state but, when activated, promote unregulated cell proliferation through specific intracellular signaling pathways.

Molecular methods based on the acquisition of specific tumor markers and unique DNA sequences that result from oncogenetic markers of larger chromosomal abnormalities (i.e., translocations or deletions that promote oncogenesis) are broadly applied to the diagnosis of malignancies. These methods can be used to establish the presence of specific tumor markers and oncogenes in biopsy specimens, to monitor the presence or persistence of circulating malignant cells after completion of a course of chemotherapy, and to identify the development of genetic resistance to specific chemotherapeutic agents. Through the use of conventional linkage analysis and candidate gene approaches, future studies will be able to identify individuals with a heritable predisposition to malignant transformation. Many of these topics are discussed in later chapters.

The advent of *gene chip* technologies or expression arrays has revolutionized molecular diagnostics and has begun to clarify the pathobiologic structures of complex diseases. These methods involve labeling the cDNA generated from the entire pool of

mRNA isolated from a cell or tissue specimen with a radioactive or fluorescent marker and annealing this heterogeneous population of polynucleotides to a solid-phase substrate to which many different polynucleotides of known sequence are attached. The signals from the labeled cDNA strands bound to specific locations on the array are monitored, and the relative abundance of particular sequences is compared with that from a reference specimen. Using this approach, microarray patterns can be used as molecular fingerprints to diagnose a particular disease (i.e., type of malignancy and its susceptibility to treatment and prognosis) and to identify the genes whose expression increases or decreases in a specific disease state (i.e., identification of disease-modifying genes).

Many other applications of molecular medicine techniques are available in addition to those in infectious diseases and oncology. Molecular methods can be used to sort out genetic differences in metabolism that may modulate pharmacologic responses in a population of individuals (i.e., pharmacogenomics), address specific forensic issues such as paternity or criminal culpability, and approach epidemiologic analysis on a precise genetic basis.

Genes and Human Disease

Human genetic diseases can be divided into three broad categories: those caused by a mutation in a single gene (e.g., monogenic disorders, mendelian traits), those caused by mutations in more than one gene (e.g., polygenic disorders, complex disease traits), and those caused by chromosomal abnormalities (Table 1-2). In all three groups of disorders, environmental factors can contribute to the phenotypic expression of the disease by modulating gene expression or unmasking a biochemical abnormality that has no functional consequence in the absence of a stimulus or stress.

Classic monogenic disorders include sickle cell anemia, familial hypercholesterolemia, and cystic fibrosis. These genetic diseases can be exclusively produced by a single specific mutation (e.g., sickle cell anemia) or by any one of several mutations (e.g., familial hypercholesterolemia, cystic fibrosis) in a given family (i.e., Pauling paradigm). Some of these disorders evolved to protect the host. For example, sickle cell anemia evolved as

protection against *Plasmodium falciparum* malaria, and cystic fibrosis developed as protection against cholera. Examples of polygenic disorders or complex disease traits include type 1 (insulin-dependent) diabetes mellitus, atherosclerotic cardiovascular disease, and essential hypertension. A common example of a chromosomal disorder is the presence of an extra chromosome 21 (i.e., trisomy 21).

The overall frequency of monogenic disorders is about 1%. About 60% of these include polygenic disorders, which includes those with a genetic substrate that develops later in life. About 0.5% of monogenic disorders include chromosomal abnormalities. Chromosomal abnormalities are frequent causes of spontaneous abortion and malformations.

Contrary to the view held by early geneticists, few phenotypes are entirely defined by a single genetic locus. Monogenic disorders are comparatively uncommon; however, they are still useful as a means to understanding some basic principles of heredity. Three types of monogenic disorders occur: autosomal dominant, autosomal recessive, and X-linked. *Dominance* and *recessiveness* refer to the nature of the heritability of a genetic trait and correlate with the number of alleles affected at a given locus. If a mutation in a single allele determines the phenotype, the mutation is said to be dominant; that is, the heterozygous state conveys the clinical phenotype to the individual. If a mutation is necessary at both alleles to determine the phenotype, the mutation is said to be recessive; that is, only the homozygous state conveys the clinical phenotype to the individual. Dominant or recessive mutations can lead to a loss or a gain of function of the gene product. If the mutation is present on the X chromosome, it is defined as X-linked (which in males can, by definition, be viewed only as dominant); otherwise, it is autosomal.

The importance of identifying a potential genetic disease as inherited by one of these three mechanisms is that the disease must involve a single genomic abnormality that leads to an abnormality in a single protein. Classically identified genetic diseases are produced by mutations that affect coding (exonic) sequences. However, mutations in intronic and other untranslated regions of the genome occur that may disturb the function or expression of specific genes. Examples of diseases with these types of mutations include myotonic dystrophy and Friedreich ataxia.

An individual with a dominant monogenic disorder typically has one affected parent and a 50% chance of transmitting the mutation to his or her offspring. Men and women are equally likely to be affected and equally likely to transmit the trait to their offspring. The trait cannot be transmitted to offspring by two unaffected parents. In contrast, an individual with a recessive monogenic disorder typically has parents who are clinically normal. Affected parents, each heterozygous for the mutation, have a 25% chance of transmitting the clinical phenotype to their offspring but a 50% chance of transmitting the mutation to their offspring (i.e., producing an unaffected carrier).

Notwithstanding the clear heritability of common monogenic disorders (e.g., sickle cell anemia), the clinical expression of the disease in an individual with a phenotype expected to produce the disease may vary. *Variability in clinical expression* is defined as the range of phenotypic effects observed in individuals carrying a given mutation. *Penetrance* refers to a smaller subset of individuals with variable clinical expression of a mutation and is defined

TABLE 1-2 MOLECULAR BASIS OF MUTATIONS

TYPE	EXAMPLES
MONOGENIC DISORDERS	
Autosomal dominant	Polycystic kidney disease 1, neurofibromatosis 1
Autosomal recessive	β -Thalassemia, Gaucher's disease
X-linked	Hemophilia A, Emery-Dreifuss muscular dystrophy
One of multiple mutations	Familial hypercholesterolemia, cystic fibrosis
POLYGENIC DISORDERS	
Complex disease traits	Type 1 (insulin-dependent) diabetes, essential hypertension, atherosclerotic disease, cancer
CHROMOSOMAL ABNORMALITIES	
Deletions, duplications	Turner Syndrome (monosomy), Down Syndrome (Trisomy)

as the proportion of individuals with a given genotype who exhibit any clinical phenotypic features of the disorder.

Three principal determinants of variability in clinical expression or incomplete penetrance of a given genetic disorder can occur: environmental factors, the effects of other genetic loci, and random chance. Environmental factors can modulate disease phenotype by altering gene expression in several ways, including acting on transcription factors (e.g., transcription factors that are sensitive to cell redox state, such as nuclear factor- κ B) or on *cis*-elements in gene promoters (e.g., folate-dependent methylation of CpG-rich regions) and post-translationally modifying proteins (e.g., lysine oxidation). That other genes can modify the effects of disease-causing mutations is a reflection of the overlay of genetic diversity on primary disease phenotype. Numerous examples exist of the effects of these *disease-modifying genes* producing phenotypic variations among individuals with the identical primary disease-causing mutations (i.e., gene-gene interactions) and the effects of disease-modifying genes interacting with environmental determinants to alter phenotype further (i.e., gene-environment interactions). These interactions are important in polygenic diseases; gene-gene and gene-environment interactions can modify the phenotypic expression of the disease. Among patients with sickle cell disease, for example, some experience painful crises, others exhibit acute chest syndrome, and still other presentations include hemolytic crises.

Genetic disorders affecting a unique pool of DNA, mitochondrial DNA, have been identified. Mitochondrial DNA is inherited only from the mother. Mutations in mitochondrial DNA can vary among mitochondria within a given cell and within a given individual (i.e., heteroplasmy). Examples of disorders of the mitochondrial genome are Kearns-Sayre syndrome and Leber hereditary optic neuropathy. The list of known mitochondrial genomic disorders is growing rapidly, and mitochondrial contributions to a large number of common polygenic disorders may also exist.

Molecular Medicine

A principal goal of molecular strategies is to restore normal gene function to individuals with genetic mutations. Methods to do so are currently primitive, and a number of obstacles must be surmounted for this approach to be successful.

Delivering a complete gene into a cell is not easy, and persistent expression of the new gene cannot be ensured because of the variability in its incorporation in the genome and the consequent variability in its regulated expression. Many approaches have been used, but none has been completely successful. They include the following: (1) packaging the cDNA in a viral vector, such as an attenuated adenovirus, and using the cell's ability to take up the virus as a means for the cDNA to gain access to the cell; (2) delivering the cDNA by means of a calcium phosphate-induced perturbation of the cell membrane; and (3) encapsulating the cDNA in a liposome that can fuse with the cell membrane and thereby deliver the cDNA.

After the cDNA has been successfully delivered to the cell of interest, the magnitude and durability of expression of the gene product are important variables. The magnitude of expression is

determined by the number of copies of cDNA taken up by a cell and the extent of their incorporation in the genome of the cell. The durability of expression appears to depend partly on the antigenicity of the sequence and protein product.

Notwithstanding these technical limitations, gene therapy has been used to treat adenosine deaminase deficiency successfully, which suggests that the principle on which the treatment is based is reasonable. Clinical trials of gene therapy slowed considerably after unexpected deaths were widely reported in the scientific and lay media. Efforts in other genetic disorders and as a means to induce expression of a therapeutic protein (e.g., vascular endothelial cell growth factor to promote angiogenesis in ischemic tissue) are ongoing.

Understanding the molecular basis of disease leads naturally to the identification of unique disease targets. Examples of this principle have led to the development of novel therapies for diseases that have been difficult to treat. Imatinib, a tyrosine kinase inhibitor that is particularly effective at blocking the action of the BCR-ABL kinase, is effective for the treatment of chronic-phase chronic myelogenous leukemia. Monoclonal antibody to tumor necrosis factor- α (infliximab) and soluble tumor necrosis factor- α receptor (etanercept) are prime examples of *biologic modifiers* that are effective in the therapy of chronic inflammatory disorders, including inflammatory bowel disease and rheumatoid arthritis. This approach to molecular therapeutics is rapidly expanding and holds great promise for improving the therapeutic armamentarium for a variety of diseases.

Beyond cancer-related categories (e.g., DNA, RNA repair), gene expression arrays have identified additional interactions of regulatory pathways of clinical interest. The limitation of gene expression profiling using microarrays, which does not account for post-transcriptional and other post-translational modifications of protein-coding products, will likely be overcome by advances in proteomics. Such processes by signaling networks tend to amplify or attenuate gene expression on time scales lasting seconds to weeks. Much work remains to improve current knowledge about the pathways that initiate and promote tumors. The basic pathways and nodal points of regulation will be identified for rational drug design and targets from mechanistic insights gleaned from expression profiling of cultured cell lines, from small animal models of human disease, and from human samples. Although accounting for tissue heterogeneity and variation among different cell types, the new systems' approach for incorporating genomic and computational research appears particularly promising for deciphering the pathways that promote tumorigenesis. Biologists and clinicians will use information derived from these tools to understand the events that promote survival, proangiogenesis, and immune escape, all of which may confer metastatic potential and progression.

What potential diagnostic tools are available to establish genetic determinants of drug response? Genome-wide approaches from the Human Genome Project in combination with microarrays, proteomic analysis, and bioinformatics will identify multiple genes encoding drug targets (e.g., receptors). Similar high-throughput screening should provide insights into the predisposition to adverse effects or outcomes from treatments that are linked to genetic polymorphisms.

Genome Editing

Improvements of genome editing tools are revolutionizing the ability of researchers to make precision changes in the genomes of stem cells from humans, facilitating the fast and cost-effective production of genetically engineered animals (e.g., mouse and rat) and human cells. The clustered regularly interspaced short palindromic repeats (CRISPR) pathway was first discovered in bacteria, in which it provides an immunologic memory of previous viral infection.

Along with CRISPR-associated protein 9 (Cas9) and guide RNA (gRNA), this relatively simple prokaryotic system has been shown to function as an efficient site-specific nuclease with low off-targeting effects at recognition sequences in mammalian cells. From dermal fibroblasts of an affected organism or patient, for example, we can generate induced pluripotent stem cells (iPSCs) used for the differentiation of iPSC-derived cardiomyocytes or skeletal muscle, or both. Correction of the mutation involves a co-targeting strategy in which a selection cassette capable of the zinc finger-stimulated homologous recombination is targeted to the affected locus at the same time as the mutation is corrected. The CRISPR system is increasingly being used to target a variety of mammalian loci of stem cells and functionality of this targeting vector containing an excisable piggyback construct, allowing the stem cells to be gene corrected “without a trace.”

Pharmacogenetics

The future of pharmacogenetics is to know all the factors that influence adverse drug effects. In this way, the premature abandonment of special drug classes can be avoided in favor of rational drug design and therapy.

Many hurdles must be overcome for pharmacogenetics to become more widespread and to be integrated into medical practice. Current approaches of trial and error in medical practice are well engrained, but the allure of blockbuster drugs produced by the pharmaceutical industry warrants a new model for approaching individualized doses. Training for physicians in molecular biology and genetics should complement clinical pharmacogenomic studies that determine efficacy in an era of evidence-based medicine. Pharmacogenetic polymorphisms, unlike other clinical variables such as renal function, need only a single test, ideally performed for newborns.

Polygenic models of therapeutic optimization still face hurdles that reduce the chances for abuse of genetic information and additional costs. However, SNP haplotyping has the potential to identify genetically similar subgroups of the population and to randomize therapies based on more robust genetic markers. On a population level, genomic variability is much greater within than among distinct racial and ethnic groups.

Therapeutic efficacy and host toxicity are influenced by the patient’s specific disease, age, renal function, nutritional status, and other comorbid factors. New challenges will be posed for the selection of drug therapy for patients with cancer, hypertension, and diabetes. Treatment of multisystem disorders (e.g., metabolic syndrome) may be derived from novel therapeutics based on individual, interacting, and complementary molecular pathways.

Regenerative Medicine

Regenerative medicine entails the uses of novel applications and approaches to repair damaged cells or tissues with the anticipated full restoration of normal function. By harnessing the compendium of biologics, drugs, medical devices, and cell-based therapies, this emerging field represents the convergence of multiple disciplines that integrate tissue engineering, stem cell biology, biomaterials, and gene therapy. Over 50 years, the transplantation of solid organs such as corneas, hearts, lungs, kidneys, and living-donor livers has become a well-established medical-surgical intervention, but the limited availability of organs restricts widespread applications. Tissue-engineered grafts for skin replacement of wounds after burns and diabetic foot ulcers are the antecedent strategies for the use of a patient’s own cells, grown outside the body, to ultimately replace a bladder or vascular grafts used for bypass surgery.

A new era of regenerative biology has emerged with the discoveries by James Thomson that human embryonic stem cells can be cultured in a Petri dish and by Shinya Yamanaka that adult mammalian cells can be reprogrammed to become iPSCs. The iPSCs share the common features of somatic cell reprogramming but with the aid of one to four transcription factors. Embryonic stem (ES) cells share common features of clonogenicity, self-renewal, and multipotentiality, a prerequisite for differentiation into diverse cell lineages of multicellular adult organism. Technical and ethical concerns propelled the search for new sources, including the isolation of ES cells from a single blastomere, which circumvents destruction of the embryo, and the use of postimplantation embryos as ES cell donors. Somatic cell nuclear transplantation (SCNT) or nuclear transfer is a technique for successful cloning and reprogramming of adult animal cell nuclei from healthy oocyte host cells. SCNT provides a source of stem cells tailored to the donor organism and promises to accelerate the pace for human use. Because stem and precursor cells can be obtained from a variety of sources (e.g., embryos, adult tissues), their manipulation and transplantation in animal models and pilot human studies are increasingly providing alternative and complementary strategies to solid organ transplantation, thereby expanding the platform for regenerative medicine.

Previous dogmas that postmitotic, terminally differentiated organs are devoid of regenerative capacity have been overturned by evidence for cellular plasticity and low-level regeneration of adult solid organs throughout adult life. Age, gender, disease status, and other risk factors influence cellular regenerative plasticity, proliferation, and cellular functions.

Can progenitor cells derived from bone marrow or circulating blood be administered safely and efficaciously? Clinical and translational scientists are actively pursuing clinical trials to address whether stem cell therapy has efficacy for the victims of stroke, heart attack, and spinal cord injury. Given the large investments from federal, state, and private agencies, there have been concerns raised about the claims of stem cell therapy to engender false hopes. Notwithstanding, stem cell transplantation of bone marrow has become the standard of care for several blood dyscrasias, and new combinatorial strategies are in clinical trials. Beyond the questions of feasibility related to benefits from

transplantation originating from embryonic, fetal, or adult stem cell lineages, the era of large-scale clinical trials will be increasingly challenged as precision medicine that tailors therapy to the individual's genome and disease profile enters the clinic.

Structure and Function of the Normal Heart and Blood Vessels

Nicole L. Lohr and Ivor J. Benjamin

DEFINITION

The circulatory system comprises the heart, which is connected in series to the arterial and venous vascular networks, which are arranged in parallel and connect at the level of the capillaries (Fig. 2-1). The heart is composed of two atria, which are low-pressure capacitance chambers that function to store blood during ventricular contraction (systole) and then fill the ventricles with blood during ventricular relaxation (diastole). The two ventricles are high-pressure chambers responsible for pumping blood through the lungs (right ventricle) and to the peripheral tissues (left ventricle). The left ventricle is thicker than the right, in order to generate the higher systemic pressures required for perfusion.

There are four cardiac valves that facilitate unidirectional blood flow through the heart. Each of the four valves is surrounded by a fibrous ring, or annulus, that forms part of the structural support of the heart. Atrioventricular (AV) valves separate the atria and ventricles. The mitral valve is a bileaflet valve that separates the left atrium and left ventricle. The tricuspid valve is a trileaflet valve that separates the right atrium and right ventricle. Strong chords (chordae tendineae) attach the ventricular aspects of these valves to the papillary muscles of their respective ventricles. Semilunar valves separate the ventricles from the arterial chambers: the aortic valve separates the left ventricle from the aorta, and the pulmonic valve separates the right ventricle from the pulmonary artery.

A thin, double-layered membrane called the pericardium surrounds the heart. The inner, or visceral, layer adheres to the outer surface of the heart, also known as the epicardium. The outer layer is the parietal pericardium, which attaches to the sternum, vertebral column, and diaphragm to stabilize the heart in the chest. Between these two membranes is a pericardial space filled with a small amount of fluid (<50 mL). This fluid serves to lubricate contact surfaces and limit direct tissue-surface contact during myocardial contraction. A normal pericardium exerts minimal external pressure on the heart, thereby facilitating normal movement of the interventricular septum during the cardiac cycle. Too much fluid in this space (i.e., pericardial effusion), can cause impaired ventricular filling and abnormal septal movement. Please refer to Chapter 77, “Pericardial Diseases,” in *Goldman-Cecil Medicine*, 25th Edition.

CIRCULATORY PATHWAY

The purpose of the circulatory system is to bring deoxygenated blood, carbon dioxide, and other waste products from the tissues

to the lungs for disposal and reoxygenation (see Fig. 2-1A). Deoxygenated blood drains from peripheral tissues through venules and veins, eventually entering the right atrium through the superior and inferior venae cavae during ventricular systole. Venous drainage from the heart enters the right atrium through the coronary sinus. During ventricular diastole, the blood in the right atrium flows across the tricuspid valve and into the right ventricle. Blood in the right ventricle is ejected across the pulmonic valve and into the main pulmonary artery, which bifurcates into the left and right pulmonary arteries and perfuses the lungs. After multiple bifurcations, blood reaches the pulmonary capillaries, where carbon dioxide is exchanged for oxygen across the alveolar-capillary membrane. Oxygenated blood then enters the left atrium from the lungs via the four pulmonary veins. Blood flows across the open mitral valve and into the left ventricle during diastole and is ejected across the aortic valve and into the aorta during systole. The blood reaches various organs, where oxygen and nutrients are exchanged for carbon dioxide and metabolic wastes, and the cycle begins again.

The heart receives its blood supply through the left and right coronary arteries, which originate in outpouchings of the aortic root called the *sinuses of Valsalva*. The left main coronary artery is a short vessel that bifurcates into the left anterior descending (LAD) and the left circumflex (LCx) coronary arteries. The LAD supplies blood to the anterior and anterolateral left ventricle through diagonal branches and to the anterior interventricular septum through septal perforator branches. The LAD travels anteriorly in the anterior interventricular groove and terminates at the cardiac apex. The LCx traverses posteriorly in the left AV groove (between left atrium and left ventricle) to perfuse the lateral aspect of the left ventricle (through obtuse marginal branches) and the left atrium. The right coronary artery (RCA) courses down the right AV groove to the *crux* of the heart, the point at which the left and right AV grooves and the inferior interventricular groove meet. The RCA gives off branches to the right atrium and acute marginal branches to the right ventricle.

The blood supply to the diaphragmatic and posterior aspects of the left ventricle varies. In 85% of individuals, the RCA bifurcates at the crux to form the posterior descending coronary artery (PDA), which travels in the inferior interventricular groove to supply the inferior left ventricle and the inferior third of the interventricular septum, and the posterior left ventricular (PLV) branches. This course is termed a *right-dominant circulation*. In 10% of individuals, the RCA terminates before reaching the crux, and the LCx supplies the PLV and PDA. This course is termed a *left-dominant circulation*. In the remaining individuals, the RCA

FIGURE 2-1 **A**, Schematic representation of the systemic and pulmonary circulatory systems. The venous system contains the greatest amount of blood at any one time and is highly distensible, accommodating a wide range of blood volumes (high capacitance). The arterial system is composed of the aorta, arteries, and arterioles. Arterioles are small muscular arteries that regulate blood pressure by changing tone (resistance). **B**, A schematic representation of the cardiac conduction system.

gives rise to the PDA and the LCx gives rise to the PLV in a co-dominant circulation.

CONDUCTION SYSTEM

The sinoatrial (SA) node is a collection of specialized pacemaker cells, 1 to 2 cm long, that is located in the right atrium between

the superior vena cava and the right atrial appendage (see Fig. 2-1B). The SA node is supplied by the SA nodal artery, which is a branch of the RCA in about 60% of the population and a branch of the LCx in about 40%. An electrical impulse originates in the SA and is conducted to the AV node by internodal tracts within the atria.

The AV node is a critical electrical interface between the atria and ventricles, because it facilitates electromechanical coupling. The AV node is located at the inferior aspect of the right atrium, between the coronary sinus and the septal leaflet of the tricuspid valve. The AV node is supplied by the AV nodal artery, which is a branch of the RCA in about 90% of the population and a branch of the LCx in 10%. Electrical impulse conduction slows through the AV node and continues to the ventricles by means of the His-Purkinje system. The increased impulse time through the AV node allows for adequate ventricular filling.

The bundle of His extends from the AV node down the membranous interventricular septum to the muscular septum, where it divides into the left and right bundle branches, finally terminating in Purkinje cells, which are specialized cells that facilitate the rapid propagation of electrical impulses. The Purkinje cells directly stimulate myocytes to contract. The right bundle and the left bundle are supplied by septal perforator branches from the LAD. The distal and posterior portion of the left bundle has an additional blood supply from the AV nodal artery (PDA origin); for that reason, it is more resistant to ischemia. Conduction can be impaired at any point, from ischemia, medications (e.g., β -blockers, calcium channel blockers), infection, or congenital abnormalities. Please refer to Chapter 61, "Principles of Electrophysiology," in *Goldman-Cecil Medicine*, 25th Edition.

NEURAL INNERVATION

The autonomic nervous system is an integral component in the regulation of cardiac function. In general, sympathetic stimulation increases the heart rate (HR) (chronotropy) and the force of myocardial contraction (inotropy). Sympathetic stimulation commences in preganglionic neurons located within the superior five or six thoracic segments of the spinal cord. They synapse with second-order neurons in the cervical sympathetic ganglia and then propagate the signal through cardiac nerves that innervate the SA node, AV node, epicardial vessels, and myocardium. The parasympathetic system produces an opposite physiologic effect by decreasing HR and contractility. Its neural supply originates in preganglionic neurons within the dorsal motor nucleus of the medulla oblongata, which reach the heart through the vagus nerve. These efferent neural fibers synapse with second-order neurons located in ganglia within the heart which terminate in the SA node, AV node, epicardial vessels, and myocardium to decrease HR and contractility. Conversely, afferent vagal fibers from the inferior and posterior aspects of the ventricles, the aortic arch, and the carotid sinus conduct sensory information back to the medulla, which mediates important cardiac reflexes.

MYOCARDIUM

The proper cellular organization of cardiac tissue (myocardium) is critical for the generation of efficient myocardial contraction. Disruptions in this structure and organization lead to cardiac dyssynchrony and arrhythmias, which cause significant

morbidity and mortality. Atrial and ventricular myocytes are specialized, branching muscle cells that are connected end to end by intercalated disks. These disks aid in the transmission of mechanical tension between cells. The myocyte plasma membrane, or sarcolemma, facilitates excitation and contraction through small transverse tubules (T tubules). Subcellular features specific for myocytes include increased mitochondria number for production of adenosine triphosphate (ATP); an extensive network of intracellular tubules, called the *sarcoplasmic reticulum*, for calcium storage; and *sarcomeres*, which are myofibrils comprised of repeating units of overlapping thin actin filaments and thick myosin filaments and their regulatory proteins troponin and tropomyosin. Specialized myocardial cells form the cardiac conduction system (described earlier) and are responsible for the generation of an electrical impulse and organized propagation of that impulse to cardiac myocytes, which, in turn, respond by mechanical contraction.

MUSCLE PHYSIOLOGY AND CONTRACTION

Calcium-induced calcium release is the primary mechanism for myocyte contraction. When a depolarizing stimulus reaches the

myocyte, it enters special invaginations within the sarcolemma called T tubules. Specialized channels open in response to depolarization, permitting calcium flux into the cell (Fig. 2-2). The sarcoplasmic reticulum is in close proximity to the T tubules, and the initial calcium current triggers the release of large amounts of calcium from the sarcoplasmic reticulum into the cell cytosol. Calcium then binds to the calcium-binding regulatory subunit, troponin C, on the actin filaments of the sarcomere, resulting in a conformational change in the troponin-tropomyosin complex. The myosin binding site on actin is now exposed, to facilitate binding of actin-myosin cross-bridges, which are necessary for cellular contraction. The energy for myocyte contraction is derived from ATP. During contraction, ATP promotes dissociation of myosin from actin, thereby permitting the sliding of thick filaments past thin filaments as the sarcomere shortens.

The force of myocyte contraction is regulated by the amount of free calcium released into the cell by the sarcoplasmic reticulum. More calcium allows for more frequent actin-myosin interactions, producing a stronger contraction. On repolarization of the sarcolemmal membrane, intracellular calcium is rapidly and

FIGURE 2-2 Calcium dependence of myocardial contraction. (1) Electrical depolarization of the myocyte results in an influx of Ca²⁺ ions into the cell through channels in the T tubules. (2) This initial phase of calcium entry stimulates the release of large amounts of Ca²⁺ from the sarcoplasmic reticulum (SR). (3) The Ca²⁺ then binds to the troponin-tropomyosin complex on the actin filaments, resulting in a conformational change that facilitates the binding interaction between actin and myosin. In the presence of adenosine triphosphate (ATP), the actin-myosin association is cyclically dissociated as the thick and thin filaments slide past each other, resulting in contraction. (4) During repolarization, the Ca²⁺ is actively pumped out of the cytosol and sequestered in the SR. ATPase, Adenosine triphosphatase; M, mitochondrion.

actively resequenced into the sarcoplasmic reticulum, where it is stored by various proteins, including calsequestrin, until the next wave of depolarization occurs. Calcium is also extruded from the cytosol by various calcium pumps in the sarcolemma. The active removal of intracellular calcium by ATP ion pumps facilitates ventricular relaxation, which is necessary for proper ventricular filling during diastole.

Circulatory Physiology and the Cardiac Cycle

The term *cardiac cycle* describes the pressure changes within each cardiac chamber over time (Fig. 2-3). This cycle is divided into *systole*, the period of ventricular contraction, and *diastole*, the period of ventricular relaxation. Each cardiac valve opens and closes in response to pressure gradients generated during these periods. At the onset of systole, ventricular pressure exceeds atrial pressures, so the AV valves passively close. As myocytes contract, the intraventricular pressures rise initially, without a change in ventricular volume (isovolumic contraction), until they exceed the pressures in the aorta and pulmonary artery. At this point, the semilunar valves open, and ventricular ejection of blood occurs. When intracellular calcium levels fall, ventricular relaxation begins; arterial pressures exceed intraventricular pressures, so the semilunar valves close. Ventricular relaxation initially does not change ventricular volume (isovolumic relaxation). At the point at which intraventricular pressures fall below atrial pressures, the AV valves open. This begins the rapid and passive ventricular filling phase of diastole, during which blood in the atria empties into the ventricles. At the end of diastole, active atrial contraction augments ventricular filling. When the myocardium exhibits increased stiffness due to age, hypertension, diabetes, or systolic heart failure, the early passive phase of ventricular filling is decreased. The end result is reliance on atrial contraction to sufficiently fill the ventricle during diastole. In atrial fibrillation, the atrium does not contract; patients often have worse symptoms because this additional ventricular filling is lost.

Pressure tracings obtained from the periphery complement the hemodynamic changes exhibited in the heart. In the absence of valvular disease, there is no impediment to blood flow moving from the ventricles to the arterial beds, so the systolic arterial pressure rises sharply to a peak. During diastole, no further blood volume is ejected into the aorta, so the arterial pressure gradually falls as blood flows to the distal tissue beds and elastic recoil of the arteries occurs.

Atrial pressure can be directly measured in the right atrium, but the left atrial pressure is indirectly measured by occluding a small pulmonary artery branch and measuring the pressure distally (the pulmonary capillary wedge pressure). An atrial pressure tracing is shown in Figure 2-3. It is composed of several waves. The *a wave* represents atrial contraction. As the atria subsequently relax, the atrial pressure falls, and the *x descent* is seen on the pressure tracing. The *x descent* is interrupted by a small *c wave*, which is generated as the AV valve bulges toward the atrium during ventricular systole. As the atria fill from venous return, the *v wave* is seen, after which the *y descent* appears as the AV valves open and blood from the atria empties into the ventricles. The normal ranges of pressures in the various cardiac chambers are shown in Table 2-1.

Cardiac Performance

The amount of blood ejected by the heart each minute is referred to as the cardiac output (CO). It is the product of the stroke volume (SV), which is the amount of blood ejected with each ventricular contraction, and the HR:

$$CO = SV \times HR$$

FIGURE 2-3 Simultaneous electrocardiogram (ECG) and pressure tracings obtained from the left atrium (LA), left ventricle (LV), and aorta and the jugular venous pressure during the cardiac cycle. (For simplification, pressures on the right side of the heart have been omitted. Normal right atrial (RA) pressure closely parallels that of the LA, and right ventricular and pulmonary artery pressures are timed closely with their corresponding left-sided counterparts; they are reduced only in magnitude. Normally, closure of the mitral and aortic valves precedes closure of the tricuspid and pulmonic valves; whereas valve opening reverses this order. The jugular venous pulse lags behind the RA pulse.) During the course of one cardiac cycle, the electrical (ECG) events initiate and therefore precede the mechanical (pressure) events, and the latter precede the auscultatory events (heart sounds) that they themselves produce (red boxes). Shortly after the P wave, the atria contract to produce the *a wave*. The QRS complex initiates ventricular systole, followed shortly by LV contraction and the rapid buildup of LV pressure. Almost immediately, LV pressure exceeds LA pressure, closing the mitral valve and producing the first heart sound. After a brief period of isovolumic contraction, LV pressure exceeds aortic pressure and the aortic valve opens (AVO). When the ventricular pressure once again falls to less than the aortic pressure, the aortic valve closes to produce the second heart sound and terminate ventricular ejection. The LV pressure decreases during the period of isovolumic relaxation until it drops below LA pressure and the mitral valve opens (MVO). See text for further details.

**TABLE 2-1** NORMAL VALUES FOR COMMON HEMODYNAMIC PARAMETERS

Heart rate	60-100 beats/min
PRESSURES (mm Hg)	
Central venous	≤9

Systolic	100-140
End-diastolic	3-12
Aortic	
Systolic	100-140
Diastolic	60-90
RESISTANCE	
Systemic vascular resistance	800-1500 dynes-sec/cm ⁻⁵
Pulmonary vascular resistance	30-120 dynes-sec/cm ⁻⁵
Cardiac output	4-6 L/min
Cardiac index	2.5-4 L/min

The cardiac index is a way of normalizing the CO to body size. It is the CO divided by the body surface area and is measured in L/min/m². The normal CO is 4 to 6 L/min at rest and can increase fourfold to sixfold during strenuous exercise.

The main determinants of SV are preload, afterload, and contractility (Table 2-2). *Preload* is the volume of blood in the ventricle at the end of diastole; it is primarily a reflection of venous return. Venous return is determined by the plasma volume and the venous compliance. Clinically, intravenous fluids increase preload, whereas diuretics or venodilators such as nitroglycerin decrease preload. When the preload is increased, the ventricle stretches, and the ensuing ventricular contraction becomes more rapid and forceful, because the increased sarcomere length facilitates actin and myosin cross-bridge kinetics by means of an increased sensitivity of troponin C to calcium. This phenomenon is known as the Frank-Starling relationship. Ventricular filling pressure (ventricular end-diastolic pressure, atrial pressure, or pulmonary capillary wedge pressure) is frequently used as a surrogate measure of preload.

Afterload is the force against which the ventricles must contract to eject blood. The main determinants of afterload are the arterial pressure and the dimensions of the left ventricle. As the arterial blood pressure increases, the amount of blood that can be ejected into the aorta decreases. Wall stress, an often overlooked determinant of afterload, is directly proportional to the size of the ventricular cavity and inversely proportional to the ventricular wall thickness (Laplace's law). Therefore, ventricular wall hypertrophy is a compensatory mechanism to reduce afterload. Drugs such as angiotensin-converting enzyme (ACE) inhibitors and hydralazine reduce blood pressure (BP) by reducing afterload. Diuretics decrease left ventricular volume and size, which can reduce wall stress-mediated afterload.

Contractility, or inotropy, represents the force of ventricular contraction in the presence of constant preload and afterload. Inotropy is regulated at a cellular level through stimulation of

TABLE 2-2 FACTORS AFFECTING CARDIAC PERFORMANCE

PRELOAD (LEFT VENTRICULAR DIASTOLIC VOLUME)	
Total blood volume	
Venous (sympathetic) tone	
Body position	
Intrathoracic and intrapericardial pressures	
Atrial contraction	
Pumping action of skeletal muscle	
AFTERLOAD (IMPEDANCE AGAINST WHICH THE LEFT VENTRICLE MUST EJECT BLOOD)	
Peripheral vascular resistance	
Left ventricular volume (preload, wall tension)	
Physical characteristics of the arterial tree (elasticity of vessels or presence of outflow obstruction)	
CONTRACTILITY (CARDIAC PERFORMANCE INDEPENDENT OF PRELOAD OR AFTERLOAD)	
Sympathetic nerve impulses	
Increased contractility	
Circulating catecholamines	
Digitalis, calcium, other inotropic agents	
Increased heart rate or post-extrasystolic augmentation	
Anoxia, acidosis	
Decreased contractility	
Pharmacologic depression	
Loss of myocardium	
Intrinsic depression

Autonomic nervous system	
Temperature, metabolic rate	
Medications, drugs	

catecholaminergic (epinephrine, norepinephrine, and dopamine) receptors, intracellular signaling cascades (phosphodiesterase inhibitors), and intracellular calcium levels (affected by levosimendan and, indirectly, by digoxin). Many antihypertensive medications (e.g., β -blockers, calcium channel antagonists) interfere with adrenergic receptor activation or intracellular calcium levels, which can decrease the strength of ventricular contractions. Please refer to Chapter 53, "Cardiac Function and Circulatory Control," in *Goldman-Cecil Medicine*, 25th Edition.

Physiology of the Coronary Circulation

The normally functioning heart maintains equilibrium between the amount of oxygen delivered to myocytes and the amount of oxygen consumed by them (myocardial oxygen consumption, or MvO_2). If a myocyte works harder because it is contracting with increased frequency (HR), with increased intensity (contractility), or against an increased load (wall stress), then it will use more oxygen and its MvO_2 will increase. In order to meet this increase in demand for more oxygen, the heart will have to either increase blood flow or increase its efficiency in extracting oxygen. The heart is unique in that its oxygen extraction is almost maximal at resting conditions. Therefore, increasing blood flow is the only reasonable means of increasing oxygen supply.

Microvascular blood flow in the coronary circulation is impaired during systole because the intramyocardial blood vessels are compressed by contracting myocardium. Therefore, most coronary flow occurs during diastole. Accordingly, the diastolic pressure is the major pressure driving flow within the coronary circulation. Systolic pressure impedes intramyocardial

arterial blood flow but augments venous flow. On a clinical note, tachycardia is particularly detrimental because coronary flow is reduced when the diastolic filling time is abbreviated, and the MvO_2 increases with increasing HR. In order to sustain constant perfusion to the myocardium, coronary blood flow is maintained constant over a wide range of pressures in a process called autoregulation.

In response to a change in MvO_2 , the coronary arteries dilate or constrict, which changes the vascular resistance and thereby appropriately changes flow. This regulation of arterial resistance occurs at the arterioles and is mediated by several factors. Adenosine, a metabolite of ATP, is released during contraction and acts as a potent vasodilator. Other consequences of myocardial metabolism, such as decreased oxygen tension, increased carbon dioxide, acidosis, and hyperkalemia, also mediate coronary vasodilation. The endothelium produces several potent vasodilators, including nitric oxide and prostacyclin. Nitric oxide is released by the endothelium in response to acetylcholine, thrombin, adenosine diphosphate (ADP), serotonin, bradykinin, platelet aggregation, and an increase in shear stress (called *flow-dependent vasodilation*). Finally, the coronary arteries are innervated by the autonomic nervous system, and activation of sympathetic neurons mediates vasoconstriction or vasodilation through α - or β -receptors, respectively. Parasympathetic neurons from the vagus nerve secrete acetylcholine, which mediates vasodilation. Vasoconstricting factors, notably endothelin, are produced by the endothelium and may be important in conditions such as coronary vasospasm. Please refer to Chapter 53, “Cardiac Function and Circulatory Control,” in *Goldman-Cecil Medicine*, 25th Edition.

Physiology of the Systemic Circulation

The normal cardiovascular system delivers appropriate blood flow to each organ of the body under a wide range of conditions. This regulation is achieved by maintaining BP through adjustments in cardiac output and tissue blood flow resistance by neural and humoral factors.

Poiseuille’s law generally describes the relationship between pressure and flow in a vessel. Fluid flow (F) through a tube is proportional (proportionality constant = K) to the pressure (P) difference between the ends of the tube:

$$F = K \times \Delta P$$

K is equivalent to the inverse of resistance to flow (R); that is, $K = 1/R$. Resistance to flow is determined by the properties of both the fluid and the tube. In the case of a steady, streamlined flow of fluid through a rigid tube, Poiseuille found that these factors determine resistance:

$$R = 8\eta L / \pi r^4$$

Where r is the radius of the tube, L is its length, and η is the viscosity of the fluid. Notice that changes in radius have greater influence than changes in length, because resistance is inversely proportional to the fourth power of the radius. Poiseuille’s law incorporates the factors influencing flow, so that:

$$F = \Delta P / R = \Delta P \pi r^4 / 8\eta L$$

Therefore, the most important determinants of blood flow in the cardiovascular system are ΔP and r^4 . Small changes in arterial radius can cause large changes in flow to a tissue or organ. Practically, systemic vascular resistance (SVR) is the total resistance to flow caused by changes in the radius of resistance vessels (small arteries and arterioles) of the systemic circulation. The SVR can be calculated as the pressure drop across the peripheral capillary beds (mean arterial pressure – right atrial pressure) divided by the blood flow across the beds (i.e., $SVR = BP/CO$). It is normally in the range of 800 to 1500 dynes-sec/ cm^{-5} .

The autonomic nervous system alters systemic vascular tone through sympathetic and parasympathetic innervation as well as metabolic factors (local oxygen tension, carbon dioxide levels, reactive oxygen species, pH) and endothelium-derived signaling molecules (NO, endothelin). Neural regulation of BP occurs by means of constitutive and reflex changes in autonomic efferent outflow to modulate cardiac chronotropy, inotropy, and vascular resistance.

The baroreflex loop is the primary mechanism by which BP is neurally modulated. Baroreceptors are stretch-sensitive nerve endings that are distributed throughout various regions of the cardiovascular system. Those located in the carotid artery (e.g., carotid sinus) and aorta are sometimes referred to as *high-pressure baroreceptors* and those in the cardiopulmonary areas as *low-pressure baroreceptors*. After afferent impulses are transmitted to the central nervous system, the signals are integrated, and the efferent arm of the reflex projects neural signals systemically through the sympathetic and parasympathetic branches of the autonomic nervous system. In general, an increase in systemic BP increases the firing rate of the baroreceptors. Efferent sympathetic outflow is inhibited (reducing vascular tone, chronotropy, and inotropy), and parasympathetic outflow is increased (reducing cardiac chronotropy). The opposite occurs when BP decreases. Please refer to Chapter 53, “Cardiac Function and Circulatory Control,” in *Goldman-Cecil Medicine*, 25th Edition.

Physiology of the Pulmonary Circulation

Like the systemic circulation, the pulmonary circulation consists of a branching network of progressively smaller arteries, arterioles, capillaries, and veins. The pulmonary capillaries are separated from the alveoli by a thin alveolar-capillary membrane through which gas exchange occurs. The partial pressure of oxygen (PO_2) is the main regulator of pulmonary blood to optimize blood flow toward well-ventilated lung segments and away from poorly ventilated segments.

Evaluation of the Patient with Cardiovascular Disease

James Kleczka and Ivor J. Benjamin

DEFINITION AND EPIDEMIOLOGY

Cardiovascular disease is a major cause of morbidity and mortality around the world, and its spectrum is wide-reaching. Included in this population of patients are people with coronary artery disease (CAD), congestive heart failure, stroke, hypertension, peripheral arterial disease, atrial fibrillation and other arrhythmias, valvular disease, and congenital heart disease. In the United States alone, these diseases affect more than 82 million individuals at any given time. The impact of cardiovascular disease is unmistakable: It accounted for more inpatient hospital days in the years of 1990-2009 than other disorders such as chronic lung disease and cancer. The high number of inpatient days associated with cardiovascular disease led to a total economic cost of more than \$297 billion in the year 2008 alone. Cardiovascular disease was also the number one cause of death in the United States in 2008; more than half of these deaths were from CAD, which was the top cause of mortality among individuals older than 65 years of age.

Given these facts, the proper evaluation of a patient with cardiovascular disease can have a major impact on multiple fronts, from an economic standpoint as well as an individual's morbidity and mortality. Therefore, one must obtain a very thorough history and detailed physical examination to accurately assess and manage patients with cardiovascular disease.

PATHOLOGY

A patient with cardiovascular disease may have one or more of a number of problems. *Coronary artery disease*, discussed in depth in [Chapter 8](#), is a leading cause of morbidity and mortality. At presentation, patients with CAD may have stable angina or an acute coronary syndrome such as unstable angina, non-ST segment elevation myocardial infarction (NSTEMI), or ST segment elevation myocardial infarction (STEMI). For some patients, their first presentation with CAD is sudden cardiac death, the result of arrhythmia often caused by atherosclerosis of the coronary vasculature.

Congestive heart failure is the end result of many cardiac disorders and is generally classified as systolic or diastolic in etiology. Various forms of cardiomyopathy, such as dilated cardiomyopathy or hypertrophic cardiomyopathy, may lead to systolic dysfunction and a decline in ejection fraction. Without proper management, this will inevitably lead to alterations in hemodynamics that result in development of pulmonary vascular

congestion, edema, and a decline in functional capacity. Diastolic dysfunction can be present with systolic dysfunction and is often the result of uncontrolled hypertension or infiltrative disorders such as hemochromatosis or amyloidosis. Heart failure with a preserved ejection fraction is often caused by diastolic dysfunction. Various forms of heart failure are further discussed in [Chapter 5](#).

Stroke is caused by cerebral hypoperfusion, which can result from such problems as carotid disease, thromboembolism, or emboli of infectious origin. A more detailed discussion can be found in [Chapter 116](#).

Peripheral arterial disease (PAD), addressed in [Chapter 12](#), includes such entities as aneurysms of the ascending, descending, and abdominal aorta; aortic dissection; carotid disease; and atherosclerosis of branch vessels of the aorta and vessels in the limbs. PAD is often present in patients with CAD.

Atrial fibrillation and *hypertension* (see [Chapters 9](#) and [12](#)) are not uncommon and increase in prevalence with age. Although they are not typically the primary cause of mortality, these problems often predispose to other causes of cardiovascular disease mortality, such as stroke and heart failure. Arrhythmias other than atrial fibrillation are also common and can lead to significant morbidity and mortality.

Valvular heart disease may lead to cardiomyopathy and is found in all age groups.

Congenital heart disease includes a wide variety of disorders, ranging from valve abnormalities and coronary anomalies to cardiomyopathy and other structural abnormalities including shunts and malformations of the cardiac chambers. With advances in surgical techniques and medical therapy, these patients are often living beyond previous expectations, increasing the likelihood that they will live into adulthood. For more detailed information on congenital heart diseases, see [Chapter 6](#).

CLINICAL PRESENTATION

There have been major advances in technology over the years that allow for specialized testing to assist in the diagnosis of cardiovascular diseases. We now rely on such tests as angiography, ultrasound scanning, and advanced imaging modalities such as high-resolution computed tomography and magnetic resonance imaging to determine how to manage an individual case. However, these techniques should be used not as a primary method of assessment but rather to supplement the findings from a thorough history and physical examination. Despite the availability

of rather costly imaging techniques and laboratory tests, a relatively inexpensive but detailed history and physical examination is often all that is required to establish a diagnosis.

When evaluating patients with cardiovascular disease, it is important to allow them to express their symptoms in their own words. For example, many patients who deny chest pain when asked specifically about this symptom, will, in their very next breath, describe the chest pressure they feel, which they do not consider to be “pain.” It is very important to delve into details regarding the setting in which the symptom occurs (e.g., at rest, with activity, with extreme emotional stress). The location, quality, intensity, and radiation of the symptom should be elicited. One should ask whether there are aggravating or alleviating factors and whether there are other symptoms that accompany the primary symptom. It is also important to note the pattern of the symptom in terms of stability or progression in intensity or frequency over time. An assessment of functional status should always be a part of the history in a patient with cardiovascular disease, because a recent decline in exercise tolerance can be very telling in regard to severity of disease.

A detailed past medical history and review of systems are necessary because cardiovascular conditions can be associated with other medical conditions; for example, patient may have arrhythmias in the setting of hyperthyroidism. A comprehensive list of medications must be reviewed, and a social history must be taken detailing alcohol use, smoking, and occupational history. Patients should also be questioned regarding major risk factors such as hypertension, hyperlipidemia, and diabetes mellitus. A thorough family history is needed, not only to identify such entities as early-onset CAD but also to assess for other potentially inherited disorders, such as familial cardiomyopathy or arrhythmic disorders (e.g., long-QT syndrome).

Chest Pain

Chest pain is one of the cardinal symptoms of cardiovascular disease, but it may also be present in many noncardiovascular

diseases (Tables 3-1 and 3-2). Chest pain may be caused by cardiac ischemia but also may be related to aortic pathology such as dissection, pulmonary disease such as pneumonia, gastrointestinal pathology such as gastroesophageal reflux, or musculoskeletal pain related to chest wall trauma. Issues with organs in the abdominal cavity such as the gallbladder or pancreas can also cause chest pain. It is therefore very important to characterize the pain in terms of location, quality, quantity, location, duration, radiation, aggravating and alleviating factors, and associated symptoms. These details will help determine the origin of the pain.

Myocardial ischemia due to obstructive CAD often leads to typical angina pectoris. Angina is often described as tightness, pressure, burning, or squeezing discomfort that patients may not identify as true pain. Patients frequently describe angina as a sensation of “bricks on the center of the chest” or an “elephant standing on the chest.” Angina is more common in the morning, and the intensity may be affected by heat or cold, emotional stress, or eating. This discomfort is typically located in the substernal region or left side of the chest. If it is reproduced by palpation, it is unlikely to be angina. Anginal pain often radiates to the left shoulder and arm, particularly the ulnar aspect. It may also radiate to the neck, jaw, or epigastrium. Pain that radiates to the back, the right or left lower anterior chest, or below the epigastric region is less likely to be anginal in etiology. Anginal chest pain is usually brought on with exertion, in particular with more intense activity or walking up inclines, in extremes of weather, or after large meals. It is typically brief in duration, lasting 2 to 10 minutes, and resolves with rest or administration of nitroglycerine within 1 to 5 minutes. Associated symptoms often include nausea, diaphoresis, dyspnea, palpitations, and dizziness. Patients typically report a stable pattern of angina that is relatively predictable and reproducible with a given amount of exertion. When this pain begins to increase in frequency and severity or occurs with lesser amounts of exertion or at rest, one must then consider unstable angina. Anginal pain that occurs at rest with increased

TABLE 3-1 CARDIOVASCULAR CAUSES OF CHEST PAIN

CONDITION	LOCATION	QUALITY	DURATION	AGGRAVATING OR ALLEVIATING FACTORS	ASSOCIATED SYMPTOMS OR SIGNS
Angina	Retrosternal region; radiates to or occasionally isolated to neck, jaw, shoulders, arms (usually left), or epigastrium	Pressure, squeezing, tightness, heaviness, burning, indigestion	<2-10 min	Precipitated by exertion, cold weather, or emotional stress; relieved by rest or nitroglycerin; variant (Prinzmetal) angina may be unrelated to exertion, often early in the morning	Dyspnea; S ₃ , S ₄ , or murmur of papillary dysfunction during pain
Myocardial infarction	Same as angina	Same as angina, although more severe	Variable; usually >30 min	Unrelieved by rest or nitroglycerin	Dyspnea, nausea, vomiting, weakness, diaphoresis
Pericarditis	Left of the sternum; may radiate to neck or left shoulder, often more localized than pain of myocardial ischemia	Sharp, stabbing, knifelike	Lasts many hours to days; may wax and wane	Aggravated by deep breathing, rotating chest, or supine position; relieved by sitting up and leaning forward	Pericardial friction rub
Aortic dissection	Anterior chest; may radiate to back, interscapular region	Excruciating, tearing, knifelike	Sudden onset, unrelenting	Usually occurs in setting of hypertension or predisposition, such as Marfan's syndrome	Murmur of aortic insufficiency; pulse or blood pressure asymmetry; neurologic deficit

TABLE 3-2 NONCARDIAC CAUSES OF CHEST PAIN

CONDITION	LOCATION	QUALITY	DURATION	AGGRAVATING OR ALLEVIATING FACTORS	ASSOCIATED SYMPTOMS OR SIGNS
Pulmonary embolism (chest pain often not present)	Substernal or over region of pulmonary infarction	Pleuritic (with pulmonary infarction) or angina-like	Sudden onset (minutes to hours)	Aggravated by deep breathing	Dyspnea, tachypnea, tachycardia; hypotension, signs of acute right ventricular heart failure, and pulmonary hypertension with large emboli; pleural rub; hemoptysis with pulmonary infarction
Pulmonary hypertension	Substernal	Pressure; oppressive	—	Aggravated by effort	Pain usually associated with dyspnea; signs of pulmonary hypertension
Pneumonia with pleurisy	Located over involved area	Pleuritic	—	Aggravated by breathing	Dyspnea, cough, fever, bronchial breath sounds, rhonchi, egophony, dullness to percussion, occasional pleural rub
Spontaneous pneumothorax	Unilateral	Sharp, well localized	Sudden onset; lasts many hours	Aggravated by breathing	Dyspnea; hyperresonance and decreased breath and voice sounds over involved lung
Musculoskeletal disorders	Variable	Aching, well localized	Variable	Aggravated by movement; history of exertion or injury	Tender to palpation or with light pressure
Herpes zoster	Dermatomal distribution	Sharp, burning	Prolonged	None	Vesicular rash appears in area of discomfort
Esophageal reflux	Substernal or epigastric; may radiate to neck	Burning, visceral discomfort	10-60 min	Aggravated by large meal, postprandial recumbency; relief with antacid	Water brash
Peptic ulcer	Epigastric, substernal	Visceral burning, aching	Prolonged	Relief with food, antacid	—
Gallbladder disease	Right upper quadrant; epigastric	Visceral	Prolonged	Spontaneous or after meals	Right upper quadrant tenderness may be present
Anxiety states	Often localized over precordium	Variable; location often moves from place to place	Varies; often fleeting	Situational	Sighing respirations; often chest wall tenderness

intensity and lasts longer than 30 minutes may represent acute myocardial infarction. Angina-like pain at rest may also occur with coronary vasospasm and noncardiac chest pain.

There are several other potential causes of chest pain that may be confused with angina pectoris (see Table 3-2). Pain associated with acute pericarditis is typically sharp, is located to the left of the sternum, and radiates to the neck, shoulders, and back. This may be rather severe pain that is present at rest and can last for hours. It typically improves with sitting up and forward and worsens with inspiration. Acute aortic dissection usually causes sudden onset of severe tearing chest pain which radiates to the back between the scapulae or to the lumbar region. Typically, there is a history of hypertension, and pulses may be asymmetric between the extremities. A murmur of aortic regurgitation may also be heard. Pain associated with pulmonary embolism is also acute in onset and is usually accompanied by shortness of breath. This pain is typically pleuritic, worsening with inspiration.

Dyspnea

Dyspnea is another hallmark symptom of cardiovascular disease, but it is also a primary symptom of pulmonary disease. It is defined as an uncomfortable heightened awareness of breathing.

This can be an entirely normal sensation in individuals performing moderate to extreme exertion, depending on their level of conditioning. When it occurs at rest or with minimal exertion, dyspnea is considered abnormal. Dyspnea may accompany a large number of noncardiac conditions such as anemia due to a lack of oxygen-carrying capacity, pulmonary disorders such as obstructive or restrictive lung disease and asthma, obesity due to an increased work of breathing and restricted filling of the lungs, and deconditioning. In the cardiovascular patient, dyspnea is typically caused by left ventricular dysfunction, either systolic or diastolic; CAD and resultant ischemia; or valvular heart disease which, when severe, can lead to a drop in cardiac output. In cases of left ventricular dysfunction and valvular disease, the mechanism of dyspnea often involves increased intracardiac pressures that lead to pulmonary vascular congestion. Fluid then leaks into the alveolar space, impairing gas exchange and causing dyspnea.

Breathing difficulties can also be secondary to a low-output state without pulmonary vascular congestion. Patients often notice dyspnea with exertion, but it can also occur at rest in patients with severe cardiac disease. Shortness of breath at rest is also a symptom in patients with pulmonary edema, large pleural

effusions, anxiety, or pulmonary embolism. A patient with left ventricular systolic or diastolic failure may describe the acute onset of breathing difficulty when sleeping. This problem, called paroxysmal nocturnal dyspnea (PND), is caused by pulmonary edema that is redistributed in a prone position; it is usually secondary to left ventricular failure. These patients often notice the acute onset of dyspnea followed by coughing roughly 2 to 4 hours after going to sleep. This can be a very uncomfortable feeling, and it leads the patient to sit up immediately or get out of bed. Symptoms typically resolve over 15 to 30 minutes. Patients with left ventricular failure also often complain of orthopnea, which is dyspnea that occurs when one assumes a prone position. This is relieved by sleeping on multiple pillows or remaining seated to sleep.

Patients with sudden onset of dyspnea may be experiencing flash pulmonary edema, which is very rapid and acute accumulation of fluid in the lungs. This can be associated with severe CAD and may also be a cause of dyspnea in patients with coarctation of the aorta and renal artery stenosis. Sudden dyspnea is associated with pulmonary embolism, and this symptom is typically accompanied by pleuritic chest pain and possibly hemoptysis in such patients. Pneumothorax can cause dyspnea accompanied by acute chest pain. Dyspnea due to lung disease is present with exertion, although in severe cases it may be present at rest. This is often accompanied by hypoxia and is relieved by pulmonary bronchodilators or steroids or both. Dyspnea may also be an “angina equivalent.” Not all patients with CAD develop typical anginal chest pain. Dyspnea that comes on with exertion or emotional stress, is relieved with rest, and is relatively brief in duration might be a manifestation of significant CAD. This type of dyspnea is also usually improved with the administration of nitroglycerine.

Palpitation

Palpitation is another symptom commonly seen in the cardiovascular patient. This is the subjective sensation of rapid or forceful beating of the heart. Patients often are able to describe in detail the sensation they feel, such as jumping, skipping, racing, fluttering, or an irregularity in the heartbeat. It is important to ask the patient about the onset of the palpitations because they may begin abruptly at rest, only with exertion, with emotional stress, or with ingestion of certain foods such as chocolate. One should also inquire about associated symptoms such as chest pain, dyspnea, dizziness, and syncope. It is important to note other medical issues, such as thyroid disease, and bleeding, which can lead to anemia, because these conditions may be associated with arrhythmias. A social history focusing on drug use and intake of alcohol is important because use of these substances can lead to certain rhythm disturbances. The family history is also important, because there are many inherited disorders (e.g., long-QT syndromes) that might lead to significant arrhythmias.

Potential etiologies of palpitation include premature atrial or ventricular beats, which are typically described as isolated skips and can be uncomfortable. Supraventricular tachycardias such as atrial flutter, AV nodal reentrant tachycardia, and paroxysmal atrial tachycardia often start and stop abruptly and can be rapid. Atrial fibrillation is usually rapid and very irregular. Ventricular arrhythmias are more often associated with severe dizziness or

syncope. Gradual onset of tachycardia with a gradual decline in HR is more indicative of sinus tachycardia or anxiety.

Syncope

Syncope may be caused by a variety of cardiovascular diseases. It is the transient loss of consciousness due to inadequate cerebral blood flow. In the patient presenting with syncope as a primary complaint, one must try to differentiate true cardiac causes from neurologic issues such as seizure and metabolic causes such as hypoglycemia. Determination of the timing of the syncopal event and associated symptoms is very helpful in determining the etiology. True cardiac syncope is typically very sudden, with no prodromal symptoms. It is typically caused by an abrupt drop in cardiac output which may be due to tachyarrhythmias such as ventricular tachycardia or fibrillation, bradyarrhythmias such as complete heart block, severe valvular heart disease such as aortic or mitral stenosis, or obstruction of flow due to left ventricular outflow tract (LVOT) obstruction. True cardiac syncope often has no accompanying aura. In situations such as aortic stenosis or LVOT obstruction, syncope typically occurs with exertion. Patients usually regain consciousness rather quickly with true cardiac syncope.

Neurocardiogenic syncope involves an abnormal reflexive response to a change in position. When one rises from a prone or seated position to a standing position, the peripheral vasculature usually constricts and the HR increases to maintain cerebral perfusion. With neurocardiogenic syncope, the peripheral vasculature abnormally dilates or the HR slows or both. This leads to a reduction in cerebral perfusion and syncope. A similar mechanism is responsible for carotid sinus syncope and syncope associated with micturition and cough. The patient usually describes a gradual onset of symptoms such as flushing, dizziness, diaphoresis, and nausea before losing consciousness, which lasts seconds. When these patients wake, they are often pale and have a lower HR. In the patient with syncope due to seizures, a prodromal aura is typically present before loss of consciousness occurs. Patients regain consciousness much more slowly and at times are incontinent, complain of headache and fatigue, and have a post-ictal confusional state. Syncope due to stroke is rare, because there must be significant bilateral carotid disease or disease of the vertebrobasilar system causing brainstem ischemia. Neurologic deficits accompany the physical examination findings in these patients.

The history is very important in determining the cause of a syncopal episode. This was previously studied by Calkins and colleagues, who found that men older than 54 years of age who had no prodromal symptoms were more likely to have an arrhythmic cause of their episodes. However, those with prodromal symptoms such as nausea, diaphoresis, dizziness, and visual disturbances before passing out were more likely to have neurocardiogenic syncope. Many inherited disorders such as long-QT syndrome and other arrhythmias, hypertrophic cardiomyopathy with LVOT obstruction, and familial dilated cardiomyopathy lead to states conducive to syncope. For this reason, a very detailed family history is necessary.

Edema

Edema often accompanies cardiovascular disease but may be a manifestation of liver disease (cirrhosis), renal disease (nephrotic

syndrome), or local issues such as chronic venous insufficiency or thrombophlebitis. Edema related to cardiac disease is caused by increased venous pressures that alter the balance between hydrostatic and oncotic forces. This leads to extravasation of fluid into the extravascular space. Peripheral edema is common with right-sided heart failure, whereas the same process in left-sided heart failure leads to pulmonary edema.

Edema due to a cardiac etiology is typically bilateral and begins distally with progression in a proximal fashion. The feet and ankles are affected first, followed by the lower legs, thighs, and, ultimately, the abdomen, sometimes accompanied by ascites. If edema is visible, it is usually preceded by a weight gain of at least 5 to 10 pounds. Edema with heart disease is typically pitting, leaving an indentation in the skin after pressure is applied to the area. The edema is usually worse in the evening, and patients often describe an inability to fit into their shoes. While these patients are lying prone, the edema can shift to the sacral region after several hours, only to accumulate again the next day when they are on their feet again (dependent edema).

Total body edema, or anasarca, may be caused by heart failure but is also seen in nephrotic syndrome and cirrhosis. Unilateral edema is more likely associated with a localized issue such as deep venous thrombosis or thrombophlebitis. Other parts of the history may shed light on the etiology of edema. Patients who report PND and orthopnea are likely have a cardiac etiology. If there is a history of alcohol abuse and jaundice is present, liver disease is a probable cause. Edema of the eyes and face in addition to lower-extremity edema is more likely related to nephrotic syndrome. Edema associated with discoloration or ulcers of the lower extremities is often seen with chronic venous insufficiency. In a patient with insidious onset of edema progressing to anasarca and ascites, one must consider constrictive pericarditis.

Cyanosis

Cyanosis is defined as an abnormal bluish discoloration of the skin resulting from an increase in the level of reduced hemoglobin or abnormal hemoglobin in the blood. When present, it typically represents an oxygen saturation of less than 85% (normal, >90%). There are several types of cyanosis. Central cyanosis often manifests in discoloration of the lips or trunk and usually represents low oxygen saturations due to right-to-left shunting of blood. This can occur with structural cardiac abnormalities such as large atrial or ventricular septal defects, but it also happens with impaired pulmonary function, as in with severe chronic obstructive lung disease. Peripheral cyanosis is typically secondary to vasoconstriction in the setting of low cardiac output. This can also occur with exposure to cold and can represent local arterial or venous thrombosis. When localized to the hands, peripheral cyanosis suggests Raynaud's phenomenon. Cyanosis in childhood often indicates congenital heart disease with resultant right-to-left shunting of blood.

Other

There are other, nonspecific symptoms that may indicate cardiovascular disease. Although fatigue is present with a myriad of medical conditions, it is very common in patients with cardiac disease when low cardiac output is present. It can be seen with hypotension due to aggressive medical treatment of hypertension

or with overdiuresis in patients with heart failure. Fatigue may also be a direct result of medical therapy for cardiac disease itself, such as with β -blocking agents. Although cough is commonly associated with pulmonary disease, it may also indicate high intracardiac pressures which can lead to pulmonary edema. Cough may be present in patients with heart failure or significant left-sided valve disease. A patient with congestive heart failure may describe a cough productive of frothy pink sputum, as opposed to frank bloody or blood-tinged sputum, which is seen more typically with primary lung pathology. Nausea and emesis can accompany acute myocardial infarction and may also be a reflection of heart failure leading to hepatic or intestinal congestion due to high right heart pressures. Anorexia, abdominal fullness, and cachexia may occur with end-stage heart failure. Nocturia is also a symptom described with heart failure; renal perfusion improves when the patient lies in a prone position, leading to an increase in urine output. Hoarseness of voice can occur due to compression of the recurrent laryngeal nerve. This may happen with enlarged pulmonary arteries, enlarged left atrium, or aortic aneurysm.

Despite the myriad symptoms of cardiovascular disease described here, many patients with significant cardiac disease are asymptomatic. Patients with CAD may have periods of asymptomatic ischemia that can be documented on ambulatory electrocardiographic monitoring. Up to one third of patients who have suffered a myocardial infarction are unaware that they had an event. This is more common in diabetics and in older patients. A patient may have severely depressed ventricular function for some time before presenting with symptoms. In addition, patients with atrial fibrillation can be entirely asymptomatic, with this rhythm discovered only after a physical examination is performed.

At times, patients do not report having symptoms related to usual activities of daily living, yet symptoms are present when functional testing is performed. Therefore, assessing functional capacity is a very important part of the history in a patient with known or suspected cardiovascular disease. The ability or inability to perform various activities plays a substantial role in determining the extent of disability and in assessing response to therapy and overall prognosis, and it can influence decisions regarding the timing and type of therapy or intervention. The New York Heart Association Functional Classification is a commonly used method to assess functional status based on "ordinary activity" (Table 3-3). Patients are classified in one of four functional classes. Functional class I includes patients with known cardiac disease who have no limitations with ordinary activity. Functional classes II and III describe patients who have symptoms with less and less activity, whereas patients in functional class IV have symptoms at rest. The Canadian Cardiovascular Society has provided a similar classification of functional status specifically for patients with angina pectoris. These tools are very useful in classifying a patient's symptoms at a given time, allowing comparison at a future point and determination as to whether the symptoms are stable or progressive.

DIAGNOSIS AND PHYSICAL EXAMINATION

General

Like the detailed history, the physical examination is also vital when assessing a patient with cardiovascular disease. This

consists of more than simply auscultating the heart. Many diseases of the cardiovascular system can affect and be affected by other organ systems. Therefore, a detailed general physical examination is essential. The general appearance of a patient is helpful: Such observations as skin color, breathing pattern, whether pain is present, and overall nutritional status can provide clues regarding the diagnosis. Examination of the head may reveal evidence of hypothyroidism, such as hair loss and periorbital edema, and examination of the eyes may reveal exophthalmos associated with hyperthyroidism. Both conditions can affect the heart. Retinal examination may reveal macular edema or flame hemorrhages which can be associated with uncontrolled hypertension. Findings such as clubbing or edema when examining the extremities, and jaundice or cyanosis when evaluating the skin, may provide clues to undiagnosed cardiovascular disease.

Examination of the Jugular Venous Pulsations

Examination of the neck veins can provide a great deal of insight into right heart hemodynamics. The right internal jugular vein should be used, because the relatively straight course of the right innominate and jugular veins allows for a more accurate reflection of the true right atrial pressure. The longer and more winding course of the left-sided veins does not allow for as accurate a transmission of hemodynamics. For examination of the right internal jugular vein, the patient should be placed at a 45-degree angle—higher in patients with suspected elevated venous pressures and lower in those with lower venous pressures. The head should be turned to the left and light shined at an angle over the neck. Although the internal jugular vein itself is not visible, the pulsations from that vessel are transmitted to the skin and can be seen in most cases. The carotid artery lies in close proximity to the jugular vein, and its pulsations can sometimes be seen as well. Therefore, one must be certain one is observing the correct vessel. This can be accomplished by applying gentle compression at the site of pulsations. An arterial pulse will not be obliterated by this maneuver, whereas a venous pulse likely will become diminished or absent with compression. In addition, an arterial pulse is usually much more forceful and vigorous.

Both the level of venous pressure and the morphology of the venous waveforms should be noted. Once the pulsations have been located, the vertical distance from the sternal angle (angle of Louis) to the top of the pulsations is determined. Because the right atrium lies about 5 cm vertically below the sternal angle,

this number is added to the previous measurement to arrive at an estimated right atrial pressure in centimeters of water. The right atrial pressure is normally 5 to 9 cm H₂O. It can be higher in patients with decompensated heart failure, disorders of the tricuspid valve (regurgitation or stenosis), restrictive cardiomyopathy, or constrictive pericarditis.

With inspiration, negative intrathoracic pressure develops, venous blood drains into the thorax, and venous pressure in the normal patient falls; the opposite occurs during expiration. In a patient with conditions such as decompensated heart failure, constrictive pericarditis, or restrictive cardiomyopathy, this pattern is reversed (Kussmaul sign), and the venous pressure increases with inspiration. When the neck veins are examined, firm pressure should be applied for 10 to 30 seconds to the right upper quadrant over the liver. In a normal patient, this will cause the venous pressure to increase briefly and then return to normal. In the patient with conditions such as heart failure, constrictive pericarditis, or substantial tricuspid regurgitation, the neck veins will reveal a sustained increase in pressure due to passive congestion of the liver. This finding is called hepatogastric reflux.

The normal waveforms of the jugular venous pulse are depicted in Figure 3-1A. The *a* wave results from atrial contraction. The *x* descent results from atrial relaxation after contraction and the pulling of the floor of the right atrium downward with right ventricular contraction. The *c* wave interrupts the *x* descent and is generated by bulging of the cusps of the tricuspid valve into the right atrium during ventricular systole. This occurs at the same time as the carotid pulse. Atrial pressure then increases as a result of venous return with the tricuspid valve closed during ventricular systole; this generates the *v* wave, which is typically smaller than the *a* wave. The *y* descent follows as the tricuspid valve opens and blood flows from the right atrium to the right ventricle during diastole.

Understanding of the normal jugular venous waveforms is paramount, because these waveforms can be altered in different disease states. Abnormalities of these waveforms reflect underlying structural, functional, and electrical abnormalities of the heart (see Fig. 3-1B to G). Elevation of the right atrial pressure leading to jugular venous distention can be found in heart failure (both systolic and diastolic), hypervolemia, superior vena cava syndrome, and valvular disease. The *a* wave is exaggerated in any condition in which a greater resistance to right atrial emptying occurs. Such conditions include pulmonary hypertension, tricuspid stenosis, and right ventricular hypertrophy or failure. *Cannon a waves* occur when the atrium contracts against a closed tricuspid valve, which can occur with complete heart block or any other situation involving AV dissociation. The *a* wave is absent during atrial fibrillation. With significant tricuspid regurgitation, the *v* wave becomes very prominent and may merge with the *c* wave, diminishing or eliminating the *x* descent. With tricuspid stenosis, there is impaired emptying of the right atrium, which leads to an attenuated *y* descent. In pericardial constriction and restrictive cardiomyopathy, the *y* descent occurs rapidly and deeply, and the *x* descent may also become more prominent, leading to a waveform with a w-shaped appearance. With pericardial tamponade, the *x* descent becomes very prominent while the *y* descent is diminished or absent.

TABLE 3-3 CLASSIFICATION OF FUNCTIONAL STATUS*

Class I	Uncompromised	Ordinary activity does not cause symptoms; symptoms occur only with strenuous or prolonged activity.
Class II	Slightly compromised	Ordinary physical activity results in symptoms; no symptoms at rest.
Class III	Moderately compromised	Less than ordinary activity results in symptoms; no symptoms at rest.
Class IV	Severely compromised	Any activity results in symptoms; symptoms may be present at rest.

*Symptoms refers to undue fatigue, dyspnea, palpitations, or angina in the New York Heart Association classification and refers specifically to angina in the Canadian Cardiovascular Society classification.

FIGURE 3-1 Normal and abnormal jugular venous pulse (JVP) tracings. **A**, Normal jugular pulse tracing with simultaneous electrocardiogram (ECG) and phonocardiogram. **B**, Loss of the *a* wave in atrial fibrillation. **C**, Large *a* wave in tricuspid stenosis. **D**, Large *c-v* wave in tricuspid regurgitation. **E**, Prominent *x* and *y* descents in constrictive pericarditis. **F**, Prominent *x* descent and diminutive *y* descent in pericardial tamponade. **G**, JVP tracing and simultaneous ECG during complete heart block demonstrates cannon *a* waves occurring when the atrium contracts against a closed tricuspid valve during ventricular systole. P, P waves correlating with atrial contraction; S₁ to S₄, heart sounds.

Examination of Arterial Pressure and Pulse

Arterial blood pressure is measured noninvasively with the use of a sphygmomanometer. Before the blood pressure is taken, the patient ideally should be relaxed, allowed to rest for 5 to 10 minutes in a quiet room, and seated or lying comfortably. The cuff is typically applied to the upper arm, approximately 1 inch above

the antecubital fossa. A stethoscope is then used to auscultate under the lower edge of the cuff. The cuff is rapidly inflated to approximately 30 mm Hg above the anticipated systolic pressure and then slowly deflated (at approximately 3 mm Hg/sec) while the examiner listens for the sounds produced by blood entering the previously occluded artery. These sounds are the Korotkoff sounds. The first sound is typically a very clear tapping sound

which, when heard, represents the systolic pressure. As the cuff continues to deflate, the sounds will disappear; this point represents the diastolic pressure.

In normal situations, the pressure in both arms is relatively equal. If the pressure is measured in the lower extremities rather than the arms, the systolic pressure is typically 10 to 20 mm Hg higher. If the pressures in the arms are asymmetric, this may suggest atherosclerotic disease involving the aorta, aortic dissection, or obstruction of flow in the subclavian or innominate arteries. The pressure in the lower extremities can be lower than arm pressures in the setting of abdominal aortic, iliac, or femoral disease. Coarctation of the aorta can also lead to discrepant pressures between the upper and lower extremities. Leg pressure that is more than 20 mm Hg higher than the arm pressure can be found in the patient with significant aortic regurgitation, a finding called Hill's sign. A common mistake in taking the arterial blood pressure involves using a cuff of incorrect size. Use of a small cuff on a large extremity leads to overestimation of pressure. Similarly,

use of a large cuff on a smaller extremity underestimates the pressure.

Examination of the arterial pulse in a cardiovascular patient should include palpation of the carotid, radial, brachial, femoral, popliteal, posterior tibial, and dorsalis pedis pulses bilaterally. The carotid pulse most accurately reflects the central aortic pulse. One should note the rhythm, strength, contour, and symmetry of the pulses. A normal arterial pulse (Fig. 3-2A) rises rapidly to a peak in early systole, plateaus, and then falls. The descending limb of the pulse is interrupted by the incisura or dicrotic notch, which is a sharp deflection downward due to closure of the aortic valve. As the pulse moves toward the periphery, the systolic peak is higher and the dicrotic notch is later and less noticeable.

The normal pattern of the arterial pulse can be altered by a variety of cardiovascular diseases (see Fig. 3-2B to F). The amplitude of the pulse increases in conditions such as anemia, pregnancy, thyrotoxicosis, and other states with high cardiac output. Aortic insufficiency, with its resultant increase in pulse

FIGURE 3-2 Normal and abnormal carotid arterial pulse contours. **A**, Normal arterial pulse with simultaneous electrocardiogram (ECG). The dicrotic wave (*D*) occurs just after aortic valve closure. **B**, Wide pulse pressure in aortic insufficiency. **C**, Pulsus parvus et tardus (small amplitude with a slow upstroke) associated with aortic stenosis. **D**, Bisferiens pulse with two systolic peaks, typical of hypertrophic obstructive cardiomyopathy or aortic insufficiency, especially if concomitant aortic stenosis is present. **E**, Pulsus alternans, characteristic of severe left ventricular failure. **F**, Paradoxical pulse (systolic pressure decrease >10 mm Hg with inspiration), most characteristic of cardiac tamponade.

pressure (difference between systolic and diastolic pressure), leads to a bounding carotid pulse often referred to as a Corrigan pulse or a water-hammer pulse. The amplitude of the pulse is diminished in low-output states such as heart failure, hypovolemia, and mitral stenosis. Tachycardia, with shorter diastolic filling times, also lowers the pulse amplitude. Aortic stenosis, when significant, leads to a delayed systolic peak and diminished carotid pulse, referred to as *pulsus parvus et tardus*. A bisferiens pulse is most perceptible on palpation of the carotid artery. It is characterized by two systolic peaks and can be found in patients with pure aortic regurgitation. The first peak is the percussion wave, which results from the rapid ejection of a large volume of blood early in systole. The second peak is the tidal wave, which is a reflected wave from the periphery. A bisferiens pulse may also be found in those with hypertrophic cardiomyopathy, in which the initial rapid upstroke of the pulse is interrupted by LVOT obstruction. The reflected wave produces the second impulse. Pulsus alternans is beat-to-beat variation in the pulse and can be found in patients with severe left ventricular systolic dysfunction.

Pulsus paradoxus is an exaggeration of the normal inspiratory fall in systolic pressure. With inspiration, negative intrathoracic pressure is transmitted to the aorta, and systolic pressure typically drops by as much as 10 mm Hg. In pulsus paradoxus, this drop is greater than 10 mm Hg and can be palpable when marked (>20 mm Hg). It is characteristic in cardiac tamponade but can also be seen in constrictive pericarditis, pulmonary embolism, hypovolemic shock, pregnancy, and severe chronic obstructive lung disease.

Because peripheral vascular disease often accompanies CAD, a detailed examination of the peripheral pulses is an absolute necessity in patients with known ischemic heart disease. In addition to the carotid, brachial, radial, femoral, popliteal, dorsalis pedis, and posterior tibial pulses, the abdominal aorta should be palpated. When the abdominal aorta is palpable below the umbilicus, the presence of an abdominal aortic aneurysm is suggested. Impaired blood flow to the lower extremities can cause claudication, a cramping pain located in the buttocks, thigh, calf, or foot, depending on the location of disease. With significant stenosis in the peripheral vasculature, the distal pulses may be significantly reduced or absent. Blood flow in a stenotic artery may be turbulent, creating an audible bruit. With normal aging, the peripheral arteries become less compliant and this change may obscure abnormal findings.

Examination of the Precordium

A complete cardiovascular examination should always include careful inspection and palpation of the chest, because this may reveal valuable clues regarding the presence of cardiac disease. Abnormalities of the chest wall including skin findings should be observed. The presence of pectus excavatum is associated with Marfan's syndrome and mitral valve prolapse. Pectus carinatum can also be found in patients with Marfan's syndrome. Kyphoscoliosis can lead to right-sided heart failure and secondary pulmonary hypertension. One should also assess for visible pulsations, in particular in the regions of the aorta (second right intercostal space and suprasternal notch), pulmonary artery (third left intercostal space), right ventricle (left parasternal region), and left

ventricle (fourth to fifth intercostal space at the left midclavicular line). Prominent pulsations in these areas suggest enlargement of these vessels or chambers. Retraction of the left parasternal area can be observed in patients with severe left ventricular hypertrophy, whereas systolic retraction at the apex or in the left axilla (Broadbent sign) is more characteristic of constrictive pericarditis.

Palpation of the precordium is best performed when the patient, with chest exposed, is positioned supine or in a left lateral position with the examiner located on the right side of the patient. The examiner should then place the right hand over the lower left chest wall with fingertips over the region of the cardiac apex and the palm over the region of the right ventricle. The right ventricle itself is typically best palpated in the subxiphoid region with the tip of the index finger. In those patients who have chronic obstructive lung disease, are obese, or are very muscular, the normal cardiac pulsations may not be palpable. In addition, chest wall deformities may make pulsations difficult or impossible to palpate. The normal apical cardiac impulse is a brief and discrete (1 cm in diameter) pulsation located in the fourth to fifth intercostal space along the left midclavicular line. In a patient with a normal heart, this represents the point of maximal impulse (PMI). If the heart cannot be palpated with the patient supine, a left lateral position should be tried. If the left ventricle is enlarged for any reason, the PMI will typically be displaced laterally. With volume overload states such as aortic insufficiency, the left ventricle dilates, resulting in a brisk apical impulse that is increased in amplitude. With pressure overload, as in long-standing hypertension and aortic stenosis, ventricular enlargement is a result of hypertrophy, and the apical impulse is sustained. Often, it is accompanied by a palpable S_4 gallop. Patients with hypertrophic cardiomyopathy can have double or triple apical impulses. Those with apical aneurysm may have an apical impulse that is larger and dyskinetic.

The right ventricle is usually not palpable. However, in those with right ventricular dilation or hypertrophy, which can be related to severe lung disease, pulmonary hypertension, or congenital heart disease, an impulse may be palpated in the left parasternal region. In some cases of severe emphysema, when the distance between the chest wall and right ventricle is increased, the right ventricle is better palpated in the subxiphoid region. With severe pulmonary hypertension, the pulmonary artery may produce a palpable impulse in the second to third intercostal space to the left of the sternum. This may be accompanied by a palpable right ventricle or a palpable pulmonic component of the second heart sound (S_2). An aneurysm of the ascending aorta or arch may result in a palpable pulsation in the suprasternal notch. Thrills are vibratory sensations best palpated with the fingertips; they are manifestations of harsh murmurs caused by such problems as aortic stenosis, hypertrophic cardiomyopathy, and septal defects.

Auscultation

Techniques

Auscultation of the heart is accomplished by the use of a stethoscope with dual chest pieces. The diaphragm is ideal for high-frequency sounds, whereas the bell is better for

low-frequency sounds. When one is listening for low-frequency tones, the bell should be placed gently on the skin with minimal pressure applied. If the bell is applied more firmly, the skin will stretch and higher-frequency sounds will be heard (as when using the diaphragm). Auscultation should ideally be performed in a quiet setting with the patient's chest exposed and the examiner best positioned to the right of the patient. Four major areas of auscultation are evaluated, starting at the apex and moving toward the base of the heart. The mitral valve is best heard at the apex or location of the PMI. Tricuspid valve events are appreciated in or around the left fourth intercostal space adjacent to the sternum. The pulmonary valve is best evaluated in the second left intercostal space. The aortic valve is assessed in the second right intercostal space. These areas should be evaluated from apex to base using the diaphragm and then evaluated again with the bell. Auscultation of the back, the axillae, the right side of the chest, and the supraclavicular areas should also be done. Having the patient perform maneuvers such as leaning forward, exhaling, standing, squatting, and performing a Valsalva maneuver may help to accentuate certain heart sounds (Table 3-4).

Normal Heart Sounds

All heart sounds should be described according to their quality, intensity, and frequency. There are two primary heart sounds heard during auscultation: S_1 and S_2 . These are high-frequency

sounds caused by closure of the valves. S_1 occurs with the onset of ventricular systole and is caused by closure of the mitral and tricuspid valves. S_2 is caused by closure of the aortic and pulmonic valves and marks the beginning of ventricular diastole. All other heart sounds are timed based on these two sounds.

S_1 has two components, the first of which (M_1) is usually louder, heard best at the apex, and caused by closure of the mitral valve. The second component (T_1), which is softer and thought to be related to closure of the tricuspid valve, is heard best at the lower left sternal border. Although there can be two components, S_1 is typically heard as a single sound. S_2 also has two components, which typically can be easily distinguished. A_2 , the component caused by closure of the aortic valve, is usually louder and is best heard at the right upper sternal border. P_2 , caused by closure of the pulmonic valve, is recognized best over the left second intercostal space. With expiration, a normal S_2 is perceived as a single sound. With inspiration, however, venous return to the right heart is augmented, and the increased capacitance of the pulmonary vascular bed results in a delay in pulmonic valve closure. A slight decline in pulmonary venous return to the left ventricle leads to earlier aortic valve closure. Therefore, physiologic splitting of S_2 , with A_2 preceding P_2 during inspiration, is a normal finding.

Additional heart sounds can at times be heard in normal individuals. A third heart sound can sometimes be heard in healthy children and young adults. This is referred to as a physiologic S_3 , which is rarely heard after the age of 40 years in a normal individual. A fourth heart sound is caused by forceful atrial contraction into a noncompliant ventricle; it is rarely audible in normal young patients but is relatively common in older individuals.

Murmurs are auditory vibrations generated by high flow across a normal valve or normal flow across an abnormal valve or structure. Murmurs that occur early in systole and are soft and brief in duration are not typically pathologic and are termed *innocent murmurs*. These usually are caused by flow across normal left ventricular or right ventricular outflow tracts and are found in children and young adults. Some systolic murmurs may be associated with high-flow states such as fever, anemia, thyroid disease, and pregnancy and are not innocent, although they are not typically associated with structural heart disease. They are called *physiologic murmurs* because of their association with altered physiologic states. All diastolic murmurs are pathologic.

Abnormal Heart Sounds

Abnormalities in S_1 and S_2 are related to either intensity (Table 3-5) or respiratory splitting (Table 3-6). S_1 is accentuated with tachycardia and with short PR intervals, whereas it is softer in the setting of a long PR interval. S_1 varies in intensity if the relationship between atrial and ventricular systole varies. In those patients with atrial fibrillation, atrial filling and emptying is not consistent because the variable HR leading to beat-to-beat changes in the intensity of S_1 . This also can occur with heart block or AV dissociation. In early mitral stenosis, S_1 is often accentuated, but with severe stenosis, there is decreased leaflet excursion and S_1 is diminished in intensity or altogether absent (Figs. 3-3 and 3-4). As previously mentioned, splitting of S_1 is not frequently heard.

TABLE 3-4 EFFECTS OF PHYSIOLOGIC MANEUVERS ON AUSCULTATORY EVENTS

MANEUVER	MAJOR PHYSIOLOGIC EFFECTS	USEFUL AUSCULTATORY CHANGES
Respiration	↑ Venous return with inspiration	↑ Right heart murmurs and gallops with inspiration; splitting of S_2 (see Fig. 3-3)
Valsalva (initial ↑ BP, phase I; followed by ↓ BP, phase II)	↓ BP, ↓ venous return, ↓ LV size (phase II)	↓ HCM ↓ AS, MR MVP click earlier in systole; murmur prolongs
Standing	↑ Venous return ↑ LV size	↑ HCM ↓ AS, MR MVP click earlier in systole; murmur prolongs
Squatting	↑ Venous return ↑ Systemic vascular resistance ↑ LV size	↑ AS, MR, AI ↓ HCM MVP click delayed; murmur shortens
Isometric exercise (e.g., handgrip)	↑ Arterial pressure ↑ Cardiac output	↑ Gallops ↑ MR, AI, MS ↓ AS, HCM
Post PVC or prolonged R-R interval	↑ Ventricular filling	↑ AS
Amyl nitrate	↑ Contractility ↓ Arterial pressure ↑ Cardiac output ↓ LV size	Little change in MR ↑ HCM, AS, MS ↓ AI, MR, Austin Flint murmur MVP click earlier in systole; murmur prolongs
Phenylephrine	↑ Arterial pressure ↑ Cardiac output ↓ LV size	↑ MR, AI ↓ AS, HCM MVP click delayed; murmur shortens

↑, Increased intensity; ↓, decreased intensity; AI, aortic insufficiency; AS, aortic stenosis; BP, blood pressure; HCM, hypertrophic cardiomyopathy; LV, left ventricle; MR, mitral regurgitation; MS, mitral stenosis; MVP, mitral valve prolapse; PVC, premature ventricular contraction; R-R, interval between the R waves on an electrocardiogram.

However, it is more apparent in conditions that delay closure of the tricuspid valve, including right bundle branch block and Ebstein's anomaly (Audio Clip 3-1, Ebstein Abnormalities).

S_2 can be accentuated in the presence of hypertension, when the aortic component will be louder, or in pulmonary hypertension, when the pulmonic component will be enhanced. In the setting of severe aortic or pulmonic stenosis, leaflet excursion of the respective valves is reduced and the intensity of S_2 is significantly diminished. It may become absent altogether if the accompanying murmur obscures what remains of S_2 .

There are several patterns of abnormal splitting of S_2 . S_2 can remain single throughout respiration if either A_2 or P_2 is not present or if they occur simultaneously. A_2 can be absent, as previously mentioned, with severe aortic stenosis. P_2 can be absent with a number of congenital abnormalities of the pulmonic valve. Splitting may be persistent throughout the respiratory cycle if A_2 occurs early or if P_2 is delayed, as in the presence of right bundle branch block. In that case, splitting is always present but the interval between A_2 and P_2 varies somewhat. In fixed splitting, the interval between A_2 and P_2 is consistently wide and unaffected by respiration. This finding is observed in the presence of an ostium secundum atrial septal defect or right ventricular failure. Paradoxical splitting of S_2 occurs when P_2 precedes A_2 . This leads to splitting with expiration and a single S_2 with inspiration. It is commonly found in situations of delayed electrical activation of the left ventricle, as in patients with left bundle branch block or right ventricular pacing. It can also be seen with prolonged mechanical contraction of the left ventricle, as in patients with aortic stenosis or hypertrophic cardiomyopathy.

TABLE 3-5 ABNORMAL INTENSITY OF HEART SOUNDS

	S_1	A_2	P_2
Loud	Short PR interval Mitral stenosis with pliable valve	Systemic hypertension Aortic dilation Coarctation of the aorta	Pulmonary hypertension Thin chest wall
Soft	Long PR interval Mitral regurgitation Poor left ventricular function Mitral stenosis with rigid valve Thick chest wall	Calcific aortic stenosis Aortic regurgitation	Valvular or subvalvular pulmonic stenosis
Varying	Atrial fibrillation Heart block	—	—

A_2 , Component of second heart sound caused by closure of aortic valve; P_2 , component of second heart sound caused by closure of pulmonic valve; S_1 , first heart sound.

TABLE 3-6 ABNORMAL SPLITTING OF S_2

SINGLE S_2	WIDELY SPLIT S_2 WITH NORMAL RESPIRATORY VARIATION	FIXED SPLIT S_2	PARADOXICALLY SPLIT S_2
Pulmonic stenosis Systemic hypertension Coronary artery disease Any condition that can lead to paradoxical splitting of S_2	Right bundle branch block Left ventricular pacing Pulmonic stenosis Pulmonary embolism Idiopathic dilation of the pulmonary artery Mitral regurgitation Ventricular septal defect	Atrial septal defect Severe right ventricular dysfunction	Left bundle branch block Right ventricular pacing Angina, myocardial infarction Aortic stenosis Hypertrophic cardiomyopathy Aortic regurgitation

S_2 , Second heart sound.

The third heart sound, S_3 , is a low-pitched sound heard best at the apex in mid diastole. Because it is low pitched, it is best recognized with use of the bell on the stethoscope. As stated previously, S_3 can be physiologic in children but is pathologic in older individuals and often associated with underlying cardiac disease. An S_3 occurs during the rapid filling phase of diastole and is thought to indicate a sudden limitation of the expansion of the left ventricle. This can be seen in cases of volume overload or tachycardia. Maneuvers that increase venous return accentuate an S_3 , whereas those that reduce venous return diminish the intensity. The fourth heart sound, S_4 , is also a low-frequency sound, but in contrast to S_3 , it is heard in late diastole, just before S_1 . The S_4 gallop occurs as a result of active ejection of blood into a noncompliant left ventricle. Therefore, when atrial contraction is absent, such as in atrial fibrillation, an S_4 cannot be heard. This heart sound is also best recognized with the use of a bell at the apex. It can be heard in patients with left ventricular hypertrophy, acute myocardial infarction, or hyperdynamic left ventricle. At times, an S_3 and an S_4 can be heard in the same patient. In tachycardic states, the two sounds can fuse in mid diastole to form a summation gallop.

As stated earlier, S_3 and S_4 gallops are heard in mid diastole and late diastole, respectively. There are other abnormal sounds that can be heard during systole and early diastole. *Ejection sounds* are typically heard in early systole and involve the aortic and pulmonic valves. These are high-frequency sounds that can be heard with a diaphragm shortly after S_1 . Ejection sounds are caused by the opening of abnormal valves to their full extent, such as with a bicuspid aortic valve or congenital pulmonic stenosis. They are frequently followed by a typical ejection murmur of aortic or pulmonic stenosis. Ejection sounds can also be heard with systemic or pulmonary hypertension, in which case the exact mechanism is not clear.

Midsystolic to late systolic sounds are called *ejection clicks*. They are most commonly associated with mitral valve prolapse. They are also high pitched and easily auscultated with the diaphragm. The click occurs because of maximal displacement of the prolapsed mitral leaflet into the left atrium and resultant tensing of chordae and redundant leaflets (Audio Clip 3-2, MVP). The click is usually followed by a typical murmur of mitral regurgitation. Any maneuver that decreases venous return will cause the click to occur earlier in systole, whereas increasing ventricular volume will delay the click (see Table 3-4).

The opening of abnormal mitral or tricuspid valves can be heard in early diastole. This *opening snap* is most frequently associated with rheumatic mitral stenosis. It is heard if the valve leaflets remain pliable and is generated when the leaflets abruptly

FIGURE 3-3 Abnormal heart sounds can be related to abnormal intensity, abnormal presence of a gallop rhythm, or abnormal splitting of the second heart sound (S_2) with respiration. A_2 , Component of S_2 caused by closure of aortic valve; ECG, electrocardiogram; P_2 , component of S_2 caused by closure of pulmonic valve.

dome during diastole. The frequency, intensity, and timing of the click have diagnostic significance. For example, the shorter the interval between S_2 and the opening snap, the more severe the degree of mitral stenosis, because this is a reflection of higher left atrial pressure. The *pericardial knock* of constrictive pericarditis and *tumor plop* generated by an atrial myxoma also occur in

FIGURE 3-4 The relationship of extra heart sounds to the normal first (S_1) and second (S_2) heart sounds. S_1 is composed of the mitral (M_1) and tricuspid (T_1) closing sounds, although it is frequently perceived as a single sound. S_2 is composed of the aortic (A_2) and pulmonic (P_2) closing sounds, which are usually easily distinguished. A fourth heart sound (S_4) is soft and low pitched and precedes S_1 . A pulmonic or aortic ejection sound (ES) occurs shortly after S_1 . The systolic click (C) of mitral valve prolapse may be heard in mid systole or late systole. The opening snap (OS) of mitral stenosis is high pitched and occurs shortly after S_2 . A tumor plop or pericardial knock occurs at the same time and can be confused with an OS or an S_3 , which is lower in pitch and occurs slightly later.

TABLE 3-7 GRADING SYSTEM FOR INTENSITY OF MURMURS

GRADE	DESCRIPTION
1	Barely audible murmur
2	Murmur of medium intensity
3	Loud murmur, no thrill
4	Loud murmur with thrill
5	Very loud murmur; stethoscope must be on the chest to hear it; may be heard posteriorly
6	Murmur audible with stethoscope off the chest

early diastole and may be confused with an opening snap. They can typically be differentiated from an S_3 gallop because they are higher-frequency sounds.

Murmurs

Murmurs are a series of auditory vibrations generated by either abnormal blood flow across a normal cardiac structure or normal flow across an abnormal cardiac structure, both of which result in turbulent flow. These sounds are longer than individual heart sounds and should be described on the basis of their location, frequency, intensity, quality, duration, shape, and timing in the cardiac cycle. The intensity of a given murmur is typically graded on a scale of 1 to 6 (Table 3-7). Murmurs of grade 4 or higher are associated with palpable thrills. The intensity or loudness of a murmur does not necessarily correlate with the severity of disease. For example, a murmur can be quite harsh when it is associated with a moderate degree of aortic stenosis. If stenosis is critical, however, the flow across the valve is diminished and the murmur becomes rather quiet. In the presence of a large atrial septal defect, flow is almost silent, whereas flow through a small

ventricular septal defect is typically associated with a loud murmur.

The frequency of a murmur can be high or low; higher-frequency murmurs are more correlated with high velocity of flow at the site of turbulence. It is also important to notice the configuration or shape of a murmur, such as crescendo, crescendo-decrescendo, decrescendo, or plateau (Fig. 3-5). The quality of a murmur (e.g., harsh, blowing, rumbling) and the pattern of radiation are also helpful in diagnosis. Physical maneuvers can sometimes help clarify the nature of a particular murmur (see Table 3-4).

Murmurs can be divided into three different categories (Table 3-8). Systolic murmurs begin with or after S_1 and end with or before S_2 . Diastolic murmurs begin with or after S_2 and end with or before S_1 . Continuous murmurs begin in systole and continue through diastole. Murmurs can result from abnormalities on the left or right side of the heart or in the great vessels. Right-sided murmurs become louder with inspiration because of increased venous return. This can help differentiate them from left-sided murmurs, which are unaffected by respiration.

Systolic murmurs should be further differentiated based on timing (i.e., early systolic, midsystolic, late systolic, and holosystolic murmurs). Early systolic murmurs begin with S_1 , are decrescendo, and end typically before mid systole. Ventricular septal defects and acute mitral regurgitation may lead to early systolic murmurs. Midsystolic murmurs begin after S_1 and end before S_2 , often in a crescendo-decrescendo shape. They are typically caused by obstruction to left ventricular outflow, accelerated flow through the aortic or pulmonic valve, or enlargement of the aortic root or pulmonary trunk. Aortic stenosis, when

less than severe in degree, causes a midsystolic murmur that may be harsh and may radiate to the carotids. Pulmonic stenosis leads to a similar murmur that does not radiate to the carotid arteries but may change with inspiration. The murmur of hypertrophic cardiomyopathy may be mistaken for aortic stenosis; however, it does not radiate to the carotids and becomes exaggerated with diminished venous return. Innocent or benign murmurs may also occur as a result of aortic valve sclerosis, vibrations of a left ventricular false tendon, or vibration of normal pulmonary leaflets. They are generally less harsh and shorter in duration. High-flow states such as those found in patients with fever, during pregnancy, or with anemia may also lead to midsystolic murmurs.

Holosystolic murmurs begin with S_1 and end with S_2 ; the classic examples are the murmurs associated with mitral regurgitation and tricuspid regurgitation. They may also occur with ventricular septal defects and patent ductus arteriosus. Late systolic murmurs begin in mid to late systole and end with S_2 . They can be characteristic of more severe aortic stenosis and are also typical of murmurs associated with mitral valve prolapse.

Diastolic murmurs are also classified by timing (i.e., early diastolic, mid diastolic, and late diastolic). Early diastolic murmurs begin with S_2 and can result from aortic or pulmonic regurgitation; they are usually decrescendo in shape. Shorter and quieter murmurs typically represent an acute process or mild regurgitation, whereas longer-lasting and louder murmurs are likely due to more severe regurgitation. Mid-diastolic murmurs begin after S_2 and are usually caused by mitral or tricuspid stenosis. They are low pitched and are often referred to as *diastolic rumbles*. Because

FIGURE 3-5 Abnormal sounds and murmurs associated with valvular dysfunction displayed simultaneously with left atrial (LA), left ventricular (LV), and aortic pressure tracings. The shaded areas represent pressure gradients across the aortic valve during systole or across mitral valve during diastole; they are characteristic of aortic stenosis and mitral stenosis, respectively. AVO, Aortic valve opening; E, ejection click of the aortic valve; MVO, mitral valve opening; OS, opening snap of the mitral valve; S_1 , first heart sound; S_2 , second heart sound.

TABLE 3-8 CLASSIFICATION OF HEART MURMURS

CLASS	DESCRIPTION	CHARACTERISTIC LESIONS
SYSTOLIC		
Ejection	Begins in early systole; may extend to mid or late systole Crescendo-decrescendo pattern Often harsh in quality Begins after S ₁ and ends before S ₂	Valvular, supra- and subvalvular aortic stenoses Hypertrophic cardiomyopathy Pulmonic stenosis Aortic or pulmonary artery dilation Malformed but nonobstructive aortic valve ↑ Transvalvular flow (e.g., aortic regurgitation, hyperkinetic states, atrial septal defect, physiologic flow murmur)
Holosystolic	Extends throughout systole* Relatively uniform in intensity	Mitral regurgitation Tricuspid regurgitation Ventricular septal defect
Late	Variable onset and duration, often preceded by a nonejection click	Mitral valve prolapse
DIASTOLIC		
Early	Begins with A ₂ or P ₂ Decrescendo pattern with variable duration Often high pitched, blowing	Aortic regurgitation Pulmonic regurgitation
Mid	Begins after S ₂ , often after an opening snap Low-pitched <i>rumble</i> heard best with bell of stethoscope Louder with exercise and left lateral position Loudest in early diastole	Mitral stenosis Tricuspid stenosis ↑ Flow across atrioventricular valves (e.g., mitral regurgitation, tricuspid regurgitation, atrial septal defect)
Late	Presystolic accentuation of mid-diastolic murmur	Mitral stenosis Tricuspid stenosis
CONTINUOUS		
	Systolic and diastolic components “Machinery murmurs”	Patent ductus arteriosus Coronary atrioventricular fistula Ruptured sinus of Valsalva aneurysm into right atrium or ventricle Mammary soufflé Venous hum

A₂, Component of S₂ caused by closure of aortic valve; P₂, component of S₂ caused by closure of pulmonic valve; S₁, first heart sound; S₂, second heart sound.

*Encompasses both S₁ and S₂.

they are of low frequency, they are better auscultated with the bell of the stethoscope. Similar murmurs can be heard with obstructing atrial myxomas. Severe chronic aortic insufficiency can lead to premature closure of the mitral valve, causing a mid-diastolic rumble called an Austin-Flint murmur. Late diastolic murmurs occur immediately before S₁ and reflect presystolic accentuation of the mid-diastolic murmurs resulting from augmented mitral or tricuspid flow after atrial contraction.

Continuous murmurs begin with S₁ and last though part or all of diastole. They are generated by continuous flow from a vessel or chamber with high pressure into a vessel or chamber with lower pressure. They are referred to as *machinery murmurs* and are caused by aortopulmonary connections such as a patent ductus arteriosus, AV malformations, or disturbances of flow in arteries or veins.

Other Cardiac Sounds

Pericardial rubs occur in the setting of pericarditis and are coarse, scratching sounds similar to rubbing leather. They are typically heard best at the left sternal border with the patient leaning forward and holding the breath at end-expiration. A classic pericardial rub has three components: atrial systole, ventricular systole, and ventricular diastole. One might also hear a pleural rub caused by localized irritation of surrounding pleura. Continuous venous murmurs, or *venous hums*, are almost always present in children. They can be heard in adults during pregnancy, in the setting of anemia, or with thyrotoxicosis. They are

heard best at the base of the neck with the patient's head turned to the opposite direction.

Prosthetic Heart Sounds

Prosthetic heart valves produce characteristic findings on auscultation. Bioprosthetic valves produce sounds that are similar to those of native heart valves, but they are typically smaller than the valves that they replace and therefore have an associated murmur. Mechanical valves have crisp, high-pitched sounds related to valve opening and closure. In most modern valves such as the St. Jude valve, which is a bileaflet mechanical valve, the closure sound is louder than the opening sound. An ejection murmur is common. If there is a change in murmur or in the intensity of the mechanical valve closure sound, dysfunction of the valve should be suspected.

 For a deeper discussion of this topic, please see Chapter 51, “Approach to the Patient with Possible Cardiovascular Disease,” in Goldman-Cecil Medicine, 25th Edition.

Diagnostic Tests and Procedures in the Patient with Cardiovascular Disease

Ivor J. Benjamin

CHEST RADIOGRAPHY

The chest radiograph is an integral part of the cardiac evaluation, and it gives valuable information regarding the structure and function of the heart, lungs, and great vessels. A routine examination includes posteroanterior and lateral projections (Fig. 4-1).

In the posteroanterior view, cardiac enlargement may be identified when the transverse diameter of the cardiac silhouette is greater than one half of the transverse diameter of the thorax. The heart may appear falsely enlarged when it is displaced horizontally, such as with poor inflation of the lungs, and when the film is an anteroposterior projection, which magnifies the heart shadow. Left atrial enlargement is suggested when the left-sided heart border is straightened or bulges toward the left. The main bronchi may be widely splayed, and a circular opacity or *double density* may be seen in the cardiac silhouette. Right atrial enlargement may be confirmed when the right-sided heart border bulges toward the right. Left ventricular enlargement results in

downward and lateral displacement of the apex. A rounding of the displaced apex suggests ventricular hypertrophy. Right ventricular enlargement is best assessed on the lateral view and may be diagnosed when the right ventricular border occupies more than one third of the retrosternal space between the diaphragm and thoracic apex.

The aortic arch and thoracic aorta may become dilated and tortuous in patients with severe atherosclerosis, long-standing hypertension, and aortic dissection. Dilation of the proximal pulmonary arteries may occur when pulmonary pressures are elevated and pulmonary vascular resistance is increased. Disease states associated with increased pulmonary artery flow and normal vascular resistance, such as atrial or ventricular septal defects, may result in dilation of the proximal and distal pulmonary arteries.

Pulmonary venous congestion due to elevated left ventricular heart pressure results in redistribution of blood flow in the lungs and prominence of the apical vessels. Transudation of fluid into the interstitial space may result in fluid in the fissures and along

FIGURE 4-1 Schematic illustration of the parts of the heart, whose outlines can be identified on a routine chest radiograph. **A**, Posteroanterior chest radiograph. **B**, Lateral chest radiograph. Ao, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

the horizontal periphery of the lower lung fields (i.e., Kerley B lines). As venous pressures further increase, fluid collects in the alveolar space, which early on collects preferentially in the inner two thirds of the lung fields, resulting in a characteristic butterfly appearance.

Fluoroscopy or plain films may identify abnormal calcification involving the pericardium, coronary arteries, aorta, and valves. Fluoroscopy can be instrumental in evaluating the function of mechanical prosthetic valves. Specific radiographic signs of congenital and valvular diseases are discussed in later sections.

Electrocardiography

The electrocardiogram (ECG) represents the electrical activity of the heart recorded by skin electrodes. This wave of electrical activity is represented as a sequence of deflections on the ECG (Fig. 4-2). The horizontal axis of the graph paper represents time, and at a standard paper speed of 25 mm/second, each small box (1 mm) represents 0.04 second, and each large box (5 mm) represents 0.20 second. The vertical axis represents voltage or amplitude (10 mm = 1 mV). The heart rate can be estimated by dividing the number of large boxes between complexes (i.e., R-R interval) into 300.

In the normal heart, the electrical impulse originates in the sinoatrial (SA) node and is conducted through the atria. Given that depolarization of the SA node is too weak to be detected on the surface ECG, the first, low-amplitude deflection on the surface ECG represents atrial activation and is called the *P wave*. The interval between the onset of the P wave and the next rapid deflection (QRS complex) is known as the *PR interval*. It primarily represents the time taken for the impulse to travel through the atrioventricular (AV) node. The normal PR segment ranges from 0.12 to 0.20 second. A PR interval greater than 0.20 second defines AV nodal block.

After the wave of depolarization has moved through the AV node, the ventricular myocardium is depolarized in a sequence of four phases. The interventricular septum depolarizes from left to right. This phase is followed by depolarization of the right ventricle and inferior wall of the left ventricle, then the apex and central portions of the left ventricle, and finally the base and the

posterior wall of the left ventricle. Ventricular depolarization results in a high-amplitude complex on the surface ECG known as the *QRS complex*. The first downward deflection of this complex is the Q wave, the first upward deflection is the R wave, and the subsequent downward deflection is the S wave. In some individuals, a second upward deflection may occur after the S wave, and it is called *R prime* (R'). Normal duration of the QRS complex is less than 0.10 second. Complexes greater than 0.12 second are usually secondary to some form of interventricular conduction delay.

The isoelectric segment after the QRS complex is the ST segment, which represents a brief period during which relatively little electrical activity occurs in the heart. The junction between the end of the QRS complex and the beginning of the ST segment is the J point. The upward deflection after the ST segment is the T wave, which represents ventricular repolarization. The QT interval, which reflects the duration and transmural gradient of ventricular depolarization and repolarization, is measured from the onset of the QRS complex to the end of the T wave. The QT interval varies with heart rate, but for rates between 60 and 100 beats/minute, the normal QT interval ranges from 0.35 to 0.44 second. For heart rates outside this range, the QT interval can be corrected (QT_c) using the following formula (all measurements in seconds):

$$QT_c = QT / R-R \text{ interval}^{1/2}$$

In some individuals, the T wave may be closely followed by a U wave (0.5 mm deflection, not shown in Figure 4-2), the cause of which is unknown.

The standard ECG consists of 12 leads: six limb leads (I, II, III, aVR, aVL, and aVF) and six chest or precordial leads (V₁ to V₆) (Fig. 4-3). The electrical activity recorded in each lead represents the direction and magnitude (i.e., vector) of the electrical force as seen from that lead position. Electrical activity directed toward a particular lead is represented as an upward deflection, and an electrical impulse directed away from a particular lead is represented as a downward deflection. Although the overall direction of electrical activity can be determined for any of the waveforms previously described, the mean QRS axis is the most clinically useful and is determined by examining the six limb leads.

Figure 4-4 illustrates the axial reference system, a reconstruction of the Einthoven triangle, and the polarity of each of the six limb leads of the standard ECG. Skin electrodes are attached to both arms and legs, with the right leg serving as the ground. Leads I, II, and III are bipolar leads and represent electrical activity between two leads. Lead I represents electrical activity between the right and left arms (left arm positive), lead II between the right arm and left leg (left leg positive), and lead III between the left arm and left leg (left leg positive). Leads aVR, aVL, and aVF are designated the *augmented leads*. Using these leads, the QRS is positive or has a predominant upward deflection when the electrical forces are directed toward the right arm for aVR, left arm for aVL, and left leg for aVF. These six leads form a hexaxial frontal plane of 30-degree arc intervals. The normal QRS axis ranges from -30 to +90 degrees. An axis more negative than -30 defines left axis deviation, and an axis greater than +90 defines right axis deviation. A positive QRS complex

FIGURE 4-2 Normal electrocardiographic complex with labeling of waves and intervals.

FIGURE 4-3 Normal 12-lead electrocardiogram.

FIGURE 4-4 Hexaxial reference figure for frontal plane axis determination, indicating values for abnormal left and right QRS axis deviations.

in leads I and aVF suggests a normal QRS axis between 0 and 90 degrees.

The six standard precordial leads (V_1 to V_6) are attached to the anterior chest wall (Fig. 4-5). Lead placement should be as follows: V_1 : fourth intercostal space, right sternal border; V_2 : fourth intercostal space, left sternal border; V_3 : midway between V_2 and V_4 ; V_4 : fifth intercostal space, left midclavicular line; V_5 : level with V_4 , left anterior axillary line; V_6 : level with V_4 , left midaxillary line. The chest leads should be placed under the breast.

Electrical activity directed toward these leads results in a positive deflection on the ECG. Leads V_1 and V_2 are closest to the right ventricle and interventricular septum, and leads V_5 and V_6 are closest to the anterior and anterolateral walls of the left ventricle. Normally, a small R wave occurs in lead V_1 , reflecting septal

depolarization, along with a deep S wave, reflecting predominantly left ventricular activation. From V_1 to V_6 , the R wave becomes larger (and the S wave smaller) because the predominant forces directed at these leads originate from the left ventricle. The transition from a predominant S wave to a predominant R wave usually occurs between leads V_3 and V_4 .

Right-sided chest leads are used to look for evidence of right ventricular infarction. ST-segment elevation in V_{4R} has the best sensitivity and specificity for making this diagnosis. For right-sided leads, standard V_1 and V_2 are switched, and V_{3R} to V_{6R} are placed in a mirror image of the standard left-sided chest leads. Some groups have advocated the use of posterior leads to increase the sensitivity for diagnosing lateral and posterior wall infarction or ischemia—areas that are often deemed to be *electrically silent* on traditional 12-lead ECGs. To do this, six additional leads are placed in the fifth intercostal space continuing posteriorly from the position of V_6 .

ABNORMAL ELECTROCARDIOGRAPHIC PATTERNS

Chamber Abnormalities and Ventricular Hypertrophy

The P wave is normally upright in leads I, II, and F; inverted in aVR; and biphasic in V_1 . Left atrial abnormality (i.e., enlargement, hypertrophy, or increased wall stress) is characterized by a wide P wave in lead II (0.12 second) and a deeply inverted terminal component in lead V_1 (1 mm). Right atrial abnormality is identified when the P waves in the limb leads are peaked and at least 2.5 mm high.

Left ventricular hypertrophy may result in increased QRS voltage, slight widening of the QRS complex, late intrinsicoid deflection, left axis deviation, and abnormalities of the ST-T segments (see Fig. 4-5A). Multiple criteria with various degrees of sensitivity and specificity for detecting left ventricular hypertrophy are available. The most frequently used criteria are given in Table 4-1.

Right ventricular hypertrophy is characterized by tall R waves in leads V_1 through V_3 ; deep S waves in leads I, aVL, V_5 , and V_6 ;

FIGURE 4-5 **A**, Left ventricular hypertrophy as seen on an electrocardiographic recording. Characteristic findings include increased QRS voltage in precordial leads (i.e., deep S in lead V_2 and tall R in lead V_5) and downsloping ST depression and T-wave inversion in lateral precordial leads (i.e., strain pattern) and leftward axis. **B**, Right ventricular hypertrophy with tall R wave in right precordial leads, downsloping ST depression in precordial leads (i.e., RV strain), right axis deviation, and evidence of right atrial enlargement.

and right axis deviation (see Fig. 4-5B). In patients with chronically elevated pulmonary pressures, such as with chronic lung disease, a combination of ECG abnormalities reflecting a right-sided pathologic condition may be identified and include right atrial abnormality, right ventricular hypertrophy, and right axis deviation. In patients with acute pulmonary embolus, ECG changes may suggest right ventricular strain and include right axis deviation; incomplete or complete right bundle branch block (RBBB); S waves in leads I, II, and III; and T-wave inversions in leads V_1 through V_3 .

Interventricular Conduction Delays

The ventricular conduction system consists of two main branches, the right and left bundles. The left bundle further divides into the anterior and posterior fascicles. Conduction block can occur in either of the major branches or in the fascicles (Table 4-2).

Fascicular block results in a change in the sequence of ventricular activation but does not prolong overall conduction time (i.e., QRS duration remains <0.10 second). Left anterior fascicular block is a relatively common ECG abnormality and is sometimes associated with RBBB. This conduction abnormality is identified when extreme left axis deviation occurs (i.e., more

negative than -45 degrees), when the R wave is greater than the Q wave in leads I and aVL, and when the S wave is greater than the R wave in leads II, III, and aVF. Left posterior fascicular block is uncommon but is associated with right axis deviation (>90 degrees); small Q waves in leads II, III, and aVF; and small R waves in leads I and aVL. The ECG findings associated with fascicular blocks can be confused with myocardial infarction (MI). For example, with left anterior fascicular block, the prominent QS deflection in leads V_1 and V_2 can mimic an anteroseptal MI, and the rS deflection in leads II, III, and aVF can be confused with an inferior MI. Similarly, the rS deflection in leads I and aVL in left posterior fascicular block may be confused with a high lateral infarct. Abnormal ST- and T-wave segments and pathologic Q waves (see [Myocardial Ischemia and Infarction](#)) are helpful findings for differentiating MI from a fascicular block.

Bundle branch blocks are associated with a QRS duration longer than 120 milliseconds. In left bundle branch block (LBBB), depolarization proceeds down the right bundle, across the interventricular septum from right to left, and then to the left ventricle. Characteristic electrocardiographic findings include a wide QRS complex; a broad R wave in leads I, aVL, V_5 , and V_6 ; a deep QS wave in leads V_1 and V_2 ; and ST depression and

TABLE 4-1 ELECTROCARDIOGRAPHIC MANIFESTATIONS OF ATRIAL ABNORMALITIES AND VENTRICULAR HYPERTROPHY

LEFT ATRIAL ABNORMALITY
P-wave duration ≥ 0.12 second
Notched, slurred P wave in leads I and II
Biphasic P wave in lead V_1 with a wide, deep, negative terminal component
RIGHT ATRIAL ABNORMALITY
P-wave duration ≤ 0.11 second
Tall, peaked P waves of ≥ 2.5 mm in leads II, III, and aVF
LEFT VENTRICULAR HYPERTROPHY
Voltage criteria
R wave in lead aVL ≥ 12 mm
R wave in lead I ≥ 15 mm
S wave in lead V_1 or V_2 + R wave in lead V_5 or V_6 ≥ 35 mm
Depressed ST segments with inverted T waves in the lateral leads
Left axis deviation
QRS duration ≥ 0.09 second
Left atrial enlargement
RIGHT VENTRICULAR HYPERTROPHY
Tall R waves over right precordium (R-to-S ratio in lead V_1 > 1.0)
Right axis deviation
Depressed ST segments with inverted T waves in leads V_1 to V_3
Normal QRS duration (if no right bundle branch block)
Right atrial enlargement

TABLE 4-2 ELECTROCARDIOGRAPHIC MANIFESTATIONS OF FASCICULAR AND BUNDLE BRANCH BLOCKS

LEFT ANTERIOR FASCICULAR BLOCK
QRS duration ≤ 0.1 second
Left axis deviation (more negative than -45 degrees)
rS pattern in leads II, III, and aVF
qR pattern in leads I and aVL
RIGHT POSTERIOR FASCICULAR BLOCK
QRS duration ≤ 0.1 second
Right axis deviation ($+90$ degrees or greater)
qR pattern in leads II, III, and aVF
rS pattern in leads I and aVL
Exclusion of other causes of right axis deviation (e.g., chronic obstructive pulmonary disease, right ventricular hypertrophy)
LEFT BUNDLE BRANCH BLOCK
QRS duration ≥ 0.12 second
Broad, slurred, or notched R waves in lateral leads (I, aVL, V_5 , and V_6)
QS or rS pattern in anterior precordium leads (V_1 and V_2)
ST-T-wave vectors opposite to terminal QRS vectors
RIGHT BUNDLE BRANCH BLOCK
QRS duration ≥ 0.12 second
Large R' wave in lead V_1 (rsR')
Deep terminal S wave in lead V_6
Normal septal Q waves
Inverted T waves in leads V_1 and V_2

T-wave inversion opposite the QRS deflection (Fig. 4-6A). Given the abnormal sequence of ventricular activation with LBBB, many ECG abnormalities, such as Q-wave MI and left ventricular hypertrophy, are difficult to evaluate. In some cases, acute MI is apparent even with LBBB. An LBBB typically indicates underlying myocardial disease—most commonly fibrosis due to ischemic injury or hypertrophy. With RBBB, the interventricular septum depolarizes normally from left to right, the initial QRS

deflection remains unchanged, and ECG abnormalities such as Q-wave MI can still be interpreted. After septal activation, the left ventricle depolarizes, followed by the right ventricle. The ECG is characterized by a wide QRS complex; a large R' wave in lead V_1 (R-S-R'); and deep S waves in leads I, aVL, and V_6 , representing delayed right ventricular activation (see Fig. 4-6B). Although RBBB may be associated with underlying cardiac disease, it may also appear as a normal variant or be seen intermittently when heart rate is elevated. In the latter case, it is referred to as *rate-related bundle branch block*.

Myocardial Ischemia and Infarction

Myocardial ischemia and MI may be associated with abnormalities of the ST segment, T wave, and QRS complex. Myocardial ischemia primarily affects repolarization of the myocardium and is often associated with horizontal or down-sloping ST-segment depression and T-wave inversion. These changes may be transient, such as during an anginal episode or an exercise stress test, or they may be long-lasting in the setting of unstable angina or MI. T-wave inversion without ST-segment depression is a non-specific finding and must be correlated with the clinical findings. Localized ST-segment elevation suggests more extensive myocardial injury and is often associated with acute MI (Fig. 4-7). Vasospastic or Prinzmetal angina may be associated with reversible ST-segment elevation without MI. ST-segment elevation may occur in other settings not related to acute ischemia or infarction. Persistent, localized ST-segment elevation in the same leads as pathologic Q waves is consistent with a ventricular aneurysm. Acute pericarditis is associated with diffuse ST-segment elevation and PR depression. Diffuse J-point elevation in association with upward-coving ST segments is a normal variant common among young men and is often referred to as *early repolarization*.

A Q wave is one of the criteria used to diagnose MI. Infarcted myocardium is unable to conduct electrical activity, and electrical forces are directed away from the surface electrode overlying the infarcted region, producing a Q wave on the surface ECG. Knowing which region of the myocardium each lead represents enables the examiner to localize the area of infarction (Table 4-3). A pathologic Q wave has a duration greater than or equal to 0.04 second or a depth one fourth or more of the height of the corresponding R wave.

Not all MIs result in the formation of Q waves. Small R waves can return many weeks to months after an MI.

Abnormal Q waves, or *pseudoinfarction*, may be associated with nonischemic cardiac disease, such as ventricular pre-excitation, cardiac amyloidosis, sarcoidosis, idiopathic or hypertrophic cardiomyopathy, myocarditis, and chronic lung disease.

Abnormalities of the ST Segment and T Wave

A number of drugs and metabolic abnormalities may affect the ST segment and T wave (Fig. 4-8). Hypokalemia may result in prominent U waves in the precordial leads and prolongation of the QT interval. Hyperkalemia may result in tall, peaked T waves. Hypocalcemia typically lengthens the QT interval, whereas hypercalcemia shortens it. A commonly used cardiac medication, digoxin, often results in diffuse, scooped ST-segment depression. Minor or *nonspecific* ST-segment and T-wave abnormalities may occur in many patients and have no definable cause. In these

FIGURE 4-6 A, Left bundle branch block (LBBB). B, Right bundle branch block (RBBB). Criteria for bundle branch blocks are summarized in Table 4-2.

instances, the physician must determine the significance of the abnormalities based on clinical findings. Several excellent websites containing examples of normal and abnormal ECGs are available.

LONG-TERM AMBULATORY ELECTROCARDIOGRAPHIC RECORDING

An ambulatory ECG (i.e., Holter monitoring) is a widely used, noninvasive method to evaluate cardiac arrhythmias and conduction disturbances over an extended period and to detect electrical abnormalities that may be brief or transient. With this approach, ECG data from two to three surface leads are stored on a tape recorder that the patient wears for at least 24 to 48 hours. The recorders have patient-activated event markers and time markers so that any abnormalities can be correlated with the patient's symptoms or time of day. These data can then be printed in a standard, real-time ECG format for review.

For patients with intermittent or rare symptoms, an event recorder, which can be worn for several weeks, may be helpful in identifying the arrhythmia. The simplest device is a small, handheld monitor that is applied to the chest wall when symptoms occur. The ECG data are recorded and can be transmitted later by telephone to a monitoring center for analysis. A more sophisticated system uses a wrist recorder that allows continuous-loop

storage of 4 to 5 minutes of ECG data from one lead. When the patient activates the system, ECG data preceding the event and for 1 to 2 minutes after the event are recorded and stored for further analysis. With both devices, the patient must be physically able to activate the recorder during the episode to store the ECG data. Implantable (subcutaneous) recording devices are sometimes used to diagnose infrequent events over extended periods (i.e., months).

Stress Testing

Stress testing is an important noninvasive tool for evaluating patients with known or suggested coronary artery disease (CAD). During exercise, the increased demand for oxygen by the working skeletal muscles is met by increases in heart rate and cardiac output. In patients with significant CAD, the increase in myocardial oxygen demand cannot be met by an increase in coronary blood flow, and myocardial ischemia may produce chest pain and characteristic ECG abnormalities. Combined with the hemodynamic response to exercise, these changes can give useful diagnostic and prognostic information for the patient with cardiac abnormalities. The most common indications for stress testing include establishing a diagnosis of CAD in patients with chest pain, assessing prognosis and functional capacity of patients with chronic stable angina or after an MI, evaluating exercise-induced

A

B

FIGURE 4-7 **A**, Evolutionary changes in a posteroinferior myocardial infarction (MI). Control tracing is normal. The tracing recorded 2 hours after onset of chest pain demonstrated development of early Q waves, marked ST-segment elevation, and hyperacute T waves in leads II, III, and aVF. A larger R wave, ST-segment depression, and negative T waves have developed in leads V₁ and V₂. These early changes indicate acute posteroinferior MI. The 24-hour tracing demonstrates further evolutionary changes. In leads II, III, and aVF, the Q wave is larger, the ST segments have almost returned to baseline, and the T wave has begun to invert. In leads V₁ to V₂, the duration of the R wave exceeds 0.04 seconds, the ST segment is depressed, and the T wave is upright. (In this example, electrocardiographic changes of true posterior involvement extend past lead V₂; ordinarily, only leads V₁ and V₂ may be involved.) Only minor further changes occur through the 8-day tracing. Six months later, the electrocardiographic pattern shows large Q waves, isoelectric ST segments, and inverted T waves in leads II, III, and aVF and shows large R waves, isoelectric ST segment, and upright T waves in leads V₁ and V₂, indicative of an old posteroinferior MI. **B**, Electrocardiogram from a patient with an underlying left bundle branch block (LBBB) who experienced an acute anterior MI. Characteristic ST segment elevation and hyperacute T waves are seen in leads V₁ through V₆ and leads I and aVL despite the presence of the LBBB. This is not always the case, and a patient with typical symptoms, an LBBB, and no definite ischemic ST-segment elevations should be treated as if the individual is having a myocardial infarction or acute coronary syndrome.

arrhythmias, and assessing for ischemia after a revascularization procedure.

The most common form of stress testing uses continuous ECG monitoring while the patient walks on a treadmill. With each advancing stage, the speed and incline of the belt increases, increasing the amount of work the patient performs. The commonly used Bruce protocol employs 3 minutes of exercise at each

stage. The modified Bruce protocol incorporates two beginning stages with slower speeds and lesser inclines than are used in the standard Bruce protocol.

The modified Bruce or similar protocols are used for older, markedly overweight, and unstable or more debilitated patients. Exercise testing may also be performed using a bicycle or arm ergometer. The stress test is deemed adequate if the patient achieves 90% of his or her predicted maximal heart rate, which is equal to 220 minus the patient's age. Indications for stopping the test include fatigue, severe hypertension (>220 mm Hg systolic), worsening angina during exercise, developing marked or widespread ischemic ECG changes, significant arrhythmias, or hypotension. The diagnostic accuracy of stress testing is improved with adjunctive echocardiography or radionuclide imaging. Contraindications to stress testing include unstable angina, acute MI, poorly controlled hypertension (blood pressure >220/110 mm Hg), severe aortic stenosis (valve area <1.0 cm²), and decompensated congestive heart failure. In the era of reperfusion therapy (i.e. thrombolytic and percutaneous interventions), for acute coronary syndromes or acute MI, little role exists for the pre-discharge submaximal stress test that was commonly used in the past.

The diagnostic accuracy of the exercise test depends on the pretest likelihood of CAD in a given patient, the sensitivity and specificity of the test results in that patient population, and the

TABLE 4-3 ELECTROCARDIOGRAPHIC LOCALIZATION OF MYOCARDIAL INFARCTION

INFARCT LOCATION	LEADS DEPICTING PRIMARY ELECTROCARDIOGRAPHIC CHANGES	LIKELY VESSEL INVOLVED*
Inferior	II, III, aVF	RCA
Septal	V ₁ , V ₂	LAD

ECG criteria used to define a positive test. Clinical features that are most useful for predicting important angiographic coronary disease before exercise testing include advanced age, male sex, and typical (versus atypical) anginal chest pain.

The diagnostic accuracy and cost-effectiveness of exercise testing is best for patients at intermediate risk for CAD (30% to 70%) and when ischemic ECG changes are accompanied by chest pain during exercise. Exercise testing is less cost-effective in diagnosing CAD in a patient with classic symptoms of angina because a positive test result does not significantly increase the post-test probability of CAD, and a negative test result likely represents a false-negative result. Nonetheless, prognostic information and objective information about the efficacy of pharmacologic therapy may still be obtained. Similarly, exercise testing in young patients with atypical chest pain may not be diagnostically useful because an abnormal test result is likely a false-positive result and does not significantly increase the post-test probability of CAD.

The normal physiologic response to exercise is an increase in heart rate and systolic and diastolic blood pressures. The ECG maintains normal T-wave polarity, and the ST segment remains unchanged or, if depressed, has a rapid upstroke back to baseline. An ischemic ECG response to exercise is defined as 1.5 mm of up-sloping ST-segment depression measured 0.08 second past the J point, at least 1 mm of horizontal ST depression, or 1 mm of down-sloping ST-segment depression measured at the J point. Given the large amount of artifact on the ECG that may occur with exercise, these changes must be seen in at least three consecutive depolarizations. Other findings that suggest more extensive CAD include early onset of ST depression (6 minutes); marked, down-sloping ST depression (>2 mm), especially if present in more than five leads; ST changes persisting into recovery for more than 5 minutes; and failure to increase systolic blood pressure to 120 mm Hg or more or a sustained decrease of 10 mm Hg or more below baseline.

The ECG is not diagnostically useful for left ventricular hypertrophy, LBBB, Wolff-Parkinson-White syndrome, or

chronic digoxin therapy. In these instances, nuclear or echocardiographic imaging is needed to diagnose ischemia. For patients who are unable to exercise, pharmacologic stress testing with myocardial imaging has the sensitivity and specificity for detecting CAD equal to those of exercise stress imaging. Intravenous dipyridamole and adenosine and newer selective adenosine A2A receptor agonists are coronary vasodilators that increase blood flow in normal arteries without significantly changing the flow in diseased vessels. The resulting heterogeneity in blood flow can be detected by nuclear imaging techniques, and the regions of myocardium supplied by diseased vessels can be identified.

Another commonly used technique to evaluate ischemia is dobutamine-stress echocardiography. Dobutamine is an inotropic agent that increases myocardial oxygen demand by increasing heart rate and contractility. The echocardiogram is used to monitor for ischemia, which is defined as new or worsening wall motion abnormalities during the infusion. Demonstrating improvement in wall thickening with low-dose dobutamine suggests that there is myocardial viability of abnormal segments (i.e., segments that are hypokinetic or akinetic at baseline).

Echocardiography

Echocardiography is a widely used, noninvasive technique in which sound waves are used to image cardiac structures and evaluate blood flow. A piezoelectric crystal housed in a transducer placed on the patient's chest wall produces ultrasound waves. As the sound waves encounter structures with different acoustic properties, some of the ultrasound waves are reflected to the transducer and recorded. Ultrasound waves emitted from a single, stationary crystal produce an image of a thin slice of the heart (M mode), which can be followed through time. Steering the ultrasound beam across a 90-degree arc multiple times per second creates two-dimensional imaging (Fig. 4-9). Transthoracic echocardiography is safe, simple, fast, and relatively inexpensive. It is the most commonly used test to assess cardiac size, structure, and function.

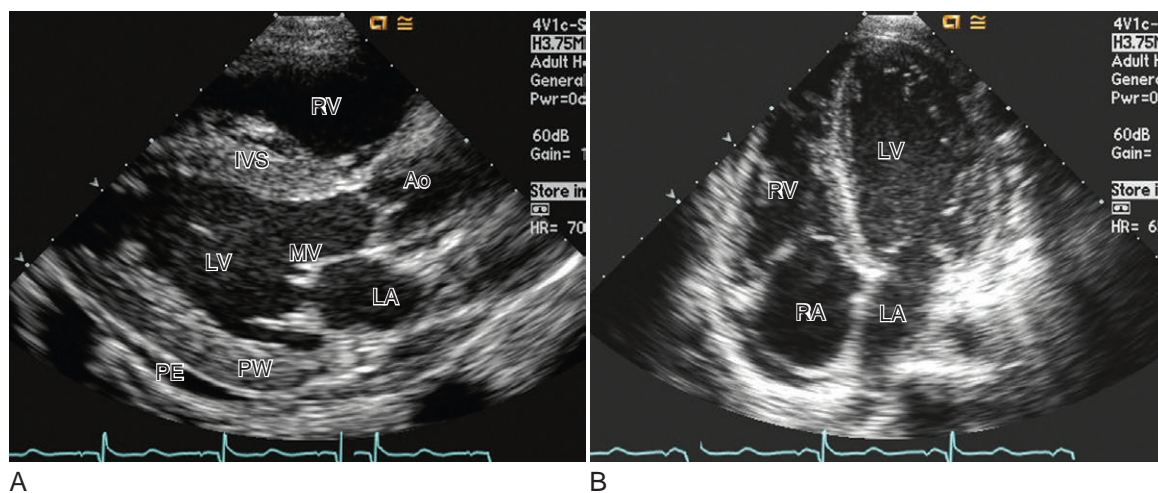

FIGURE 4-9 Portions of standard two-dimensional echocardiograms show the major cardiac structures in a parasternal long-axis view (A) and apical four-chamber view (B). Video 4-3 shows a moving image of a two-dimensional echocardiogram. Ao, Aorta; IVS, interventricular septum; LA, left atrium; LV, left ventricle; MV, mitral valve; PE, pericardial effusion; PW, posterior left ventricular wall; RV, right ventricle. (Image courtesy Sheldon E. Litwin, MD, Division of Cardiology, University of Utah, Salt Lake City, Utah.)

The development of three-dimensional echocardiographic imaging techniques offers great promise for more accurate measurements of chamber volumes and mass, as well as the assessment of geometrically complex anatomy and valvular lesions.

Video 4-1 shows a three-dimensional image.

Doppler echocardiography allows assessment of the direction and velocity of blood flow in the heart and great vessels. When ultrasound waves encounter moving red blood cells, the energy reflected to the transducer is altered. The magnitude of this change (i.e., Doppler shift) is represented as velocity on the echocardiographic display and can be used to determine whether the blood flow is normal or abnormal (Fig. 4-10). The velocity of a particular jet of blood can be converted to pressure using the modified Bernoulli equation ($\Delta P \cong 4V^2$). This process allows assessment of pressure gradients across valves or between chambers. Color Doppler imaging allows visualization of blood flow through the heart by assigning a color to the red blood cells based on their velocity and direction (Fig. 4-11, Video 4-2). By convention, blood moving away from the transducer is represented in shades of blue, and blood moving toward the transducer is represented in red. Color Doppler imaging is particularly useful in identifying valvular insufficiency and abnormal shunt flow between chambers. The use of Doppler techniques to record myocardial velocities or strain rates has provided insights into myocardial function and hemodynamics.

Two-dimensional echocardiography and Doppler echocardiography are often used in conjunction with exercise or pharmacologic stress testing. Although sensitivity and specificity values vary among studies, the sensitivity of stress echocardiography is apparently slightly lower and the specificity slightly higher compared with myocardial perfusion imaging using nuclear tracers. The estimated cost-effectiveness of stress echocardiography is significantly better than nuclear perfusion imaging because of the lower cost.

The development of ultrasound contrast agents composed of microbubbles that are small enough to transit through the pulmonary circulation has greatly improved the ability to use ultrasound to image obese patients, patients with lung disease, and those with otherwise difficult acoustic windows (Fig. 4-12).

Video 4-3 shows a dynamic contrast echocardiographic image.

FIGURE 4-10 Doppler tracing in a patient with aortic stenosis and regurgitation. The velocity of systolic flow is related to the severity of obstruction.

These agents are being developed for molecular imaging by complexing the bubbles to compounds that can selectively bind to the target site of interest (i.e., clots, neovessels).

Transesophageal echocardiography (TEE) allows two-dimensional and Doppler imaging of the heart through the esophagus by having the patient swallow a gastroscope mounted with an ultrasound crystal in its tip. Given the proximity of the esophagus to the heart, high-resolution images can be obtained, especially of the left atrium, mitral valve apparatus, and aorta. TEE is particularly useful in diagnosing aortic dissection, endocarditis, prosthetic valve dysfunction, and left atrial masses (Fig. 4-13, Video 4-4).

Nuclear Cardiology

Radionuclide imaging of the heart allows quantification of left ventricular size, systolic function, and myocardial perfusion. For radionuclide ventriculography, the patient's red blood cells are labeled with a small amount of a radioactive tracer (usually technetium-99m).

Left ventricular function can then be assessed by one of two methods. With the first-pass technique, radiation emitted by the tagged red blood cells as they initially flow through the heart is detected by a gamma camera positioned over the patient's chest. With the gated equilibrium method, or multigated acquisition (MUGA) method, the tracer is allowed to achieve an equilibrium distribution throughout the blood pool before count acquisition begins. This second method improves the resolution of the ventriculogram. For both techniques, the gamma camera can be gated to the ECG, allowing determination of the total emitted end-diastole counts (EDCs) and end-systole counts (ESCs). Left

FIGURE 4-11 Color Doppler recording demonstrates severe mitral regurgitation. The regurgitant jet seen in the left atrium is represented in blue because blood flow is directed away from the transducer. The yellow components are the mosaic pattern traditionally assigned to turbulent or high-velocity flow. The arrow points to the hemisphere of blood accelerating proximal to the regurgitant orifice (i.e., proximal isovelocity surface area [PISA]). The size of the PISA can be used to help grade the severity of regurgitation. Video 4-2 shows a dynamic echocardiographic image in a patient with mitral regurgitation. LA, Left atrium; LV, left ventricle. (Image courtesy Sheldon E. Litwin, MD, Division of Cardiology, University of Utah, Salt Lake City, Utah.)

FIGURE 4-12 Echocardiogram enhanced with intravenous ultrasound contrast agent: apical four-chamber view (A) and apical long-axis view (B). Highly echo-reflectant microbubbles make the left ventricular cavity appear white, whereas the myocardium appears dark. Video 4-3 shows a dynamic image of echocardiographic contrast. (Image courtesy Sheldon E. Litwin, MD, Division of Cardiology, University of Utah, Salt Lake City, Utah.)

FIGURE 4-13 Transesophageal echocardiogram demonstrates a vegetation (arrow) adherent to the ring of a bileaflet, tilting-disk mitral valve prostheses. A, In systole, the leaflets are closed with the vegetation seen in the left atrium. B, In diastole, the leaflets are open, with the vegetation prolapsing into the left ventricle. Transesophageal echocardiography is the diagnostic test of choice for assessing prosthetic mitral valves because the esophageal window allows unimpeded views of the atrial surface of the valve. Video 4-4 shows a dynamic transesophageal echocardiographic image. LA, Left atrium; LV, left ventricle; MV, prothetic mitral valve disks; V, vegetation. (Courtesy Sheldon E. Litwin, MD, Division of Cardiology, University of Utah, Salt Lake City, Utah.)

ventricular ejection fraction (LVEF) can then be calculated as follows:

$$\text{LVEF} = (\text{EDC} - \text{ESC}) / \text{EDC}$$

If scintigraphic information is collected throughout the cardiac cycle, a computer-generated image of the heart can be displayed in a cinematic fashion. This allows assessment of wall motion.

Myocardial perfusion imaging is usually performed in conjunction with exercise or pharmacologic (vasodilator) stress testing. Dipyridamole (Persantine), or more commonly adenosine, is used as the coronary vasodilator. Each agent can increase myocardial blood flow by fourfold to fivefold. Adenosine is more expensive, but it has the advantage over dipyridamole of a very short half-life. Newer adenosine-like agents with reduced side effect profiles are starting to be used clinically.

Technetium-99m sestamibi is the most frequently used radio-nuclide, and it is usually injected just before completion of the stress test. Single-photon emission computed tomography (SPECT) images of the heart are obtained for qualitative and quantitative analyses at rest and after stress. In the normal heart, the radioisotope is relatively equally distributed throughout the myocardium. In patients with ischemia, a localized area of decreased uptake occurs after exercise but partially or completely fills in at rest (i.e., redistribution). A persistent defect at peak exercise and rest (i.e., fixed defect) is consistent with MI or scarring. However, in some patients with apparently fixed defects, repeat rest imaging at 24 hours or after reinjection of a smaller quantity of isotope demonstrates improved uptake, indicating viable, but severely ischemic myocardium.

The use of new approaches such as combined low-level exercise and vasodilators, prone imaging, attenuation correction, and

computerized data analysis has improved the quality and reproducibility of the data from these studies. Myocardial perfusion imaging may also be combined with ECG-gated image acquisition to allow simultaneous assessment of ventricular function and perfusion. LVEF can be quantitated with this technique, and regional wall motion can be assessed to help rule out artifactual perfusion defects (Video 4-5).

Positron emission tomography (PET) is a noninvasive method of detecting myocardial viability by the use of perfusion and metabolic tracers. In patients with left ventricular dysfunction, metabolic activity in a region of myocardium supplied by a severely stenotic coronary artery suggests viable tissue that may regain more normal function after revascularization (Fig. 4-14). PET is less widely available than conventional SPECT imaging; however, PET offers improved spatial resolution because of the higher energy of the isotopes used for this type of imaging.

Cardiac Catheterization

Cardiac catheterization is an invasive technique in which fluid-filled catheters are introduced percutaneously into the arterial

and venous circulation. This method allows direct measurement of intracardiac pressures and oxygen saturation and, with the injection of a contrast agent, visualization of the coronary arteries, cardiac chambers, and great vessels. Cardiac catheterization is indicated when a clinically suggested cardiac abnormality requires confirmation and its anatomic and physiologic importance needs to be quantified. Coronary angiography for the diagnosis of CAD is the most common indication for this test.

Compared with catheterization, noninvasive testing is safer, cheaper, and equally effective in the evaluation of most valvular and hemodynamic questions. Most often, catheterization precedes some type of beneficial intervention, such as coronary artery angioplasty, coronary bypass surgery, or valvular surgery. Although cardiac catheterization is usually safe (0.1% to 0.2% overall mortality rate), procedure-related complications such as vascular injury, renal failure, stroke, and MI can occur.

An important objective during cardiac catheterization is documentation of filling pressures in the heart and great vessels. This task is accomplished through use of fluid-filled catheters that transmit intracardiac pressures to a transducer that displays the

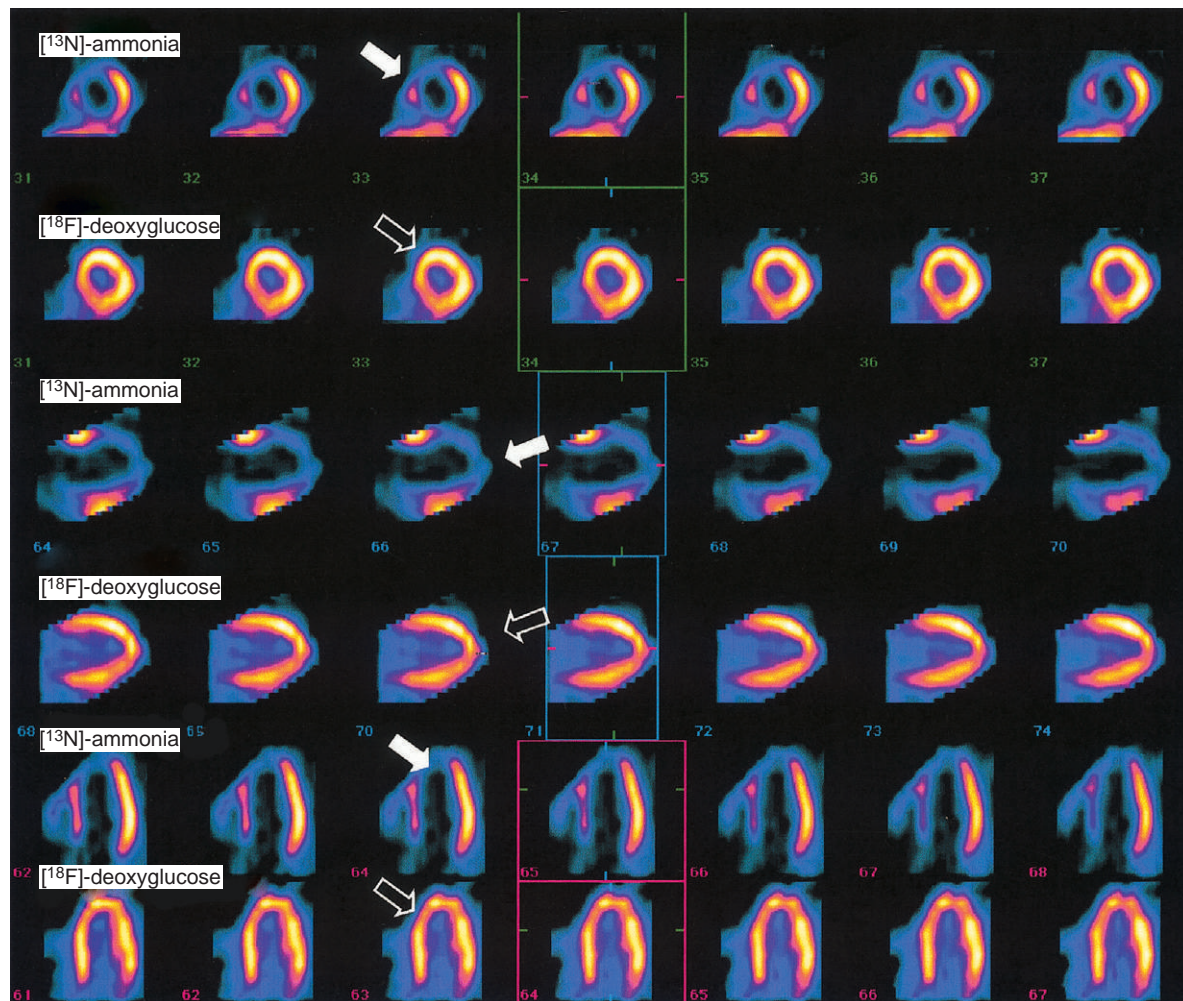

FIGURE 4-14 Resting myocardial perfusion (obtained with $[^{13}\text{N}]$ -ammonia) and metabolism (obtained with $[^{18}\text{F}]$ -deoxyglucose) is seen in positron emission tomography images of a patient with ischemic cardiomyopathy. The study demonstrates a perfusion-metabolic mismatch (reflecting hibernating myocardium) in which large areas of hypoperfused (solid arrows) but metabolically viable (open arrows) myocardium involve the anterior, septal, and inferior walls and the left ventricular apex. Video 4-5 shows a dynamic image obtained with cardiac single-photon emission computed tomography imaging. (Courtesy Marcelo F. Di Carli, MD, Brigham and Women's Hospital, Boston, Mass.)

pressure waveform on an oscilloscope. During a right ventricular heart catheterization, pressures in the right atrium, right ventricle, and pulmonary artery are routinely measured in this manner. The catheter can then be advanced further until it wedges in the distal pulmonary artery. The transmitted pressure measured in this location originates from the pulmonary venous system and is known as the *pulmonary capillary wedge pressure*. In the absence of pulmonary venous disease, the pulmonary capillary wedge pressure reflects left atrial pressure, and if no significant mitral valve pathologic condition exists, it reflects left ventricular diastolic pressure. A more direct method of obtaining left ventricular filling pressures is to advance an arterial catheter into the left ventricular cavity. With these two methods of obtaining intracardiac pressures, each chamber of the heart can be assessed and the gradients across any of the valves determined (Fig. 4-15).

Cardiac output can be determined by one of two widely accepted methods: the Fick oxygen method and the indicator dilution technique. The basis of the Fick method is that total uptake or release of a substance by an organ is equal to the product of blood flow to that organ and the concentration difference of that substance between the arterial and venous circulation of that organ. If this method is applied to the lungs, the substance released into the blood is oxygen; if no intrapulmonary shunts exist, pulmonary blood flow is equal to systemic blood flow or cardiac output. The cardiac output can be determined by the following equation:

$$\text{Cardiac output} = \frac{\text{oxygen consumption}}{\text{arterial oxygen content} - \text{venous oxygen content}}$$

Oxygen consumption is measured in milliliters per minute by collecting the patient's expired air over a known period while simultaneously measuring oxygen saturation in a sample of arterial and mixed venous blood (i.e., arterial and venous oxygen content, respectively, measured in milliliters per liter). The cardiac output is expressed in liters per minute and then corrected for body surface area (i.e., cardiac index). The normal range of cardiac index is 2.6 to 4.2 L/min/m². Cardiac output can

also be determined by the indicator dilution technique, which most commonly uses cold saline as the indicator. With this method, cold saline is injected into the blood, and the resulting temperature change *downstream* is monitored. This action generates a curve in which temperature change is plotted over time, and the area under the curve represents cardiac output.

Detection and localization of intracardiac shunts can be performed by sequential measurement of oxygen saturation in the venous system, right side of the heart, and two main pulmonary arteries. In patients with left-to-right shunt flow, an increase in oxygen *step-up* (i.e., saturation increase from one chamber to the successive chamber) occurs as arterial blood mixes with venous blood. By using the Fick method for calculating blood flow in the pulmonary and systemic systems, the shunt ratio can be calculated. Noninvasive approaches have largely supplanted catheterization laboratory assessment of shunts.

Left ventricular size, wall motion, and ejection fraction can be accurately assessed by injecting contrast into the left ventricle (i.e., left ventriculography). Aortic and mitral valve insufficiency can be qualitatively assessed during angiography by observing the reflux of contrast medium into the left ventricle and left atrium, respectively. The degree of valvular stenosis can be determined by measuring pressure gradients across the valve and determining cardiac output (i.e., Gorlin formula).

The coronary anatomy can be defined by injecting contrast medium into the coronary tree. Atherosclerotic lesions appear as narrowing of the internal diameter (lumen) of the vessel. A hemodynamically important stenosis is defined as 70% or more narrowing of the luminal diameter. However, the hemodynamic significance of a lesion can be underestimated by coronary angiography, particularly when the atherosclerotic plaque is eccentric or elongated. Intravascular ultrasound, Doppler flow wires, or miniaturized pressure sensors can be used during invasive procedures to help evaluate the severity or estimate the physiologic significance of intermediate lesions.

Biopsy of the ventricular endomyocardium can be performed during cardiac catheterization. With this technique, a biptome is introduced into the venous system through the right internal jugular vein and guided into the right ventricle by fluoroscopy. Small samples of the endocardium are taken for histologic evaluation. The primary indication for endomyocardial biopsy is the diagnosis of rejection after cardiac transplantation and documentation of cardiac amyloidosis; however, endomyocardial biopsy may have some use in diagnosing specific etiologic agents responsible for myocarditis.

Right Ventricular Heart Catheterization

A right ventricular heart catheterization can be performed at the bedside with a balloon-tipped pulmonary artery (Swan-Ganz) catheter. This technique enables serial measurements of right atrial, pulmonary artery, and pulmonary capillary wedge pressures and cardiac output by thermodilution (Fig. 4-16). These measurements may be useful in monitoring the response to various treatments, such as diuretic therapy, inotropic agents, and vasopressors (Table 4-4). The pulmonary artery catheter is most useful in the critically ill patient for assessing volume status and differentiating cardiogenic from noncardiogenic pulmonary edema. However, several papers have suggested no

FIGURE 4-15 Electrocardiographic tracing and left ventricular (LV) and aortic (AO) pressure curves in a patient with aortic stenosis. A pressure gradient occurs across the aortic valve during systole.

FIGURE 4-16 Electrocardiographic (ECG) (A) and Swan-Ganz flotation catheter (C) recordings are shown. The recordings of a catheter in the radial artery and Swan-Ganz floating catheter in the right atrium are shown in B and D, respectively. The left portion of tracing C was obtained with the balloon inflated, yielding the pulmonary arterial wedge pressure. The right portion of tracing C was recorded with the balloon deflated, depicting the pulmonary arterial pressure. In this patient, the pulmonary arterial wedge pressure (i.e., left ventricular filling pressure) is normal, and the pulmonary artery pressure is elevated because of lung disease.

TABLE 4-4 DIFFERENTIAL DIAGNOSIS USING A BEDSIDE BALLOON FLOW-DIRECTED (SWAN-GANZ) CATHETER

DISEASE STATE	THERMODILUTION CARDIAC OUTPUT	PCW PRESSURE	RA PRESSURE	COMMENTS
Cardiogenic shock	↓	↑	nl or ↓	↑ Systemic vascular resistance
Septic shock (early)	↑	↓	↓	↑ Systemic vascular resistance; myocardial dysfunction can occur late
Volume overload	nl or ↑	↑	↑	
Volume depletion	↓	↓	↓	
Noncardiac pulmonary edema	nl	nl	nl	
Pulmonary heart disease	nl or ↑	nl	↑	↑ PA pressure
RV infarction	↓	↓ or nl	↑	
Pericardial tamponade	↓	nl or ↑	↑	Equalization of diastolic RA, RV, PA, and PCW pressure
Papillary muscle rupture	↓	↑	nl or ↑	Large v waves in PCW tracing
Ventricular septal rupture	↑	↑	nl or ↑	Artifact caused by RA → PA sampling higher in PA than RA; may have large v waves in PCW tracing

nl, Normal; PA, pulmonary artery; PCW, pulmonary capillary wedge; RA, right atrium; RV, right ventricle; ↑, increased; ↓, decreased.

improvements in outcomes of critically ill patients in whom pulmonary artery catheterization was performed. Improvements in noninvasive imaging techniques have made the pulmonary artery catheter much less important in diagnosing cardiac conditions, such as pericardial tamponade, constrictive pericarditis, right ventricular infarction, and ventricular septal defect.

Magnetic Resonance Imaging

Magnetic resonance angiography or imaging (MRI) is a noninvasive method that is increasingly used for studying the heart and vasculature, especially in patients who have contraindications to standard contrast angiography. MRI offers high-resolution dynamic and static images of the heart that can be obtained in any plane. Good-quality images can be obtained in a higher number of subjects than is typically possible with echocardiography. Obesity, claustrophobia, inability to perform multiple breath-holds of 10 to 20 seconds, and arrhythmias are causes of reduced image quality. The presence of cardiac pacemakers or implantable defibrillators is considered a contraindication for MRI. Magnetic resonance angiography is useful in the evaluation of cerebral, renovascular, and lower extremity arterial disease.

MRI offers significant advantages over other imaging techniques for the characterization of tissues (e.g., muscle, fat, scar). MRI is useful in the evaluation of ischemic heart disease because

stress-rest myocardial perfusion (Fig. 4-17A) and areas of prior infarction (see Fig. 4-17B to D) can be visualized with excellent spatial resolution. Delayed gadolinium contrast enhancement in the myocardium is characteristic of scar or permanently damaged tissue (Video 4-6). The greater the transmural extent of delayed enhancement in a given segment, the lower is the likelihood of improved function in that segment after revascularization. Because of the better spatial resolution, delayed enhancement imaging can depict localized or subendocardial scars that are not detectable with nuclear imaging techniques. The combined use of stress-rest perfusion and delayed enhancement imaging has performance characteristics for diagnosing CAD that are as good as and probably superior to those of conventional stress tests using nuclear scintigraphy or echocardiography.

MRI is excellent for evaluating a variety of cardiomyopathies (Fig. 4-18). In addition to morphology and function, characteristic patterns of delayed enhancement have been reported in myocarditis, hypertrophic cardiomyopathy, and cardiac amyloidosis. MRI has also been used to help assess right ventricular morphology and function in patients with suspected arrhythmogenic right ventricular cardiomyopathy.

Computed Tomography of the Heart

Newer applications of computed tomography (CT) have greatly advanced our ability to diagnose cardiovascular disease

FIGURE 4-17 Use of cardiac magnetic resonance imaging in the evaluation of chest pain or ischemic heart disease. **A**, First-pass perfusion study during vasodilator stress shows a large septal perfusion defect (arrow). The hypoperfused area appears dark compared with the myocardium with normal perfusion. **B**, Example of delayed enhancement imaging of an almost transmural infarction of the mid-inferolateral wall, including the posterior papillary muscle. Infarcted myocardium appears white, whereas normal myocardium is black (arrow). **C**, Nontransmural (subendocardial) infarction of the septum and apex (arrow). **D**, Patient with acute myocarditis mimicking an acute coronary syndrome. Mid-myocardial, rather than subendocardial, delayed enhancement is characteristic of myocarditis (arrow).

FIGURE 4-18 Cardiac magnetic resonance imaging (MRI) is used in the evaluation of cardiomyopathies. **A**, Severe left ventricular hypertrophy in a patient with hypertrophic cardiomyopathy. Diastolic frame shows open mitral valve (*arrow*). **B**, Systolic frame shows systolic anterior motion of the mitral valve with flow disturbance in the left ventricular outflow tract (*arrow*). **C**, Patient has left ventricular noncompaction as evidenced by deep trabeculations in the left ventricular apex (*arrow*). **D**, Patient with ischemic cardiomyopathy has transmural apical infarction and adjacent mural thrombus (*arrow*). Video 4-6 shows a dynamic cardiac MRI image. (Images courtesy Sheldon E. Litwin, MD, Division of Cardiology, University of Utah, Salt Lake City, Utah.)

noninvasively. The development of fast gantry rotation speeds and the addition of multiple rows of detectors (i.e., multidetector CT) have allowed unprecedented visualization of the great vessels, heart, and coronary arteries with images acquired during a single breath-hold lasting 10 to 15 seconds. CT is used to diagnose aortic aneurysm, acute aortic dissection, pulmonary embolism, and it is useful for defining congenital abnormalities and detecting pericardial thickening or calcification associated with constrictive pericarditis. ECG-gated dynamic CT images have been used to quantify ventricular size, function, and regional wall motion (Video 4-7), and in contrast to echocardiography, CT is not limited by lung disease or chest wall deformity. However, obesity and implanted prosthetic materials (i.e., mechanical valves or pacing wires) may affect image quality.

The greatest excitement and controversy about cardiac CT relates to the evaluation of coronary atherosclerosis. Electron beam and multidetector CT scans can be used to quickly and reliably visualize and quantitate the extent of coronary artery calcification (Fig. 4-19). The presence of coronary calcium is

pathognomonic of atherosclerosis, and the extent of coronary calcium (usually reported as an Agatston score) is a powerful marker of future cardiac events. The coronary calcium score adds substantial, independent improvement in risk prediction to the commonly employed clinical risk scores (e.g., Framingham risk score). Although the extent of coronary artery calcification does not reliably predict the severity of stenoses, the calcium score is a good marker of the overall atherosclerotic burden.

Contrast-enhanced coronary computed tomography angiography (CTA) has improved dramatically in recent years. Coronary CTA has a sensitivity of more than 95% in diagnosing significant coronary artery obstruction. This is superior to the sensitivity of stress echo or nuclear myocardial perfusion scanning. Given the speed and accuracy of this test, it is likely to assume a major role in the evaluation of patients with acute chest pain syndromes.

Some advocates of cardiac CT have proposed the use of CTA for the *triple rule-out* in patients with acute chest pain—the ability to diagnose pulmonary embolism, aortic dissection, and CAD

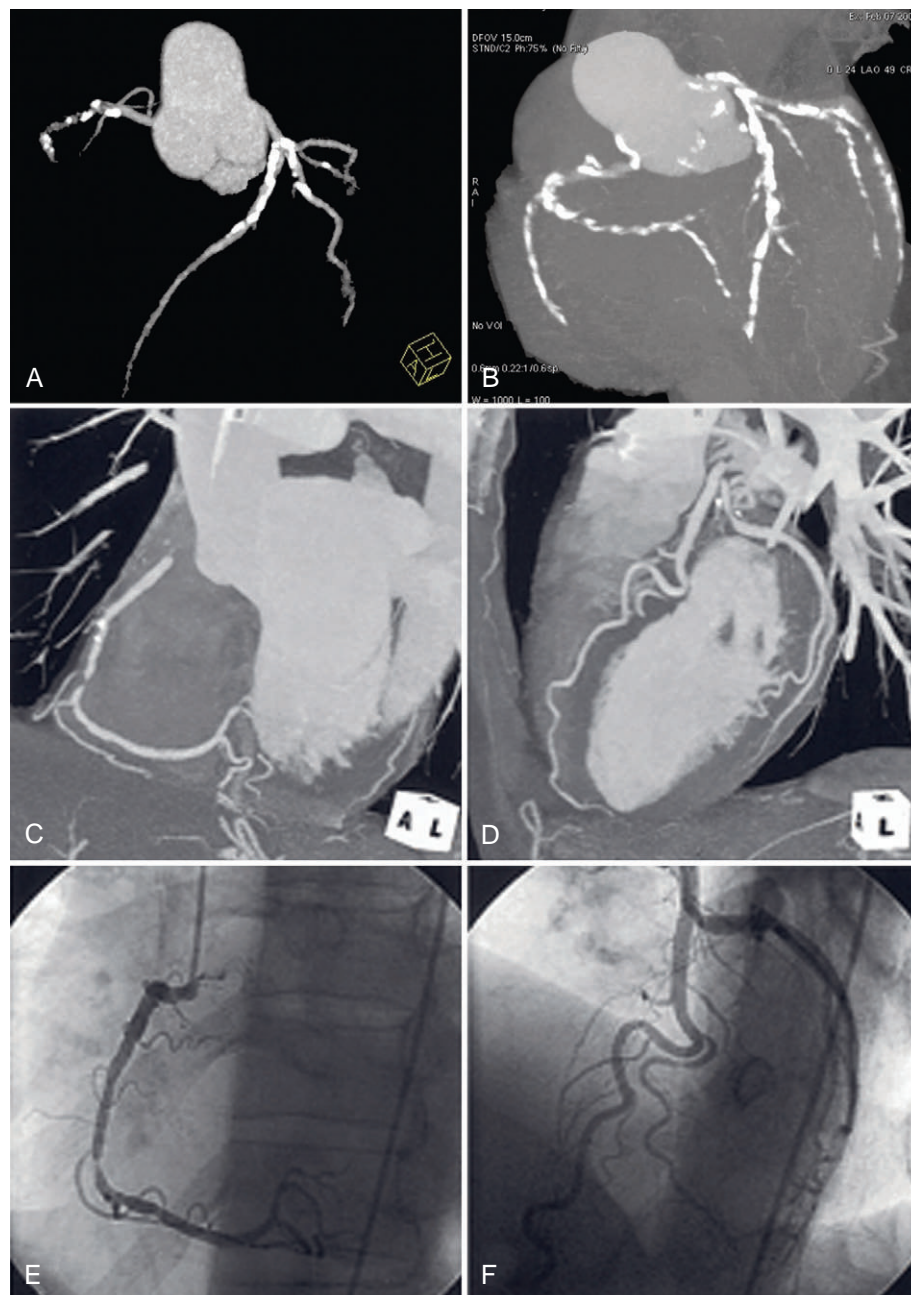

FIGURE 4-19 Computed tomography coronary angiography compared with conventional radiographic contrast angiography. **A** and **B**, Volume-rendering technique demonstrates stenosis of the right coronary artery and normal left coronary artery. **C** and **D**, Maximal intensity projection of the same arteries demonstrates severe noncalcified plaque in the right coronary artery with superficial calcified plaque. **E** and **F**, Invasive angiography of the same arteries. (From Raff GL, Gallagher MJ, O'Neill WW, et al: Diagnostic accuracy of noninvasive coronary angiography using 64-slice spiral computed tomography, *J Am Coll Cardiol* 46:552–557, 2005.)

with one imaging study. Formal evaluation of this hypothesis needs to be undertaken. Detractors of cardiac CT most frequently cite the risks of radiation and contrast exposure and the lack of prospective studies showing improvement in outcome with this testing modality. The calculated radiation exposure of cardiac CTA is about double that of a diagnostic invasive coronary angiogram, but it is similar to that of a typical nuclear myocardial perfusion scan. The future role of cardiac CTA in routine clinical practice remains uncertain.

Noninvasive Vascular Testing

Assessment for the presence and severity of peripheral vascular disease is an important component of the cardiovascular

evaluation. Comparison of the systolic blood pressure in the upper and lower extremities is one of the simplest tests to detect hemodynamically important arterial disease. Normally, the systolic pressure in the thigh is similar to that in the brachial artery. An ankle-to-brachial pressure ratio (i.e., ankle-brachial index) of less than or equal to 0.9 is abnormal. Patients with claudication usually have an index ranging from 0.5 to 0.8, and patients with rest pain have an index less than 0.5. In some patients, measuring the ankle-brachial index after treadmill exercise may help to determine the importance of borderline lesions. During normal exercise, blood flow increases to the upper and lower extremities and decreases in peripheral vascular resistance, whereas the ankle-brachial index remains unchanged. In the presence of a

hemodynamically significant lesion, the increase in systolic blood pressure in the arm is not matched by an increase in blood pressure in the leg. As a result, the ankle-brachial index decreases, the magnitude of which is proportional to the severity of the stenosis.

After significant vascular disease in the extremities has been identified, plethysmography can be used to determine the location and severity of the disease. With this method, a pneumatic cuff is positioned on the leg or thigh, and when inflated, it temporarily obstructs venous return. Volume changes in the limb segment below the cuff are converted to a pressure waveform, which can be analyzed. The degree of amplitude reduction in the pressure waveform corresponds to the severity of arterial disease at that level.

Doppler ultrasound uses reflected sound waves to identify and localize stenotic lesions in the peripheral arteries. This test is particularly useful for patients with severely calcified arteries, for whom pneumatic compression is not possible and ankle-brachial indices are inaccurate. In combination with real-time imaging (i.e., duplex imaging), this technique is useful in assessing specific arterial segments and bypass grafts for stenotic or occlusive lesions.

Magnetic resonance angiography and CTA allow high-quality and comprehensive imaging of the entire peripheral arterial circulation in a single study. The three-dimensional nature of these studies and the ability to perform extensive postprocessing views, including cross-sectional views, of all vessels, even those that are very tortuous, are attractive features of these modalities.

HEART FAILURE

Definition

Heart failure (HF) is a clinical syndrome characterized by structural or functional impairment of ventricular filling or ejection of blood that results in inadequate blood flow to meet the metabolic needs of the body's tissues and organs. HF can be caused by numerous disease processes (Table 5-1).

HF can be classified as HF with reduced ejection fraction (HFrEF) or HF with preserved ejection fraction (HFpEF). HFrEF (i.e., systolic HF) is defined as a left ventricular ejection fraction (LVEF) of less than 40%. Efficacious therapies have been demonstrated for this patient population. HFpEF (i.e., diastolic dysfunction) is defined as an LVEF greater than 50%, and it is more common in women than in men. No efficacious therapies have been discovered for this patient population.

The New York Heart Association (NYHA) functional classification (Table 5-2) defines four functional classes. Class I HF requires no limitations of physical activity; ordinary physical

activity does not cause symptoms. Class II requires slight limitations of physical activity; patients are comfortable at rest, but ordinary physical activity results in HF symptoms. Class III requires marked limitations of physical activity; patients are comfortable at rest, but less than ordinary activity causes symptoms of HF. Patients with class IV HF are unable to carry on any physical activity without HF symptoms or have symptoms when at rest.

The American College of Cardiology Foundation and American Heart Association (ACCF/AHA) staging system (Fig. 5-1) classifies patients either as being at risk for HF or as having the clinical syndrome of HF. Stage A HF includes patients with risk factors for the development of HF, such as hypertension, obesity, atherosclerotic disease, and the metabolic syndrome. Stage B HF includes patients with structural heart disease (i.e., previous myocardial infarction [MI], asymptomatic valvular disease, and LV hypertrophy) but without symptoms of HF. Stage C HF is structural heart disease with prior or current symptoms of HF. Stage D HF is refractory or end-stage HF.

HF should further be characterized by cause (e.g., ischemic, nonischemic, valvular). It can be classified as predominantly left, right, or biventricular; high output or low output; and acute or chronic.

Idiopathic cardiomyopathy is a primary abnormality of the myocardium in the absence of structural or systemic disease. Secondary cardiomyopathies may be related to a significant number of disorders, but in the United States, it is most often the result

TABLE 5-1 CAUSES OF CONGESTIVE HEART FAILURE AND CARDIOMYOPATHY

CORONARY ARTERY DISEASE	Doxorubicin (Adriamycin) Methamphetamine
Acute ischemia Myocardial infarction Ischemic cardiomyopathy with hibernating myocardium	METABOLIC-ENDOCRINE CONDITIONS
IDIOPATHIC CONDITIONS	Thiamine deficiency Diabetes Hemochromatosis Thyrotoxicosis Obesity Hemochromatosis
Idiopathic dilated cardiomyopathy* Idiopathic restrictive cardiomyopathy Peripartum cardiomyopathy	INFILTRATIVE CONDITIONS

*Genetic bases for these cardiomyopathies have been identified in many individual patients and families. Most of the mutations have been found in cardiac contractile or structural proteins.

TABLE 5-2 NEW YORK HEART ASSOCIATION FUNCTIONAL CLASSIFICATION OF HEART FAILURE

CLASS	SYMPTOMS
I (Mild)	No limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, or dyspnea (shortness of breath).
II (Mild)	Slight limitation of physical activity. Comfortable at rest, but ordinary physical activity results in fatigue, palpitation, or dyspnea.
III (Moderate)	Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes fatigue, palpitation, or dyspnea.
IV (Severe)	Unable to carry out any physical activity without discomfort. Symptoms of include cardiac insufficiency at rest. If physical activity is undertaken, discomfort is increased.

of ischemic heart disease. Ventricular dysfunction can result from excessive pressure overload, as in long-standing hypertension or aortic stenosis, or from volume overload, as in aortic insufficiency or mitral regurgitation. Diseases that result in infiltration and replacement of normal myocardial tissue, such as amyloidosis, are rare causes of HF. Hemochromatosis can cause a dilated cardiomyopathy that is thought to result from iron-mediated mitochondrial damage. Diseases of the pericardium, such as chronic pericarditis or pericardial tamponade, can impair cardiac function without directly affecting the myocardial tissue. Long-standing tachyarrhythmias have been associated with myocardial dysfunction that is often reversible.

High-output failure is an uncommon disorder characterized by an elevated resting cardiac index of greater than 2.5 to 4.0 L/min/m² and low systemic vascular resistance. Causes of high-output failure are severe anemia, vascular shunting, hyperthyroidism, and vitamin B₁ deficiency. It results from ineffective blood volume and pressure, which stimulate the sympathetic nervous system and renin-angiotensin-aldosterone system (RAAS), causing release of antidiuretic hormone (ADH), which results in ventricular enlargement, negative remodeling, and HF. Treatment targets the specific cause.

Low-output failure is much more common than high-output failure. It is characterized by insufficient forward cardiac output,

particularly during times of increased metabolic demand. Cardiac dysfunction may predominantly affect the left ventricle, as with a large MI, or the right ventricle, as with an acute pulmonary embolus. However, in many disease states, both ventricles are impaired (i.e., biventricular HF).

Acute HF usually refers to the situation in which an individual who was previously asymptomatic develops HF signs or symptoms after an acute injury to the heart, such as MI, myocarditis, or acute valvular regurgitation. Chronic HF refers to situations in which symptoms have developed over a long period, most often in the setting of preexisting cardiac disease. However, a patient with myocardial dysfunction from any cause may remain compensated for extended periods and then develop acute HF symptoms in the setting of arrhythmia, anemia, hypertension, ischemia, systemic illness, dietary or medication noncompliance, and progression of chronic HF.

The severity of HF symptoms does not correlate closely with the usual clinical measures of cardiac function, although the LVEF is a reasonable prognostic marker. This situation likely reflects the fact that ventricular filling pressures are a more important determinant of symptoms than myocardial function. The predisposing conditions for HF (e.g., hypertension, advanced age, coronary artery disease, renal dysfunction) are similar, and the prognosis is similar whether the LVEF is preserved or reduced. Despite many similarities, medical treatments that have proved beneficial in HF with reduced EF have not shown similar efficacy in HF with preserved ejection fraction.

HEART FAILURE WITH PRESERVED EJECTION FRACTION

Slowed relaxation of the left ventricle and increased chamber stiffness impairs ventricular filling and may contribute to elevated left ventricular (LV), left atrial, and pulmonary venous pressures. Some patients with a diagnosis of HF have normal or almost normal EFs. These patients are diagnosed with HFpEF, which is the preferred terminology for describing this condition. Relaxation abnormalities occur in most people older than 65 years and are almost universal after age 75 years; however, most of these individuals do not have HF. Isolated abnormalities of LV relaxation are insufficient to directly cause HF in the absence of other predisposing conditions. In patients with a variety of cardiovascular diseases, relaxation abnormalities appear at earlier ages than otherwise expected. No therapeutic agents that specifically target impaired relaxation have been developed. The use of diuretics to manage volume overload and the vigorous treatment of hypertension with evidence-based therapy, including angiotensin-converting enzyme (ACE) inhibitors, are the mainstay of pharmacotherapy for this condition.

Epidemiology

Prevalence

The lifetime risk of developing HF is 20%, or 1 in 5 Americans 40 years of age or older. HF affects almost 7 million Americans, and the incidence of HF has largely remained stable in the United States, with approximately 670,000 new HF cases diagnosed annually (Fig. 5-2). As patients continue to live longer, it is expected that the incidence of HF will continue to rise.

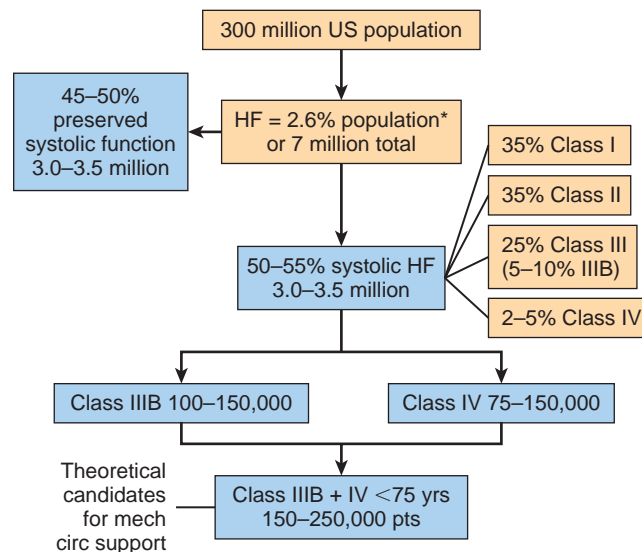

FIGURE 5-2 The lifetime risk of developing heart failure (HF) is 20%, or 1 in 5 for Americans 40 years of age or older. As patients continue to live longer, it is expected that the incidence of HF will continue to rise. HF affects almost 7 million Americans, and the incidence of HF has largely remained stable in the United States, with approximately 670,000 new HF cases diagnosed annually.

Incidence

The rate of HF increases with age, rising from 20 per 1000 people 65 to 69 years of age to more than 80 per 1000 people older than 85 years. African Americans have higher incidence and 5-year mortality rates compared with non-Hispanic whites. Despite advances in medical therapy, the mortality rate for HF remains 50% at 5 years after diagnosis.

Risk Factors

Risk factors for the development of HF include increasing age, gender (males > females), race (black > white), coronary artery disease (the cause of 60% to 75% of symptomatic HF in developed countries), hypertension, LV hypertrophy, diabetes mellitus, and obesity.

Pathogenesis

Numerous cardiac diseases can lead to HFpEF (see Table 5-1). Adaptive mechanisms maintain cardiac output and blood flow to vital organs. They include compensatory increases in ventricular volume and pressure achieved through the Frank-Starling mechanism and neurohormonal activation. Left untreated, these adaptive responses ultimately are detrimental and result in sodium and fluid retention, which worsen ventricular remodeling and further deteriorate systolic function (Fig. 5-3).

Normally, increasing either the stroke volume or the heart rate can augment cardiac output. Stroke volume depends on the contractility of the myocardium, LV filling (i.e., preload), and resistance to LV emptying (i.e., afterload). According to the Frank-Starling law, stroke volume can be increased with minimal elevation in LV pressure as long as contractility is normal.

When there is depressed contractility (Fig. 5-4A), the end-diastolic volume is increased in an attempt to maintain stroke volume. However, when the LV end-diastolic pressure approaches 20 to 25 mm Hg, pulmonary edema may develop due to

Pathophysiology of Heart Failure

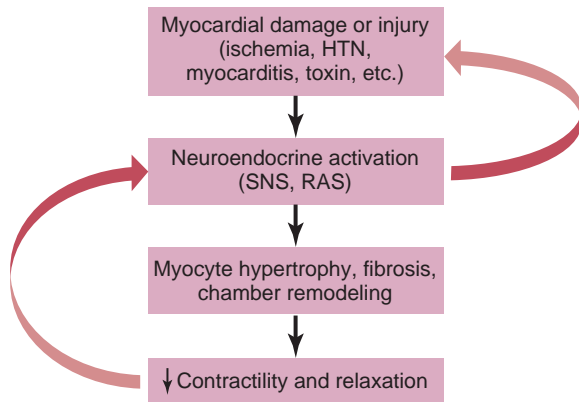

FIGURE 5-3 The diagram illustrates the progressive nature of left ventricular dysfunction that can follow an initial cardiac insult. Attenuation of the neurohumoral activation (or blockade of the downstream effects) may interrupt the positive feedback and slow or reverse the progression of heart failure. HTN, Hypertension; RAS, renin-angiotensin system; SNS, sympathetic nervous system.

differences between the hydrostatic pressure in the pulmonary capillaries and the oncotic pressure of the lungs. Depressed myocardial contractility (in HFrEF) and increased chamber stiffness (in HFpEF) can lead to pulmonary congestion through this same mechanism.

After the initial compensatory mechanism, the failing heart undergoes ventricular remodeling, characterized by myocardial structural and functional abnormalities resulting in a dilated, spherical ventricle with reduced contractility. Ventricular remodeling occurs in response to pressure and volume overload, myocyte loss, or a combination of these factors, resulting in progressive decline in contractility. Ventricular remodeling begins with ventricular hypertrophy in response to increased wall stress to decrease myocardial oxygen consumption. If the extent of hypertrophy is inadequate to normalize wall stress, a vicious cycle is established.

The remodeling changes occur to make the failing ventricle more efficient and can be understood in the context of LaPlace's law ($T = P \times r/w_t$), where T = tension, P = pressure, r = the radius of the chamber or vessel, and w_t = the thickness of the wall. As tension (force) increases, pressure increases proportionally. Untreated, this mechanism leads to progressive ventricular dilation and chamber enlargement, causing increased wall stress, increased myocardial oxygen consumption, and progressively worsening contractility.

Neurohormonal Activation

Activation of the sympathetic nervous system is the first response to decreased cardiac output. It results in the release of epinephrine and norepinephrine, which bind all adrenergic receptors. This results in stimulation or inhibition of G proteins (i.e., G_s and G_i subtypes). G protein activation upregulates adenylate cyclase, which converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). cAMP signals protein kinase A, which phosphorylates ryanodine receptors, leading to increased intracellular calcium levels, which increase contractility by phosphorylating and inhibiting phospholamban. Stimulation of the

FIGURE 5-4 Normal and abnormal ventricular function curves. When the left ventricular end-diastolic pressure acutely rises above 20 mm Hg (point A), pulmonary edema often occurs. The effect of diuresis or venodilation is to move leftward along the same curve, with a resultant improvement in pulmonary congestion and with minimal decrease in cardiac output. The stroke volume is poor at any point along this depressed contractility curve; therapeutic maneuvers to raise it more toward the normal curve are necessary to improve cardiac output significantly. Unlike the effect of diuretics, the effect of vasodilator therapy in a patient with heart failure is to move the patient into another ventricular function curve intermediately between the normal and depressed curves. When the patient's ventricular function moves from point A to B by the administration of one of these agents, the LVEDP may also decrease because of improved cardiac function. Further administration of diuretics or venodilators may shift the patient further to the left along the same curve from point B to C and eliminate the risk for pulmonary edema. A vasodilating agent that has arteriolar and venous dilating properties (e.g., nitroprusside) would shift this patient directly from point A to C. If this agent shifts the patient from point A to D because of excessive venodilation or administration of diuretics, the cardiac output may fall too low, even though the LVEDP would be normal (10 mm Hg) for a normal heart. LVEDPs between 15 and 18 mm Hg are usually optimal in the failing heart to maximize cardiac output but avoid pulmonary edema. (Modified from the Heart Failure Society of America: Questions about heart failure. Available at http://www.abouthf.org/questions_stages.htm. Accessed August 2, 2014.)

sympathetic nervous system also increases ventricular relaxation (i.e., lusitropy) and increases the basal heart rate. These effects, although beneficial initially, are ultimately detrimental to the myocardium.

The RAAS is stimulated by the sympathetic nervous system and by decreased blood flow to the afferent arteriole of the nephron, resulting in the release of renin. This ultimately leads to activation of angiotensin II, which is a potent vasoconstrictor, with the initial response to supply adequate blood to vital organs. However, angiotensin II increases afterload, wall stress, and myocardial oxygen consumption and leads to a decrease in stroke volume. Angiotensin II also leads to sympathetic nervous system activation, aldosterone release, and myocardial fibrosis, perpetuating the cycle.

The release of aldosterone prompts sodium reabsorption, promoting water retention to effectively maintain cardiac output. Aldosterone also has fibrotic properties. The release of vasopressin promotes free water absorption by the kidney. These changes are responsible for many of the clinical signs and symptoms associated with HF.

The body attempts to counter these effects by secreting atrial natriuretic peptide and brain natriuretic peptide (BNP) from the myocardium. Endogenous natriuretic peptides promote salt and water excretion by the kidneys and cause arterial vasodilation, but they are relatively ineffective at reversing the changes associated with stimulating the sympathetic nervous system and the RAAS.

Clinical Presentation and Diagnosis

The approach to the patient with suspected HF starts with the history, physical examination, and testing to help establish the diagnosis. The history should assess for NYHA functional class, including symptoms of fatigue, weakness, dyspnea, orthopnea, edema, abdominal distention, and chest discomfort. The examiner should also assess for comorbidities, including hypertension, diabetes mellitus, dyslipidemia, obesity, and sleep-disordered breathing.

The medical history should inquire about exposure to cardiotoxic agents, including anthracycline-based chemotherapy. The social history evaluates past and current use of tobacco products, alcohol, and illicit drugs. The family history assesses for sudden cardiac death, coronary artery disease, and cardiomyopathy. For patients with an idiopathic dilated cardiomyopathy, a three-generation history should be obtained to establish a familial component.

The physical examination starts by assessing vital signs. Worrisome vital signs for significant cardiac dysfunction include faint pulses, a narrow pulse pressure due to peripheral vasoconstriction and low stroke volume, and resting tachycardia. Assessment of the peripheral pulse includes evaluating the patient for pulsus alternans, which is defined as beat-to-beat variation in the amplitude of the peripheral pulse, and it is pathognomonic for severe LV dysfunction.

Most symptoms of HF are related to elevated filling pressures. Dyspnea (in men) and fatigue (in women) are some of the most common symptoms of HF. They may have an acute onset resulting in pulmonary edema, or they may be chronic and progressive and occur at rest. Dyspnea on exertion has a sensitivity of 84% to 100% but a specificity of 17% to 34%. Dyspnea from HF is often exacerbated in the supine position (i.e., orthopnea), and it is caused by increased distribution of blood to the pulmonary circulation when lying flat. Patients with HF tend to use increased numbers of pillows to overcome orthopnea. Orthopnea has a sensitivity of 22% to 50% and a specificity of 74% to 77% for HF. Episodes of paroxysmal nocturnal dyspnea (PND) awaken patients from sleep and are likely caused by central redistribution of edema, leading to a sudden rise in intracardiac pressures. The sensitivity of PND for the diagnosis of HF is 39% to 41%, and the specificity ranges from 80% to 84%. Patients with stage D HF may exhibit Cheyne-Stokes respirations, which is associated with a poor prognosis.

Evaluation of volume status includes assessment of serial weights, jugular venous pressure, pulmonary congestion, and peripheral edema. The jugular venous pressure is best assessed using the right internal jugular vein with the patient lying at a 30- to 45-degree angle. Patients with markedly elevated venous pressures may need to be positioned at a higher angle. The jugular venous pressure is an estimate of the central venous pressure

(CVP) (i.e., right atrial pressure) and therefore of volume status. A normal CVP is in the range of 5 to 9 cm H₂O. An abnormally elevated CVP may be seen in hypervolemia, pericardial constriction, or pulmonary hypertension.

Evaluating the abdominal jugular reflux (i.e., hepatojugular reflux) involves gently compressing the abdomen or right upper quadrant for 15 to 30 seconds and assessing jugular venous distention. This method assesses volume status and right ventricular dysfunction and compliance. An abnormal abdominal jugular reflux is defined as a sustained increase in jugular venous pressure of more than 4 cm H₂O.

On lung auscultation, crackles may be heard. Crackles are a specific finding for HF, but they are not detected in approximately 60% of patients with chronic HF. Before auscultation, the precordium should be examined and the point of maximal impulse (PMI) evaluated. An abnormal PMI is defined as displacement below the fifth intercostal space and lateral to the mid-clavicular line. It offers the clinician an assessment of heart size and function if it is sustained for more than one third of systole or is palpable over two intercostal spaces.

On auscultation of the heart, abnormal findings include an early diastolic third heart sound (S₃). A third heart sound is compatible with elevated atrial pressures and increased ventricular chamber stiffness. The sound results from rapid deceleration of the passive component of blood flow from the atrium into the noncompliant ventricle. An S₃ sound can be generated from the left or right ventricle; the latter changes in intensity with respiration. A fourth heart sound (S₄) results from an exaggerated atrial contribution to LV filling, but it is not specific for HF. Patients may also have an accentuated P₂ pulmonic valve component of S₂ if pulmonary hypertension also exists. Poor prognostic signs on physical examination include elevated jugular venous pressures and an S₃ sound.

Peripheral edema usually involves the lower extremities, but edema can involve the thighs and abdomen. Abdominal ascites may develop, particularly in the setting of worsening right ventricular failure and severe tricuspid regurgitation. Lower extremity edema can occur in many other disease states, including nephrotic syndrome, cirrhosis, venous stasis, and lymphedema, and it is not specific for HF.

The murmurs of mitral and tricuspid regurgitation are common in patients with HF. They may become worse during an acute decompensation.

Diagnostic Testing

The electrocardiogram in patients with congestive HF usually is nonspecific, but it may reveal changes suggesting a prior MI, conduction system disease, and chamber enlargement. The chest radiograph may show cardiomegaly and signs of pulmonary congestion (Fig. 5-5). Treatment of HF improves the vascular congestion seen on the chest radiograph, but radiographic changes may lag 24 to 48 hours behind clinical improvement.

Transthoracic echocardiography (TTE) is recommended for all patients with suspected HF. A noninvasive echocardiogram can assess ventricular chamber sizes, ventricular wall thickness, systolic function, diastolic function, and valvular stenosis or regurgitation. It can provide an estimation of left and right atrial pressures and quantification of stroke volume and cardiac output (Fig. 5-6). These measurements, including chamber size,

FIGURE 5-5 **A**, Posteroanterior chest radiograph showing cardiomegaly. **B**, Lateral chest radiograph showing pulmonary vascular congestion that is typical of pulmonary edema.

ventricular hypertrophy, and ventricular function, have been used in clinical trials to assess the efficacy of therapies.

Laboratory Evaluation

Initial laboratory evaluation includes a complete blood count (CBC) to assess for anemia and a basic chemistry panel for electrolyte abnormalities. The serum sodium level may be impaired, and there may be evidence of renal dysfunction due to decreased cardiac output and renal artery vasoconstriction or elevated venous pressures reflected in the renal veins (i.e., cardiorenal syndrome). Patients should be evaluated for hyperthyroidism or hypothyroidism and for hemochromatosis (i.e., with a serum ferritin level) because it is a reversible cause of HF. Patients should be tested for human immunodeficiency virus (HIV) infection. Laboratory tests for other modifiable risk factors include a fasting lipid panel and a blood glucose level. Liver function enzymes may be elevated in patients with HF and hepatic congestion, which can result from volume overload and significant LV dysfunction and may be seen in cases of right ventricular HF or severe tricuspid regurgitation.

Tests for plasma natriuretic peptide levels (BNP or NT-pro-BNP) were initially developed to evaluate patients with acute dyspnea when the diagnosis of HF was in doubt. When results are normal, this test has strong discriminatory power to eliminate HF as the cause of dyspnea. The Valsartan Heart Failure Trial (Val-HeFT) established that serial measurements of natriuretic peptide levels correlate with prognosis.

Acute Treatment

After the clinical diagnosis of HF is established, a model proposed by Stevenson and colleagues (Fig. 5-7) focuses on assessing volume status and perfusion and then further characterizes the patient according to volume overload/congestion-related and perfusion/output-related presentations. Using the history and physical examination findings, a physician can make astute

clinical decisions based on one of four profiles for patients with HF.

In patients with acute onset of pulmonary edema, initial management should be directed at improving oxygenation and providing hemodynamic stability. Patients commonly have marked elevation of blood pressure, myocardial ischemia, and worsening mitral regurgitation. Standard therapy includes supplemental oxygen and an intravenous loop diuretic.

Nitroglycerin helps to reduce preload through venodilation and may provide symptomatic relief for patients with ischemic and nonischemic ventricular dysfunction. For patients with hypertensive urgency, severe hypertension, or decompensated HF related to aortic or mitral regurgitation, an arterial vasodilator such as nitroprusside may be helpful in reducing afterload. Evaluation of the patient's response to treatment requires serial assessment of blood pressure, heart rate, end-organ perfusion, and oxygen saturation. For severely decompensated patients with refractory hypoxia or respiratory acidosis, mechanical ventilation or continuous positive airway pressure (CPAP) therapy may be necessary.

Pulmonary artery catheterization may be helpful in documenting filling pressures and the cardiac index and in hemodynamically guiding the response to therapy. Although invasive monitoring has not been associated with improved outcomes, it is impossible to adjust these studies for disease severity. In patients with refractory pulmonary edema or a markedly impaired cardiac index, inotropic agents or short-term mechanical circulatory support (e.g., intra-aortic balloon pump) may become necessary.

Treatment of Heart Failure

Treatment of HF is directed at relieving the patient's symptoms, mitigating the underlying or precipitating causes (Table 5-3), and slowing disease progression. Patients should be educated about the importance of adherence to medical therapy and restriction of dietary sodium and fluid. Rhythm disturbances such as atrial

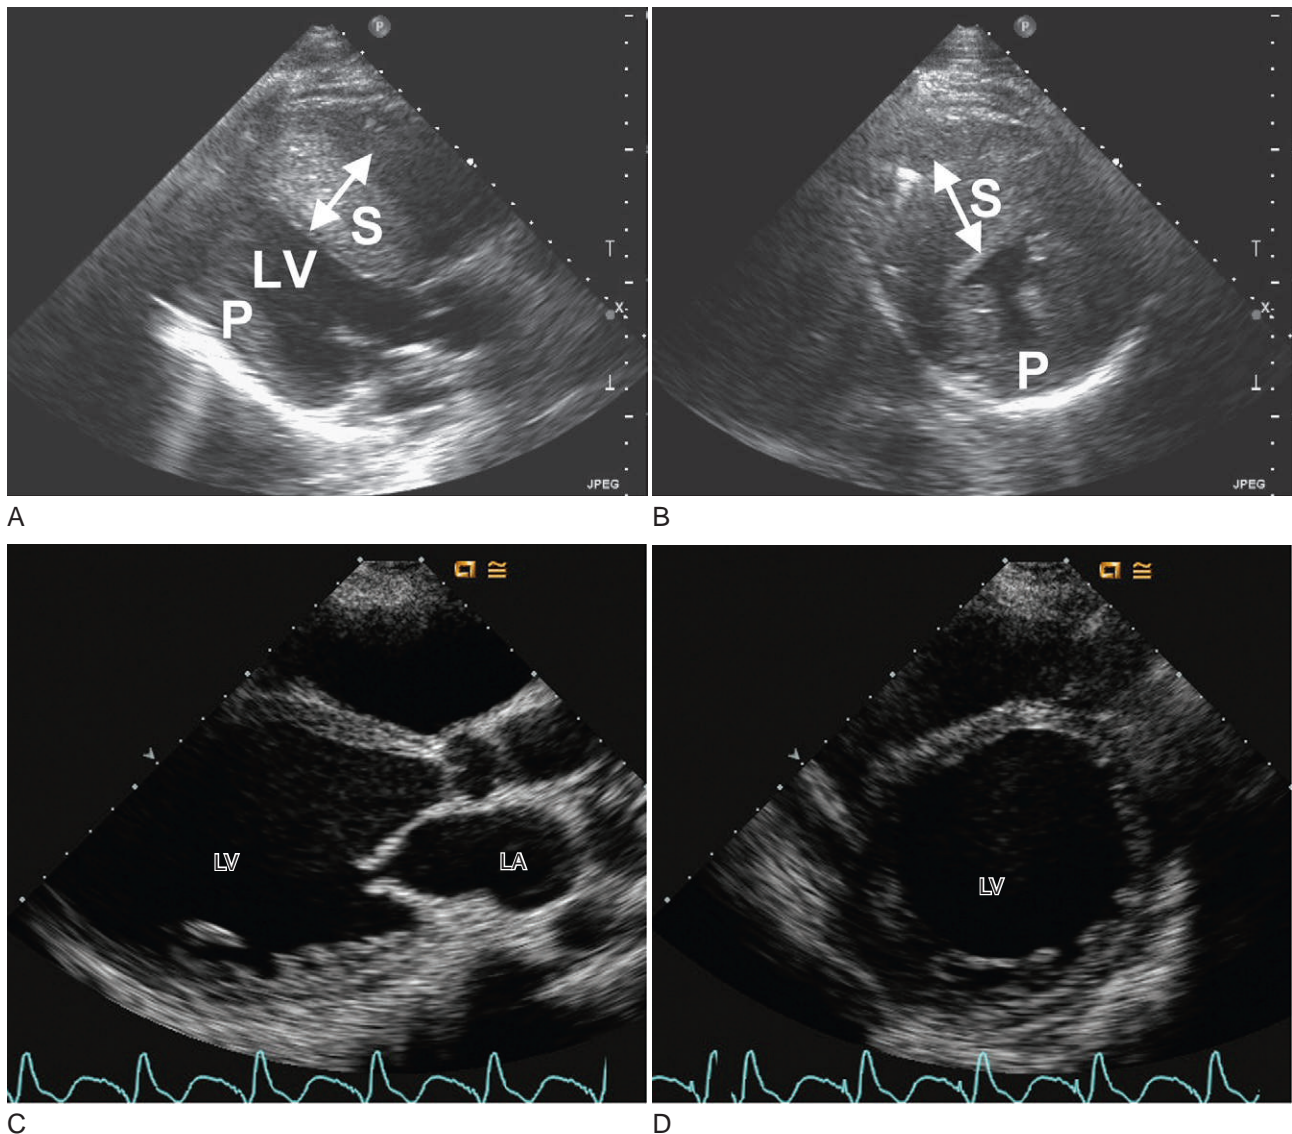

FIGURE 5-6 Echocardiographic examples of hypertrophic cardiomyopathy seen in long-axis (A) and short-axis (B) views. Notice the normal size of the left ventricular (LV) cavity and marked thickening of the interventricular septum (S) compared with posterior wall (P). In contrast, similar views of a patient with dilated cardiomyopathy (C and D) reveal a markedly enlarged LV cavity with diffuse wall thinning.

fibrillation may precipitate decompensated HF and may require specific therapy. Treatment of coronary artery disease with active ischemia, hypertension, or valvular disease may improve HF symptoms. Correction of concomitant medical problems (e.g., sleep-disordered breathing, pulmonary hypertension) may improve heart function.

Nonpharmacologic Treatment

All patients with HF should be encouraged to restrict sodium intake to about 2 g/day. Fluid intake should also be limited to avoid hyponatremia. Weight reduction by the obese patient helps to reduce the workload of the failing heart. A structured cardiovascular exercise program can reduce HF symptoms and improve functional capacity in most patients.

Pharmacologic Treatment

Table 5-4 lists all medications approved for HF and their dosing requirements.

Diuretics

Symptoms of volume overload are commonly seen in HF due to activation of the RAAS, and diuretics help to promote renal excretion of sodium and water and provide rapid relief of pulmonary congestion and peripheral edema. Loop diuretics, such as furosemide, torsemide or bumetanide, are the preferred agents in the treatment of hypervolemic HF due to their quick onset and rapid relief of symptoms by decreasing preload and lowering ventricular filling pressures. Unfortunately, there are no randomized, controlled trial data that support a mortality benefit for diuretics. Diuretics actually activate the RAAS and sympathetic nervous system, both of which can potentiate the progression of HF. The Diuretic Optimization Strategies Evaluation (DOSE) trial attempted to discern whether continuous intravenous administration of loop diuretics compared with intermittent bolus infusion would produce better outcomes for patients with acute decompensated HF. Results were equivocal according to

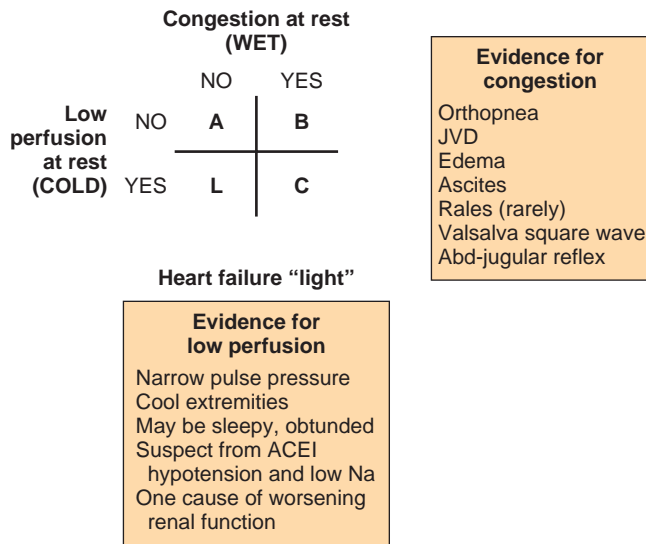

FIGURE 5-7 Diagram of a 2×2 table of hemodynamic profiles for patients with heart failure. Most patients can be classified in a 2-minute bedside assessment according to the signs and symptoms shown, although in practice, some patients may be on the border between the warm-and-wet and cold-and-wet profiles. The classification helps guide initial therapy and prognosis for patients with advanced heart failure. Most patients with hypoperfusion also have elevated filling pressures (i.e., cold and wet profile). Patients with symptoms of heart failure at rest or minimal exertion without clinical evidence of elevated filling pressures or hypoperfusion (i.e., warm and dry profile) should be carefully evaluated to determine whether their symptoms result from heart failure. A, Warm and dry profile; Abd, abdominal; ACEI, angiotensin-converting enzyme inhibitor; B, warm and wet profile; C, cold and wet profile; JVD, jugular venous distention; L, cold and dry profile; Na, serum sodium. (Modified from Nohria A, Lewis E, Stevenson LW: Medical management of advanced heart failure, *JAMA* 287:628–640, 2002.)

TABLE 5-3 PRECIPITANTS OF HEART FAILURE

Dietary (sodium and fluid) indiscretion
Noncompliance with medications

Superimposed medical illness (pneumonia, renal dysfunction)
New cardiac abnormality (acute ischemia, acute valvular insufficiency)

patient symptom reports, and there was no significant change in renal function.

If a patient remains volume overloaded and does not adequately respond to loop diuretic monotherapy, adding additional agents (i.e., metolazone, thiazide diuretics, carbonic anhydrase inhibitors, aldosterone receptor blocker, and arginine vasopressin blockers) that block reabsorption at other locations in the nephron may provide adequate diuresis, an approach called *sequential nephron blockade*. This strategy is particularly useful for patients with intrinsic renal dysfunction or significant hyponatremia due to volume overload.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

ACE inhibitors and angiotensin receptor blockers (ARBs) inhibit the RAAS and reduce afterload primarily by vasodilation. Both

drug classes have an excellent safety profile and significant morbidity and mortality benefits for symptomatic and asymptomatic LV dysfunction with or without coronary artery disease. On a cellular level, ACE inhibitors slow the progression of cardiovascular disease by multiple pleiotropic effects, including improved endothelial function; antiproliferative effects on smooth muscle cells, neutrophils, and monocytes; and anti-thrombotic effects. Meta-analyses suggest a 23% reduction in mortality and a 35% reduction in the combination end point of mortality and hospitalizations for HF among patients treated with ACEI inhibitors.

ACE inhibitors should be avoided in pregnant patients, patients considering pregnancy, and patients with a history of angioedema. The major side effect of ACE inhibitors is a persistent dry cough, which occurs in up to 20% of patients and is related to increased bradykinin levels associated with ACE inhibitor use. Other possible side effects include hypotension, hyperkalemia, and azotemia. Renal function and potassium levels should be checked 1 week after initiation and after dose titration.

ARBs prevent the binding of angiotensin II to its receptor, which decreases the release of bradykinin. ARBs should be reserved for patients who proved to be ACE inhibitor intolerant, primarily because of cough. Angioedema occurs in less than 1%.

β-Blockers

Historically, β-blockers were considered contraindicated in HF for many years due to the reliance on sympathetic tone to maintain adequate cardiac output and end-organ perfusion. Because unopposed adrenergic stimulation was ultimately found to be deleterious to the myocardium, β-blockers were introduced into clinical practice. The beneficial effects were thought to result from decreasing heart rate, β-receptor upregulation, altered myocardial metabolism, improved calcium transport, inhibition of the RAAS, improvement in endothelial dysfunction, and decreased levels of circulating cytokines.

The three approved β-blockers used in HF are metoprolol succinate, carvedilol, and bisoprolol. The estimated reduction in all-cause mortality in the Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF), Carvedilol Post-Infarct Survival Control in Left Ventricular Dysfunction Study (CAPRICORN), Carvedilol Prospective Randomized Cumulative Survival (COPERNICUS), and Cardiac Insufficiency Bisoprolol Study II (CIBIS-II) trials was approximately 35%. These effects largely result from prevention of sudden cardiac death through mechanisms inhibiting the adrenergic pathway and its deleterious effects.

Long-term treatment with β-blockers can lessen the symptoms of HF, improve the patient's clinical status, and improve the overall sense of well-being. β-Blockers should be withheld from patients with markedly decompensated acute HF until they are clinically stable, because the drugs are negatively chronotropic and acutely result in diminished cardiac output. β-Blockers should be titrated to the maximum doses achieved in clinical trials because they have been proved to improve LVEF and reduce or reverse the degree of negative LV remodeling.

TABLE 5-4 MEDICATIONS USED AND APPROVED FOR HEART FAILURE

DRUG	INITIAL DOSES	MAXIMUM DOSES	MEAN DOSES ACHIEVED IN CLINICAL TRIALS*
ANGIOTENSIN-CONVERTING ENZYME INHIBITORS			
Captopril	6.25 mg tid	50 mg tid	122.7 mg/day (421)
Enalapril	2.5 mg bid	10 to 20 mg bid	16.6 mg/day (412)
Fosinopril	5 to 10 mg qd	40 mg qd	—
Lisinopril	2.5 to 5 mg qd	20 to 40 mg qd	32.5 to 35.0 mg/day (444)
Perindopril	2 mg qd	8 to 16 mg qd	—
Quinapril	5 mg bid	20 mg bid	—
Ramipril	1.25 to 2.5 mg qd	10 mg qd	—
Trandolapril	1 mg qd	4 mg qd	—
ANGIOTENSIN-RECEPTOR BLOCKERS			
Candesartan	4 to 8 mg qd	32 mg qd	24 mg/day (419)
Losartan	25 to 50 mg qd	50 to 150 mg qd	129 mg/day (420)
Valsartan	20 to 40 mg bid	160 mg bid	254 mg/day (109)
ALDOSTERONE ANTAGONISTS			
Spironolactone	12.5 to 25 mg qd	25 mg qd or bid	26 mg/day (424)
Eplerenone	25 mg qd	50 mg qd	42.6 mg/day (445)
β-BLOCKERS			
Bisoprolol	1.25 mg qd	10 mg qd	8.6 mg/day (118)
Carvedilol	3.125 mg bid	50 mg bid	37 mg/day (446)
Carvedilol CR	10 mg qd	80 mg qd	—
Metoprolol succinate extended release (metoprolol CR/XL)	12.5 to 25 mg qd	200 mg qd	159 mg/day (447)
HYDRALAZINE AND ISOSORBIDE DINITRATE			
Fixed dose combination (423)	37.5 mg hydralazine and 20 mg isosorbide dinitrate tid	75 mg hydralazine and 40 mg isosorbide dinitrate tid	≈175 mg hydralazine/90 mg isosorbide dinitrate qd
Hydralazine and isosorbide dinitrate (448)	Hydralazine, 25 to 50 mg tid or qid, and isosorbide dinitrate, 20 to 30 mg tid or qid	Hydralazine, 300 mg qd in divided doses, and isosorbide dinitrate, 120 mg qd in divided doses	—

Modified from Yancy CW, Jessup M, Bozkurt B, et al: 2013 ACCF/AHA guidelines for the management of heart failure: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 62:e147–e239, 2013.

*Number of patients enrolled is given in parentheses.

Carvedilol is the least β -selective of the three drugs, and bisoprolol and metoprolol succinate are much more β_1 -selective. Carvedilol is also an antioxidant and an α -blocker, which may result in lowered blood pressure and improved endothelial function and may be beneficial in patients with HF. Compared with bisoprolol or metoprolol, carvedilol can cause hypotension and may cause more bronchospasm in patients with underlying lung disease. According to the American College of Cardiology and American Heart Association (ACC/AHA) 2013 HF guidelines, use of one of the three β -blockers proven to reduce mortality (i.e., bisoprolol, carvedilol, and sustained-release metoprolol succinate) is recommended for all patients with current or prior symptoms of HFrEF (LVEF <40%), unless contraindicated, to reduce morbidity and mortality.

Aldosterone Receptor Antagonists

After initiating first-line therapy with ACE inhibitors and β -blockers, the next class of beneficial agents is aldosterone receptor antagonists. Two agents studied are spironolactone and eplerenone. Aldosterone receptor antagonists are weak diuretics and have important antifibrotic properties. Use of aldosterone receptor antagonists is a class I indication according to the ACC/AHA 2013 HF guidelines, and they are recommended for patients with NYHA class II through IV HF and who have an LVEF of 35% or less, unless otherwise contraindicated, to reduce morbidity and mortality. The landmark Randomized Aldactone Evaluation Study (RALES), which evaluated spironolactone in

patients with NYHA class III or IV HF with an EF less than 35% demonstrated a 30% relative risk reduction for death from progressive HF and sudden death from cardiac causes. Eplerenone was studied in the Eplerenone in Mild Patients Hospitalization and Survival Study in Heart Failure (EMPHASIS-HF) trial, which evaluated patients with NYHA class II symptoms and found a relative risk reduction of 37% for the primary end point of death and hospital readmissions.

Hydralazine and Nitrates

Hydralazine in combination with oral nitrates has reduced mortality rates for African American patients with ongoing symptomatic HF after institution of the three regimens previously described (i.e., ACE inhibitors or ARBs, β -blockers, and aldosterone receptor antagonists). This combination provides an alternative for patients who are ACE inhibitor intolerant or may require additional therapy for blood pressure control. Although this drug combination has not proved to be efficacious in non-African Americans, all patients who cannot tolerate ACE inhibitors or ARBs may use this regimen.

The ACC/AHA HF guidelines class I recommendation states that the combination of hydralazine and isosorbide dinitrate can be used to reduce morbidity and mortality for patients self-described as African Americans with NYHA class III through IV HFrEF receiving optimal therapy with ACE inhibitors and β -blockers, unless contraindicated. The class IIa recommendation states that a combination of hydralazine and

isosorbide dinitrate can be used to reduce morbidity or mortality rates among patients with current or prior symptomatic HFrEF who cannot be given an ACE inhibitor or ARB because of drug intolerance, hypotension, or renal insufficiency, unless contraindicated.

Digoxin

Perhaps the oldest treatment of HF, digoxin works through the inhibition of the sodium-potassium pump to increase intracellular calcium and increase contractility. Unlike the medications previously described, there is no proven mortality benefit from treatment with digoxin, but there may be a reduction in the number of rehospitalizations. Digoxin has been proved to improve symptoms, exercise tolerance, and health-related quality of life in men, but not women. Digoxin has many potential side effects, including nausea, vomiting, induction of ventricular or atrial arrhythmias, and heart block, and it may cause hyperkalemia. It is most famously known for causing visual color disturbances. Caution should be used to avoid toxicity for patients with intrinsic renal disease because digoxin is renally cleared.¹

Drugs to Avoid

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) cause sodium retention, vasoconstriction, renal impairment, and increased blood pressure. They enhance the toxicity of diuretics, ACE inhibitors, and ARBs.

Calcium-Channel Blockers

Calcium-channel blockers should be avoided in patients with HFrEF. Diltiazem and the nondihydropyridines are contraindicated in patients with an LVEF less than 40% due to their negative inotropic effects and reflex adrenergic system activation.

Antiarrhythmics

Two antiarrhythmic medications are approved for patients with a reduced LVEF. They are amiodarone and dofetilide, and both appear to be mortality neutral in properly selected patients.

Thiazolidinediones

Thiazolidinediones are used in the treatment of diabetes mellitus. They lead to increased sodium reabsorption and ultimately to fluid retention. They are contraindicated for patients with HF.

Hormonal Therapy and Nutritional Supplements

There are no proven benefits for hormonal therapies, unless there is needed replacement due to a specific hormonal deficiency. There are no data to support using nutritional supplements to improve HF symptoms or outcomes. However, some data support the use of omega-3 fatty acids by HF patients

Implantable Cardiac Defibrillators and Cardiac Resynchronization Therapy

Patients with cardiomyopathies of ischemic and nonischemic origins and reduced LVEFs are prone to ventricular arrhythmias. Many studies have demonstrated the survival benefits of implanting a defibrillator for primary prevention of sudden cardiac death.

The guidelines recommend implantable cardiac defibrillator (ICD) therapy for patients with nonischemic dilated cardiomyopathy or ischemic heart disease at least 40 days after an MI with an LVEF of 35% or less and NYHA class II or III HF and who have been treated with optimal medical therapy for a minimum of 3 to 6 months and have a life expectancy of more than 1 year. An ICD is also recommended for patients with NYHA class I symptoms and an LVEF less than 30% 40 days after an MI and who have been treated with optimal medical therapy for 3 to 6 months.

Resynchronization Therapy

Intraventricular conduction delays, demonstrated as a prolonged QRS duration of more than 120 milliseconds by surface ECG, are a common complication in patients with HF. The delay leads to dyssynchronous contraction of the left ventricle and can result in reduced systolic function, decreased cardiac output, and reduced exercise capacity.

Cardiac resynchronization therapy (i.e., biventricular pacing) aims to improve intraventricular synchrony and has been associated with improved cardiac output and LVEF. Biventricular pacing may have a beneficial effect on LV remodeling by reducing LV volume, LV mass, and severity of mitral regurgitation. These hemodynamic and structural changes have translated into a clinical improvement of functional capacity, exercise tolerance, and quality of life.

Biventricular pacing has reduced mortality rates and hospitalization for HF in multiple randomized, controlled trials. A systematic review of 14 randomized trials was published in 2007 by McAlister and colleagues. It evaluated 4420 patients with LVEF values less than 35%, QRS duration longer than 120 msec, NYHA class III and IV HF, and optimal medical therapy. They reported that cardiac resynchronization therapy (CRT) improved LVEF by 3% and improved LV remodeling, quality of life, and exercise capacity; 59% of patients had improvement by at least one NYHA class. Hospitalizations were decreased by 37%, and all-cause mortality was decreased by 22%. CRT was beneficial for patients with NYHA class III and IV symptoms, and there was a mortality benefit for patients with NYHA class I and II symptoms.

One third of patients undergoing biventricular pacemaker placements are found to be nonresponders. Patients with the best response to CRT have a wide QRS in a left bundle branch block pattern. The class I recommendation from the ACC guidelines proposes CRT for patients who have an LVEF of 35% or less, sinus rhythm, left bundle branch block with a QRS duration of 150 milliseconds or greater, and NYHA class II, III, or ambulatory IV symptoms who are receiving optimal medical therapy (Fig. 5-8).

Anticoagulation

Patients with HF; persistent, paroxysmal, or permanent atrial fibrillation; and one other risk factor in the CHADS₂ index (i.e., congestive heart failure, hypertension, age 75 years or greater, diabetes mellitus, and stroke) should receive chronic anticoagulant therapy. According to the guidelines, it is reasonable to anticoagulate patients with HF and atrial fibrillation without additional risk factors.

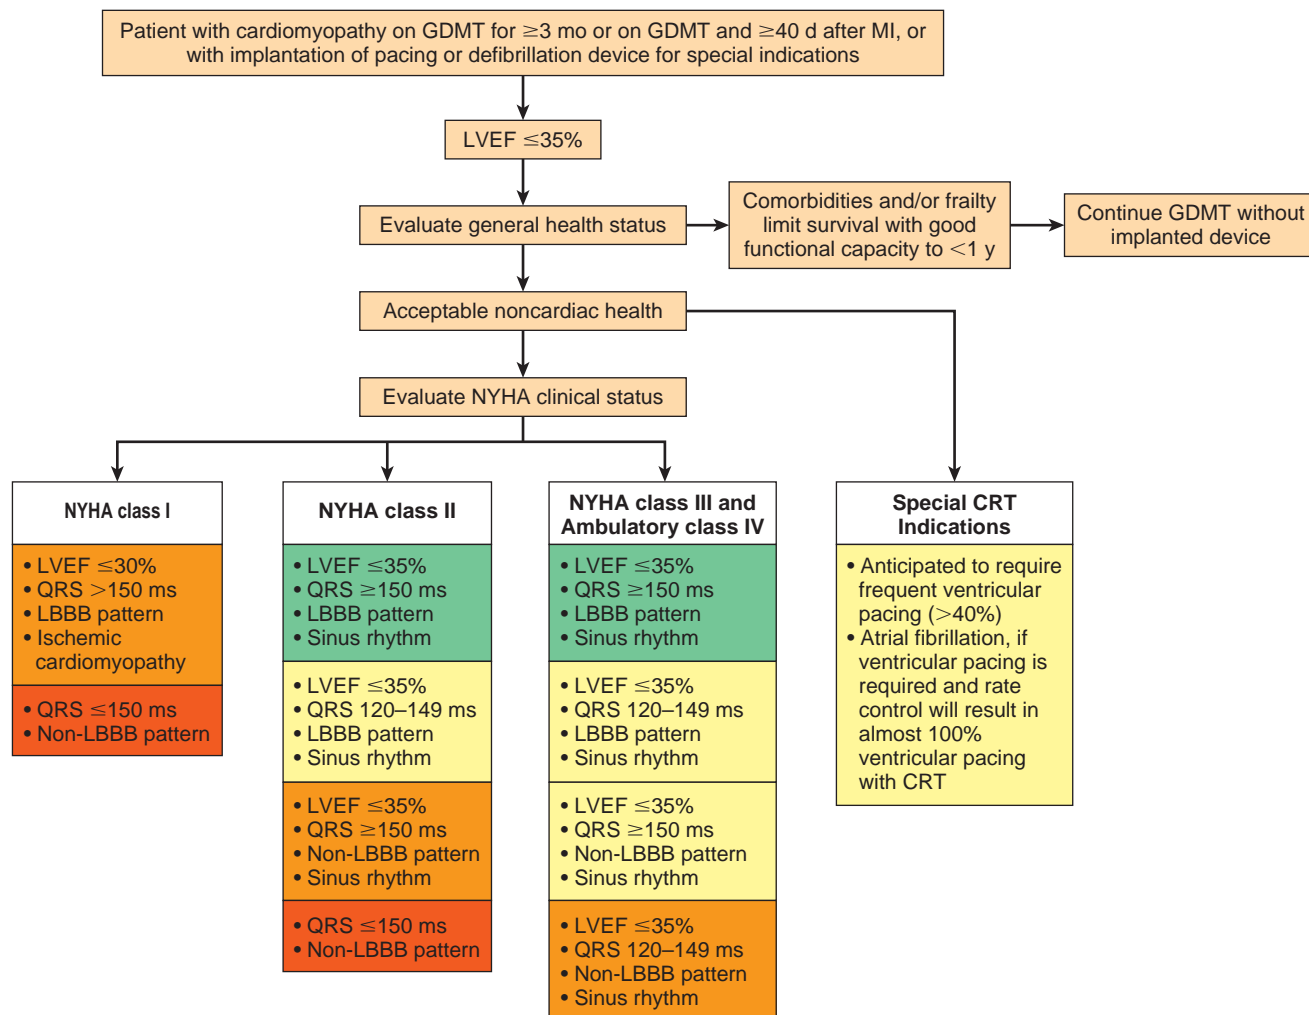

FIGURE 5-8 Left ventricular ejection fraction (LVEF) and New York Heart Association (NYHA) functional class that correlates with the American College of Cardiology and American Heart Association (ACC/AHA) guidelines for recommendations for defibrillators and cardiac resynchronization therapy (CRT). Class I recommendations are shown in green, class IIa recommendations are shown in yellow, class IIb recommendations are shown in orange, and class III recommendations are shown in red. GDMT, Guideline-directed medical therapy; LBBB, left bundle branch block; MI, myocardial infarction.

Stage D Heart Failure

Despite optimal medical therapy, many patients with HF fail to have significant improvement in symptoms. In these instances, a trial of hemodynamically guided (i.e., using a Swan-Ganz catheter) HF therapy may be necessary to optimize volume status and perfusion and to assess the degree of impairment of the cardiac index.

This approach allows assessment of candidacy for advanced HF therapies, such as cardiac transplantation and mechanical circulatory support with ventricular assist devices. One commonly used agent is milrinone, an intravenous phosphodiesterase inhibitor that has similar effects on contractility and afterload. Administration increases the cardiac index and promotes spontaneous diuresis. In patients with markedly elevated systemic vascular resistance, the use of intravenous vasodilators (e.g., nitroglycerin, sodium nitroprusside) can significantly reduce afterload and may improve cardiac output.

If the previously described measures fail to produce a satisfactory diuretic response, dopamine given in doses ranging

from 2 to 5 $\mu\text{g}/\text{kg}/\text{min}$ may facilitate sodium and water excretion by stimulating renal dopaminergic receptors. Table 5-5 shows the clinical signs and laboratory values that a clinician should recognize in patients with stage D or advanced HF. The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) scale is used to appropriately risk-stratify these patients for potential mechanical circulatory support.

Mechanical Circulatory Support

Two permanent ventricular assist devices (VADs) are approved by the U.S. Food and Drug Administration. The first device is the HeartMate II, which is an axial flow device that is approved for bridge-to-transplantation use and for destination therapy in transplantation-ineligible patients. The second device is a third-generation VAD called Heartware (HVAD), which is a centrifugal pump. Both pumps require chronic anticoagulation and antiplatelet therapy. The current estimated aggregate survival rate is approximately 80% at 1 year and approximately 70% at 2 years.

TABLE 5-5 IDENTIFYING ADVANCED HEART FAILURE

Repeated (≥ 2) hospitalizations or ED visits for HF in the past year
Progressive deterioration in renal function (e.g., rise in BUN and creatinine)
Weight loss without other cause (e.g., cardiac cachexia)
Intolerance to ACE inhibitors due to hypotension and/or worsening renal function
Intolerance to β -blockers due to worsening HF or hypotension
Frequent systolic blood pressure <90 mm Hg
Persistent dyspnea with dressing or bathing requiring rest
Inability to walk 1 block on the level ground due to dyspnea or fatigue
Recent need to escalate diuretics to maintain volume status, often reaching daily furosemide equivalent dose >160 mg/day and/or use of supplemental metolazone therapy
Progressive decline in serum sodium, usually to <133 mEq/L
Frequent ICD shocks

Modified from Yancy CW, Jessup M, Bozkurt B, et al: 2013 ACCF/AHA guidelines for the management of heart failure: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 62:e147–e239, 2013.

ACE, Angiotensin-converting enzyme; BUN, blood urea nitrogen; ED, emergency department; HF, heart failure; ICD, implantable cardiac defibrillator.

FIGURE 5-9 Conceptualizing comprehensive heart failure (HF) care. Early in therapy (1), supportive efforts focus on education for the patient and family about HF and self-management. Diuresis and evidence-based therapies achieve a plateau of improved function (2). Even when a plateau of improved function is achieved, the patient and family can benefit from efforts that improve symptoms and assist them in coping with HF and its impact on their lives. Functional status declines with intermittent exacerbations of HF that respond to rescue efforts (3). Heart transplantation or destination therapy ventricular assist devices (4) improve function for patients for a period and carry a different burden of chronic illness. At the end of life or when significant physical frailty or comorbidities predominate (5), the major focus of care is palliation, but some HF therapies remain important. HF is different from cancer, for which potentially curative treatments are discontinued as the patient reaches the end stage. (Modified from Goodlin S: Palliative care in congestive heart failure, *J Am Coll Cardiol* 54:386–396, 2009.)

Prognosis

The disease trajectory of HF is complex and characterized by variable intervals of clinical stability (Fig. 5-9). Although many randomized, controlled trials have demonstrated a symptom and mortality benefit with ACE inhibitors, ARBs, β -blockers, mineralocorticoid receptor blockers, and ICD and CRT therapy, the sobering 5-year mortality rate for HF remains at 50%, and the 10-year survival rate for patients with symptomatic HF is only 20%.

For a deeper discussion on this topic, please see Chapter 58, “Heart Failure: Pathophysiology and Diagnosis,” in *Goldman-Cecil Medicine, 25th Edition*.

Congenital Heart Disease

Scott Cohen and Michael G. Earing

INTRODUCTION

Congenital heart defects are the most common group of birth defects, occurring in approximately 9 of 1000 live births. Without treatment, most patients die in infancy or childhood, with only 5% to 15% surviving into adulthood. Advancements in surgical and medical practices have resulted in survival of approximately 90% of these children to adulthood. For the first time in history, estimates suggest that more adults than children are living with congenital heart disease in the United States and that there is a 5% increase every year.

Most adults living with congenital heart disease have had interventions performed (Table 6-1). Although most children who undergo surgical intervention survive to adulthood, total correction usually is not the rule. Adult patients with congenital heart disease are surviving longer than ever before, and it is becoming apparent that even the simplest lesions can be associated with long-term cardiac complications (i.e., arrhythmias and conduction abnormalities, ventricular dysfunction, residual shunts, valvular lesions, hypertension, and aneurysms) and non-cardiac complications (i.e., renal dysfunction, restrictive lung disease, anxiety, depression, and liver dysfunction). Most adults with congenital heart disease need lifelong follow-up.

ACYANOTIC HEART DISEASE

Atrial Septal Defects

Definition and Epidemiology

Atrial septal defects (ASDs) are communications between the atria that allow shunting of blood from one atrium to the

other. They are among the most common congenital anomalies seen in adolescents and young adults, occurring in 1 of 1500 live births and constituting 6% to 10% of all congenital heart defects.

There are four main types of ASDs. Ostium secundum defects are the most common, accounting for 75% of all ASDs. This defect occurs in the region of the fossa ovalis and results from excessive absorption of the septum primum or insufficient development of the septum secundum, or both.

Ostium primum defects represent about 20% of all ASDs and represent a form of atrioventricular septal defect (i.e., partial or incomplete atrioventricular canal). These defects are located in the inferior aspect of the atrial septum adjacent to the mitral and tricuspid valves. The defects result from lack of closure of the ostium primum by the endocardial cushions, which are embryologic swellings in the heart that form the primum atrial septum, the inlet portion of the ventricular septum, and parts of the mitral and tricuspid valve. The lesions often are associated with clefts in the mitral and tricuspid valves.

Sinus venosus ASDs represent 5% of all ASDs and are located at the entry of the superior vena cava into the right atrium. Frequently, there is associated partial anomalous drainage of the right upper pulmonary vein. This defect results from resorption of the wall between the vena cava and pulmonary veins.

An unroofed coronary sinus is a rare form of ASD, representing less than 1% of all ASDs. The coronary sinus is in apposition to the posterior aspect of the left atrium, but the orifice is in the right atrium. When a defect exists in the roof of the coronary sinus, a communication between the left atrium and right atrium exists, allowing shunting.

Pathology

All four types of ASDs allow oxygenated blood to pass from the left atrium into the right atrium, resulting in volume overload of the right atrium and right ventricle (Fig. 6-1). The degree of shunting is determined by the size of the ASD and the compliance of the left and right cardiac chambers. Comorbidities that increase left-sided filling pressures (i.e., left ventricular [LV] diastolic dysfunction, myocardial infarction, and mitral stenosis) may result in an increased left-to-right shunt. Over time, significant left-to-right shunting can cause enlargement of the right atrium and right ventricle, eventually leading to right ventricular (RV) systolic dysfunction and failure. Pulmonary hypertension may occur in approximately 26% of patients with a secundum ASD. However, significant elevation in pulmonary vascular resistance is rare.

TABLE 6-1 MOST COMMON CONGENITAL HEART DEFECTS SURVIVING TO ADULTHOOD WITHOUT SURGERY OR INTERVENTIONAL CATHETERIZATION

Mild pulmonary valve stenosis
Bicuspid aortic valve
Small to moderate size atrial septal defect
Small ventricular septal defect
Small patent ductus arteriosus
Mitral valve prolapse
Partial atrioventricular canal (ostium primum atrial septal defect and cleft mitral valve)
Marfan syndrome
Ebstein's anomaly
Congenitally corrected transposition (atrioventricular and ventriculoarterial discordance)

FIGURE 6-1 The diagram shows three types of shunt lesions that commonly survive until adulthood and their effects on chamber size. **A**, Uncomplicated atrial septal defect with left-to-right shunt flow across the interatrial septum, resulting in dilation of the right atrium (RA), right ventricle (RV), and pulmonary artery (PA). **B**, Uncomplicated ventricular septal defect, resulting in dilation of the RV, left atrium (LA), and left ventricle (LV). **C**, Uncomplicated patent ductus arteriosus, resulting in dilation of the LA, LV, and PA. Ao, Aorta. (From Liberthson RR, Walkman H: Congenital heart disease in the adult. In Kloner RA, editor: Guide to cardiology, ed 3, Greenwich, Conn., 1991, Le Jacq Communications, pp 24–27.)

Clinical Presentation

Although most individuals with an ASD are diagnosed during childhood after a murmur is noticed, a few patients have symptoms for the first time as adults. Most patients are asymptomatic during the first and second decades of life. In the third decade, an increasing numbers of patients develop exercise intolerance, palpitations due to atrial arrhythmias, and cardiac enlargement on the chest radiograph. In patients with ASDs, the RV impulse at the left lower sternal border often has increased force compared with normal. On auscultation, the second heart sound typically is widely split and fixed (i.e., does not vary with inspiration).

All patients have a systolic ejection murmur, which is best heard at the left upper sternal border and is related to increased flow across a usually normal pulmonary valve. When there is a large left-to-right shunt, a mid-diastolic murmur can be heard at the left lower sternal border; it is related to increased flow across a normal tricuspid valve. When a mid-diastolic murmur is identified, the degree of left-to-right shunt is considered to be 1.5 times normal. In the setting of a primum ASD, an additional holosystolic murmur at the apex may be caused by a cleft in the anterior leaflet of the mitral valve, resulting in mitral regurgitation.

Diagnosis

On the electrocardiogram (ECG), the features of ASD depend on the size and type of defect. In the setting of a large ostium secundum, sinus venosus, or unroofed coronary sinus defect, the ECG typically demonstrates evidence of right atrial (RA) enlargement, RV hypertrophy, and right axis deviation. In the setting of an ostium primum ASD, like other forms of atrioventricular defects, there is a superior axis. The chest radiograph is helpful for evaluating the degree of left-to-right shunting. With a small shunt, the radiograph will be normal. As the shunt increases in size, the heart size and pulmonary vascular markings also increase.

The diagnosis of an ASD and its location is confirmed by transthoracic echocardiography in most cases. A sinus venosus ASD is the exception. In this setting, transesophageal echocardiography may be necessary. Cardiac catheterization is rarely performed to diagnose an ASD. However, transcatheter closure has become the preferred treatment option for most ostium secundum defects.

Treatment

The treatment of ASDs involves surgical or transcatheter device closure. For secundum ASD, surgical closure and transcatheter device closure are accepted treatment options. Device closure is the most commonly used technique for closure of secundum defects. This technique, however, requires an adequate rim of septal tissue around the entire defect to allow for device stabilization. For ostium primum, sinus venosus, and unroofed coronary sinus forms of ASDs, surgical closure remains the only option.

Prognosis

Most patients who have undergone early closure of a defect have excellent long-term survival rates with low morbidity rates if repair is undertaken before 25 years of age. Older age at repair is associated with decreased late survival rates and an associated increased risk of atrial arrhythmias, thromboembolic events, and pulmonary hypertension. After the age of 40 years for patients with unrepaired ASDs, the mortality rate increases by 6% per year, and more than 20% of patients develop atrial fibrillation. By 60 years of age, the number of patients with atrial fibrillation increases to more than 60%. Long-term rates of late complications and survival after transcatheter device closure remain unknown.

Ventricular Septal Defects

Definition and Epidemiology

Ventricular septal defects (VSDs) occur in 1.5 to 3.5 of 1000 live births. They constitute 20% of congenital heart defects.

There are four types of VSD: perimembranous, muscular, supracristal, and inlet. Perimembranous VSDs are the most common, comprising 70% of all VSDs. The membranous septum is relatively small and sits directly under the aortic valve. Perimembranous VSDs involve the membranous septum and typically extend into the muscular tissue adjacent to the membranous septum. If not large, these defects may close

spontaneously by tissue from the septal leaflet of the tricuspid valve.

Muscular VSDs are the second most common VSD and account for 5% to 20% of all VSDs. Multiple muscular VSDs commonly are found at the time of diagnosis. Muscular VSDs have the highest rate of spontaneous closure.

Supracristal VSDs represent 5% to 8% of all VSDs. These defects are located superior to the crista supraventricularis (i.e., within the RV outflow tract directly below the right cusp of the aortic valve). These defects are associated with prolapse of the right aortic cusp, which can lead to progressive aortic regurgitation. In some cases, the prolapsed right aortic cusp may restrict the defect, but rarely do they spontaneously close.

Inlet VSDs are located in the posterior ventricular septum, just inferior to the tricuspid and mitral valve. They account for 5% to 8% of all VSDs and never close spontaneously.

Pathology

Shunting through a VSD is typically left to right and can cause overcirculation of the pulmonary vasculature and increased pulmonary venous return, resulting in left-sided chamber enlargement (see Fig. 6-1). The degree of shunting depends on the size of the defect and the pulmonary vascular resistance. Small defects (i.e., restrictive defects) typically have a small degree of shunting and normal pulmonary artery pressure. Moderate-sized defects have enough left-to-right shunting to cause mildly elevated pulmonary artery pressures and some left-sided chamber enlargement. Large defects (i.e., nonrestrictive defects) allow LV systolic pressures to be transmitted to the pulmonary circulation. This can cause irreversible obstructive pulmonary vascular disease early in childhood. Eventually, if the pulmonary vascular resistance exceeds the systemic vascular resistance, the shunt may reverse to right to left (i.e. Eisenmenger's physiology).

Clinical Presentation

The physical findings for a patient with a VSD depend on the size of the VSD, magnitude of the shunt, and the level of pulmonary artery hypertension. For patients with a small VSD, the apical impulses of the right ventricle and left ventricle typically have normal intensity on palpation, but there may be a palpable thrill. The first and second heart sounds typically are normal, and in most cases, there is a holosystolic murmur of moderate intensity at the left lower sternal border.

Patients with Eisenmenger's syndrome have cyanosis and secondary erythrocytosis. The RV impulse usually is increased at the left lower sternal border, and the pulmonary component of the second heart sound may be palpable. Typically, no systolic murmur is detected, but a diastolic murmur is often heard at the left upper sternal border due to a severely dilated main pulmonary artery and resultant pulmonary regurgitation.

Diagnosis

The ECG should be normal for patients with small VSDs. For those with Eisenmenger's syndrome, the ECG usually demonstrates RV hypertrophy with right axis deviation. Patients with a small VSD have a normal chest radiograph. Patients with Eisenmenger's syndrome may have mild cardiac enlargement with enlarged proximal pulmonary arteries and peripheral pruning

with oligemic lung fields. Echocardiography allows confirmation of the diagnosis, localization of defect, identification of long-term complications, and estimation of pulmonary artery pressure. Cardiac catheterization allows direct measurement of the degree of left-to-right shunting, pulmonary artery pressure, and pulmonary vascular reactivity.

Treatment

Because patients with small VSDs are asymptomatic, they should be treated conservatively. Because of the long-term risks, they need intermittent follow-up for life to monitor for the development of late complications. The exceptions to this rule are those with small supracristal or perimembranous VSDs with associated prolapse of the aortic cusp into the defect that results in progressive aortic regurgitation. These patients should be considered for surgical repair at the time of diagnosis to prevent progressive aortic valve damage.

Prognosis

Although isolated VSDs are common forms of congenital heart disease, the diagnosis of a VSD in an adult is rare. Most patients with a hemodynamically significant VSD have undergone repair in childhood or died earlier in life. As result, the spectrum of isolated VSDs in adults is limited to those with small restrictive defects, those with Eisenmenger's syndrome, and those who had their defects closed in childhood.

For patients with small restrictive VSDs, long-term survival is excellent, with an estimated 25-year survival rate of 96%. The rate of long-term morbidity for patients with a restrictive VSD also appears to be low. However, the clinical course is not completely benign. Reported long-term complications include endocarditis, progressive aortic regurgitation due to prolapse of aortic valve into the defect (i.e., highest risk for the supracristal type but can occur with a perimembranous defect), and the development of right and left outflow tract obstruction from a double-chamber right ventricle or a subaortic membrane.

For patients who develop Eisenmenger's syndrome, survival into the third decade is common. However, with increasing age, the long-term complications of right heart failure, paradoxical emboli, and erythrocytosis usually result in a progressive drop in survival, with an average age of death of 37 years. Adults with previous VSD closure and without pulmonary hypertension or residual defects have a normal life expectancy.

Complete Atrioventricular Septal Defects

Definition and Epidemiology

Complete atrioventricular septal defects (AVSDs) consist of several cardiac malformations that result from abnormal development of the endocardial cushions. AVSDs account for 4% to 5% of congenital heart defects. Down syndrome is a common association; 40% of Down syndrome patients have congenital heart disease, and 40% of these have some form of AVSD.

AVSDs are categorized as partial (or incomplete) or complete. Both forms share common structural abnormalities—ostium primum ASD, inlet VSD, and cleft anterior mitral and septal tricuspid valve—in various combinations.

Pathology

A combination of the previously described defects results in interatrial and interventricular shunts, LV-to-RA shunt, and atrioventricular regurgitation. Because these defects include deficiency of the inlet portion of the ventricular septum, the LV outflow tract is lengthened and may be narrowed, producing the characteristic goose-neck deformity.

The natural history for patients with complete AVSD is characterized by the early development of pulmonary vascular disease, leading to irreversible damage that often occurs by 1 year of age, particularly for patients with Down syndrome. Surgery needs to be undertaken early if it is to be successful. Patients who are diagnosed in adulthood can be categorized in two groups: those with Eisenmenger's syndrome and those who had their defects closed in childhood.

Clinical Presentation

On physical examination, most previously repaired patients are cardiovascularly normal. However, patients with significant left atrioventricular (AV) valve regurgitation have a grade 3 or 4 (of 6) holosystolic regurgitant murmur at the apex. For the rare patient with subaortic stenosis, a grade 2 or 3 systolic murmur can be detected at the left midsternal border and radiating to the neck. The physical examination findings for patients with Eisenmenger's syndrome are similar to those for patients with unoperated VSDs.

Diagnosis

On the ECG, first-degree heart block is a common finding for patients with AVSD. All patients have a superior, leftward QRS axis. For those with Eisenmenger's syndrome, the chest radiograph demonstrates cardiomegaly, large proximal pulmonary arteries, and small peripheral pulmonary arteries (i.e., peripheral pruning). Patients who underwent previous repair and have significant systemic left AV valve regurgitation have cardiomegaly with increased vascular markings.

Treatment

Patients who underwent previous repair with significant left AV valve regurgitation causing symptoms, atrial arrhythmias, or deterioration in ventricular function should undergo elective repair or replacement. Previously repaired patients who develop significant subaortic stenosis (i.e., peak cardiac catheterization or echo gradient of ≥ 50 mm Hg) should undergo surgical repair.

Prognosis

Overall, for patients who underwent early repair before the development of pulmonary vascular disease, the long-term prognosis is good. The most common long-term complication is left AV valve regurgitation, with approximately 5% to 10% of patients requiring surgical revision for left AV valve repair or replacement during follow-up. The second most common long-term complication for this group is subaortic stenosis, occurring in up to 5% of patients after repair. Other long-term complications include residual atrial- or ventricular-level shunts, complete heart block, atrial and ventricular arrhythmias, and endocarditis.

Patients with Eisenmenger's syndrome are symptomatic with exertional dyspnea, fatigue, palpitations, edema, and syncope. Survival is similar to that for other forms of Eisenmenger's syndrome, with a mean age at death of 37 years. In retrospective studies, strong predictors for death included syncope, age at presentation of symptoms, poor functional class, low oxygen saturation ($\leq 85\%$), increased serum creatinine and serum uric acid concentrations, and Down syndrome.

Coarctation of the Aorta

Definition

Coarctation of the aorta is an abnormal narrowing of the aortic lumen. It constitutes 5% of congenital heart defects. Coarctation of the aorta may occur anywhere along the descending aorta, even below the diaphragm, but in more than 95% of cases, the narrowing is just below the takeoff of the left subclavian artery. In 50% to 85% of cases, there is an associated bicuspid aortic valve. Other associated lesions include VSDs, subaortic stenosis, and mitral valve stenosis.

Pathology

Coarctation of the aorta is an aortopathy of the entire aorta rather than a localized abnormality. In the young, significant coarctation can decrease blood flow to the kidneys, gut, and lower extremities, resulting in severe acidosis and shock requiring immediate treatment. Unrepaired coarctation of the aorta can be seen in adults, but it is rare. Affected individuals develop extensive arterial collateralization to maintain distal perfusion. Most patients seen in adulthood are patients who have had previous coarctation of the aorta repair using a variety of different techniques.

Even after successful repair to relieve the obstruction, multiple studies have demonstrated that patients have persistent abnormalities in the media of the aorta proximal and distal to the coarctation repair site. The stiff aortic wall is characterized by decreased distensibility and endothelial and vascular dysfunction. Examples include resting and exercise-induced hypertension, increased carotid intimal thickness, and abnormal peripheral arterial responses to augmented blood flow and nitroglycerin. Patients with coarctation of the aorta are at increased risk for other left-sided obstructive lesions, particularly a bicuspid aortic valve, which occurs in 50% of cases.

Clinical Presentation

The clinical presentation of coarctation of the aorta depends on the severity of obstruction and the associated anomalies. Unrepaired coarctation of the aorta typically manifests with symptoms before adulthood. Symptoms include headaches related to hypertension, leg fatigue or cramps, exercise intolerance, and systemic hypertension. Untreated patients surviving to adulthood typically have only mild coarctation of the aorta.

Cardinal clinical features in the setting of a significant coarctation of the aorta include upper body hypertension, weak and delayed femoral pulses, and a blood pressure gradient between the right arm and right leg determined by blood pressure cuff. On auscultation, the aortic valve closure sound is usually loud; in the setting of a bicuspid aortic valve, an ejection click, often with a

crescendo-decrescendo systolic murmur, is heard at the right upper sternal border. Often, a continuous systolic murmur is heard over the left scapula. It is related to continuous flow across the coarctation of the aorta.

Diagnosis

Patients with significant coarctation of the aorta typically show various degrees of left atrial (LA) and LV enlargement on an ECG. The chest radiograph typically demonstrates normal heart size with dilation of the ascending aorta and kinking or double contouring in the region of the descending aorta in the area of the coarctation, producing the characteristic figure-3 sign.

Most adult patients have rib notching. It is caused by the dilated intercostal collateral arteries eroding the undersurface of the ribs. Echocardiography is used to identify site, structure, and degree of stenosis or restenosis. Echocardiography is valuable for identifying other lesions, LV systolic function, and degree of LV hypertrophy.

Cardiac catheterization remains the gold standard for determining the anatomy and absolute degree of stenosis. In adult patients, cardiac catheterization with balloon dilation and stent placement has become the procedure of choice for the treatment of recoarctation. Newer magnetic resonance imaging (MRI) methods are quite good for imaging coarctation, defining the arch vessel anatomy, and identifying collaterals.

Treatment

Patients with significant native or residual coarctation of the aorta (i.e., symptomatic with a peak gradient across the coarctation of ≥ 30 mm Hg) should be considered for surgical repair or catheter intervention with balloon angioplasty with or without stent placement. Surgical repair in the adult patient is technically difficult and is associated with high rates of morbidity. As result, catheter based intervention has become the preferred method in most experienced congenital heart disease centers.

Prognosis

After surgical repair, long-term survival is good but directly correlates with the age at repair. Those repaired after 14 years of age have a lower 20-year survival rate than those repaired earlier (79% vs. 91%). Long-term outcome data for catheter-based treatment is limited, but studies suggest that stented patients have lower acute and long-term complications at 60 months (25% for surgery vs. 12.5% for stents). Irrespective of the type of repair, the most common long-term complication is persistent or new systemic hypertension at rest or during exercise. Other long-term complications include aneurysms of the ascending or descending aorta (especially after Dacron patch repair), recoarctation at the site of previous repair, coronary artery disease, aortic stenosis or regurgitation (in the setting of a bicuspid aortic valve), rupture of an intracranial aneurysm, and endocarditis.

Patent Ductus Arteriosus

Definition and Epidemiology

Patent ductus arteriosus (PDA) represents 9% to 12% of congenital heart defects. It is patent in the fetus but normally closes within several days of birth. However, it remains open in about 1

of 2500 to 5000 births. In infants born prematurely, the incidence is even higher, occurring in 8 of 1000 live births. The incidence of PDA is 30 times greater for babies born at high altitudes than for those born at sea level.

Pathology

A PDA allows transit of blood from the aorta into the pulmonary artery and recirculation through the pulmonary vasculature and the left side of the heart. This can result in left-sided chamber enlargement (see Fig. 6-1). As with VSDs, the size of the defect is the primary determinant of the clinical course in the adult patient. PDAs can be clinically categorized as silent PDAs; small, hemodynamically insignificant PDAs; moderate-size PDAs; large PDAs; and previously repaired PDAs.

Clinical Presentation

A silent PDA is a tiny defect that cannot be heard by auscultation and is detected only by other nonclinical means such as echocardiography. Life expectancy is always normal for this population, and the risk of endocarditis is extremely low.

Patients with a small PDA have an audible, long-ejection or continuous murmur that is heard best at the left upper sternal border and radiating to the back. They have normal peripheral pulses. Because there is negligible left-to-right shunting, these patients have normal LA and LV sizes and normal pulmonary artery pressure. Like those with silent PDAs, these patients are asymptomatic and have a normal life expectancy. However, they do have a higher risk of endocarditis.

Patients with moderate-size PDAs may be diagnosed during adulthood. These patients often have wide, bouncy peripheral pulses and an audible, continuous murmur. They have significant volume overload and develop some degree of LA and LV enlargement and some degree of pulmonary hypertension. These patients are symptomatic with dyspnea, palpitations, and heart failure. Patients with large PDAs typically have signs of severe pulmonary hypertension and Eisenmenger's syndrome. By adulthood, the continuous murmur is typically absent, and there is differential cyanosis (i.e., lower extremity saturations are lower than the right arm saturation).

Diagnosis

Patients with silent and small PDAs appear normal by echocardiography and chest radiography. Calcifications may be seen on the posteroanterior and lateral films of an older patient with a PDA. In patients with significant left-to-right shunting, there typically is dilation of the central pulmonary arteries with increased pulmonary vascular markings. On an ECG, broad P waves and tall QRS complexes suggest LA and LV volume overload. A tall R wave in lead V_1 with a right axis deviation suggests significant pulmonary hypertension. Echocardiography is important to estimate the size of the defect, degree of LA or LV enlargement, and degree of pulmonary artery hypertension.

Treatment

All patients with clinical evidence of a PDA are at increased risk for endocarditis. Except for patients with small or silent PDAs and those with severe, irreversible pulmonary hypertension, PDA closure should be considered. Catheter device closure is the preferred method in most centers. Surgical closure is reserved for

patients with PDAs too large for device closure and for distorted anatomy such as a large ductal aneurysm.

Prognosis

Patients with a large PDA who have developed Eisenmenger's syndrome have a prognosis similar to that of other patients with Eisenmenger's syndrome. Patients who underwent PDA repair before the development of pulmonary hypertension have a normal life expectancy without restrictions.

Pulmonary Valve Stenosis

Definition and Epidemiology

Pulmonary valve stenosis occurs in approximately 4 of 1000 live births and constitutes 5% to 8% of congenital cardiac defects. It is one of the most common adult forms of unoperated congenital heart disease. It can occur in isolation or with other congenital heart defects, such as an ASD.

Pathology

In congenital pulmonary valve stenosis, the pulmonary valve leaflets are often fused or thickened, which obstructs blood flow out of the right ventricle. The obstruction elevates RV pressure, and compensatory RV hypertrophy develops. Pulmonary stenosis is often tolerated better than aortic stenosis. Over time, RV dilation and dysfunction may occur.

Clinical Presentation

Most patients with pulmonary valve stenosis are asymptomatic and have a cardiac murmur at presentation. Most unoperated adults with severe stenosis have jugular venous distention, and on palpation, a RV lift at the left lower sternal border and a thrill at the left upper sternal border can be identified. On auscultation, the second heart sound is widely split, and a systolic ejection click may or may not be heard, depending on the mobility of the pulmonary valve leaflets. In most cases, there is a harsh, crescendo-decrescendo systolic ejection murmur, which is heard best at the left upper sternal border; it radiates to the back and varies with inspiration.

Diagnosis

With moderate to severe pulmonary valve stenosis, the ECG demonstrates right axis deviation, RV hypertrophy, and RA enlargement. The ECG is usually normal for patients with mild pulmonary valve stenosis. On the chest radiograph, a prominent main pulmonary artery caused by poststenotic dilatation is a common finding regardless of the degree of stenosis. In patients with severe pulmonary valve stenosis, cardiomegaly due to RA and RV enlargement is often seen.

Echocardiography is the diagnostic method of choice. It allows visualization of the valve anatomy and degree of stenosis and enables estimation of the valve gradient.

Treatment

Survival into adult life and the need for intervention directly correlate with the degree of obstruction. In the Second Natural History Study of Congenital Heart Disease, patients with trivial stenosis (i.e., peak gradient ≤ 25 mm Hg) who were followed

for 25 years remained asymptomatic and had no significant progression of obstruction over time. For those with moderate pulmonary valve stenosis (i.e., peak gradient between 25 and 49 mm Hg), there was an approximately 20% chance of requiring intervention by 25 years of age. Most patients with severe stenosis (i.e., peak gradient of ≥ 50 mm Hg) require intervention (i.e., surgery or balloon valvuloplasty) by age 25 years. Patients with moderate to severe pulmonary stenosis should be considered for intervention even in the absence of symptoms.

Since 1985, percutaneous balloon valvuloplasty has been the accepted treatment for patients of all ages. Before 1985, surgical valvotomy had been the gold standard. Today, surgical valvotomy is reserved for patients who are unlikely to have successful results from balloon valvuloplasty, such as those with an extremely dysplastic or calcified valve.

Prognosis

After surgical valvotomy for isolated pulmonary stenosis, long-term survival is excellent. However, with longer follow-up the incidence of late complications and the need for reintervention do increase. The most common indication for reintervention is pulmonary valve replacement for severe pulmonary regurgitation. Other long-term complications include recurrent atrial arrhythmias, endocarditis, and residual subpulmonary obstruction.

Aortic Valve Stenosis

Definition and Epidemiology

Aortic valve stenosis is a common abnormality in adults with congenital heart disease. It is usually caused by a bicuspid aortic valve, which occurs in 1% to 2% of adults and is three times more common in males. It typically is an isolated lesion but can be associated with other defects such as coarctation of the aorta or VSD.

Pathology

Aortic valve stenosis results in pressure overload of the left ventricle, which increases wall stress and causes compensatory LV hypertrophy. Diastolic dysfunction and oxygen delivery-demand mismatch ensues. The patient may remain well compensated and asymptomatic for many years, but compensatory mechanisms eventually begin to fail, and LV dysfunction can develop. Patients with a bicuspid aortic valve have abnormal structure of the aortic wall that often leads to ascending aortic dilation.

Clinical Presentation

Most patients with aortic valve stenosis are asymptomatic and are diagnosed after a murmur is detected. The severity of obstruction at the time of diagnosis correlates with the pattern of progression. Symptoms are rare until patients have severe aortic valve stenosis (i.e., mean gradient by echocardiography of ≥ 40 mm Hg). Symptoms include chest pain, exertional dyspnea, near-syncope, and syncope. With any of these symptoms, the risk of sudden cardiac death is very high, and surgical intervention is mandated.

Patients with moderate to severe stenosis typically have decreased peripheral pulses, an increased apical impulse, and a

palpable thrill at the base of the heart. On auscultation, these patients have an ejection click followed by a crescendo-decrescendo systolic murmur, which is heard best at the left mid-sternal border and radiating to the right upper sternal border and the neck. Correlation between the degree of stenosis and the intensity of the murmur is not good. However, it is rare for a murmur of 2/6 or less to be associated with severe stenosis. Some patients with aortic stenosis also have aortic regurgitation, in which case a decrescendo diastolic murmur at the left midsternal border that radiates to the apex is detected at presentation.

Diagnosis

Many patients with significant aortic stenosis have LV hypertrophy identified on the ECG. However, the correlation between the severity of stenosis and the finding of LV hypertrophy on the ECG is unreliable. On chest radiography, most patients with severe aortic stenosis have a normal heart size unless there is concurrent aortic regurgitation. Post-stenotic dilation of the ascending aorta is common irrespective of degree of stenosis, and ascending aorta dilation is a common finding. It appears on the chest radiograph as a widened mediastinum.

Echocardiography is the gold standard for evaluation of the severity of aortic valve stenosis and the anatomic morphology of the aortic valve. Cardiac catheterization is primarily indicated to evaluate coronary artery disease before surgical intervention, because approximately one half of adults with symptomatic aortic valve stenosis have concurrent coronary artery disease.

Treatment

Patients with severe aortic stenosis and symptoms or asymptomatic patients with severe aortic valve stenosis and reduced LV systolic function (<50%) should be considered for intervention. Treatment involves manipulating the valve to reduce stenosis. This can be accomplished by transvenous balloon dilation of the valve, open surgical valvotomy, or surgical or catheter-based valve replacement. In absence of significant aortic regurgitation, most centers favor balloon dilation or surgical valvotomy for children and young adults who have pliable valves with fusion of the commissures. In older adults, aortic valve replacement is the treatment of choice.

Prognosis

The natural history of aortic valve stenosis in adults varies but is characterized by progressive stenosis over time. By 45 years of age, approximately 50% of bicuspid aortic valves have some degree of stenosis. Most patients requiring surgical valvotomy to relieve the stenosis before adulthood do well. However, by the 25-year follow-up, up to 40% of patients required a second operation for residual stenosis or regurgitation.

CYANOTIC HEART DISEASE

Tetralogy of Fallot

Definition and Epidemiology

Tetralogy of Fallot (TOF) is the most common cyanotic heart disease seen in adulthood, and it represents 10% of congenital heart defects. It consists of a large VSD, pulmonary stenosis

(which may be valvular, subvalvular, and or supra-valvular), an aorta that overrides the VSD, and RV hypertrophy.

Pathology

Newborns with TOF are cyanotic because of the right-to-left shunt through the VSD and decreased pulmonary blood flow. The amount of pulmonary blood flow depends on the severity of the obstruction through the RV outflow tract. By the time TOF patients reach adulthood, most have had complete repair or palliative surgery.

Many adults with repaired TOF have had a transannular patch (i.e., synthetic patch across the pulmonary annulus) placed to relieve the RV outflow tract obstruction. This patch causes obligatory free pulmonary regurgitation. Free pulmonary regurgitation can be well tolerated by the right ventricle for many years, but usually in the third or fourth decades, the right ventricle begins to dilate, and it may become dysfunctional. Significant RV dilation and dysfunction can lead to LV dysfunction, significant tricuspid regurgitation, and atrial or ventricular arrhythmias. Almost 29% of adults with repaired TOF also have a dilated ascending aorta due to increased blood flow through the aorta before repair.

Clinical Presentation

Patients with repaired TOF typically have normal oxygen saturation levels. On palpation, there often is an RV lift at the left lower sternal border. On auscultation, there typically is a widely split second heart sound with a to-and-fro murmur in the pulmonary area due to significant pulmonary regurgitation or, less commonly, aortic regurgitation. A holosystolic murmur due to tricuspid regurgitation may be heard at the left lower sternal border. Symptoms in the adult with repaired TOF may include exertional dyspnea, palpitations, syncope, and sudden cardiac death.

Diagnosis

The ECG almost universally reveals a right bundle branch block pattern in patients who underwent repair of TOF. The QRS duration from the standard surface ECG correlates with the degree of RV dilation and dysfunction. A maximum QRS duration of 180 milliseconds or more is a highly sensitive and relatively specific marker for sustained ventricular tachycardia and sudden cardiac death. Patients with significant pulmonary regurgitation often have cardiomegaly with dilated central pulmonary arteries identified on the chest radiograph. A right aortic arch occurs in 25% of cases, and it can be detected by close observation of the chest radiograph. An echocardiogram is useful for evaluating the RV outflow tract (e.g., pulmonary regurgitation, residual stenosis), biventricular size and function, tricuspid valve function, and ascending aortic size. MRI is the gold standard for assessing RV size and function (Fig. 6-2). It can also give an accurate assessment of the degree of pulmonary insufficiency and branch pulmonary artery anatomy.

Treatment

Treatment for TOF is surgical repair. Repair is typically performed between 3 to 12 months of age and consists of patch closure of the VSD and relief of the pulmonary outflow tract obstruction by patch augmentation of the RV outflow tract or

FIGURE 6-2 Short axis magnetic resonance images of the right and left ventricles with epicardial and endocardial tracings of both ventricular cavities. There are a predefined number of slices through the heart with a constant thickness. The volumes of the left and right ventricles in each slice are calculated and summed together in end diastole and end systole to determine the total right and left ventricular volumes (i.e., Simpson's method).

pulmonary valve annulus, or both. Reintervention is necessary in approximately 10% of adults with repaired TOF after 20 years of follow-up. With longer follow-up, the incidence of reintervention continues to increase. The most common indication for reintervention is pulmonary valve replacement for severe pulmonary valve regurgitation.

Prognosis

In the developed world, the unoperated adult with TOF has become a rarity because most patients undergo palliation (i.e., stenting) or repair in childhood. Survival of the unoperated patient to the seventh decade has been described but is rare. Only 11% of unrepaired patients are alive at 20 years of age and only 3% at 40 years.

Late survival after repair of TOF is excellent. Survival rates at 32 and 35 years are 86% and 85%, respectively, compared with 95% for age- and sex-matched controls. Importantly, most patients live an unrestricted life. However, many patients over time develop late symptoms related to numerous, long-term complications after TOF repair. Late complications include endocarditis, aortic regurgitation with or without aortic root dilation (typically due to damage of the aortic valve during VSD closure or to an intrinsic aortic root abnormality), LV dysfunction (from inadequate myocardial protection during previous repair or chronic LV volume overload due to long-standing palliative arterial shunts), residual pulmonary obstruction, residual pulmonary valve regurgitation, RV dysfunction (due to pulmonary regurgitation or pulmonary stenosis), atrial arrhythmias (typically atrial flutter), ventricular arrhythmias, and heart block.

Transposition of the Great Arteries

Definition and Epidemiology

Transposition of the great arteries (TGA) represents 3.8% of all congenital heart disease. In complete TGA, the aorta arises from the right ventricle and the pulmonary artery from the left ventricle. As a result, the systemic venous flow (i.e., blood with low oxygen content) is returned to the right ventricle and is then

pumped to the body through the aorta without passing through the lungs for gas exchange. The pulmonary venous flow (i.e., oxygenated blood) returning to the left ventricle is then pumped back to the lungs. As a result, the systemic and pulmonary circulations run in parallel. Oxygenation and survival depend on mixing between the systemic and pulmonary circulations at the atrial, ventricular, or PDA level. In 50% of cases, there are other anomalies: VSD (30%), pulmonary stenosis (5% to 10%), aortic stenosis, and coarctation of the aorta ($\leq 5\%$).

The first definitive operations for TGA (i.e., atrial switch procedures) were described by Senning in 1959 and Mustard in 1964. In these procedures, the systemic and pulmonary venous returns are rerouted in the atrium by constructing baffles. The systemic venous return from the superior and inferior vena cavae is directed through the mitral valve and into the left ventricle, which is connected to the pulmonary artery. The pulmonary venous return is then directed through the tricuspid valve into the right ventricle, which is connected to the aorta. These procedures leave the left ventricle as the pulmonary ventricle and the right ventricle as the systemic ventricle.

Over the past 10 to 20 years, the arterial switch procedure has gained popularity. During the procedure, the great arteries are transected and reanastomosed to the correct ventricle (i.e., left ventricle to the aorta and right ventricle to the pulmonary artery) along with coronary artery transfer. Operative survival after the arterial switch procedure is very good, with a surgical mortality rate of 2% to 5%.

Pathology

Most infants who do not have surgical intervention die in the first few months of life. For adults born with complete TGA who have had an atrial switch procedure, the right ventricle continues to be the systemic ventricle, and the left ventricle is the subpulmonic ventricle. Long-term follow-up series have demonstrated that the right ventricle can function as the systemic ventricle for 30 to 40 years, but with longer follow-up, systemic ventricular dysfunction continues to increase. At the 35-year follow-up, approximately 61% of patients have developed moderate or severe RV dysfunction.

Another common postoperative problem is the tricuspid valve. After the atrial switch procedure, the tricuspid valve remains the systemic atrioventricular valve and must tolerate systemic pressures. Due to changes in RV morphology and abnormal chordal attachments, the tricuspid valve is prone to become dysfunctional and develop significant regurgitation.

Significant coronary lesions, such as occlusions or stenoses, occur in 6.8% of patients who have had the arterial switch procedure. These lesions are likely related to suture lines or kinking at the time of reimplantation of the coronary arteries into the neo-aorta. Systemic LV function is usually normal. LV dysfunction is associated with coronary anomalies.

Clinical Presentation

In the repaired adult with an atrial switch procedure, the physical examination may reveal a murmur consistent with tricuspid valve insufficiency and a prominent second heart sound due to the anterior position of the aorta. Patients who have had an atrial switch procedure tend to have worsening functional status as the length of follow-up increases. They often have resting sinus bradycardia or a junctional rhythm. Palpitations due to atrial arrhythmias are common, occurring in up to 48% of patients 23 years after the atrial switch procedure.

In those who undergo the arterial switch procedure, the physical examination may reveal a murmur of neo-aortic or neo-pulmonic regurgitation. These patients usually have normal function status, but because of denervation of the heart, myocardial ischemia may manifest as atypical chest discomfort.

Diagnosis

After the atrial switch procedure, the ECG may show a loss of sinus rhythm with evidence of RV hypertrophy. Chest radiographs may show an enlarged cardiac silhouette in those with a dilated systemic right ventricle. An echocardiogram can demonstrate qualitative systemic RV size and function and the degree of tricuspid regurgitation. MRI is often used to accurately quantify systemic RV size and function, tricuspid valve function, and atrial baffle anatomy.

Echocardiography is used to assess pulmonary artery and branch pulmonary artery stenosis, neo-aortic and neo-pulmonic valve regurgitation, and ventricular function. MRI or computed tomography may be used to assess the anatomy of the branch pulmonary arteries. An exercise stress test is often used to evaluate myocardial ischemia.

Treatment

Treatment options are limited for adults with complete TGA repaired by atrial switch who have failing systemic right ventricles or significant tricuspid regurgitation, and evidence of significant benefit is lacking. However, potential treatments include medical therapy, revision of atrial baffles, pulmonary artery banding, resynchronization therapy, ventricular assist devices, and possible transplantation.

After the arterial switch procedure, catheter-based or surgical reintervention for pulmonary artery stenosis may be required in 5% to 25% of patients, Coronary artery revascularization is rarely required (0.46% of patients), as is neo-aortic valve repair or replacement (1.1% of patients).

Prognosis

Long-term follow-up studies after the atrial switch procedure show a small but ongoing attrition rate, with numerous intermediate- and long-term complications. Long-term complications include systemic RV dysfunction and tricuspid valve regurgitation, loss of sinus rhythm with the development of atrial arrhythmias (50% incidence by age 25), endocarditis, baffle leaks, baffle obstruction, and sinus node dysfunction requiring pacemaker placement. Intermediate-term complications include coronary artery compromise, pulmonary outflow tract obstruction (at the supra-avalvular level or takeoff of the peripheral pulmonary arteries), neo-aortic valve regurgitation, endocarditis, and neo-aorta dilation.

As a result of the long-term complications associated with the atrial switch procedure, the arterial switch operation has been the procedure of choice since 1985. Long-term data on the survival after the arterial switch operation do not exist, but intermediate-term results are promising: 88% at 10 and 15 years.

Valvular Heart Disease

Timothy D. Woods

INTRODUCTION

Although rheumatic fever remains a major cause of valvular heart disease in undeveloped countries, degenerative disease is the most common etiology in industrialized countries. As expected, the prevalence increases with age, to as high as 13.2% in those 75 years of age and older. The aortic and mitral valves are by far the most commonly affected valves.

There have been few randomized studies in valvular heart disease to guide management, and most of the joint guideline recommendations from the American College of Cardiology (ACC) and American Heart Association (AHA) are based on single-center studies or expert consensus (level C evidence).

AORTIC STENOSIS

Definition

When three normal aortic valve leaflets open fully in systole, they permit the left ventricular (LV) stroke volume to pass through the valve with little resistance to ejection. In aortic stenosis, leaflet excursion becomes progressively restricted over time. In advanced disease, the high resistance to ejection in systole invokes a cascade of physiologic sequelae that lead to the symptoms and physical examination findings of severe aortic stenosis.

Pathology

Aortic leaflet motion can become restricted for a variety of reasons. In westernized societies, the most common cause is senile degeneration. This term is a misnomer, in that this is not a degenerative disease but an active process involving the leaflet tissue that shares many characteristics with atherosclerosis. As plaques progress over time, calcified deposits accumulate on leaflets and increasingly restrict their motion.

A less common but important cause of aortic stenosis is congenitally abnormal leaflets. A two-leaflet, or bicuspid, aortic valve occurs in approximately 2% of the general population. Many patients with this condition develop premature thickening, fusion of the commissures, and calcification, resulting in abnormal flow characteristics and aortic stenosis at a relatively young age. Bicuspid aortic valves also put patients at increased risk for aortic enlargement and dissection and are associated with coarctation of the aorta.

Rheumatic fever is an uncommon cause of aortic stenosis in developed countries but is still seen in economically depressed regions. Rheumatic aortic stenosis is almost always associated

with concomitant involvement of the mitral valve. See [Table 7-1](#) for differential diagnosis of the valve lesions most commonly encountered clinically.

Clinical Presentation

Patients typically remain asymptomatic from aortic stenosis until the lesion reaches the severe range. Even after that point, most patients still experience an asymptomatic period of variable length. The onset of symptoms heralds an increase in mortality risk, as first described in 1968 by Ross and Braunwald, and guides management of this disorder. In order of increasing severity and decreasing survival, these symptoms are angina, syncope, and congestive heart failure ([Fig. 7-1](#)). Evaluation of patients with severe aortic stenosis must include careful screening for the development of these symptoms, and their detection can be especially challenging in sedentary individuals.

Diagnosis

The physical examination can be both sensitive and specific for the detection of aortic valve stenosis. The findings in severe stenosis either result from the outflow obstruction itself or are based on the direct physiologic sequelae of the obstruction.

The resistance to flow causes a pressure overload state of the left ventricle, resulting in concentric LV hypertrophy. This is

identified as increased voltages on the electrocardiogram (ECG) and a sustained but nondisplaced point of maximal impulse on palpation. The resistance to blood flow in systole results in the classic harsh crescendo-decrescendo systolic murmur. Although it is typically heard best in the aortic position, the murmur may radiate to the apical region (known as Gallivardin's phenomenon). Because the stiff, calcified, and restricted aortic valve leaflets make little excursion in systole, their closing no longer produces a sound; this results in an inaudible aortic component of S_2 . The ventricle cannot quickly eject blood through the small aortic orifice, and the carotid pulses may have a resulting low amplitude (described in Latin as *pulsus parvus*) and delay in reaching their peak (*et tardus*). See [Table 7-2](#) for a summary of physical examination, ECG, and chest radiography findings for chronic valvular heart lesions.

Transthoracic echocardiography (TTE) has become the “gold standard” for confirming the presence of severe aortic valve stenosis. It offers the ability to visualize the valve as well as the use of Doppler imaging to estimate the peak instantaneous and mean valve gradients. Importantly, an estimated valve area can be derived for a more reliable measure of stenosis severity. Criteria for differentiating mild, moderate, and severe stenosis have been published ([Table 7-3](#)). In most cases, echocardiography is sufficiently accurate for clinical decision making regarding the valve, but patients may still require invasive coronary or computed tomographic (CT) angiography to exclude obstructive coronary disease before valve replacement. If doubt remains regarding stenosis severity, hemodynamic measurements at the time of cardiac catheterization can confirm the degree of stenosis.

Treatment

For decades, surgical replacement of the aortic valve was the only treatment proven to prolong life in symptomatic severe aortic valve stenosis. Aortic valve replacement (AVR) is a class I indication (level B evidence) for symptomatic patients with severe aortic stenosis. AVR is also a class I indication in patients with asymptomatic aortic stenosis who have LV systolic dysfunction that is believed to be the result of the stenosis (level C evidence). AVR can restore survival rates in these patients almost to normal.

For patients who are deemed to be at acceptable surgical risk, there are two prosthetic options that may be considered for AVR. Mechanical prosthetic valves (see example in [Fig. 7-2](#)) have the advantage of excellent flow characteristics; they typically last for the patient's lifetime but require anticoagulation. Bioprosthetic valves ([Fig. 7-3](#)), which are made from either porcine or bovine material, have the advantage of not requiring long-term anticoagulation. Because the leaflets are made of biologic tissue, the lifespan and durability of bioprosthetic valves are finite, and valve re-replacement is invariably required 10 to 20 years after implantation.

In those for whom open surgical replacement of their aortic valve would pose an inappropriately high risk, a third option became available in the United States in November of 2012 when the U.S. Food and Drug Administration (FDA) approved the use of a percutaneously placed bioprosthetic valve ([Fig. 7-4](#)). In appropriately selected patients, this valve may be delivered via a catheter through the femoral artery to the aortic valve, and then expanded into position by a balloon, effectively squeezing the native valve against the aortic wall. It can also be placed through a small apical incision in the chest wall, entering the heart through the LV apex. Complications may include regurgitation around the prosthesis, stroke, and damage to the peripheral vessels during catheter insertion. Currently, these techniques are approved in the United States only for patients with symptomatic severe stenosis who have been declared ineligible for open surgical valve replacement due to excessive risk.

Prognosis

The mortality risk of asymptomatic severe aortic valve stenosis appears to be very low based on available studies, probably less than 1% per year. However, in sedentary individuals, absence of symptoms can be deceiving. On occasion, it is reasonable to perform carefully monitored exercise stress testing in patients professing to be asymptomatic. Once symptoms have appeared, the survival rate with severe stenosis, as demonstrated by Ross and Braunwald, is abysmal, with about half of those patients who develop heart failure dying within 2 years after symptom onset.

AORTIC REGURGITATION

Definition

When aortic valve leaflets fail to adequately coapt in diastole, blood regurgitates into the left ventricle. As with other compensatory mechanisms of the body, the left ventricle can tolerate large volumes if the progression to severe regurgitation occurs slowly enough. When severe regurgitation develops rapidly, hemodynamic collapse and death can occur. Therefore, the causes, clinical presentation, and management of acute versus chronic severe aortic regurgitation should be considered separately.

Pathology

Aortic regurgitation may occur as a result of leaflet abnormalities, aortic root disease, or a combination of these factors. Infectious endocarditis and aortic dissection are the two most

TABLE 7-2 CHARACTERISTIC PHYSICAL, ELECTROCARDIOGRAPHIC, AND CHEST RADIOGRAPHIC FINDINGS IN CHRONIC ACQUIRED VALVULAR HEART DISEASE

CAUSE	PHYSICAL FINDINGS*	ELECTROCARDIOGRAM	RADIOGRAPH
Aortic stenosis	Pulsus parvus et tardus (may be absent in older patients or in patients with associated aortic regurgitation); carotid <i>shudder</i> (coarse thrill) Ejection murmur radiates to base of neck; peaks late in systole if stenosis is severe Sustained but not significantly displaced LV impulse A ₂ decreased, S ₂ single or paradoxically split S ₄ gallop, often palpable	LV hypertrophy Left bundle branch block is also common Rare heart block from calcific involvement of conduction system	LV prominence without dilation Post-stenotic aortic root dilation Aortic valve calcification
Aortic regurgitation	Increased pulse pressure Bifid carotid pulses Rapid pulse upstroke and collapse LV impulse hyperdynamic and displaced laterally Diastolic decrescendo murmur; duration related to severity Systolic flow murmur S _{3G} common	LV hypertrophy, often with narrow deep Q waves	LV and aortic dilation
Mitral stenosis	Loud S ₁ OS S ₂ -OS interval inversely related to stenosis severity S ₁ not loud and OS absent if valve heavily calcified Signs of pulmonary arterial hypertension	LA abnormality Atrial fibrillation common RV hypertrophy pattern may develop if associated pulmonary arterial hypertension is present	Large LA: double-density sign, posterior displacement of esophagus, elevation of left mainstem bronchus Straightening of left heart border as a result of enlarged left appendage Small or normal-sized LV Large pulmonary artery Pulmonary venous congestion Enlarged LA and LV Pulmonary venous congestion
Mitral regurgitation	Hyperdynamic LV impulse S ₃ Widely split S ₂ may occur Holosystolic apical murmur radiating to axilla (murmur may be atypical with acute mitral regurgitation, papillary muscle dysfunction, or mitral valve prolapse)	LA abnormality LV hypertrophy Atrial fibrillation	Enlarged LA and LV Pulmonary venous congestion
Mitral valve prolapse	One or more systolic clicks, often midsystolic, followed by late systolic murmur Auscultatory findings dynamic Symptoms may include tall thin habitus, pectus excavatum, straight back syndrome	Often normal Occasionally ST-segment depression or T wave changes or both in inferior leads	Depends on degree of valve regurgitation and presence or absence of those abnormalities
Tricuspid stenosis	Jugular venous distention with prominent <i>a</i> wave if sinus rhythm Tricuspid OS and diastolic rumble at left sternal border; may be overshadowed by concomitant mitral stenosis Tricuspid OS and rumble increased during inspiration	Right atrial abnormality Atrial fibrillation common	Large RA
Tricuspid regurgitation	Jugular venous distention with large regurgitant (systolic) wave Systolic murmur at left sternal border, increased with inspiration Diastolic flow rumble RV S ₃ increased with inspiration Hepatomegaly with systolic pulsation	RA abnormality; findings are often related to the cause of the tricuspid regurgitation	RA and RV enlarged; findings are often related to the cause of the tricuspid regurgitation

LA, Left atrium; LV, left ventricle; OS, opening snap; RA, right atrium; RV, right ventricle; S_{3G}, S₃ gallop.

*Findings are influenced by the severity and chronicity of the valve disorder.

common causes of acute severe aortic valve regurgitation. Congenitally abnormal (most commonly bicuspid) aortic valve leaflets often lead to chronic severe aortic regurgitation (see [Table 7-1](#)).

Clinical Presentation

Acute Severe Regurgitation

Patients may have symptoms related to their underlying pathology, such as fever and malaise from endocarditis or severe chest pain due to aortic dissection. In addition, they are likely to suffer progressive signs and symptoms of cardiogenic shock, including tachycardia and hypotension caused by severely impaired cardiac

output and fulminant pulmonary edema due to markedly elevated filling pressures. In general, the more rapidly the severity of regurgitation evolves, the less well it is hemodynamically tolerated.

Chronic Severe Aortic Regurgitation

When severe regurgitation develops slowly over months to years, compensatory mechanisms such as LV remodeling lead to chamber dilatation and increased compliance, permitting even large regurgitant volumes to be well tolerated. At onset, the symptoms are typically exertional, including dyspnea and fatigue. Orthopnea and occasionally chest pain can develop in the absence of epicardial coronary disease.

TABLE 7-3 MEASURES OF AORTIC STENOSIS SEVERITY

INDICATOR	NORMAL	MILD	MODERATE	SEVERE
Aortic valve area (cm ²)	>2.0	1.5-2.0	1.0-1.5	<1.0
Mean gradient (mm Hg)		<25	25-40	>40
Peak jet velocity (m/sec)	<2.0	2-3	3-4	>4

Data from Baumgartner H, Hung J, Bermego J, et al: Echocardiographic assessment of valve stenosis: EAE/ASE recommendations for clinical practice, *J Am Soc Echocardiogr* 22:1-22, 2009.

**FIGURE 7-2** Medtronic bileaflet mechanical prosthetic valve. (Courtesy of Medtronic, Inc.)**FIGURE 7-3** Medtronic Hancock II bioprosthetic valve. (Courtesy of Medtronic, Inc.)

Diagnosis

Acute Severe Regurgitation

The sudden development of severe regurgitation is poorly tolerated by the normal left ventricle. Left heart filling pressures rise rapidly, and respiratory failure from pulmonary edema develops.

**FIGURE 7-4** Edwards SAPIEN transcatheter heart valve. (Courtesy of Edwards Lifesciences LLC, Irvine, Calif.)

The decreased effective cardiac output results in a resting tachycardia and hypotension. The patient's tachypnea and rapid heart rate impede recognition of the typical diastolic decrescendo murmur because of marked shortening of diastole and early termination of the murmur. The diagnosis can be easily missed, particularly with hasty and errant performance of a cursory examination of an unstable patient in a noisy emergency room. A chest radiograph showing a normal-size heart with pulmonary edema should raise suspicions. Timely TTE or transesophageal echocardiography (TEE) is key to establishing the diagnosis early in the disease course.

Chronic Severe Regurgitation

When time permits compensatory mechanisms such as LV dilation to gradually evolve, even a very large regurgitant volume can be tolerated well for many years. The resulting large stroke volume, along with the regurgitation, is responsible for many of the findings on physical examination.

The enlarged heart caused by ventricular volume overload results in a laterally displaced and diffuse point of maximal impulse (PMI), as well as cardiomegaly by chest radiography. A low diastolic blood pressure is present and results in a large pulse pressure. The increased diastolic filling results in a soft S_1 heart sound, and an S_3 gallop may be present even in the absence of clinical heart failure. Auscultation of the typical diastolic decrescendo murmur, heard at either the left or the right sternal border, can be improved by examining the patient as he or she is leaning forward at end-expiration. A diastolic flow rumble at the left sternal border may be confused with mitral stenosis; this is known as an Austin-Flint murmur. A soft systolic murmur may be present because of the large stroke volume ejected in systole (see Table 7-2). The large stroke volume also results in a number of peripheral physical examination findings such as Quincke's pulse (systolic plethora and diastolic nail bed blanching with pressure), Musset's sign (head bobbing) and Corrigan's pulse (a bounding full carotid pulse with rapid downstroke). These findings, including the increased pulse pressure, are present only after compensatory cardiac changes have evolved and are not present with acute severe regurgitation.

Treatment

Acute Severe Regurgitation

The mainstay of management in the patient with cardiogenic shock consists of attempts at medical stabilization through afterload reduction while preparing for urgent surgery. Death due to pulmonary edema, ventricular arrhythmias, or hemodynamic collapse is well described, and surgery is the established standard of care for these severely ill patients.

Drugs such as intravenous nitroprusside can be useful to rapidly achieve afterload reduction and improve cardiac output while the patient is prepared for urgent surgery. Diuretics may be used simultaneously to improve pulmonary edema. β -Blockers, although useful with aortic dissection, can cause further hemodynamic deterioration when acute severe regurgitation accompanies the dissection.

Chronic Severe Regurgitation

Patients may tolerate this lesion well due to compensatory mechanisms, remaining asymptomatic for many years. Although one study suggested that antihypertensive therapy with a dihydropyridine calcium blocker delays the need for surgery, a more recent study called into question the efficacy of either calcium blocker or angiotensin-converting enzyme (ACE) inhibitor therapy. These antihypertensives are considered a class IIb indication (level B evidence) for use in cases of asymptomatic severe aortic regurgitation with LV enlargement and normal systolic function. No studies of level A evidence have been completed to evaluate indications for AVR. Level B and C evidence indicates that AVR should be recommended based on the development of symptoms or asymptomatic structural changes in the heart. Specifically, a decrease in LV ejection fraction to 50% or less, even in an asymptomatic patient, is considered a class I indication for surgery. Similarly, marked diastolic (>75 mm) or systolic (>55 mm) LV enlargement, despite an absence of symptoms, is a class IIa indication for AVR. Finally, AVR has a class I indication in symptomatic patients, regardless of the status of their LV systolic function.

Options for prosthetic valve selection are similar to those for aortic stenosis, with the exception that a percutaneous method of valve replacement has not been approved by the FDA for this indication.

Prognosis

Acute Severe Regurgitation

Any cardiac surgery that has to be performed urgently entails greater surgical risk. When the cause of aortic regurgitation is infectious endocarditis, the long-term mortality rate, even with surgery, can be as high as 50%.

Chronic Severe Regurgitation

Close monitoring of patients for the evolution of surgical indications, as described earlier, leads to an excellent prognosis with acceptably low surgical mortality rates and survival curves that approach those of an otherwise normal population.

MITRAL STENOSIS

Definition

When the mitral leaflets open in diastole, they permit the entire stroke volume to pass from the atria to the left ventricle at relatively low pressure gradients. If mitral leaflet motion becomes restricted in opening, resistance to flow develops. The resulting severity of stenosis can be described by the pressure gradient that develops between the left atrium and left ventricle during diastole or by the size of the mitral valve opening.

Pathology

Both leaflet- and non-leaflet-related causes of stenosis can occur. Although restricted mitral leaflet motion due to rheumatic heart disease is by far the most common cause, immune disease affecting the valve and congenital abnormalities can also result in stenosis. Mitral inflow stenosis can also occasionally occur from severe calcification around the mitral annulus. A left atrial myxoma may lodge persistently or intermittently in the mitral annulus, resulting in obstruction to ventricular inflow. Finally, mitral stenosis can be the inadvertent outcome of surgical mitral valve repair or replacement.

Regardless of the etiology, the symptoms of mitral stenosis develop as left atrial pressure increases in response to forward flow limitation. As this increased pressure is reflected back to the lungs, pulmonary congestion evolves and, if severe enough, ultimately leads to pulmonary edema. The resulting pulmonary hypertension eventually results in right ventricular (RV) failure.

The mean gradient between the left atrium and left ventricle, measured at the valve orifice during diastole, is the most common way of describing the stenosis severity. The normal mitral valve area is 4 to 5 cm², and a normal gradient is less than 2 mm Hg. Although symptoms typically do not develop until the valve area is reduced to less than 2.5 cm², both cardiac output and heart rate can significantly affect the onset of symptoms for any particular degree of stenosis. Increased cardiac output, with a resulting increase in gradient, can lead to symptoms in a previously asymptomatic patient without change in mitral valve area (Fig. 7-5). Pregnancy is an example of a physiologic state of increased cardiac output that may produce symptoms in someone who was previously asymptomatic without any change in valve area. Shortening of the diastolic filling period after onset of a tachyarrhythmia is another reason that symptoms may suddenly develop without any anatomic change in valve size.

Rheumatic Valve Disease

In some patients who develop group A streptococcal pharyngitis, an abnormal immune response results in rheumatic fever, which can occur anywhere from 10 days to 3 weeks after the initial infection if left untreated. It typically occurs in children 6 to 15 years of age, with clinical manifestations leading to a diagnosis as summarized in the revised Jones Criteria (Table 7-4). The diagnosis is made based on the presence of two major or one major and two minor Jones criteria occurring after a recent documented group A streptococcal infection.

The pancarditis that occurs affects the pericardium and the myocardium as well as the valve tissue. The inflammation eventually leads to chordal thickening, shortening, and together with

FIGURE 7-5 Graphic illustration of the relationship between the diastolic gradient across the mitral valve and the flow through the mitral valve. As the mitral valve becomes more stenotic, the pressure gradient across the valve must increase to maintain flow into the left ventricle. If the mitral opening is 1 cm^2 or smaller, the flow rate into the left ventricle cannot be significantly increased, despite a significantly elevated pressure gradient across the mitral valve. (Modified from Wallace AG: Pathophysiology of cardiovascular disease. In Smith LH Jr, Thier SO, editors: The international textbook of medicine (vol 1), Philadelphia, 1981, Saunders, p. 1192.)

TABLE 7-4 REVISED JONES CRITERIA FOR DIAGNOSIS OF RHEUMATIC FEVER*

MAJOR CRITERIA	MINOR CRITERIA
Carditis (pleuritic chest pain, friction rub, heart failure)	Fever
Polyarthritides	Arthralgia
Chorea	Previous rheumatic fever or known rheumatic heart disease
Erythema marginatum	
Subcutaneous nodules	

*Rheumatic fever is diagnosed based on the presence of two major criteria or one major and two minor criteria after a recent documented group A streptococcal infection.

leaflet commissural fusion, a funnel-shaped, flow-limiting orifice forms. Although the aortic valve can be affected as well, it is almost never involved without concomitant mitral valve involvement. In less developed countries, the incidence is much higher than in westernized societies, and the time from acute rheumatic fever to symptomatic stenosis is often years instead of decades.

Clinical Presentation

Patients typically remain asymptomatic until the valve area is reduced to approximately 1.5 cm^2 or less. Initial symptoms are usually exertional in nature, with noticeable dyspnea or fatigue that resolves with rest. As the stenosis progresses, symptoms develop earlier with exercise, until ultimately they are markedly limiting. If the cause remains undetected, the markedly elevated left atrial and pulmonary pressures will lead to significant left atrial enlargement. Even in the absence of atrial fibrillation, there is increased risk of thromboembolism. When atrial fibrillation occurs, it carries an approximate 18-fold increased risk of cerebrovascular accident. Secondary changes in the pulmonary vasculature may occur over time, rarely resulting in fixed pulmonary hypertension that is not relieved by valve surgery performed at this late stage. Finally, the right ventricle responds adversely to

the chronic severe pulmonary hypertension, and clinical right-sided heart failure ensues.

Diagnosis

Only about 60% of patients with rheumatic heart disease recall having rheumatic fever as a child, and the history cannot be relied on to suspect the diagnosis. Elicitation of the symptoms, followed by confirming physical examination findings, is the cornerstone of diagnosis.

Early in the disease course, there is typically a prominent S_1 sound. As motion of the leaflets becomes increasingly restricted, S_1 may become soft. The opening in diastole begins with a snap and is followed by a low-pitched diastolic rumble, heard best with the bell of a stethoscope at the apex in the left lateral decubitus position. The length of time from S_2 to the mitral opening snap can help in estimating stenosis severity, with shorter intervals indicating proportionally increased severity.

The ECG may show left atrial enlargement and, ultimately, right atrial enlargement; right axis deviation and right bundle branch block are possible in later stages. Left atrial enlargement and dilation of the main pulmonary artery are often identified by chest radiography. In advanced cases, RV enlargement may be evident (see Table 7-2).

Confirmation is typically by echocardiography, and the valve can be evaluated by several methods. The restricted motion of the mitral leaflets in diastole is highly characteristic of rheumatic disease. The valve leaflets appear to dome or form the shape of a hockey stick. The motion of the valve leaflets forms an overall funnel-shaped mitral orifice (Fig. 7-6). Finally, a Doppler examination can be used to estimate the mitral valve area and to measure the mean diastolic gradient across the valve. If doubt remains regarding mitral stenosis severity despite these techniques, invasive pressure measurements taken directly from the left ventricle and atrium will permit calculation of a valve area and mean mitral gradient.

Treatment

In general, symptoms guide the treatment of mitral stenosis. It is believed that asymptomatic cases do not require treatment unless significant pulmonary hypertension has developed (class I indication, level C evidence) or new-onset atrial fibrillation has occurred (class IIb, level C).

In most patients, exertional symptoms drive the need for therapy. As with all other valve lesions, a mechanical (percutaneous or surgical) intervention is required to alter the natural history. In the case of mitral stenosis, an invasive procedure that can be performed in a catheterization laboratory, known as percutaneous balloon mitral valvuloplasty (PBMV), has gained favor over the past 2 decades. A balloon is delivered through the femoral vein across the mitral orifice and inflated (Fig. 7-7); this procedure is repeated with successively larger balloons until the valve area is significantly improved. PBMV has a class I indication for symptomatic patients with moderate or severe mitral stenosis, providing their leaflet morphology is acceptable for this technique.

If the patient is deemed a poor candidate for PBMV, surgical commissurotomy or valve replacement is considered to be a class IIa indication in the symptomatic patient. Because mitral stenosis

FIGURE 7-6 Abnormal motion of the mitral valve in rheumatic mitral stenosis. **A**, Transesophageal echocardiographic (TEE) image demonstrates the abnormal doming motion of the mitral leaflets in diastole. The blue arrow denotes the orientation of image **B**. **B**, Three-dimensional TEE image demonstrates the appearance of the mitral opening if viewed looking down at the valve from inside the left atrium (LA), a surgeon's orientation to the valve. The area of the mitral opening between anterior and posterior leaflets is well visualized, and the area measured from this view is used to estimate stenosis severity. LV, Left ventricle.

FIGURE 7-7 Balloon inflation during percutaneous balloon mitral valvuloplasty for treatment of mitral stenosis. Orientation is the same as in Figure 7-6A, and the inflated balloon is visible between the leaflets. LA, Left atrium; LV, left ventricle.

is primarily an anatomic problem, there is a limited role for medical therapy in improving survival. However, diuretics and heart rate slowing can be very helpful in controlling symptoms while a definitive mechanical solution to the problem is sought. Anticoagulation is key to prevent thromboembolism in any patient with a previous event or with onset of atrial fibrillation.

Prognosis

Although survival in asymptomatic patients is good, onset of symptoms heralds a rise in risk. Given the physiology of the disease, these risks understandably include heart failure, thromboembolism, and death. One study suggested a 5-year survival rate of only 44% in symptomatic patients who declined treatment.

MITRAL REGURGITATION

Definition

Mitral leaflet coaptation in systole should produce a tight seal to prevent regurgitation. This mechanism can fail for a variety of

reasons, resulting in a problem for the left ventricle similar to that caused by aortic regurgitation—both being states of volume overload. Severe mitral regurgitation is also similar to aortic regurgitation in that its hemodynamic and clinical significance depend on the rapidity of onset.

Pathology

In considering the causes of mitral regurgitation, it is important to understand the anatomic components, which act collectively to provide valvular competence. Correct function of this system starts at the LV wall where the papillary muscles attach. A system of primary, secondary, and tertiary chordae provides the anatomic and structural attachments between the papillary muscles and the mitral leaflets. The leaflets, in turn, are attached at their circumference to the annulus. When one or more of these components are defective, regurgitation occurs. Given the complexity of this system, it is useful to divide major causes into valve leaflet abnormalities (i.e., primary or organic etiology) and causes related to structures other than the leaflets (i.e., secondary or functional etiology) (see Table 7-1).

Valvular etiologies include mitral valve prolapse (Fig. 7-8) and rheumatic valvular disease. When the LV wall fails to contract (after myocardial infarction) or the mitral annulus is enlarged, the normal valve leaflets are prevented from coapting properly, resulting in functional regurgitation.

Some causes, such as endocarditis of the valve leaflet or rupture of valve chordae, can occur suddenly and result in acute severe mitral regurgitation. Like aortic regurgitation, this condition is poorly tolerated medically and can be life-threatening without surgical intervention. In contrast, mitral valve prolapse can result in slow progression to chronic severe mitral regurgitation.

Acute severe mitral regurgitation results in a sudden increase in left atrial pressure. Given that a significant portion of the LV stroke volume then passes into the low-impedance left atrium during systole, cardiac output drops. The resulting pulmonary edema and hypotension often become life-threatening if the progression is not interrupted.

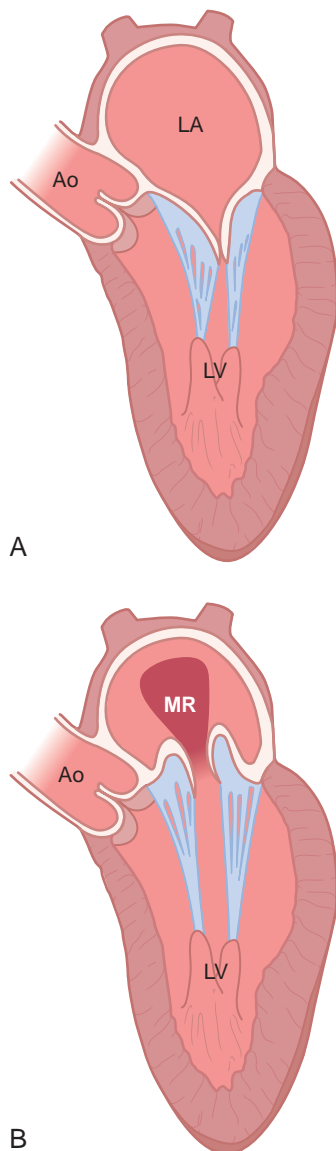

FIGURE 7-8 Degenerative mitral valve disease is an inheritable leaflet abnormality that often results in mitral valve prolapse, the most common cause of mitral regurgitation. **A**, Diagram shows normal leaflet position during closure in systole. **B**, Prolapsing motion of the mitral leaflets above the mitral annulus during systole results in mitral regurgitation (MR). Ao, Aorta; LA, left atrium; LV, left ventricle.

When the regurgitation develops slowly over months to years, the heart typically compensates with ventricular remodeling, enlargement, and increased compliance. This permits the stroke volume to be maintained at normal filling pressures for prolonged periods, preventing symptoms. Eventually, the systolic function declines or the patient develops symptoms, heralding the need for surgery.

Clinical Presentation

Patients with acute severe mitral regurgitation are acutely ill at presentation and often are in cardiogenic shock. In addition to dyspnea, hypotension, and tachycardia, they may have signs and symptoms of the primary etiology. For example, a patient who has a ruptured papillary muscle due to a myocardial infarction may also have chest pain and ECG changes at presentation.

When the heart has time to develop compensatory mechanisms with chronic severe regurgitation, patients may remain asymptomatic and not even realize the condition is present until it is identified by physical examination. Over time, exertional fatigue and shortness of breath develop. If the condition is not identified in these early stages, the patient will ultimately develop typical signs and symptoms of chronic congestive heart failure and arrhythmia.

Diagnosis

In patients with acute severe regurgitation, the examination findings typically observed with mitral regurgitation may be absent or difficult to detect. Rapid rise in left atrial pressure during systole results in an abbreviated systolic murmur. When tachypnea and tachycardia are present as additional confounders to the physical examination, the diagnosis can be easily missed at the bedside (see [Table 7-2](#)). If clinical suspicion is present, echocardiography is an essential tool in rapidly confirming the diagnosis.

A patient with chronic severe mitral regurgitation is more likely to have a classic holosystolic murmur present at the LV apex. If the cause of the regurgitation is mitral valve prolapse, there is often a mid-systolic click followed by a late-peaking systolic murmur. The cardiac enlargement that has evolved may be appreciated by a diffuse, laterally displaced PMI. An S_3 gallop may be present, even in the absence of congestive heart failure.

Diagnosis is best confirmed by TTE. This technique is important, not only for quantitatively estimating the regurgitation severity but for defining the anatomic mechanism, which has significant implications for management. If the valvular abnormality cannot be confirmed by transthoracic imaging, both two- and three-dimensional TEEs are very sensitive for identifying the anatomic mechanism of regurgitation.

Techniques in the cardiac catheterization laboratory can be useful in evaluating the severity of regurgitation, but these are less commonly used and have been largely supplanted by echocardiography.

Treatment

As in patients with acute severe aortic regurgitation, the primary objective is to stabilize the patient while urgently arranging for definitive mechanical correction—namely, repair or replacement of the mitral valve. In contrast to acute severe aortic regurgitation, an intraaortic balloon pump is an option for reducing afterload and improving cardiac output in patients with mitral regurgitation. Otherwise, intravenous sodium nitroprusside or hydralazine can be attempted to lower afterload, or a diuretic can be used to reduce pulmonary edema if hypotension is not prohibitive.

In patients with chronic severe mitral regurgitation, the clinical status may remain stable, and many experts advocate a strategy of “watchful waiting.” In general, the active patient may be monitored for development of exertional symptoms. However, even in the absence of symptoms, patients can develop occult LV systolic dysfunction. Therefore, periodic echocardiographic surveillance in asymptomatic patients is critical to prevent irreversible systolic dysfunction.

When a patient develops exertional symptoms or congestive heart failure, providing there has not already been a large decline

in LV systolic function, mitral repair or replacement surgery is considered a class I indication (level B evidence). When an asymptomatic patient develops an LV ejection fraction of 60% or less, surgery is again a class I level B recommendation. When patients with chronic severe mitral regurgitation develop new-onset atrial fibrillation or confirmed significant pulmonary hypertension, surgery is advised with a class IIa recommendation (level C evidence). There are no medications that have been confirmed as able to alter the natural history of chronic severe mitral regurgitation, and no specific medical therapy in the absence of hypertension is recommended.

Prognosis

Rarely, patients with acute severe mitral regurgitation rapidly improve and enter a prolonged compensated phase in which watchful waiting is appropriate. However, most patients require urgent surgical intervention for survival. In chronic severe mitral regurgitation, it has been demonstrated that a program of watchful waiting, if diligently followed for appearance of a surgical indication as described, leads to excellent patient outcomes. However, failure to act when surgical criteria are met clearly leads to increased risk of morbidity and mortality.

TRICUSPID VALVE DISEASE

Definition

Anatomic requirements for tricuspid competence are similar to those described for the mitral valve: A complex of valve tissue and supportive structures must work in concert to maintain competence. With the tricuspid valve, however, three leaflets must come together appropriately to prevent regurgitation.

Tricuspid valve stenosis is similar to mitral stenosis in that the restriction of leaflet motion results in obstruction of right atrial emptying in diastole. The degree of stenosis determines the onset and severity of symptoms.

Pathology

Tricuspid stenosis in adults most often occurs as a result of rheumatic heart disease, which is uncommon in developed countries. Tricuspid valve involvement is less common than mitral and aortic valve involvement in rheumatic disease, and it almost never occurs without the mitral valve also being affected. Congenital abnormalities resulting in stenosis occur but are typically identified in childhood. Large leaflet vegetations and carcinoid disease may rarely cause stenosis, as may orifice obstruction from a large myxoma.

Tricuspid regurgitation can result from leaflet abnormalities (primary) or from another pathology affecting the right ventricle (functional). Functional tricuspid regurgitation is more common clinically; it occurs in patients with significant pulmonary hypertension, often caused by left-sided heart disease or lung disease. RV enlargement resulting from an atrial septal defect or anomalous pulmonary venous return can lead to severe functional tricuspid regurgitation. Primary leaflet abnormalities can occur from infectious endocarditis, carcinoid, or blunt chest trauma or iatrogenically from pacemaker or defibrillator leads (see Table 7-1).

Clinical Presentation

Because patients with tricuspid stenosis most often have mitral or aortic valve disease, or both, it is difficult to differentiate those symptoms that are solely caused by tricuspid disease. Symptoms of isolated tricuspid stenosis are similar to those of right-sided heart failure, although RV function is typically normal. These symptoms include edema and ascites as well as fatigue and dyspnea from low cardiac output.

Tricuspid regurgitation similarly results in heart failure symptoms of peripheral edema and low cardiac output that can include fatigue and exertional dyspnea. As RV systolic function deteriorates over time, symptoms progress and become more challenging to treat. Eventually, bowel edema results in decreased appetite and decreased absorption of oral diuretics, leading to malnutrition and a downward clinical spiral. As in tricuspid stenosis, the enlarging right atrium can precipitate atrial arrhythmias that further confound therapy.

Diagnosis

Physical examination for tricuspid stenosis is confounded by findings from left-sided valve disease in most cases. In normal sinus rhythm, an atrium contracting against a restricted tricuspid orifice can result in a prominent *a* wave on inspection of jugular venous pulsations. An opening snap may be audible. A soft diastolic-flow rumble may be identified by placing the bell of a stethoscope at the right parasternal border but may be inaudible. The key to distinguishing murmurs of right-sided origin is the respiratory variation in intensity, which augments with inspiration. Chest radiography may demonstrate right atrial enlargement, but there is no RV or pulmonary artery enlargement or prominence (see Table 7-2). A normal tricuspid valve has an area of 4 to 5 cm². Severe stenosis is thought to be present when the area is reduced to less than 1 cm² or the mean tricuspid valve gradient is 7 mm Hg or greater. Right heart catheterization is possible but is rarely needed to confirm the diagnosis of tricuspid stenosis.

The holosystolic murmur of tricuspid regurgitation can be soft or absent, and the diagnosis may go unsuspected. When present, the murmur is typically loudest at the left sternal border and increases with inspiration. Inspection of the jugular veins may demonstrate a characteristic *v* wave. Hepatic enlargement, with a pulsatile liver in systole, may be felt. Right atrial and ventricular enlargement may be seen on a chest radiograph.

TTE is the gold standard imaging modality for identifying the presence, cause, and severity of both tricuspid stenosis and tricuspid regurgitation. If the right heart cannot be adequately visualized by this technique, TEE or magnetic resonance imaging (MRI) can be helpful.

Treatment

There is no effective medical treatment for symptomatic isolated severe tricuspid valve stenosis. Diuretics typically reduce the cardiac output further, improving fluid status at the cost of worsening fatigue and dyspnea. Although percutaneous valvuloplasty of the tricuspid valve has been described, patients do poorly if there is resulting significant regurgitation. Although there are no studies to confirm optimal treatment of isolated symptomatic

severe tricuspid stenosis, the European Society of Cardiology rates valvuloplasty or valve replacement in symptomatic patients, or in those undergoing left-sided valve intervention, as a class I indication (level C evidence).

Severe tricuspid regurgitation is associated with increased risks of morbidity and mortality. Diuretics are useful initially to improve edema. As the disease progresses, increasing doses are required, until eventually patients become unresponsive. The improvement in their edema also comes at the expense of more fatigue and dyspnea due to limited cardiac output. Tricuspid valve repair or replacement is the only proven method of interrupting this clinical progression. Severe symptomatic tricuspid regurgitation therefore carries a class I recommendation for surgery (level C evidence).

Prognosis

There are few data on the natural history of isolated unoperated tricuspid valve stenosis. Guideline recommendations for therapy are based on expert consensus, and individual patient management is largely based on clinical judgment given the infrequency of isolated stenosis.

A study performed at the Mayo Clinic examined 60 patients with severe tricuspid regurgitation treated over a 20-year period. Patients with unoperated tricuspid regurgitation had a 4.5% per year mortality rate, significantly higher than that for a matched U.S. population, supporting the class I recommendation for surgery.

PULMONARY VALVE DISEASE

Definition

Pulmonary valve stenosis, similar to stenosis of the aortic valve, results from incomplete opening of the three valve leaflets in systole and leads to a pressure gradient between right ventricle and the pulmonary artery. The severity of the resulting obstruction to flow determines the clinical sequelae. Isolated significant pulmonary valve regurgitation is uncommon and is well tolerated unless severe.

Pathology

Pulmonary valve stenosis is rare. It is caused predominantly by congenital heart disease and typically is identified in childhood. It is very common in certain congenital disorders, such as Noonan's syndrome. Rare acquired causes of the disease include carcinoid tumor and rheumatic heart disease, but other valves are typically involved as well in these conditions.

Moderate or severe pulmonary valve regurgitation can similarly result from congenital heart disease or, even more likely, from previous mechanical treatment of congenital pulmonary valve stenosis. Valvular causes include trauma, carcinoid, and endocarditis. RV outflow tract and pulmonary artery enlargement may also result in failed central leaflet coaptation with resulting regurgitation.

Clinical Presentation

Although the diagnosis of pulmonary valve stenosis is most often made in childhood, it is occasionally first identified in an adult.

The RV pressure overload of severe stenosis results most commonly in symptoms of fatigue and dyspnea. Angina, exertional lightheadedness, or syncope can occur in more advanced stages of the disease.

Pulmonary regurgitation typically has a benign course unless it becomes severe. Even after that point, the volume overload of the right ventricle may be tolerated well for many years, similar to the overload of the left ventricle in aortic regurgitation. The right ventricle eventually enlarges, with some increased risk of arrhythmia. Ultimately, there is loss of RV systolic function, and patients develop signs and symptoms of right-sided heart failure, as previously described.

Diagnosis

On physical examination, the patient with severe pulmonary stenosis may have an RV lift as a result of the RV hypertrophy that develops. A prominent *a* wave may be identifiable on inspection of jugular venous pulsations. A crescendo-decrescendo systolic murmur is best heard at the left upper sternal border and may vary with respiration. S_2 may have relative fixed slitting, with the P_2 pulmonic component becoming soft or absent as the stenosis progresses. Chest radiography may demonstrate right heart and pulmonary artery enlargement with decreased vascular markings.

Similarly, the RV enlargement of pulmonary valve regurgitation may result in an RV lift. A diastolic decrescendo murmur may be present at the left sternal border and varies with respiration, but it may be inaudible if pulmonary pressures are normal. Chest radiography demonstrates right-sided heart enlargement.

TTE is sensitive and specific for diagnosis of both stenosis and regurgitation of the pulmonary valve if actively sought on the examination. Severe pulmonary valve stenosis is considered to be present when the peak gradient is greater than 64 mm Hg. Cardiac MRI may be useful in quantitating regurgitation severity or in estimating the gradient in stenosis if echocardiography is inconclusive.

Treatment

Percutaneous balloon valvuloplasty is an effective treatment for symptomatic severe pulmonary valve stenosis (class I indication, level C evidence). Surgical valvotomy or valve replacement is used only when anatomic features prevent balloon valvuloplasty or if there has been a poor result from previous attempts.

Valve replacement for severe pulmonary valve regurgitation is thought by most to be indicated when patients become symptomatic or RV systolic dysfunction develops, although there is no consensus on recommendations for the approach to this problem.

Prognosis

Studies have suggested that survival in pulmonary stenosis is related to the pressure gradient, with decreased survival in those with gradients greater than 50 mm Hg. Therefore, balloon valvuloplasty is a class I (level C evidence) recommendation for asymptomatic patients with peak pulmonary valve gradients at catheterization of at least 40 mm Hg and a class IIb recommendation for asymptomatic patients with a gradient of 30 to 39 mm Hg (level C evidence).

Coronary Heart Disease

Michael P. Cinquegrani

DEFINITION AND EPIDEMIOLOGY

The term *coronary heart disease* (CHD) describes a number of cardiac conditions that result from the presence of atherosclerotic lesions in the coronary arteries. The development of atherosclerotic plaque within the coronary arteries can result in obstruction to blood flow, producing ischemia, which can be acute or chronic in nature. Atherosclerosis is a disease process that starts at a young age and can be present for years in an asymptomatic form until the degree of vessel obstruction leads to ischemic symptoms. Obstructive atherosclerotic lesions can cause chronic symptoms of exercise- or stress-related angina; or, in the case of plaque rupture and acute thrombosis, sudden death, unstable angina, or myocardial infarction (MI) may ensue.

In the United States, more than 17 million people experience some form of CHD. Approximately 10 million suffer from symptoms of angina, and at least 380,000 deaths occur each year from acute MI or CHD-related sudden death. Despite progress in therapy and overall reductions in CHD-related mortality, CHD remains the number one cause of death in both men and women, accounting for 27% of deaths in women (more than deaths due to cancer). The incidence of CHD increases with age for both men and women. There are at least 1.2 million MIs per year in the United States, and many more cases of unstable angina. CHD frequently results in lifestyle-limiting symptoms due to angina or impairment of left ventricular (LV) function. The cost of care related directly to CHD and indirectly to lost productivity from CHD is in the range of \$156 billion per year. CHD remains a major life-threatening disease process associated with significant economic impact.

RISK FACTORS FOR ATHEROSCLEROSIS

Before delving into discussion of the pathology of atherosclerosis, a description of risk factors is warranted. There are a number of well-known risk factors for coronary artery disease (CAD), some of which are modifiable (Table 8-1). Although women ultimately also carry a significant atherosclerotic burden, men develop CAD at younger ages, and the prevalence of the disease also increases as men age. Another potent risk factor for the development of CAD is a family history of premature CAD. This speaks to a nonmodifiable, genetically based risk. Commonly, multiple family members develop symptomatic CAD before the age of 55 years (65 years for women). Risks are additive, making it very important to appreciate the modifiable risk factors such as hyperlipidemia, hypertension, diabetes mellitus, metabolic syndrome, cigarette smoking, obesity, sedentary lifestyle, and heavy alcohol intake.

Metabolic syndrome deserves particular attention given that up to 25% of the adult U.S. population may satisfy the definition of the disorder as laid out by the National Cholesterol Education Program Adult Treatment Panel. The definition of metabolic syndrome requires the presence of at least three of the following five criteria: waist circumference greater than 201 cm in men or 88 cm in women, triglyceride level 150 mg/dL or higher, high-density lipoprotein (HDL) cholesterol level lower than 40 mg/dL in men or 50 mg/dL in women, blood pressure 130/85 mm Hg or higher, and fasting serum glucose level 110 mg/dL or higher. The features of metabolic syndrome are largely modifiable risk factors for CAD.

Hyperlipidemia, in particular elevated levels of low-density lipoprotein (LDL) cholesterol, plays a pivotal role in the development and evolution of atherosclerosis. HDL-cholesterol is believed to be protective, likely due to its role in transporting cholesterol from the vessel wall to the liver for degradation. Increased levels of HDL are inversely proportional to the risk of CAD-related problems. The interplay among circulating lipids is complex. Elevated levels of triglycerides are a risk factor for CAD and are frequently associated with reduced levels of protective HDL. Hyperlipidemia is highly modifiable, and clinical trials have shown that drug treatment directed at lowering LDL-cholesterol significantly reduces the risk of CAD-related complications or death.

TABLE 8-1 RISK FACTORS AND MARKERS FOR CORONARY ARTERY DISEASE

NONMODIFIABLE RISK FACTORS

Age
Male sex
Family history of premature coronary artery disease

MODIFIABLE INDEPENDENT RISK FACTORS

Hyperlipidemia
Hypertension
Diabetes mellitus
Metabolic syndrome
Cigarette smoking
Obesity
Sedentary lifestyle
Heavy alcohol intake

MARKERS

Elevated lipoprotein(a)
Hyperhomocysteinemia
Elevated high-sensitivity C-reactive protein (hsCRP)
Coronary arterial calcification detected by EBCT or MDCT

EBCT, Electron beam computed tomography; MDCT, multidetector computed tomography.

As with hyperlipidemia, hypertension (systolic pressure >140 mm Hg or diastolic pressure >90 mm Hg) contributes to the risk of CAD-related complications. Hypertension, probably through sheer stress, causes vessel injury that supports the development of atherosclerotic plaque. Increasing severity of hypertension is associated with greater risk of CAD. Control of hypertension is associated with a reduced risk of CAD.

Diabetes mellitus is a prominent risk factor for CAD, and the disease is becoming epidemic. Diabetes mellitus typically is associated with other risk factors, such as elevated triglycerides, reduced HDL, and hypertension, which accounts for the enhanced risk of CAD-related problems in diabetic patients. It is not clear that control of hyperglycemia in diabetic patients translates into a reduced risk of CAD, but the presence of diabetes mellitus drives the need to ensure good treatment of other modifiable risk factors.

Cigarette smoking has long been known as a significant risk factor for both CAD and lung cancer. Cigarette smoking is associated with increased platelet reactivity and increased risk of thrombosis, as well as lipid abnormalities. This addictive habit is modifiable, and smoking cessation can lead to a decrease in CAD event rates by 50% in the first 2 years of cessation.

Similar to diabetes mellitus, obesity (body mass index >30 kg/m²) is associated with risk factors such as hypertension, hyperlipidemia, and glucose intolerance. Although multiple risk factors are frequently present in obese people, obesity itself carries some independent risk for CAD. The location and type of adipose tissue appear to influence CAD risk, with abdominal obesity posing a greater risk for CAD in men and women.

Numerous clinical studies have shown the benefit of regular aerobic exercise in decreasing the risk for CAD-related problems, both in the people without known CAD and in those with the disease. Sedentary lifestyles carry an increased risk that is modifiable through exercise.

Another common attribute of life, alcohol consumption, can influence the risk of CAD in both directions. One to two ounces of alcohol per day may reduce the risk for CAD-related events, but more than 2 ounces of alcohol per day is associated with an increased risk of events. Lower levels of alcohol consumption can increase HDL levels, although it is not clear that this is the mechanism of benefit. In contrast, excessive alcohol consumption is associated with hypertension, a definite risk for CAD, although other effects of high-dose alcohol may also be at play.

Additional factors that may have some role in adding CAD risk include lipoprotein(a) and homocysteine. Lipoprotein(a) is structurally similar to plasminogen and may interfere with the activity of plasmin, thus contributing to a prothrombotic state. Hyperhomocysteinemia has been associated with increased vascular risks, including coronary, cerebral, and peripheral vascular disease. It is not clear that a causal link exists, and the use of folic acid supplementation to lower homocysteine levels has not been shown to reduce the risk of MI or stroke.

C-reactive protein (CRP) is a marker of systemic inflammation, and it indicates an increased risk for coronary plaque rupture. High-sensitivity assays for CRP (hsCRP) have measured elevated levels that correlate with risk for MI, stroke, peripheral vascular disease, and sudden cardiac death. Another marker for the presence of CAD is coronary calcification. The

process of atherosclerosis is often associated with deposition of calcium within the plaque. Coronary artery calcification can be detected by fluoroscopy during cardiac catheterization as well by computed tomography (CT) scanning using either multidetector computed tomography (MDCT) or electron beam computed tomography (EBCT). CT technology allows for a quantitative measure of coronary calcium deposits that correlates with the probability of having significant obstructive lesions. The value of routine use of either hsCRP or CT for coronary calcification remains unclear, but patients in whom coronary calcification is identified should be approached with aggressive risk-factor modification.

PATHOLOGY

The process of atherosclerosis is known to begin at a young age. Autopsies of teenagers frequently demonstrate the presence of atherosclerotic changes in coronary arteries. Atherosclerosis is a process linked to the subintimal accumulation of small lipoprotein particles that are rich in LDL. Subintimal deposits of LDL are oxidized, setting off a cascade of events that culminate in not only the development of atherosclerotic plaque but also vascular inflammation. Vascular inflammation drives progression of atherosclerosis as well as the potential rupture of plaque leading to vessel occlusion. The process of lipoprotein uptake by the vessel wall is enhanced by vascular endothelial injury, which may be triggered by hypercholesterolemia, the toxic effects of cigarette smoking, sheer stresses associated with hypertension, or vascular effects of diabetes mellitus.

Oxidized LDL aggregates trigger the expression of endothelial cell surface adhesion molecules, including vascular adhesion molecule-1, intracellular adhesion molecule-1, and selectins, which results in the binding of circulating macrophages to the endothelium. In response to cytokines and chemokines released by endothelial and smooth muscle cells, macrophages migrate into the subintimal region, where they ingest oxidized LDL aggregates. These LDL-laden macrophages are also called foam cells (based on the microscopic appearance), and the accumulation of foam cells represents the development of atherosclerosis.

Foam cells break down, releasing pro-inflammatory substances that promote ongoing accumulation of both macrophages and T lymphocytes. This process potentiates the development of atherosclerotic plaque. Growth factors are also released that promote smooth muscle cell and fibroblast proliferation. The net result is the development of a fibrous cap, which covers a lipid-rich core.

Important contributors to the pathologic evolution of atherosclerotic plaque include impaired endothelial synthesis of nitric oxide and prostacyclin, both of which play major roles in vascular homeostasis. The loss of these vasodilators leads to abnormal regulation of vascular tone and also plays a role in evolving a local prothrombotic state. Platelets adhere to areas of vascular injury and are not only prothrombotic but also release growth factors that help drive the aforementioned proliferation of smooth muscle cells and fibroblasts. A key structural constituent of the fibrous cap is collagen, and its synthesis by fibroblasts is inhibited by cytokines elaborated by accumulating T lymphocytes. Foam cell degradation also releases matrix metalloproteinases that break down collagen, leading to weakening of the fibrous core

and making it prone to rupture. T lymphocytes tends to accumulate at the border of plaque, which is the frequent site of plaque rupture.

As the fibrous cap thins through collagen degradation and eventually ruptures, blood is exposed to the thrombogenic triggers of collagen and lipid. In this setting, platelets are activated and begin to aggregate at the site of rupture. Platelets release vasoconstrictor substances thromboxane and serotonin, but more importantly, they serve as the trigger for thrombin formation, which leads to local thrombosis. Thrombin accumulation along with ongoing platelet activation can lead to rapid accumulation of thrombus in the vessel lumen. The combination of platelet-mediated thrombus accumulation and vasoconstriction can significantly limit blood flow, leading to myocardial ischemia. The degree of ischemia and its duration can culminate in MI. Complete vessel occlusion by thrombus leads to the greatest degree of myocardial ischemia and infarction, typically resulting in an ST elevation myocardial infarction (STEMI). Incomplete vessel occlusion limits blood flow enough to cause symptomatic myocardial ischemia and lesser degrees of MI, resulting in the syndromes of unstable angina or non-ST elevation myocardial infarction (NSTEMI).

MI is the most profound consequence of atherosclerotic plaque pathology, but significant disability can also develop when atherosclerotic plaques expand in size, leading to obstruction of blood flow and resultant myocardial ischemia. Plaque growth, driven by smooth muscle cell proliferation, initially causes the vessel to expand toward the adventitia (Glagov remodeling). Once a limit of lateral expansion is reached, the enlarging plaque encroaches on the vessel lumen. Typically, when the diameter of the lumen is decreased by at least 70%, myocardial ischemia and symptoms of angina can develop under conditions of increasing demand for blood flow. In the case of exercise, increases in heart rate and blood pressure lead to increasing myocardial oxygen demand; when flow-limiting atherosclerotic lesions are present,

oxygen demand may not be met by supply and myocardial ischemia ensues. The greater the degree of vessel obstruction, the more likely it is that myocardial ischemia and angina will occur at low workloads, even to the point of angina at rest (Fig. 8-1). Other forms of stress, such as emotional stress or cold exposure, can also cause symptoms of angina in patients with significant obstructive plaque through mechanisms such as hypertension (increased myocardial oxygen demand) or sympathetically mediated vasoconstriction.

CLINICAL PRESENTATIONS OF CORONARY ARTERY DISEASE

The clinical syndromes that patients experience due to the presence of CAD principally relate to the occurrence of myocardial ischemia. Myocardial ischemia develops when there is a mismatch of oxygen delivery and oxygen demand. Given that extraction of oxygen by the myocardium is very high, any increase in oxygen demand must be met with an increase in coronary blood flow. Oxygen demand is directly related to increases in heart rate, myocardial contractility, and wall stress (which are related to blood pressure and cardiac dimensions). There is a reflex increase in myocardial oxygen demand driven by these factors as the heart is required to deliver more systemic blood flow in the face of various stresses, the most common of which is increased exertion. Coronary blood flow also depends on the vascular tone of arterioles that are under the control of vasodilators derived from normal functioning endothelium and autonomic tone.

Coronary blood flow increases to meet an increase in myocardial oxygen demand through endothelium-mediated vasodilation. In the face of atherosclerosis, endothelial dysfunction may develop, resulting in reduced endothelium-mediated vasodilation. Endothelial dysfunction coupled with a flow-limiting stenosis sets the stage for the development of myocardial ischemia. The coronary vessel distal to a flow-limiting stenosis tends to be maximally dilated. As myocardial oxygen demand increases, the

FIGURE 8-1 Angiograms of the right coronary artery. **A**, Discrete stenosis is observed in the middle segment of the artery (arrow). **B**, The same artery is shown after successful balloon angioplasty of the stenosis and placement of an intracoronary stent (arrow).

myocardium distal to a flow-limiting stenosis is no longer able to augment flow by additional dilation. An overall limitation in the ability to increase coronary blood flow due to flow-limiting stenosis and endothelial dysfunction results in supply/demand mismatch and myocardial ischemia.

The major clinical manifestation of myocardial ischemia is chest discomfort (angina pectoris), which is usually described as a pressure or sensation of midsternal tightness. It may be quite pronounced in intensity or relatively subtle. Myocardial ischemia produces not only the sensation of angina pectoris but also a number of derangements in myocyte function. As in any tissue, inadequate oxygen delivery leads to a transition to anaerobic glycolysis, increased lactate production causing cellular acidosis, and abnormal calcium homeostasis. The net consequences of these cellular abnormalities include reductions in myocardial contractility and relaxation. Decreased myocardial contractility results in systolic wall motion abnormalities in the area of ischemia, and the abnormality of relaxation causes reduced ventricular compliance. These changes cause an increase in LV filling pressures above the normal range. The cellular abnormalities related to myocardial ischemia also translate into changes in cellular electrical activity that appear as abnormalities in the electrocardiogram (ECG). Myocardial ischemia may result in either ST depression or ST elevation, depending on the duration, severity, and location of the ischemia. The cellular, mechanical, and electrical abnormalities caused by ischemia typically precede the patient's perception of angina.

Myocardial dysfunction due to ischemia may recover quickly to normal if the duration of ischemia is brief. Prolonged myocardial ischemia can lead to conditions of myocardial stunning or myocardial hibernation. In the case of stunning, the mechanical dysfunction induced by prolonged ischemia persists for hours or days until function returns to normal. In the face of chronic ischemia, myocyte viability may be maintained, but because of ischemia, mechanical dysfunction persists; in this condition, known as hibernation, restoration of blood flow can result in recovery of myocardial function.

The heart's conduction system is less prone to ischemic injury, but ischemia can lead to impaired conduction. Ischemic disruption of myocyte electrical homeostasis also sets the stage for potentially life-threatening arrhythmias.

Angina Pectoris and Stable Ischemic Heart Disease

Definition

Angina pectoris is a clinical manifestation of obstructive CAD, which in turn is usually the result of atherosclerotic plaque formation over a number of years. The term *angina pectoris* refers to the symptom of chest discomfort that may be described by the patient as a sensation of chest tightness or burning. Of the 17,600,000 adults in the United States with heart disease, as many as 10,200,00 have angina pectoris. It is estimated that 785,000 people experience a new ischemic episode annually, and recurrent events occur in at least 470,000 Americans each year.

Pathology

As a symptom, angina pectoris is experienced when myocardial ischemia develops. Myocardial ischemia and angina pectoris may occur in the face of obstructive atherosclerotic plaque that limits blood flow in the face of increased demand such as exertion or emotional excitement. Myocardial oxygen demand is directly related to increases in heart rate and blood pressure; these variables, in turn, can be manipulated with medical therapy to reduce the demand. Restricted oxygen supply, in the form of reduced blood flow, can also induce myocardial ischemia. Blood flow reduction is a prominent feature of acute presentations of CAD such as NSTEMI and STEMI, but atherosclerosis-mediated coronary vasoconstriction, or coronary vasospasm, is also a potential cause of flow limitation leading to myocardial ischemia. Another example of supply limitation is anemia, whereby reduced oxygen-carrying capacity coupled with obstructive lesions leads to myocardial ischemia and symptoms of angina pectoris. The term *stable* angina pectoris refers to myocardial ischemia caused by either plaque-mediated flow limitation in the face of excess demand or supply limitation due to coronary vasospasm.

Clinical Presentation

Angina pectoris may manifest in either stable or unstable patterns (Table 8-2), but the symptom expression is similar. Typically, patients complain of retrosternal discomfort that they may describe as pressure, tightness, or heaviness. The symptom can be subtle in its presentation, and inquiry as to the presence of

TABLE 8-2 ANGINA PECTORIS

TYPE	PATTERN	ECG	ABNORMALITY	MEDICAL THERAPY
Stable	Stable pattern, induced by physical exertion, exposure to cold, eating, emotional stress	Baseline often normal or nonspecific ST-T changes	≥70% Luminal narrowing of one or more coronary arteries from atherosclerosis	Aspirin Sublingual nitroglycerin
Unstable	Lasts 5-10 min Relieved by rest or nitroglycerin Increase in anginal frequency, severity, or duration Angina of new onset or now occurring at low level of activity or at rest May be less responsive to sublingual nitroglycerin	Signs of previous MI ST-segment depression during angina Same as stable angina, although changes during discomfort may be more pronounced Occasional ST-segment elevation during discomfort	Plaque rupture with platelet and fibrin thrombus, causing worsening coronary obstruction	Anti-ischemic medications Statin Aspirin and clopidogrel Anti-ischemic medications Heparin or LMWH Glycoprotein IIb/IIIa inhibitors
Prinzmetal or variant angina	Angina without provocation, typically occurring at rest	Transient ST-segment elevation during pain Often with associated AV block or ventricular arrhythmias	Coronary artery spasm	Calcium channel blockers Nitrates

AV, Atrioventricular; ECG, electrocardiography; LMWH, low-molecular-weight heparin; MI, myocardial infarction.

“chest pain” may lead to a negative response in a patient experiencing angina pectoris. When taking a history aimed at discerning angina pectoris, one needs to seek answers to these more nuanced descriptions of symptoms. In addition to chest discomfort, patients may have associated discomfort in the arm, throat, back, or jaw. They also may experience dyspnea, diaphoresis, or nausea associated with angina pectoris.

There is a good deal of variability in the expression of symptoms related to myocardial ischemia, although each person tends to have a unique signature of symptoms. Some have no chest discomfort but only radiated arm, throat, or back symptoms; dyspnea; or abdominal discomfort. Myocardial ischemia can also manifest in a “silent” form, particularly in the elderly and in patients with long-standing diabetes mellitus. The duration of angina pectoris varies, probably depending on the magnitude of the underlying myocardial ischemia. Exertion-related angina pectoris, the hallmark of stable obstructive CAD, typically resolves with rest or with decreased intensity of exercise. In stable angina pectoris, the duration of events is usually in the range of 1 to 3 minutes. Prolonged symptoms in the 20- to 30-minute range are indicative of a more serious problem such as NSTEMI or STEMI.

The physical examination of patients with CAD is typically normal. However, if the patient is physically examined during an episode of myocardial ischemia, either at rest or after exertion, significant changes may be present. As with any form of discomfort, there may be a reflex increase in heart rate and blood pressure. Elevated heart rate and blood pressure may act to sustain the duration of angina by increasing myocardial oxygen demand in the face of supply-limiting coronary stenosis. Acute mitral regurgitation can develop if the distribution of myocardial ischemia includes a papillary muscle, the supporting structure of the mitral valve. The physical examination in such cases would demonstrate a new systolic murmur consistent with mitral regurgitation. If severe enough in degree, this mitral regurgitation will cause decreased LV compliance and, consequently, an acute elevation in left atrial and pulmonary vein pressure leading to pulmonary congestion. In this setting, the patient will have not only the symptom of angina pectoris but also the symptom of dyspnea and the physical finding of rales. Ischemia-induced increases in LV filling pressure due to diminished compliance also can occur independently of ischemia-induced mitral regurgitation. Decreased LV compliance can produce the abnormal heart sound S_4 ; in the case of severe diffuse myocardial ischemia causing LV systolic dysfunction, an S_3 may also be perceived. Resolution of myocardial ischemia results in not only a cessation of angina pectoris but also a return to the patient’s baseline physical examination status.

Diagnosis and Differential Diagnosis

Three basic forms of testing have played major roles in assessing patients with chest discomfort possibly due to CAD. All of these tests capitalize on the effect of myocardial ischemia on various aspects of cardiac physiology. First, myocardial ischemia induced by exercise or by spontaneous coronary occlusion results in subendocardial ischemia, which appears on an ECG as diffuse ST depression (Fig. 8-2). Once ischemia resolves, the ECG returns to normal. Second, myocardial ischemia typically affects a segment of heart muscle, and that territory develops a wall

motion abnormality that can be detected by either echocardiography or nuclear scintigraphy. Third, the basis for myocardial ischemia is a decrease in coronary and myocardial blood flow. This abnormality can be detected by assessing the distribution of radioactive tracers such as thallium 201 or technetium sestamibi using specialized detectors for imaging myocardial perfusion. All stress test techniques used in diagnosing patients with possible CAD rely on these means of detecting the impact of myocardial ischemia on cardiac electrical activity, mechanical function, or myocardial perfusion.

Stress testing in its various forms frequently plays a pivotal role in the assessment of patients with possible CAD. In using stress testing, it is important to understand the significance of pretest probability of CAD in interpreting the results of any stress test method. For a patient with a high pretest probability of CAD, a positive test is highly predictive of underlying CAD, and a negative test carries the weight of being falsely negative. The opposite is true in a patient with a low pretest probability of CAD: A negative test is associated with a high negative predictive value for the presence of CAD, but a positive test is likely to be falsely positive. These factors play into a clinician’s interpretation of test results and must always factor into decision making regarding the need for additional testing.

Stress testing is useful not only as a diagnostic tool but also in the long-term management of established CAD. Exercise stress testing, through its ability to quantify exercise capacity, can monitor the effectiveness of medical therapy directed at reducing myocardial ischemia. The findings of an exercise stress test also have predictive value in that patients with ischemia induced at low workloads are more likely to have extensive multivessel disease, whereas those who achieve high workloads are less prone to ischemic complications of CAD. A higher risk for poor outcomes related to CAD is implied by (1) ECG changes of ST depression early during exercise and persisting late into recovery; (2) exercise-induced reduction in systolic blood pressure; and (3) poor exercise tolerance (<6 minutes on the Bruce stress test protocol).

Patients with a normal resting ECG can reliably be assessed by standard exercise stress testing with ECG monitoring (Fig. 8-3). The specificity of ST changes with exertion is significantly reduced in the face of baseline ECG abnormalities related to LV hypertrophy, left bundle branch block (LBBB), pre-excitation, or use of digoxin. Various imaging techniques (echocardiography, nuclear scintigraphy, magnetic resonance imaging) have been developed to overcome the impact of baseline ECG abnormalities on the validity of stress testing. Because women also have lower specificity for ECG changes during exercise testing than men, an imaging technique is frequently used in the assessment of women. Overall, the addition of an imaging technique to stress testing significantly improves the sensitivity, specificity, and predictive value of the stress test but also greatly increases its cost.

Radionuclide stress testing is a common form of imaging-based stress test. Near peak exertion, a radionuclide tracer (thallium 201, technetium 99, or tetrofosmin) is administered intravenously. The tracer is distributed to the myocardium in a quantity directly proportional to blood flow. This type of image testing relies on a disparity of tracer uptake to detect an area of ischemia. Thallium 201 redistributes over 4 hours to viable

A

FIGURE 8-2 Electrocardiogram obtained during angina (A) and after the administration of sublingual nitroglycerin and subsequent resolution of angina (B). During angina, transient ST-segment depression and T-wave abnormalities are present.

myocardium, allowing for comparison of stress-induced ischemia to a baseline state. The other tracers do not share this redistribution feature, and tests using technetium 99 or tetrofosmin require both “rest” and “stress” injections of tracer to differentiate ischemic myocardium. Patients with normal perfusion studies have a low risk of coronary events (<1%/year). The presence of a positive perfusion study confers a risk of about 7%/year for coronary events, with the risk increasing relative to the extent of perfusion abnormality.

An alternative means of imaging for exercise testing is the use of echocardiography to detect ischemia-induced wall motion abnormalities. This form of testing is increasingly favored because

there is no radiation associated with its use, whereas radionuclide tracers expose the patient to a significant dose of radiation. Stress echocardiography carries with it the same enhancement in sensitivity, specificity, and predictive value as radionuclide imaging. An additional benefit of echocardiography imaging is more discrete anatomic data on valve function. If it is coupled with Doppler flow imaging, information regarding exercise-induced mitral regurgitation can be obtained.

Another means of assessing for exercise-induced wall motion abnormalities is the use of radionuclide ventriculography or multigated acquisition scanning (MUGA). This technique is usually included as part of the interpretation of an exercise stress

FIGURE 8-3 Treadmill exercise test demonstrates a markedly ischemic electrocardiogram (ECG) response. The resting ECG is normal. The test was stopped when the patient developed angina at a relatively low workload, accompanied by ST-segment depression in lead II and ST-segment elevation in lead V₂. These changes worsened early in recovery and resolved after administration of sublingual nitroglycerin. Only leads II and V₂ are shown; however, ischemic changes were seen in 10 of the 12 recorded leads. Severe atherosclerotic disease of all three coronary arteries was documented at subsequent cardiac catheterization.

radionuclide study. This imaging technique does not provide the anatomic detail associated with echocardiography, and it has the negative feature of significant radiation exposure.

An emerging imaging technique for stress testing is the use of magnetic resonance imaging. Radiation is not a concern, and cardiac structural imaging can match echocardiography (or exceed it in patients with poor images on echocardiography). The technique is not as easy to execute as echocardiography, but magnetic resonance imaging is likely to gain favor in exercise testing.

Not all patients who require noninvasive testing for CAD are able to exercise to a degree sufficient to induce ischemia, and for some patients exercise testing is not an option at all. For these patients, pharmacologic stress testing has evolved as a viable alternative to exercise testing. The prognostic benefit of exercise workload is not available from this form of testing, but information regarding the presence of ischemia-inducing atherosclerosis is obtainable. One common form of pharmacologic testing relies on inducing coronary vasodilation (as with dipyridamole, adenosine, or regadenosine), which produces a disparity of myocardial blood flow based on the presence of coronary stenosis. Radionuclide administered during the infusion of the coronary vasodilator allows for detection of myocardial ischemia similar to that observed with exercise testing. An alternative pharmacologic approach uses the inotropic and chronotropic effects of dobutamine to increase myocardial oxygen demand and induce segmental ischemia. Echocardiography is commonly used to detect dobutamine-induced wall motion abnormalities with this approach, although radionuclide or magnetic resonance imaging could also be used.

All of the stress testing techniques discussed here are able to assess for the presence of inducible myocardial ischemia associated with CAD. The presence of CAD can also be determined by assessment of coronary calcification using either EBCT or the

now more common MDCT. Coronary calcification is present only because of underlying CAD. Although detecting its presence does not directly indicate the presence of obstructive CAD as would an abnormal imaging stress test, studies have shown a direct correlation between the amount of coronary calcification and the probability that a 70% stenosis is present. At the least, this type of information informs the physician that CAD is present and directs aggressive attention toward risk factor modification. MDCT scanners can reliably perform coronary angiography with the use of intravenous contrast agents and specifically timed imaging protocols. This technique is becoming increasingly used to detect the presence of obstructive CAD, although it cannot precisely define the severity of stenosis. MDCT is also valuable in defining coronary anomalies, and a negative study carries a high negative predictive value for the occurrence of coronary events.

Invasive coronary angiography has been considered the “gold standard” for detecting the extent and severity of underlying CAD. This approach carries a small risk of MI, stroke, or death, so it must not be taken lightly. In the case of patients with positive stress tests, particularly those with high-risk features, coronary angiography adds more discrete information regarding the underlying disease and guides the potential use of revascularization techniques (i.e., percutaneous coronary intervention or coronary artery bypass surgery) versus medical therapy to treat CAD (Table 8-3). Additional tools, such as pressure wires used to perform fractional flow reserve studies (FFR), add to the diagnostic power of invasive catheterization by allowing one to discriminate between physiologically significant lesions and those not likely to cause ischemia. Revascularization is not indicated for lesions that do not cause ischemia.

The physician must also be cognizant of the fact that not all chest discomfort is related to CAD. Although CAD as a cause of chest discomfort poses the biggest risk for poor outcomes, other

TABLE 8-3 INDICATIONS FOR CORONARY ANGIOGRAPHY IN PATIENTS WITH STABLE ANGINA PECTORIS

Unacceptable angina despite medical therapy (for consideration of revascularization)
 Noninvasive testing results with high-risk features
 Angina or risk factors for coronary artery disease in the setting of depressed left ventricular systolic function
 For diagnostic purposes, in the individual in whom the results of noninvasive testing are unclear

considerations of chest discomfort include esophageal disease (esophageal reflux may mimic typical angina pectoris), chest wall–related pain, pulmonary embolism, pneumonia, and trauma. The clinical presentation of the patient usually points in one direction or another, but patients with chest discomfort commonly undergo an evaluation for CAD, typically with the use of stress testing. Once CAD is reliably ruled out, the physician needs to consider alternative causes of the symptom. In the acute setting of severe chest discomfort, particularly in a hemodynamically unstable patient, the differential diagnosis includes acute MI, pulmonary embolism, and aortic dissection. Prompt and accurate diagnostic evaluation, commonly with the use of invasive angiography, can be lifesaving in this situation.

Treatment

Medical Management of Stable Angina

The treatment of CAD and angina pectoris is multifaceted. The presence of CAD with or without angina requires the physician to recommend risk factor modification, frequently associated with lifestyle changes. For angina pectoris, pharmacologic therapy is typically used to control symptoms, allowing for maintenance of reasonable exercise tolerance. Revascularization is commonly used to control symptoms to a degree better than what can be achieved with medications alone, but only a small group of patients with CAD benefit from revascularization in terms of increased longevity.

It is also incumbent on the physician to recognize other medical conditions that can lower the threshold for angina, thus worsening symptoms and affecting quality of life. Anemia is a common medical problem that, when addressed, can significantly reduce the frequency of angina pectoris. Hyperthyroidism, with its increased metabolic demand and tachycardia, can increase the frequency of angina pectoris. Uncompensated congestive heart failure lowers the anginal threshold through the effects of LV dilation and filling pressure elevation on myocardial oxygen demand. Chronic obstructive pulmonary disease (COPD) and obstructive sleep apnea leading to hypoxemia can trigger angina pectoris.

Attention to the major modifiable risk factors for CAD is a cornerstone of therapy. Poorly controlled diabetes mellitus, hypertension, hyperlipidemia, and ongoing smoking all drive the progression of CAD and increase the risk for catastrophic events such as MI or sudden death. The wealth of clinical research on preventing death and disability from CAD has led to the development of evidence-based guidelines that form the basis of contemporary therapy for CAD (Table 8-4). Complete smoking cessation is a must for patients with CAD regardless

TABLE 8-4 GOALS OF RISK FACTOR MODIFICATION

RISK FACTOR	GOAL
Dyslipidemia	
Elevated LDL-cholesterol level	
Patients with CAD or CAD equivalent*	LDL <70 mg/dL
Without CAD, ≥2 risk factors [†]	LDL <130 mg/dL (or <100 mg/dL [‡])
Without CAD, 0-1 risk factors [†]	LDL <160 mg/dL
Elevated TG	TG <200 mg/dL
Reduced HDL-cholesterol level	HDL >40 mg/dL
Hypertension	Systolic blood pressure <140 mm Hg Diastolic blood pressure <90 mm Hg
Smoking	Complete cessation
Obesity	<120% of ideal body weight for height
Sedentary lifestyle	30-60 min moderately intense activity (e.g., walking, jogging, cycling, rowing) five times per week

CAD, Coronary artery disease; CRP, C-reactive protein; HDL, high-density lipoprotein; hsCRP, high-sensitivity C-reactive protein; LDL, low-density lipoprotein; TG, triglycerides.

*CAD equivalents include diabetes mellitus, noncoronary atherosclerotic vascular disease, or >20% 10-year risk for a cardiovascular event as predicted by the Framingham risk score.

[†]Risk factors include cigarette smoking, blood pressure ≥140/90 mm Hg or taking antihypertensive medication, HDL-cholesterol level <40 mg/dL, family history of premature coronary atherosclerosis (male, <45 yr; female, <55 yr).

[‡]Target of 100 mg/dL should be strongly considered for men ≥60 yr and for individuals with a high burden of subclinical atherosclerosis (coronary calcification >75th percentile for age and sex), hsCRP >3 mg/dL, or metabolic syndrome.

of the presence of symptoms. The use of statin medications to reduce LDL cholesterol (to <100 mg/dL, with possible additional benefit if ≤70 mg/dL) has revolutionized the therapy for CAD. Statins have been shown to reduce the risk of MI in patients with proven CAD and in those at significant risk. There is also interest low HDL levels, which appear to confer increased risk for coronary events. It is unclear whether niacin, which raises HDL, actually reduces the risk of MI or death. Exercise increases HDL levels and may confer protective effects through other mechanisms. Pharmacologic strategies to elevate HDL and hopefully reduce risk are under development.

Antiplatelet therapy is known to reduce the risk of MI in those who have known CAD or are at risk. Patients should be instructed to take aspirin, 81 to 325 mg/day (clopidogrel 75 mg/day may be used in those who are aspirin intolerant or allergic). Angiotensin-converting enzyme (ACE) inhibitors reduce the risk of recurrent MI and are also beneficial for patients with diabetes mellitus or reduced LV function. Angiotensin receptor blockers (ARBs) can be substituted in those who experience significant side effects from ACE inhibitors.

Regular aerobic exercise can benefit patients with CAD by reducing their risk for complications related to the disease. Aerobic exercise also increases exercise tolerance and may reduce the frequency of exercise-related angina pectoris. Positive benefits also accrue from weight loss related to exercise and improved blood pressure control. In sedentary individuals, isometric activities such as snow shoveling can trigger MI and should be avoided. There may be some benefits to judicious weight training in patients with CAD.

In addition to antiplatelet therapy, the commonly employed medications to control angina pectoris include β-blockers, nitrates, and calcium channel blockers. These agents work by

correcting supply/demand blood flow mismatch that is the cause of myocardial ischemia and angina pectoris (Table 8-5). Interestingly, these drugs principally control symptoms in chronic stable angina pectoris, but they do not reduce mortality risk as therapy with aspirin or statins does.

Nitrates in various forms have a long history of use in patients with symptomatic CAD and can be very effective in controlling exertion-related angina. Nitrates work by venodilating large-capacitance veins and thus shifting blood out of the heart, reducing preload and myocardial oxygen demand. Nitrates are also potent coronary vasodilators and can reverse coronary spasm, allowing for improved perfusion. Short-duration but quick-acting sublingual nitroglycerin has been a mainstay both for treatment of an anginal episode and for prophylaxis against angina in situations where it is likely to occur. Patients who respond well to nitrates are frequently treated with long-acting oral or topical preparations. Both methods can effectively prevent angina pectoris, but continued use can induce tolerance. There is a recognized need for patients to have a nitrate-free period of about 8 hours every day to prevent tolerance. This usually involves cessation of use during sleep. Intravenous nitroglycerin administered by continuous drip is reserved for patients with unstable angina or acute MI.

β -Blocker therapy is very effective at reducing the likelihood of exertion-related angina. β -Blockers bind to cell surface β -receptors and by so doing reduce heart rate, contractility, and blood pressure, all of which tip the balance in favor of reduced oxygen demand and less angina. The use of β -blockers can be limited by the degree of bradycardia they induce or by baseline atrioventricular (AV) conduction abnormalities. Patients with higher degrees of AV block, β -blockers can induce complete heart block. These drugs also vary in their β -receptor selectivity. Blockade of β_2 -adrenergic receptors can lead to bronchospasm and vasoconstriction. Even selective β_1 -adrenergic antagonists such as atenolol and metoprolol have some β_2 activity at higher doses. Intolerance of β -blockers can limit their use in patients

with significant COPD or peripheral vascular disease. β -Blockers may also add to glucose intolerance and may affect lipids by increasing triglycerides or reducing HDL. In general, these effects do not preclude their use if they prove effective in controlling angina pectoris.

Calcium channel blocking drugs can decrease myocardial oxygen demand by causing arterial vasodilation, bradycardia, and decreased contractility. The magnitude of these effects varies according to the class of agent used. Dihydropyridines such as nifedipine and amlodipine cause arterial vasodilation leading to a blood pressure-lowering effect. In the dose ranges administered, they have no significant effect on contractility or heart rate. In contrast, verapamil, a phenylalkylamine, has significant effects on heart rate, AV conduction, and contractility. Benzothiazepine agents such as diltiazem manifest less vasodilation than dihydropyridines and less effect on contractility than phenylalkylamine drugs. The net effect of calcium channel blocking drugs is reduced myocardial oxygen demand and less angina pectoris. Diltiazem should be used with caution in patients who are also taking a β -blocker, because severe bradycardia or heart block can occur. Verapamil should not be co-administered with a β -blocker.

A newer class of antianginal drug is represented by ranolazine. This drug is a selective inhibitor of late sodium current and reduces sodium-induced calcium overload in myocytes. Although it has no effect on heart rate or blood pressure, ranolazine demonstrates antianginal properties. It is typically used when other medical therapy is insufficient in controlling angina.

Revascularization Therapy for Chronic Stable Angina Pectoris

Revascularization therapy is an option to be considered when medical therapy is not sufficiently controlling symptoms leading to impaired lifestyle. It is also frequently pursued in the face of high-risk situations such as unstable angina, STEMI, heart failure complicated by angina, arrhythmias associated with angina, or

TABLE 8-5 MEDICATIONS FOR ANGINA PECTORIS

DRUG CLASS	EXAMPLES	ANTIANGINAL EFFECT	PHYSIOLOGIC SIDE EFFECTS	COMMENTS
Nitroglycerin	Sublingual Topical Intravenous Oral	Decreased preload and afterload Coronary vasodilation Increased collateral blood flow	Headache Flushing Orthostasis	Tolerance develops with continuous use
β -Adrenergic blocking agents	Metoprolol Atenolol Propranolol Nadolol	Decreased heart rate Decreased blood pressure Decreased contractility	Bradycardia Hypotension Bronchospasm Depression	May worsen heart failure and AV conduction block; avoid in vasospastic angina
Calcium channel blocking agents (non-dihydropyridine)	Phenylalkylamine (verapamil) Benzothiazepine (diltiazem)	Decreased heart rate Decreased blood pressure Decreased contractility Coronary vasodilation	Bradycardia Hypotension Constipation with verapamil	May worsen heart failure and AV conduction
Calcium channel blocking agents	Dihydropyridine (nifedipine, amlodipine)	Decreased blood pressure Coronary vasodilation	Hypotension, reflex tachycardia Peripheral edema	Short-acting nifedipine is associated with increased risk for cardiovascular events.
Late sodium current blocking agents	Ranolazine	Inhibits cardiac late I_{Na} Prevents calcium overload	Dizziness Headache Constipation Nausea	No effects on blood pressure or heart rate Modest QTc prolongation

the presence of large areas of myocardial ischemia documented by noninvasive imaging. The two types of revascularization procedures are coronary bypass grafting (CABG) and percutaneous coronary intervention (PCI).

Percutaneous transluminal coronary angioplasty was the initial mode of catheter-based revascularization introduced in the late 1970s (see Video, Angioplasty, <http://www.heartsite.com/html/ptca.html>). In this technique, a guidewire is placed through a stenotic segment of artery, after which a balloon-tipped catheter is threaded over the wire to the area of stenosis and then inflated. Angioplasty of this form enlarges the vessel lumen in an irregular geometry through disruption of the plaque and injury to the vessel intima. Plain old balloon angioplasty (POBA), as the procedure later became to be known, was effective at improving myocardial perfusion and reducing exercise-related angina. However, because of plaque disruption, there was a 2% to 5% risk of abrupt vessel closure frequently leading to MI. In addition, there was a high incidence of injury-mediated restenosis (up to 50%) during the first 3 to 6 months after the procedure. The process of restenosis involved intimal hyperplasia and remodeling, yielding a recurrent stenosis sometimes more severe in nature than the original lesion.

The innovation of coronary stents pioneered through the 1980s and clinically available in the early 1990s represented a significant advance in PCI (see Video, Intracoronary Stenting, <http://www.heartsite.com/html/stent.html>). Coronary stents are expandable metallic mesh tubes that are mounted on an angioplasty balloon, allowing delivery to an area of stenosis, where balloon inflation expands the stent into the vessel wall. The stent becomes permanently embedded in the vessel wall and scaffolds the artery to keep it open. This procedure not only reduces the risk of abrupt vessel occlusion to 1% or less, but it is also associated with a significant reduction in restenosis risk (20% to 25%, compared with 50% for POBA). The benefit of stenting for a patient is clear in terms of less risk of procedure-related acute MI and less need for repeat procedures. Vessels smaller than 2 mm in diameter are not good targets for stenting, because the smallest-diameter stent is 2 mm. Stents do have a risk of thrombosis, necessitating lifelong aspirin therapy and the use of clopidogrel for 4 weeks to 1 year after the procedure (there may be some advantage to longer-duration clopidogrel for 1 year).

Despite the reduction achieved with coronary stents, there was still a significant risk of restenosis, leading investigators to search for a means to lower that risk. Drug-eluting stents (DES) were found to significantly reduce the risk of restenosis compared to bare metal stents. The first DES, released for use in 2003, was coated with either sirolimus or paclitaxel, both of which inhibited the hyperplastic response in the vessel wall triggered by PCI. The current generations of DES are coated with either zotarolimus or everolimus, both very effective at reducing restenosis. The predicted restenosis rate for current-generation DES is in the range of 5% to 10%. Vessel diameter affects restenosis risk, with larger-diameter vessels demonstrating less restenosis. The benefit of inhibiting tissue overgrowth within the stent is also associated with delayed endothelialization of the stent, which increases the risk of stent thrombosis for a longer time than with bare metal stents. Therefore, dual antiplatelet therapy with aspirin and clopidogrel should be maintained for at least 1 year.

Aspirin should never be discontinued after 1 year, to minimize the risk of late stent thrombosis. Decision making regarding the use of DES needs to take into account the patient's ability to tolerate long-term dual antiplatelet therapy, the potential for noncompliance with medications, and any need for major surgery in the near future after stent placement. The benefits of DES also confer the need for additional planning and caution.

A host of other devices to treat stenotic coronary arteries have come and gone over time. In this era, rotational atherectomy plays a role in treating calcified lesions in about 5% of patients. Catheter-based aspiration of thrombus has gained a role in patients with STEMI. Intravascular ultrasound is an important imaging adjunct that can be helpful in interrogating lesions or defining the end result of stent placement.

CABG emerged in the 1970s as an effective means of coronary revascularization for the control of angina. Bypass grafts take the form of saphenous vein from the leg, free radial artery segments, or intact left or right internal mammary artery grafts. The vein or radial artery grafts are placed on the ascending aorta and then anastomosed to the coronary vessels distal to the site of obstruction. In contrast, left or right internal mammary arteries are left intact at their origins and anastomosed distal to the obstruction. The left internal mammary artery is typically placed onto the left anterior descending coronary artery. This is the most important vessel to graft because of its size and distribution, and the left internal mammary artery is ideal given an expected patency rate of 90% at 10 years. Saphenous vein grafts degenerate over time, leading to episodes of symptomatic abrupt occlusion and a 50% patency rate at 10 years. Free radial artery grafts perform better than vein grafts but less well than intact mammary artery grafts. CABG is a major cardiac surgical procedure, but in skilled hands the mortality rate is expected to be 1% to 2%, with a similar risk of stroke. Periprocedural MI rates are in the range of 5% to 10%. There has been controversy over whether the use of the heart-lung machine to support CABG causes more problems for patients than "beating heart" surgery does. Recent studies suggest there is no long term difference in outcomes, such as death, MI, or stroke, for patients undergoing CABG, either on- or off-pump.

Most CABG procedures are performed for symptom control and are not likely to enhance longevity. The categories of patients likely to have life prolonged by CABG include those with a left main coronary artery more than 50% narrowed, those with severe three-vessel obstructive disease associated with a decrease in ejection fraction (EF, 35% to 50%), and those with two- or three-artery disease whose proximal left anterior descending artery is severely stenosed.

Clinical trials comparing CABG and PCI have consistently shown that patients undergoing CABG require fewer repeat procedures during the first 2 years after surgery. In the first 2 years, it is more likely that patients with PCI will experience symptomatic restenosis than that patients with CABG will have graft failure. Over time, this advantage is lost as vein grafts begin to fail 5 to 10 years after surgery. However, there is evidence that a survival advantage exists for diabetic patients with multivessel CAD who undergo CABG as opposed to PCI. A recent study also demonstrated long-term survival benefit for CABG over PCI in the face of multivessel CAD. Some of the survival advantage in

favor of CABG may be linked to the use of the left internal mammary artery as a graft.

Despite the use of either revascularization technique, patients remain prone to progressive atherosclerotic disease with the potential to form plaque at previously unaffected sites. This necessitates aggressive long-term medical therapy and risk factor modification to achieve the lowest possible risk of symptomatic progression or MI. Retreatment with CABG is possible but is fraught with higher risk, and the outcome of repeat stenting for in-stent restenosis is never as good as for de novo lesions.

In a small group of patients, PCI and/or CABG fails and the patient has refractory angina. Once medical therapy has been maximized, few truly effective options remain. Transmyocardial laser revascularization in areas of ischemia has been used to reduce symptoms, but this technique is now of uncertain value. External counterpulsation is a technique whereby blood pressure cuffs are placed on each leg, inflated during diastole and deflated during systole. Patients typically have a 1-hour session that may be repeated 35 times. Angina relief has been reported with this procedure and may reflect some beneficial effect on endothelial function. Spinal cord stimulation using electrodes placed in the C7-T1 dorsal epidural space can reduce anginal symptoms in the short term, although the long-term role needs definition.

Other Anginal Syndromes

Variant Angina

Whereas typical angina pectoris is usually triggered by physical or emotional stress, some patients experience a syndrome termed *variant angina*. Variant angina was first described in 1959 by Prinzmetal and colleagues, who observed patients with chest discomfort at rest, not triggered by physical or emotional stress, and associated with ST segment elevation (Fig. 8-4). Episodes of AV block and ventricular ectopy were observed, but MI was not a common feature. These patients typically did not have the common CAD risk factors other than smoking. Coronary angiography demonstrated these patients to be experiencing transient coronary vasospasm. The vasospasm tended to occur in

an area of atherosclerotic plaque, but some patients had spasm in angiographically normal segments of coronary artery.

In the course of investigating the pathophysiology of variant angina, a number of provocative tests were developed to induce coronary spasm in susceptible individuals. Intracoronary ergonovine or acetylcholine can induce spasm in patients with variant angina, probably as a result of underlying endothelial dysfunction. Other spasm-inducing provocations include the cold pressor test (placing a hand in an ice bath), the induction of alkalosis (hyperventilation or intravenous bicarbonate), and histamine infusion. Provocative testing to induce coronary vasospasm has fallen out of favor in the routine assessment of patients with angina.

Coronary vasospasm usually resolves promptly with the administration of nitroglycerin (sublingual, intravenous, or intra-arterial). The combination of oral nitrates and calcium channel blockers is often used to prevent spasm. β -Blockers may aggravate coronary spasm by inhibiting the action of vasodilating β_2 -receptors, allowing for unopposed α -receptor induced vasoconstriction. Rare patients do not respond to vasodilator medical therapy and may benefit from coronary stent placement in spasm-prone atherosclerotic lesions.

Microvascular Angina with Normal Coronary Arteries

Angina can occur in some patients in the face of normal-appearing coronary arteries and no provokable spasm. Decreased endothelium-dependent vasodilation may be the underlying pathophysiology of microvascular angina. Patients with this condition may demonstrate an increase in coronary resistance and an inability to increase coronary blood flow sufficiently when challenged by increases in myocardial oxygen demand. Women are more likely to be affected with microvascular angina, and the symptoms not uncommonly occur at rest or with emotional stress. Exercise can also trigger angina.

A host of diagnostic tests can detect the presence of ischemia in patients with microvascular angina. In the case of stress testing, ST changes of ischemia can be detected as well as nuclear

FIGURE 8-4 Continuous electrocardiogram recording in a patient with Prinzmetal (variant) angina. The spontaneous onset of chest discomfort began during the *top strip*, accompanied by transient ST-segment elevation. By the *bottom strip*, several minutes later, both discomfort and ST-segment elevation had resolved.

perfusion defects and transient wall motion abnormalities on echocardiography. More sophisticated invasive testing may demonstrate the presence of stress-induced metabolic abnormalities characteristic of ischemia and endothelial dysfunction.

Exercise-related ischemic symptoms may respond to β -blocker therapy. Microvascular angina also tends to respond well to nitrates, both short-acting sublingual nitroglycerin and long-acting oral nitrates. Calcium channel antagonists are sometimes used together with nitrates to control angina related to microvascular ischemia.

Silent Myocardial Ischemia

Not all episodes of myocardial ischemia are associated with angina. Some patients may only experience episodes of silent myocardial ischemia as evidenced by transient ST depression with ECG monitoring. Such patients can also have silent MI. It is also possible, and probably not uncommon, for patients to have both silent myocardial ischemia episodes and typical angina; this is termed *mixed angina*. Episodes of silent myocardial ischemia can be observed in all settings of CAD: chronic stable angina, unstable angina, and coronary vasospasm. Silent ischemia is more common in diabetic patients. Medical therapy directed at controlling symptomatic angina also reduces the number of episodes of silent ischemia.

Prognosis

Contemporary therapies for stable ischemic heart disease have significantly reduced the risks of cardiac events and mortality. The annual rate of major ischemic events such as MI is in the range of 1% to 2%, and the yearly mortality rate is 1% to 3%. CAD is frequently associated with systemic vascular disease, making these patients prone to a host of other events. Patients with stable ischemic heart disease have a yearly combined outcome risk for cardiovascular death, MI, or stroke in the range of 4.5%.

Despite advances in medical and revascularization therapies, up to 30% of patients face some limiting symptoms of recurrent angina. Revascularization does not abolish the need for ongoing antianginal medical therapy in 80% of patients.

Patients with stable ischemic heart disease should first be treated with medical therapy appropriate to reduce the risk of ischemic events (aspirin, statins) and to control symptoms of angina (nitrates, β -blockers, calcium channel antagonists). Revascularization therapy with either PCI or CABG is an option for patients who continue to have lifestyle-limiting symptoms despite the use of medical therapy and risk factor modification. The goal of all therapies for patients with stable ischemic heart disease should be individualized, taking advantage of information from controlled trials and directed at improving overall lifestyle and reducing the risk of death and disability due to progressive CAD or systemic vascular disease.

Acute Coronary Syndrome: Unstable Angina and NSTEMI

Definition

Asymptomatic CAD or chronic stable angina may undergo transition to a more aggressive stage of disease called acute coronary syndrome (ACS). ACS comprises a spectrum of clinical

presentations, ranging from unstable angina to NSTEMI or STEMI. Unstable angina represents the new onset of angina at rest or on exertion, or an increase in frequency of previously stable anginal symptoms, particularly at rest. ACS manifesting as MI, either NSTEMI or STEMI, is differentiated from unstable angina on the basis of prolonged symptoms, characteristic ECG changes, and the presence of biomarkers in blood. Unstable angina may be a harbinger of either NSTEMI or STEMI, and the diagnosis of unstable angina identifies a patient who requires careful assessment and treatment.

Epidemiology

The occurrence of ACS represents a significant clinical event in up to 1.4 million Americans annually. One third of those categorized as having ACS are diagnosed with NSTEMI. More than half of patients with NSTEMI are 65 years of age or older, and approximately one-half are women. NSTEMI is more common in patients with diabetes, peripheral vascular disease, or chronic inflammatory disease (e.g., rheumatoid arthritis).

Primary ACS is the most common form of the disease and reflects underlying plaque rupture leading to intracoronary thrombus formation and limitation of blood flow. Secondary ACS reflects imbalances in myocardial oxygen supply and demand leading to myocardial ischemia. Examples of decreased oxygen supply include profound anemia, systemic hypotension, and hypoxemia. Increased demand occurs in the face of severe systemic hypertension, fever, tachycardia, and thyrotoxicosis. Secondary ACS not uncommonly unmasks previously asymptomatic obstructive CAD, but it may also occur in the absence of CAD. Treatment of secondary ACS is directed at correcting the underlying medical condition.

Pathology

Most patients who experience NSTEMI do so as a result of plaque rupture with subsequent thrombosis causing subtotal occlusion of the coronary artery. The limitation of coronary blood flow in this situation leads to subendocardial ischemia in the distribution of the affected coronary artery. The same pathology underlies STEMI, although in that case complete vessel occlusion occurs, leading to more extensive MI. It is possible for patients with obstructive CAD to develop collateral support of the affected artery, and in that case plaque rupture with complete vessel occlusion may lead to NSTEMI as opposed to STEMI.

A smaller percentage of patients have ACS due to coronary vasospasm, which, if severe and prolonged, can lead to myocardial necrosis. Vasospasm may occur in regions of endothelial dysfunction induced by atherosclerotic plaque, or it may be triggered by exogenous vasoconstrictors such as cocaine ingestion, the use of serotonin agonists (for migraine therapy), or chemotherapeutic agents (e.g., 5-fluorouracil). Less common causes of ACS include coronary vasculitis and spontaneous coronary dissection (peripartum coronary dissection).

Atherosclerotic plaques rich in LDL are prone to develop inflammation, which in turn degrades the collagen-rich fibrous cap, leading to rupture and thrombosis. Oxidized LDL within the plaque leads to accumulation of macrophages and T lymphocytes, causing inflammation within the plaque. Cytokines

elaborated in the inflammatory process inhibit collagen synthesis. The fibrous structure of the plaque is further compromised by matrix metalloproteinases released by macrophages. Degradation of the plaques' fibrous structure makes them prone to rupture. Systemic inflammatory conditions may also play a role in plaque rupture in some patients. It is possible to have multiple sites of plaque ulceration or rupture.

Plaque rupture leads to platelet adherence and subsequent activation at the site of rupture. As platelets aggregate, the thrombosis cascade is triggered, leading to progressive accumulation of intravascular thrombus. The severity of myocardial ischemia and MI depends on the degree to which thrombus occludes the vessel. It is also possible for ACS to occur as a result of embolization of platelet aggregates or thrombus.

Clinical Presentation

ACS may manifest as a first symptom of angina pectoris in a previously asymptomatic patient. Alternatively, patients with pre-existing angina pectoris experience more frequent angina, angina at lower levels of exertion, or angina at rest. Patients who have developed ACS commonly experience their typical symptom of angina in terms of location and radiation but with increased intensity and duration. Patients with subtotal or total occlusion of a coronary artery may be much less responsive or completely unresponsive to the effects of nitroglycerin.

Physical examination during myocardial ischemia may reveal a patient who is clearly anxious and uncomfortable and who may also be experiencing dyspnea, nausea, or vomiting. Sinus tachycardia and hypertension is a common response to the discomfort of ACS, but in some instances sinus bradycardia and varying degrees of heart block may be observed. Bradyarrhythmias may also be associated with hypotension. Auscultation may reveal the presence of an S_4 , reflecting diminished LV compliance, or an S_3 if there is extensive LV dysfunction. In the case of ischemia-induced papillary muscle dysfunction, the systolic

murmur of mitral regurgitation can be heard. Patients with large areas of ischemic myocardium develop elevated LV filling pressures leading to pulmonary congestion, dyspnea, and the physical finding of rales on lung auscultation.

Diagnosis

Patients presenting with ACS require urgent care directed at rapid diagnosis and treatment. The ECG is critically important in early diagnosis of presumed ACS. The finding of ST elevation in multiple leads (Fig. 8-5) is diagnostic of STEMI and portends a more extensive MI and the need for prompt revascularization. The distribution of ST elevation reflects the region of myocardium affected by thrombotic coronary occlusion. For example, ST elevation in leads II, III, and aVF reflects an inferior MI due to occlusion of the right coronary artery (or circumflex coronary artery in some cases). ST elevation in leads V_2 through V_6 (see Fig. 8-5) reflects an anterior MI caused by obstruction of the left anterior descending coronary artery.

Unstable angina or NSTEMI is caused by subtotal vessel occlusion by thrombus leading to reduced coronary blood flow. This results in subendocardial ischemia and the characteristic ECG changes of ST depression (Fig. 8-6). It is important to recognize that up to half of patients with acute MI do not have significant ECG abnormalities on the initial study. Sequential ECGs are frequently required to establish a diagnosis. If there is a high index of suspicion for MI and ECGs are persistently nondiagnostic, the use of leads extending to the patient's back (V_7 to V_9) may demonstrate ST changes related to posterior LV ischemia (usually a circumflex coronary artery occlusion). Echocardiography showing regional wall motion abnormalities can also help to establish the diagnosis of acute MI.

Serum biomarkers also play an important role in the diagnosis of acute MI. Myocardial necrosis leads to the release of biomarkers that can be measured in serial fashion to document the occurrence of MI. The presence of specific biomarkers is

FIGURE 8-5 Acute anterolateral myocardial infarction. Leads I, aVL, and V_2 to V_6 demonstrate ST-segment elevation. Reciprocal ST-segment depression is seen in leads II, III, and aVF. Deep Q waves have developed in leads V_2 and V_3 .

Boston University Hospital

FIGURE 8-6 Marked ST-segment depression in a patient with prolonged chest pain resulting from an acute non-ST-segment elevation myocardial infarction. Between 1 and 3 mm of ST-segment depression is seen in leads I, aVL, and V₄ to V₆. The patient was known to have had a previous inferior myocardial infarction.

definitive evidence of MI, and they are particularly helpful to provide prognostic significance when symptoms are mild and ECG changes are minimal. Common biomarkers include creatine kinase (CK), troponin I, troponin T, lactate dehydrogenase (LDH), and aspartate aminotransferase (AST). Sequential measurement of biomarkers demonstrates their various time courses for abnormal elevation after an acute MI (Fig. 8-7). This information can be helpful in retrospectively timing the occurrence of an event. In contemporary practice, troponin has become the most frequently measured biomarker, although CK is still used. LDH and AST are no longer routinely measured for the diagnosis of MI.

Troponins I and T are the most sensitive and most specific markers of myocardial necrosis, and as a consequence, they have become the standard in the biochemical diagnosis of acute MI. The myocardial-specific isozyme CK-MB may be in the normal range while concomitant measurement of troponin I or T reveals the presence of myocardial necrosis. Troponins I and T begin to rise within 4 hours of myocardial necrosis and remain elevated for 7 to 10 days after the MI event. Confounding elevations of troponin T occur in patients with renal failure and congestive heart failure not related to ACS. Troponin release also occurs in the case of demand ischemia not related to coronary thrombosis. This requires careful attention to the entire clinical presentation in discerning the likelihood of underlying ACS due to coronary thrombosis.

In the absence of clear evidence of NSTEMI (i.e., normal examination, ECG findings, and biomarkers), patients who present with the diagnosis of unstable angina should undergo stress testing. A negative exercise stress test is very helpful for distinguishing those patients who require more aggressive diagnostic testing (e.g., catheterization) from those who can be monitored as outpatients. Some centers have embraced the use of CT coronary angiography in the assessment of low-risk patients. This

FIGURE 8-7 Typical time course for the detection of enzymes released after myocardial infarction. AST, Serum aspartate aminotransferase; CK, creatine kinase; cTnI, cardiac troponin I; cTnT, cardiac troponin T; LDH, lactate dehydrogenase.

technique has a high negative predictive value in establishing a diagnosis of CAD.

Echocardiography can be helpful in patients with equivocal ECG findings for ischemia and normal biomarkers. The presence of regional wall motion abnormalities, particularly if they correlate with the distribution of ECG abnormalities, raises the risk

for underlying CAD as a cause of symptoms. The echocardiogram may also show evidence of other abnormalities as causes of chest discomfort, such as pericarditis, pulmonary embolism, or aortic dissection.

Patients with a high risk for future coronary events should be directed toward coronary angiography. In the absence of contraindications, coronary angiography is indicated for patients with clear evidence of NSTEMI based on clinical presentation of symptoms, ECG changes, and positive biomarkers. Patients undergoing evaluation for unstable angina who have significant stress test abnormalities are also candidates for coronary angiography. Some patients who have ambiguous stress test findings or ongoing symptoms in the absence of other findings of NSTEMI require coronary angiography to resolve the issue as to whether underlying CAD is present.

Up to 15% of patients undergoing coronary angiography for NSTEMI have no significant obstructive CAD. In a number of patients, there will be a clear “culprit” lesion showing the earmarks of plaque rupture with ulceration, associated thrombus, or reduced coronary flow. Lesions that may have played a role in symptoms, ECG findings, or biomarker release that are not clearly stenotic may be assessed for physiologic significance with the use of a fractional flow reserve (FFR) study using a pressure wire device.

Patients who have new-onset chest pain require careful monitoring in an appropriate care setting that allows for rhythm monitoring as well as repeat evaluations of ECG findings and biomarker measurements. Risk assessment is aided by the use of risk scores calculated with either the Thrombolysis in Myocardial Infarction (TIMI) or the Global Registry of Acute Coronary Events (GRACE) algorithms (see Chapter 72, “Acute Coronary Syndrome: Unstable Angina and Non-ST Elevation Myocardial Infarction,” in *Goldman-Cecil Medicine*, 25th Edition). The overall assessment in cases of new symptoms of chest discomfort aims to triage patients based on risk for coronary events. Low-risk patients can be spared aggressive anticoagulation protocols and coronary angiography, whereas high-risk patients are likely to benefit from these approaches. The use of appropriate therapies in high-risk patients (medical therapy or revascularization or both) leads to a 20% to 40% decrease in recurrent ischemic events and a 10% reduction in mortality.

Differential Diagnosis

The initial assessment of patients with possible ACS should include consideration of other potentially life-threatening conditions such as pulmonary embolism and aortic dissection. These considerations are particularly important if the patient’s presentation does not entirely fit that of ACS. Pulmonary embolism can be associated with ECG changes and troponin elevation, and such findings lead to early use of coronary angiography. If there is no CAD-related explanation of the patient’s presentation, prompt investigation for pulmonary embolism is warranted. If the patient has findings suggestive of aortic dissection, that diagnosis should be aggressively pursued with appropriate imaging techniques, given the high risk of mortality associated with that disease. Valvular heart diseases such as aortic stenosis or regurgitation and hypertrophic cardiomyopathy can manifest with symptoms and ECG findings suggestive of ACS. Physical

examination should aid in consideration of these conditions. Pericarditis and myopericarditis can also present diagnostic dilemmas related to chest pain, ECG abnormalities (ST and T-wave changes mimicking ischemia), and positive biomarkers. Stress cardiomyopathy (Takotsubo’s syndrome) also manifests with chest pain, T-wave inversion, and positive biomarkers. Patients with this diagnosis frequently undergo urgent catheterization to assess for CAD. The absence of a culprit lesion and findings of characteristic wall motion abnormalities establish the diagnosis.

Treatment

Patients with chest pain suggestive of ACS need urgent evaluation for evidence of ischemia (serial ECGs) and myocardial necrosis (serial biomarkers). Serial biomarker measurements, in the current era usually troponin, establish the diagnosis of MI. Continuous ECG monitoring is important given the risk of ischemia-mediated arrhythmias, and serial ECGs establish a pattern of ST changes consistent with ischemia. Patients are also prescribed bedrest and supplemental oxygen. Those with a high index of suspicion for ACS require hospital admission for observation and appropriate diagnostic testing. Chest pain lends itself well to diagnosis and treatment algorithms that guide the clinician through decision trees based on expert opinion and evidence-based medicine (see Chapter 72, “Acute Coronary Syndrome: Unstable Angina and Non-ST Elevation Myocardial Infarction,” in *Goldman-Cecil Medicine*, 25th Edition). STEMI is typically diagnosed at the time of initial presentation. Those without evidence of ST elevation can be risk stratified, as discussed earlier, using the guidance of recurrent symptoms, ECG changes, or abnormal biomarker levels. Treatment of patients who are categorized as having unstable angina or NSTEMI is directed by their allocation to either low- or high-risk status.

Once recognized as having ACS, patients require antiplatelet therapy with aspirin (75 to 162 mg per day) and clopidogrel, because plaque rupture and thrombosis is a frequent underlying pathology. Prasugrel, another thienopyridine, is an option in place of clopidogrel for those going to coronary angiography. Antiplatelet therapy significantly reduces mortality risk in patients with NSTEMI. The aspirin/clopidogrel combination is indicated as ongoing therapy in the year following diagnosis of NSTEMI. Symptoms of chest discomfort can be treated with nitrates (sublingual, topical, or intravenous drip) and β -blockers. The latter therapy slows heart rate and reduces blood pressure, effects that translate into reduced myocardial oxygen demand in the face of limited supply. It is important not to give nitrates to patients who have taken phosphodiesterase-5 inhibitors (sildenafil, tadalafil, or vardenafil) within the previous 24 to 48 hours. Attention to this detail minimizes the risk for nitrate-induced hypotension. Calcium channel antagonists may be used in lieu of β -blockers, particularly if there is a need for blood pressure control, but they should be avoided in patients with reduced EF or overt heart failure. The dihydropyridine calcium channel blocker nifedipine can be effective in controlling blood pressure and promoting coronary vasodilation, but it should be given in conjunction with a β -blocker because of the potential for the drug to induce reflex tachycardia and thereby increase myocardial oxygen demand.

Glycoprotein IIb/IIIa inhibitors block platelet aggregation and can reduce ischemic events in patients undergoing PCI as treatment for NSTEMI. These drugs are usually reserved for high-risk patients at the time of PCI. They require intravenous administration and are given for 12 to 24 hours after PCI. The use of this class of drugs for PCI has decreased in light of data suggesting advantages of bivalirudin, a direct thrombin inhibitor, over the glycoprotein IIb/IIIa inhibitors.

Heparin, given in its unfractionated form or as a low-molecular-weight (LMW) preparation, has been shown to reduce the risk of ischemic complications in patients with NSTEMI. Heparin acts by activating antithrombin and thereby inhibiting the formation and activity of thrombin. The anti-ischemic effect of heparin is additive to that of aspirin. Unfractionated heparin is given by continuous intravenous drip for up to 48 hours. It is usually not continued after revascularization. Heparin may be associated with mild thrombocytopenia, and 1% to 5% of patients experience profound antibody-mediated thrombocytopenia. These patients usually have been exposed to heparin in the past, and a known diagnosis of heparin-induced thrombocytopenia necessitates the use of alternative antithrombin therapy.

LMW heparins are fragments of unfractionated heparin that are more predictable in their antithrombin activity and are associated with reduced risks for thrombocytopenia and bleeding complications. The drug should be avoided in patients who have a history of heparin-induced thrombocytopenia. Clinical studies of patients with NSTEMI have shown superiority of LMW heparin over unfractionated heparin in reducing the end point of death or MI during hospitalization. LMW heparin, either enoxaparin or dalteparin, is administered subcutaneously for up to 8 days after hospitalization. As with unfractionated heparin, LMW heparin is not continued after revascularization. Dosing of LMW heparin is based on renal function status, age, and weight. LMW heparin has a long duration of action and cannot be reversed with protamine. Unfractionated heparin has a shorter duration of action and is reversible with protamine, making unfractionated heparin the preferred anticoagulant for patients who may require CABG.

Fondaparinux is a selective factor Xa inhibitor that does not induce thrombocytopenia. It can reduce ischemic events in patients with NSTEMI and is associated with a lower risk of bleeding than is seen with enoxaparin. There is an increased risk of catheter-related thrombosis in patients treated with fondaparinux who are undergoing coronary angiography. This drug is reserved for cases that will be managed noninvasively and where there is a higher risk for heparin-related bleeding.

Bivalirudin, a direct thrombin inhibitor, is an alternative to heparin for patients who are undergoing PCI. It is as effective as the combination of heparin and glycoprotein IIb/IIIa inhibitor in reducing the risk of ischemic complications related to PCI, and it is associated with a reduced risk of postprocedure bleeding. Bivalirudin is used preferentially in patients with a history of heparin-induced thrombocytopenia.

Statin therapy is also indicated in patients with NSTEMI at presentation. Statins act to stabilize plaque and improve endothelial function. These drugs should be initiated at the time of admission to the hospital and continued after discharge. There is

evidence that high-dose atorvastatin (80 mg/day) given to patients with NSTEMI reduces the risk of subsequent ischemic events.

Risk stratification is important in appropriately evaluating patients with ACS. Low-risk patients (age <75 years, normal troponin levels, 0 to 2 TIMI risk factors) should be evaluated with noninvasive testing, either exercise or pharmacologic stress testing, before hospital discharge. Those with tests are positive for ischemia should be considered for predischARGE coronary angiography. This approach leads to selective use of invasive testing and subsequent revascularization. Patients with high-risk ACS profiles (age >75 years, elevated troponin levels, ≥ 3 TIMI risk factors) are candidates for coronary angiography and, when appropriate, revascularization. The high-risk ACS patient group will have fewer subsequent ischemic events when approached in this way. Risk stratification occurs early after admission for possible ACS. An early invasive strategy (coronary angiography within 24 hours of admission) for high-risk patients has been shown to reduce the combined end point of death, MI, or stroke compared with a delayed invasive approach. The occurrence of acute heart failure, hypotension, or ventricular arrhythmias in the face of ACS prompts urgent coronary angiography to identify patients with high-risk coronary anatomy that requires urgent revascularization (see Video, Cardiac Cath, http://www.heartsite.com/html/cardiac_cath.html).

Invasive coronary angiography always carries with it a risk of bleeding complications that is no doubt enhanced by the concomitant use of potent antiplatelet and antithrombin therapies. Those at increased risk for bleeding complications include patients with female gender, low body weight, diabetes mellitus, renal insufficiency, low hematocrit, and hypertension. Some cardiologists recommend the preferential use of a radial artery approach to catheterization in order to minimize bleeding complications that are associated with the femoral artery approach.

Prognosis

The extent and magnitude of ST depression noted on ECG in patients with NSTEMI predicts mortality risk. Patients who exhibit 2 mm or more of ST depression in multiple leads have a 10-fold increased mortality rate at 1 year. The degree of elevation in troponin also identifies patients with an increased risk of mortality during the following year. It has also been observed that the combined measurement of troponin, hsCRP, and brain natriuretic peptide (BNP) predicts an increased mortality risk better than any individual biomarker.

Contemporary practice significantly reduced the risk of mortality for patients with ACS at presentation. Risk stratification with appropriate revascularization and use of antiplatelet therapy, statins, and overall coronary risk factor reduction also contribute to this decrease in mortality risk. Whereas the immediate mortality risk for patients with NSTEMI is lower than for patients with STEMI (5% vs. 7%), those with NSTEMI are more prone to subsequent recurrent coronary events. The cumulative mortality rate for STEMI and NSTEMI is similar at 6 months after presentation (12% vs. 13%). NSTEMI identifies a patient group with significant long-term mortality risk who require aggressive attention to modifiable coronary risk factors.

Acute STEMI and Complications of Myocardial Infarction

Definition and Epidemiology

Sustained myocardial ischemia, regardless of its cause, can result in myocardial necrosis, which underlies the clinical syndrome of MI. MI represents a spectrum of myocardial necrosis, from relatively small amounts of muscle in the case of demand ischemia, to more extensive subendocardial MI that characterizes NSTEMI, to typically large transmural MIs commonly manifesting as STEMI. The current accepted definition of acute MI accounts for clinical setting and mechanism. STEMI represents the range of large MIs that are almost always caused by total occlusion of an epicardial coronary artery resulting in extensive transmural myonecrosis (Fig. 8-8). In contrast, NSTEMI reflects subtotal coronary occlusion leading to subendocardial myonecrosis. Whereas both NSTEMI and STEMI are life-threatening, their different underlying mechanisms mandate different therapeutic strategies and affect the urgency with which they are applied.

One half of all deaths in the United States and developed countries are related to cardiovascular disease. In the United States, there are approximately 1.2 million nonfatal or fatal MIs each year. CAD plays a role in 650,000 deaths each year, and 250,000 deaths are caused by acute MI. One half of patients with acute MI at presentation die within 1 hour of onset, before therapy can be instituted. Of the 5 million patients who come to emergency rooms with chest pain, 1.5 million are admitted to hospital with ACS. In this group of patients, the presence of ST elevation on ECG or an LBBB indicates the diagnosis of STEMI and the need for prompt intervention to open an occluded coronary artery. STEMI accounts for 30% of all MIs, but this mechanism of MI is associated with the highest immediate mortality risk, prompting the need for urgent therapeutic intervention.

Pathology

Lipid-rich coronary plaques are subject to inflammation incited by the response to oxidation of LDL-cholesterol within the plaque. A sequence of inflammatory events leads to macrophage accumulation and the elaboration of metalloproteinases that

degrade collagen in the fibrous cap of the plaque. Thinning of the fibrous cap makes the plaque vulnerable to rupture and exposure of blood to thrombogenic stimuli, resulting in platelet aggregation and activation, thrombin generation, and the evolution of fibrin-based thrombus. If the occlusion is total, transmural myocardial ischemia and necrosis ensue and the ECG demonstrates ST elevation. In contrast, partially occlusive thrombus can result in unstable angina or NSTEMI (subendocardial MI). The presence of coronary collaterals can limit the extent of ischemia and necrosis in either scenario. Both STEMI and NSTEMI can set the stage for arrhythmias and LV dysfunction. Whereas coronary thrombosis is the cause of most MIs, there are patients who develop MI related to coronary embolization, coronary vasospasm, vasculitis, coronary anomalies, dissection of the aorta or a coronary artery, or trauma.

One key feature of the pathology of MI is its time-dependent nature. Experimental and clinical studies have documented that coronary occlusion leads to ischemia and myonecrosis in a wave-front manner, from endocardium to epicardium. Restoration of flow to the vessel within 6 hours after occlusion is associated with limitation of infarct size and a favorable effect on mortality risk. The principle of time dependency of MI drives the need to aggressively reperfuse occluded coronary arteries, and this is the cornerstone of contemporary therapy for STEMI.

Clinical Presentation

Patients with acute MI usually have a combination of chest discomfort, ECG changes (ST elevation in contiguous leads or LBBB), and elevation in biomarkers such as CK-MB and troponin. The high sensitivity and high specificity of troponin have made it the preferred biomarker in the diagnosis of MI. The chest discomfort associated with MI is similar to angina pectoris but more severe in nature. It is usually described as substernal pressure, tightness, or fullness. Patients may have symptoms of discomfort that radiate to the neck, jaw, one or both arms, or the back. Not uncommonly, patients with symptoms of acute MI also experience nausea, vomiting, diaphoresis, apprehension, dyspnea, or weakness. In contrast to angina pectoris associated with stable CAD, acute MI symptoms last longer than 20 to 30 minutes (up to hours).

FIGURE 8-8 Right coronary artery angiogram in a patient with acute inferior myocardial infarction. The *left panel* demonstrates total occlusion of the right coronary artery. The *right panel* depicts restoration of flow 90 minutes after the intravenous administration of tissue-type plasminogen activator.

Occasionally, patients only have symptoms in the non-chest areas usually associated with radiation. Up to 20% of patients, particularly the elderly and diabetics, do not have typical chest discomfort at presentation. The index of suspicion for acute MI should be high in these groups if the patient exhibits profound weakness, acute dyspnea or pulmonary edema, nausea, vomiting, ventricular arrhythmias, or hypotension. The differential diagnosis for patients with chest discomfort suspicious for acute MI includes aortic dissection, pulmonary embolism, chest wall pain, esophageal reflux, acute pericarditis, pleuritis, and panic attacks. Given the life-threatening nature of aortic dissection and pulmonary embolism, these diagnoses should always be paramount, along with acute MI, in patients presenting with chest discomfort.

Physical Examination

A comprehensive examination should be undertaken if acute MI is suspected. Attention must be paid to vital signs, because patients may be either hypertensive or hypotensive during the course of an MI. In some cases, such as inferior MI, profound bradycardia may be present. Auscultation of the heart may reveal an S_4 . In the case of a large MI, the patient may have symptoms and signs of heart failure such as dyspnea, rales, elevated central venous pressure, and an S_3 . Severe heart failure may lead to cardiogenic shock with hypotension and vasoconstriction causing the extremities to be cool to touch. Patients with acute MI are also subject to mechanical problems such as mitral regurgitation due to papillary muscle dysfunction.

Electrocardiogram

The ECG is an important tool in the diagnosis of acute MI. ST elevation of 1 mm or greater in contiguous leads is seen in most patients with acute MI. The initial ECG may be nondiagnostic, so it is important to obtain serial tracings no more than 20 minutes apart to detect the evolutionary changes characteristic of STEMI. The first stage of ECG presentation is ST elevation that subtends the region of the heart affected by transmural ischemia. ST depression may be present in opposing leads, and these are termed *reciprocal changes* (see Chapter 73, “ST Elevation Acute Myocardial Infarction and Complications of Myocardial Infarction,” in *Goldman-Cecil Medicine*, 25th Edition). The presence of reciprocal changes may indicate a larger and more threatening MI. As the MI progresses, ST elevation gives way to T wave inversion. Varying degrees of resolution of ST and T wave changes occur over time, but patients with transmural MI develop pathologic Q waves in the leads subtending the infarcted muscle. Other causes of ST elevation include pericarditis and a chronic repolarization finding of “early repolarization.” The presence of either cause of ST elevation can confound the early ECG diagnosis of acute MI.

Approximately 30% of acute MIs originate from the circumflex coronary artery on the posterior wall of the heart. This type of MI appears on the ECG as precordial ST depression. The presence of precordial ST depression should raise suspicion of the presence of “true posterior MI,” and additional leads placed through the axilla to the back may reveal the presence of posterior ST elevation. Echocardiography demonstrating posterior hypokinesis is also useful in discriminating true posterior MI. Acute inferior MI due to occlusion of the right coronary artery can also

be associated with right ventricular infarction if the right coronary artery’s acute marginal branch is compromised. Right ventricular infarction can lead to some challenging management issues, and its diagnosis is aided by the use of right precordial leads to detect ST elevation.

LBBB can mask ST elevation due to acute MI. Patients with clinical features of acute MI who have an LBBB (particularly a new LBBB) should be presumed to have STEMI and treated appropriately. Right bundle branch block (RBBB) does not mask the ST elevation of STEMI.

Differential Diagnosis

The diagnosis of STEMI is usually straightforward based on symptoms and ECG findings, but a number of conditions can mimic the ST elevation of STEMI and confound the diagnosis. The ECG changes of early repolarization, Takotsubo’s syndrome, acute myocarditis, or pericarditis can be difficult or impossible to distinguish from those of STEMI. In the face of ST elevation and chest discomfort, it may be necessary to perform coronary angiography in patients who ultimately are diagnosed with a condition other than STEMI so as to not miss this critical diagnosis.

Diagnostic Testing

Cardiac troponins (cTnI and cTnT) are sarcomere proteins that, when measured in blood, are specific for myocardial injury. The troponin level becomes elevated 2 to 4 hours after the onset of injury, and the abnormal elevation can persist for up to 2 weeks after the event. The CK-MB isomere is not as specific for heart injury as troponin, but it can still be useful in documenting the presence of MI. CK-MB is found elevated within 4 hours after an acute MI, but it clears more rapidly than troponin. In the case of persistently elevated troponin, a measurable increase in CK-MB may herald another episode of myocardial necrosis. Chronic renal insufficiency is associated with false-positive elevations of troponin T, more so than troponin I. In addition to biomarkers of myocardial injury, other laboratory studies obtained in patients with acute MI include a complete blood count, blood chemistries, lipid panel, prothrombin time (PT), and partial thromboplastin time (PTT). Leukocytosis is a common finding in acute MI, reflecting the inflammatory nature of myocardial necrosis.

At the time of admission, chest radiographs are obtained to assess for the presence of pulmonary edema or mediastinal widening suspicious for dissection. Echocardiography is important in delineating the extent of MI and assessing EF. In cases of diagnostic ambiguity, early use of echocardiography can demonstrate the presence of regional wall motion abnormalities consistent with acute MI. Echocardiography with color Doppler is also helpful in diagnosing complications of acute MI such as infarct-related mitral regurgitation or ventricular septal defect (VSD), pericardial effusion, or evidence of pseudoaneurysm as a result of myocardial rupture. Follow-up echocardiography in the months after acute MI can also reveal recovery of LV function. Radionuclide tracer studies are not useful in diagnosing acute MI. CT, cardiac MRI, and transesophageal echocardiography are all useful in diagnosing aortic dissection when there is an increased index of suspicion. Cardiac MRI can also distinguish myopericarditis.

Treatment

Acute STEMI is caused by occlusion of the epicardial coronary artery by thrombus after rupture of a vulnerable plaque. The process of myocardial necrosis is time dependent, so diagnosis and treatment of STEMI to preserve myocardium must occur as quickly as possible. More than half of deaths occur within 1 hour after onset of symptoms, before the patient can be reached for emergency care. Patients often delay seeking care for symptoms of acute MI despite efforts to alert the public to the risk of ignoring symptoms of chest discomfort. Emergency medical personnel who respond to patients with possible MI begin to institute initial therapy in the field. Patients are monitored with ECG for rhythm disturbances such as ventricular tachycardia (VT) or ventricular fibrillation (VF) that require prompt cardioversion or defibrillation. Oxygen is administered via nasal cannula, and intravenous access is established. Aspirin (162 to 325 mg) is administered to the patient, and sublingual nitroglycerin may also be given in attempt to relieve chest discomfort. Some emergency response systems perform 12-lead ECGs and telemeter the results to the emergency department, allowing for early diagnosis of STEMI and early decision making regarding revascularization strategies.

Once the patient arrives in the emergency department, an ECG, if not already available, will be preformed within 5 minutes. If the ECG is nondiagnostic, a second study is obtained no more than 20 minutes after presentation. A diagnosis of STEMI triggers decision making regarding reperfusion strategies that are used by the particular institution (see Chapter 73, “ST Elevation Acute Myocardial Infarction and Complications of Myocardial Infarction,” in *Goldman-Cecil Medicine*, 25th Edition). Hospitals that are capable of performing emergency cardiac catheterization for the purpose of reperfusion therapy have an established rapid response system to activate the catheterization laboratory for this urgent therapy. There is evidence that primary PCI therapy for STEMI is superior to fibrinolytic therapy, but its use depends on the timely availability of a well-trained catheterization team. The quality of primary PCI is signified by a so-called door-to-balloon time of less than 90 minutes. Likewise, the standard for fibrinolytic therapy is a door-to-needle time of less than 30 minutes. Regardless of the means of reperfusion, it is important for the hospital treating patients with STEMI to have a structured protocol for timely diagnosis, decision making, and initiation of therapy.

In addition to aspirin, the patient should be given a loading dose of thienopyridine (clopidogrel 600 mg or prasugrel 60 mg), assuming he or she will be treated with primary PCI. Unfractionated heparin in a dose of 60 IU/kg should be administered (no more than 4000 IU bolus) with a drip rate of 12 IU/kg/hour (maximum dose, 1000 IU/hour). LMW heparin may also be used (enoxaparin 30 mg IV bolus with 1 mg/kg subcutaneously every 12 hours for patients younger than 75 years of age who have normal renal function). Other agents such as glycoprotein IIb/IIIa inhibitors or bivalirudin are administered depending on the protocols of the catheterization laboratory.

Intravenous morphine (2 to 4 mg, repeated every 5 to 15 minutes as needed) is frequently used for pain control. Patients also are commonly given sublingual nitroglycerin 0.4 mg (repeat every 5 minutes for no more than three total doses), which may

help to diminish chest discomfort. Intravenous nitroglycerin may be helpful for control of both pain and hypertension if present. Intravenous β -blockers such as metoprolol (5-mg bolus every 10 minutes for a total dose of 15 mg) is indicated in the treatment of STEMI, but it should be avoided in the face of heart failure, severe COPD, hypotension, or bradycardia. β -Blockers (metoprolol, propranolol, atenolol, timolol, and carvedilol) have been shown to significantly reduce the risk of future MI and cardiovascular mortality. Statin therapy, as mentioned for NSTEMI, is recommended for all patients with STEMI as a presenting symptom regardless of their history of hypercholesterolemia. Other adjunctive measures include bedrest for the first 12 hours, ongoing oxygen by nasal cannula with pulse oximeter monitoring, continuous rhythm monitoring, anxiolytic agents as needed, and stool softeners. Atropine is kept in reserve for the treatment of hemodynamically significant bradycardia, which may occur with inferior MI.

ACE-inhibitor therapy also plays an important role in the long-term survival of patients after STEMI. ACE-inhibitor therapy has been shown to reduce the incidence of heart failure, recurrent MI, and long-term mortality after STEMI. ACE inhibitors commonly used for this purpose include lisinopril, captopril, enalapril, and ramipril. The decision to initiate ACE-inhibitor therapy is directed by the patient's tolerance. Care is warranted early after STEMI, because the patient may be prone to hypotension related to ACE-inhibitor therapy. A low dose should be administered first, with gradual upward titration.

Aldosterone receptor blockade with eplerenone (25 to 50 mg/day) reduces cardiovascular mortality after MI in patients with heart failure and a reduced EF of less than 40% or diabetes. Spironolactone also reduces mortality in patients with heart failure and a history of remote MI.

Reperfusion Therapy

Timely reperfusion therapy, either thrombolytic therapy or primary PCI, is critical to limiting the extent of MI and reducing the risks of future morbidity and mortality. Primary PCI has been shown to have advantages over thrombolytic therapy, with higher immediate and long-term vessel patency. Primary PCI depends on the availability of cardiac catheterization facilities and staff to conduct the reperfusion procedure quickly (see earlier discussion). If the patient has not had access to a catheterization facility for longer than 2 hours after presentation, thrombolytic therapy is a reasonable alternative.

In the randomized, placebo-controlled Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto (GISSI) study, thrombolytic therapy with intravenous streptokinase was shown to reduce the risk of mortality in patients with STEMI if it was administered early after presentation. The time-dependent nature of therapy was also demonstrated, in that patients treated more than 12 hours after the onset of symptoms had no measurable benefit from thrombolysis. The next generation of thrombolytic agents, recombinant tissue-type plasminogen activators (rt-PA), improved on mortality reduction when compared with streptokinase (30-day mortality rate, 7.3% with streptokinase vs. 6.3% with rt-PA). The advantage of rt-PA appeared to be related to enhanced vessel patency at 90 minutes after administration (80% with rt-PA vs. 53% to 60% with streptokinase). Subsequent forms

of rt-PA, although easier to administer, did not further reduce mortality. The major attribute of thrombolytic therapy is its ease of administration, but there is a significant risk (0.5% to 1%) of catastrophic bleeding complications in the form of intracerebral hemorrhage. Age older than 75 years, female gender, hypertension, and concomitant use of heparin increase the risk of this complication. In the case of failed thrombolytic therapy, rescue PCI may be pursued.

Primary PCI has been shown to be superior to thrombolytic therapy based on lower overall mortality rates and reduced risk of recurrent nonfatal MI. It is also associated with higher vessel patency rates and a low risk of intracranial hemorrhage. Primary PCI is frequently performed by mechanical aspiration of thrombus and placement of a coronary stent. Balloon angioplasty may or may not be needed during this procedure. Patients should receive preprocedure thienopyridine (clopidogrel 600 mg or prasugrel 60 mg). Bivalirudin was shown in a clinical trial of primary PCI to be superior to both heparin- and glycoprotein IIb/IIIa–based anticoagulation with lower post-MI mortality and fewer bleeding complications. Centers that are dedicated to primary PCI as the preferred therapy are likely to have the best outcomes when operators are sufficiently skilled and the institution cares for this patient population on a regular basis. Primary PCI is the best option for patients in cardiogenic shock (within 18 hours after onset of shock), for patients with prior CABG (graft occlusion is not amenable to thrombolysis), and for patients older than 70 years of age (conferring a reduced risk of intracerebral hemorrhage compared with thrombolysis).

Complications of Myocardial Infarction

Recurrent Chest Pain

MI is associated with a number of possible problems related to the extent of injury (Table 8-6). Patients can experience post-infarction angina which may reflect re-occlusion of the infarct related vessel. This can occur either in patients who underwent primary PCI with stent placement (stent thrombosis) or thrombolysis. Post-infarction angina usually requires cardiac catheterization for appropriate diagnosis and treatment. Patients with transmural MI are also subject to pericarditis 2 to 4 days after the event. This diagnosis is usually established by the symptom nature and pattern (worse with inspiration or supine position,

improved with sitting), which is different from their initial presentation with acute MI. A less common event is the development of pericarditis due to Dressler's syndrome up to 10 weeks after acute MI. This is likely an immune-mediated phenomenon. Pericarditis is treated with aspirin or nonsteroidal anti-inflammatory drugs.

Arrhythmias

The highest risk of life-threatening arrhythmias is during the first 24 to 48 hours after the onset of acute MI. Ischemic myocardium is susceptible to arrhythmia generation, probably based on micro-re-entry associated with ischemic myocardium. The significant mortality risk in the early hours of acute MI is largely attributed to arrhythmias such as VF or VT. The risk of VF is about 3% to 5% in the early hours of MI and diminishes over 24 to 48 hours. One of the benefits of rhythm monitoring during the first 48 hours after presentation is prompt recognition and treatment of life-threatening ventricular arrhythmias.

Accelerated idioventricular rhythm occurs early in the course of MI and may be associated with reperfusion. This arrhythmia is well tolerated and does not require specific therapy.

Ventricular arrhythmias occurring late (>48 hours) after acute MI usually are associated with large underlying MIs and heart failure. Late episodes of VF or VT portend a poor prognosis. Immediate therapy for VF is electrical defibrillation. VT that causes hemodynamic embarrassment is treated with synchronized electrical cardioversion. β -Blocker therapy may help to suppress arrhythmias in patients who are prone to them, as may the use of amiodarone. Correction of residual ischemia may also play a role in controlling VF or VT events. Patients with late VF or hemodynamically significant VT are candidates for an implantable cardioverter defibrillator device (ICD). An ICD can also improve survival in asymptomatic patients with a persistently reduced EF less than 30% at 40 days after their acute MI. ICD therapy is also indicated if the EF is less than 35% at 40 days after MI in a patient with symptomatic heart failure.

Atrial fibrillation (AF) occurs in 10% to 15% of patients after MI. Those more prone to AF include patients with older age, large MI, hypokalemia, hypomagnesemia, hypoxia, or increased sympathetic activity. Rate control with β -blockers (e.g., metoprolol), digoxin, calcium channel blockers (e.g., diltiazem) or some combination of these agents is warranted, as is the use of intravenous heparin to reduce the risk of systemic embolization. Cardioversion is warranted in the face of rapid rates that cause ischemia, heart failure, or hypotension. Amiodarone is sometimes used to help maintain sinus rhythm for the first few months after MI-related AF.

Sinus bradycardia or AV block due to increased vagal tone is common in cases of inferior MI (30% to 40%). Reperfusion of the right coronary artery may be associated with significant bradycardia (Bezold-Jarisch reflex). Atropine (0.5 to 1.5 mg IV) can resolve severe inferior MI–related bradycardia. In contrast, heart block and wide-complex escape rhythms associated with anterior MI suggest an infra-AV node block. This may be worsened by the use of atropine.

Advanced degrees of heart block may require the placement of a permanent pacemaker. Intermittent second-degree or third-degree AV block associated with bundle branch block or

TABLE 8-6 COMPLICATIONS OF ACUTE MYOCARDIAL INFARCTION

Tachyarrhythmias (supraventricular, ventricular)
Conduction abnormalities (bundle branch and fascicular blocks)

symptomatic AV block are indications for a permanent pacemaker. Type I AV block (Wenckebach) is usually not persistent and rarely causes symptoms that warrant a permanent pacemaker.

Heart Failure and Low-Output States

MI involving 20% to 25% of the left ventricle can result in significant heart failure manifesting with dyspnea due to pulmonary congestion and findings of LV dysfunction such as an S_3 or S_4 . Cardiogenic shock is associated with loss of 40% of the myocardium. This condition carries a very high risk of mortality. In the era of widespread use of reperfusion therapy, the incidence of post-MI heart failure or cardiogenic shock has declined. Early use of reperfusion therapies limits infarct size and the risk of complications related to heart failure. When acute heart failure occurs with MI, therapeutic interventions including oxygen, intravenous morphine, and diuretics can help stabilize the patient. Nitroglycerin can also help by reducing the elevated preload. Long-term therapy for heart failure related to reduced EF after acute MI includes the use of ACE inhibitors (or ARBs), appropriate β -blockers, aldosterone receptor antagonists such as eplerenone or spironolactone, and diuretics as needed.

The acutely infarcted ventricle requires an increased filling pressure and volume to optimize its performance. Patients with acute MI may become relatively fluid depleted due to nausea, vomiting, or decreased fluid intake, leading to reduced LV volume and a fall in cardiac output. This can translate into hypotension that is best treated by judicious administration of fluids.

Acute inferior MI is usually associated with a low mortality risk once the early arrhythmia-prone hours have passed. Occlusion of the right coronary artery and a significant acute marginal branch can lead to right ventricular infarction. Approximately 10% to 15% of patients with inferior MI have associated right ventricular infarction. This condition produces a significant increase in mortality risk (in-hospital mortality, 25% to 30% vs. <6%). Hallmarks of right ventricular infarction include elevated jugular venous pressure with Kussmaul sign and hypotension. Right ventricular function frequently recovers, but it may be necessary to administer sufficient volume to maintain right heart output. Short-term inotropic support with dobutamine in sometimes needed, and venodilators and diuretics should be avoided. High-degree AV block, usually transient with inferior MI, may worsen hemodynamics and necessitate temporary AV sequential pacing. AF may not be tolerated and may require cardioversion.

Cardiogenic Shock

Cardiogenic shock is a clinical syndrome associated with extensive loss of myocardium, which leads to a reduced cardiac index ($<1.8 \text{ L/min/m}^2$) in the face of elevated LV filling pressures (pulmonary capillary wedge pressure $>18 \text{ mm Hg}$), resulting in systemic hypotension and reduced organ perfusion. This shock state is associated with mortality rates in the range of 70% to 80%. Aggressive diagnosis with hemodynamic monitoring and appropriate support with an intra-aortic balloon pump (IABP) and inotropic agents as indicated can help to stabilize the patient. IABP therapy is at best temporizing, and the patient's survival depends on the presence of reversible factors such as ischemia

that respond to revascularization or correction of a mechanical complication of MI (e.g., mitral regurgitation or VSD). IABP therapy cannot be used in the face of significant aortic insufficiency and may not be feasible in the presence of significant peripheral vascular disease. Some centers now resort to ventricular assist devices to stabilize the patient with cardiogenic shock, but recovery of LV function is not guaranteed with this approach.

Mechanical Complications

Mechanical complications of acute MI include mitral regurgitation (due to ischemic papillary muscle dysfunction or rupture), VSD, free wall rupture, and LV aneurysm formation. These problems usually occur during the first week after MI, and they account for as much as 15% of MI-related mortality. A new murmur, sudden onset of heart failure, or hemodynamic collapse should also raise suspicion of a mechanical complication of MI. Patients who either were not reperfused or were reperfused late after onset of MI are most at risk for these problems. Echocardiography usually identifies the mechanical problem, and hemodynamic assessment with right heart catheterization can aid the diagnosis. Surgical correction of the defect is usually required.

Papillary muscle rupture or dysfunction leading to acute severe mitral regurgitation results in severe heart failure and up to 75% mortality within 24 hours after onset. Afterload reduction with intravenous nitroprusside and the use of IABP can help to stabilize the patient, but surgical valve repair or replacement will be needed to provide some chance of survival. Surgery is associated with a 25% to 50% mortality risk, but that still is better than the risk with medical or IABP therapy only.

Elderly patients, particularly those with hypertension, are more prone to MI-related VSD. Thrombolytic therapy may also place patients at risk for this complication. Acute VSD with resultant left-to-right shunting can produce severe hemodynamic instability. As with acute mitral regurgitation, afterload reduction and IABP may help to stabilize the patient, but ultimately surgical repair will be required. Moderate to large VSDs are not well tolerated and are associated with significant mortality risk. VSDs related to anterior MI may offer a better opportunity for surgical repair than those resulting from inferior MI. Some patients have been helped by the use of percutaneous closure devices, which can afford an opportunity to delay surgery until there is better tissue healing in the infarct area.

LV free wall rupture is similar to VSD in terms of risk for occurrence and underlying myocardial pathology. Free wall rupture is usually associated with sudden death due to cardiac tamponade. On occasion, a pseudoaneurysm forms and the patient can be treated surgically.

Thromboembolic Complications

In earlier years, thromboembolism in the form of either cardioembolic stroke or pulmonary embolism contributed to 25% of post-MI in-hospital mortality, and clinical events were diagnosed in 10% of patients. The risk of thromboembolism is linked to the presence of LV mural clot, which is more likely to be found in anterior MI with associated apical akinesis and deep venous thrombosis due to prolonged bed-rest. Contemporary methods

of care for acute MI have greatly reduced the risk of post-MI thromboembolism.

Reperfusion therapy, when applied in a timely fashion, results in less extensive MI and less impairment of LV function. Patients with anterior MI treated with reperfusion therapy are less likely to have extensive apical akinesis, which is the breeding ground for mural thrombus. It is advised that patients treated for acute MI have an echocardiogram to assess for overall LV function; in the case of anterior MI, the presence of apical mural thrombus can be detected by echocardiography. If LV mural thrombus is present, the patient should receive therapeutic anticoagulation with unfractionated or LMW heparin while oral anticoagulation with warfarin is initiated. Warfarin therapy should be continued for 6 months after MI when LV apical mural thrombus is detected. Early ambulation after MI, along with the use of compression stockings and subcutaneous heparin prophylaxis (unfractionated or LMW) for deep venous thrombosis, has greatly diminished the threat of pulmonary embolism.

PROGNOSIS

Risk Stratification after Myocardial Infarction

Key to understanding an individual patient's risk for future coronary events or mortality related to MI is a thorough assessment of drivers for those risks: status of LV function and its impact on clinical functional status, residual myocardial ischemia, and spontaneous or exercise-induced arrhythmias. Appropriate pre-discharge assessments provide a comprehensive picture of the patient's risk status and prognosis.

Electrocardiographic Monitoring

Patients are routinely monitored by telemetry systems that capture arrhythmic events in the first 48 hours after MI. Late ventricular arrhythmias such as VF or sustained VT identify patients who are likely to benefit from ICD therapy. This is particularly true if EF is reduced to less than 40%. ICD implantation is also indicated for patients with persistently reduced EF (<30%).

Cardiac Catheterization and Noninvasive Testing

Predischarge risk stratification may involve cardiac catheterization, submaximal predischarge exercise stress testing (on days 4 to 6), or maximal exercise stress testing after discharge (at 2 to 6 weeks). The presence or absence of high-risk coronary anatomy is demonstrated for patients who have undergone primary PCI at the time presentation. Many patients who have been treated with thrombolytic therapy undergo coronary angiography before discharge to determine the extent and severity of underlying CAD as well as the status of the culprit lesion. If coronary angiography is not performed, predischarge submaximal exercise testing (up to 70% of maximal predicted heart rate) is done to identify those who are at increased risk for postdischarge coronary ischemic events. Patients who undergo submaximal exercise stress testing in lieu of coronary angiography frequently have a follow-up maximal exercise stress test within 2 to 6 weeks after discharge. During stress testing, positive results that suggest the

need for coronary angiography include exercise-induced angina, ST changes of ischemia (ST depression), exercise-induced hypotension, exercise-induced ventricular arrhythmias, and low functional capacity. The sensitivity and specificity of stress testing after MI is enhanced by the use of imaging modalities such as stress echocardiography or nuclear perfusion imaging. All patients should have their EF assessed, typically by echocardiography, before discharge.

Secondary Prevention, Patient Education, and Rehabilitation

The goal of secondary prevention is to reduce the risk of recurrent MI and cardiovascular mortality. Risk factor modification is key to the secondary prevention strategy. All patients should have their lipid status assessed at the time of admission, but statin therapy is warranted in patients with acute MI at presentation. The target LDL level is less than 100 mg/dL, preferably closer to 70 mg/dL. Smoking cessation is of critical importance because it can reduce the risk of reinfarction, and ongoing smoking can double the risk of recurrent MI or mortality in the first year after MI. Structured smoking cessation programs and the use of pharmacologic aids (e.g., nicotine patches or gum, bupropion, varenicline) can increase the success of smoking cessation efforts.

Antiplatelet therapy with aspirin (75 to 162 mg/day) is given indefinitely to all patients after MI. Regardless of whether primary PCI has been performed, patients will benefit from the use of clopidogrel 75 mg/day for the first year after MI. Those patients who have received a stent during primary PCI should continue either clopidogrel 75 mg/day or prasugrel 10 mg/day for a duration appropriate for the type of stent employed. At the least, patients should receive dual antiplatelet therapy (aspirin + thienopyridine) for 1 month for a bare metal stent, 3 months for a sirolimus-based stent, and 6 months for a paclitaxel-eluting stent. Most patients who have been treated with any type of stent receive dual antiplatelet therapy for the first year after their MI. The use of antiplatelet therapy in any form should be tempered by an individual patient's risk of hemorrhagic complications.

The use of warfarin anticoagulation (target international normalized ratio [INR], 2.0 to 3.0) is indicated for patients with persistent or paroxysmal AF, guided by their CHADS-2 score (congestive heart failure, hypertension, age \geq 75 years, diabetes mellitus, and stroke). Patients who have experienced pulmonary or systemic thromboembolism also warrant warfarin therapy. Patients who are at high risk for thromboembolism after acute MI, such as those with low EF related to anterior MI, should also be considered for warfarin. The concomitant use of dual antiplatelet therapy along with warfarin requires careful monitoring for bleeding complications.

Acute anterior MI that has resulted in significant injury to the ventricle with an EF of less than 40% places the patient at risk for future negative remodeling of the left ventricle and potential heart failure. ACE-inhibitor therapy has been shown to reduce the risk of negative remodeling and the occurrence of heart failure in such patients. This group of patients also experiences a reduction in future recurrent MI risk with the use of ACE-inhibitor therapy. This observation does not appear to carry over to patients with stable CAD. ACE-inhibitor therapy (captopril, ramipril, lisinopril) is indicated for all patients after MI. The use

of ARBs (e.g., valsartan, losartan) is reasonable for patients who are intolerant of ACE-inhibitor therapy. The aldosterone receptor antagonist eplerenone (25 mg/day, titrated to 50 mg/day) is indicated as additive therapy to ACE or ARB in MI patients who have reduced EF (<40%) or diabetes. Careful monitoring of serum potassium is required after initiation of eplerenone together with ACE or ARB.

Beta blocker therapy reduces mortality risk in patients who have reduced EF post-MI. This therapy should be avoided in patients with uncompensated heart failure early after MI or the presence of other contraindications. Metoprolol succinate (25 mg/day titrated up to 200 mg/day) or carvedilol (3.125–6.25 mg titrated to 25 mg twice each day) should be initiated at low doses and titrated upward as tolerated. The role of beta blockers in patients with no residual myocardial ischemia, arrhythmias, or normal EF is not clear.

Nitrates, either short-acting sublingual nitroglycerin or long-acting versions, may be useful in the treatment of stable angina. Calcium channel blocking drugs should be avoided in patients with reduced EF (<40%). In patients with normal EF, either diltiazem or verapamil may be useful as a substitute in patients who are intolerant of β -blockers when either antianginal therapy or rate control for AF is needed. The dihydropyridine, amlodipine, may be a useful adjunct for control of hypertension or treatment of angina. It should be used with caution in the face of reduced EF.

After acute MI, women should refrain from initiating hormone therapy with estrogen or estrogen/progesterone preparations; these agents do not decrease the risk of recurrent MI but do increase the risk of thromboembolic events. The ongoing use of hormone therapy in women already receiving treatment should be individualized, with a bias toward discontinuing therapy. Diabetic patients need attention to their degree of glycemic control, with a target of hemoglobin A_{1c} less than 7%. Vitamin supplements have no clear role in therapy for MI patients. Fish oil supplements do not appear to benefit patients who have experienced acute MI.

Patient Education and Cardiac Rehabilitation

It is important to begin the education of patients early after acute MI so that they understand the value of their various prescribed

medical therapies and the need for risk factor modification. Cardiac rehabilitation programs are very useful in the ongoing education of patients; they reinforce positive lifestyle changes and provide exercise training in the post-MI period. Such programs not only educate patients but also help them to regain confidence in their ability to perform the tasks of daily living and other activities they enjoy. Early follow-up with the physician after discharge is also important to ensure clinical stability and tolerance of medical therapy and to monitor the progress of lifestyle changes.

Cardiac Arrhythmias

Marcie G. Berger, Jason C. Rubenstein, and James A. Roth

BASIC CELLULAR ELECTROPHYSIOLOGY

Cardiac myocytes actively maintain a negative resting membrane potential (E_m) through the differential distribution of ions between intracellular and extracellular compartments, which is an energy-dependent process that relies on ion channels, pumps, and exchangers. Transmembrane differences in voltage and ionic concentration create electrical and chemical forces that drive charged ions in and out of cells.

The resting E_m of cardiac myocytes is controlled by potassium ions (K^+). Active K^+ transport by the sodium-potassium adenosine triphosphatase pump (Na^+ , K^+ -ATPase) produces a transmembrane ionic gradient, with the intracellular concentration of K^+ exceeding the extracellular concentration. This favors the net efflux of K^+ from cells, yielding a resting negative charge within the cardiac myocytes. K^+ continues to flow from the intracellular to the extracellular compartment until the negative intracellular charge counterbalances the transmembrane K^+ concentration gradient at a potential called the *equilibrium potential* for K^+ . This potential, at which the net K^+ current is zero, is close to the resting E_m of nonpacemaker cardiac myocytes. Pacemaker cells (i.e., sinoatrial and atrioventricular [AV] nodal cells) are characterized by a resting E_m of -50 to -60 mV. The resting E_m of atrial and ventricular myocytes is typically -80 to -90 mV.

The depolarization of a cardiac myocyte to threshold potential triggers a sequence of ionic movements resulting in a cardiac action potential (Fig. 9-1). The action potential is divided into five phases. Phase 0 is the rapid depolarization of nonpacemaker myocytes resulting from rapid sodium ion (Na^+) entry through fast Na^+ channels. These channels have three conformational states: closed (resting state), open (conducting Na^+ current), and inactivated, from which recovery is voltage dependent. Phase 1 is early, rapid, partial repolarization of the cell mediated by K^+ efflux. During phase 2, the plateau phase, there is a small net current flow, with inward calcium ion (Ca^{2+}) flow balanced by outward K^+ flow.

During phase 3, repolarization is mediated by an increase in K^+ efflux and a decline in Ca^{2+} influx. The dominant repolarizing current is I_{Kr} , the rapidly activating delayed rectifier K^+ current, a channel encoded by the *KCNE2* gene (also called *HERG*). The I_{Ks} current, or slowly activating delayed rectifier K^+ current, also contributes to repolarization. Phase 3 determines to a large degree the cellular refractory period. Importantly, I_{Kr} is inhibited by a large number of drugs that prolong the action potential duration.

Phase 4 is particularly significant in cardiac pacemaker cells because slow depolarization occurs from the resting membrane

potential to the threshold potential. The resting E_m , rate of spontaneous phase 4 depolarization, and rate of phase 0 depolarization differentiate slow-response from fast-response cardiac myocytes. Slow-response cells, located in the sinoatrial node and AV node, normally display automaticity or spontaneous depolarization during phase 4. Resting E_m in slow-response cells is less negative, and Ca^{2+} current mediates phase 0 depolarization. Conduction in these pacemaker cells is slow, and recovery from

FIGURE 9-1 Electrophysiologic basis of the cardiac cellular action potential. **A**, Fast-response cells found in working myocardium and the specialized infranodal conduction system maintain a strongly negative resting membrane potential and a brisk phase 0 upstroke mediated by rapid sodium influx at the start of the action potential. **B**, In contrast, slow-response cells found in the sinus node and atrioventricular nodal tissue exhibit less-negative resting membrane potentials, slower calcium-channel-dependent action potential upstrokes, and phase 4 depolarization.

inactivation is time dependent. The fast-response cells found in atrial myocytes, ventricular myocytes, and the His-Purkinje system display slow phase 4 depolarization and do not typically display automaticity. The resting E_m is more negative, and the fast Na^+ current drives rapid phase 0 depolarization and rapid conduction. Recovery from inactivation in these cells is voltage dependent.

The sinus node typically displays the fastest phase 4 depolarization. Other cardiac tissues have the capacity to depolarize spontaneously, and subsidiary pacemakers may take over when sinus rates slow and under conditions of increased automaticity. Typically, the AV node, located above the AV ring, serves as the heart's secondary pacemaker, with a spontaneous rate of depolarization of 40 to 50 beats per minute. Automaticity of cardiac myocytes is increased when the slope of phase 4 depolarization increases, with a shift of threshold potentials to more negative values, or in the presence of more positive maximal diastolic potentials.

The sinus node is the primary intrinsic pacemaker, and spontaneous depolarization leads to action potential generation, with normal resting rates of 60 to 100 beats per minute. Depolarization then spreads through the atria to the AV node, where conduction slows, introducing a delay between atrial and ventricular activation, and then to the His-Purkinje system fibers, which originate at the AV node with the bundle of His and split to form the left bundle branch and the right bundle branch, rapidly conducting depolarization to the ventricular myocardium. Cardiac myocytes are joined by electrical synapses called *gap junctions*, which permit the flow of intracellular current from cell to cell.

Classification of Arrhythmias

Mechanistically, cardiac arrhythmias can be broadly divided into disorders of action potential formation and disorders of impulse conduction. Clinically, arrhythmias are classified as bradycardias and tachycardias, with further categorization according to arrhythmia origin. This information is used to guide evaluation and management strategies.

Electrophysiologic Mechanisms of Arrhythmias

Automaticity is a normal function of pacemaker cells, occurring during phase 4 depolarization. *Enhanced automaticity* occurs when pacemaker cells depolarize at a faster rate due to an increased slope of phase 4 depolarization, a shift of threshold potential to a more negative value, or a shift of the maximal diastolic potential to a more positive value. These changes may occur with sympathetic stimulation. Enhanced automaticity may be normal (e.g., appropriate sinus tachycardia) or abnormal (e.g., inappropriate sinus tachycardia). Spontaneous depolarization occurring in nonpacemaker cardiac myocytes is called *abnormal automaticity*. Conditions as ischemia, electrolyte abnormalities, and sympathetic stimulation may produce abnormal automaticity. Premature atrial and ventricular depolarizations, atrial tachycardia, and ventricular tachycardia (VT) may result.

Triggered activity occurs when secondary cardiac depolarizations are initiated by prior depolarizations. If these secondary

depolarizations reach threshold potential, they may generate action potentials during or immediately after phase 3 of the action potential. *Early afterdepolarizations* (EADs) are observed when triggered depolarization occurs during phase 3 of the action potential. Inciters of EADs include QT-prolonging drugs, hypokalemia, and bradycardia. Patients with congenital long QT syndrome (LQTS) are prone to develop EADS, resulting in *torsades de pointes* (TdP).

When triggered activity occurs during phase 4, *delayed afterdepolarizations* (DADs) result. DADs are exaggerated at rapid heart rates and observed with digoxin toxicity and high-level catecholamine states, conditions that are associated with intracellular calcium overload. DADs are thought to be the chief arrhythmic mechanism underlying catecholaminergic polymorphic VT (CPVT).

Reentry is the dominant mechanism underlying clinical tachyarrhythmias. Reentry describes the reexcitation of a localized region of cardiac tissue by the same impulse, requiring bifurcating conduction pathways with different velocities and refractory periods. To permit reentry, unidirectional block in one pathway and slowed conduction in the other are required. Reentry is further categorized as anatomic, circling around a fixed anatomic obstacle, or functional, in which the inexcitable center of a reentrant circuit is not fixed but functionally refractory. [Figure 9-2](#) illustrates reentry as an arrhythmic mechanism. The two pathways join proximally and distally. Pathway A conducts rapidly but has a long refractory period. Pathway B is slowly conducting but has a shorter refractory period. A normally timed impulse enters the two pathways through the proximal common pathway, conducting rapidly down A and slowly down B. As the impulse from pathway A reaches the distal common pathway, while continuing distally, it may also turn around to activate B retrogradely. This impulse collides with the slowly conducting antegrade impulse in pathway B, extinguishing the impulse. However, a sufficiently premature stimulus may enter the proximal common pathway, finding pathway A with its long refractory period inexcitable, traveling slowly down pathway B, and finally reaching the distal common pathway. Due to the slow conduction velocity in pathway B, pathway A may no longer be refractory, and the impulse may successfully travel retrograde up pathway A, potentially repeatedly activating the circuit. Reentry is the most common mechanism producing supraventricular tachycardia (SVT) and VT.

 For a deeper discussion on this topic, please see Chapter 61, "Principles of Electrophysiology," in Goldman-Cecil Medicine, 25th Edition.

GENERAL APPROACH TO MANAGEMENT

Diagnostic Procedures

Electrocardiography

The baseline 12-lead electrocardiogram (ECG) is essential for the initial evaluation of patients with arrhythmic symptoms. The baseline ECG may indicate an underlying structural heart disease, with Q waves or fractionated QRS complexes suggesting prior myocardial infarction (MI). Slow sinus rates or AV conduction

FIGURE 9-2 Mechanism of reentry. Reentry requires two distinct pathways with different refractoriness and a region of slowed conduction. One pathway (*A*) has normal rapid conduction but a long refractory period. The second pathway (*B*) has slowed conduction but a relatively shorter refractory period. To initiate reentry, conduction must fail down one pathway in the antegrade direction but then permit later retrograde reactivation of this pathway. This is referred to as a *unidirectional block*. A fixed or functional obstacle must maintain separation of the two pathways. Although drawn schematically as a circular loop, the anatomy of circuits is often complex and circuitous and is different in different arrhythmia mechanisms. **A**, In normal rhythm, the circuit is activated in an antegrade direction down both pathways. However, because of slowed conduction in the *B* limb, distal activation is mediated by the faster *A* pathway, which arrives first and may activate the slowly conducting pathway in a retrograde direction. This retrograde conduction is electrocardiographically concealed (invisible), collides with the antegrade wave front, and is extinguished, and no tachycardia results. **B**, Reentry is usually initiated by a premature beat originating independently of the circuit. The premature beat fails to propagate down the rapidly conducting *A* limb due to differential refractoriness of the two limbs, but it is able to propagate down the slowly conducting *B* pathway, where it may encounter substantial delay due to increased conduction time with prematurity (i.e., decremental conduction), allowing recovery of the previously blocked rapidly conducting *A* limb. This permits the rapidly conducting *A* limb to act as a return path and for ultimate reentrant reactivation of the slowly conducting *B* pathway, initiating sustained reentrant tachycardia in the circuit.

abnormalities may point to susceptibility to symptomatic bradycardia. Delta waves confirm an accessory pathway and direct the evaluation of arrhythmic symptoms toward the diagnosis of Wolff-Parkinson-White (WPW) syndrome while localizing the accessory pathway.

Evidence for hereditary cardiomyopathies and cardiac ion channel disorders that predispose to sudden death may be detected on a baseline ECG. Patients with arrhythmogenic right ventricular (RV) dysplasia may have epsilon waves and inverted T waves in the right precordial leads. QT interval prolongation or shortening may indicate congenital or acquired long QT or short QT syndrome, respectively. Brugada syndrome can be diagnosed based on coved ST-segment elevation in leads V₁ and V₂.

A 12-lead ECG obtained during arrhythmic symptoms can establish the cause of a patient's symptoms. A symptom ECG is most useful in discriminating between SVT and VT. The specific mechanism underlying narrow complex tachycardia can often be inferred from the ECG. Documentation of QRS morphology

during VT on a 12-lead ECG aids in localizing the site of origin, identifying the VT mechanism, and guiding catheter ablation.

Ambulatory Monitoring

Although a 12-lead ECG obtained during arrhythmic symptoms is ideal, it is difficult to obtain in practice because of the transient and intermittent nature of these symptoms. Ambulatory recording devices permit electrocardiographic monitoring over longer periods to establish symptom-rhythm correlations.

Three types of monitoring devices are available. *Holter monitors* provide continuous electrogram storage for 24 to 48 hours. Holter monitoring is helpful for patients with frequent symptoms. The prolonged sampling period provides useful information about heart rate variability, rate control with atrial fibrillation (AF), AF burden, asymptomatic arrhythmias, and the frequency of ventricular ectopy.

External event monitors or loop recorders, which can be worn for 30 days, store electrograms when triggered by patients for symptoms or are autoactivated based on heart rate detection above or below a programmed threshold value. Some external loop monitors have algorithms to detect AF. Episode storage varies from seconds to minutes. After events are recorded, patients transmit the data by telephone. External loop recorders are intended to identify cardiac rhythm disturbances underlying infrequent symptoms.

For patients with arrhythmia symptoms occurring less than once per month, *implantable loop recorders* may be useful. These small devices implanted in a subcutaneous pocket in the left chest record patient-triggered and autotriggered ECGs based on programmed heart rate parameters. With a 3-year anticipated battery longevity, implantable loop recorders are valuable in establishing the cause of recurrent infrequent syncope.

Electrophysiologic Testing

To perform electrophysiologic studies, temporary transvenous pacing catheters are positioned in multiple locations in the heart, permitting pacing and recording of intracardiac electrograms. Catheters are typically placed in the right atrium, the right ventricle, close to the bundle of His, and in the coronary sinus for left atrial recording and pacing. Electrophysiologic studies can define the mechanism of tachyarrhythmias and guide therapy. In patients with prior MI, induction of VT may assist in determining patient susceptibility to life-threatening arrhythmias and inform decisions regarding defibrillator implantation. Electrophysiologic testing also can evaluate sinus node function and AV conduction.

Pharmacologic Therapy

Antiarrhythmic drugs are traditionally divided according to the Singh–Vaughan Williams classification, which categorizes agents based on their primary physiologic effect (Table 9-1). When this classification system was first proposed, knowledge of electrophysiologic mechanisms was limited. Although the simplicity of categorizing antiarrhythmic drugs according to Singh–Vaughan Williams classes I through IV is appealing, the system has many limitations. As hybrid classifications, class I and III agents block ion channels, and class II and IV drugs block receptors. Some drugs cross classes and have several mechanisms of action. There

TABLE 9-1 SINGH–VAUGHAN WILLIAMS CLASSIFICATION OF ANTIARRHYTHMIC DRUGS

CLASS	PHYSIOLOGIC EFFECT*	EXAMPLES
I	Blocks sodium channels; predominantly reduces the maximum velocity of the upstroke of the action potential (phase 0)	
IA	Intermediate-potency blockade	Quinidine, procainamide, disopyramide
IB	Least-potent blockade	Lidocaine, tocainide, mexiletine, phenytoin
IC	Most-potent blockade	Flecainide, propafenone, moricizine
II	β -Adrenergic receptor blockade	Propranolol, metoprolol, atenolol
III	Potassium channel blockade: predominantly prolongs action potential duration	Amiodarone, sotalol, bretylium, ibutilide, dofetilide, dronedarone
IV	Calcium-channel blockade	Verapamil, diltiazem

*Several agents have physiologic effects characteristic of more than one class.

are drugs with antiarrhythmic action that are excluded from the classification, such as digitalis and adenosine. The system categorizes drugs based on their in vitro electrophysiologic effects in normal cardiac tissues.

Available antiarrhythmic drugs have limited efficacy and carry the risk of adverse events, including proarrhythmic potential. Knowledge of drug metabolism, interactions, electrophysiologic effects, and side effects is essential. Certain antiarrhythmics may suppress left ventricular systolic function and may affect pacing and defibrillation thresholds. Excepting β -blockers, none of the antiarrhythmics has been demonstrated to reduce mortality rates. The use of antiarrhythmic agents may confer an increased risk of cardiovascular mortality, particularly in heart failure patients. Tables 9-2 and 9-3 summarize major characteristics and side effects of commonly used antiarrhythmic drugs.

Class I Antiarrhythmic Agents

Class I antiarrhythmic drugs include sodium-channel blockers that bind fast sodium channels in their open and inactivated states and dissociate from sodium channels during their resting state. Blocking voltage-gated fast sodium channels slows phase 0 depolarization and conduction velocity. Class I agents demonstrate use-dependent blockade, and their effect is potentiated at faster heart rates. The drug dissociation rate from sodium channels during phase 4 of the action potential determines the degree to which these agents depress cardiac conduction velocity.

Class IA agents have a slow rate of drug dissociation from sodium channels, conferring moderate potency. In addition to blocking voltage-gated fast sodium channels, class IA drugs block delayed rectifier potassium channels. Slowing of conduction velocity and action potential prolongation are observed. All are antimuscarinic, especially disopyramide. Clinical applications include SVT, AF, atrial flutter, and VT. In the setting of atrial flutter and AF, class IA drugs are vagolytic. They may improve AV nodal conduction and should be used in conjunction with a β -blocker or calcium-channel blocker to avoid uncontrolled ventricular response rates. Quinidine is infrequently used due to its

side effect profile, including diarrhea, thrombocytopenia, and QT prolongation, triggering polymorphic VT. Clinical studies highlight the proarrhythmic risk and increased mortality associated with quinidine therapy. Procainamide, available as an intravenous formulation, has an active metabolite N-acetylprocainamide (NAPA) and may induce a reversible lupus-like syndrome. Disopyramide, with its potent negative inotropic and antimuscarinic activity, has been used to treat vagally mediated AF.

Class IB agents rapidly dissociate from sodium channels during phase 4, providing weak sodium-channel blockade. Their therapeutic role is restricted to ventricular arrhythmias due to a lack of effect on the sinoatrial node, AV node, and atrial tissue. Lidocaine, which is available parentally, undergoes extensive first-pass hepatic inactivation. Lidocaine is more effective in relatively depolarized ventricular tissue due to preferential affinity for inactivated sodium channels; the drug is more potent in ischemic tissue. Mexiletine, which is available orally, has slower hepatic metabolism and a longer half-life than lidocaine.

Class IC drugs are potent fast sodium-channel blockers with little effect on K^+ current. These agents have a role in the therapy of SVTs and VTs. Their use is relegated to patients without coronary disease or significant structural heart disease. The Cardiac Arrhythmia Suppression Trial proved that the use of flecainide and moricizine to suppress ventricular arrhythmias after MI increased mortality rates. These agents may convert AF to atrial flutter and slow atrial conduction sufficiently to permit 1:1 AV conduction during atrial flutter, necessitating the simultaneous use of AV nodal-blocking therapies in patients with atrial arrhythmias. Flecainide is associated with bronchospasm, leukopenia, thrombocytopenia, and neurologic side effects. Flecainide, which inhibits Ca^{2+} release from the sarcoplasmic reticulum cardiac ryanodine receptor, may be useful in the therapy for CPVT. Propafenone has β -blocking effects and can cause agranulocytosis, anemia, and thrombocytopenia.

Class II and IV Antiarrhythmic Agents

β -Adrenoceptor antagonists, the class II agents, inhibit sympathetic activation of cardiac automaticity and conduction, resulting in slowing of the heart rate, decreased AV node conduction velocity, and prolongation of the AV node refractory period. Side effects include bradycardia, hypotension, exacerbation of reactive airway disease, fatigue, worsening symptoms of peripheral vascular disease, and depression. β -Blockers have different half-lives, lipid solubilities, elimination routes, and specificities for β_1 and β_2 receptors.

Class IV agents include the nondihydropyridine calcium-channel blockers. Blockade of voltage-gated L-type calcium channels decreases AV nodal conduction velocity, increases AV nodal refractory period, slows sinus node automaticity, and decreases myocardial contractility. Calcium-channel blockers may cause hypotension, bradycardia, and heart failure. Clinical applications for these agents include rate control for atrial tachyarrhythmias, termination and suppression of SVT, and normal heart VT. In the setting of atrial arrhythmias with underlying WPW, they can potentiate accessory pathway conduction and should be avoided.

TABLE 9-2 SELECTED CHARACTERISTICS OF ANTIARRHYTHMIC DRUGS

DRUG	EFFECT ON SURFACE ECG	EFFECT ON LV FUNCTION	IMPORTANT DRUG INTERACTIONS	EFFECT ON PACING AND DEFIBRILLATION THRESHOLDS	MAJOR ROUTE OF ELIMINATION
Quinidine	Prolongs QRS and QT	Negative inotrope	Increases digoxin level and warfarin effect Cimetidine increases quinidine level Phenobarbital, phenytoin, and rifampin decrease quinidine level	Increases PT and DT at high doses	Liver and kidney
Procainamide	Prolongs PR, QRS, and QT	Negative inotrope	Cimetidine, alcohol, and amiodarone increase procainamide level	Increases PT at high doses	Liver and kidney
Disopyramide	Prolongs QRS and QT	Negative inotrope	Phenobarbital, phenytoin, and rifampin decrease disopyramide level	Increases PT at high doses	Liver and kidney
Lidocaine	Shortens QT	None	Propranolol, metoprolol, and cimetidine increase lidocaine level	Increases DT	Liver
Mexiletine	Shortens QT	None	Increases theophylline level Phenobarbital, phenytoin, and rifampin decrease mexiletine level	Various effects	Liver
Flecainide	Prolongs PR and QRS	Negative inotrope	Increases digoxin level	Increases PT; variable effect on DT	Liver and kidney
Propafenone	Prolongs PR and QRS	Negative inotrope	Increases digoxin, theophylline, and cyclosporine levels; increases warfarin effect Phenobarbital, phenytoin, and rifampin decrease propafenone level Cimetidine and quinidine increase propafenone level	Increases PT; variable effect on DT	Liver
Dronedarone	Prolongs PR and QT; slows sinus rate	Negative inotrope	CYP3A inhibitors (ketoconazole, clarithromycin, calcium-channel blockers) increase dronedarone levels; additive effect with drugs that prolong QT (macrolides, class I and III antiarrhythmics) increasing risk of TdP; increases dabigatran levels	Little effect	Liver
Amiodarone	Prolongs PR and QT; slows sinus rate	None	Increases digoxin and cyclosporine levels; increases warfarin effect	Increases DT	Liver
Sotalol	Prolongs PR and QT; slows sinus rate	Negative inotrope	Additive effects with other β -blockers	Decreases DT	Kidney
Ibutilide	Prolongs PR and QT	None	Additive effect on QT prolongation with class IA and other class III anti-arrhythmic agents	Decreases DT	Liver
Dofetilide	Prolongs QT	None	Verapamil, diltiazem, Cimetidine, and ketoconazole increase dofetilide level	Decreases DT	Liver and kidney

DT, Defibrillation threshold; ECG, electrocardiogram; LV, left ventricle; PT, pacing threshold; TdP, torsades de pointes.

Class III Antiarrhythmic Agents

Class III antiarrhythmic agents are a heterogeneous group of drugs that block the potassium rectifier currents responsible for phase 3 cardiac repolarization, prolonging the cardiac action potential duration and refractory period. These agents demonstrate reverse-use dependence, with more potent potassium-channel blockade at slower heart rates. Prolonging the action potential duration can be therapeutic or proarrhythmic (e.g., TdP). This class represents the dominant category of antiarrhythmic agents in use.

Amiodarone is an iodinated compound available orally and parentally. With oral administration, it is slowly absorbed.

Deposition of amiodarone in body fat stores prolongs the time to reach steady-state levels. The elimination half-life of the drug is 35 to 100 days. Amiodarone's pharmacology is complex, with class I through IV activity, although its primary therapeutic mechanism is prolongation of the action potential duration. It is effective in treating SVTs and VTs. It is hepatically metabolized and proven safe to use in the setting of congestive heart failure. Amiodarone is commonly used to treat atrial and ventricular arrhythmias in patients with structural heart disease and renal failure. Amiodarone is superior to other parental antiarrhythmic agents used to treat cardiac arrest and recurrent VT or ventricular fibrillation (VF). Widespread use of amiodarone has been limited by significant side effects necessitating drug discontinuation in

TABLE 9-3 COMMON SIDE EFFECTS OF SELECT ANTIARRHYTHMIC DRUGS

DRUG	MAJOR SIDE EFFECTS
Quinidine	Nausea, diarrhea, abdominal cramping Cinchonism: decreased hearing, tinnitus, blurred vision, delirium Rash, thrombocytopenia, hemolytic anemia Hypotension, torsades de pointes (quinidine syncope)
Procainamide	Drug-induced lupus syndrome Nausea, vomiting Rash, fever, hypotension, psychosis, agranulocytosis Torsades de pointes
Disopyramide	Anticholinergic: dry mouth, blurred vision, constipation, urinary retention, closed angle glaucoma Hypotension, worsening heart failure
Lidocaine	CNS: dizziness, perioral numbness, paresthesias, altered consciousness, coma, seizures
Mexiletine	Nausea, vomiting CNS: dizziness, tremor, paresthesias, ataxia, confusion
Flecainide	CNS: blurred vision, headache, ataxia Congestive heart failure, ventricular proarrhythmia
Propafenone	Nausea, vomiting, constipation, metallic taste to food Dizziness, headache, exacerbation of asthma, ventricular proarrhythmia
β -Blockers	Bronchospasm, bradycardia, fatigue, depression, impotence Congestive heart failure
Calcium-channel blockers	Congestive heart failure, bradycardia, heart block, constipation
Amiodarone	Agranulocytosis, pulmonary fibrosis, hepatopathy, hyperthyroidism or hypothyroidism, corneal microdeposits, bluish discoloration of the skin, nausea, constipation, bradycardia
Sotalol	Same as β -blockers, torsades de pointes
Dronedarone	Diarrhea, QT prolongation and torsades de pointes, death, bradycardia, congestive heart failure, hepatocellular injury, interstitial lung disease
Ibutilide	Torsades de pointes
Dofetilide	Torsades de pointes, headache, dizziness, diarrhea

CNS, Central nervous system.

up to 20% of patients. Serious adverse effects include potentially irreversible pulmonary fibrosis, optic neuropathy producing visual impairment, hyperthyroidism, and severe hepatic toxicity. Less serious adverse effects include hypothyroidism, neurologic toxicity, sun sensitivity, QT prolongation, and bradycardia.

Sotalol blocks β -adrenoreceptors and delayed rectifier K^+ channels, decreasing sinoatrial node automaticity, slowing AV conduction velocity, and prolonging repolarization. It effectively treats a large number of ventricular and supraventricular arrhythmias.

Dofetilide, a selective class III agent used primarily to treat atrial arrhythmias, blocks delayed rectifier K^+ channels to prolong action potential duration and QT intervals. The risk of TdP is about 1% among patients without structural heart disease but as high as 4.8% among patients with congestive heart failure.

Ibutilide, an intravenous class III agent, is used for the acute termination of recent-onset AF and atrial flutter. The risk of polymorphic VT with administration of ibutilide is 8.3%.

Dronedarone is an orally available class III drug demonstrated to reduce the risk of first hospitalization due to cardiovascular events or death from any cause for patients in sinus rhythm

with a history of paroxysmal or persistent AF. Dronedarone may not be used in the setting of permanent AF or in patients with New York Heart Association (NYHA) class IV heart failure or symptomatic heart failure with recent decompensation because the drug increases the risk of cardiovascular death in these populations. Other major side effects of dronedarone are severe hepatotoxicity, interstitial lung disease, bradycardia, and QT prolongation.

Other Antiarrhythmic Agents

The Singh–Vaughn Williams classification scheme does not describe several agents commonly used in cardiac arrhythmia management. *Adenosine* is a parental agent with an elimination half-life of 1 to 6 seconds. The drug binds to A1 receptors to activate K^+ channels, decreasing the action potential duration and hyperpolarizing membrane potentials in the atria, sinoatrial node, and AV node. Indirectly, adenosine blocks catecholamine-stimulated adenylate cyclase activation, decreasing cAMP and consequently decreasing Ca^{2+} influx. Used clinically for its ability to produce transient AV block, adenosine can terminate SVT when the AV node contributes to the reentrant circuit.

Digoxin inhibits Na^+ , K^+ -ATPase, increasing intracellular Na^+ concentrations and stimulating the Na^+ - Ca^{2+} exchanger to increase intracellular Ca^{2+} , accounting for its positive inotropic effect. Digoxin also acts through the autonomic nervous system to enhance vagal tone, slowing sinus rates, shortening the atrial refractory period, and prolonging AV conduction. Digoxin is therefore used for rate control in patients with atrial arrhythmias.

Cardioversion and Defibrillation

Direct current cardioversion and defibrillation represent the cornerstone of acute therapy for unstable tachyarrhythmias and play an important role in the termination of medication-refractory stable tachyarrhythmias. Organized VTs and SVTs may be terminated by synchronized cardioversion—shock delivery synchronized to the QRS complex—to restore normal rhythm. Synchronization is critical to avoid induction of VF by delivering energy during the relative refractory period of the cardiac cycle. Defibrillation entails the asynchronous delivery of electrical current to depolarize a critical mass of myocardium and terminate VF. Successful defibrillation is time dependent, with the likelihood of success declining by approximately 10% per minute from the onset of VF.

Defibrillation may be delivered internally through an implantable cardioverter-defibrillator (ICD) or externally through an automatic external defibrillator (AED). Current-generation AEDs use biphasic waveforms, achieving greater first-shock efficacy compared with older devices delivering monophasic waveforms. ICDs, implanted in patients for primary and secondary prevention of sudden cardiac death (SCD), deliver defibrillation shocks directly to the endocardium through an RV lead. With direct delivery of energy, relatively lower energy levels (<40 J) are typically effective.

Ablation

Catheter ablation plays an important role in the therapy of a broad range of arrhythmias, such as SVT, atrial arrhythmias, and VT. The ascendance of catheter ablation derives in part from the

poor efficacy and side effect profiles of available antiarrhythmic drugs. Radiofrequency ablation (i.e., applying radiofrequency-range energy) and cryoablation (i.e., administering freezing temperatures, to produce localized cellular and tissue injury) are commonly used.

Focal and reentrant arrhythmias are defined and localized, permitting targeted delivery of ablation energy to eliminate the tachyarrhythmia. Ablation is associated with varied success and complication rates, depending on the mechanism and location of the arrhythmogenic focus. Cure rates for tricuspid and caval isthmus–dependent atrial flutter, AV nodal reentry tachycardia (AVNRT), and accessory pathway–mediated tachycardias exceed 95%, with low complication rates of about 2%. Although an important therapeutic option in the treatment of AF and VT, success rates are lower and procedural risks are higher.

 For a deeper discussion on this topic, please see Chapter 62, “Approach to the Patient with Suspected Arrhythmia,” in Goldman-Cecil Medicine, 25th Edition.

BRADYCARDIA

Bradycardia, defined as a heart rate of less than 60 beats per minute, may occur as a consequence of physiologic adaptations or pathology. Bradycardia always results from failure of sinus node function or AV conduction disturbances, or both processes. Clinically significant bradycardia or pauses may result from autonomic disturbances, drugs, chronic intrinsic conduction system disease, or acute cardiac damage as occurs with endocarditis or infarction.

Normal Conduction System: Anatomy and Physiology

Because of the normal gradient of intrinsic automaticity, heart rate usually is determined by intrinsic automaticity of the sinus node. The sinus node is a complex of cells that extends from the superior vena cava and along the upper right atrial free wall in the sulcus terminalis. Blood supply is derived from the sinus node artery, which arises from the right coronary in 66% or left coronary in 34% of patients.

Activation proceeds through the right atrium to the AV node, which is located in the low interatrial septum adjacent to the tricuspid annulus. The AV node is a complex structure with at least three preferential atrial insertions. The anterior atrial insertion has a short conduction time and usually determines the normal AV conduction time in sinus rhythm. The posterior right and left atrial insertions have long conduction times. Because they do not normally mediate AV conduction in humans, they are functionally vestigial. However, the posterior slowly conducting insertions become important in mediating paroxysmal supraventricular tachycardia (PSVT). The AV node derives its blood supply from the AV nodal artery, which is supplied by the right coronary artery in 73% or the left coronary artery in 27% of patients.

After entry into the AV node, conduction proceeds to the His bundle through the fibrous annulus and along the membranous septum before splitting into a leftward Purkinje branch, which ramifies over the left ventricular endocardium, and a rightward branch, which similarly ramifies over the RV endocardium. The

leftward branch may be damaged proximally, resulting in full left bundle branch block, or damaged more distally in its anterior or posterior divisions, resulting in fascicular hemiblock patterns.

Normal Autonomic Regulation of Heart Rate

Normal heart rate is a consequence of tonic and phasic autonomic modulation of intrinsic sinus node automaticity. The intrinsic heart rate in the absence of autonomic modulation ranges from 85 to 110 beats per minute and is somewhat faster than normal resting heart rates. That the normal heart rate is slower than the intrinsic rate is a consequence of the dominance of parasympathetic tone over adrenergic tone in the resting state.

Based on a review of Holter recordings in a normal population, the normal resting heart rate is 46 to 93 beats per minute in men and 51 to 95 beats per minute in women. It has been proposed that 50 to 90 is a clinically more accurate working definition of normal heart rate for adults than the traditional 60 to 100 beats per minute commonly used by consensus. However, heart rates well below these estimates may be seen in normal people, especially during hours of sleep. For these reasons, defining a cutoff value for pathologic bradycardia in the absence of symptoms is problematic for an otherwise healthy patient.

The maximal stress-induced heart rate (HR_{max}) is related to maximal sympathetic stimulation, accompanied by withdrawal of parasympathetic tone. This is commonly estimated as $HR_{max} = (220 - \text{age})$.

Sinus Node Dysfunction

Sick sinus syndrome, also called *sinus node dysfunction*, is a common clinical syndrome that increases in prevalence with age. The estimated prevalence is 1 case per 600 patients older than 65 years of age, and it accounts for about one half of all pacemaker implantations. Sinus node dysfunction is a consequence of two distinct processes: failure of intrinsic automaticity and failure of propagation of sinus node impulses to the surrounding atrial tissue, also referred to a *sinus node exit block*.

Sinus node dysfunction manifests clinically as one of several patterns: persistent or episodic sinus bradycardia, inability to appropriately augment rate with exercise (i.e., chronotropic incompetence), sinus pauses, or commonly a combination of these patterns. The sinus node is at the top of a cascade of automaticity and is normally backed up by a competent AV junctional escape mechanism. Severe bradycardia and associated symptoms due to sinus node dysfunction always imply sinus node dysfunction and simultaneous failure of normal subsidiary escape mechanisms. In the setting of a competent escape mechanism, even severe sinus node dysfunction may be completely asymptomatic, clinically well tolerated, and require no specific therapy.

Resting Sinus Bradycardia

Sinus bradycardia is frequently observed during routine clinical practice. Modest sinus bradycardia in the high 40s in men and 50s in women is normal and called *bradycardia* only because of the conventional choice of 60 beats per minute as the lower limit of normal rates. Because there is no set rate at which sinus bradycardia can be labeled as pathologic, pathologic sinus node

dysfunction is best defined as significant bradycardia associated with symptoms plausibly attributable to bradycardia.

Modest persistent bradycardia is often asymptomatic. When symptoms occur, they are commonly nonspecific, such as fatigue, listlessness, or dyspnea, making the attribution of symptoms to resting bradycardia difficult. Sinus bradycardia may also exacerbate congestive heart failure and limit effective use of β -blocker therapy, a cornerstone of therapy for heart failure, coronary disease, and tachyarrhythmias. When inappropriate sinus bradycardia is persistent, especially when severe, plausible symptoms are present, and alternate causes of symptoms have been excluded, pacemaker implantation is reasonable. Asymptomatic sinus bradycardia should rarely be treated with pacing unless a need for medical therapy is expected to further exacerbate bradycardia.

Chronotropic Incompetence

Cardiac output during exercise is increased by augmentation in stroke volume and an increase in heart rate. If heart rate rise with exercise is inadequate, exertional symptoms such as fatigue or dyspnea may ensue. As in the case of resting sinus bradycardia, unless severe, attribution of symptoms to chronotropic incompetence is difficult. Various criteria for this condition have been proposed that rely on the inability to achieve a set fraction of age-predicted heart rate or heart rate reserve. As for resting sinus bradycardia, the decision to implant a pacemaker for chronotropic incompetence is a matter of judgment more than criteria.

Sinus Pauses or Arrest

An abrupt failure of sinus node automaticity or failure of propagation from the sinus node to the atrium can result in a pause in atrial activity. P waves are absent, and if of adequate duration and not accompanied by a competent subsidiary escape mechanism, it can result in abrupt symptoms of lightheadedness, presyncope or true syncope. Sinus pauses of less than 3 seconds are commonly seen for normal subjects, who are rarely symptomatic. Sinus pauses exceeding 3 seconds and not occurring during sleep are often pathologic and may result in symptoms. Sinus pauses associated with simultaneous symptoms and documentation of pauses lasting 3 seconds or longer in patients with a history of symptoms plausibly related to bradycardia are indications for pacemaker therapy.

Sinoatrial Exit Block

Sinus node dysfunction is often accompanied by significant atrial fibrosis, which may lead to a block in the tissues surrounding the sinus node complex and impede propagation to the atrial tissue. Bradycardia due to sinus node dysfunction may result, not from a failure of automaticity, but from failure of propagation from the sinus node complex to the atrium. Because sinus node activity is not directly apparent from the surface ECG, the diagnosis is made indirectly by the observation of abrupt halving in the sinus P-wave rate, followed by an abrupt return to the baseline sinus rate (Fig. 9-3C and D). Although other patterns may be observed, 2:1 exit block is the most common. Therapy for sinoatrial exit block is identical to that for intermittent sinus bradycardia (discussed earlier).

Bradycardia-Tachycardia Syndrome as a Consequence of Sinus Node Dysfunction

Bradycardia-tachycardia (“brady-tachy”) syndrome refers to a clinically significant tachyarrhythmia sometimes accompanied by clinically significant bradycardia. The term may be confusing because the mechanism of tachycardia is often unrelated to the mechanism of bradycardia.

This syndrome most commonly manifests as intermittent pathologic atrial arrhythmias, often intermittent AF with concomitant sinus node dysfunction resulting in long pauses or symptomatic sinus bradycardia when the patient is in sinus rhythm. A typical manifestation of this syndrome is a prolonged period of asystole after termination of AF (see Fig. 9-3E) due to slow recovery of sinus node automaticity with resultant presyncope or syncope.

The combination of two seemingly independent processes is in part a consequence of the high prevalence of AF and sinus node dysfunction in the elderly and the need to use potent drugs to decrease ventricular response during AF with resultant unintended secondary sinus node dysfunction between periods of atrial arrhythmias. This type of bradycardia-tachycardia syndrome represents an important form of clinical sinus node dysfunction and is a common indication for pacemaker implantation.

Sinus node dysfunction causing bradycardia-tachycardia should be distinguished from a common, unrelated form of bradycardia-tachycardia syndrome, which is characterized by chronic rather than intermittent AF with periods of rapid and slow ventricular responses. This condition is often incorrectly referred to as *sick sinus syndrome*. However, in this syndrome, the atrium is chronically fibrillating, and the sinus node therefore has no influence on heart rate. Bradycardia or protracted pauses in the setting of chronic AF is a consequence of impaired AV conduction and is unrelated to sinus node dysfunction.

Atrioventricular Conduction Disturbances

AV conduction disturbances include disorders in which the normal physiologic AV relationship is not maintained due to pathologic delay in AV conduction or to intermittent or complete loss of AV conduction. The PR interval includes three distinct phases of AV conduction. Although the individual components of AV conduction can be readily recorded by a His bundle catheter in an electrophysiology laboratory, the salient features of AV conduction disturbances can usually be elucidated by careful interpretation of the surface ECG without resorting to invasive recording techniques.

The right atrial conduction time from the area of the sinus node where the P wave begins to the region of the AV node occupies a short first portion of the PR interval and usually lasts no more than 30 milliseconds. Because the atrial conduction time is short and does not change much over time in a given patient, it can conveniently be ignored when assessing AV conduction. The second portion of the PR interval is the propagation time through the AV node, which is normally 50 to 120 milliseconds. The last component of the PR interval is the time for propagation through the His bundle and bundle branches, which is typically 30 to 55 milliseconds. Although this last portion,

FIGURE 9-3 Sinus node dysfunction. **A**, Sinus bradycardia in a patient receiving metoprolol. This bradycardia results from diminished normal automaticity of the sinus node. **B**, Pauses related to blocked premature atrial contractions (PACs). Blocked PACs are a common cause for apparent sinus pauses because the PAC may be early enough to be concealed by the T wave of the preceding beat (*arrows*). The pauses are not a sign of sinus node dysfunction but rather a physiologic response to an early coupled PAC. **C**, The sinus pause is an abnormal finding that suggests sinus node disease. The pause is exactly two sinus cycles and may represent sinoatrial exit block. **D**, Sinoatrial Wenckebach type exit block. As is the case with the RR interval preceding atrioventricular nodal Wenckebach, progressive shortening of the PP interval preceding a doubling in sinus cycle length likely represents Wenckebach exit block from the sinus node tissue to the atrium. **E**, Bradycardia tachycardia syndrome due to sinus node dysfunction. An episode of rapidly conducted atrial fibrillation or flutter terminates and is followed for a protracted period of sinus arrest before recovery of sinus rhythm and ultimate relapse of rapidly conducted atrial fibrillation. These pauses may result in syncope or near-syncope.

constituting His-Purkinje conduction, is short, it is the major prognostic component of AV conduction and therefore clinically important. Because the last portion of the PR interval is the time from the onset of His bundle to the time of ventricular activation, it is commonly referred to as the HV interval. Although the HV interval cannot be measured directly from the surface ECG, a block in the His-Purkinje system can be inferred from the characteristic features that can be gleaned from review of the surface ECG.

First-Degree Atrioventricular Block

First-degree AV block is defined as a PR interval exceeding 0.2 seconds (200 milliseconds) in the setting of otherwise preserved AV conduction (Fig. 9-4A). First-degree block implies a conduction delay in one of the components of AV conduction, usually at the level of the AV node or His-Purkinje system (i.e., infranodal conduction system). First-degree AV block is usually asymptomatic, but it is a sign of AV conduction system disease and may be a diagnostic clue to the mechanism of intermittent electrocardiographically undocumented symptoms in a patient with unexplained syncope.

Second-Degree Atrioventricular Block

Second-degree AV block is defined as intermittent failure of AV conduction with interspersed periods of intact AV conduction.

Second-degree AV block, like sinus bradycardia and pauses, may be seen normally during hours of sleep as well as in athletes with high parasympathetic tone. Alone, it is not an indication of AV conduction system disease.

Second-degree block may be asymptomatic, may be associated with mild symptoms such as palpitations, or if resulting in protracted pauses or persistent bradycardia, may result in hemodynamic symptoms, including lightheadedness, syncope, and fatigue. Second-degree AV block at the level of the AV node is usually indolent and gradually progressive. Because of stable junctional escape mechanisms associated with progression to complete heart block at the level of the AV node, second-degree AV block at this level tends to have a benign prognosis and, in the absence of symptoms, can be followed safely without intervention.

Second-degree block in the infranodal conduction system, which is composed of the His bundle and bundle branches, can be malignant with a tendency to progress abruptly and unpredictably to higher degrees of AV block accompanied by unstable or absent subsidiary escape mechanisms. After a patient becomes symptomatic, the infranodal block may progress to complete heart block and, in some cases, to sudden death. Despite its malignant nature, SCD is rarely attributable to complete heart block, suggesting that most patients have symptoms permitting intervention before progression to sudden death.

FIGURE 9-4 Heart block. **A**, First-degree atrioventricular (AV) block is associated with 1:1 conduction but a prolonged PR interval more than 200 milliseconds. **B**, Mobitz type I (Wenckebach) second-degree AV block. Notice the progressive PR prolongation preceding the blocked P wave (arrows) followed by recovery of conduction with a shorter PR interval before repetition of the same pattern. **C**, Mobitz type II second-degree AV block. Notice that the PR interval does not prolong in the beat preceding the blocked P wave (arrows). **D**, A 2:1 second-degree AV block. Notice that every other P wave fails to conduct. Because there are never two consecutively conducted P waves to assess for the presence or absence of progressive prolongation, this type of block is neither Mobitz I nor Mobitz II. **E**, Complete heart block with a junctional escape rhythm. Notice that the atrial rate is faster than the ventricular rate and that there is AV dissociation. The narrow QRS escape rhythm implies a level of block high in the conduction system near the AV node.

Because of the profound difference in natural history of second-degree AV block at the AV node and that at an infranodal level, the major clinical task in evaluating patients with second-degree AV block is to establish the probable level of the block. The surface ECG and pattern of block are quite useful.

Mobitz Type I Second-Degree Atrioventricular Block

Also referred to a Wenckebach block, *Mobitz type I second-degree AV block* is a progressive prolongation in the PR interval before development of AV block, usually for one cycle followed by recovery of conduction with a return to the baseline PR interval (see Fig. 9-4B). Because the degree of prolongation of the PR interval is less with each successive beat before the block, the RR intervals can paradoxically shorten in the final beats before the block.

Mobitz I AV block typically is associated with block at the level of the AV node. However, this pattern is rarely seen with advanced infranodal disease in the His bundle and bundle branches. Because Mobitz type I AV block usually occurs at the level of the AV node, infranodal conduction is commonly normal and associated with a narrow conducted QRS complex. In ambiguous cases, other clues may be helpful. Because AV node function is improved with exercise, Mobitz I block tends to normalize with activity and return at rest. Second-degree block at the level of the AV node is improved with atropine and exacerbated by carotid sinus massage. If associated with periods of complete heart block,

a block at the level of the AV node is associated with a junctional escape with a QRS morphology similar to that in conducted sinus rhythm. In contrast, the observation of a wide complex escape that is different from the conducted QRS points to infranodal causes of block in the His-Purkinje system. The block may be malignant (discussed later) and require expeditious use of ventricular pacing to prevent catastrophic bradycardia.

Mobitz Type II Second-Degree Atrioventricular Block

Mobitz type II second-degree AV block is intermittent failure of AV conduction during stable atrial rates without antecedent PR prolongation and followed by recovery of AV conduction (see Fig. 9-4C). Mobitz II AV block is believed to always be a sign of block in the infranodal tissues, including the His bundle and bundle branches. Whereas infranodal block may rarely display Mobitz I (Wenckebach) periodicity, AV block at the level of the AV node does not result in true Mobitz II AV block periodicity.

The finding of Mobitz II AV block is always reason for concern. Although it may result from block in the His bundle or subsidiary bundle branches. Block within the His bundle accompanied by a narrow QRS complex is uncommon. In practice, Mobitz II AV block is usually preceded by the development of fixed bundle branch block. It has been believed that such bundle branch block patterns implied disease of the bundle branches themselves as they ramify within the ventricles. However in many cases of left bundle branch block, the disease process may actually be within

the His bundle affecting fibers which will ultimately extend to the left bundle branch. Regardless of the exact anatomical level of clinical bundle branch block, it remains a good clinical rule that most patients exhibiting Mobitz II AV Block will also exhibit a full bundle branch block pattern during periods of conduction between episodes of second degree AV block.

In ambiguous cases, other clues may be helpful. Because infranodal function improves relatively little with exercise, infranodal block tends to worsen with the increasing heart rates associated with exercise or stress. Atropine is not helpful for infranodal block, and because it may accelerate sinus rates, it may cause a patient to progress to higher degrees of AV block with a consequent decrease in the conducted ventricular rate. Exogenous catecholamines such as isoproterenol infusion may be helpful acutely but should not be relied on. Because of its malignant potential, hemodynamically significant Mobitz II AV block should be addressed with early temporary or permanent pacing.

2:1 and High-Degree Atrioventricular Blocks

2:1 AV block is a failure of conduction of every other P wave (see Fig. 9-4D). This pattern is most commonly seen with an infranodal block in the His bundle or bundle branches. However, 2:1 AV block may also be observed in advanced AV nodal disease. It can be distinguished from the more common infranodal form of 2:1 block by the typical Mobitz I periodicity accompanied by a usually narrow QRS complex at other times in the same patient. Because two consecutive conducted P waves are not available to assess the Mobitz pattern, a 2:1 AV block is neither Mobitz I nor Mobitz II.

High-degree AV block is second-degree AV block with conduction failure of two or more consecutive P waves. High-degree AV block is neither Mobitz I nor Mobitz II. Although Mobitz periodicity cannot be assigned, like other forms of second-degree AV blocks, the level of block must be established to assess prognosis and guide therapy. In this case, the ancillary clues described for Mobitz blocks remain useful.

Third-Degree Atrioventricular Block

Third-degree AV block or equivalently complete heart block is a complete failure of AV conduction. In the setting of underlying sinus rhythm, this is an atrial rate faster than the ventricular rate associated with AV dissociation (see Fig. 9-4E). However, when the underlying rhythm is AF, the definition of complete heart block cannot rely on the demonstration of AV dissociation. Because conducted AF always results in an *irregular* ventricular response, the finding of a *regular and slow* ventricular response during AF implies an associated complete heart block.

As is the case for second-degree AV block, the level of the third-degree block determines the clinical behavior and prognosis of complete heart block. Complete heart block at the level of the AV node is associated with a generally stable junctional escape with rates between 40 and 50 beats per minute and usually with a narrow QRS complex. If the patient had a bundle branch block before the development of complete heart block, a block at the level of the AV node is associated with a wide QRS escape, identical to the conducted QRS before the development of a block.

Complete heart block at an infranodal level is associated with a wide and slow ventricular escape rhythm, which often is slower

than 40 beats per minute with a QRS different from the antecedent conducted morphology. Unfortunately, infranodal escape rhythms may be absent entirely, leading to asystole and loss of consciousness. When infranodal complete heart block is suspected, regardless of tolerance of the ventricular escape rhythm, prompt institution of temporary or permanent ventricular pacing is appropriate.

TACHYCARDIAS

Overview and Classification

Tachyarrhythmias are categorized as supraventricular and ventricular arrhythmias. SVT relies mechanistically on the atrium or the AV node, or both. During SVT, normal depolarization of the ventricles by the His-Purkinje system produces a narrow complex tachycardia. SVT can manifest as a wide complex tachycardia in the setting of aberrancy or antegrade conduction down an accessory pathway, producing an abnormal sequence of ventricular activation. Ventricular tachyarrhythmias do not depend on the atrium or AV node; they originate in the ventricles, generating a wide complex tachycardia.

Supraventricular Tachycardias

SVTs can be categorized as PSVT, focal atrial tachycardia, atrial flutter and related organized reentrant atrial tachycardias, and AF. This classification scheme, which addresses the underlying arrhythmic mechanism, clinical presentation, and prognosis, guides evaluation and therapy.

PSVT typically manifests in young patients without structural heart disease. The PSVT syndrome is characterized by recurrent tachypalpitations with abrupt onset and offset. Focal atrial tachycardia is more often observed in patients with underlying atrial enlargement and valvular heart disease. AF and atrial flutter are associated with advancing age, hypertension, structural heart disease, diabetes, obstructive sleep apnea, and pulmonary disease. Unlike PSVT, AF carries an increased risk of stroke, heart failure, and death.

Paroxysmal Supraventricular Tachycardia

The incidence of PSVT is 35 cases per 100,000 person-years, with a prevalence of 2.25 per 1000 person-years. Patients report recurrent tachypalpitations. Associated symptoms may include shortness of breath, lightheadedness, chest pain, and syncope. Anginal chest pain and ischemic ST-segment depression are common and related to increased myocardial oxygen demand coupled with the loss of normal diastolic coronary perfusion time. These findings do not necessarily indicate underlying coronary artery disease and typically resolve with tachycardia termination.

PSVT typically occurs independent of structural heart disease and may manifest at any point from infancy to advanced age. PSVT relies on reentry, which is localized in the AV node in approximately 60% of cases and uses a concealed or manifest accessory pathway in 40%. Unless a delta wave indicative of WPW is identified, the underlying mechanism of PSVT is not usually apparent on initial clinical presentation.

An ECG obtained during PSVT can provide useful clues to establish the diagnosis and guide management. The AV relationship should be assessed during tachycardia. By ascertaining the

relationship of the P wave to the preceding QRS complex, it is possible to classify PSVT as a *short RP tachycardia* or a *long RP tachycardia*. Short RP tachycardias demonstrate a short RP pattern with P waves embedded within or occurring closely after the preceding QRS complex. Short RP tachycardias occur with reentrant SVT when the retrograde VA conduction time is shorter than the antegrade AV conduction time. This pattern is observed in the two most common forms of PSVT: typical AV nodal reentry tachycardia and reciprocating AV tachycardia related to an accessory pathway.

Long RP tachycardias are characterized by an RP interval that is longer than the next PR interval during tachycardia. This pattern occurs when the retrograde VA conduction time in reentrant arrhythmias is long due to a slowly conducting retrograde pathway during tachycardia. Atypical AV node reentry, in which retrograde conduction occurs over the slow AV nodal pathway, is the most common example of a long RP reentrant tachycardia.

Atrioventricular Nodal Reentry Tachycardia

AVNRT is the most common form of PSVT. The arrhythmic mechanism depends on two distinct pathways in the AV node: a slowly conducting pathway with a short effective refractory period (i.e., slow pathway) and a rapidly conducting pathway with a longer refractory period (i.e., fast pathway). The atrial insertion sites of the two pathways are different. The fast pathway inserts anteriorly near the bundle of His, and the slow pathway inserts posteriorly near the coronary sinus ostium. Although the dual pathways are a normal feature of the AV node, patients with clinical tachycardia have more robust slow pathway conduction.

Tachycardia is most commonly triggered by a premature atrial contraction that blocks the fast pathway due to its prolonged refractory period and conducts slowly antegrade down the slow pathway, producing a long PR interval on the ECG. On reaching the distal common pathway where the fast and slow AV nodal inputs meet, if the fast pathway is no longer refractory, the impulse may penetrate the fast pathway in a retrograde direction and rapidly activate the atrium, producing a short RP interval and reinitiating reentry down the slow pathway and up the fast pathway. In typical slow-fast AVNRT, the RP interval is so short that the P wave is often buried in the preceding QRS complex (Fig. 9-5A).

Atypical fast-slow AVNRT may occur with antegrade conduction over the fast pathway and retrograde conduction over the slow pathway. This form of AVNRT is uncommon and produces a long RP pattern on the ECG with characteristically deeply inverted retrograde P waves in leads II, III, and aVF.

Vagal maneuvers cause temporary AV nodal blockade and may terminate sustained AVNRT. Alternatively, intravenous adenosine is a highly effective acute therapy. The need for chronic or definitive therapy is determined by symptoms, arrhythmia frequency, and patient preference. Catheter ablation of the slow pathway at the posterior AV node is highly successful, eliminating AVNRT with a greater than 90% success rate and a low risk of complications. Drug therapy with β -blockers and calcium-channel blockers directed at the AV node may be helpful for chronic suppression. Occasionally, class IC and III antiarrhythmics may be required. AVNRT should be easily distinguished

from automatic junctional tachycardia, with a narrow complex and rapid, irregular rhythm typically demonstrating AV dissociation (see Fig. 9-5B).

Reciprocating Atrioventricular Tachycardia and Preexcitation Syndromes

Congenital anomalous extranodal AV muscle fibers or accessory pathways may arise as a consequence of incomplete development of the AV annulus. These pathways are usually observed in patients with otherwise anatomically normal hearts, although right-sided accessory pathways are associated with Ebstein's anomaly and left-sided accessory pathways with hypertrophic cardiomyopathy.

Accessory pathways, or bypass tracts, may conduct antegradely, retrogradely, or bidirectionally. They typically fail to demonstrate decremental conduction or the slowed conduction with increasingly frequent stimulation that characterizes the AV node. Accessory pathways capable of antegrade conduction produce early activation of the ventricle in sinus rhythm because conduction over the accessory pathway surpasses conduction over the AV node. The relatively rapid AV conduction produces a shortened PR interval, and eccentric ventricular activation over the pathway slurs the QRS onset, resulting in a delta wave (see Fig. 9-5C). If the accessory pathway is capable only of retrograde conduction, the baseline ECG in sinus rhythm does not show evidence of an accessory pathway, and the extranodal AV connection is called *concealed*.

Short PR intervals are also observed in patients with Lown-Ganong-Levine syndrome. These patients have a normal-appearing QRS complex without a delta wave because ventricular activation occurs through the His-Purkinje system (see Fig. 9-5D).

Whether accessory pathways are concealed or manifest, the most common associated arrhythmia is *orthodromic AV reentrant tachycardia* (AVRT). Tachycardia is mediated by antegrade conduction down the AV node to the ventricle and subsequent retrograde conduction up the accessory pathway to activate the atrium and then move back down the AV node. Because the ventricles are activated during tachycardia exclusively over the AV node, the resulting tachycardia is typically a narrow complex unless aberrancy occurs (see Fig. 9-5E). A short RP pattern is observed on the ECG, although the RP is slightly longer than commonly observed in a typical AVNRT. Because the atria and ventricles constitute portions of the reentrant circuit, tachycardia depends on 1 : 1 AV conduction.

Less frequently, *antidromic AV reentrant tachycardia* is seen in patients with accessory pathways capable of antegrade conduction. The accessory pathway provides the antegrade limb of the reentrant circuit, and the AV node serves as the retrograde pathway, resulting in a wide QRS tachycardia due to complete preexcitation of the ventricles.

Special Considerations for Patients with Supraventricular Tachycardia and Delta Waves in Sinus Rhythm

Asymptomatic patients may have delta waves on the ECG, which is called a *WPW pattern*. Prevalence of the WPW pattern in the general population is approximately 1 case per 1000 people. Accessory pathways may be poorly conducting and less likely to

FIGURE 9-5 Atrioventricular (AV) nodal (junctional) rhythm disturbances. **A**, Supraventricular tachycardia. The lack of visible P waves during tachycardia suggests that they are concealed within the QRS complex, a pattern indicative of underlying AV nodal reentrant tachycardia. **B**, Automatic junctional tachycardia. Notice the AV dissociation during tachycardia. The P waves (arrows) are dissociated from the QRS complexes. **C**, Sinus rhythm with a short PR interval due to the presence of delta waves in a patient with Wolff-Parkinson-White (WPW) syndrome. The slurred QRS upstroke of the delta wave results from early activation of the ventricle by the extranodal bypass tract, followed by fusion with rapid conduction down the normal conduction system and resulting in narrowing of the terminal QRS. **D**, Sinus rhythm with a short PR interval but no delta waves. Despite the short PR, the P wave is normally vectored, excluding a junctional rhythm that appears similar but with an inverted P wave. A short PR interval in sinus rhythm without delta waves is caused by an abnormally rapid AV nodal conduction and is described as a Lown-Ganong-Levine pattern. **E**, Supraventricular tachycardia. Unlike tracing **A**, there is a clear P wave (arrow) inscribed immediately after each QRS in the ST segment. This pattern is seen most commonly with orthodromic AV reciprocating tachycardia in a patient with WPW syndrome. The early P wave in WPW is caused by retrograde conduction up the accessory pathway after ventricular activation during tachycardia. **F**, Preexcited atrial fibrillation (AF) in a patient with WPW syndrome. Notice the rapid and irregular ventricular response with widening of the QRS due to preexcitation. This pattern results from rapid conduction of the AF down the accessory pathway, bypassing the normal conduction system. As in this arrhythmia, occasional conduction down the AV node may occur during ongoing tachycardia, resulting in periods with a narrow QRS complex.

promote tachycardia, accounting for the absence of symptoms. These patients have a favorable prognosis, particularly if spontaneous and abrupt cessation of preexcitation occurs with exercise or during ambulatory monitoring. In most cases, no specific therapy is required.

Occasionally, patients participating in high-risk activities with WPW pattern may be subjected to invasive electrophysiologic testing for risk stratification. Patients with delta waves demonstrating SVT or suggestive arrhythmic symptoms are said to have WPW syndrome, and invasive electrophysiologic testing is ordinarily recommended in these patients. Testing helps to stratify the risk of SCD.

Curative ablation is highly effective, with a success rate of 95%, and poses a low risk of procedural complications. Chronic therapy with antiarrhythmic drugs that prolong the accessory pathway refractory period (i.e., class IA, IC, or III agents) may be effective, but the potential for adverse drug effects has made accessory pathway ablation the treatment of choice for symptomatic patients.

The use of agents that slow AV nodal conduction in patients with WPW syndrome warrants special mention. Digoxin, β -blockers, and calcium-channel blockers should not be used in patients with WPW because they slow conduction through the AV node, resulting in preferential excitation of the ventricles over the accessory pathway. In the setting of AF or atrial flutter, this may cause rapid ventricular rates and hemodynamic instability.

Wolff-Parkinson-White Syndrome and Atrial Fibrillation

WPW syndrome is associated with a 0.25% per year risk of SCD, which is related to the development of AF with rapid antegrade conduction over the accessory pathway and to VF. This risk is greatest for patients demonstrating very short preexcited RR intervals during AF. For some WPW patients, SCD may be the initial presentation. Successful catheter ablation of the accessory pathway eliminates this possibility.

Patients with WPW and rapidly conducted AF have the characteristic electrocardiographic findings of a rapid, irregularly

irregular, wide QRS rhythm with various degrees of QRS widening or preexcitation from beat to beat (see Fig. 9-5F). During AF in the setting of underlying WPW, activation of the ventricle over the AV node produces concealed retrograde activation of the accessory pathway, prolonging the refractory period of the pathway and moderating the rate of antegrade accessory pathway conduction.

Treating patients with AV nodal–blocking therapy decreases concealed retrograde activation of the pathway, facilitating antegrade accessory pathway conduction and potentiating hemodynamic instability. Appropriate acute therapy includes drugs that prolong the accessory pathway refractory period, such as intravenous procainamide, ibutilide, or amiodarone. In the event of hemodynamic instability, electrical cardioversion is preferred.

Role of Catheter Ablation in Wolff-Parkinson-White Syndrome

Catheter ablation is highly effective for treating WPW, with success rates of approximately 95% and recurrence rates of only 5%. Procedural complications are uncommon, with major complications occurring in 2% to 4% of cases and deaths related to ablation occurring in 0.1%.

Although antiarrhythmic drug therapy may control symptoms, the expense and risks of pharmacologic therapy along with the safety and efficacy of ablation have made radiofrequency ablation the first-line therapy for symptomatic WPW. Because most patients with asymptomatic WPW patterns have a favorable prognosis, they should not be subjected to ablation.

Atrial Arrhythmias

Overview and Classification

Atrial arrhythmias depend entirely on the atria but are mechanically independent of AV conduction. As a consequence, intra-atrial arrhythmias persist despite the development of spontaneous or pharmacologically induced AV block. Tachycardias originating in the atria may be organized and repetitive, resulting from automaticity or intra-atrial reentry, or may be chaotic and disorganized, as is the case in AF. Therapy is directed at moderating the ventricular response during episodes of tachycardia or suppressing the underlying atrial arrhythmia.

Focal arrhythmias originate from a point source in one of the atria, and circumferential spread encompasses the remainder of the atrium. These arrhythmias display distinct P waves separated by a clear isoelectric segment. Focal arrhythmias commonly have an automatic mechanism, but in some cases, they may result from micro-reentry involving a geographically small portion of the atrium (e.g., around a single pulmonary vein), followed by radial spread to the rest of the atrium. Although most commonly a single abnormal focus may be active, in the setting of severe physiologic stress, multiple foci may be active simultaneously, leading to a chaotic electrocardiographic appearance with multiple distinct P waves, referred to as *multifocal atrial tachycardia* (MAT) (Fig. 9-6B). Automatic arrhythmias tend to be episodic and nonsustained, sometimes recurring incessantly. Cycle length often varies within a run, between runs, and with changes in autonomic tone.

FIGURE 9-6 Atrial arrhythmias. **A**, Runs of focal atrial tachycardia with variable atrioventricular (AV) block. The tachycardia occurs in salvos with interspersed periods of sinus rhythm. The P waves (arrows) during tachycardia appear uniform although their cycle length varies, resulting in variable patterns of AV conduction and an irregular ventricular rate. **B**, Multifocal atrial tachycardia. Notice the incessant atrial premature beats (arrows) with at least three distinct morphologies. Because of the irregularly irregular response, this arrhythmia can be easily misdiagnosed as atrial fibrillation (which lacks discrete P waves) if the tracing is not carefully reviewed. **C**, Atrial flutter with rapid, variable conduction. Notice the continuous sawtooth atrial activity. Although commonly manifesting with stable 2:1 block and a regular response, the block varies in this patient, progressing through periods of 2:1 and 3:1 ratios and resulting in an irregular ventricular response. **D**, Atrial fibrillation with a rapid ventricular response. Notice the wavering baseline without distinct P waves and an irregularly irregular response.

Macro-reentrant atrial arrhythmias are a consequence of stable reentrant circuits, which encompass large portions of the atria. All such circuits require a central obstacle and a region of slowed atrial conduction related to atrial dilation or fibrosis. The most common of these arrhythmias is *typical atrial flutter*, which is mediated by right atrial reentry around normal anatomic obstacles. In addition to typical flutter, reentry may occur around acquired obstacles, most commonly scars resulting from prior cardiac surgery or ablation involving the atria. Reentrant arrhythmias tend to manifest clinically as paroxysmal sustained or persistent arrhythmias. Although they may be self-terminating and episodic, individual episodes tend to be protracted.

The final mechanism of atrial arrhythmia is AF. This arrhythmia involves components of focal automatic mechanisms and reentry. The major advances made in the understanding and management of this common arrhythmia are reviewed in the following sections.

Focal Atrial Tachycardia

Focal atrial tachycardia also is referred to as ectopic atrial tachycardia and automatic atrial tachycardia. These terms describe a characteristic clinical pattern that usually manifests as runs of unifocal PACs lasting for seconds or minutes, usually followed by spontaneous termination and subsequent spontaneous reinitiation of additional salvos of tachycardia (see Fig. 9-6A). This arrhythmia less commonly manifests as a paroxysmal sustained tachycardia. When mapped in the electrophysiologic laboratory, these arrhythmias have a focal origin, and although they are sometimes triggered by rapid pacing, suggesting triggered activity, they appear to be automatic rather than a reentrant mechanism.

The electrocardiographic features are characteristic and usually permit accurate diagnosis. Because the arrhythmia is focal and automatic, the morphology of the first PAC of the run is identical to the subsequent PACs. Cycle length tends to vary between and within runs, and tachycardia is unaffected by intermittent AV block, which may occur during the runs. The same focus often fires erratically between runs, resulting in frequent atrial ectopy that is morphologically similar to the P wave observed during the runs.

The arrhythmia appears to be caused by intracellular calcium overload and resultant triggered activity related to delayed afterdepolarizations, making it responsive to calcium-channel blockers and β -blockers. The paroxysmal sustained form of this arrhythmia is also adenosine responsive, giving the false impression of dependence on AV conduction. The use of digoxin may exacerbate triggered causes of atrial tachycardia. Class IC agents, such as flecainide and propafenone, may be useful in patients without structural heart disease or coronary artery disease. Amiodarone can also be used in these patients for rhythm control. The arrhythmia is readily amenable to catheter ablation if ectopy occurs frequently enough to permit mapping.

Typical Atrial Flutter

Atrial flutter is a persistent atrial arrhythmia with an atrial rate of at least 250 beats per minute (see Fig. 9-6C). Because the normal AV node cannot conduct 1 : 1 at these rates, this arrhythmia characteristically manifests with 2 : 1 conduction and a ventricular

response of about 140 to 150 beats per minute. During 2 : 1 conduction, the difficulty in perceiving flutter waves may lead to diagnostic confusion. Typical atrial flutter is the most common form of this arrhythmia, and it is mediated by macro-reentry restricted to the right atrium. The central obstacles in this circuit consist of normal anatomic structures, accounting for its stereotyped pattern.

Typical atrial flutter is mediated by counterclockwise reentry around the tricuspid valve as viewed from the ventricle. The valve prevents anterior collapse of the circuit, and posteriorly a long ridge in the atrial wall (i.e., crista terminalis) forms a functional line of block, preventing the circuit from collapsing posteriorly. Because the normal obstacles already exist, flutter development results from the abnormally slowed conduction related to atrial enlargement, fibrosis, or edema, which sometimes is combined with shortened atrial refractory periods due to catecholamine stress. Typical counterclockwise atrial flutter demonstrates a deeply negative F wave in leads II, III, and aVF; a sharply positive F wave in V_1 ; and a negative F wave in V_6 .

A less common reversed form of this arrhythmia is caused by clockwise reentry around the tricuspid valve. It demonstrates an ECG exactly opposite to the counterclockwise form, with a strongly positive F wave in leads II, III, and aVF; a sharply negative F wave in V_1 ; and a positive F wave in V_6 . In both cases, the F waves are often difficult to perceive because of 2 : 1 conduction. If the unusual F-wave vector is not recognized, the ECG may be misinterpreted as sinus tachycardia. Clues to identification of atrial flutter are persistent, unexplained heart rates of about 150 beats per minute with a variation of only a few beats per minute over time and the finding of a negative P wave in the inferior leads, which is expected to be positive in sinus rhythm.

The most fruitful method of diagnosis is the provocation of transient AV block with carotid sinus massage or adenosine infusion. This transiently exposes the underlying flutter waves but does not terminate the arrhythmia.

Although acute therapy involves rate control or cardioversion if drugs are poorly tolerated, long-term rate control for this arrhythmia is difficult. Drug doses that result in acceptable block at rest often fail to control exercise rates, and doses that result in exercise rate control often provoke bradycardia at rest. Early restoration of sinus rhythm is preferred for this arrhythmia.

Atrial flutter is a common transient arrhythmia in acute care hospital settings. The right atrial wall is thin, and pericarditis resulting from cardiac or thoracic surgery results in atrial edema and inflammation that may permit adequate slowing and promote transient atrial flutter. Acute pulmonary decompensation may result in right heart failure and may promote transient atrial flutter. In all of these settings, endogenous or pharmacologic catecholamine stimulation exacerbates the arrhythmia. Transient therapy for up to a month is appropriate in these settings.

When atrial flutter occurs in the absence of an acute precipitant, long-term therapy is required. Given the difficulty of achieving rate control in atrial flutter and the need for antiarrhythmic agents with associated potential morbidity to maintain sinus rhythm, catheter ablation has become the primary means of treating this arrhythmia. Antiarrhythmic therapy for atrial flutter is similar to that for AF (discussed later). Antiarrhythmic drug

therapy should be reserved for temporary treatment of likely transient flutter or for patients who are not suitable candidates for invasive management. Catheter ablation of typical atrial flutter is a low-risk procedure with a long-term success rate exceeding 90% in experienced centers.

Atypical Atrial Flutter and Macro-reentrant Atrial Tachycardia

In addition to the typical atrial flutter circulating around normal anatomic obstacles, atrial disease with associated fibrosis or, more commonly, atrial scars created at the time of cardiac surgery for valvular or congenital heart disease may create alternative substrates for intra-atrial reentry. Common to these arrhythmias is a significant region of scar with a channel of surviving myocardium bridging the scar or between the scar and a normal anatomic obstacle. Within the channel, conduction is slow and electrocardiographically silent, resulting in an isoelectric PP interval. Because the circuit is different from that of typical atrial flutter, the P-wave morphology is atypical.

When the rate is 250 beats per minute or greater, the arrhythmia is arbitrarily classified as atypical atrial flutter, and when the rate is less than 250 beats per minute, it is arbitrarily classified as atrial tachycardia. Like typical atrial flutter, these arrhythmias are paroxysmal sustained or persistent arrhythmias, and when manifesting with 2:1 conduction, they may be misdiagnosed as sinus tachycardia if the abnormal P-wave vector and fixed heart rate over time are not recognized. Therapy and prognosis are otherwise similar to those for typical atrial flutter.

Atrial Fibrillation

Overview and Classification

AF is a chaotic atrial rhythm related to continuous and variable activation of the atria. There are no distinct P waves or periods of atrial quiescence. It is characterized electrocardiographically by a wavering baseline associated with an irregular ventricular response (see Fig. 9-6D).

AF is the most common clinically significant arrhythmia. It affects 2.2 million people in the United States. Its prevalence is between 0.4% and 1% in the general population, and it increases with age, reaching 8% in those older than 80 years. Patients with AF have a higher risk of stroke, heart failure, and mortality. However, the role of AF as an independent determinant of mortality is uncertain because it commonly coexists with other important conditions. Patients with lone AF do not have an increased mortality rate, and carefully designed trials exploring the benefit of maintenance of sinus rhythm over rate control show no survival benefit for sinus rhythm. Whether AF is merely a marker for increased mortality or a mechanism remains uncertain.

AF is often classified by its clinical presentation and pattern. When AF is first detected, it is called *new onset*, and its ultimate pattern is initially undetermined. When AF relapses during follow-up, it is called *recurrent* and classified by its clinical pattern. If AF terminates spontaneously, it is called *paroxysmal* AF. Although episodes lasting up to 7 days are defined as paroxysmal, most episodes of paroxysmal AF terminate within the first 24 hours and many terminate within minutes or hours of onset.

When AF lasts longer than 7 days, it is designated as *persistent*. AF that persists for a long interval, typically more than a year, without return of an interim period of sinus rhythm (spontaneously or as a result of medical intervention such as cardioversion) is often called *permanent* AF.

Mechanisms of Atrial Fibrillation

Because of its chaotic nature, it has been difficult to study AF, and its mechanisms remain incompletely understood. The initiation of spontaneous AF is a consequence of rapid electrical firing from preferential focal sites of origin. The most common site of focal origin is from left atrial muscle sleeves extending along the outer surface of the pulmonary veins. When firing does not originate from a pulmonary vein, it is commonly from the left atrial tissue immediately adjacent to one of the veins or occasionally from one of the other thoracic veins such as the ostium of the superior vena cava or the ostium of the coronary sinus. Atrial rates recorded in and around the pulmonary veins are significantly higher than at other atrial sites, suggesting that activity in the region of the veins is important in perpetuating AF after initiation.

These insights have produced highly effective techniques for the cure of AF. Ablation techniques designed to isolate these trigger sites from the atrium have success rates of 70% to 80% for the cure of paroxysmal AF and somewhat lower rates for the cure of persistent AF. Ablation restricted to the region of the pulmonary veins and adjacent left atrium is curative in most patients with AF, implying that most cases of AF are arrhythmias entirely contained within and maintained by the left atrium and connecting veins. In the same way that typical atrial flutter is the characteristic arrhythmia of the right atrium, AF is the characteristic arrhythmia of the left atrium.

Anticoagulation and Atrial Fibrillation

During AF (and to some extent, atrial flutter), the atria have incomplete and ineffective contractions. Blood stasis occurs and may result in the formation of intracardiac thrombus, which may lead to thromboembolism and stroke. The overall risk of stroke in patients with AF is 5% per year. Certain risk factors may adjust this risk, including age, gender, rheumatic heart disease, prior stroke, left ventricular dysfunction, left atrial enlargement, hypertension, and diabetes.

Scoring systems have been developed to estimate a patient's AF-related stroke risk based on his or her constellation of risk factors. The most used system is the CHADS₂ score (cardiac failure, hypertension, age ≥ 75 years, diabetes mellitus, and prior stroke). This system has been well validated in assessing the stroke risk of patients with AF. It assigns a single point for age of 75 years or older, diabetes, history of heart failure, and hypertension. It assigns two points for a history of stroke or transient ischemic attack. A score of 0 correlates with a relatively low risk of stroke at 1.9% per year, a score of 1 has a stroke risk of 2.8% per year, a score of 2 has a risk of 4.0% per year, and a score of 3 or higher has a stroke risk of more than 5.9% per year.

The CHADS₂ underwent further refinement to increase the granularity of stroke risk stratification with the creation of the CHA₂DS₂-VASc (vascular disease, age, and sex) scoring system. In this system, congestive heart failure, hypertension, diabetes

mellitus, vascular disease, age between 65 and 74 years, and female gender are assigned 1 point, and age of 75 years or older and prior stroke are assigned 2 points. A CHA₂DS₂-VASc score of 0 was associated with a 0% stroke rate, a score of 1 with a 0.6% per year risk, a score of 2 with a 1.6% risk, and a score of 3 with a risk of 3.9%. This system may be most useful for patients with an intermediate risk based on a CHADS₂ score of 1 or 2.

After a patient's individualized stroke risk is determined, it can be balanced against the risk of anticoagulation to determine what would be appropriate for stroke prevention. A useful tool for estimating bleeding risk due to oral anticoagulation is the HAS-BLED (*hypertension, abnormal renal/liver function, stroke, bleeding history or predisposition, labile international normalized ratio, elderly, drugs/alcohol*) score. Patients with a HAS-BLED score of 0 had a risk of 0.59 severe bleeds per 100 patient-years, those with a score of 1 had a risk of 1.51, those with a score of 2 had a risk of 3.20, and those with a score of 3 had a risk of 19.51.

Aspirin and warfarin are the longest-studied antithrombotics used for reducing the rate of AF-related stroke. Aspirin reduces the risk of AF-related stroke by 25%, and warfarin reduces the risk by 50%. Warfarin can be difficult to administer; the level of blood-thinning effect must be constantly monitored with international normalized ratio (INR) blood testing. An INR less than 2.0 is associated with higher rates of ischemic stroke; a level greater than 3.0 is associated with increased intracranial bleeding. On average, a therapeutic INR (between 2.0 and 3.0) is maintained in only two thirds of cases, and there are many drug and dietary interactions with warfarin.

The combination of aspirin plus clopidogrel is somewhat more effective than aspirin alone in preventing stroke (2.4% versus 3.3% per year), but it comes at the cost of almost twice the major bleeding rate. Coumadin is superior to the combination of aspirin and clopidogrel, especially if the INR can be kept within the therapeutic range at least 65% of the time.

Several newer oral anticoagulants have effectiveness and bleeding risk rates similar to warfarin, but they do not require drug level monitoring. They include dabigatran, rivaroxaban, and apixaban, which have been studied in large patient groups and found to be noninferior to warfarin, and some may be superior in certain aspects.

The highest risk of stroke related to AF occurs at time of conversion to sinus rhythm achieved spontaneously or by chemical or electrical cardioversion. If thrombus has formed within the left atrium or left atrial appendage, it may not leave the atria during AF due to ineffective atrial mechanics. However, after sinus rhythm is restored, the improved atrial function may eject the thrombus and cause embolic stroke or other systemic embolic sequelae. Even with restoration of electrical atrial systole, the recovery of normal atrial mechanics may be delayed several days to weeks (i.e., atrial stunning). To reduce the risk of pericardioversion stroke, it is important to reduce the risk of preexisting thrombus and to prevent formation in the time period immediately after cardioversion.

The risk of preexisting thrombus can be reduced by 3 weeks of oral anticoagulation or Doppler transesophageal echocardiography (TEE) before cardioversion. These steps are recommended for any patient who has been in AF for an unknown period or has

been documented to be in AF more than 48 hours. Although thrombi have been identified in patients with AF for shorter periods, current clinical practice presumes that most thrombus formation requires at least 48 hours. Thrombus related to AF occurs most commonly in the left atrial appendage, which cannot be well visualized by transthoracic echocardiography; TEE is often recommended before cardioversion for optimal imaging of the left atrial appendage. After cardioversion, at least 4 weeks of oral anticoagulation is recommended (regardless of CHADS₂ score).

Acute Management of Atrial Fibrillation: Rate Control

The acute management of AF centers on the control of the ventricular response, timely restoration of sinus rhythm, and identification of potentially reversible factors that might have precipitated the arrhythmia. AF with rapid ventricular response results in acute deterioration in stroke volume and cardiac output and an increase in myocardial oxygen demand with the potential for coronary ischemia. Patients who are symptomatic must be controlled promptly. When pursuing rate control for acute AF of recent onset, the fastest way to achieve rate control is the restoration of sinus rhythm. If rate control proves difficult or is not well tolerated, cardioversion should be undertaken early.

For the acute control of rapidly conducted AF, intravenous administration of a β -blocker (i.e., esmolol, metoprolol, or propranolol) or a nondihydropyridine calcium-channel blocker (i.e., diltiazem or verapamil) is preferred. In the setting of decompensated heart failure, the use of a calcium-channel blocker may exacerbate heart failure and should be avoided. In this setting, digoxin is a useful agent for resting rate control. Digoxin is also a useful second-line drug in addition to a calcium-channel or β -blocker for resting rate control. If this therapy is ineffective or not tolerated, intravenous amiodarone is a useful rate control agent, especially in the setting of congestive heart failure, and it may facilitate restoration of sinus rhythm.

Long-term targets for rate control of permanent AF have been a matter of debate. The recently completed Rate Control Efficacy in Permanent Atrial Fibrillation II (RACE II) study showed no advantage to strict rate control. Targeting a resting rate of less than 80 beats per minute showed no advantage over a target of less than 110 and was much harder to achieve. For long-term management, the results suggest that achieving a resting heart rate of less than 110 beats per minute may be sufficient and safe.

Acute Management of Atrial Fibrillation: Restoration of Sinus Rhythm

When sinus rhythm is restored in the first 48 hours of acute AF, the thromboembolic risk is low, and anticoagulation is not required. New-onset AF should be managed with a plan to restore sinus rhythm during this period if possible. At least one half of new-onset AF episodes terminate spontaneously in the first 24 to 48 hours.

Pharmacologic Conversion of Atrial Fibrillation

Pharmacologic conversion of AF can be undertaken when restoration of sinus rhythm is not urgent. Several antiarrhythmic drugs

have been effective in increasing the rate of early conversion of AF. Pharmacologic conversion usually is more successful with AF of recent onset than with chronic AF.

Oral agents with efficacy in the early conversion of AF include flecainide, propafenone, and dofetilide. Oral amiodarone and sotalol have been associated with a 27% and 24% conversion rate, respectively, occurring after 28 days of therapy. However, due to low early conversion rates, these oral drugs are not recommended for conversion. Intravenous agents with efficacy for early conversion include ibutilide and amiodarone. Ibutilide is limited by a relatively high 4% rate of drug-induced QT prolongation and TdP VT. This risk is even higher in the setting of LV dysfunction, electrolyte disturbances, or heart failure. Ibutilide should be reserved for the pharmacologic conversion of stable patients with a baseline normal QT interval. In contrast, intravenous amiodarone is well tolerated by unstable patients and is the preferred pharmacologic agent for conversion in the critically ill.

Electrical Cardioversion of Atrial Fibrillation

Electrical cardioversion should be performed urgently in the case of severe compromise related to acute AF, including angina, heart failure, hypotension, and shock. Cardioversion should also be attempted at least once electively in most cases of new-onset AF regardless of tolerance. When performing electrical cardioversion, an anterior-posterior patch or paddle position is more effective than the conventional anterior-to-lateral patch or paddle position used for ventricular defibrillation. Although low-output discharges may be effective in some patients, a strategy of starting at higher outputs decreases the number of shocks required and the average cumulative energy delivered. An initial shock energy of 200 J is recommended. After a failed initial shock, full output should be used for the next attempt.

Long-Term Maintenance of Sinus Rhythm

Antiarrhythmic Therapy

Despite the association of AF with an increase in stroke-related and all-cause mortality, no study has established a benefit for pharmacologic maintenance of sinus rhythm in terms of stroke risk or survival. This may be because AF is merely a marker and not a mechanism of mortality. It may also be a consequence of the relative inefficacy of pharmacologic therapy in the maintenance of sinus rhythm and the difficulty establishing whether patients thought to be in sinus rhythm are consistently in sinus rhythm at follow-up.

The largest and best designed trial addressing this issue was the Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) trial. The study included 4060 patients randomly assigned to rhythm control with antiarrhythmic drugs, most commonly amiodarone, or to rate control without attempts to maintain sinus rhythm. AFFIRM demonstrated no advantage in stroke or mortality rates using a strategy of sinus rhythm maintenance compared with rate control. Either strategy can be offered to patients with an expectation of similar outcomes with regard to hard end points. The decision to pursue sinus rhythm usually is determined by the management of symptoms that may be better addressed by maintaining sinus rhythm in selected patients.

In the absence of antiarrhythmic drugs, more than 80% of patients relapse during the first year after cardioversion of AF. Antiarrhythmic drugs remain the primary strategy for maintaining sinus rhythm after cardioversion and for preventing symptomatic episodes in patients with paroxysmal AF. However, antiarrhythmic therapy has many limitations, and alternative ablative therapies may over time overtake antiarrhythmic therapy in the management of AF.

All antiarrhythmic drugs have the potential for proarrhythmia, the unintended precipitation of a new arrhythmic problem caused by the drug. Adverse rhythm effects of drugs may include sinus node dysfunction, heart block, promotion of drug-slowed atrial flutter permitting rapid 1:1 conduction, and promotion of potentially lethal ventricular arrhythmias. Class I drugs such as flecainide, propafenone, and disopyramide may result in significant direct myocardial depression and consequent exacerbation of heart failure. The array of potential adverse effects of antiarrhythmic drugs is beyond the scope of this chapter, but certain essential concepts are important to recognize.

Class I drugs such as flecainide and propafenone, which work by slowing conduction, have a high risk of ventricular proarrhythmia and potential for sudden death in the setting of heart failure, LV dysfunction, and coronary artery disease. Use of these drugs is restricted to patients with preserved cardiac function and no evidence of obstructive coronary artery disease. However, in this selected group of patients with normal hearts, these drugs are exceedingly safe, well tolerated, and often effective.

Class III drugs, which prolong repolarization and refractoriness, include sotalol, dofetilide, dronedarone, and amiodarone. They are safe for patients with coronary artery disease, and in the case of dofetilide and amiodarone, they are safe for those with congestive heart failure. However, sotalol and dofetilide may provoke TdP, even in patients with normal cardiac function, and they must be used with caution. Amiodarone has greater long-term efficacy than other drugs and a lower risk of proarrhythmia, but long-term somatic toxicity consisting of thyroid dysfunction, pulmonary, and occasional hepatotoxicity limits the use of this drug in older patients or those with limited expected longevity or an inability to safely tolerate alternative agents due to advanced cardiac disease or proarrhythmia. Amiodarone is highly effective for the short-term, acute management of arrhythmias in critically ill patients when the potential risk of long-term toxicity is not an issue.

Dronedarone, which was approved in 2009, was derived by modification of the amiodarone molecule. Like amiodarone, the drug has a low risk of proarrhythmia and TdP VT. Unlike amiodarone, the drug does not cause thyroid toxicity. In common use, hepatotoxicity is also uncommon with dronedarone. However, rare cases of hepatic failure have been associated with dronedarone use. Dronedarone has increased mortality rates for patients with recently decompensated heart failure and when used as a simple rate control agent in patients with permanent AF. It is contraindicated in these settings.

In addition to being useful agents for the prevention of AF, sotalol, dronedarone, and amiodarone provide substantial rate control during relapses of AF. However, rate control with other antiarrhythmic agents may not be adequate to prevent rapid

conduction with relapse, and class I drugs such as flecainide may accelerate response at the time of relapse. Antiarrhythmic drugs other than sotalol, dronedarone, or amiodarone should therefore be combined with a rate control agent such as a β -blocker or nondihydropyridine calcium-channel blocker during long-term therapy. Figure 9-7 is a proposed strategy for antiarrhythmic drug selection for the long-term maintenance of sinus rhythm in patients with AF.

Surgical Ablation of Atrial Fibrillation

The surgical treatment of AF was pioneered by Cox with the development of the atrial maze procedure. The procedure was predicated on the concept that AF was maintained by multiple interacting wave fronts of activity. By surgically dividing the atria into narrow channels, most with connection back to the sinus node, it was thought that AF could be abolished while preserving physiologic activation and contraction of the atrium. The circuitous path left for atrial activation and the multiple barriers created in the atrium intended to prevent AF gave rise to the term *maze procedure* to describe the technique. The initial procedure was thought to be highly successful but was associated with significant surgical risks and problems with sinus node dysfunction. Because of the surgical complexity of making and then closing multiple incisions in the atria and the complications associated with the procedure, the initial cut-and-sew maze procedure has fallen out of clinical use.

Although the original maze procedure is no longer used, many techniques have been developed to simplify the operation by

substituting linear thermal ablation (by heating or cooling tissue) to create lines of conduction block in the atria without the need for extensive atrial dissection and reconstruction. Surgical ablation is commonly applied in patients with a history of AF who are undergoing concomitant heart operations for other indications such as valvular or coronary disease. Less frequently, surgical ablation has been applied as a stand-alone procedure for the sole management of AF. In that setting, various minimally invasive techniques have been developed. However, the techniques used vary widely from one center to another and long-term reporting of outcomes is inconsistent. In a large series that included 282 patients undergoing an open bi-atrial ablation procedure, 78% were in sinus rhythm without antiarrhythmic therapy at the 1 year follow-up evaluation.

Another important potential benefit of surgical ablation for AF is that it provides an opportunity to eliminate the left atrial appendage as a potential site of thrombus formation and source of thromboembolism. This can be accomplished by complete amputation of the appendage with oversewing of the appendage or clamping off the opening to the appendage with special devices designed for this purpose. This may be especially important in patients with absolute or relative contraindications to anticoagulation.

Catheter Ablation of Atrial Fibrillation

Catheter ablation has become a common procedure for the management of AF after failure of initial attempts at medical therapy of AF. Initial attempts to cure AF using catheter techniques were based on attempts in the early 1990s to emulate the linear lesion set of the Cox maze procedure with multiple endocardial lesions. High complication rates and limited efficacy led to abandonment of this approach.

In 1998, Haissaguerre reported the important role of rapid activity originating in the musculature of the pulmonary veins in initiation of paroxysmal AF. This led to the development of procedures designed to target the pulmonary veins and eventuated in the technique of electrical pulmonary vein isolation (PVI), which is currently the primary ablative approach to treatment of paroxysmal AF by catheter techniques. This technique has had acceptably high success rates ($\approx 70\%$) at multiple centers for the treatment of paroxysmal AF without antiarrhythmic therapy.

Despite the high success rate of catheter PVI ablation for the treatment of paroxysmal AF, this technique has not proved reliably effective in the management of more persistent forms of AF, especially long-standing persistent AF. This likely reflects the importance of factors other than pulmonary vein activity in the initiation and maintenance of persistent AF that are not addressed by PVI ablation. Multiple ablative techniques are currently used in an attempt to increase the success rates for patients with persistent AF. They have included addition of linear lesions to block reentrant wave fronts, ablation of regions of unusually rapid atrial activity during ongoing AF, and interruption of stable rotors of atrial activity identified during multisite mapping of AF. Although these techniques have improved success rates in limited series, it is uncertain which, if any, of these methods represents the optimal approach to the ablation of long-standing persistent AF.

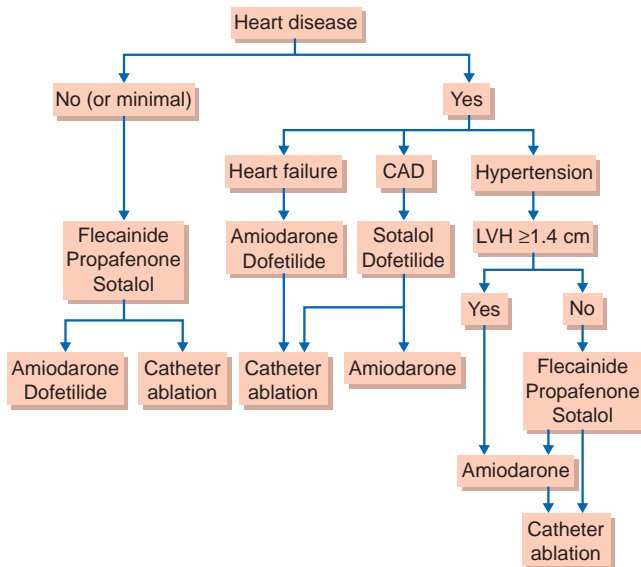

FIGURE 9-7 A strategy for the selection of therapy to maintain sinus rhythm in patients with recurrent atrial fibrillation. Patients are stratified by the presence or absence of structural heart disease, and drugs expected to have the greatest efficacy and lowest therapeutic risk in each group are selected. Catheter ablation becomes a therapeutic option after failure of at least one antiarrhythmic drug. The class IC drugs flecainide and propafenone are not advised for patients with heart failure or coronary artery disease (CAD). Amiodarone is an acceptable first-line drug for those with heart failure and severe left ventricular hypertrophy. Because of its potential for somatic toxicity, amiodarone is otherwise reserved as a second-line agent that is used as an alternative to catheter ablation.

In summary, catheter ablation is the preferred secondary strategy for treatment of symptomatic AF after initial attempts at medical therapy have failed. Simple pulmonary vein isolation has a high success rate for the management of patients with paroxysmal AF. Success rates for all ablative techniques are lower for persistent AF, especially for long-term AF. As in the case of surgical ablation, multiple techniques are used at various centers, and the different strategies for follow-up and definitions of response have made it difficult to ascertain the relative efficacy of the various approaches in common use.

Catheter Ablation of the Atrioventricular Node

Although less commonly used today than in the past, the older technique of catheter ablation of the AV node resulting in complete heart block followed by placement of a ventricular pacemaker to maintain physiologic heart rates remains an option for patients when rate control cannot be achieved medically. This technique continues to have an important role in the management of patients who are too infirm to safely undergo AF ablation or in patients for whom ablative techniques have failed to control the arrhythmia.

 For a deeper discussion on this topic, please see Chapter 64, “Cardiac Arrhythmias with Supraventricular Origin,” in Goldman-Cecil Medicine, 25th Edition.

SYNCOPE

Syncope is a sudden loss of consciousness that is transient. Syncope has cardiac causes (e.g., low cerebral blood pressure) and noncardiac causes. Common causes and categories of syncope are outlined in Table 9-4. Cerebrovascular disease or stroke uncommonly manifests as syncope unless a large cerebral territory is involved. Syncope is a common reason for emergency room or hospital admission.

The diagnostic approach to a patient with syncope is given in Figure 9-8. Most causes can be identified by the medical history and physical examination alone. Conditions surrounding the syncopal episode often suggest a cause. For example, vasovagal episodes often occur during stress, pain, straining, coughing, or urination. Exercise-induced syncope may indicate obstructive coronary disease, channelopathies such as long QT or CPVT, obstructive cardiomyopathy, aortic stenosis, or arrhythmia. A history of palpitations or syncope with no warning may be related to cardiac arrhythmias. Very long episodes of syncope (>5 minutes) suggest noncardiac causes. A recent change in medications or dizziness with position changes suggests orthostatic hypotension. Witnessed limb movements or posturing is not specific for neurologic causes and can result from any type of cerebral hypoperfusion, even from cardiac causes.

Beyond the history, physical examination, and routine ECG, further testing has little diagnostic utility. Holter or loop recorders may be useful. Implantable loop recorders may have utility in cases of recurrent, infrequent syncope. Electrophysiologic testing may be useful in some patients with other abnormalities suggesting an arrhythmic cause.

Despite thorough evaluations, more than 30% of patients with syncope have no identifiable cause. Cardiac causes of syncope have the highest morbidity and mortality rates. Because patients

TABLE 9-4 CAUSES OF SYNCOPE

CAUSE	FEATURES
PERIPHERAL VASCULAR OR CIRCULATORY	
Vasovagal syncope (neurally mediated)	Prodrome of pallor, yawning, nausea, diaphoresis; precipitated by stress or pain; occurs when patient is upright, aborted by recumbency; fall in blood pressure with or without a decrease in heart rate
Micturition syncope	Syncope with urination (probably vagal)
Post-tussive syncope	Syncope after paroxysm of coughing
Hypersensitive carotid sinus syndrome	Vasodepressor and/or cardioinhibitory responses with light carotid sinus massage
Drugs	Orthostasis; occurs with antihypertensive drugs, tricyclic antidepressants, phenothiazines
Volume depletion	Orthostasis; occurs with hemorrhage, excessive vomiting or diarrhea, Addison's disease
Autonomic dysfunction	Orthostasis; occurs in diabetes, alcoholism, Parkinson's disease, deconditioning after a prolonged illness
CENTRAL NERVOUS SYSTEM	
Cerebrovascular	Transient ischemic attacks and strokes are unusual causes of syncope; associated neurologic abnormalities are usually identified
Seizures	Warning aura sometimes present, jerking of extremities, tongue biting, urinary incontinence, postictal confusion
METABOLIC	
Hypoglycemia	Confusion, tachycardia, jitteriness before syncope; patient may be taking insulin
CARDIAC	
Obstructive	Syncope is often exertional; physical findings consistent with aortic stenosis, hypertrophic obstructive cardiomyopathy, cardiac tamponade, atrial myxoma, prosthetic valve malfunction, Eisenmenger's syndrome, tetralogy of Fallot, primary pulmonary hypertension, pulmonary stenosis, massive pulmonary embolism
Arrhythmias	Syncope may be sudden and occurs in any position; episodes of dizziness or palpitations; may be history of heart disease; bradyarrhythmias or tachyarrhythmias may be responsible—check for hypersensitive carotid sinus

with unknown causes of syncope have long-term outcomes similar to those with noncardiac syncope, and the major goal of an evaluation is to identify cardiac causes of syncope.

VENTRICULAR ARRHYTHMIAS AND SUDDEN CARDIAC DEATH

Ventricular ectopy is defined as cardiac beats that originate from within the right or left ventricular muscle or conduction system. Premature ventricular contractions (PVCs) can occur singly or as ventricular couplets or triplets. VT is four or more consecutive beats that originate from the ventricle at a rate of at least 100 beats per minute. VT is classified as *sustained* if it lasts longer than 30 seconds or requires termination due to hemodynamic instability; otherwise, it is classified as *nonsustained* VT (NSVT).

Ventricular ectopy also may be classified based on maintenance of a similar electrocardiographic morphology. The beats of monomorphic VT (MMVT) appear to be identical and usually originate from the same area of the heart. *Ventricular flutter* is a term that may be used to describe MMVT with rates of more than 300 beats per minute. Polymorphic VT (PMVT) has a more

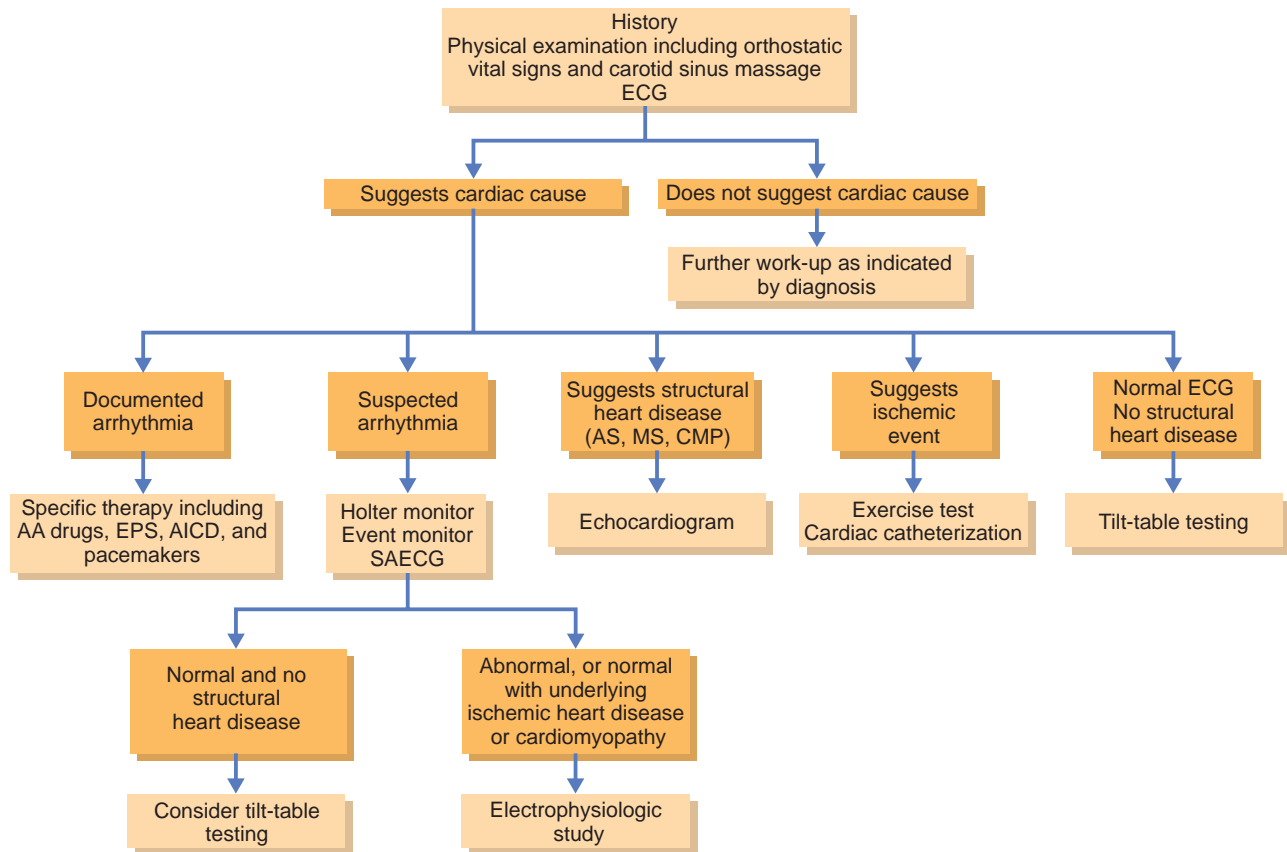

FIGURE 9-8 Approach to the evaluation of syncope. AA, Antiarrhythmic; AICD, automatic implantable cardioverter-defibrillator; AS, aortic stenosis; CMP, cardiomyopathy; ECG, electrocardiogram; EPS, electrophysiologic study; MS, mitral stenosis; SAECG, signal-averaged ECG.

variable appearance on the ECG than MMVT. TdP is a special form of PMVT that has a repetitive, undulating periodicity and usually implies a long-QT triggered mechanism. VF is the most chaotic form of ventricular ectopy. It is associated with no meaningful cardiac output and usually leads to death unless rapidly treated. The other forms of VT may eventually degrade into VF.

Determining whether a patient has a rhythm of ventricular origin usually is done by 12-lead surface ECG. Ventricular ectopy typically has a wide QRS morphology (Fig. 9-9). Not all wide QRS morphologies are ventricular in origin, and there are criteria for determining whether a wide complex tachycardia is supraventricular or ventricular. SVT may appear as a wide complex tachycardia if it conducts to the ventricle with aberrancy (e.g., bundle branch block) or through an accessory pathway (e.g., WPW syndrome). Features that may help distinguish between SVT and VT include AV dissociation with capture beats and fusion beats and the QRS morphology and duration (Table 9-5). The Brugada algorithm is commonly used for determining the site of origin of wide complex tachycardia. The tachycardia has a ventricular origin in more than 90% of patients with a history of ischemic heart disease.

VT may occur by the same mechanisms as other tachycardias, such as reentry, enhanced automaticity, or triggered activity. VT often occurs as a reentrant tachycardia around an area of prior MI scar in the left ventricle. VT in the chronic phase of ischemic heart disease is mediated by reentry through channels or sheets of surviving myocardium, especially in the partially spared border zone of a region of scar resulting from a prior MI. In these

FIGURE 9-9 Ventricular arrhythmias. **A**, Monomorphic ventricular tachycardia (VT). Notice the wide QRS with a stable appearance with each beat. Detecting P waves during VT is difficult due to the overlying ventricular activity, but it is visible at several points on this tracing, some of which are marked by arrows. The AV dissociation is diagnostic of VT and excludes supraventricular tachycardia. **B**, An initially organized agonal (preterminal) rhythm (arrows) degenerates into coarse ventricular fibrillation. Notice the irregular baseline and the absence of organized QRS complexes. During ventricular fibrillation, there is no forward cardiac output, and cardiac arrest immediately ensues.

channels, conduction is abnormally slow due to poor coupling between sparse surviving myocytes. Susceptibility to sustained VT increases with worsening left ventricular dysfunction, likely due to the greater extent of ventricular scar.

VT can occur in the absence of ischemic heart disease in the form of idiopathic VT, nonischemic cardiomyopathies, hypertrophic cardiomyopathies, arrhythmogenic RV dysplasia, bundle branch reentry, cardiac ion channel disorders, or electrolyte

TABLE 9-5 DIFFERENTIATION OF VENTRICULAR TACHYCARDIA FROM SUPRAVENTRICULAR TACHYCARDIA WITH ABERRANCY

HELPFUL FEATURES	IMPLICATIONS
Positive QRS concordance	Diagnostic of VT
AV dissociation, capture beats, or fusion beats	Diagnostic of VT
Atypical RBBB (monophasic R, QR, RS, or triphasic QRS in V ₁ ; R:S ratio <1, QS or QR, monophasic R in V ₆)	Suggests VT
Atypical LBBB (R >30 min or R to S [nadir or notch] >60 min in V ₁ or V ₂ ; R:S ratio <1, QS or QR in V ₆)	Suggests VT
Shift of axis from baseline	Suggests VT
History of CAD	Suggests VT
QRS during tachycardia identical to QRS during sinus rhythm	Suggests SVT
Termination with adenosine	Suggests SVT

disturbances. The right ventricular outflow tract (RVOT) is the most common origin of idiopathic VT, which is likely caused by triggered activity. This form of VT (or PVCs) is usually sensitive to catecholamines and may terminate with adenosine (i.e., adenosine-sensitive VT). Another common form of idiopathic VT originates from the left ventricular conduction system (i.e., fascicular VT) and may be verapamil sensitive. Idiopathic VTs are common targets for successful catheter ablation.

Nonsustained VT usually does not require specific therapy unless the patient is symptomatic. The Cardiac Arrhythmia Suppression Trial treated PVCs and NSVT after the acute phase of MI with class I antiarrhythmic drugs, and the trial demonstrated increased mortality rates when the arrhythmias were treated. If VT is attributed to reversible causes such as electrolyte disturbances or acute ischemia, the underlying mechanism should be treated. VT not due to reversible causes may be treated with β -blockers, antiarrhythmic drug therapy (e.g., amiodarone), or catheter ablation. If urgent treatment is required due to hemodynamic instability, direct current cardioversion is performed. It should be synchronized to the QRS complex if a regular morphology exists; otherwise, it should be nonsynchronized. Performing direct current cardioversion during the refractory period (T wave) of MMVT may degrade the rhythm to VF. An ICD often is used in patients who survive VT or VF to quickly treat recurrent episodes. Endocardial and epicardial catheter ablation has become an effective treatment for VT.

Prevention of Sudden Cardiac Death

SCD is defined as death within 1 hour of the onset of symptoms. It may result from a variety of cardiac or noncardiac conditions (Table 9-6). SCD is one of the most common causes of death, with 400,000 events occurring annually in the United States. The most common cause of SCD is VT or VF. Cardiac conditions that increase the risk of SCD include LQTS, hypertrophic cardiomyopathy, Brugada syndrome, arrhythmogenic RV dysplasia, and nonischemic or ischemic cardiomyopathy. The most common cardiac condition that may lead to SCD is acute or distant MI.

The successful treatment of SCD due to VF usually requires rapid access to cardioversion; if treatment is delayed by more than 5 to 10 minutes, permanent brain injury is common. AEDs

TABLE 9-6 CAUSES OF SUDDEN CARDIAC DEATH

NONCARDIAC CAUSES	
Central nervous system hemorrhage	Bradyarrhythmias, sick sinus syndrome
Massive pulmonary embolus	Aortic stenosis
Drug overdose	Tetralogy of Fallot
Hypoxia secondary to lung disease	Pericardial tamponade
Aortic dissection or rupture	Cardiac tumors
	Complications of infective endocarditis
CARDIAC CAUSES	
Ventricular fibrillation	Hypertrophic cardiomyopathy (arrhythmia or obstruction)
Myocardial ischemia or injury	Myocardial ischemia
Long QT syndrome	Atherosclerosis
Short QT syndrome	Prinzmetal angina
Brugada syndrome	Kawasaki arteritis
Arrhythmogenic right ventricular dysplasia	
Ventricular tachycardia	

can reduce the time to defibrillation and improve survival when placed in public areas, although they have been less effective when installed in private residences, even for patients at risk for SCD.

ICDs used in the treatment of SCD have improved mortality rates. Patients who are at high risk for SCD are often offered an ICD to enable rapid defibrillation before the onset of anoxic brain injury. If a patient survives the first episode of SCD due to documented or presumed VT or VF from nonreversible or unknown causes, he or she is offered an ICD. ICDs are extremely successful in the detection and treatment of VT or VF. They do not always prevent loss of consciousness because it takes 15 to 20 seconds to treat the arrhythmia, and low cardiac output may cause syncope before restoration of normal rhythm, especially if several cardioversions are required.

The earliest ICD trials examined their use in the secondary prevention of SCD (i.e., treating patients who had already survived an episode of cardiac arrest). The largest study was the Antiarrhythmics Versus Implantable Defibrillators (AVID) trial, which randomized patients with a history of poorly tolerated sustained VT or cardiac arrest to empirical amiodarone or ICD implantation. In this trial and several others, ICD therapy was associated with a lower risk of arrhythmic and all-cause death compared with antiarrhythmic therapy.

Several trials have examined the use of ICDs for the primary prevention of SCDs (i.e., treating patients who are at risk for SCD). The first was the Multicenter Automatic Defibrillator Implantation Trial (MADIT), which enrolled patients with a prior MI and an ejection fraction of 35% or less who had frequent ventricular ectopy and inducible VT at electrophysiologic testing. The study demonstrated a substantial mortality reduction with ICD therapy. MADIT-II enrolled patients with a prior MI and an ejection fraction of 30% or less in the chronic phase, without requiring invasive testing. A significant mortality benefit was associated with ICD therapy.

The Sudden Cardiac Death in Heart Failure trial enrolled a broader population consisting of patients with ischemic and nonischemic cardiomyopathy, symptomatic heart failure, and an ejection fraction of 35% or less. A survival benefit was found for patients treated with an ICD compared with conventional therapy or empirical amiodarone therapy. The degree of benefit was similar for patients with ischemic or nonischemic

cardiomyopathy, suggesting that primary prevention with ICDs for patients with prior MI or nonischemic cardiomyopathy and heart failure was appropriate.

The risk of SCD after MI is highest in the few months after the index event. However, ICDs have not been effective when implanted immediately after MI or revascularization procedures. The reason for this is unclear; it may reflect the large percentage of patients who have improved cardiac function early on, which decreases the risk of SCD and therefore the benefit of an ICD. Alternatively, the mechanism for SCD in the early period after an MI or revascularization procedure may be recurrent ischemia rather than reentrant tachycardia and therefore less amenable to ICD therapy. The Defibrillator in Acute Myocardial Infarction Trial (DINAMIT) randomized 675 patients with low ejection fractions immediately after MI to ICD or medical therapy; no difference in mortality rates was seen. The current recommendations are to avoid primary prevention with ICDs within 40 days of an MI or 3 months of revascularization.

A significant challenge in modern medicine is identifying patients who have an elevated risk of SCD to allow effective use of primary prevention interventions such as ICDs. Some known predictors of SCD after MI are shown in Table 9-7, but many are not specific or sensitive enough for practical use. Reduced ejection fraction has been the most successful noninvasive measure that can predict increased risk of SCD. An electrophysiologic study is a minimally invasive catheter procedure that with electrical stimulation can help to identify patients who are prone to VT. Electrophysiologic studies are most sensitive in patients with prior MI, but they may be less useful in other cardiac conditions. Cardiac magnetic resonance imaging (MRI), which can directly image cardiac function and cardiac scar or fibrosis, is showing great promise as a more sensitive and specific, noninvasive risk predictor of SCD.

Ventricular Tachycardia and Ventricular Fibrillation without Evident Heart Disease

Ventricular arrhythmias occurring in the absence of structural heart disease usually carry a benign prognosis but can be associated with SCD in patients with genetic arrhythmic syndromes predisposing to life-threatening polymorphic VT. Genetic screening for these syndromes is important to identify at-risk family members.

Idiopathic Ventricular Tachycardia

Idiopathic VT most commonly originates from the outflow tracts, with approximately 80% localized to the RVOT and the

remainder originating in the left ventricular outflow tract (LVOT), the aortic sinuses of Valsalva, and the region of the aortomitral continuity. Idiopathic RVOT VT manifests with the characteristic electrocardiographic findings of left bundle branch block and inferior axis VT QRS morphology. Triggered activity is the mechanism underlying outflow tract tachycardias. This calcium-dependent mechanism explains why an outflow tract VT often terminates with adenosine, β -blockers, and calcium-channel blockers.

Patients in their third or fourth decade typically have palpitations, shortness of breath, and lightheadedness at presentation. Reports of cardiac arrest are rare, and treatment is directed at controlling symptoms. β -Blockers and calcium-channel blockers are often used initially, although some patients require catheter ablation or antiarrhythmic drug therapy. A subset of asymptomatic patients may develop tachycardia-mediated cardiomyopathy due to frequent ventricular ectopy. The PVC burden posing the greatest risk for producing left ventricular dysfunction is likely more than 10,000 PVCs daily. Fortunately, PVC suppression with catheter ablation usually improves ventricular function.

Arrhythmogenic Right Ventricular Cardiomyopathy or Dysplasia

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is an inherited cardiomyopathy with typically autosomal dominant transmission. It is associated with mutations affecting desmosomes, which are molecular complexes of cell adhesion proteins that bind cardiac myocytes. Although morphologic changes in the RV free wall predominate, biventricular or primary left ventricular variants occur. Due to myocyte death, large portions of the right ventricle are replaced with adipose tissue, leading to wall motion abnormalities, cardiac dysfunction, and aneurysm formation. Structural changes spread from the epicardium to the endocardium. RV imaging classically demonstrates RV enlargement with focal wall motion abnormalities and RV hypokinesis. The RV free wall is not well imaged by routine cardiac echocardiography, and MRI has become the gold standard for the diagnosis of ARVC.

ARVC patients develop ventricular arrhythmias with associated symptoms, including palpitations, lightheadedness, syncope, and SCD. Given the typical RV origin of arrhythmias in ARVC, the ventricular arrhythmias have a left bundle branch morphology. The surface ECG during sinus rhythm may demonstrate inverted T waves in the V_1 to V_3 leads or epsilon waves, which are low-amplitude deflections at the end of the QRS complex in the right precordial leads resulting from slowed RV conduction.

Distinguishing ARVC from idiopathic RVOT VT is essential because of the different prognostic and therapeutic implications of the two diagnoses. The diagnosis of ARVC is established by the ARVC Task Force Criteria. Risk factors for SCD of ARVC patients include prior aborted episodes of SCD, syncope, young age, LV dysfunction, and markedly diminished RV function.

Patients with documented ARVC typically receive ICDs. Adjunctive therapy with antiarrhythmic drugs or ablation, particularly strategies incorporating combined epicardial and endocardial ablation, may be useful in treating symptomatic VT.

TABLE 9-7 PREDICTORS OF SUDDEN CARDIAC DEATH AFTER MYOCARDIAL INFARCTION

Decreased left ventricular ejection fraction
Residual ischemia
Delayed enhancement on cardiac MRI
Late potentials on signal-averaged electrocardiography
Decreased heart rate variability
Prolonged QT on ECG
Induction of sustained MMVT with programmed electrical stimulation
Complex ventricular ectopy (eg, NSVT) on ambulatory monitoring

ECG, Electrocardiogram; MMVT, monomorphic ventricular tachycardia; MRI, magnetic resonance imaging; NSVT, nonsustained ventricular tachycardia.

Congenital Long QT Syndrome

Congenital LQTS is a genetic disorder characterized by abnormal cardiac repolarization producing QT prolongation on the ECG (corrected QT [QTc] >440 milliseconds in men and >460 milliseconds in women). It is a leading cause of SCD in the young.

Mutations in 16 genes that participate in cardiac repolarization have been identified in patients with LQTS. Mutations of *KCNQ1* (encodes the α -subunit of the I_{Ks} potassium channel) produce LQT1; mutations of *KCNH2* (encodes the α -subunit of the I_{Kr} potassium channel) produce LQT2; and mutations of *SCN5A* (encodes the α -subunit of the cardiac sodium channel) cause LQT3. Together, they account for 75% of cases of congenital LQTS.

Decreased outward potassium currents or increased inward sodium currents prolong action potential duration, predisposing to early afterdepolarizations and TdP, a specific type of polymorphic VT. Symptoms typically begin during adolescence and include syncope, seizures, and SCD. The arrhythmia triggers in LQTS are gene specific. Patients with LQT1 are at risk during high adrenergic states, such as exercise; arrhythmias in LQT2 are triggered by sudden noises such as alarms; and LQT3 patients are more likely to experience arrhythmias during sleep. The autosomal dominant Romano-Ward variant has a prevalence of 1 case in 2000 live births.

Chronic treatment is directed at prevention of SCD. Initial therapy includes avoidance of QT-prolonging agents and initiation of β -blockers in symptomatic patients and asymptomatic patients with significant QT prolongation. ICDs are recommended after resuscitation from a cardiac arrest and for recurrent syncope despite β -blockade. The acute treatment of TdP is different from that of other forms of VT because many antiarrhythmic agents prolong the QT interval and should therefore be avoided.

Brugada Syndrome

The Brugada syndrome is a genetic disorder predisposing to polymorphic VT and SCD. The ECG characteristically displays coving ST elevation in the right precordial leads, V_1 to V_3 , and a right bundle branch block pattern. These electrocardiographic abnormalities may be dynamic, and they are characteristically exacerbated by fever and therapy that blocks sodium channels.

In most cases, the syndrome is linked to mutations in *SCN5A*, which encodes the cardiac sodium channel. Mutations result in a reduction in the sodium current. The mode of transmission is autosomal dominant. Patients typically have syncope or cardiac arrest, often occurring during sleep.

Although quinidine, by virtue of its ability to block transient outward potassium current (I_{to}), may have a therapeutic role, there are no established medical therapies to prevent VT in Brugada syndrome. Intravenous β -adrenergic stimulation with isoproterenol or a similar agent, by virtue of its ability to augment the sodium current, is potentially useful in the acute management of recurrent VT or VF in Brugada syndrome. Paradoxically, because of a protective effect of catecholamine stimulation, β -blockers are potentially harmful in patients with Brugada syndrome and should be avoided.

ICDs represent the only proven therapy for prevention of cardiac arrest. ICD therapy is recommended for secondary prevention of SCD. For high-risk patients with a spontaneous Brugada electrocardiographic pattern and syncope, primary prevention with an ICD is indicated.

Catecholaminergic Polymorphic Ventricular Tachycardia

CPVT is a genetic disorder that alters myocardial calcium handling, resulting in exercise-induced polymorphic or bidirectional VT. Exercise-triggered syncope or SCD during childhood is the common presenting symptom. About 50% to 60% of patients have an inherited or sporadic autosomal dominant mutation affecting the cardiac ryanodine receptor gene (*RYR2*), producing abnormal calcium-induced calcium release from the sarcoplasmic reticulum and intracellular calcium overload.

β -Blockers along with exercise restriction represent the primary therapy, although arrhythmia breakthrough is common. ICD therapy may be used for secondary prevention, although ICD shocks can produce catecholamine surges that may exacerbate the underlying arrhythmia. Left cardiac sympathetic denervation is useful in selected cases.

Acquired Long QT Syndrome

Environmental factors may prolong cardiac repolarization and produce QTc prolongation, leading to the development of early afterdepolarizations and TdP. Patients with acquired LQTS may have background genetics predisposing them to develop excessive QTc prolongation and polymorphic VT in response to electrolyte abnormalities (i.e., hypokalemia, hypomagnesemia, and hypocalcemia), bradycardia, and the use of QT-prolonging medications. Most QTc-prolonging drugs block the rapid component of the delayed rectifier potassium channel (I_{Kr}) encoded by the *KCNE2* gene. Drugs known to prolong the QTc interval are updated on an Internet registry. Therapy for acquired LQTS requires reversal of inciting physiologic factors and discontinuation of offending medications.

Genetic Testing for Channelopathies

Commercial laboratories offer genetic testing for congenital LQTS, Brugada syndrome, and CPVT. The yields of genetic testing vary from 25% for Brugada syndrome up to 80% for congenital LQTS. The limited sensitivity of current assays and the common finding of genetic variants of unknown significance represent ongoing challenges. Despite these considerations, cascade screening or screening of family members for a disease-causing mutation once characterized in a proband has been effectively used to identify mutation carriers.

Mutation-positive family members may benefit from prophylactic therapy. Reassurance for mutation-negative individuals is also valuable. Before ordering genetic testing, patients should be thoroughly informed of the risks, benefits, and limitations of testing. Genetic counselors ideally play an important advisory role.

 For a deeper discussion on this topic, please see Chapter 65, "Ventricular Arrhythmias," in Goldman-Cecil Medicine, 25th Edition.

SUMMARY

Cardiac arrhythmias are caused by disorders of action potential formation or propagation and are broadly categorized as abnormally slow rhythms (i.e., bradycardias) or abnormally rapid rhythms (i.e., tachycardias). The cardiac cellular action potential is composed of five phases determined by the activity of multiple ion channels, including the rapid sodium channel, several potassium channels, and a calcium current. Disruptions of these currents may lead to abnormal automaticity and triggered activity, which may mediate pathologic tachyarrhythmias. Reentry is the dominant mechanism of clinically significant tachyarrhythmias and requires a functional or fixed obstacle to propagation, an area of slowed conduction, and differential refractoriness for initiation and perpetuation of the arrhythmia.

Antiarrhythmic drugs are commonly divided into four broad groups using the Singh–Vaughn Williams classification. Despite its clinical utility, many antiarrhythmic drugs have multiple effects and do not fit neatly into this framework. Some, such as adenosine and digoxin, fall completely outside of it. Class I drugs slow membrane conduction by blockade of the sodium channel. Class II drugs, or β -blockers, function by blockade of the cardiac β -receptor. Class III drugs prolong repolarization and the QT interval. Class IV drugs block the slow calcium channel and are primarily active in slow-response myocytes such as the sinus and AV node.

All bradycardia is a consequence of impairment of sinus node function or AV conduction, or both. Sinus and AV nodal function is strongly influenced by autonomic tone. Parasympathetic tone dominates at rest, and significant bradycardia and second-degree AV block may be observed in normal patients due to increased parasympathetic tone, especially during sleep or athletic training. Clinical sinus node dysfunction manifests as one of several syndromes, including sinus bradycardia, chronotropic incompetence, exit block, and bradycardia-tachycardia syndrome due to sinus pauses and bradycardia when concomitant atrial arrhythmias terminate to sinus rhythm.

AV conduction disturbances may occur at the AV nodal level or infranodal level. A block at the level of the AV node tends to be indolent, characterized by gradual progression and competent subsidiary escapes that usually protect the patient from catastrophic bradycardia. This permits asymptomatic patients to be followed clinically for the development of symptoms before intervention. In contrast, second- or third-degree infranodal block at the His bundle, or more commonly at the level of the bundle branches, is potentially malignant and is often not accompanied by stable escape mechanisms. If not managed appropriately, it can cause sudden death. Clues to an infranodal level of block are Mobitz II periodicity, associated bundle branch block, worsening heart block with tachycardia or exercise, and a wide QRS escape rhythm different from the conducted QRS in the setting of a high-degree or third-degree AV block.

Tachycardias are broadly categorized as SVTs, which depend on the atrium and AV conduction system, and ventricular arrhythmias, which depend on the ventricular myocardium. Supraventricular arrhythmias are further categorized as PSVTs, which depend on AV nodal conduction, and intra-atrial arrhythmias, which depend only on atrial tissue and not on AV

conduction. The PSVTs include AVNRT and AV reciprocating tachycardia related to WPW syndrome. Intra-atrial arrhythmias include organized atrial arrhythmias, such as focal atrial tachycardia, atrial flutter, macro-reentrant atrial tachycardia, and AF, a common disorganized atrial arrhythmia. Recurrent atrial flutter and AF carry a risk of thromboembolism and, based on risk stratification, should be treated with antithrombotic therapy when appropriate. Catheter ablation has an important role in the management of all supraventricular arrhythmias but remains a second-line strategy for AF, for which success rates are lower and complication rates are higher than for other supraventricular arrhythmias.

Ventricular arrhythmias include isolated ventricular premature beats; short, nonsustained runs of tachycardia; and sustained ventricular arrhythmias. Sustained VT lasts more than 30 seconds or requires intervention before then. It is classified as monomorphic if beats all share a single electrocardiographic morphology, polymorphic if the electrocardiographic morphology is variable, TdP when the morphology is variable and the arrhythmia is associated with pathologic QT prolongation, and VF when the surface ECG continuously varies without distinct QRS complexes. VT is poorly tolerated and is the major cause of cardiac arrest. Although commonly seen in the setting of ischemic heart disease, idiopathic VT may be seen in the absence of structural heart disease.

Antiarrhythmic drugs have not been effective in reducing the risk of SCD after MI. In contrast, ICDs have been shown to improve mortality rates for patients with impaired LV function after an MI and patients with heart failure and impaired LV function with or without coronary disease.

In addition to advanced structural heart disease as a cause for VT, several syndromes may result in VT in the absence of evident structural heart disease. They include the syndrome of idiopathic VT, ARVC, arrhythmogenic RV dysplasia, congenital LQTS, Brugada syndrome, and CPVT. Several of these conditions are familial, and genetic testing and family screening have important roles in their management.

Pericardial and Myocardial Disease

Jennifer L. Strande, Panayotis Fasseas, and Ivor J. Benjamin

PERICARDIAL DISEASE

The pericardium is a thin, fibrous sac that envelops the heart and consists of two layers: visceral and parietal. The space between these two layers contains a small amount of fluid (15 to 50 mL), which is a plasma ultrafiltrate. The pericardium has mechanical, immunologic, and anatomic barrier functions.

Due to a paucity of randomized trial data and absence of practice guideline statements, the recommendations for assessment and treatment of pericardial disorders in this chapter are largely based on expert opinion and professional consensus.

Acute Pericarditis

Definition and Epidemiology

Acute pericarditis is an inflammatory disorder of the pericardium that has several causes. It is difficult to determine the exact incidence of acute pericarditis because a subclinical course is common.

Pathology

About 85% of cases are idiopathic or viral. Less common causes include infection (other than viral), uremia, trauma, metabolic disorders, autoimmune disorders, and neoplastic involvement. Causes of acute pericarditis are listed in [Table 10-1](#).

Clinical Presentation

Patients may have symptoms of low-grade fever, malaise, dyspnea, and less frequently, hiccups (i.e., phrenic nerve irritation). The classic manifestation of acute pericarditis is chest pain, which is often severe, sharp, and positional. It is aggravated by a supine position, inspiration, and cough, and it is relieved by sitting up and leaning forward. The pain is usually substernal and left precordial, and it may radiate to the neck, shoulder, and scapular ridge, mimicking that of myocardial ischemia. Chest discomfort may be mild or absent in patients with connective tissue disorders, uremia, or neoplastic involvement.

In the absence of significant pericardial effusion, results of the inspection and palpation of the precordium are normal. A high-pitched, rasping pericardial friction rub is heard on cardiac auscultation in most patients with acute pericarditis. It may have three components corresponding to atrial contraction, ventricular systole, and early diastole, and it is best appreciated at end expiration with the patient leaning forward. It can be intermittent, and serial auscultation is recommended.

Diagnosis

The electrocardiographic (ECG) changes of acute pericarditis typically evolve over days to weeks. In the early stages, there is diffuse ST segment elevation (i.e., concave upward) with upright T waves and PR depression, which occasionally precedes the ST segment elevation. Resolution of the ST elevations is followed by diffuse T wave inversion. These ECG changes are not always seen, and serial tracings should be obtained.

The laboratory findings of acute idiopathic pericarditis are not specific and consist of mild elevation of the white blood cell count, sedimentation rate, and C-reactive protein level. If indicated, specific testing for tuberculosis, human immunodeficiency virus (HIV), thyroid disease, or autoimmune disorders is recommended. However, routine performance of viral serologic testing has limited utility. Elevation of serum cardiac biomarkers (e.g., creatine kinase, troponin) reflects involvement of the adjacent

myocardium. In uncomplicated acute pericarditis, the chest radiograph and echocardiographic findings are normal. Although not essential for the diagnosis of pericarditis, echocardiography is the diagnostic imaging modality of choice for the detection and determination of the hemodynamic significance of a pericardial effusion.

Treatment

Patients with uncomplicated idiopathic or viral pericarditis can be managed as outpatients. For patients with fever, large pericardial effusions, or elevated levels of cardiac biomarkers and for those with possible secondary causes or immunocompromised status, hospitalization for further investigation and treatment should be considered. Treatment consisting of high-dose nonsteroidal anti-inflammatory drugs (NSAIDs) is usually effective. Colchicine with NSAIDs or as monotherapy provides prompt resolution of symptoms and decreases the recurrence rate. The use of glucocorticoids results in rapid symptomatic improvement. However, it is associated with higher rates of symptomatic recurrence.

Prognosis

Most patients with idiopathic or viral pericarditis have an uneventful clinical course with complete recovery. Possible complications include recurrent pericarditis, cardiac tamponade, and constrictive pericarditis.

Pericardial Effusion and Cardiac Tamponade

Definition and Epidemiology

Pericardial effusion, an abnormal collection of fluid in the pericardial space, is a relatively common and incidental echocardiographic finding that is encountered in approximately 10% of studies. Cardiac tamponade occurs when fluid accumulation results in increased intrapericardial pressure, leading to cardiac compression, impaired ventricular filling, and reduced cardiac output. Accumulation of pericardial fluid can be caused by virtually any type of acute pericarditis. Pericardial effusions due to bacterial pericarditis (including tuberculosis), neoplastic involvement, uremic pericarditis, and trauma have a high incidence of progression to tamponade.

Pathology

The hemodynamic consequences of a pericardial effusion depend on the rate of accumulation. The normal pericardium has relatively limited reserve volume. The mechanical properties of the parietal pericardium are such that when stretched, it becomes rapidly inelastic and resistant to further expansion. As a result of these physical characteristics, rapidly accumulating effusions may result in significant hemodynamic compromise with only 100 to 200 mL of fluid. Conversely, when the accumulation of fluid is slow, the pericardium undergoes adaptive changes and can accommodate large (>1500 mL) effusions without the development of tamponade.

Clinical Presentation

The clinical manifestations of a pericardial effusion depend on the size and rate of fluid accumulation and may range from

dyspnea, chest discomfort, and orthopnea to circulatory collapse, pulseless electrical activity, and death. Compression of adjacent structures such as the phrenic nerve and the recurrent laryngeal nerve can result in cough or hiccups and hoarseness, respectively. A complaint of dysphasia may indicate compression of the esophagus.

A normal cardiac examination is not uncommon in patients with small effusions. With larger effusions, the apical impulse can be decreased or absent, and the cardiac sound may be muffled. In patients with acute pericarditis, disappearance of the pericardial friction rub may indicate development of an effusion. Compression of the base of the left lung can result in dullness to percussion, egophony, and bronchial breath sounds under the left scapula (i.e., Ewart's sign).

Patients with tamponade usually appear to be in distress with tachypnea and tachycardia. The classic physical findings are hypotension, jugular venous distention with absent *y* descent, and muffled or absent heart sounds. Pulsus paradoxus, defined as a greater than 10 mm Hg of inspiratory decline of the systolic blood pressure, is a characteristic physical finding. It is the result of the inspiratory decrease of the left ventricular stroke volume and systemic blood pressure. Under normal conditions, the intrathoracic pressure decreases during inspiration, resulting in enhanced right ventricular filling and enlargement. In cases of cardiac tamponade, the total heart volume is fixed, and the right ventricular expansion displaces the interventricular septum toward the left ventricle, with consequent reduction of the left ventricular stroke volume and systemic hypotension. Pulsus paradoxus is not pathognomonic of cardiac tamponade and can be detected in severe chronic obstructive airway disease, pulmonary embolism, bronchial asthma, constrictive pericarditis, and hypovolemic shock.

Diagnosis

The ECG findings of moderate to large pericardial effusions include low-voltage QRS complexes and occasionally include electrical (QRS) alternans caused by the heart's swinging motion within the fluid-filled pericardium. The chest radiograph demonstrates an enlarged cardiac silhouette. Transthoracic echocardiography, the imaging modality of choice, provides information regarding the size, location (circumferential vs. loculated), and most importantly, the hemodynamic consequences of the pericardial effusion suggesting tamponade.

The two-dimensional findings of tamponade include right atrial and right ventricular collapse, distention of the inferior vena cava, and evidence of increased ventricular interdependence (Fig. 10-1). Doppler quantification of the mitral and tricuspid inflow velocity respiratory variation is more sensitive than two-dimensional echocardiography for determining the hemodynamic significance of pericardial effusions. Right heart catheterization demonstrates decreased cardiac output, elevated right atrial pressure with diminished or absent *y* descent, and equalization of the cardiac filling pressures (i.e., right atrial, pulmonary wedge, and diastolic pulmonary artery pressures).

Computed tomography (CT) and magnetic resonance imaging (MRI) can accurately identify pericardial effusions and may be used with echocardiography in the assessment of loculated effusions, pericardial thickening, and extracardiac

FIGURE 10-1 Parasternal long axis echocardiographic views of the right ventricle in systole and diastole show right ventricular diastolic collapse (arrow) in a patient with a large, circumferential pericardial effusion. LV, Left ventricle; PE, pericardial effusion; RV, right ventricle.

surrounding structures. A diagnostic pericardiocentesis is the procedure of choice for evaluating for bacterial, tuberculous, or malignant causes.

Treatment

Routine drainage of pericardial effusions is unnecessary in the absence of hemodynamic compromise. Cardiac tamponade is a life-threatening emergency requiring urgent drainage of the pericardial effusion. Fluid resuscitation should be initiated to increase preload and filling of the cardiac chambers. Inotropic and vasopressor support has limited utility. Surgical drainage is appropriate and therapeutic for loculated, purulent, and tuberculous effusions and for tissue biopsy.

Fluid should be analyzed for pH, cell count, glucose, protein, cholesterol, triglycerides, and acid-fast bacilli by Gram stain, culture, cytology, and laboratory tests. For patients with chronic, recurring effusions, the surgical creation of a pleuropericardial window provides a long-term solution.

Prognosis

The underlying cause of the pericardial effusion and the availability of effective treatment determine the prognosis.

Constrictive Pericarditis

Definition and Epidemiology

Pericardial constriction is a condition characterized by a rigid, scarred pericardium that limits diastolic filling of the ventricles, resulting in increased intracardiac pressures. It can be caused by any type of pericardial inflammation. The most common causes are infection, prior cardiac surgery, trauma, and irradiation. Less common causes include connective tissue disorders, uremia, and neoplastic involvement of the pericardium. In developing countries, tuberculous pericarditis is a common cause of pericardial constriction. Often a specific cause cannot be determined.

Pathology

Constriction is the end result of pericardial inflammation with scarring, fibrosis, calcification, and adhesion of the parietal and visceral layers of the pericardium. Although pericardial thickening is a usual pathologic finding, its absence does not exclude constriction.

Clinical Presentation

In the early stages, symptoms consist of dyspnea, fatigue, decreased exercise tolerance, and lower extremity edema. As the disease progresses, early signs and symptoms may be accompanied by ascites, anasarca, cachexia, and muscle wasting.

Physical examination reveals jugular venous distention with prominent *x* and *y* descents and an increase (or failure to decrease) of central venous pressure with inspiration (i.e., Kussmaul sign). The arterial blood pressure is usually normal, and pulsus paradoxus is absent in most patients. Ascites and hepatomegaly can be prominent with advanced disease. On cardiovascular examination, the apical impulse may be decreased and the cardiac sounds muffled. An early diastolic sound (i.e., pericardial knock) corresponding to the abrupt cessation of early ventricular diastolic filling is pathognomonic of pericardial constriction, but it is not always detected.

Diagnosis

The diagnosis of pericardial constriction may be challenging and frequently requires the use of multiple imaging modalities. The electrocardiogram may display low QRS voltage, left atrial enlargement, and nonspecific T-wave changes. Atrial fibrillation occurs in one third of cases. The chest radiograph may reveal pleural effusions and pericardial calcification, which are best appreciated in the lateral projection.

Transthoracic echocardiography shows dilation of the inferior vena cava, abnormal interventricular septal motion, and pericardial thickening. Doppler echocardiography demonstrates abnormal respirophasic variations of the pulmonary and hepatic venous flow and mitral valve inflow. CT and MRI can accurately measure pericardial thickness.

Cardiac catheterization is essential in the diagnosis of pericardial constriction and differentiation from restrictive cardiomyopathy (RCM). The right atrial pressure tracing shows prominent *x* and *y* descents with equalization of the end-diastolic atrial and ventricular pressures. The ventricular pressure tracings show a rapid early diastolic filling of the ventricles, with abrupt cessation in middle and end diastole due to the finite volume of the rigid pericardium (i.e., dip-and-plateau morphology or the square root sign) (Fig. 10-2). Enhanced ventricular interdependence demonstrated by simultaneous measurement of right and left ventricular pressures during respiration is a more specific finding of pericardial constriction.

FIGURE 10-2 Pressure recordings from a patient with constrictive pericarditis. Simultaneous right ventricular and left ventricular pressure tracings show equalization of diastolic pressure and dip-and-plateau morphology. LV, Left ventricle; RV, right ventricle.

Treatment

Medical therapy with sodium restriction and diuretics is of limited efficacy and is only appropriate in patients who are not surgical candidates in view of comorbidities. Pericardiectomy is the only definitive treatment for constrictive pericarditis.

Prognosis

Pericardiectomy is associated with substantial operative risk that depends on the extent of cardiac involvement and existence of comorbid conditions. Successful pericardial resection leads to resolution of the symptoms of constriction over a period of weeks to months. For patients who are not surgical candidates, the prognosis is poor.

Effusive Constrictive Pericarditis

Effusive constrictive pericarditis is characterized by a pericardial effusion and a noncompliant or fibrotic parietal and visceral pericardium. Although it may result from any type of pericardial inflammation, it is usually seen after cardiac surgery or radiation injury. It likely represents a transition stage between acute pericarditis with effusion and pericardial constriction. It shares the clinical and hemodynamic features of both conditions.

Typically, drainage of the effusion does not result in resolution of symptoms, and the central venous and right atrial pressures remain elevated. In the early stage of the disease, patients may respond to prolonged treatment with NSAIDs. However, visceral and parietal pericardiectomy is often required. For a deeper discussion of this topic, please see Chapter 77, “Pericardial Diseases,” in *Goldman-Cecil Medicine*, 25th Edition.

DISEASES OF THE MYOCARDIUM

Myocarditis

Definition and Epidemiology

Myocarditis is an inflammation of the myocardium caused by a variety of toxins, medications, and viruses. Viral myocarditis, which accounts for about 20% of cases of dilated cardiomyopathy

(DCM), is commonly caused by the enteroviruses, specifically Coxsackie group B serotypes and, less commonly, adenoviruses, parvovirus B19, hepatitis C virus, cytomegalovirus, and HIV.

Other causes include bacterial infections such as diphtheria, brucellosis, clostridial infections, legionnaires disease, and meningococcal, streptococcal, and *Mycoplasma pneumoniae* infections. Rickettsial infections (e.g., Q fever, Rocky Mountain spotted fever), spirochetal infections (e.g., leptospirosis, Lyme disease), fungal infections, and parasitic infections (e.g., *Trypanosoma cruzi* [Chagas’ disease]) are also known causes of myocarditis.

Pathology

The pathogenesis of viral myocarditis is thought to begin with direct viral invasion of the myocardium and subsequent immunologic activation. Normal cellular and antibody-mediated immune responses lead to viral clearing and myocardial healing. However, a few patients go on to develop DCM and heart failure due to an abnormal immune response, furthering myocardial damage. The exact mechanisms are unknown, but they involve cytokines, autoantibodies, and possibly other processes associated with persistent, low-level viral replication in myocytes, leading to myocyte atrophy, myocyte apoptosis, and adverse remodeling of the ventricles. In nonviral infections, the damage is attributed to the bacterial toxins or abnormal immune responses, and in parasitic infections, it is largely immune mediated.

Multiple chemicals and drugs can lead to myocardial inflammation by direct effect or as part of a hypersensitivity reaction. Some of the common causes include cocaine, chemotherapeutics (e.g., daunorubicin, doxorubicin), and antibiotics.

Giant cell myocarditis is a rare disorder of uncertain origin, but it can be rapidly fatal. It is usually associated with ventricular arrhythmias and progressive, severe heart failure. Multinucleated giant cells seen on myocardial biopsy are pathognomonic.

Clinical Presentation

The clinical manifestations range from asymptomatic ECG abnormalities to cardiogenic shock. Patients report heart failure symptoms, including exercise intolerance, shortness of breath, fluid retention, and persistent fatigue, and in the case of viral myocarditis, they often report a viral prodrome, including fever, myalgia, fatigue, respiratory symptoms, and gastroenteritis that precedes the heart failure symptoms. Patients are often tachycardic and hypotensive, and they may have an elevated jugular venous pressure, S_3 gallop, crackles, and peripheral edema. Myocarditis can masquerade as an acute coronary syndrome.

Diagnosis

Testing is performed to determine a possible infectious cause. Rising viral titers are often seen in cases of viral myocarditis. Serum cardiac enzymes (e.g., troponin, creatine kinase) are measured when myocarditis is suspected. Sinus tachycardia and non-specific ST- and T-wave abnormalities are common ECG findings. When pericardium is also involved by the inflammatory process, diffuse ST-segment elevations typical for acute pericarditis are also seen. Ventricular ectopy is common, and atrioventricular

conduction defects are seen in myocarditis associated with Lyme disease.

Echocardiography is recommended in the initial diagnostic evaluation to identify ventricular remodeling, including increasing chamber size and ventricular systolic dysfunction. Cardiac MRI is a promising technique to detect myocardial inflammation and injury based on small, observational clinical studies.

Transvenous endomyocardial biopsy should be performed only when there is rapid deterioration of the clinical condition (level of evidence B). Histopathologic abnormalities such as infiltrating white cells (i.e., macrophages, lymphocytes, and eosinophils), evidence of myocardial damage, and a finding of interstitial fibrosis are used to establish acute myocarditis, but the determination is subject to significant intraobserver and interobserver variability, and the biopsy often does not provide a conclusive diagnosis. The endomyocardial biopsy is helpful in diagnosing giant cell myocarditis (i.e., multinucleated giant cells are seen) or hypersensitivity myocarditis (i.e., eosinophilic infiltrate is seen). The polymerase chain reaction can detect specific viral genomes in the myocardium.

Treatment

Supportive care is the mainstay of treatment. A few patients with fulminant or acute myocarditis require an intensive level of hemodynamic support and aggressive pharmacologic intervention similar to that for patients with advanced heart failure.

After initial hemodynamic stabilization, treatment should follow current American College of Cardiology and American Heart Association (ACC/AHA) recommendations for the management of left ventricular systolic dysfunction. Treatment includes β -adrenergic blockers, angiotensin-converting enzyme inhibitors, aldosterone receptor blockers, and diuretics.

No evidence-based guided therapy for viral myocarditis has been established. Clinical trials of various forms of antiviral or immunosuppressive therapy (e.g., prednisone, cyclosporine, azathioprine, intravenous immunoglobulin, interferon immunoadsorption) have not resulted in conclusive evidence of benefit. Treatment of nonviral myocarditis is aimed at eradication of the specific infectious agent. For Chagas disease, treatment with anti-protozoal therapy, if initiated early in the course of infection, may be beneficial.

Hypersensitivity myocarditis and myocarditis associated with toxins respond to withdrawal of the offending agent. Immunosuppressive therapy has been effective in giant cell myocarditis.

Prognosis

Understanding the natural history of myocarditis has been limited by its diverse clinical presentations and causes. It is thought that one third of the patients fully recover, one third of the patients have some sequelae in the form of left ventricular systolic dysfunction but are stable on medical therapy, and one third of patients progress to advanced heart failure. Patients who progress to chronic DCM have 5-year survival rates of less than 50%.

Cardiomyopathies

Cardiomyopathies are a heterogeneous group of diseases in which the major structural abnormality is limited to the

myocardium. The four main cardiomyopathic groups are dilated, hypertrophic, restrictive, and arrhythmogenic right ventricular cardiomyopathy. Familial (genetic) and nonfamilial (acquired) forms of the diseases have been described.

Dilated Cardiomyopathy

Definition and Epidemiology

Cardiac enlargement and systolic dysfunction in DCM result from a wide spectrum of genetic, inflammatory, toxic, and metabolic causes (Table 10-2), although most cases are idiopathic. Abnormal loading conditions such as hypertension, valvular disease, or coronary artery disease can lead to similar structural and functional changes; these conditions are not considered to be part of the DCM group and are discussed elsewhere.

Most cases are thought to result from acute viral myocarditis, a process described earlier. Exposures to cardiac toxins such as chemotherapeutic agents, alcohol, cocaine, and radiation, along with deficiency of nutrients such as thiamine (causes beriberi), vitamin C (causes scurvy), carnitine, selenium, phosphate, and calcium, can cause DCM. Peripartum cardiomyopathy is a rare cause of DCM that can develop during the last month of pregnancy and up to 6 months after delivery.

The pathogenesis of this often life-threatening disease is not completely understood, and it is a diagnosis of exclusion. Risk factors include older maternal age, being African American, and having multiple pregnancies. Prolonged periods of supraventricular or ventricular tachycardia can lead to idiopathic DCM (i.e., tachycardia-induced cardiomyopathy). The structural and functional changes usually reverse after the rapid heart rhythm is controlled.

Familial forms of DCM may be responsible for 20% to 30% of cases. Specific mutations described involve genes that encode proteins of the sarcomere, cytoskeleton, nuclear membrane, and mitochondria; many mutations remain unknown. The mode of inheritance is typically autosomal dominant, but it can be an X-linked or mitochondrial pattern.

Pathology

Marked enlargement of all four cardiac chambers is typical of DCM, although the disease sometimes is limited to the left or right chambers. The dilation is out of proportion to the ventricular thickness. Histology reveals evidence of myocyte degeneration with irregular hypertrophy and atrophy of myofibers with often extensive interstitial and perivascular fibrosis.

Clinical Presentation

DCM usually manifests with symptoms of heart failure, including fatigue, weakness, dyspnea, and edema. In some patients, the presenting episode is related to arrhythmia or an embolic event. On physical examination, signs of decreased cardiac output are often found, including cool extremities, narrow pulse pressure, and tachycardia. The cardiac examination reveals a laterally displaced apex. An S_3 gallop is common, along with murmurs of mitral and tricuspid regurgitation. Pulmonary edema manifests as auscultatory crackles over the lung fields, and breath sounds may be diminished if there are pleural effusions. In some patients, the clinical features of right ventricular heart failure may

TABLE 10-2 CARDIOMYOPATHIES

DISORDER	DESCRIPTION AND CAUSE
Dilated cardiomyopathy Familial (genetic) Nonfamilial	Dilation and impaired systolic function of the left or both ventricles Known or unknown genetic mutations Viral myocarditis, nonviral infective myocarditis, idiopathic (immune) myocarditis Toxins (drugs, alcohol) Pregnancy (peripartum cardiomyopathy) Nutritional (thiamine deficiency [beriberi], vitamin C deficiency [scurvy], selenium deficiency) Endocrine (diabetes mellitus, hyperthyroidism, hypothyroidism, hyperparathyroidism, pheochromocytoma, acromegaly) Autoimmune (rheumatoid arthritis, systemic lupus erythematosus, dermatomyositis) Tachycardia induced
Hypertrophic cardiomyopathy Familial (genetic)	Left and/or right ventricular hypertrophy, often asymmetrical (usually more prominent hypertrophy of the interventricular septum) Mutations of sarcomeric proteins (several hundred described) Metabolic storage diseases of the myocyte
Restrictive cardiomyopathy Familial (genetic)	Restrictive filling of the ventricles; ventricles are usually small, atria are markedly enlarged Mutations of sarcomeric proteins Familial amyloidosis (transthyretin, apolipoprotein) Hemochromatosis Desminopathy, pseudoxanthoma elasticum, glycogen storage diseases Unknown genetic mutations
Nonfamilial	Amyloidosis, sarcoidosis, carcinoid, scleroderma Endomyocardial fibrosis (hypereosinophilic syndrome, idiopathic, chromosomal defect, drugs) Radiation, metastatic cancer, anthracycline toxicity
Arrhythmogenic right ventricular Familial	Progressive fibrofatty replacement of the right and, to a lesser degree, left ventricular cardiomyopathy Unknown gene mutation Mutations of intercalated disk protein, cardiac ryanodine receptor, transforming growth factor- β 3
UNCLASSIFIED CARDIOMYOPATHIES	
Takotsubo (stress-induced) cardiomyopathy	Transient dilation and dysfunction of the distal parts of the left ventricle (apical ballooning) in the setting of a stressful situation; usually resolves within weeks
Left ventricular noncompaction	Characterized by prominent left ventricular trabeculae and deep intertrabecular recesses; familial in most cases, caused by arrest in the normal embryogenesis of the heart; apex and periapical regions of the left ventricle most affected; some patients remain asymptomatic, but others develop left ventricular dilation and systolic dysfunction
Cardiomyopathies associated with muscular dystrophies and neuromuscular disorders	Duchenne-Becker muscular dystrophy, Emery-Dreifuss muscular dystrophy, myotonic dystrophy, Friedreich's ataxia, neurofibromatosis, tuberous sclerosis
Ion channelopathies	Disorders caused by mutations in genes encoding ionic channel proteins; not considered cardiomyopathies because they are not associated with typical structural changes of the heart but rather manifest with electrical dysfunction; some classifications include these disorders as cardiomyopathies: long QT syndrome, short QT syndrome, Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia

predominate, with jugular venous distention, hepatomegaly, ascites, and peripheral edema.

Diagnosis

Standard diagnostic procedures include a chest radiograph, an electrocardiogram, serum markers, and echocardiography. The radiograph shows cardiomegaly, pulmonary venous congestion, and pleural effusions. The electrocardiogram may reveal enlargement of the heart chambers along with other nonspecific ST- and T-wave abnormalities. Serum B-type natriuretic peptide (BNP) levels are elevated.

Echocardiography provides a comprehensive evaluation of ventricular size and function and valvular function, and it can show a ventricular thrombus. Similar information can be obtained with MRI.

A complete work-up should rule out ischemic, valvular, and hypertensive heart disease as the cause of myocardial dysfunction, and it should include evaluation for potentially reversible causes of DCM (e.g., alcohol, nutritional deficiencies). Myocardial biopsy may be considered if the cause of DCM is in question. In patients with a strong family history, a referral for genetic testing should be considered.

Treatment

Potential reversible causes of DCM should be addressed (e.g., alcohol cessation, correction of nutritional deficiencies, removal of cardiotoxic agents). Treatment should follow current ACC/AHA recommendations for the management of left ventricular systolic dysfunction and include β -adrenergic blockers, angiotensin-converting enzyme inhibitors, aldosterone receptor blockers, and diuretics.

Patients with idiopathic DCM who have persistent, moderate to severe symptoms of heart failure and a QRS duration longer than 120 milliseconds may benefit from cardiac resynchronization therapy with a biventricular pacemaker. Survival of patients with a left ventricular ejection fraction less than 35% despite maximal medical management is improved with the use of implantable cardioverter-defibrillators (ICDs). Patients with limiting heart failure symptoms despite use of the previously described therapies may be considered for heart transplantation or support with a left ventricular assist device.

Prognosis

The prognosis of patients with DCM depends on the response to medical therapy. Some patients have a significant improvement

in symptoms and cardiac function, but in others, the disease is progressive and associated with a high mortality rate.

Hypertrophic Cardiomyopathy

Definition and Epidemiology

Hypertrophic cardiomyopathy (HCM) is a disease state characterized by unexplained left ventricular hypertrophy with nondilated ventricular chambers in the absence of an apparent cause for hypertrophy (e.g., hypertensive disease, aortic stenosis). This is a relatively common genetic disease (1 case in 500 people in the general population) with autosomal dominant inheritance, although spontaneous mutations have been described. More than 1400 mutations identified among at least eight genes encoding proteins of the cardiac sarcomere have been described, with mutations of the β -myosin heavy chain being the most common.

Pathology

The main pathophysiologic abnormalities seen in HCM are left ventricular outflow obstruction, diastolic dysfunction, mitral regurgitation, and arrhythmias. Obstruction of left ventricular outflow occurs in roughly one half of the patients. During systole, the hypertrophied septum bulges into the left ventricular outflow tract, creating a gradient between the lower part of the left ventricular cavity and the left ventricular outflow. This causes high-velocity turbulent flow through the narrowed path, which results in a suction force (i.e., Venturi effect) that pulls the anterior leaflet of the mitral valve into the outflow tract. This worsens the obstruction and causes mitral regurgitation. Diastolic dysfunction from impaired relaxation properties of the abnormal myocardium causes marked elevation of left ventricular filling and pulmonary venous pressures, pulmonary congestion, and limitation in cardiac output. Patients with HCM are also predisposed to supraventricular and ventricular arrhythmias.

Clinical Presentation

HCM is a heterogeneous cardiac disease with a diverse course and clinical manifestations. Most patients probably do not suffer sequelae from this disease during their lifetimes. When the disease does result in complications, there are three relatively discrete but not mutually exclusive clinical manifestations: sudden cardiac death due to unpredictable ventricular tachyarrhythmia, most commonly in young asymptomatic patients (<35 years of age); heart failure characterized by exertional dyspnea (with or without chest pain) that may progress despite preserved systolic function and sinus rhythm; and atrial fibrillation that associates with various degrees of heart failure.

Heart failure symptoms result from the dynamic obstruction to left ventricular outflow and diastolic dysfunction. The most frequent symptom is dyspnea on exertion, followed by ischemic chest pain due to the increased oxygen demand by the hypertrophied ventricle and elevated wall tension that reduces blood flow to the subendocardium. Abnormalities of the structure of small myocardial arteries in HCM can contribute to myocardial ischemia. Presyncope or syncope can result from outflow tract obstruction and an inability to increase cardiac output during exertion or from arrhythmias that can be triggered by exertion. In some, sudden death caused by ventricular arrhythmia is the initial manifestation of the disease.

Physical examination findings include pulsus bisferiens, a brisk initial upstroke in pulse followed by a mid-systolic dip corresponding to the development of left ventricular outflow tract obstruction, followed by another rise in late systole. Cardiac examination may show a forceful and sustained apical impulse, an audible S_4 gallop, and a harsh crescendo-decrescendo systolic murmur best heard along the left sternal border with radiation to the base of the heart.

Patients may also have an apical holosystolic murmur of mitral regurgitation. The intensity of the murmur of HCM varies with changing degrees of obstruction. This can be observed with physiologic or pharmacologic maneuvers that change preload (i.e., left ventricular filling) or contractility. The intensity of the murmur increases with a Valsalva maneuver, with assuming a standing position, and after administration of nitroglycerin or inotropic drugs. The intensity of the murmur decreases with squatting, volume loading, and administration of β -blockers.

Diagnosis

Clinical diagnosis is made most commonly with echocardiography and increasingly with cardiac MRI. The diagnosis is based on a maximal left ventricular wall thickness of 15 mm or more; a wall thickness of 13 to 14 mm is considered borderline. The diagnosis can be made in the setting of other compelling information (e.g., family history of HCM). Genetic testing is available to confirm the diagnosis and to screen family members.

Treatment

The ACC/AHA hypertrophic cardiomyopathy guideline recommends tailored therapy based on the individual patient. For asymptomatic patients, the usefulness of β -blockade and verapamil is a class IIb recommendation. For patients symptomatic with dyspnea or angina, β -blockers and verapamil are recommended (level of evidence B). If patients remain symptomatic, it is reasonable to add disopyramide to a β -blocker or verapamil (level of evidence B).

Nonpharmacologic therapies should be considered in patients with considerable symptoms despite medical management. Septal reduction therapy is recommended only for patients with severe drug-refractory symptoms and left ventricular outflow tract obstruction (level of evidence C) (Fig. 10-3). Use of ICD therapy is guided by the perceived risk for ventricular arrhythmias in individual patients; it can prevent sudden death in these patients (level of evidence C). Some of the characteristics that have been associated with this risk are prior cardiac arrest or sustained ventricular tachycardia; great (>30 mm) ventricular wall thickness; syncope, especially if exertional or recurrent; and a first-degree relative with sudden cardiac death. Certain genotypes appear to convey an increased risk of sudden cardiac death. Patients with HCM should be excluded from most competitive sports and should avoid strenuous exercise.

Prognosis

The clinical course of HCM varies. Sudden cardiac death is the leading cause of mortality. Heart failure symptoms may gradually progress, and some patients who are unresponsive to conventional therapy may require heart transplantation.

Restrictive Cardiomyopathies

Definition and Epidemiology

RCM is an uncommon form of cardiomyopathy characterized by impaired ventricular filling of nondilated ventricles. RCM can be genetic or acquired. Causes include infiltrative disorders (e.g., amyloidosis, sarcoidosis, Gaucher's disease, Hurler's syndrome,

fatty infiltration), storage diseases (e.g., hemochromatosis, Fabry's disease, glycogen storage disease), other disorders (e.g., hypereosinophilic syndrome, carcinoid heart disease), drugs (e.g., serotonin, methysergide, ergotamine), and cancer treatment (e.g., irradiation, chemotherapy).

Pathology

In the purest form of the disease, the atria are disproportionately dilated compared with the normal ventricular size, and the left ventricle has normal or near-normal systolic function in the absence of hypertrophy. Histology is normally nondistinctive and can reveal normal findings or nonspecific degenerative changes, including myocyte hypertrophy, disarray, and degrees of interstitial fibrosis.

Clinical Presentation

Patients often have symptoms and signs of pulmonary and systemic congestion. The most common symptoms include dyspnea, palpitations, fatigue, weakness, and exercise intolerance due to poor cardiac output. As central venous pressure continues to increase in advanced cases, there may be hepatosplenomegaly, ascites, and anasarca. The chest radiograph shows atrial enlargement, pulmonary venous congestion, and pleural effusions.

Diagnosis

The diagnosis of RCM should be considered for patients with predominantly right ventricular heart failure without evidence of cardiomegaly or systolic dysfunction. The correct diagnosis often is not made until months or years after symptom onset. Constrictive pericarditis can mimic RCM, and establishing the correct diagnosis can be challenging. Distinctive features of the two disorders are described in [Table 10-3](#).

FIGURE 10-3 A to C, Schematic diagrams of a septal myectomy. (From Nishimura RA, Holmes DR Jr: Clinical practice: hypertrophic obstructive cardiomyopathy, *N Engl J Med* 350:1320–1327, 2004.)

TABLE 10-3 DIFFERENTIATION OF RESTRICTIVE CARDIOMYOPATHY FROM CONSTRICTIVE PERICARDITIS

TYPE OF EVALUATION	RESTRICTIVE CARDIOMYOPATHY	CONSTRICTIVE PERICARDITIS
Physical examination	Kussmaul sign present Apical impulse may be prominent Regurgitant murmurs are common	Kussmaul sign may be present Apical impulse usually not palpable Pericardial knock may be present
Electrocardiography	Low QRS voltage (especially in amyloidosis) Pseudoinfarction pattern Bundle branch blocks AV conduction disturbances Atrial fibrillation	Low QRS voltage Repolarization abnormalities
Chest radiography		Calcification of the pericardium may be present
Echocardiography	Marked enlargement of the atria Increased wall thickness (especially in amyloidosis)	Atria usually of normal size Normal wall thickness Pericardial thickening may be seen
Doppler echocardiography	Restrictive mitral inflow (dominant E wave with short deceleration time) No significant variation (<10%) of transvalvular velocities with respiration Reversal of forward flow in hepatic veins during inspiration	Restrictive mitral inflow (dominant E wave with short deceleration time) Increased velocity of RV filling and decreased velocity of LV filling with inspiration; opposite with expiration; variation in velocity exceeds 15% Reversal of forward flow in hepatic veins during expiration
Cardiac catheterization	Prominent atrial x and y descents (w sign) Dip-and-plateau appearance of ventricular diastolic pressure Diastolic pressures increased but not equalized; LV diastolic pressure higher than RV diastolic pressure	Prominent atrial x and y descents (w sign) Dip-and-plateau appearance of ventricular diastolic pressure Increase and equalization of diastolic pressures Discordance of RV and LV peak systolic pressures (with inspiration, RV systolic pressure increases and LV systolic pressure decreases)
Endomyocardial biopsy	May reveal specific cause of restrictive cardiomyopathy	No specific findings on endomyocardial biopsy Pericardial biopsy may reveal abnormality
Computed tomography, magnetic resonance imaging		Pericardial thickening

AV, Atrioventricular; LV, left ventricular; RV, right ventricular.

Treatment

Treatment of RCM focuses on alleviating the symptoms of heart failure. Diuretics are used for decongestion, but intravascular depletion may compromise ventricular filling and lead to reduced cardiac output and hypotension. Supraventricular tachyarrhythmias are poorly tolerated. In patients with conduction system disease such as advanced atrioventricular block, a permanent pacemaker may be indicated. Specific therapies for underlying disorders include chemotherapy in amyloidosis, phlebotomy and iron chelation therapy in hemochromatosis, and steroids in sarcoidosis and endomyocardial fibrosis.

Prognosis

The course of RCM depends on the pathology, and treatment is often unsatisfactory. In the adult population, the prognosis usually is poor, with progressive deterioration and death due to low-output heart failure.

Arrhythmogenic Right Ventricular Cardiomyopathy

Definition and Epidemiology

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is an autosomal dominant disease characterized by specific myocardial pathology. The estimated prevalence of ARVC is about 1 case in 2000 to 5000 people, and it has a male predominance.

Pathology

The myocardium of the right ventricular free wall is progressively replaced by fibrous and adipose tissue. Right ventricular function is abnormal, with regional akinesis or dyskinesis or global right ventricular dilation and dysfunction.

Clinical Presentation

The disease typically manifests in young adults as palpitations, dizziness or syncope, or sudden cardiac death. Symptoms of right ventricular failure are rare, despite evidence of right ventricular dysfunction on imaging studies.

Diagnosis

The clinical diagnosis of ARVC is suggested by integration of the information from the clinical presentation (e.g., arrhythmias), electrocardiogram, family history, and imaging studies. When available, histologic examination of the right ventricle confirms the diagnosis. The resting electrocardiogram may be normal, but common abnormalities include incomplete or complete right bundle branch block, the so-called epsilon waves that follow the QRS complex, and inverted T waves in the precordial leads. Right ventricular dilation and systolic dysfunction can be seen

with echocardiography and MRI. The latter modality can also show myocardial fat.

Treatment

Treatment consists of ICD therapy to prevent sudden cardiac death, but the indications for implantation are not well defined. Antiarrhythmics and radiofrequency ablation of ventricular tachycardia are used in patients with frequent arrhythmias, but they have not been shown to reduce the risk of sudden cardiac death. Patients with a probable or definite diagnosis of ARVC should be excluded from competitive sports.

Prognosis

The prognosis for these patients remains uncertain.

Unclassified Cardiomyopathies

Some cardiomyopathies that do not fit the current categories are described in [Table 10-2](#).

 For a deeper discussion of this topic, please see [Chapter 60, "Diseases of the Myocardium and Endocardium,"](#) in *Goldman-Cecil Medicine, 25th Edition*.

CARDIAC TUMORS

Primary cardiac tumors are extremely rare, with a prevalence of less than 0.3% in most pathologic series (Table 11-1). Myxoma, the most common primary tumor of the heart, is usually benign. Myxomas are frequently isolated lesions, arising most often in the left atrium in the region of the fossa ovalis. Less commonly, they may be detected in the right atrium, in the right or left ventricle, or in multiple sites within the heart. A familial pattern of myxomas can occur and is transmitted in an autosomal dominant manner. In these patients, multiple cardiac myxomas may be present in association with a constellation of extracardiac abnormalities including pigmented nevi, cutaneous myxomas, breast fibroadenomas, and pituitary and adrenal gland disease. In addition, patients with familial myxoma may have recurrence of the tumors after surgical excision. Whether sporadic or familial, fewer than 10% of myxomas are malignant.

Symptoms associated with myxoma are usually related to embolization of tumor fragments and obstruction of the mitral valve. Tumor involvement of the conduction system may manifest as sick sinus syndrome and dysrhythmias. In addition, patients may exhibit a constellation of nonspecific symptoms and laboratory abnormalities including fever, malaise, weight loss, anemia, and elevated erythrocyte sedimentation rate. The diagnosis is usually made with echocardiography; the transesophageal approach is the most sensitive method for detecting small left atrial tumors. Considering the propensity for embolization, most myxomas are surgically removed when diagnosed. Tumors may recur, so follow-up echocardiograms should be performed. Because of the low incidence right-sided tumors and subsequent low index of suspicion by physicians, these tumors are often misdiagnosed as thrombus on echocardiography. This leads to delayed diagnosis or inappropriate long-term commitment to anticoagulation therapy. Cardiac magnetic resonance imaging is

often warranted to differentiate cardiac thrombus from a mass when the initial findings are not consistent with the clinical signs and symptoms (Fig. 11-1).

Other, less common benign tumors include papillary fibroelastomas, fibromas, and rhabdomyomas. Fibroelastomas are pedunculated tumors with frondlike attachments that usually arise from the surface of the mitral and aortic valve leaflets. These tumors do not result in valve dysfunction but may be a source of systemic embolization. Fibromas most often arise within the interventricular septum and may be associated with arrhythmias or conduction disturbances. Rhabdomyomas are the most common cardiac tumors found in children and are often associated with tuberous sclerosis.

Cardiac lipomas may occur throughout the heart and pericardium. Pericardial lipomas can be large, whereas intramyocardial lipomas are small and often encapsulated. Surgical excision is the treatment of choice. Lipomatous hypertrophy of the interatrial septum should be considered in the differential diagnosis of atrial masses. This lesion is a consequence of nonencapsulated adipose tissue hyperplasia. Although it is occasionally found incidentally at autopsy, it may be associated with supraventricular arrhythmias, conduction disturbances, and, in rare cases, sudden cardiac death.

About one fourth of all primary cardiac tumors are malignant, and most of these are sarcomas. These tumors grow rapidly and often result in chamber obliteration and obstruction of blood flow. If there is involvement of the pericardium, a hemorrhagic effusion with pericardial tamponade may develop. The prognosis in affected individuals is poor; surgical excision is possible in rare cases. Irradiation and chemotherapy may provide palliative relief.

In contrast to primary cardiac tumors, metastatic disease involving the heart is common, occurring in up to one in five patients dying with malignancy. The most common tumors to metastasize to the heart are carcinomas of the lung, breast, and kidney; melanoma and lymphoma may also have cardiac involvement. Metastasis to the pericardium is common and is often complicated by a hemorrhagic effusion and pericardial tamponade. Infiltration of the myocardium may result in conduction disturbances and arrhythmias. Intracavitary masses are unusual but may result from local tumor invasion or direct extension of the malignancy through the venous system (e.g., renal cell carcinoma may metastasize to the heart through the inferior vena cava). Treatment is directed at the underlying malignancy. If pericardial tamponade is present, immediate drainage will help stabilize the patient. A pericardotomy is often necessary to prevent reaccumulation of fluid within the pericardial sac. Surgical excision of an obstructing tumor mass is usually palliative.

TABLE 11-1 EXAMPLES OF TUMORS OF THE HEART AND PERICARDIUM

PRIMARY	Mesothelioma
Benign	Fibrosarcoma
Myxoma lipoma	METASTATIC

TRAUMATIC HEART DISEASE

Nonpenetrating Cardiac Injuries

Blunt cardiac trauma accounts for about 10% of all traumatic heart disease (Table 11-2). Motion-related injuries secondary to abrupt body deceleration (e.g., motor vehicle accidents) and chest wall compression (e.g., steering wheel impact, athletic blow, cardiac resuscitative maneuvers) are the most common causes of blunt injury to the heart. Changes in the myocardium range from small ecchymotic areas in the subepicardium to transmural injury with myocardial hemorrhage and necrosis. Pericarditis is present in most patients and may be complicated by a tear or rupture of the pericardium or cardiac tamponade. Less common complications include rupture of a papillary muscle or chordae tendineae and coronary artery laceration.

Patients most often experience precordial pain that is similar to that associated with myocardial infarction (MI). However, musculoskeletal pain secondary to chest wall injury may confuse the clinical presentation. Congestive heart failure is unusual unless myocardial injury has been extensive or valve dysfunction has occurred. Life-threatening ventricular arrhythmias may occur with severe trauma and are a frequent cause of death in such patients. The electrocardiogram (ECG) most often demonstrates nonspecific repolarization abnormalities or ST-segment and T-wave changes consistent with acute pericarditis. If myocardial

injury is extensive, localized ST-segment elevation and pathologic Q waves may be present.

Elevation of the myocardial component of the creatine kinase muscle band (CK-MB) is supportive of a diagnosis of cardiac contusion but is of limited diagnostic use in patients with massive chest wall trauma because the CK-MB fraction may be elevated as a result of severe skeletal muscle injury. Newer markers of myocardial injury, such as troponins T and I, may be more specific for establishing a diagnosis of myocardial contusion. Echocardiography is a useful, noninvasive tool to assess for wall motion abnormalities, valve dysfunction, and the presence of hemodynamically significant pericardial effusion.

Treatment of cardiac contusion is similar to that of MI, with initial observation and monitoring, followed by a gradual increase in physical activity. Anticoagulants and thrombolytic agents are contraindicated given the risk for hemorrhage into the myocardium and pericardial sac. Most patients who survive the initial injury will have partial or complete recovery of myocardial function. However, patients should be monitored for late complications that include aneurysm formation, free-wall or papillary muscle rupture, and significant arrhythmias.

Great Vessel Injury

Rupture of the aorta is one of the most common cardiovascular injuries resulting from blunt chest wall trauma. In more than 90% of cases, rupture occurs in the descending thoracic aorta just distal to the origin of the subclavian artery. Most individuals die immediately of exsanguination. However, up to 20% of patients may survive the initial injury if the blood is confined within the aortic adventitia and surrounding mediastinal tissues (pseudoaneurysm). Characteristic symptoms and findings on presentation include chest and interscapular back pain, increased arterial pressure and pulse amplitude in the upper extremities, decreased pressure and pulse amplitude in the lower extremities, and mediastinal widening on the chest radiograph.

Previously, aortography was the standard for diagnosis of blunt aortic injury. However, aortography is a relatively invasive, time-consuming procedure with the potential for additional morbidity in this critically ill group of patients. Although conventional chest computed tomography (CT) cannot match the diagnostic accuracy of aortography, helical thin-cut CT angiography has emerged as a superior alternative to aortography for diagnosing blunt

aortic injury. Helical CT scanning is an ideal diagnostic method for aortic injury because of its relatively low cost compared with aortography, its almost universal availability in emergency departments, and its lack of operator dependence. In addition, at most trauma centers, CT scanning is already an integral part of the diagnosis and management of serious blunt injury, with patients typically undergoing simultaneous CT scanning of other areas of the body to evaluate potential injuries. The overall diagnostic accuracy for helical CT scanning in the setting of blunt aortic injury exceeds 99%, and the positive and negative predictive values meet or exceed those of aortography. Patients without direct helical CT evidence of blunt aortic injury require no further evaluation. Aortography should be reserved for indeterminate helical CT scans. Such a strategy helps to substantially reduce the morbidity and cost of unnecessary aortograms for blunt aortic injury.

The force from rapid deceleration that is sufficient to tear the aorta often leads to injuries of other organs as well. Associated injuries are present in more than 90% of patients with aortic transection, and 24% of these patients require a major surgical procedure before aortic repair. The extremely high death rate of acute blunt rupture of the thoracic aorta has led surgeons in the past to repair the tear as quickly as possible. However, this form of management results in high rates of death and complications, often because of associated injuries in other organs.

Patients with traumatic rupture of the aorta fall into two broad categories. About 5% are hemodynamically unstable or deteriorate within 6 hours of admission. These patients require emergent surgical correction because without intervention mortality exceeds 90%. The second group, 95% of patients, are hemodynamically stable at the time of presentation, allowing time for a work-up and staging of any intervention. Mortality in this group is as low as 25% and is rarely the result of free rupture if the blood pressure is controlled. In the past decade, the philosophy of managing traumatic rupture of the aorta in this subgroup of patients has changed to emphasizing blood pressure control and assessing the need for emergent repair against the risks of operation. Prospective studies have demonstrated the value of initial antihypertensive therapy to allow delayed repair of blunt aortic injury in patients with severe coexistent injuries to other organ systems. In a substantial number of cases, associated injuries or comorbidities make the risks of immediate surgical repair prohibitive.

The current indications for considering delayed aortic repair include trauma to the central nervous system, contaminated wounds, respiratory insufficiency from lung contusion or other causes, body surface burns, blunt cardiac injury, tears of solid organs that will undergo nonoperative management, and retroperitoneal hematoma, as well as age older than 50 years and the presence of medical comorbidities. Patients with significant neurologic, pulmonary, or cardiac injuries have better outcomes if their confounding pathologic condition can be ameliorated before thoracotomy.

Penetrating Cardiac Injuries

Penetrating cardiac injuries are frequently the result of physical violence leading to bullet and knife wounds. Similar wounds may result from the inward displacement of bone fragments or fractured ribs due to blunt chest wall injury. Iatrogenic injuries

may occur during placement of central venous catheters and wires.

With traumatic perforations, the right ventricle is the most frequently involved chamber, considering its anterior location in the chest. It is often associated with pericardial laceration. Symptoms are related to the size of the wound and the nature of the concomitant pericardial injury. If the pericardium remains open, extravasated blood drains freely into the mediastinum and pleural cavity, and symptoms are related to the resulting hemothorax. If the pericardial sac limits blood loss, pericardial tamponade results. In this situation, treatment includes emergent pericardiocentesis followed by emergent surgical closure of the wound. Small penetrating wounds to the ventricles that are not associated with extensive cardiac damage have the highest rate of survival. Late complications include chronic pericarditis, arrhythmias, aneurysm formation, and ventricular septal defects.

CARDIAC SURGERY

Coronary Artery Bypass Grafting

Despite the effectiveness of current medical therapy for the treatment of coronary artery disease, many patients require revascularization. Coronary artery bypass grafting (CABG) is an effective means of reducing or eliminating symptoms of angina pectoris. CABG may improve survival in certain subgroups of patients, including patients with angina refractory to medical therapy, patients with greater than 50% stenosis of the left main coronary artery, and patients with severe three-vessel coronary artery disease associated with left ventricular dysfunction. In addition, patients with two-vessel coronary artery disease in which a severe stenosis (>75%) is present in the proximal left anterior descending artery appear to benefit from CABG even if left ventricular function is normal.

Standard CABG is performed through a median sternotomy incision with cardiopulmonary bypass (CPB) and cardioplegic arrest. Operative mortality is 1% or less in stable patients with normal left ventricular function; the incidences of perioperative MI and stroke range from 1% to 4%. An increase in adverse events is associated with advancing age, female gender, short stature, diabetes, unstable angina or recent MI, and severely reduced left ventricular function. Overall survival at 10 years is about 80%, with recurrent or progressive angina occurring in about 50% of patients.

Long-term success of surgery is dependent on the type of conduit used during the surgery (saphenous vein versus internal mammary artery grafts) and the progression of atherosclerotic disease in the native and graft vessels. The internal mammary artery is particularly resistant to atherosclerotic disease and has a patency rate of about 90% at 10 years. In comparison, venous grafts are subject to closure both during the immediate postoperative period (usually secondary to technical factors) and months to years after surgery (secondary to intimal hyperplasia and progression of atherosclerosis). As a result, only 50% of venous grafts are patent 7 to 10 years after CABG.

The major predictor of development of atherosclerotic disease in the surgically placed bypass grafts is the ability of patients to control their risk factors for the development of atherosclerotic disease generally after surgery, particularly cigarette smoking,

hypertension, diabetes, hypercholesterolemia, and obesity. Aggressive lowering of low-density lipoprotein levels after CABG and the administration of a daily aspirin have been shown to reduce the incidence of venous graft occlusion.

Most cases of recurrent angina can be managed successfully with medication (see [Chapter 9](#)). In many cases, percutaneous revascularization of a native vessel or graft can provide symptomatic relief and is the initial procedure of choice in this setting. In patients with refractory symptoms not amenable to percutaneous revascularization, repeat CABG is an option; however, in this setting, repeat CABG is associated with increased perioperative mortality and less satisfactory long-term control of angina.

Minimally Invasive Cardiac Surgery

Minimally invasive approaches for cardiac surgery can be broadly grouped into two categories: those that avoid the performance of a sternotomy and those that avoid the use of CPB. During the last 15 years, progressive experience incorporating these approaches has led to the application of minimally invasive techniques to selected patients undergoing cardiac surgery. However, many of the approaches have significant limitations, and the field continues to evolve.

In highly selected patients, minimally invasive direct coronary artery bypass (MIDCAB) can be performed through a limited thoracotomy, sparing the patient the perioperative morbidity associated with a median sternotomy. This technique also avoids the use of CPB. The most common approach is through a small left anterior thoracotomy incision. This allows for harvesting of the left internal mammary artery under direct visualization. This technique is most suitable for patients with proximal disease in the distribution of the left anterior descending coronary artery, although other coronary arteries can be bypassed with the use of different thoracotomy approaches. The major limitation of this approach has been the lower patency rates in the left internal mammary grafts placed using this technique and a higher incidence of recurrent ischemia compared with conventional CABG. The MIDCAB procedure therefore is applicable only to highly selected patients with disease in the distribution of the left anterior descending coronary artery and significant comorbidities that preclude the performance of a median sternotomy and use of CPB.

The initial experience with the MIDCAB approach and the subsequent demonstration of its limitations prompted the development of port-access cardiac surgery. This technique incorporates the MIDCAB approach of a limited lateral thoracotomy, thereby avoiding a median sternotomy, but uses CPB to facilitate performance of intracardiac procedures and potential access to other coronary artery distributions beyond the left anterior descending coronary artery for CABG. The port-access approach uses an endoaortic balloon inserted through cannulas placed in the femoral vessels for CPB. A few centers have successfully used the port-access platform for performance of selected cardiac surgical procedures, particularly mitral valve repair or replacement. The widespread adoption of this platform has been limited by persistent difficulties with access to all areas of the heart for coronary revascularization and the potentially catastrophic complication of aortic dissection in a small number of patients.

The limitations encountered with both the MIDCAB and port-access platforms have spurred interest in coronary bypass surgery performed through a median sternotomy but without CPB (e.g., off-pump coronary artery bypass [OPCAB]), allowing for surgery on the beating heart. The advantages of OPCAB over other platforms for minimally invasive coronary surgery are that complete revascularization can be performed and both internal mammary arteries can be harvested. Compared with conventional CABG, OPCAB is associated with decreased blood loss, decreased need for transfusion, decreased myocardial enzyme release up to 24 hours after surgery, decreased renal dysfunction, and, typically, decreased number of grafts placed per patient. OPCAB is not associated with a decreased length of hospital stay, a decreased mortality rate, or improved long-term neurologic function compared with conventional CABG. Although the OPCAB platform has become the most widely adopted approach for minimally invasive cardiac surgery, major questions remain regarding the intermediate and long-term patencies of the bypass grafts placed with this technique and whether the decreased number of grafts placed per patient compromises the long-term cardiac outcomes, compared with conventional CABG. Large-scale prospective clinical trials need to be conducted to answer these questions definitively.

Advances in minimally invasive cardiac surgery have led to the development of robotically assisted cardiac surgery. In this approach, the surgeon sits behind a computer console and uses telemanipulation to guide robotic arms that are placed through ports in the chest wall. On- or off-pump surgeries can be performed, and CPB is achieved through the peripheral cannulation. Although a variety of cardiac surgeries are possible in selected patients, the most commonly performed robotically assisted cardiac procedure is repair or replacement of the mitral valve. CABG can be performed on a beating or arrested heart. The internal mammary artery is typically taken down with the use of the robot, and the distal anastomosis is performed freehand through a mini-thoracotomy or mini-sternotomy incision. Alternatively, totally endoscopic robotic coronary bypass (TECAB) can be performed with good results. Similar procedures using this approach include ablation of atrial fibrillation, resection of intracardiac tumors, closure of atrial septal defects, and implantation or revision of the left ventricular lead of a device.

Other benefits of minimally invasive techniques include a smaller incision, less pain, and shorter length of hospital stay. Advocates of robotically assisted cardiac surgery highlight the improved visualization, panoramic 360-degree views, wrist-like articulation of instruments, improved dexterity, and elimination of hand tremor. These procedures are continually evolving, but their widespread adoption is limited to specialized centers due to significant costs for purchase and maintenance. As the experience with the technology improves, use of robotic approaches is likely to increase and to play a substantial role in the field of minimally invasive cardiac surgery.

Valvular Surgery

Surgical repair or replacement of a diseased valve is dependent on multiple factors, including the type and severity of the valve lesion, the presence of symptoms, and the functional status of the left and, in some cases, the right ventricle (see [Chapter 8](#)). In

most adults, the diseased valve is replaced with a prosthesis, although some forms of valve disease, such as mitral valve regurgitation or mitral stenosis without significant valvular or chordal calcification, may be amenable to repair. Because prosthetic heart valves are associated with a number of complications (e.g., thrombosis, endocarditis, hemolysis), the decision to proceed with valve surgery should be made only after the risks of valve replacement have been weighed against the potential benefits of symptom relief and improved survival.

Valve surgery is performed in a manner similar to CABG, with most cases requiring a median sternotomy, CPB, and cardioplegic arrest. Minimally invasive surgery through a modified sternotomy or thoracotomy incision may be possible in selected patients with isolated aortic or mitral valve disease. Operative mortality for all techniques ranges from 1% to 8% for most patients with preserved left ventricular function and good exercise capacity. The risk of surgery increases with advancing age, depressed left ventricular ejection fraction, presence of severe coronary artery disease, and replacement of multiple valves. Symptomatic patients usually have significant clinical improvement after valve surgery; however, long-term survival is strongly dependent on the patient's preoperative functional status and ventricular function.

Mechanical Circulatory Support and Cardiac Transplantation

The term *mechanical circulatory support* refers to total or partial mechanical support of the heart to allow for continued circulation of blood and adequate tissue perfusion. John H. Gibbon performed the first clinical application of mechanical circulatory support in 1953 when he used a CPB machine for closure of an atrial septal defect. The ability to operate on a motionless and bloodless field led to the birth of cardiac surgery as a discipline and spawned the current era by providing a surgical alternative approach for the treatment of coronary artery disease, valvular heart disease, and diseases of the great vessels.

Since the advent of the CPB machine, several mechanical support systems have become available, including intra-aortic balloon pumps (IABP), extracorporeal membrane oxygenators (ECMO), ventricular assist devices (VADs), and total artificial hearts (TAHs). Because the surgical management of heart failure continues to evolve, this section focuses on the indications and associated complications of left VADs (LVADs), especially in relation to heart transplantation. Further details on the disease process and medical management of heart failure are covered in [Chapter 6](#).

Cardiopulmonary Bypass

A CPB procedure not only circumvents the normal functions of the heart and lungs during an operation but enables surgery to be carried out in a bloodless and motionless field while simultaneously providing adequate oxygenation of blood and perfusion of end organs. The heart is arrested with the use of a cardioplegic solution of blood or normal saline that is highly concentrated with potassium. Aside from creating a motionless surgical field, cardiac arrest and cooling of the heart provide cardiac protection against ischemia by decreasing metabolic demand during bypass. Other important functions of the CPB

are intraoperative regulation of blood volume and pressure, cooling and rewarming of the patient, administration of medications, filtering the blood, and providing rapid laboratory analysis of blood samples to achieve successful CPB surgery.

In a schematic diagram of standard CPB circuit shown in [Figure 11-2](#), deoxygenated blood is first drained from the right side of the heart by cannulas placed in the inferior and superior venae cavae. The blood is transported into a reservoir and then pumped through a heat exchanger, oxygenator, and filtration unit before it is returned through a cannula into the ascending aorta for whole-body circulation. Peripheral cannulation is achieved through the femoral vessels or the axillary artery or both, the latter approach being reserved for complex aortic arch surgery or in instances when standard cannulation of the great vessels is not possible.

The CPB operation is well tolerated by most patients. Similar to MCS devices discussed later, the secondary complications from contact of circulating blood with the synthetic surface of the circuit promote the activation of inflammatory pathways, systemic responses, and hypercoagulability. All patients undergoing CPB require heparin anticoagulation to a goal activated clotting time of at least 480 seconds. Corticosteroids may be administered to suppress the inflammatory response, and protamine is routinely used for reversal of heparin before decannulation. Postoperatively, patients should be monitored for heparin-induced thrombocytopenia (see also [Chapter 54](#)).

Extracorporeal Membrane Oxygenation

ECMO is the use of a simplified CPB circuit for temporary life support in patients with reversible cardiac or respiratory failure in the intensive care unit. The mechanical oxygenation and organ perfusion allows for cardiopulmonary recovery. Improved survival has been demonstrated in neonates and adults with isolated pulmonary or cardiac failure for whom maximal medical therapy has failed. As with CPB, cannulas are placed in the right side of the heart to drain blood into the ECMO circuit for oxygenation, but blood can be returned to either the right heart or the arterial system (the proximal or distal aorta). Return of blood to the right heart (i.e., veno-venous ECMO) is indicated for patients with isolated pulmonary failure. In patients with pulmonary and concomitant cardiac failure with hemodynamic instability, veno-arterial ECMO is used to return oxygenated blood to the proximal aorta to augment cardiac output and recovery. Patients on veno-arterial ECMO require anticoagulation. As with CPB, complications associated with ECMO include bleeding, thromboembolism, and heparin-induced thrombocytopenia.

Intraaortic Balloon Pump

The physiologic basis of an IABP is to provide counterpulsation and to improve the peripheral oxygen demands in the patient with a failing heart. Common indications for IABP are hemodynamic support during or after heart catheterization, cardiogenic shock, weaning from CBP, preoperative stabilization in high-risk patients, refractory unstable angina, refractory ventricular failure, and mechanical complications due to acute MI.

A helium-filled balloon is placed percutaneously or under direct vision through the femoral artery into the thoracic aorta, just distal to the left subclavian artery. The balloon is

FIGURE 11-2 Diagram of a standard cardiopulmonary bypass circuit. See text for details. (Cohn LH: Cardiac surgery in the adult, ed 4, New York, 2011, McGraw-Hill.)

synchronized with the ECG or arterial waveform of the patient to fill during diastole and deflate during systole. Balloon inflation during diastole increases aortic pressure, referred to as diastolic augmentation, allowing for maximal delivery of oxygenated blood to the coronary arteries. Deflation during systole decreases the afterload and oxygen consumption of the heart while improving cardiac output. Potential major complications include balloon leak, severe bleeding (e.g., retroperitoneal), major limb ischemia, and death.

Ventricular Assist Devices

VAD was first successfully applied in 1966 by Michael E. DeBakey for cardiogenic shock after cardiac surgery in a 37 year-old female patient. She was maintained on the device for 10 days before being discharged home. The early cardiac assist devices were developed to improve weaning off the CPB machine in cardiac surgery patients. Today, distinct VADs have been designed for short-term and long-term management of failure of the right, left, or both ventricles.

Although cardiac transplantation remains the standard of care for refractory heart failure, the number of available donor hearts has plateaued, limiting the number of heart transplantations performed in the United States to just 2000 per year. Between 15% to 25% of patients with end-stage heart failure die while awaiting transplantation. As a result, the use of VADs, in particular LVADs, has significantly increased over the last 2 decades. As discussed later, LVADs have demonstrated a viable alternative for patients awaiting transplantation and for those who do not meet heart transplant criteria. This technology of surgical intervention has changed the dynamic and expanded management capabilities for patients with advanced heart failure. For the medical management of heart failure, refer to [Chapter 60](#).

Compared with optimal medical therapy, LVADs have demonstrated improved 1- and 2-year survival rates in patients with end-stage heart failure, when compared to optimal medical therapy. The use of LVADs continues to evolve as clinical insights of the consequences of current devices are recognized and newer devices become available. Few randomized clinical trials exist,

and current recommendations for LVADs are primarily based on level C evidence (i.e., consensus based). The goal of LVAD therapy is to support cardiac function and maintain adequate end-organ perfusion to provide meaningful recovery and quality of life. In the acute setting (e.g., cardiogenic shock), a LVAD may be placed temporarily, either as a bridge to decision for a longer-term VAD and assessment of alternative management options or as a bridge to recovery if the heart failure is deemed reversible (e.g., viral myocarditis, nonischemic cardiomyopathy). Patients with chronic heart failure who have failed maximal medical therapy and are candidates for transplantation may receive a LVAD as a bridge to transplantation while awaiting the availability of a donor heart. Survival from the time of implantation of the cardiac assist device to the time of cardiac transplantation varies from 51% to 71% worldwide.

In patients with lifestyle-limiting heart failure despite maximal medical therapy who are not candidates for transplantation, a LVAD may be indicated for destination therapy. In this setting, the LVAD is placed indefinitely to maintain tissue perfusion and improve quality of life or, in some cases, until recovery is achieved or the patient becomes a candidate for heart transplantation. Destination therapy is the most common indication for LVAD placement; approximately 40% of all VADs placed in 2012 were for that purpose.

Before implantation of any MCS device, medical and psychosocial factors as well as operative risk factors should be taken into consideration and assessed by a multidisciplinary team devoted to such longitudinal care. VADs are not recommended for patients with irreversible end-organ damage and without anticipation of meaningful improvement in quality of life.

Table 11-3 lists the VADs currently approved by the U.S. Food and Drug Administration (FDA). Several types of VADs that can

be placed percutaneously or surgically in the acute setting exist for longer support. In general, LVADs decompress the left ventricle by draining blood into the aorta using a mechanical pump; they also contain a power source, such as a portable battery pack, and a cardiac and device monitoring system (Fig. 11-3). First-generation LVADs were pneumatically driven pulsatile pumps that drew blood from the apex of the heart and ejected it into the proximal aorta. The Heartmate XVE (Thoratec Corp., Pleasanton, Calif.), a first-generation LVAD, was approved by the FDA in 1994 as a bridge to transplantation. Although these pulsatile pumps are considered more physiologic, they are bulky and technically difficult to implant because they require a large body surface area, and they have a high incidence of infection and pump thrombosis. These flaws led to the development of the smaller, second-generation LVADs that were driven by axial or centrifugal pumps to provide continuous flow of blood from the left ventricle apex into the aorta (Fig. 11-4; see Fig. 11-3).

In the United States, two continuous-flow pumps are currently approved by the FDA: the HeartMate II (Thoratec), an axial pump LVAD, for destination therapy and as a bridge to transplantation, and the HeartWare (HeartWare CT, HeartWare, Inc., Miami Lakes, Fla.), a centrifugal pump LVAD, as a bridge to transplantation. Improved survival and technical ease of implantation have become the hallmarks of these pumps, rendering the use of the first-generation pumps almost obsolete. Nevertheless, the risks of infection, thrombosis, and stroke are considerable.

Increased use and improved survival rates have brought to light new complications associated with the second-generation pumps. The diminished left ventricular excursion and low pulsatility of continuous-flow pumps are associated with the development of gastrointestinal arteriovenous malformations and acquired von Willibrand's disease. Such complications can lead to potentially catastrophic gastrointestinal bleeding because these patients require chronic anticoagulation. Risk factors for increased mortality in patients with continuous-flow pumps include older age and associated fragility, renal dysfunction, respiratory dysfunction, right-sided heart failure, and history of previous or concomitant cardiac surgery at the time of device implantation. Third-generation LVADs, which use hydrodynamic or electromagnetic pump technology with few moving parts, are currently under investigation.

Surgical management of heart failure is a continually evolving field, and further technological advances are needed to address issues of size, infection, thrombosis, and diminished pulsatility. A multidisciplinary approach involving cardiac surgeons, cardiologists, intensivists, anesthesiologists, perfusionists, and specialized nurses and social workers is essential to ensure successful management of the LVAD patient and the family. Continuous emphasis on the education and training of the patient, family, local paramedics, among others, requires meticulous coordination among all team members to ensure successful outpatient management, avoid potentially lethal complications, and provide improved patient safety and health outcomes.

Total Artificial Heart

The first successful application of a TAH in humans was by Denton Cooley, in 1969, to wean a 47-year-old male patient off CPB. The TAH functioned for 64 hours until successful cardiac

transplantation was achieved. The TAH seeks to entirely restore cardiac function, and it is indicated in patients who are at risk of death from irreversible biventricular failure not amenable to medical or surgical therapy.

In the United States, the pneumatically driven SynCardia CardioWest TAH-t (temporary) (SynCardia, Inc., Tucson, Ariz.) and the hydraulically driven AbioCor TAH (Abiomed, Danvers, Mass.) are presently approved by the FDA. These pulsatile pumps are placed in the orthotopic position by excising the right and left ventricles for total replacement of bilateral valvular and ventricular function (Fig. 11-5). The CardioWest TAH-t is approved as a bridge to transplantation and has a survival rate

similar to LVAD implantation for that indication. To date, the longest survival time with the CardioWest is 1374 days. The AbioCor is currently approved for humanitarian device use. Such instances involve the compassionate use of the device, without prior evidence of effectiveness, to potentially benefit patients with a rare disease. The AbioCor TAH is entirely implantable and is intended for permanent cardiac replacement in patients younger than 75 years of age who have severe heart failure and are not candidates for transplantation but meet the criteria for humanitarian device use. Initial clinical trials in 14 patients demonstrated adequate support; the longest survival time with the AbioCor was 512 days.

FIGURE 11-4 Left image shows placement of the HeartWare ventricular assist device; right image demonstrates its relatively small size. See text for details. (Courtesy HeartWare Inc., Framingham, Mass.)

In both the CardioWest and the AbioCor TAH, morbidity and mortality are associated with significant risks of bleeding, infection, thromboembolism, and stroke. These complications are the target of current research for device improvement. Further studies are underway to assess the utility of the CardioWest TAH for destination therapy, and the AbioCor II is in development as a smaller and more durable device than the original.

Cardiac Transplantation

During the last 2 decades, cardiac transplantation has become a life-saving treatment choice for patients with end-stage congestive heart failure. With advances in surgical techniques and immunosuppressive therapy, 1- and 5-year survival rates are about 90% and 75%, respectively. These rates are far superior to the 1-year survival rate for patients with advanced heart failure, which approaches 50%. Many patients who are eligible for cardiac transplantation die before surgery because of the limited number of donor hearts available each year. The development and widespread application of LVADs has allowed many of these patients who would otherwise die awaiting transplantation to survive until a donor heart becomes available. In many centers today, more than half of patients undergoing cardiac transplantation have previously undergone placement of a LVAD.

The major indications for cardiac transplantation are to prolong survival and improve quality of life. Determining which patients are suitable for cardiac transplantation can be difficult because many patients have clinical and hemodynamic improvement with intensification of medical therapy. In general, functional capacity, as assessed by exercise stress testing with measurement of maximal oxygen consumption at peak exercise, is the best predictor of whether a patient should be selected for cardiac transplantation. Individuals with severely impaired exercise capacity (e.g., peak oxygen consumption <10 to 12 mL/kg/min, with the lower limit of normal being 20 mL/kg/min) are most likely to experience a survival benefit from transplantation. Exclusion criteria include irreversible pulmonary vascular hypertension, malignancy, active infection, diabetes mellitus with end-organ damage, and advanced liver or kidney disease. Although

advanced age is associated with higher surgical and 1-year mortality rates, an age limit for cardiac transplantation is no longer strictly enforced at most centers, with patients instead being listed for transplantation based on an overall assessment of their physiologic status and potential for long-term survival after transplantation.

The procedure is performed through a median sternotomy incision. The posterior walls of the left and right atria with their venous connections are left in place and used to suture to the donor heart. The aorta and pulmonary artery are directly anastomosed to the recipient's great vessels. Immunosuppressive therapy is begun immediately after surgery and continued throughout the patient's life. Although new immunosuppressive agents are available, most regimens still include combinations of cyclosporine, azathioprine, and prednisone. Common complications during the first year include infection and rejection of the donor heart. In addition, hyperlipidemia and hypertension are common medical problems that may require treatment.

The major long-term complication is the development of coronary vasculopathy in the transplanted heart. In contrast to coronary artery atherosclerosis, which tends to be a focal process affecting primarily the proximal vessels, this disease is characterized by diffuse myointimal proliferation involving primarily the medial and distal segments of the coronary arteries. Although the cause of this disease is not entirely known, coronary vasculopathy is thought to be related to an immune-mediated response directed against the donor vessels. Monitoring for this complication can be difficult because angina is not provoked in the denervated heart and standard exercise stress testing has a low sensitivity for detecting this disease.

Coronary angiography is performed after transplantation and yearly thereafter to monitor for significant narrowing of the coronary arteries. However, the diffuse nature of the vasculopathy reduces the accuracy of coronary angiography for detection of this disease. Intracoronary ultrasound, with measurements of the intimal layer and coronary artery lumen size, is a new technique that appears to be more sensitive than coronary angiography for detection of this complication. Treatment options are limited,

FIGURE 11-5 Total artificial hearts approved by the U.S. Food and Drug Administration: **A**, CardioWest total artificial heart. **B**, AbioCor total artificial heart. See text for details. TET, Transcutaneous energy transfer device. (Modified from National Heart, Lung, and Blood Institute, U.S. Department of Health and Human Services: What is a total artificial heart? Available at <http://www.nhlbi.nih.gov/health/health-topics/topics/tah/>. Accessed August 15, 2014.)

but aggressive management of hypercholesterolemia and the use of calcium-channel blockers, specifically diltiazem, have been associated with a slowing of disease progression and a higher survival rate. Retransplantation is reserved for patients who have severe, three-vessel coronary artery disease with reduced left ventricular function and symptoms of congestive heart failure.

Noncardiac Surgery in the Patient with Cardiovascular Disease

Noncardiac surgery in patients with known cardiovascular disease may be associated with an increased risk for death or cardiac complications such as MI, congestive heart failure, and arrhythmias. To determine an individual patient's risk for a procedure, the consulting physician must have knowledge of the type and severity of the patient's cardiac disease, the comorbid risk factors, and the type and urgency of surgery. In general, the preoperative evaluation and management are the same as in the nonoperative setting; for patients who are at risk, additional non-invasive and invasive testing may be performed if the results would affect treatment or outcome.

Usually, estimation of a patient's perioperative risk can be determined by a careful clinical evaluation, including a history, physical examination, and review of the ECG. Patients at highest risk for a perioperative cardiac event are those with a recent MI (defined as occurring >7 days but <1 month earlier), unstable or

severe angina, decompensated congestive heart failure, significant arrhythmias, or severe valvular disease (Table 11-4). Predictors of moderate or intermediate cardiac risk include a history of stable angina, compensated heart failure, prior MI, or diabetes mellitus. Advanced age, an abnormal ECG, low functional capacity, and poorly controlled hypertension are associated with cardiovascular disease but are not independent predictors of a perioperative cardiac event.

In regard to the type of surgery, risks are highest in patients who are undergoing major emergency procedures, especially older adults (Table 11-5). Cardiac complications are also common after vascular surgery, considering that the prevalence of underlying coronary artery disease is high in this patient population. In addition, any surgery associated with large volume shifts or blood loss may place increased demands on an already diseased heart. Procedures associated with the lowest risk in patients with cardiac disease are cataract extraction and endoscopy. Several risk stratification calculators have been developed and validated for patients undergoing cardiac surgery. The Society for Thoracic Surgeons risk calculator (available at <http://riskcalc.sts.org/STWebRiskCalc273/>) and the recently updated EuroSCORE II risk calculator (available at <http://www.euroscore.org/calc.html>) are used in the United States and Europe to assess risk of in-hospital mortality and morbidity and risk of 30-day in-hospital mortality, respectively.

TABLE 11-4 CLINICAL PREDICTORS OF INCREASED PERIOPERATIVE CARDIOVASCULAR RISK (MYOCARDIAL INFARCTION, CONGESTIVE HEART FAILURE, DEATH)

MAJOR

Unstable coronary syndromes
Recent myocardial infarction (e.g., >1 wk and <1 mo)
Unstable or severe angina (Canadian Cardiovascular Society angina class III or IV)
Decompensated heart failure
Significant arrhythmias
High-grade atrioventricular block
Symptomatic ventricular arrhythmias
Supraventricular arrhythmias with uncontrolled ventricular response
Severe valvular disease

INTERMEDIATE

Mild angina (Canadian Cardiovascular Society angina class I or II)
Prior myocardial infarction
Compensated or prior congestive heart failure
Diabetes mellitus

MINOR

Advanced age
Abnormal electrocardiogram (e.g., left ventricular hypertrophy, left bundle branch block)
Rhythm other than sinus
Low functional capacity (i.e., unable to climb one flight of stairs with a bag of groceries)
History of a stroke
Uncontrolled systemic hypertension

Once the clinical evaluation is complete and the type of surgery is known, the need for additional testing and treatment can be determined. If emergency surgery is contemplated, little in the way of cardiac assessment can be performed, and recommendations may be directed at perioperative medical management and surveillance. If surgery is not urgent, additional evaluation is based on the clinical assessments of the risk and type of surgery. Patients with major risk factors for cardiac complications should have surgery delayed until the cardiac condition has been treated and stabilized. Patients with intermediate predictors of cardiac risk who are scheduled for high-risk surgery should undergo noninvasive testing such as exercise or pharmacologic stress testing or echocardiography. The results of these tests will help determine future management, such as cardiac catheterization or intensification of medical therapy. Patients scheduled for low- or intermediate-risk surgery, especially those who have good exercise capacity, should proceed to surgery with appropriate medical management and postoperative surveillance. Noncardiac surgery is generally safe for patients with minor or no clinical risk factors for cardiac complications, although some patients with poor functional capacity who are scheduled for high-risk operations may benefit from additional cardiac evaluation.

DISEASE-SPECIFIC APPROACHES

Coronary Artery Disease and Myocardial Infarction

About 70% of MIs occur within the first 6 days after an operation, with the peak incidence between 24 and 72 hours. Mortality associated with noncardiac surgery has been reported to be as

TABLE 11-5 CARDIAC RISK STRATIFICATION FOR NONCARDIAC SURGICAL PROCEDURES

HIGH (REPORTED CARDIAC RISK >5%)

Emergent major operations, particularly in the older adult population
Major vascular surgery, aortic aneurysm repair
Peripheral vascular surgery
Prolonged procedures associated with large fluid shifts or blood loss or both

INTERMEDIATE (REPORTED CARDIAC RISK <5%)

Carotid endarterectomy
Head and neck
Intraperitoneal and intrathoracic
Orthopedic
Prostate

LOW (REPORTED CARDIAC RISK <1%)

Endoscopic procedures
Cataract extraction
Breast biopsy

Data from Eagle KA, Brundage BH, Chaitman BR, et al: Guidelines for perioperative cardiovascular evaluation for noncardiac surgery: report of the ACC/AHA Task Force on Practice Guidelines, *J Am Coll Cardiol* 27:910–948, 1996.

high as 30% to 40%, especially if associated with congestive heart failure or significant arrhythmias. Multiple stresses associated with surgery can provoke ischemia. Physiologic tachycardia and hypertension secondary to volume shifts, anemia, infection, and the stress of wound healing increase myocardial oxygen demand and may provoke ischemia. In addition, increased platelet reactivity during the postoperative period may increase the risk for coronary thrombosis and subsequent infarction.

Despite the high mortality rate associated with perioperative MI, few studies have examined the effects of anti-ischemic therapy to prevent this complication. Several small, uncontrolled trials have suggested that β -blockers reduce intraoperative ischemia. More recently, the use of atenolol before and after surgery was associated with a reduction in MI and cardiac death, especially during the first 6 to 12 months after surgery. Although the data are limited, the use of a perioperative β -blocker therapy should be considered for all patients with suggested or known coronary artery disease unless a specific contraindication to its use is present. The data available on the usefulness of calcium-channel blockers and nitrates are even more limited, but this approach may be appropriate for the treatment of symptomatic coronary disease in individuals who are not candidates for revascularization. Coronary angiography and revascularization should be reserved for individuals in whom this treatment would otherwise result in significant improvement in symptoms or long-term survival. In rare cases, revascularization may be indicated for high-risk patients undergoing major noncardiac surgery.

All patients with suggested or known cardiac disease should have routine ECGs the first 3 days after surgery to monitor for ischemia. If the ECG is inconclusive, measurement of troponin levels may be helpful to document an ischemic event. Treatment of an MI in this setting is similar to that for the nonsurgical patient (see [Chapter 9](#)), although the use of anticoagulants and thrombolytic agents may be contraindicated in the immediate postoperative period. Special attention should be paid to correcting abnormalities that may provoke additional ischemia (e.g., hypoxia, anemia).

Congestive Heart Failure

Several studies have shown that decompensated heart failure is associated with increased perioperative cardiac complications. In these patients, surgery should be postponed until appropriate treatment is instituted and symptoms have been stabilized. If planned surgery is associated with large blood loss or fluid shifts, a pulmonary artery catheter may be helpful.

During the postoperative period, congestive heart failure most commonly occurs in the first 24 to 48 hours, when fluid administered during surgery is mobilized from the extravascular space. However, heart failure may also result from myocardial ischemia and new arrhythmias. Initial management includes identification and treatment of the underlying cause. In addition, intravenous diuretics usually provide rapid relief of pulmonary congestion. If heart failure is complicated by hypotension or poor urine output, insertion of a pulmonary artery catheter may be helpful to guide additional therapy (see [Chapter 6](#)).

Valvular Heart Disease

In regard to valvular heart disease the greatest risk for complications after noncardiac surgery is in those with aortic or mitral stenosis. Patients with symptomatic, severe aortic stenosis should have valve replacement before noncardiac surgery. In patients with mild to moderate mitral stenosis, careful attention to volume status and heart rate control are necessary to optimize left ventricular filling and avoid pulmonary congestion. Patients with severe mitral stenosis should be considered for percutaneous valvuloplasty or mitral valve replacement before high-risk surgery. In patients with valve disease or prosthetic heart valves, prophylactic antibiotics are recommended if appropriate.

Arrhythmias and Conduction Defects

Patients with symptomatic, high-grade conduction disturbances, such as third-degree atrioventricular (AV) block, have an increased perioperative risk for cardiac complications and should have a temporary pacemaker inserted before surgery. Patients with first-degree AV block, Mobitz type I AV block, or bifascicular block (right bundle branch block and left anterior fascicular block) do not require prophylactic pacemaker insertion.

Atrial arrhythmias such as atrial fibrillation are common after surgery and usually are not associated with significant complications if the ventricular rate is well controlled. Ventricular premature beats and nonsustained ventricular tachycardia are also common after noncardiac surgery and do not require specific therapy unless they are associated with myocardial ischemia or heart failure. In most instances, treatment of the underlying cause (e.g., hypoxia, metabolic abnormalities, ischemia, volume overload) results in significant improvement or resolution of the rhythm disturbance without specific antiarrhythmic therapy.

Cardiac Disease in Pregnancy

Pregnancy is associated with dramatic changes in the cardiovascular system that may result in significant hemodynamic stress to the patient with underlying heart disease. During a normal pregnancy, plasma volume increases an average of 50%, beginning in the first trimester and peaking between the 20th and 24th weeks

of gestation. This change is accompanied by increases in stroke volume, heart rate, and, accordingly, cardiac output. In addition, a concomitant fall in systemic vascular resistance and mean arterial pressure occurs because of the effects of gestational hormones on the vasculature and the creation of a low-resistance circulation in the pregnant uterus and placenta. During labor, uterine contractions result in a transient increase of up to 500 mL of blood in the central circulation, resulting in further increases in stroke volume and cardiac output. After delivery, intravascular volume and cardiac output increase further as compression of the inferior vena cava by the gravid uterus is relieved and extravascular fluid is mobilized. Symptoms and signs that may mimic cardiac disease often accompany these hemodynamic changes; they include fatigue, reduced exercise tolerance, lower-extremity edema, distention of the neck veins, S₃ gallop, and new systolic murmurs. Differentiating symptoms produced by cardiac disease from those attributable to a normal pregnancy can be difficult. Under such circumstances, echocardiography can be a safe and helpful noninvasive test to assess cardiac structure and function in the pregnant patient.

Many pregnant women with known cardiac disease can complete a normal pregnancy and delivery without significant harm to the mother or fetus. However, certain cardiac conditions, including irreversible pulmonary hypertension, cardiomyopathy associated with severe heart failure, and Marfan syndrome with a dilated aortic root, are associated with a high risk for cardiovascular complications and death. Under these circumstances, patients should be advised against having children. If pregnancy occurs, a first-trimester therapeutic abortion should be strongly recommended.

SPECIFIC CARDIAC CONDITIONS

Mitral Stenosis

Mitral stenosis secondary to rheumatic heart disease frequently occurs in young women of childbearing age. The physiologic increases in heart rate and cardiac output during pregnancy result in a significant increase in the gradient across the mitral valve and a rise in left atrial and pulmonary venous pressures. Congestive heart failure may develop as the pregnancy progresses through the second and third trimesters, or it may occur more acutely with the onset of atrial fibrillation.

The management of mitral stenosis depends on the patient's prepregnant functional capacity and the severity of the valve obstruction. In general, patients with severely symptomatic mitral valve stenosis should have percutaneous or surgical correction of the valve before conception. Women with minimal symptoms (New York Heart Association functional classes I to II) usually tolerate pregnancy and vaginal delivery well, even if moderate to severe stenosis is present. Management includes salt restriction, diuretic therapy, and aggressive treatment of pulmonary infections. Patients who develop atrial fibrillation with a rapid ventricular response should be treated with AV nodal blocking agents and cardioversion if possible. Patients who develop refractory heart failure during pregnancy should be considered for mitral balloon valvuloplasty because surgical commissurotomy or valve replacement may be associated with fetal demise.

Aortic Stenosis

Aortic stenosis in a pregnant woman is usually congenital in origin. Patients with significant outflow obstruction may develop angina or heart failure during the later portion of the pregnancy as cardiac output increases. Supportive therapy includes bedrest and prevention of hypovolemia. If these measures fail to control symptoms and the fetus is not near term, balloon valvuloplasty, transaortic valve replacement, or aortic valve surgery should be considered to reduce the risk for maternal death.

Marfan Syndrome

Pregnant women with Marfan syndrome are at an increased risk for aortic dissection and rupture, especially during the third trimester and the first postpartum month. Patients with an aortic root diameter greater than 40 mm are at greatest risk for this complication and should strongly consider therapeutic abortion during the first trimester. Women with an aortic root diameter less than 40 mm should have serial echocardiograms to monitor the size of the aortic root during pregnancy. In addition, restriction in physical activity and treatment with a β -blocker may help prevent further dilation of the aorta.

Congenital Heart Disease

Survival to reproductive age is common in patients with corrected congenital defects. The risk for pregnancy in these patients is related to the completeness of the repair and the mother's functional capacity. Uncomplicated atrial or ventricular septal defects not associated with symptoms or pulmonary hypertension are usually well tolerated during pregnancy. Intracardiac shunts associated with pulmonary vascular hypertension are associated with a high maternal mortality rate during pregnancy as a result of increased right-to-left shunting and worsening oxygen desaturation of the blood. In these women, pregnancy is contraindicated. If pregnancy occurs, a therapeutic abortion during the first trimester should be recommended. Women with uncorrected tetralogy of Fallot should undergo palliative or definitive repair before conception to improve maternal and fetal outcomes. Women with residual obstruction of the right ventricular outflow tract remain at high risk for right ventricular heart failure during pregnancy.

Prosthetic Heart Valves

Most patients with a normal-functioning prosthetic valve tolerate pregnancy without complications. However, in patients with mechanical valves, special attention to the choice and dose of anticoagulant therapy is necessary to avoid thromboembolic complications in the mother and teratogenic effects in the fetus. Women should start subcutaneous heparin before conception to avoid the potential teratogenic effects of warfarin during the first several months of critical fetal organ development. This therapy can be continued throughout pregnancy, or, alternatively, warfarin can be reinstated late in the second trimester or during the third trimester. Although heparin therapy confers less risk of teratogenicity than warfarin use, it is associated with a high risk for maternal bleeding complications. Low-molecular-weight heparin may be an acceptable alternative, but no firm data are available to support this recommendation. At the time of

delivery, anticoagulation therapy is interrupted to avoid bleeding complications. Antibiotic prophylaxis is usually not recommended at the time of delivery.

Heart Disease Arising During Pregnancy

Cardiovascular disease can develop during pregnancy and may pose a significant risk to the mother and fetus. Hypertension is not an uncommon problem during pregnancy and is defined as a consistent increase in blood pressure of 30/15 mm Hg or an absolute blood pressure greater than 140/90 mm Hg. The three major forms of hypertension that may develop during pregnancy are chronic hypertension, gestational hypertension, and toxemia. Toxemia is a form of hypertension that develops during the second half of pregnancy and is associated with proteinuria, edema, and, in severe forms, seizures. This problem is primarily managed by the obstetrician and is not discussed in this text. Gestational hypertension is an elevation in blood pressure that occurs late in the pregnancy, during delivery, or during the first postpartum days. This disease entity is not associated with proteinuria or edema and resolves within 2 weeks after delivery.

Chronic hypertension is presumed to be present if an elevation in blood pressure is detected before the 20th week of pregnancy. No matter what the cause, fetal mortality correlates with the severity of the hypertension and begins to rise when the diastolic pressure exceeds 75 mm Hg during the second trimester or 85 mm Hg during the third trimester. Initial treatments include a reduction in physical activity and salt restriction. If the blood pressure remains greater than 150/90 mm Hg, then antihypertensive treatment should be instituted. Agents that have been safely used in pregnancy include hydralazine, α -methyl dopa, clonidine, β -blockers, and labetalol. Diuretics should be used with caution because of the increased risk for placental hypoperfusion.

Peripartum cardiomyopathy (PCM) is a form of dilated cardiomyopathy that may begin during the last trimester of pregnancy or within the first 6 months after delivery in a woman without prior heart disease or other definable causes for cardiac dysfunction. The true incidence of the disease is unknown, but estimates conclude that 1 in every 3000 to 4000 pregnancies is affected. Although the cause of PCM is unknown, myocardial injury is thought to be immunologically mediated. Women usually exhibit symptoms and signs of congestive heart failure. Echocardiography is useful to assess chamber size and degree of ventricular dysfunction. The outcome with PCM is variable, with death or progressive heart failure occurring in about one third of affected women. The prognosis is particularly poor if symptoms develop before delivery. Despite this risk, many patients have complete recovery of ventricular function, although recurrence is possible, especially with subsequent pregnancies. Treatment is similar to that for congestive heart failure (see [Chapter 6](#)) and usually includes the use of vasodilators such as hydralazine, digoxin, and diuretics. Angiotensin-converting enzyme inhibitors have been associated with increased fetal wastage in pregnant animals and should be avoided. A thorough evaluation of cardiac function should be performed before subsequent pregnancies. If a woman decides to proceed with another pregnancy, she should be monitored regularly for signs of cardiac decompensation.

About 50% of aortic dissections that occur in women younger than 40 years of age are associated with pregnancy. Although the cause of aortic dissection during pregnancy is unknown, it has been postulated that hemodynamic and hormonal changes associated with pregnancy may weaken the aortic wall. The highest incidence of dissection is during the third trimester, although it can occur at any time during the pregnancy or in the early postpartum period. The presenting symptoms and diagnostic work-up are similar to those for the nonpregnant patient (see [Chapter 13](#)). Transesophageal echocardiography is highly sensitive and specific for the detection of aortic dissection and offers the advantage of not exposing the fetus to ionizing radiation. Management includes aggressive blood pressure control and β -blocker therapy to reduce shear forces of the ejected blood. Recommendations for corrective surgery are similar to those for the nonpregnant patient and are discussed in [Chapter 13](#).

PROSPECTUS FOR THE FUTURE

CABG remains an important but now less commonly used mode for revascularization in symptomatic coronary artery disease. Technical advances in percutaneous coronary angioplasty (PTCA) have emboldened such attempts for revascularization of unprotected left main disease, the established domain for CABG, even in octogenarians. Prospective studies are needed to evaluate the efficacy, health outcomes, and costs and benefits for combined approaches of CABG and PTCA with drug-eluting stents. Percutaneous and minimally invasive surgical options are gaining more widespread application in the management of heart disease. With the limited donor pool for cardiac transplantation, advanced

heart failure will be managed with resynchronization therapy, LVADs, and stem- and cell-based therapies.

Vascular Diseases and Hypertension

Wanpen Vongpatanasin and Ronald G. Victor

INTRODUCTION

Diseases of the systemic and pulmonary vasculature are among the most common clinical problems encountered in internal medicine. Yet these important diseases are not often given the emphasis they deserve; they fall between the cracks of traditional medical subspecialties. Early clinical recognition is important because effective therapy often can prevent or at least delay needless suffering and death. This chapter reviews the causes, clinical manifestations, diagnostic evaluations, and therapeutic approaches to the major forms of systemic and pulmonary vascular diseases as well as arterial hypertension.

SYSTEMIC VASCULAR DISEASE

Peripheral Arterial Disease

The term *peripheral arterial disease* (PAD) refers to atherosclerotic vascular disease of mainly the lower extremities. Similar to other atherosclerotic vascular diseases, PAD is more prevalent in men than it is in women, particularly before the age of menopause. The prevalence increases with age, ranging from 2% to 6% for adults younger than 60 years to 20% to 30% for those older than 70 years. As with coronary atherosclerosis, the major reversible risk factors are cigarette smoking, diabetes mellitus, hyperlipidemia, and hypertension. Only 30% to 50% of patients with PAD become symptomatic. The classic syndrome of intermittent claudication refers to ischemic muscle pain or weakness brought on by exertion and promptly relieved by rest. Claudication is associated with a significant 10-year risk of morbidity and mortality. Approximately 25% of patients will develop worsening claudication, 5% will require amputation, 10% to 20% will require revascularization, and 30% will die of a cardiovascular event (e.g., heart attack, stroke) as a result of concomitant coronary artery and/or cerebrovascular atherosclerosis. To minimize progression of PAD and avoid complications, risk factor modification is absolutely essential. This includes tight control of blood pressure (BP), plasma lipids, and blood glucose. Complete cessation of tobacco use is a must.

The diagnosis of PAD begins with a careful history and physical examination and is confirmed by noninvasive laboratory testing. Ischemic pain occurs in the leg muscles supplied by arterial segments that are distal to the site of stenosis. Calf claudication is the hallmark of femoral-popliteal disease, whereas discomfort in the thigh, hip, or buttock associated with impotence indicates aortoiliac disease (Leriche's syndrome).

Depending on the severity of the stenosis, the pain is experienced at a predictable walking distance and is promptly relieved by rest. Claudication must be differentiated from the pseudoclaudication of lumbar degenerative spinal canal stenosis. In the latter condition, walking can also aggravate leg pain, but it is not relieved simply by the cessation of exercise. Rather, assuming positions that minimize lumbar extension, such as stooping forward or sitting, alleviates the pain. The characteristic physical findings of PAD are absent or diminished pulses distal to the stenosis, bruits over the diseased artery, hair loss, thin shiny skin, and muscle atrophy. Severe ischemia causes pallor, cyanosis, decreased skin temperature, ulceration, and gangrene.

Noninvasive techniques are quite good. The *ankle-brachial index* (ABI) is the ratio of the highest systolic BP measured from either the dorsalis pedis or the posterior tibialis artery to the highest systolic BP obtained from the brachial artery using a Doppler stethoscope. The normal ABI range is 1.0 to 1.4. An ABI of 0.9 or less indicates PAD. This simple noninvasive test has a sensitivity and specificity of 95% and 99%, respectively. In some patients with diabetes mellitus or renal failure, the media of the affected leg vessels become so heavily calcified that they resist compression except during very high levels of cuff inflation. The result is a falsely elevated ankle BP and an artificially normal or supernormal ABI (Table 12-1).

Duplex ultrasonography is an important adjunct to the ABI and has a similar sensitivity and specificity. This test is particularly useful to diagnose PAD in patients with noncompressible vessels due to medial wall calcification. The Doppler velocity waveform remains abnormal despite a spuriously normal or elevated ABI. Magnetic resonance (MR) angiography and computed tomographic (CT) angiography permit excellent visualization of vascular stenosis and identification of runoff vessels. With these noninvasive imaging modalities, spatial resolution is comparable to that of traditional invasive

TABLE 12-1 INTERPRETATION OF ANKLE-BRACHIAL INDEX

ANKLE-BRACHIAL INDEX	INTERPRETATION
1.00-1.40	Normal
0.90-0.99	Borderline
0.70-0.89	Mild PAD
0.40-0.69	Moderate PAD
<0.40	Severe PAD
>1.40	Noncompressible vessels

PAD, Peripheral arterial disease.

angiography, which now is reserved for patients undergoing revascularization.

The medical management of PAD includes lifestyle and risk factor modification as well as antiplatelet therapy. Smoking cessation reduces the risks of limb loss, myocardial infarction, and death. Lipid-lowering therapy with a statin (hydroxymethylglutaryl-coenzyme A [HMG-CoA] reductase inhibitor) should be initiated and intensified if the serum low-density lipoprotein (LDL) cholesterol level is greater than 100 mg/dL. Antihypertensive medication should be initiated and intensified until the BP is lower than 140/90 mm Hg. β -Adrenergic receptor blockers do not reduce walking capacity or worsen intermittent claudication in patients with PAD. Aspirin reduces the risks of myocardial infarction, death, and stroke. However, clopidogrel is an effective alternative treatment and is more effective than aspirin in reducing cardiovascular events (level B of evidence). Each patient needs an exercise prescription because exercise training improves walking capacity and quality of life. Pentoxifylline is a methylxanthine derivative that may improve maximal walking distance, but the data are inconclusive. Better data are available with cilostazol, a phosphodiesterase-3 (PDE3) inhibitor (whereas sildenafil is a PDE5 inhibitor). In several studies of patients with symptomatic PAD, cilostazol consistently improved walking capacity and quality of life. It is one of the most effective agents for intermittent claudication. However, cilostazol must be avoided in patients with congestive heart failure because its use may increase mortality in those patients.

Revascularization (percutaneous or surgical) is indicated for patients with severe claudication that is resistant to medical therapy, limb-threatening ischemia, or ischemia-induced impotence. Percutaneous revascularization offers a comparable patency rate with less morbidity and mortality than surgery in patients with short, focal stenoses of large arteries such as the distal aorta or iliac arteries (Fig. 12-1). Surgical revascularization is more suitable for longer areas of stenosis or obstructive lesions

distal to the origin of the iliac arteries. The selection of surgery versus percutaneous intervention as the initial mode of revascularization in patients with limb-threatening ischemia also depends on the patients' life expectancy. In general, bypass surgery is preferable to balloon angioplasty in patients with an expected life expectancy of more than 2 years because of greater overall long-term survival and amputation-free survival times (level B evidence). In contrast, percutaneous intervention is preferable for those with limited life expectancy because of less short-term morbidity (level B evidence).

Acute limb ischemia is a vascular emergency. Sudden occlusion of a peripheral artery is caused by either arterial embolism or thrombosis in situ. Arterial emboli usually originate in the cardiac chambers in the setting of preexisting cardiac disease such as myocardial infarction (e.g., left ventricular mural thrombus), congestive heart failure, or atrial arrhythmias (e.g., left atrial thrombus in a patient with atrial fibrillation). Thrombosis in situ usually occurs in arteries with a preexisting severe stenosis in the setting of long-standing PAD with or without previous vascular surgery. Patients with arterial embolism usually experience sudden onset of symptoms without a history of claudication, whereas those with thrombosis in situ typically have a history of claudication that has previously been stable and then suddenly assumes a crescendo pattern over a period of days. In either case, the physical examination reveals a cold, cyanotic (bluish) extremity with absent pulses distal to the site of arterial occlusion and diminished motor and/or sensory function. A handheld Doppler device is used to assess signals at various arterial segments and confirms the diagnosis of acute vascular occlusion. Anticoagulation should be initiated immediately with intravenous heparin titrated to maintain the activated partial thromboplastin time equal to 2.0 to 2.5 times control. Patients with acute limb ischemia who have symptoms for more than 14 days or occlusion in suprainguinal sites usually require surgical thromboembolectomy or bypass surgery. In contrast, patients with more recent onset of symptoms or infrainguinal occlusion should undergo

FIGURE 12-1 Angiogram of the distal abdominal aorta and iliac arteries demonstrates an occluded left common iliac artery with extensive collateral circulation from the contralateral internal iliac artery (*left*), which resolved after successful stent implantation (*right*). (Courtesy Bart Domatch, MD, Radiology Department, University of Texas Southwestern Medical Center, Dallas, Tex.)

catheter-directed infusion of thrombolytic therapy or percutaneous thrombus extraction. Irreversible tissue necrosis, regardless of the cause, should be treated with emergent amputation rather than revascularization to reduce the risk of kidney failure (myoglobinuria), sepsis, and multiorgan failure.

Aortic Aneurysm

Abdominal aortic aneurysm (AAA) is a common vascular disease in older adults, affecting 4% to 8% of men and 0.5% to 1.5% of women older than 65 years of age. Thoracic aortic aneurysm is much less prevalent (0.4% to 0.5%). Besides age, the major risk factors for AAAs are cigarette smoking, hypertension, and a family history of aortic aneurysms. Atherosclerosis is responsible for most cases of AAA, but other causes include cystic medial necrosis (Marfan syndrome, Ehlers-Danlos syndrome), vasculitis with connective tissue disease (Takayasu's arteritis, giant-cell arteritis), chronic infection (syphilitic aortitis), and trauma. AAAs grow gradually, at an average rate of 1 to 4 mm/year. The risk of rupture is low until the diameter reaches 5 cm, and then it increases exponentially. The risk of aortic rupture is 1% per year for aneurysms between 3.5 and 4.9 cm in diameter and 5% per year for aneurysms larger than 5 cm.

Most patients with AAA are asymptomatic, but some develop vascular complications such as aneurysm expansion with compression of adjacent structures. Occasionally, mural thrombi form within the aneurysm and embolize, causing acute occlusion of distal arterial segments. Patients with iliac aneurysm may develop hydronephrosis or recurrent urinary tract infections from ureteral compression. Others develop neurologic symptoms from compression of sciatic or femoral nerves. The classic physical finding is a pulsatile, nontender mass below the umbilicus (distal to the origin of the renal arteries). In thin patients, normal aortic pulsations are often palpable but above the umbilicus. Hypotension and acute abdominal pain should prompt consideration of aneurysm rupture, which requires emergent operative repair. Duplex ultrasonography is an accurate and reliable diagnostic tool for abdominal aortic and iliac aneurysms. Routine screening for AAA with ultrasonography is recommended for all men between the ages of 65 and 75 years and for men older than 60 years of age with a family history of AAA among first-degree relatives. Such screening is of proven benefit in reducing mortality. CT and MR angiography allow visualization of the thoracic and abdominal aorta as well as the iliac arteries and its branches (Fig. 12-2).

Medical treatment for aortic aneurysm includes smoking cessation, tight BP control, and cholesterol reduction. β -Blockade reduces the rate of aortic root enlargement in patients with Marfan syndrome but has not proved beneficial in patients with AAA from other causes. Patients with large aneurysms or rapid aneurysm expansion regardless of size should undergo aneurysm repair (Table 12-2). Elective AAA repair carries a perioperative mortality rate of 2% to 6%. Furthermore, a large randomized study failed to demonstrate any benefit of surgery in patients with aneurysms 4.0 to 5.5 cm in diameter (level A evidence). For these reasons, patients with small aortic aneurysms should be treated medically with close monitoring of aneurysm size by periodic imaging studies every 6 to 12 months (see Table 12-2).

FIGURE 12-2 Computed tomographic angiogram of the distal abdominal aorta shows abdominal aortic aneurysm, 6.2 cm in largest diameter, with severe stenosis at the origin of the right common iliac artery. (Courtesy Bart Domatch, MD, Radiology Department, University of Texas Southwestern Medical Center, Dallas, Tex.)

TABLE 12-2 INDICATIONS FOR SURGICAL TREATMENT OF ARTERIAL ANEURYSMS

Symptoms from expansion of aneurysm or compression of adjacent structure
Rupture of aneurysm
Rapid aortic aneurysm expansion of ≥ 1 cm/yr
Large aneurysm
Ascending aorta >4.5 cm for patients with Marfan syndrome and >5.0 cm for all others
Aortic arch >5.5 cm
Descending thoracic aorta >5.0 cm
Abdominal aorta >5.5 cm
Iliac aneurysm >3 cm

Percutaneous endovascular aneurysm repair (EVAR) is an alternative to open surgical repair for treatment of AAA. EVAR offers a lower rate of perioperative death than surgical repair with equivalent long-term survival (level A evidence). However, EVAR should be reserved for patients who are able to return for follow-up visits and repeated imaging studies of the aneurysm site to ensure that the stent graft is free from endovascular leaks or displacement (level A evidence). EVAR has not been shown to improve mortality in patients with multiple comorbidities, who are considered to be unfit for surgery, when compared to conservative management. Therefore, it should be offered only to selected patients with symptoms from compression of adjacent organs or vascular complications.

Aortic Dissection

In aortic dissection, the intimal layer is torn from the aortic wall, resulting in the formation of a false lumen in parallel with the true lumen. Risk factors include hypertension, cocaine use, trauma, hereditary connective tissue disease (e.g., Marfan syndrome, Ehlers-Danlos syndrome), vasculitis (e.g., Takayasu's arteritis, giant-cell arteritis), Behçet's disease, bicuspid aortic valve, and

aortic coarctation. Aortic dissection can be divided into types A and B (Stanford system). Type A dissection involves the ascending aorta, whereas type B involves the distal aorta. The DeBakey system subdivides aortic dissection into three subtypes: I, II, and III. Type I dissection involves the entire aorta, whereas type II involves only the ascending aorta and type III involves only the descending aorta. Aortic dissection involving the ascending aorta carries a high mortality rate of 1% to 2% per hour during the first 24 to 48 hours. Patients usually develop acute onset of severe chest or back pain. Abdominal pain, syncope, and stroke are common. Retrograde propagation of the dissection can cause pericardial tamponade or coronary artery dissection with acute myocardial infarction. Dissection involving the aortic valve causes acute severe aortic insufficiency with acute pulmonary edema. The dissection plane may propagate in an antegrade direction to compromise flow in the carotid and subclavian arteries, producing a stroke or acute upper limb ischemia.

Patients with distal (type B) aortic dissection exhibit acute onset of back pain or chest pain, often accompanied by lower-extremity ischemia and ischemic neuropathy. The physical findings include pulse deficits, neurologic deficits, or a diastolic murmur of aortic regurgitation. However, acute aortic regurgitation into an unprepared ventricle produces only a short, soft diastolic murmur that is often missed. Widened pulse pressure and associated physical findings of chronic aortic regurgitation are absent, and the clinical picture is that of an acutely ill patient with tachypnea, tachycardia, and a narrow pulse pressure. Hypotension, jugular venous distention, and pulsus paradoxus should prompt the diagnosis of pericardial tamponade. Transesophageal echocardiography, MR angiography, or CT angiography confirm the diagnosis by demonstrating an intimal flap that separates the true lumen from the false lumen (Fig. 12-3).

Type A aortic dissection is uniformly fatal without emergent surgical repair. With surgery, mortality is reduced to 10% at 24

hours and 20% at 30 days. Patients with type B aortic dissection should be treated medically because the 1-year survival rate is higher with medical therapy than with surgery (75% vs. 50%). However, surgery is indicated if type B dissection compromises blood flow to the legs, kidneys, or other viscera. Tight control of BP is essential because aortic aneurysm develops in 30% to 50% of patients with type B aortic dissection studied for 4 years.

Penetrating Aortic Ulcers and Intramural Hematoma

Penetrating aortic ulcers and intramural hematomas exhibit chest pain that is indistinguishable from that of aortic dissection. In contrast to aortic dissection, however, the pathologic condition is localized. No identifiable intimal flap, and therefore no branch vessel occlusion, is produced. Disruption of the internal elastic lamina produces aortic ulcers that erode into the medial wall and protrude into the surrounding structures. Rupture of the vasa vasorum causes formation of localized hematoma underneath the adventitia with resultant asymmetric thickening of the aortic wall. Patients with either condition typically are older than those with aortic dissection, have a larger aortic size, and have a higher prevalence of AAA. Aortic rupture is the major complication of both penetrating ulcers and intramural hematomas, particularly if the aneurysm is located in the ascending aorta. The diagnosis is made with invasive angiography, CT angiography, or MR angiography (Fig. 12-4). Surgical intervention should be considered for ulcers and hematomas of the ascending aorta, for deeply penetrating ulcers, and for severely bulging hematomas, irrespective of their location. Ulcers and hematomas of the descending aorta may be managed successfully with β -blockade and tight control of BP.

Other Arterial Diseases

Buerger's Disease

Buerger's disease is a nonatherosclerotic disease of the arteries, veins, and nerves of the arms and legs that affects mostly men

FIGURE 12-3 Computed tomographic angiogram of the aorta shows type B aortic dissection. The intimal flap (*arrow*) separates the true lumen (*T*) from the false lumen (*F*) and compromises blood flow to the right kidney, causing renal atrophy and cortical thinning. (Courtesy Bart Domatch, MD, Radiology Department, University of Texas Southwestern Medical Center, Dallas, Tex.)

FIGURE 12-4 Computed tomographic angiogram of the descending thoracic aorta shows a large penetrating aortic ulcer above the diaphragm (*arrow*). (Courtesy Bart Domatch, MD, Radiology Department, University of Texas Southwestern Medical Center, Dallas, Tex.)

younger than 45 years of age. The mechanism is unknown, but all patients have a history of heavy tobacco addiction. The presenting symptom is claudication of the feet, legs, hands, or arms. Multiple-limb involvement and superficial thrombophlebitis are common. The C-reactive protein level and erythrocyte sedimentation rate (Westergren method) typically are normal, and a search for serologic markers for connective tissue disease (e.g., antinuclear antibody, rheumatoid factor, antiphospholipid antibody) is negative. The diagnosis is based on the typical clinical presentation. If the presentation is atypical, then biopsy is needed to make the diagnosis. The histologic hallmark is inflammatory intramural thrombi within the arteries and veins with sparing of internal elastic lamina and other arterial wall structures. The most effective treatment for Buerger's disease is complete tobacco abstinence. The prostacyclin analogue iloprost constitutes adjunctive therapy to reduce limb ischemia and improve wound healing.

Raynaud's Phenomenon

Raynaud's phenomenon is a vasospastic disease of the small arteries of mainly the fingers and toes. Primary (idiopathic) Raynaud's phenomenon occurs in the absence of underlying disorders. Secondary Raynaud's phenomenon occurs in association with connective tissue diseases (e.g., scleroderma, polymyositis, rheumatoid arthritis, systemic lupus erythematosus) repeated mild physical trauma (e.g., use of jack hammers), use of certain drugs (e.g., antineoplastic chemotherapeutic agents, interferon, monamine-reuptake inhibitors such as tricyclic antidepressants, serotonin agonists), and Buerger's disease. Patients usually complain of recurrent episodes of ischemia of the digits, which exhibit a characteristic white-blue-red color sequence: Pallor is followed by cyanosis if ischemia is prolonged and then by erythema (reactive hyperemia) when the episode resolves. Episodes are precipitated by cold temperature or emotional stress. The physical examination can be entirely normal between attacks with normal radial, ulnar, and pedal pulses. Some patients have digital ulcers or thickening of the fat pad (sclerodactyly). Patients should be instructed to avoid cold temperatures and dress warmly. Calcium-channel blockers (CCBs) reduce the frequency and severity of vasospastic episodes.

Giant-Cell Arteritis

Giant-cell arteritis is an immune-mediated vasculitis that predominantly involves medium-sized and large arteries such as the subclavian artery, axillary artery, and aorta of older adults, with a strong male predominance. Approximately 40% of patients with giant-cell arteritis also have polymyalgia rheumatica, a syndrome characterized by severe stiffness and pain originating in the muscles of the shoulders and pelvic girdle. Patients may exhibit headache from temporal arteritis, jaw claudication from ischemia of the masseter muscles, or visual loss from involvement of the ophthalmic artery. Chest pain suggests the coexistence of aortic aneurysm or dissection. Physical findings include low-grade fever, scalp tenderness in the temporal area, pale and edematous fundi, or a diastolic murmur of aortic regurgitation. A BP difference of more than 15 mm Hg between the arms suggests subclavian artery stenosis. Laboratory findings include a significantly elevated C-reactive protein level and Westergren sedimentation

rate plus anemia. The diagnosis is confirmed by histologic examination of the arterial tissue (frequently obtained by temporal artery biopsy) showing infiltration of lymphocytes and macrophages (i.e., giant cells) in all layers of the vascular wall. High-dose corticosteroids are highly effective. To minimize complications from long-term corticosteroid administration, the steroid dose should be tapered to find the lowest dose needed to suppress symptoms, which often wane. Every attempt should be made to discontinue corticosteroids over time.

Takayasu's Arteritis

Takayasu's arteritis is an idiopathic granulomatous vasculitis of the aorta, its main branches, and the pulmonary artery. This condition is particularly common in young women of Asian descent, but it also occurs in non-Asian women and in men. The inflammatory process in the vascular wall can lead to stenosis or aneurysm formation or both. Hypertension, as a result of renal artery stenosis or aortic coarctation, is the most common manifestation and is present in as many as 80% of affected individuals. Because the vascular involvement is so widespread, patients may have symptoms and signs of coronary ischemia, congestive heart failure, stroke, vertebrobasilar insufficiency, or intermittent claudication. Physical findings include bruits over the subclavian arteries or aorta with diminished brachial pulses and therefore a low brachial artery BP. The diagnosis is based primarily on this clinical presentation. First-line treatment is with corticosteroids. Other immunosuppressive agents such as methotrexate or cyclophosphamide are often added to prevent disease progression and relapse. Immunosuppressive therapy does not cause regression of preexisting vascular stenoses or aneurysms. For this reason, percutaneous or surgical revascularization is usually required.

Arteriovenous Fistula

Arteriovenous (AV) fistulas are abnormal vascular communications that shunt blood flow from the arterial system directly into the venous system, bypassing the capillary beds that normally ensure optimal tissue perfusion and nutrient exchange. AV fistulas may be congenital, as in AV malformation, or acquired. The main causes of acquired AV fistula are penetrating trauma (e.g., gunshot, knife wound) and shunts created surgically for hemodialysis access. Patients may exhibit a pulsatile mass, symptoms related to compression of an adjacent organ, or bleeding from spontaneous rupture of an AV malformation. Systolic and diastolic bruits or thrills may be detectable over the fistula or malformation. An AV malformation in skeletal muscle may lead to bone malformation or a pathologic fracture, whereas an AV malformation in the brain may result in neurologic deficits or seizures. High-output heart failure is another complication from a large AV malformation or fistula. MR angiography, CT angiography, or conventional angiography confirms the diagnosis. Depending on the size and location of the lesion, treatment options include surgical resection, transcatheter embolization, or pulse laser irradiation. Patients with acquired AV fistulas from trauma usually need surgical closure.

PULMONARY VASCULAR DISEASE

Pulmonary hypertension is characterized by elevated mean pulmonary artery pressure of greater than 25 mm Hg at rest or

greater than 30 mm Hg during exercise. The many causes of pulmonary hypertension are summarized in [Table 12-3](#).

Patients with pulmonary hypertension not only have an elevated pulmonary arterial pressure but also a low cardiac output, causing symptoms of exertional dyspnea, fatigue, and syncope. Pulmonary capillary wedge pressure is usually normal (≤ 15 mm Hg) except in patients with pulmonary hypertension due to impaired left ventricular systolic or diastolic function or left-sided valvular heart disease.

Pulmonary Arterial Hypertension

Pulmonary arterial hypertension (PAH) is caused by a combination of pulmonary vasoconstriction, endothelial cell and/or smooth muscle proliferation, intimal fibrosis, and thrombosis in the pulmonary capillaries and arterioles. PAH is either idiopathic (primary pulmonary hypertension) or secondary to connective tissue disease, congenital heart disease, portal hypertension, human immunodeficiency virus (HIV) infection, or anorexic drugs or toxins. Connective tissue diseases, particularly scleroderma, are the most common secondary causes of PAH.

Patients with mild PAH can be asymptomatic, but patients with more advanced disease complain of dyspnea, chest pain, syncope, or presyncope. Physical findings include a left parasternal lift, loud pulmonary component of the second heart sound, murmur of tricuspid or pulmonic regurgitation, hepatomegaly, peripheral edema, or ascites. Associated electrocardiogram (ECG) abnormalities indicate right ventricular hypertrophy, right atrial enlargement, or right axis deviation. Echocardiography provides important information about the severity of the pulmonary hypertension (e.g., estimated pulmonary artery pressure, right ventricular dimensions and function) and its potential causes (e.g., left ventricular failure, valvular lesions, congenital heart disease with left-to-right shunt). Pulmonary function tests, ventilation-perfusion (\dot{V}/\dot{Q}) lung scans, polysomnography or overnight oximetry, autoantibody tests, HIV serology, and liver function tests also should be performed to determine other

potential causes. Right ventricular catheterization should be performed in all patients with suspected PAH. Under basal conditions in the catheterization laboratory, an elevated mean pulmonary artery pressure exceeding 25 mm Hg, a pulmonary capillary wedge pressure of less than 15 mm Hg, and a pulmonary vascular resistance exceeding 3 units confirm the diagnosis. Acute vasodilator drug challenge should be performed during right ventricular catheterization to guide appropriate treatment.

Without treatment, the prognosis of PAH is poor, with a median survival time of less than 3 years. Patients with severe symptoms should be treated with prostacyclin or epoprostenol (an intravenous prostacyclin analogue) because of their proven efficacy in improving exercise capacity, quality of life, and survival. Other prostacyclin analogues, such as treprostinil and iloprost, are also effective in reducing pulmonary artery pressure and improving exercise capacity. Other classes of drugs approved for treatment of PAH include endothelin-receptor blockers (bosentan or ambrisentan) and PDE5 inhibitors (sildenafil, tadalafil). Much higher daily doses of PDE5 inhibitors are needed to treat PAH than to treat erectile dysfunction or prostatism. Oral CCBs are indicated for the small subset of patients with mild to moderate symptoms who demonstrate significant reduction in pulmonary pressure with acute CCB challenge (decrease in mean pulmonary artery pressure of at least 10 mm Hg to an absolute level of less than 40 mm Hg without a decrease in cardiac output). Supplemental home oxygen is indicated for all patients with hypoxemia. Travel to high elevations exacerbates hypoxia, and relocation to sea level improves symptoms. Oral anticoagulation is recommended for all patients with PAH. Diuretics should be prescribed for patients with peripheral edema or hepatic congestion. Lung transplantation is recommended only for patients in whom severe symptoms occur despite intensive medical therapy.

VENOUS THROMBOEMBOLIC DISEASE

The term *venous thromboembolism* (VTE) encompasses both deep vein thrombosis (DVT) and pulmonary embolism (PE). Among the adult population in the United States, the overall combined annual incidence is as high as 1 new case per 1000 persons. The incidence of VTE is higher in men than in women and higher in African Americans and whites than in Asians and Hispanics. More than 150 years ago, Rudolf Virchow recognized three predisposing factors: endothelial damage, venous stasis, and hypercoagulation (now known as Virchow's triad). Endothelial damage is common with surgery or trauma; venous stasis is common with prolonged bedrest or immobilization (e.g., leg cast); and hypercoagulation is common with cancer. Trousseau's syndrome consists of migratory thrombophlebitis with noninfectious vegetations on the heart valves (nonbacterial thrombotic endocarditis, formerly known as marantic endocarditis), typically in the setting of mucin-secreting adenocarcinoma. Trousseau, a pathologist, diagnosed his own pancreatic carcinoma on the basis of the association that now bears his name. Hypercoagulable states include hereditary diseases such as deficiencies in antithrombin III, protein C, or protein S; mutation in the factor V gene (factor V Leiden) or the factor II gene (prothrombin G20210A); and hyperhomocysteinemia. However, a thorough search for identifiable risk factors will remain negative in 25% to 50% of patients with VTE.

TABLE 12-3 CLASSIFICATION OF PULMONARY HYPERTENSION

CATEGORY	EXAMPLES
1. Pulmonary arterial hypertension (PAH)	
A. Primary or idiopathic PAH	Sporadic Familial
B. Secondary PAH	Connective tissue disease Congenital heart disease Portal hypertension Human immunodeficiency virus infection Drugs and toxins: anorexigens, cocaine
2. Pulmonary venous hypertension	Left ventricular heart failure Left ventricular valvular heart disease
3. Pulmonary hypertension associated with chronic respiratory disease or hypoxemia	Chronic obstructive pulmonary disease Obstructive sleep apnea
4. Pulmonary hypertension associated with chronic venous thromboembolism	Deep vein thrombosis
5. Pulmonary hypertension due to miscellaneous disorders directly affecting the pulmonary vasculature	Sarcoidosis, histiocytosis X, compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)

Deep Vein Thrombosis

Most DVT starts in the calf veins. Without treatment, 15% to 30% of these clots propagate to the proximal calf veins. The risk of a subsequent PE is much higher with proximal DVT than with clots confined to the distal calf vessels (40% to 50% vs. 5% to 10%, respectively). Involvement of the upper extremities is much less common, but subclavian or axillary vein thrombosis also can lead to PE in as many as 30% of affected individuals. The same risk factors that cause lower-extremity DVT also cause upper-extremity DVT. In addition, other specific causes of upper-extremity DVT include traumatic damage of the vessel intima due to heavy exertion such as rowing, wrestling, or weight lifting (Paget-Schroetter syndrome), extrinsic compression at the level of thoracic inlet (thoracic outlet obstruction), or insertion of central venous catheters or pacemakers.

Pain and swelling are the major complaints from patients with DVT; however, a large number of patients are asymptomatic, particularly if the DVT is restricted to the calf. Patients with upper-extremity DVT can develop the superior vena cava syndrome of facial swelling, blurred vision, and dyspnea. Thoracic outlet obstruction can compress the brachial plexus, leading to unilateral arm pain associated with hand weakness. Physical examination frequently reveals tenderness, erythema, warmth, and swelling below the site of thrombosis. Pain with dorsiflexion of the foot (Homan's sign) may be present, but the low sensitivity and the low specificity limit the usefulness of this sign in the diagnosis of lower-extremity DVT. A palpable tender cord, dilated superficial veins, and low-grade fever occur in some patients. Upper-extremity DVT can cause brachial plexus tenderness in the supraclavicular fossa and atrophic hand muscles. For patients with probable thoracic outlet obstruction, several provocative tests should be performed. Adson's test is positive if the radial pulses weaken during inspiration and during extension of the arm of the affected side while rotating the head to the same side. Wright's test is positive if the radial pulses become weaker and painful symptoms are reproduced while the shoulder of the affected side is abducted with the humerus externally rotated.

The laboratory diagnosis of DVT includes measurement of D-dimers, which are fibrin degradation products. D-dimer elevation is a highly sensitive indicator of DVT that can be performed rapidly in the emergency department. In a patient in whom the index of probability is low, a negative D-dimer test effectively excludes the diagnosis of DVT. However, the test is not specific and can be elevated in many other conditions frequently encountered in hospitalized patients (e.g., inflammation, recent surgery, malignancy). Duplex ultrasonography can be used to demonstrate the presence of a blood clot or noncompressibility of the affected veins proximal to the site of occlusion. Duplex ultrasonography has greater sensitivity in detecting proximal DVT (90% to 100%) than distal DVT (40% to 90%) of the lower extremities. With upper-extremity DVT, acoustic shadowing of the clavicle may obscure detection of thrombosis in subclavian vein segments. MR angiography is particularly helpful in making the diagnosis of upper-extremity DVT and pelvic vein thrombosis. Contrast venography is the conventional "gold standard" test, but it is invasive and technically difficult in patients with edematous extremities. Therefore, invasive venography should be

reserved for patients in whom the clinical suggestion is high despite negative or inconclusive results from noninvasive imaging.

Patients with proximal lower-extremity DVT and those with upper-extremity DVT should be treated initially with subcutaneous low-molecular-weight heparin (LMWH), intravenous or subcutaneous unfractionated heparin (UFH) or the subcutaneous selective factor Xa inhibitor fondaparinux to prevent thrombus propagation and to maintain the patency of venous collaterals (level A evidence). Intravenous UFH should be given as a bolus, followed by continuous infusion to maintain an activated partial thromboplastin time of at least 1.5 times the control value. Both LMWH and fondaparinux have a longer half-life than UFH and can be given once or twice daily with similar efficacy. Oral warfarin should be initiated together with LMWH, UFH, or fondaparinux without delay and titrated until the international normalized ratio (INR) reaches a value between 2 and 3. Alternatively, rivaroxaban, an oral factor Xa inhibitor, may be used without initial parenteral anticoagulation and continued for at least 3 months. Direct thrombin inhibitors such as dabigatran have been shown to be efficacious in this clinical setting and were recently approved for treatment of DVT and pulmonary embolism in the United States. When DVT is confined to the calf, the risk of PE is low, and the risk-to-benefit ratio of anticoagulation remains controversial.

When upper-extremity DVT occurs in young patients who are otherwise healthy, two invasive approaches to thrombus removal should be considered: infusion of a fibrinolytic drug through a catheter inserted directly into the affected vein and mechanical fragmentation of the thrombus via catheter-based technology. The purpose of these invasive procedures is to prevent or minimize the post-thrombotic syndrome, which includes chronic arm pain, swelling, hyperpigmentation, and ulceration from residual venous obstruction.

Catheter-based placement of a filter in the inferior vena cava should be considered for patients with proximal DVT who either have an absolute contraindication to anticoagulation or develop recurrent PE despite an adequate trial of anticoagulation. Vena cava filters are effective in reducing the incidence of PE, but they increase the risk of recurrent DVT. Some proximal or distal migration of the filter occurs in up to 50% of cases; however, clinically evident filter embolization is limited to case reports.

Pulmonary Embolism

PE occurs when a thrombus dislodges from the deep veins of the upper or lower extremities and travels to the lungs. Pulmonary vascular resistance and pulmonary arterial pressure increase from two mechanisms: anatomic reduction in cross-sectional area of the pulmonary vascular bed and functional hypoxia-induced pulmonary vasoconstriction. The pressure overload on the right ventricle can lead to dilation, hypokinesis, and tricuspid regurgitation. Elevated right ventricular end-diastolic pressure, if severe, can compress the right coronary artery, causing subendocardial ischemia. In acute PE, areas of lung tissue are ventilated but underperfused. This \dot{V}/\dot{Q} mismatch and the resultant redistribution of pulmonary blood flow from the obstructed pulmonary artery to other lung regions with lower \dot{V}/\dot{Q} ratios cause arterial hypoxemia. In patients with a patent foramen ovale, hypoxemia

worsens when the sudden elevation in right atrial pressure causes right-to-left shunting across the foramen.

The classic symptoms of acute PE are sudden onset of dyspnea and pleuritic chest pain. Additional symptoms include anginal chest pain from right ventricular ischemia, hemoptysis from pulmonary infarction, and syncope or presyncope from massive PE with acute right ventricular failure (*cor pulmonale*). The most common physical findings are tachypnea and tachycardia. Additional physical findings include a right ventricular lift, inspiratory crackles, a loud pulmonary component of the second heart sound, expiratory wheezing, and a pleural rub. Symptoms and signs of proximal DVT are present in 10% to 20% of patients. Arterial blood gas analysis often reveals hypoxemia, respiratory alkalosis, and a high alveolar-to-arterial oxygen tension gradient. However, normal arterial blood gas values do not exclude the diagnosis.

The most common finding with ECG analysis is sinus tachycardia. Atrial fibrillation, premature atrial contraction, and supraventricular tachycardia are less common. Other ECG changes suggest acute right ventricular strain. These include the S1-Q3-T3 pattern, a new right bundle branch block or right axis deviation, and P-wave pulmonale. However, these findings are present in only 30% of patients even with massive PE. Common but nonspecific abnormalities on chest radiographic studies include atelectasis, pleural effusion, and pulmonary infiltrates. Less common but more specific radiographic findings include Hampton's hump (i.e., wedge-shaped infiltrate in the peripheral lung field), which is indicative of pulmonary infarction, and Westermarck's sign (decreased vascularity).

The plasma D-dimer level is elevated in most patients with PE as a result of activation of the endogenous fibrinolytic system, which is not sufficient to dissolve the clot. Commercially available D-dimer assays have a high sensitivity and negative predictive value but low specificity. Therefore, a normal D-dimer test effectively excludes the diagnosis of PE in patients in whom the clinical suggestion is low or intermediate, but the should not be used to screen patients with high index of suspicion because of the low negative predictive value. Elevated levels of cardiac troponin I and troponin T and other markers of myocardial injury can be found in patients with PE and are indicative of right ventricular dysfunction and a poor prognosis. Similarly, elevated natriuretic peptides, including brain natriuretic peptide (BNP) and N-terminal pro-BNP, have been shown to be predictive of adverse outcomes. In patients with suspected PE, a completely normal \dot{V}/\dot{Q} scan effectively excludes the diagnosis without further testing. However, fewer than 10% of \dot{V}/\dot{Q} scans are interpreted as definitively normal. In patients in whom a moderate or high level of clinical probability of PE exists, a high-probability \dot{V}/\dot{Q} scan has a diagnostic accuracy of 90% to 100%; however, a low or intermediate probability scan is no more helpful than a coin flip.

More recently, multidetector CT angiography has become the imaging modality of choice in patients with acute PE because of its excellent visualization of the pulmonary artery (Fig. 12-5). The resolution of 1 mm or less rivals that of conventional invasive angiography. The speed of newer-generation scanners allows acquisition of all images within a single breath-hold, avoiding respiratory motion artifacts. The overall negative predictive value

FIGURE 12-5 Spiral chest computed tomographic angiogram shows a large thrombus in the right main pulmonary artery (arrow). (Courtesy Michael Landay, MD, Department of Radiology, University of Texas Southwestern Medical Center, Dallas, Tex.)

of multidetector CT angiography exceeds 99%. A negative CT scan excludes the diagnosis of PE and eliminates the need for further diagnostic testing. The CT scan also permits detection of other pathologic conditions involving the lung parenchyma, pleura, and mediastinal structures. Such pathologic findings may mimic PE and constitute alternative causes of chest pain and dyspnea. Multidetector CT angiography is not yet available at all centers. The requirement for intravenous injection of iodinated contrast material restricts its applicability to those without a history of kidney disease or an allergic reaction to contrast dye.

Figure 12-6 presents an algorithm for the work-up of PE based on current evidence. Echocardiography may directly detect thrombi in the right atrium, right ventricle, or pulmonary artery or may indirectly demonstrate right ventricular dysfunction, signifying the presence of hemodynamically significant emboli. Therefore, it is helpful in diagnosis of PE in patients with hypotension or shock, particularly if multidetector CT is not immediately available. Invasive pulmonary angiography should be reserved for patients for whom noninvasive testing is inconclusive.

Treatment of acute PE includes immediate anticoagulation with UFH, LMWH, or fondaparinux (level A evidence). LMWH and fondaparinux are preferred agents in patients with normal renal function because of the ease of subcutaneous administration and their lower rates of thrombocytopenia. These drugs are excreted by the kidney, so they should be avoided in patients with renal failure, and intravenous UFH should be used instead. Thrombolytic therapy with recombinant tissue-type plasminogen activator (rt-PA) is indicated for patients with either (1) hypotension or shock or (2) right ventricular enlargement or dysfunction from massive PE (level B evidence). Surgical or percutaneous removal of emboli should be considered in patients with massive PE who have contraindications for thrombolytic therapy. After initiation of heparin or fondaparinux, warfarin should be administered. Infusion of heparin or fondaparinux needs to be continued for at least the first 5 days of warfarin therapy until a therapeutic INR of 2 to 3 is reached. Oral rivaroxaban without initial treatment with heparin or fondaparinux is an alternative strategy and is considered to be another option for

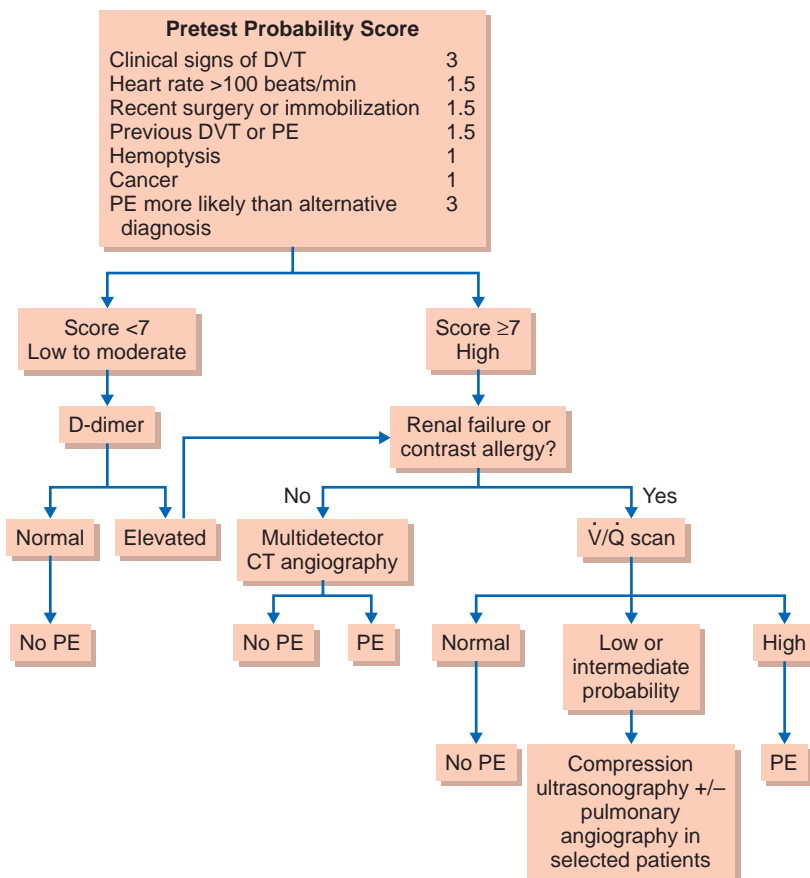

FIGURE 12-6 Diagnostic algorithm for patients with suggested pulmonary embolism (PE). CT, Computed tomographic; DVT, deep vein thrombosis; V/Q scan, ventilation-perfusion scan.

patients with advanced chronic kidney disease, in whom LMWH use is generally prohibited.

The time for which anticoagulation should be continued after an acute PE or DVT episode depends on the presence of reversible risk factors for recurrent VTE. Patients with a history of trauma or surgery typically have a low rate of recurrent VTE; therefore, warfarin can be discontinued after 3 months of administration. Patients with cancer and VTE should be treated initially with subcutaneous fixed-dose LMWH for 3 to 6 months because of the greater efficacy of LMWH compared with warfarin in preventing recurrent thromboembolism in this setting. After this initial period, treatment with LMWH or warfarin should be continued indefinitely unless the cancer is cured. Patients with idiopathic VTE and a low risk of bleeding should be treated with warfarin for longer than 3 months, whereas those with high bleeding risk should remain on treatment for at least 3 months. Beyond the 3- to 6-month period, aspirin is an alternative to long-term warfarin and should be considered for patients who have contraindications for anticoagulation or high bleeding risk.

Venous Thromboembolism Prophylaxis

Patients who are at high risk for VTE should receive prophylaxis with subcutaneous UFH or LMWH. Patients at high risk include those who are hospitalized with acute medical illness (particularly congestive heart failure, acute respiratory illness, or acute inflammatory disease), those who are expected to be immobilized for 3 days or longer, and patients with previous VTE. Major surgery, either elective or emergent, is an important indication for VTE prophylaxis.

Subcutaneous UFH is as effective as LMWH and fondaparinux in preventing symptomatic DVT in patients undergoing general surgery, gynecologic surgery, or neurosurgery. However, LMWH, fondaparinux, and warfarin (dose-adjusted to an INR between 2 and 3) are preferred to UFH for prevention of DVT in cases of orthopedic surgery such as hip surgery or total knee replacement because their superior efficacy in this setting (level A evidence). More recently, rivaroxaban has been approved by the U.S. Food and Drug Administration for prevention of VTE after knee or hip surgery; it has a higher efficacy than LMWH in reducing risks without increasing perioperative bleeding. DVT prophylaxis should be continued for 10 to 14 days after knee surgery and for 35 days after hip surgery. Patients undergoing major cancer surgery should receive continued prophylaxis after discharge up to 28 days. Mechanical prophylaxis with intermittent pneumatic compression provides additional protection from VTE and should be administered to all surgical patients whenever possible.

ARTERIAL HYPERTENSION

Arterial hypertension affects almost one third of the adult population—75 million people in the United States and 1 billion worldwide. It is the leading cause of death in the world, the most common cause for an outpatient visit to a physician, and the most easily recognized treatable risk factor for stroke, myocardial infarction, heart failure, peripheral vascular disease, aortic dissection, atrial fibrillation, and end-stage kidney disease. Despite this knowledge and unequivocal scientific proof that treating hypertension with medication dramatically reduces its

attendant morbidity and mortality, hypertension remains untreated or undertreated in the majority of affected individuals in all countries, including those with the most advanced systems of medical care. Currently, fewer than one in two Americans with hypertension have their BP treated and controlled to below 140/90 mm Hg. For this reason, hypertension remains one of the world's great public health problems. The asymptomatic nature of the condition impedes early detection, which requires regular BP measurement. Because most cases of hypertension cannot be cured, BP control requires lifelong treatment with prescription medications, which can be costly and may cause more symptoms than the underlying disease process. Effective hypertension management requires continuity of care by a regular and knowledgeable medical provider as well as sustained active participation by an educated patient. This section reviews the most important principles in the early detection and effective treatment of hypertension.

Initial Evaluation for Hypertension

The initial evaluation for hypertension needs to accomplish three goals: staging of BP, assessing the patient's overall cardiovascular risk, and detecting clues of secondary hypertension. The initial clinical data needed to accomplish these goals are obtained through a thorough history and physical examination, routine blood tests, a spot (preferably first morning) urine specimen, and a resting 12-lead ECG. Home BP monitoring is indicated in most patients to confirm the diagnosis of hypertension and to exclude the so-called white coat syndrome. In some cases, 24-hour ambulatory BP monitoring and an echocardiogram provide helpful additional data about the time-integral burden of BP on the cardiovascular system.

Goal 1: Accurate Assessment of Blood Pressure

Across populations, the risks of heart disease and stroke increase continuously and logarithmically with increasing systolic and

diastolic BP levels of 115/75 mm Hg or higher (Fig. 12-7). Therefore, the dichotomous separation of *normal* from *high* BP is artificial. BP is currently staged as normal, prehypertension, or hypertension based on the average of two or more readings taken at two or more office visits. When a patient's average systolic and diastolic pressures fall into different stages, the higher stage applies (Table 12-4).

Prehypertension is defined as BP levels in the range of 120 to 139 mm Hg systolic and 80 to 89 mm Hg diastolic. Prehypertensive individuals are twice as likely to progress to hypertension as are those with lower values.

BP normally varies dramatically throughout a 24-hour period. To minimize variability in readings, BP should be measured at least twice after 5 minutes of rest with the patient seated, the back supported, and the arm bare and at heart level. The most common mistake in measuring BP is using a standard-issue cuff that is too small for a large arm, producing spuriously elevated readings. Most overweight adults require a large adult cuff. Tobacco and caffeine should be avoided for at least 30 minutes. To avoid underestimation of systolic pressure in older adults who may have an *auscultatory gap* as a result of arteriosclerosis, radial artery palpation should be performed first to estimate systolic pressure. The cuff should be inflated to a value 20 mm Hg higher than the

TABLE 12-4 STAGING OF OFFICE BLOOD PRESSURE*

BLOOD PRESSURE STAGE	SYSTOLIC BLOOD PRESSURE (MM HG)	DIASTOLIC BLOOD PRESSURE (MM HG)
Normal	<120	<80
Prehypertension	120-139	80-89
Stage 1 hypertension	140-159	90-99
Stage 2 hypertension	≥160	≥100

From Chobanian AV, Bakris GL, Black HR, et al: The seventh report of the Joint National Committee on the Prevention, Evaluation, and Treatment of High Blood Pressure: the JNC 7 report, JAMA 289:2560-2572, 2003.

*Calculation of seated blood pressure is based on the mean of two or more readings on two separate office visits.

FIGURE 12-7 Floating absolute risk of coronary artery disease and stroke mortality by usual systolic blood pressure (BP) levels. CI, Confidence interval. (From Lewington S, Clarke R, Qizilbash N, et al: Age-specific relevance of usual blood pressure to vascular mortality: a meta-analysis of individual data for one million adults in 61 prospective studies, Lancet 360:1903-1913, 2002.)

level that obliterates the radial pulse and then deflated at a rate of 3 to 5 mm Hg per second. BP should be measured in both arms and after 5 minutes of standing, the latter to exclude a significant postural fall in BP, particularly in older persons and in those with diabetes or other conditions (e.g., Parkinson's disease) that predispose the patient to autonomic insufficiency.

However, out-of-office readings either obtained by home or ambulatory BP monitoring are required to accurately assess a person's typical BP. Because of the anxiety of going to the physician, BPs often are higher in the physician's office than when measured at home or during normal daily life outside the home. Self-monitoring of BP outside the physician's office actively engages a patient in his or her own health care and provides a better estimate of the usual BP for medical decision making. BP should be measured in the early morning and in the evening. Three BP readings should be obtained during each measurement, separated by at least 1 minute. Because the first BP measurement tends to be the highest, average BP should be used to assess home BP levels. Many electronic home monitors are available, but only a handful of models have been rigorously validated against mercury sphygmomanometry and can be recommended.

Ambulatory monitoring provides automated measurements of BP over a 24- or 48-hour period while patients are engaged in their usual activities, including sleep (Fig. 12-8). With ambulatory monitoring, current recommendations for *upper limits of normal* are a mean daytime BP of less than 135/85 mm Hg, a mean nighttime BP of 120/70 mm Hg, and a mean 24-hour BP of less than 130/80 mm Hg. However, an *optimal* mean daytime ambulatory BP is lower, less than 130/80 mm Hg. To avoid undertreating hypertension, these lower treatment thresholds must be used when incorporating ambulatory monitoring in medical decision making. With self-monitoring of BP at home, an average value of less than 135/85 mm Hg should be considered the upper limit of normal.

Up to one third of patients with elevated office BP levels have normal home or ambulatory BPs. If the 24-hour BP profile is

completely normal and no target organ damage has occurred despite consistently elevated office readings, then the patient has *office-only*, or *white-coat*, hypertension, presumably the result of a transient adrenergic response to the measurement of BP in the physician's office (see Fig. 12-8).

In other patients, office readings underestimate ambulatory BPs, presumably because of sympathetic overactivity in daily life owing to job or home stress, tobacco abuse, or other adrenergic stimulation that dissipates when coming to the office (Fig. 12-9). Such documentation prevents underdiagnosis and undertreatment of this *masked hypertension*, which is also associated with high cardiovascular risks. Masked hypertension is identified in 10% of all hypertensive patients, in up to 40% of those with diabetes, and in 70% of African American patients with hypertensive kidney disease.

Goal 2: Cardiovascular Risk Stratification

The great majority of patients with BPs in the prehypertensive or hypertensive range have one or more additional modifiable risk factors for atherosclerosis (e.g., hypercholesterolemia, cigarette smoking, diabetes). The patient's global cardiovascular risk should be calculated from the 2013 ACC/AHA pooled atherosclerotic cardiovascular disease (ASCVD) risk calculator (<http://www.cardiosource.org/Science-And-Quality/Practice-Guidelines-and-Quality-Standards/2013-Prevention-Guideline-Tools.aspx>).

Goal 3: Identification of Secondary (Identifiable) Causes of Hypertension

A thorough search for secondary causes is not cost-effective in most patients with hypertension, but it becomes critically important in two circumstances: (1) when a compelling cause is found on the initial evaluation, or (2) when the hypertensive process is so severe that it either is refractory to intensive multiple-drug therapy or necessitates hospitalization. Table 12-5 summarizes the major causes of secondary hypertension that should be

FIGURE 12-8 Twenty-four hour ambulatory blood pressure (BP) monitor tracings in two different patients. **A**, Optimal BP in a healthy 37-year-old woman. The normal variability in BP, the nocturnal dip in BP during sleep, and the sharp increase in BP on awakening are shown. **B**, Pronounced white-coat syndrome in an 80-year-old woman referred for evaluation of medically refractory hypertension. Documentation of the white-coat effect prevented overtreatment of the patient's isolated systolic hypertension.

suggested on the basis of a good history, physical examination, and routine laboratory tests.

Renal Parenchymal Hypertension

Chronic kidney disease is the most common cause of secondary hypertension. Hypertension is present in more than 85% of patients with chronic kidney disease and is a major factor causing their increased cardiovascular morbidity and mortality. The mechanisms causing the hypertension include an expanded

plasma volume and peripheral vasoconstriction, with the latter caused by both activation of vasoconstrictor pathways (renin-angiotensin and sympathetic nervous systems) and inhibition of vasodilator pathways (nitric oxide). Renal insufficiency should be considered when proteinuria is found by dipstick or when the serum creatinine level is greater than 1.2mg/dL in women with hypertension or greater than 1.4 mg/dL in men with hypertension.

Renovascular Hypertension

Unilateral or bilateral renal artery stenosis is present in fewer than 2% of patients with hypertension in a general medical practice but in up to 30% of patients with medically refractory hypertension. The main causes of renal artery stenosis are atherosclerosis (85% of patients), typically in older adults with other clinical manifestations of systemic atherosclerosis, and fibromuscular dysplasia (15% of patients), typically in women between the ages of 15 and 50 years. Unilateral renal artery stenosis leads to underperfusion of the juxtaglomerular cells, resulting in renin-dependent hypertension even though the contralateral kidney is able to maintain normal blood volume. In contrast, bilateral renal artery stenosis (or unilateral stenosis with a solitary kidney) constitutes a potentially reversible cause of progressive renal failure and volume-dependent hypertension.

The following clinical clues increase the suggestion of renovascular hypertension: any hospitalization for urgent or emergent hypertension; recurrent *flash* pulmonary edema; recent worsening of long-standing, previously well-controlled hypertension; severe hypertension in a young adult or after 50 years of age; precipitous and progressive worsening of renal function in response to angiotensin-converting enzyme (ACE) inhibition or angiotensin-receptor blockade (ARB); unilateral small kidney by any radiographic study; extensive peripheral arteriosclerosis; or a flank bruit. The diagnosis is confirmed by noninvasive testing with MR or spiral CT angiography (Fig. 12-10).

Renal artery angioplasty often cures fibromuscular dysplasia. Atherosclerotic renal artery stenosis should be treated with intensive medical management of atherosclerotic risk factors (e.g., hypertension, lipids, smoking). Revascularization should be

FIGURE 12-9 Twenty-four hour ambulatory blood pressure (BP) monitor tracing shows both masked hypertension and nocturnal hypertension in a 55-year-old man with stage 3 chronic kidney disease. Treatment with three different antihypertensive medications produced an office BP of 125/75 mm Hg, which seemed to be at goal. However, progressive hypertensive heart disease and deterioration of renal function suggested masked hypertension. Ambulatory monitoring revealed that the patient's treated BP was much higher out of the office, documenting both masked hypertension (ambulatory BP of 175/95 mm Hg) and sustained nocturnal hypertension (BP of 175/90 mm Hg). Additional medication was added. (Courtesy Ronald G. Victor, MD, Hypertension Division, Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, Tex.)

TABLE 12-5 GUIDE TO EVALUATION OF SECONDARY HYPERTENSION

PROBABLE DIAGNOSIS	CLINICAL CLUES	DIAGNOSTIC TESTING
Renal parenchymal hypertension	Estimated GFR <60 mL/min/1.73m ² Urine albumin : creatinine >30 mg/g	Renal ultrasound
Renovascular disease	New elevation in serum creatinine, significant elevation in serum creatinine with initiation of ACEIs or ARBs, refractory hypertension, flash pulmonary edema, abdominal bruit Coarctation of the aorta Arm BP > leg BP	MR or CT angiography, invasive angiogram Arm pulses > leg pulses, chest MR or CT, aortogram
Primary aldosteronism	BP, chest bruits, rib notching on chest radiograph Hypokalemia, refractory hypertension	Plasma renin and aldosterone, 24-hr urine potassium, 24-hr urine aldosterone and potassium after salt loading, adrenal CT scan, adrenal vein sampling
Cushing's syndrome	Truncal obesity, wide and blanching purple striae, muscle weakness, diabetes	24-hr Urine cortisol, dexamethasone suppression test, adrenal CT scan
Pheochromocytoma	Spells of paroxysmal hypertension, palpitations, perspiration, pallor, pain in the head	Plasma and 24-hr urine metanephrines and catecholamines, adrenal CT scan
Obstructive sleep apnea	Loud snoring, daytime somnolence, obesity, large neck	Sleep study

considered for medically refractory hypertension, progressive renal failure while on medical therapy, and bilateral renal artery stenosis or stenosis of a solitary functioning kidney.

Primary Aldosteronism

The most common causes of primary aldosteronism are a unilateral aldosterone-producing adenoma and bilateral adrenal hyperplasia. Because aldosterone is the principal ligand for the mineralocorticoid receptor in the distal nephron, excessive aldosterone production causes excessive renal Na^+ - K^+ exchange, often resulting in hypokalemia. The diagnosis should always be suggested when hypertension is accompanied by either unprovoked hypokalemia (serum $\text{K}^+ < 3.5$ mmol/L in the absence of diuretic therapy) or a tendency to develop excessive hypokalemia during diuretic therapy (serum $\text{K}^+ < 3.0$ mmol/L). However, more than one third of patients do not have hypokalemia on initial presentation, and the diagnosis should be considered in any patient with refractory hypertension.

The diagnosis is confirmed by the demonstration of nonsuppressible hyperaldosteronism during salt loading, followed by adrenal vein sampling to distinguish between a unilateral adenoma and bilateral hyperplasia. Laparoscopic adrenalectomy is the treatment of choice for unilateral aldosterone-producing adenoma, whereas pharmacologic mineralocorticoid-receptor blockade with eplerenone is the treatment for bilateral adrenal hyperplasia.

Mendelian Forms of Hypertension

Nine very rare forms of severe early-onset hypertension are inherited as mendelian traits. In each case, the hypertension is mineralocorticoid induced and involves excessive activation of the epithelial sodium channel ($\text{E}_{\text{Na}}\text{C}$), the final common pathway for reabsorption of sodium from the distal nephron. The resultant salt-dependent hypertension can be caused by gain-of-function mutations of $\text{E}_{\text{Na}}\text{C}$ (Liddle's syndrome) or the mineralocorticoid

receptor (a rare form of pregnancy-induced hypertension) or by increased production or decreased clearance of mineralocorticoids including aldosterone (glucocorticoid-remediable aldosteronism), deoxycorticosterone (17-hydroxylase deficiency), and cortisol (syndrome of apparent mineralocorticoid excess). Mutations in the potassium-channel subunit KCNJ5 and in TWIK-related acid-sensitive K^+ channel (TASK) have been linked to familial aldosteronism because they increase aldosterone release or increase proliferation of zona glomerulosa cells.

Pheochromocytoma and Paraganglioma

Pheochromocytomas are rare catecholamine-producing tumors of the adrenal chromaffin cells. Paragangliomas are even rarer extra-adrenal catecholamine-producing or nonfunctional tumors of sympathetic and parasympathetic ganglia. The diagnosis should be suggested when hypertension is accompanied by paroxysms of headaches, palpitations, pallor, or diaphoresis. However, the most common presentation of pheochromocytoma is that of an adrenal incidentaloma—an incidental adrenal mass discovered unexpectedly on abdominal imaging for another indication. In some patients, pheochromocytoma is misdiagnosed as panic disorder. A family history of early-onset hypertension may suggest pheochromocytoma as part of the multiple endocrine neoplasia (MEN) syndromes or familial paraganglioma. If the diagnosis is missed, then outpouring of catecholamines from the tumor can cause an unsuspected hypertensive crisis during unrelated radiologic or surgical procedures; the perioperative mortality rate exceeds 80% in such circumstances.

Laboratory confirmation of pheochromocytoma is made by demonstration of elevated levels of plasma or urinary metanephrines; these are methylated derivatives of norepinephrine and epinephrine that are made in the adrenal medulla and continually leak out into the plasma even between BP spikes. Pheochromocytomas are typically large adrenal tumors that can usually be localized by CT or MR imaging, although nuclear scanning with

specific isotopes that localize to chromaffin tissue is occasionally needed to identify smaller tumors and paragangliomas.

Treatment of these tumors is by surgical resection. Patients must receive adequate preoperative management with α -blockade followed by β -blockade and volume expansion to prevent the hemodynamic swings that can occur during surgical manipulation of the tumor. For unresectable tumors, chronic therapy with the α -adrenergic blocker phenoxybenzamine is usually effective.

Pheochromocytoma is a great masquerader, and the large differential diagnosis includes causes of neurogenic hypertension such as sympathomimetic agents (e.g., cocaine, methamphetamine), baroreflex failure, and obstructive sleep apnea. A history of surgery and radiation therapy for head and neck tumors suggests the possibility of baroreceptor damage. Loud snoring, obesity, and somnolence suggest obstructive sleep apnea. Weight loss, continuous positive airway pressure, and corrective surgery improve BP control in some patients with sleep apnea.

Other causes of secondary hypertension include nonsteroidal anti-inflammatory drugs (NSAIDs), hypothyroidism, hyperthyroidism, coarctation of the aorta, and immunosuppressive drugs, especially cyclosporine and tacrolimus.

TREATMENT OF HYPERTENSION

Prescription medication is the cornerstone for treatment of hypertension. Lifestyle modification should be used as an essential adjunct but not as an alternative to life-saving BP pharmacotherapy. Most dietary sodium comes from processed foods, and daily salt consumption can be reduced from 10 to 6 g by teaching patients to read food labels (6 g of NaCl = 2.4 g of Na⁺ = 100 mmol of Na⁺). The Dietary Approach to Stop Hypertension (DASH) diet, which is rich in fresh fruits and vegetables (for high potassium content) and low-fat dairy products, has been shown to lower BP in feeding trials. Other lifestyle modifications that can lower BP include weight loss in overweight patients with hypertension, regular aerobic exercise, smoking cessation, and moderation in alcohol intake.

The list of drugs marketed for the treatment of hypertension in the United States is shown in Table 12-6. Major contraindications and side effects of these drugs are summarized in Table 12-7. The following sections describe which drugs should be used for which groups of patients.

Patients with Uncomplicated Hypertension

Current guidelines (Figure 12-11) recommend blood pressure goals of less than 150/90 mm Hg for elderly patients and less than 140/90 mm Hg for most other patients. Some experts recommend the goal of less than 140/90 mm Hg in patients older than 60 years if they are not frail and are able to tolerate such treatment without side effects. Multiple guidelines recommend initiating drug treatment with one or more of three classes of first-line drugs, which have additive or synergistic effects when used in combination: (1) CCBs, (2) renin-angiotensin system blockers—either ACE inhibitors or ARBs, and (3) thiazide diuretics.

The European Society of Hypertension makes no specific drug class recommendation, arguing that the most effective drugs are those that the patient can tolerate and will take. Long-term

patient adherence is best with an ARB, intermediate with an ACEI or CCB, and worst with a thiazide. The British Hypertension Society advocates a treatment strategy that is based on the patient's age and ethnicity. It recommends initiating therapy with an ACEI or ARB for younger white patients (<55 years of age), who often have high-renin hypertension, but a CCB or diuretic for older and black patients, who often have low-renin hypertension.

A growing body of evidence from clinical trials emphasizes the overriding importance of lowering BP with combinations of drugs rather than belaboring the choice of a single, best agent to begin therapy. Primary hypertension is multifactorial, and typically several medications with different mechanisms of action (see Table 12-4) are required simultaneously to reach the BP goal. In most patients with hypertension, low-dose combination drug therapy is the only way to control BP adequately while minimizing side effects. With many classes of antihypertensive medications, the dose-response relationship for BP is rather flat. Most of the BP lowering occurs at the lower end of the dose range. However, many of the side effects are steeply dose dependent, becoming problematic mainly at the high end of the clinical dose range. Therefore, low-dose combinations achieve therapeutic synergy and minimize side effects. Fixed-dose combinations reduce pill burden and cost.

One highly effective, well-tolerated combination is a CCB plus an ACEI or ARB. A recent clinical trial demonstrated a large benefit of combination therapy with an ACEI plus a dihydropyridine CCB, compared with the combination of an ACEI plus a thiazide diuretic, in reducing cardiovascular events in high-risk patients (level A evidence). In contrast, the combination of an ARB plus an ACEI (“dual renin-angiotensin system blockade”) should be avoided because it results in deterioration of renal function and increases the risk of hypotension without added cardiovascular benefit (level A evidence).

Kaiser-Permanente of Northern California, a large managed care organization, has increased the control of hypertension among its membership over the last decade from 44% to an astounding 80% by increasing access through walk-in BP checks by medical assistants, establishing registry rounds to identify and contact patients with elevated office BP, and instituting a system-wide simple medication treatment protocol that features once-daily combination therapy.

Along with antihypertensive medication, lipid-lowering medication should be strongly considered as an integral part of most antihypertensive regimens. A sizeable cardiovascular benefit of adding 10 mg of the HMG-CoA reductase inhibitor atorvastatin to antihypertensive therapy was demonstrated in patients older than 60 years of age who had moderate hypertension and an average LDL-cholesterol level of only 130 mg/dL (level A evidence).

Hypertension in African Americans

Hypertension disproportionately affects African Americans. The explanation is unknown, but the dominant importance of environmental factors is indicated by geographic variation in hypertension prevalence among African-origin and European-origin populations. Hypertension is rare among Africans living in Africa and is more prevalent in several European countries than it is in

TABLE 12-6 ORAL ANTIHYPERTENSIVE AGENTS

DRUG	DOSE RANGE, TOTAL (MG/DAY)	DOSES PER DAY	DRUG	DOSE RANGE, TOTAL (MG/DAY)	DOSES PER DAY
DIURETICS			ANGIOTENSIN-RECEPTOR BLOCKERS		
Thiazide Diuretics			Azilsartan	40-80	1
Hydrochlorothiazide (HCTZ)	6.25-50	1	Candesartan	8-32	1
Chlorthalidone	6.25-25	1	Eprosartan	400-800	1-2
Indapamide	1.25-5	1	Irbesartan	150-300	1
Metolazone	2.5-5	1	Losartan	25-100	2

TABLE 12-7 MAJOR CONTRAINDICATIONS AND SIDE EFFECTS OF ANTIHYPERTENSIVE DRUGS

DRUG CLASS	MAJOR CONTRAINDICATIONS	SIDE EFFECTS
DIURETICS		
Thiazides	Gout	Insulin resistance, new-onset type 2 diabetes (especially in combination with β -blockers) Hypokalemia, hyponatremia Hypertriglyceridemia Hyperuricemia, precipitation of gout Erectile dysfunction (more than other drug classes) Potentiate nondepolarizing muscle relaxants Photosensitive dermatitis
Loop diuretics	Hepatic coma	Interstitial nephritis Hypokalemia Potentiate succinylcholine Potentiate aminoglycoside ototoxicity
Potassium-sparing diuretics	Serum K >5.5 mEq/L GFR <30 mg/mL/1.73 m ²	Fatal hyperkalemia if used with salt substitutes, ACEIs, ARBs, high-potassium foods, NSAIDs
β -Blockers	Heart block Asthma Depression Cocaine and/or methamphetamine abuse	Insulin resistance, new-onset type 2 diabetes (especially in combination with thiazides) Heart block, acute decompensated CHF Bronchospasm Depression, nightmares, fatigue Cold extremities, claudication (β_2 effect) Stevens-Johnson syndrome Agranulocytosis
ACEIs	Pregnancy Bilateral renal artery stenosis Hyperkalemia	Cough Hyperkalemia Angioedema Leukopenia Fetal toxicity Cholestatic jaundice (rare fulminant hepatic necrosis if the drug is not discontinued)
ARBs	Pregnancy Bilateral renal artery stenosis Hyperkalemia	Hyperkalemia Angioedema (very rare) Fetal toxicity
Direct renin inhibitors	Pregnancy Bilateral renal artery stenosis Hyperkalemia	Hyperkalemia Diarrhea
Dihydropyridine CCBs	As monotherapy in chronic kidney disease with proteinuria	Fetal toxicity Headaches Flushing Ankle edema CHF Gingival hyperplasia Esophageal reflux
Nondihydropyridine CCBs	Heart block Systolic heart failure	Bradycardia, atrioventricular block (especially with verapamil) Constipation (often severe with verapamil) Worsening of systolic function, CHF Gingival edema and/or hypertrophy Increase cyclosporine blood levels Esophageal reflux
α -Blockers	Monotherapy for hypertension Orthostatic hypotension Systolic heart failure Left ventricular dysfunction	Orthostatic hypotension Drug tolerance (in the absence of diuretic therapy) Ankle edema CHF First-dose effect (acute hypotension) Potentiate hypotension with PDE5 inhibitors (e.g., sildenafil)
Central sympatholytics	Orthostatic hypotension	Depression, dry mouth, lethargy Erectile dysfunction (dose dependent) Rebound hypertension with clonidine withdrawal Coombs-positive hemolytic anemia and elevated LFTs with α -methyldopa
Direct vasodilators	Orthostatic hypotension	Reflex tachycardia Fluid retention Hirsutism, pericardial effusion with minoxidil Lupus with hydralazine

ACEIs, Angiotensin-converting enzyme inhibitors; ARBs, angiotensin-receptor blockers; CCBs, calcium-channel blockers; CHF, congestive heart failure; GFR, glomerular filtration rate; LFTs, liver function tests; MI, myocardial infarction; NSAIDs, nonsteroidal anti-inflammatory drugs; PDE5, phosphodiesterase type 5.

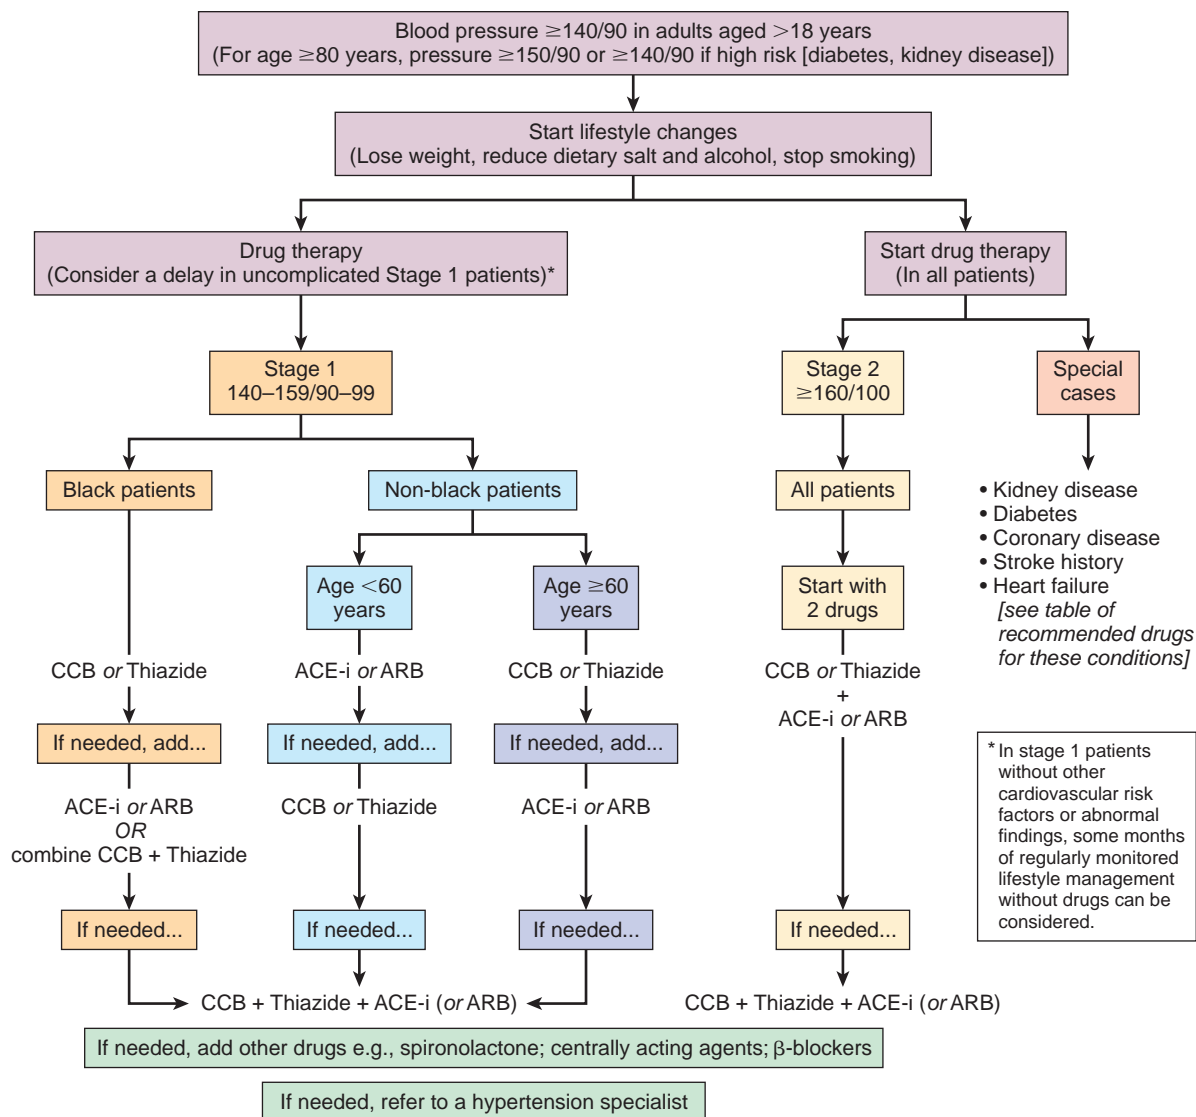

FIGURE 12-11 2014 Hypertension Management Algorithm Recommended by the American Society of Hypertension and the International Society of Hypertension. At any stage it is entirely appropriate to seek help from a hypertension expert if treatment is proving difficult. In patients with stage 1 hypertension in whom there is no history of cardiovascular, stroke, or renal events or evidence of abnormal findings and who do not have diabetes or other major risk factors, drug therapy can be delayed for a short trial of lifestyle modification; however, most patients will require medication to achieve recommended blood pressure targets. In all other patients (including those with stage 2 hypertension), it is recommended that drug therapy be started as soon as the diagnosis of hypertension is made. Blood pressure values are in mm Hg. ACE-i, Angiotensin-converting enzyme inhibitors; ARB, angiotensin receptor blocker; CCB, calcium channel blocker; thiazide, thiazide or thiazide-like diuretics. (From Weber MA, Schiffrin EL, White WB et al: Clinical practice guidelines for the management of hypertension in the community. A statement by the American Society of Hypertension and the International Society of Hypertension, *J Clin Hypertens* 16:14–26, 2014.)

the United States. As monotherapy for hypertension, an ACEI (or ARB) typically yields a smaller decrease in BP in an African American patient than it does in a non-African American patient and therefore affords less protection against stroke. However, when an ACEI or ARB is used in combination with a CCB or a diuretic, antihypertensive efficacy is amplified and ethnic differences disappear. When used as part of an appropriate multidrug regimen, an ACEI-based treatment can achieve excellent control of hypertension in African American patients with hypertensive nephrosclerosis, and it slows the deterioration in renal function.

Hypertensive Nephrosclerosis

Hypertension is the second most common cause of chronic kidney disease, accounting for more than 25% of cases.

Hypertensive nephrosclerosis is the result of persistently uncontrolled hypertension causing chronic glomerular ischemia. Typically, proteinuria is mild (<0.5 g/24 hours). Nondiabetic chronic kidney disease is a compelling indication for ACEI-based or ARB-based antihypertensive therapy. ACEIs cause greater dilation of the efferent renal arterioles, thereby minimizing intraglomerular hypertension. In contrast, arterial vasodilators such as dihydropyridine CCBs, when used without an ACEI or ARB, preferentially dilate the afferent arteriole and impair renal autoregulation. Glomerular hypertension can result if the systemic BP is not sufficiently lowered. The ACEI should be withdrawn only if the rise in serum creatinine exceeds 30% of the baseline value or the serum potassium level increases to greater than 5.6 mmol/L.

Hypertensive Patients with Diabetes

Compared with its 25% prevalence in the general adult population, hypertension is present in 75% of patients with diabetes and is a major factor contributing to excessive risk of myocardial infarction, stroke, heart failure, microvascular complications, and diabetic nephropathy progressing to end-stage renal disease. The Action to Control Cardiovascular Risk in Diabetes blood pressure trial (ACCORD BP) failed to show reduced overall mortality or cardiovascular mortality from lowering the systolic BP to less than 120 mm Hg in patients with type 2 diabetes mellitus. However, the risk of stroke was reduced by 60% in these patients. The findings from the ACCORD trial have led to revised European and British hypertension guidelines increasing the target BP goal from 130/80 mm Hg to 140/90 mm Hg in most diabetic patients. However, the benefits of lowering systolic BP to less than 130 mm Hg in reducing the risk of stroke in diabetics and nondiabetic patients with high cardiovascular risks remains to be further determined. An ACEI or ARB plus a CCB is an excellent combination to treat hypertension in patients with diabetes. Thiazide diuretics and standard β -blockers exacerbate glucose intolerance, whereas the vasodilating β -blockers such as carvedilol and nebivolol have neutral or possibly beneficial effects.

Hypertensive Patients with Coronary Artery Disease

To lower myocardial oxygen demands in patients with coronary artery disease, the antihypertensive regimen should reduce BP without causing reflex tachycardia. For this reason, a β -blocker is often prescribed in conjunction with a dihydropyridine CCB such as amlodipine. β -Blockers are indicated for patients with hypertension who have sustained a myocardial infarction and for most patients with chronic heart failure. ACEIs are indicated for almost all patients with left ventricular systolic dysfunction and may be considered after myocardial infarction even in the absence

of ventricular dysfunction. Among patients with stable coronary artery disease, a cardioprotective effect of ACE inhibition has also been demonstrated in those with moderate cardiovascular risk profiles but not in those with lower risk profiles.

Isolated Systolic Hypertension in Older Adults

In developed countries, systolic pressure rises progressively with age; if individuals live long enough, then almost all (>90%) develop hypertension. Diastolic pressure rises until the age of 50 years and decreases thereafter, producing a progressive rise in pulse pressure (i.e., systolic pressure minus diastolic pressure) (Fig. 12-12).

Different hemodynamic faults underlie hypertension in younger and older persons. Patients who develop hypertension before 50 years of age typically have *combined systolic and diastolic hypertension*: systolic pressure greater than 140 mm Hg and diastolic pressure greater than 90 mm Hg. The main hemodynamic fault is vasoconstriction at the level of the resistance arterioles. In contrast, most patients who develop hypertension after 50 years of age have *isolated systolic hypertension*: systolic pressure greater than 140 mm Hg but diastolic pressure lower than 90 mm Hg (often <80 mm Hg). In isolated systolic hypertension, the primary hemodynamic fault is decreased distensibility of the aorta and other large conduit arteries (see Fig. 12-12). Collagen replaces elastin in the elastic lamina of the aorta, an age-dependent process that is accelerated by atherosclerosis and hypertension. The cardiovascular risk associated with isolated systolic hypertension is related to pulsatility, the repetitive pounding of the blood vessels with each cardiac cycle and a more rapid return of the arterial pulse wave from the periphery, both begetting more systolic hypertension. In the United States and Europe, the majority of uncontrolled hypertension occurs in older patients with isolated systolic hypertension. A BP of 160/60 mm Hg (pulse pressure, 100 mm Hg) carries twice the

FIGURE 12-12 Age-dependent changes in systolic and diastolic blood pressure in the United States (left). Schematic diagram explains the relation between aortic compliance and pulse pressure (right). (Left, From Burt V, Whelton P, Rocella EJ, et al: Prevalence of hypertension in the U.S. adult population: results from the Third National Health and Nutrition Examination Survey, 1988–1991, *Hypertension* 25:305–313, 1995; Right, Courtesy Dr. Stanley Franklin, University of California, Irvine, Calif.)

FIGURE 12-13 Joint influences of systolic blood pressure (BP) and diastolic BP on the risk of fatal coronary heart disease in the Multiple Risk Factor Intervention Trial. (Neaton JD, Wentworth D: Serum cholesterol, blood pressure, cigarette smoking, and death from coronary heart disease: overall findings and differences by age for 316,099 white men, *Arch Intern Med* 152:56–64, 1992.)

risk of fatal coronary heart disease as a BP of 140/110 mm Hg (pulse pressure, 30 mm Hg) (Fig. 12-13).

In older persons with isolated systolic hypertension, lowering the systolic pressure from more than 160 to less than 150 mm Hg reduces the risks of stroke, myocardial infarction, and overall cardiovascular mortality; it also reduces heart failure admissions and slows the progression of dementia (level A evidence). Trial data do not yet exist in older persons to determine whether treatment of isolated elevations in systolic pressure below 140 mm Hg is beneficial. However, in the absence of such data, treatment may be warranted to prevent progression of systolic hypertension, if the patient can tolerate the treatment without side effects such as orthostatic hypotension.

The combination of a low-dose thiazide diuretic with a dihydropyridine CCB or an ACEI reduces the risk of cardiovascular events in older patients with isolated systolic hypertension (level A evidence). To prevent orthostatic hypotension, medication should be titrated to standing BP, and one low-dose medication should be started at a time.

Blood Pressure Lowering for Secondary Prevention of Stroke

Most neurologists do not recommend BP reduction during an acute stroke. After the acute phase, BP should be lowered with a thiazide diuretic, and an ACEI or additional drugs should be added as needed to achieve BP levels lower than 140/90 mm Hg; whether BP should be lowered further is unclear.

Hypertensive Disorders of Women

Oral contraceptives cause a small increase in BP in most women but rarely cause a large increase into the hypertensive range. If hypertension develops, oral contraceptive therapy should be

discontinued in favor of other methods of contraception. Oral estrogen replacement therapy seems to cause a small increase in BP. In contrast, transdermal estrogen (which bypasses first-pass hepatic metabolism) seems to cause a small but consistent decrease in BP.

Hypertension, the most common nonobstetric complication of pregnancy, is present in 10% of all pregnant women. One third of these cases are caused by chronic hypertension, and two thirds are caused by preeclampsia, which is defined as an increase in BP to 160/110 mm Hg or greater after the 20th week of gestation accompanied by proteinuria (>300 mg/24 hours) and pathologic edema, sometimes accompanied by seizures (eclampsia) and the multisystem HELLP syndrome of hemolysis (H), elevated liver enzymes (EL), and low platelets (LP). Oral drug therapy should be initiated with any one of three preferred drugs: labetalol (400 to 2400 mg daily). Intravenous labetalol (0.5 to 2 mg/minute up to a cumulative dose of 300 mg) has replaced hydralazine as the drug of choice to treat severe preeclampsia/eclampsia.

Resistant Hypertension

Resistant hypertension, defined as persistence of usual BP above 140/90 mm Hg despite treatment with full doses of three or more different classes of medications in rational combination and including a diuretic, is the most common reason for referral to a hypertension specialist. In practice, most of these patients have pseudoresistant hypertension due to (1) *white-coat aggravation*, a white-coat reaction superimposed on chronic hypertension that is well controlled with medication outside the physician's office; (2) an inadequate medical regimen; (3) nonadherence; or (4) ingestion of pressor substances. Common shortcomings of the medical regimen include undertreatment of hypertension with monotherapy and use of clonidine, a potent central sympatholytic that causes rebound hypertension between doses particularly, with PRN dosing. Several common causes of pseudoresistant hypertension are related to the patient's behavior, including medication nonadherence, recidivism with lifestyle modification (e.g., obesity, high-salt diet, excessive alcohol intake), and habitual use of pressor substances such as sympathomimetics (e.g., tobacco, cocaine, methamphetamine, phenylephrine-containing cold or herbal remedies) or NSAIDs, with the latter causing renal sodium retention. Once these behavioral factors have been excluded, the search should begin for causes of secondary hypertension.

The most common forms of secondary hypertension are chronic kidney disease and primary aldosteronism. Significant impairment in renal function can be present with serum creatinine in the range of 1.2 to 1.4 mg/dL or even lower, particularly in older patients with little muscle mass. To avoid this pitfall, calculation of the glomerular filtration rate (GFR) by equations based on serum creatinine, age, weight, and measurement of the urinary albumin-to-creatinine ratio from a spot-urine specimen should be an essential part of the routine evaluation of every patient with hypertension. Either a loop diuretic (e.g., a furosemide) or a potent thiazide-type diuretic (e.g., chlorthalidone) may be required to control hypertension in patients with chronic kidney disease. The treatment of primary aldosteronism was discussed earlier.

After exclusion of pseudoresistant hypertension and secondary hypertension, some patients have severe drug-resistant primary hypertension. Fourth- and fifth-line therapies include a vasodilating β -blocker and spironolactone (even in the absence of primary aldosteronism). Percutaneous catheter-based renal denervation is being investigated as a novel interventional approach to treat drug-resistant hypertension.

Acute Severe Hypertension

Of all the patients in the emergency department, 25% have an elevated BP. *Hypertensive emergencies* are acute, often severe, elevations in BP that are accompanied by acute or rapidly progressive target-organ dysfunction such as myocardial or cerebral ischemia or infarction, pulmonary edema, or renal failure. *Hypertensive urgencies* are severe elevations in BP without severe symptoms and without evidence of acute or progressive target-organ dysfunction. The key distinction and approach to the patient depends on the state of the patient and the assessment of target-organ damage, not simply the absolute level of BP. The full-blown clinical picture of a hypertensive emergency is a critically ill patient with a BP greater than 220/140 mm Hg, headaches, confusion, blurred vision, nausea and vomiting, seizures, heart failure, oliguria, and grade III or IV hypertensive retinopathy (Fig. 12-14).

Hypertensive emergencies require immediate admission in an intensive care unit for intravenous therapy and continuous BP monitoring, whereas hypertensive urgencies can often be managed with oral medications and appropriate outpatient follow-up in 24 to 72 hours. The most common hypertensive cardiac emergencies are acute aortic dissection, hypertension after coronary artery bypass grafting, acute myocardial infarction, and unstable angina. Other hypertensive emergencies include eclampsia, head trauma, severe body burns, postoperative bleeding from vascular suture lines, and epistaxis that cannot be controlled with anterior and posterior nasal packing. Neurologic emergencies, which include acute ischemic stroke, hemorrhagic stroke, subarachnoid hemorrhage, and hypertensive encephalopathy, can be difficult to distinguish from one another. Hypertensive encephalopathy is characterized by severe hypertensive retinopathy (i.e., retinal hemorrhages and exudates with or without papilledema) and a posterior leukoencephalopathy affecting mainly the white matter of the parieto-occipital regions as seen on cerebral MR imaging or CT scanning. A new focal neurologic deficit suggests a stroke-in-evolution, which demands a much more conservative approach to correcting the elevated BP.

In most other hypertensive emergencies, the goal of parenteral therapy is to achieve a controlled and gradual lowering of BP. A good rule of thumb is to lower the initially elevated arterial pressure by 10% in the first hour and by an additional 15% over the next 3 to 12 hours to a BP of no less than 160/110 mm Hg. BP can be reduced further over the next 48 hours. Unnecessarily rapid correction of the elevated BP to completely normal values places the patient at high risk for worsening cerebral, cardiac, and renal ischemia. In chronic hypertension, cerebral autoregulation is reset to higher-than-normal BPs. This compensatory adjustment prevents tissue overperfusion (i.e., increased intracranial pressure) at very high BPs, but it also predisposes the patient to

FIGURE 12-14 Hypertensive retinopathy is traditionally divided into four grades. **A**, Grade 1 shows very early and minor changes in a young patient; increased tortuosity of a retinal vessel and increased reflectivity (silver wiring) of a retinal artery are seen at the one o'clock position in this view. Otherwise, the fundus is completely normal. **B**, Grade 2 also shows increased tortuosity and silver wiring (arrowheads). In addition, nipping of the venules at arteriovenous crossings is visible (arrow). **C**, Grade 3 shows the same changes as grade 2 plus flame-shaped retinal hemorrhages and soft cotton-wool exudates. **D**, In grade 4, swelling of the optic disc (papilledema) is observed, retinal edema is present, and hard exudates may collect around the fovea, producing a typical macular star. (From Forbes CD, Jackson WF: Color atlas and text of clinical medicine, ed 3, London, 2003, Mosby.)

tissue underperfusion (i.e., cerebral ischemia) when an elevated BP is lowered too quickly. In certain clinical settings, such as aortic dissection or acute pulmonary edema, more rapid reduction in BP may be required to avoid further propagation of dissection or to minimize myocardial oxygen demand and increase oxygenation. Secondary causes of hypertension should be considered in every patient who is admitted to the intensive care unit with hypertensive crisis.

Parenteral agents for the treatment of hypertensive emergency are summarized in Table 12-8. Intravenous labetalol (a combined α - and β -blocker) is an effective first-line drug for many hypertensive crises, particularly myocardial ischemia with preserved ventricular function. Sodium nitroprusside, a nitric oxide donor, is popular because it can be titrated rapidly to control BP. Intravenous nitroglycerin, another nitric oxide donor, is indicated mainly for hypertension in the setting of acute coronary syndrome or decompensated heart failure. Nicardipine is a parenteral dihydropyridine CCB that is particularly useful in the postoperative cardiac patient and in patients with renal failure to avoid the thiocyanate toxicity with nitroprusside. Urapadil is a new central sympatholytic agent.

TABLE 12-8 INTRAVENOUS DRUGS FOR HYPERTENSIVE EMERGENCIES

DRUG	ONSET OF ACTION	HALF-LIFE	DOSE	CONTRAINDICATIONS AND SIDE-EFFECTS
Labetalol	5-10 min	3-6 hours	0.25-0.5 mg/kg; 2-4 mg/min until goal BP is reached, thereafter 5-20 mg/hr	2nd or 3rd degree AV block; systolic heart failure, COPD (relative); bradycardia
Nicardipine	5-15 min	30-40 min	5-15 mg/hr as continuous infusion, starting dose 5 mg/hr, increase Q 15-30 min with 2.5 mg until goal BP, thereafter decrease to 3 mg/hr	Liver failure
Nitroprusside	Immediate	1-2 min	0.3-10 µg/kg/min, increase by 0.5 µg/kg/min Q 5 min until goal BP	Liver/kidney failure (relative), cyanide toxicity
Nitroglycerine	1-5 min	3-5 min	5-200 µg/min, 5 µg/min increase Q 5 min	
Urapadil	3-5 min	4-6 hrs	12.5-25 mg as bolus injections; 5-40 mg/hr as continuous infusion	
Esmolol	1-2 min	10-30 min	0.5-1.0 mg/kg as bolus; 50-300 µg/kg/min as continuous infusion	2nd or 3rd degree AV block, systolic heart failure, COPD (relative); bradycardia
Phentolamine	1-2 min	3-5 min	1-5 mg, repeat after 5-15 min until goal BP is reached; 0.5-1 mg/hr as continuous infusion	Tachyarrhythmia, angina pectoris

Modified from van den Born BJ, Beutler JJ, Gaillard CA, et al: Dutch guideline for the management of hypertensive crisis—2010 revision, *Neth J Med* 69:248–255, 2011.

Most patients in the emergency department with hypertensive urgencies are nonadherent to their medical regimen or are being treated with an inadequate regimen. To expedite the necessary changes in medications, outpatient follow-up should be arranged within 72 hours. To manage BP during the short interim period, effective oral medication includes labetalol, clonidine, or captopril, which is a short-acting ACEI.

BPs greater than 160/110 mm Hg are a common incidental finding among patients in emergency departments and other acute care settings for urgent medical or surgical care of symptoms that are unrelated to BP (e.g., musculoskeletal pain, orthopedic injury). In these settings, the elevated BP is more often the first indication of chronic hypertension than a simple physiologic stress reaction, providing an important opportunity to initiate primary care referral for formal evaluation and treatment of chronic hypertension. Home and ambulatory BP monitoring are indicated to determine whether the patient's BP normalizes completely once the acute illness has resolved.

PROGNOSIS

One of the most important prognostic factors in hypertension is ECG or echocardiographic left ventricular hypertrophy, the latter of which is already present in as many as 25% of patients with newly diagnosed hypertension. Left ventricular hypertrophy predisposes the patient to heart failure, atrial fibrillation, and sudden cardiac death.

Because of their relatively short duration (typically <5 years), randomized controlled trials underestimate the lifetime protection against premature disability and death afforded by several decades of antihypertensive therapy in clinical practice. In the Framingham Heart Study, treatment of hypertension for 20 years in middle-aged adults reduced total cardiovascular mortality by 60%, which is considerably greater than the results achieved in most randomized trials, despite the less intense treatment guidelines when therapy was initiated in the 1950s through the 1970s.

PROSPECTUS FOR THE FUTURE

1. Further delineation of genetic causes of hypertension and application of this research to the treatment and prevention of hypertension, including development of pharmacologic

and nonpharmacologic therapies that target the various signaling pathways in hypertension and prehypertension.

2. Further work to define the efficacy of catheter-based renal denervation to treat resistant hypertension.
3. Evaluation of drug-eluting stents for the prevention of restenosis after percutaneous revascularization of infrainguinal vascular disease.
4. Further assessment of safety and efficacy of emerging antithrombotic therapies in patients with atrial fibrillation, venous thromboembolism, and vascular disease.
5. Improvements in techniques for noninvasive imaging of the vasculature, including three-dimensional reconstruction using CT angiography, MR angiography, and duplex ultrasonography.

 For a deeper discussion on this topic, please see Chapters 67, "Arterial Hypertension," and 68, "Pulmonary Hypertension," in *Goldman-Cecil Medicine, 25th Edition*.

Lung in Health and Disease

Sharon Rounds and Matthew D. Jankowich

INTRODUCTION

The lung is part of the respiratory system (Fig. 13-1). The respiratory system includes the centers for respiratory control in the brain cortex and medulla, the spinal cord, and peripheral nerves that innervate the skeletal muscles of respiration and the airways and vessels. The upper airway, including the nose, pharynx, and larynx, is where inspired air is humidified and particulate matter is filtered. The bony structure of the chest wall protects the heart, lungs, and liver, and the lungs are maintained in an inflated state by mechanical coupling of the chest wall with the lungs. The skeletal muscles of respiration include the diaphragm and the accessory muscles; the latter are important when disease causes diaphragm fatigue.

The lung consists of conducting airways, blood vessels, and gas exchange units with alveolar gas spaces and capillaries. The lung is a complex organ with an extensive array of airways and vessels arranged to efficiently transfer the gases necessary for sustaining life. The organ has an immense capacity for gas exchange. It is not a limiting factor in exercise tolerance in healthy individuals, but

gas exchange becomes compromised in lung disease, rendering the host unable to function properly. The most dramatic consequence of acute and chronic abnormalities in lung function is systemic hypoxemia, which causes tissue hypoxia. The sequelae of lung dysfunction include detrimental effects to other organs.

In addition to gas exchange, the lungs have other functions, such as defense against inhaled infectious agents and environmental toxins. The entire cardiac output passes through the pulmonary circulation, which serves as a filter for blood-borne clots and infections. The massive surface area of endothelial cells lining the pulmonary circulation has metabolic functions, such as conversion of angiotensin I to angiotensin II.

Lung disorders are common and range from well-known conditions such as asthma and chronic obstructive pulmonary disease (COPD) to rarely encountered disorders such as lymphangioliomyomatosis. The chapters in Section III discuss the diagnosis, evaluation, and management of pulmonary disorders that develop in direct response to lung injury and those that develop indirectly through injuries to other organs. Section III also addresses illnesses requiring critical care, such as acute lung injury and sepsis, which are often triggered by injuries to the lung and are frequently managed by pulmonary or critical care specialists.

This chapter reviews the structural-functional relationships of the lung during development, the epidemiology of pulmonary disease, and the classification of pulmonary disorders.

LUNG DEVELOPMENT

The lung begins to develop during the first trimester of pregnancy through complex and overlapping processes that transform the embryonic lung bud into a functioning organ with an extensive airway network, two complete circulatory systems, and millions of alveoli responsible for the transfer of gases to and from the body. Lung development occurs in five consecutive stages: embryonic, pseudoglandular, canalicular or vascular, saccular, and alveolar postnatal (Table 13-1).

During the embryonic stage (between 21 days and 7 weeks' gestation), the rudimentary lung emerges from the foregut as a single epithelial bud surrounded by mesenchymal tissue. This stage is followed by the pseudoglandular stage (between 5 and 17 weeks' gestation), during which repeated monochotomous and dichotomous branching forms rudimentary airways, a process called *branching morphogenesis* (Fig. 13-2). Coinciding with airway formation, new bronchial arteries arise from the aorta.

The canalicular stage (between 17 and 24 weeks' gestation) is characterized by the formation of the acinus, differentiation of

FIGURE 13-1 The respiratory system includes neural structures that control breathing, the chest wall and skeletal muscles of breathing, the upper airway, and lung parenchyma.

the acinar epithelium, and development of the distal pulmonary circulation. Through the processes of angiogenesis and vasculogenesis, capillary networks derived from endothelial cell precursors are formed, extend from and around the distal air spaces, and connect with the developing pulmonary arteries and veins. By the end of this stage, the thickness of the alveolar capillary membrane is similar to that in the adult.

During the saccular or prenatal alveolar stage (between 24 and 38 weeks' gestation), vascularized crests emerging from the parenchyma divide the terminal airway structures called *sacculi*. Thinning of the interstitium continues, bringing capillaries from adjacent alveolar structures into close apposition and producing a double capillary network. Near birth, capillaries from opposing networks fuse to form a single network, and capillary volume increases with continuing lung growth and expansion.

During the alveolar postnatal stage (between 36 weeks' gestation and 2 years of age), alveolar development continues, and maturation occurs. The lung continues to grow through the first few years of childhood with the creation of more alveoli through septation of the air sacs. By age 2 years, the lung contains double arterial supplies and venous drainage systems, a complex airway system designed to generate progressive decreases in resistance to airflow as the air travels distally, and a vast alveolar network that efficiently transfers gases to and from the blood.

The processes that drive lung development are tightly controlled, but mishaps occur. Congenital lung disorders include cystic adenomatoid malformation of the lung, lung hypoplasia or agenesis, bullous changes in the lung parenchyma, and abnormalities in the vasculature, including aberrant connections between systemic vessels and lung compartments (e.g., lung sequestration) and congenital absence of one or both pulmonary arteries. In children without congenital abnormalities, lung disorders are uncommon, except for those caused by infection and accidents.

Congenital lung disorders are rare compared with the number of infants born annually with abnormal lung function as a result of prematurity. In premature infants, the type II pneumocytes of the lung are underdeveloped and produce insufficient quantities of surfactant, a surface-active substance produced by specific alveolar epithelial cells that helps to decrease surface tension and prevent alveolar collapse. This disorder is called *infant respiratory distress syndrome* (IRDS). The treatment of IRDS is administration of exogenous surfactant and corticosteroids to enhance lung maturation. To sustain life while allowing maturation, mechanical ventilation and oxygen supplementation are required but may promote the development of bronchopulmonary dysplasia.

TABLE 13-1 STAGES OF LUNG DEVELOPMENT

STAGE	PERIOD	COMMENTS
Embryonic	3-7 wk	Embryonic lung bud emerges from the foregut.
Pseudoglandular	5-17 wk	Airway tree is formed through a process of monochotomous and dichotomous branching accompanied by growth.
Canalicular	17-24 wk	Angiogenesis and vasculogenesis form the developing vascular network.
Saccular	24-38 wk	Alveoli begin to form through thinning of the mesenchyme, apposition of vascular structures with the air spaces, and maturation.
Alveolar (postnatal)	36 wk-2 yr	Further alveoli development and maturation occurs.

PULMONARY DISEASE

Epidemiology

Diseases of the adult respiratory system are some of the most common clinical entities confronted by physicians. According to the Centers for Disease Control and Prevention data for 2010, three of the top 10 causes of death due to medical illnesses in the United States are lung diseases: lung cancer, chronic lower respiratory diseases, and influenza or pneumonia.

Chronic obstructive pulmonary disease (COPD) is the third leading cause of death and the second leading cause of disability in the United States. At a time when the age-adjusted death rate for other common disorders such as coronary artery disease and stroke is decreasing, the death rate for COPD continues to increase. More than 16 million Americans are estimated to have COPD, but the number is expected to rise because COPD takes years to develop and the incidence of cigarette smoking (the most common etiologic factor for COPD) is staggering. In 2010, more than 46.6 million Americans were daily smokers, and 40% of

FIGURE 13-2 Lung branching morphogenesis occurs during the pseudoglandular stage of lung development. It is the process by which the embryonic lung develops the primitive airway system through monochotomous and dichotomous branching.

nonsmokers were exposed to secondhand smoke. The true disease burden of COPD is much greater than these numbers indicate.

Other pulmonary conditions are common. Asthma affects 8% of adults and 9.5% of children in the United States. The prevalence, hospitalization rate, and mortality rate related to asthma continue to increase. In 2010, there were 1.1 million hospital discharges for pneumonia and almost 50,000 deaths. Sleep-disordered breathing affects an estimated 7 to 18 million people in the United States, and 1.8 to 4 million of them have severe sleep apnea. Interstitial lung diseases are increasingly recognized, and their true incidence appears to have been underestimated. For example, idiopathic pulmonary fibrosis, the most common of the idiopathic interstitial pneumonias, affects 85,000 to 100,000 Americans annually.

These conditions affect males and females of all ages and races. However, a disproportionate increase in the incidence, morbidity, and mortality related to lung diseases exists for minority populations. This finding is true for COPD, asthma, certain interstitial lung disorders, and other diseases. Although these differences point to genetic differences among these populations, they also indicate differences in culture, socioeconomic status, exposure to pollutants (e.g., inner-city living), and access to health care.

Classification

Lung diseases are often classified on the basis of the affected anatomic areas of the lung (e.g., interstitial lung diseases, pleural diseases, airways diseases) and the physiologic abnormalities detected by pulmonary function testing (e.g., obstructive lung diseases, restrictive lung diseases). Classification schemes based exclusively on physiologic factors are inaccurate because distinctly different disorders with different causes, consequences, and responses to therapy have similar physiologic abnormalities (Fig. 13-3).

The obstructive lung diseases have in common a limitation of airflow, called an *obstructive pattern*, as determined by pulmonary function testing. Obstructive lung diseases include COPD, asthma, and bronchiectasis.

The interstitial lung diseases are less common disorders but are more difficult to categorize because they include more than 120 distinct entities, some of which are inherited, but most do not have an obvious cause. These disorders are characterized by a restrictive physiologic condition due to decreased lung compliance and small lung volumes, which is the reason they are often referred to as *restrictive lung disorders* (e.g., idiopathic pulmonary fibrosis). However, not all interstitial lung diseases exhibit a purely restrictive pattern on pulmonary function testing. They may have airflow limitation as a result of small airway involvement (e.g., sarcoidosis, cryptogenic organizing pneumonia).

In the pulmonary vascular diseases, involvement of the pulmonary vasculature causes increased pulmonary vascular resistance. These diseases range from disorders caused by obstruction to blood flow as a result of blood clots (e.g., pulmonary embolus) to disorders characterized by tissue remodeling and obliteration of blood vessels by vascular remodeling (e.g., pulmonary arterial hypertension, formerly known as primary pulmonary hypertension).

FIGURE 13-3 Lung diseases are caused by abnormalities in the lung structure (e.g., airways, interstitium, vasculature) or in the chest wall or by external forces (e.g., infection). Disorders affecting the lung structure cause physiologic derangements (e.g., obstruction to airflow, restricted lung volumes, pulmonary hypertension, hypoxia). These derangements are not necessarily specific to any particular Lung diseases, but there is extensive overlap among them, so that different disorders can have similar physiologic abnormalities. COPD, Chronic obstructive pulmonary disease.

Disorders of respiratory control include conditions in which extrapulmonary abnormalities cause respiratory system dysfunction and abnormal ventilation. Included are sleep disorders such as obstructive sleep apnea and neuromuscular system disorders such as myasthenia gravis and polymyositis, in which ventilatory abnormalities result from poor excursion of the respiratory muscles.

Disorders of the pleura, chest wall, and mediastinum are classified as such because they affect these structures. Infectious agents, commonly viruses and bacteria, cause infectious diseases of the lung. Neoplastic disorders of the lung include benign (e.g., hamartomas) and malignant (e.g., lung carcinoma) tumors, which can affect the lung parenchyma or its surrounding pleura (e.g., mesothelioma).

PROSPECTUS FOR THE FUTURE

Important questions about lung development remain. What are the primary stimuli for branching morphogenesis? How does gene regulation alter lung development? How is lung airway and blood vessel development coordinated? What are the environment-gene interactions that cause abnormal lung development and subsequent lung diseases?

There are important fundamental questions about the epidemiology of lung diseases. For example, it is not clear whether or how childhood asthma and adult COPD are related. The role of fine particulate matter air pollution in the pathogenesis of lung diseases is unknown, and the causes and pathogenesis of many lung diseases, such as sarcoidosis, are unclear.

General Approach to Patients with Respiratory Disorders

Rizwan Aziz and Brian Casserly

INTRODUCTION

Effective assessment of a patient who may have pulmonary disease requires a detailed history and review of symptoms. Patients with lung disorders often complain of one or more of the following symptoms: dyspnea, fatigue, exercise intolerance, chest tightness, cough, sputum production, and chest pain. Although individually these symptoms are not diagnostic, a combination of symptoms in an individual may point to a specific diagnosis.

Common symptoms of respiratory disease, such as dyspnea and cough, frequently occur with diseases of other organ systems (Table 14-1). For example, dyspnea is a cardinal symptom of heart disease, and cough may be caused by gastroesophageal reflux or chronic sinusitis. An organized approach to the patient, starting with a careful history and a detailed physical examination, further focuses the investigation to determine the cause of the symptom.

For a deeper discussion on this topic, please see Chapter 83, "Approach to the Patient with Respiratory Disease," in Goldman-Cecil Medicine, 25th Edition.

CLINICAL PRESENTATION

Dyspnea (i.e., shortness of breath) is a common complaint of patients with pulmonary disease (Table 14-2). Timing and acuity of onset, exacerbating and alleviating factors, and degree of functional impairment are key elements of the history. Associated symptoms such as cough, hemoptysis, chest pain, wheezing, orthopnea, and paroxysmal nocturnal dyspnea and the environmental triggers are helpful in developing a differential diagnosis. If dyspnea is recent, of sudden onset, and accompanied by chest pain, pneumothorax, pulmonary embolism, and pulmonary edema should be considered. If the dyspnea is slowly progressive, chronic conditions such as chronic obstructive pulmonary disease (COPD), pulmonary fibrosis, pulmonary arterial hypertension, and neuromuscular disorders are in the differential diagnosis.

TABLE 14-1 MAJOR SYMPTOMS OF RESPIRATORY DISEASE

Cough	Chest pain
Sputum	Fever
Hemoptysis	Hoarseness
Dyspnea (acute, progressive, or paroxysmal)	Night sweats
Wheezing	

The progression of chronic dyspnea may be insidious. Asking specific questions to quantify changes in functional status over time is important. Dyspnea may occur during exertion or at rest and may be episodic or continuous. Episodic dyspnea associated with exertion suggests parenchymal lung disease or cardiac dysfunction. Dyspnea that is seasonal or triggered by

TABLE 14-2 CAUSES OF DYSPNEA

CAUSE	EXAMPLES
Airways disease	Chronic obstructive lung diseases Laryngeal disorders Epiglottitis, bronchiolitis, and croup in children Tracheal obstruction or stenosis Tracheomalacia

Noncardiorespiratory disorders	Psychogenic diseases Midbrain lesion
Metabolic or endocrine disorders	Metabolic acidosis (diabetic ketoacidosis, sepsis, severe dehydration, inborn errors of metabolism) Hyperthyroidism Hypothyroidism Hyperammonemia Hypocalcemia (laryngospasm) Anaphylaxis Smoke inhalation Chemical agent exposures (phosgene, chlorine, cyanide)
Other causes	Biologic and chemical weapons (anthrax, tularemia, phosgene, nitrogen mustard, nerve agents, ricin) Submersion injury (near-drowning) Acute chest syndrome (sickle cell disease)

environmental exposure suggests diseases such as asthma and hypersensitivity pneumonitis. Positional dyspnea can occur in patients with severe obstructive lung disease, diaphragmatic paralysis, or neuromuscular weakness.

Orthopnea is dyspnea that occurs in the supine position. This condition may result from a decrease in vital capacity caused by abdominal contents exerting force against the diaphragm. Paroxysmal nocturnal dyspnea is dyspnea that occurs 1 to several hours after lying down and is associated with congestive heart failure. Increased venous return to the heart causes this condition, resulting in mild interstitial pulmonary edema. Asthma can also be associated with nocturnal dyspnea and is thought to result from decreased vital capacity in the supine position, decreased production of endogenous agents with bronchodilator functions, and increased exposure to allergens in bedding. Exercise-induced asthma causes dyspnea out of proportion to the degree of exertion, with dyspnea often being most severe in the 15 to 30 minutes after the cessation of exercise.

Wheezing has many causes, including asthma. However, the absence of wheezing does not rule out asthma in any setting, and the presence of wheezing does not establish the diagnosis. Other conditions that cause wheezing are congestive heart failure; endobronchial obstruction by tumor, foreign body, or mucus; vocal cord abnormalities; and acute bronchitis.

Cough is a frustrating symptom for the patient and the physician. The three most common causes of chronic cough are post-nasal drip, asthma, and gastroesophageal reflux disease. Cough may be mild and infrequent, or it may be severe enough to induce emesis or syncope. Cough may be dry or may produce sputum or blood (i.e., hemoptysis). The symptom may begin months after initiation of a drug (e.g., angiotensin-converting enzyme [ACE] inhibitors), leading to a dry, hacking cough. *Bordetella pertussis* infection (i.e., whooping cough) and viral lower respiratory tract infections can produce a cough that may last for 3 months or longer. Patients with asthma often have a cough. Occasionally, cough is their only symptom, a condition referred to as *cough-variant asthma*. Nocturnal cough suggests asthma, heart failure, or gastroesophageal reflux disease.

More than occasional production of sputum is abnormal and should be characterized with regard to quantity, color, timing, and presence or absence of blood. The physician should ask the patient to estimate the frequency and volume of sputum produced in 24 hours and describe diurnal variations. Chronic bronchitis is defined as a persistent cough resulting in sputum production for more than 3 months in each of the past 3 years. Patients with asthma often have a productive cough resulting from excess mucus production. Colored sputum does not always signify a bacterial infection because the concentration of cellular debris—predominantly white cells in inflammatory processes— influences sputum color. Patients with difficult to control asthma who report brown plugs or casts of the small bronchi in their sputum may have allergic bronchopulmonary aspergillosis.

Hemoptysis is a frightening symptom. The volume of blood may be scant or large enough to cause asphyxiation or exsanguination. The most common cause of hemoptysis in the United States is bronchitis, whereas the most common cause worldwide is pulmonary tuberculosis. Most cases of hemoptysis are small in volume and self-limited, and they resolve with the treatment of

the underlying process. Massive hemoptysis, defined as more than 500 mL of blood in 24 hours, is rare and considered a medical emergency when it occurs. Causes of massive hemoptysis include lung cancer, lung cavities containing mycetomas, cavitary tuberculosis, pulmonary hemorrhage syndromes, pulmonary arteriovenous malformations, and bronchiectasis. The physician should distinguish among hemoptysis, epistaxis, and hemateme-sis. Because many patients have trouble identifying the source of the bleeding, a careful upper airway physical examination is essential.

Chest pain attributable to the lungs usually results from pleural disease, pulmonary vascular disease, or musculoskeletal pain precipitated by coughing because no pain receptors exist in the lung parenchyma. Lung cancer, for example, does not cause pain until it invades the pleura, chest wall, vertebral bodies, or mediastinal structures. Disease or inflammation of the pleura causes pleuritic chest pain characterized as a sharp or stabbing pain with deep inspiration. Pain caused by pulmonary emboli, infection, pneumothorax, and collagen vascular disease is usually pleuritic. Pulmonary hypertension may produce dull anterior chest pain unrelated to respiration caused by right ventricular strain and demand ischemia. Other examples of noncardiac causes of chest pain are esophageal disease, herpetic neuralgia, musculoskeletal pain, and trauma. Older patients or those with a history of chronic systemic steroid use may have thoracic pain resulting from vertebral compression or rib fractures.

Adequate analgesia, including narcotics, is essential in the treatment of chest pain in patients with underlying lung disease to prevent the reduction in vital capacity caused by splinting of the chest in reaction to the pain. The diagnosis of musculoskeletal chest pain should be considered after other causes have been ruled out. This pain is usually reproducible with movement or palpation over the affected area.

HISTORY

The examiner should always ask about previous respiratory illness, including pneumonia, tuberculosis, or chronic bronchitis, and abnormalities seen on the chest radiograph that have been previously reported to the patient. Patients with the acquired immunodeficiency syndrome (AIDS) are at high risk for *Pneumocystis jiroveci* pneumonia and other chest infections, including tuberculosis. Immunosuppression from long-standing steroid use may predispose to tuberculosis and other lung infections.

Most classes of drug can be associated with lung toxicity. Examples include pulmonary embolism from use of the oral contraceptive pill, interstitial lung disease from cytotoxic agents (e.g., methotrexate, cyclophosphamide, bleomycin), bronchospasm from β -adrenergic receptor blockers or nonsteroidal anti-inflammatory drugs, and cough from ACE inhibitors. Some drugs known to cause lung disease may not be mentioned by the patient because they are illegal (e.g., cocaine, heroin).

An accurate history of tobacco use and other toxic and environmental exposures is essential for patients with respiratory complaints. Tobacco smoke is the most prevalent environmental toxin causing lung disease. Asking about tobacco use and attempting to motivate patients to quit smoking are the physician's duty. The risk for lung disease from smoking is directly related to individual genetic susceptibility and the total

pack-years of exposure, and it is inversely related to the age at onset of smoking and, in the case of lung cancer, the interval since smoking cessation.

A history of exposure to other inhaled toxins, irritants, or allergens should be elicited. A careful occupational history often uncovers exposure to inorganic dust or fibers such as asbestos, silica, or coal dust. Organic dusts may cause hypersensitivity pneumonitis and other interstitial lung diseases. Solvents and corrosive gases also cause pulmonary disease. The presence of pets in the home should be documented. Cats are the most allergenic for asthma, and birds may cause hypersensitivity or fungal lung disease.

A travel history is important in evaluating infectious causes of pulmonary disease. For example, histoplasmosis is common in the Ohio and Mississippi River valleys, and coccidioidomycosis is found in the desert Southwest. Travel to developing countries increases the risk of exposure to tuberculosis. A family history is important in assessing the risk for genetic lung diseases such as cystic fibrosis and α_1 -antitrypsin deficiency and susceptibility to asthma, emphysema, or lung cancer.

PHYSICAL EXAMINATION

The physical examination should be complete, with emphasis on areas highlighted by the history. The first steps in the physical examination of the patient with pulmonary disease are observation and inspection, which must be done when the patient's chest is bare. The physician should start by evaluating the general appearance of the patient. Particular attention should be given to the presence or absence of respiratory distress. This observation helps in making the diagnosis and suggests the urgency of the case.

Body habitus is important because morbid obesity in a patient with exercise intolerance and sleepiness may point to a diagnosis of sleep-disordered breathing, whereas dyspnea in a thin, middle-aged man with pursed lips may suggest emphysema. Race and sex should be considered because certain conditions are more frequently encountered in specific populations. For example, sarcoidosis is most common in African Americans in the Southeast, whereas lymphangiomyomatosis is a rare disorder that essentially affects young women of childbearing age. Tachycardia and pulsus paradoxus are important signs of severe asthma.

The physician should watch the patient breathe and notice the effort required for breathing. Increased respiratory rate, use of accessory muscles of respiration, pursed-lip breathing, and paradoxical abdominal movement indicate increased work of breathing. Paradoxical abdominal movement indicates diaphragm weakness and impending respiratory failure. The patient's inability to speak in full sentences indicates severe airway obstruction or neuromuscular weakness. The physician should listen for cough during the history and physical examination and should observe the strength of the cough because it may signal respiratory muscle weakness or severe obstructive lung disease. The patient's rib cage should expand symmetrically with inspiration. The shape of the thoracic cage should be considered. Increased anteroposterior diameter is observed in those with lung hyperinflation due to obstructive lung disease. Severe kyphoscoliosis, pectus excavatum, ankylosing spondylitis, and morbid obesity

can produce restrictive ventilatory disease as a consequence of distortion and restriction of the volume of the thoracic cavity.

The patient's hands may reveal important signs of lung diseases. Clubbing is commonly associated with respiratory disease. An uncommon association with clubbing is hypertrophic pulmonary osteoarthropathy (HPO). HPO is characterized by periosteal inflammation at the distal ends of long bones, the wrists, the ankles, and the metacarpal and metatarsal bones. There is swelling and tenderness over the wrists and other involved areas. Rarely, HPO may occur without clubbing. The causes of HPO include pleural mesothelioma, pulmonary fibrosis, and chronic lung infections, such as lung abscess.

Staining of the fingers (caused by tar because nicotine is colorless) is a sign of cigarette smoking. The patient should be asked to dorsiflex the wrists with the arms outstretched and to spread out the fingers. A flapping tremor (i.e., asterixis) may be seen with severe carbon dioxide retention. Wasting and weakness are signs of cachexia due to malignancy or end-stage emphysema. Compression and infiltration by a peripheral lung tumor of a lower trunk of the brachial plexus results in wasting of the small muscles of the hand and weakness of finger abduction.

Examination of the head and neck is important. The eyes are inspected for evidence of Horner's syndrome (i.e., constricted pupil, partial ptosis, and loss of sweating), which can be caused by an apical lung tumor compressing the sympathetic nerves in the neck. The voice is assessed for hoarseness, which may indicate recurrent laryngeal nerve palsy associated with carcinoma of the lung (usually left sided) or laryngeal carcinoma. However, the most common cause is laryngitis.

The patient is examined for nasal polyps (associated with asthma), engorged turbinates (various allergic conditions), and a deviated septum (nasal obstruction). Sinusitis is indicated by tenderness over the sinuses on palpation.

The tongue is assessed for central cyanosis. The mouth may hold evidence of an upper respiratory tract infection (i.e., reddened pharynx and tonsillar enlargement with or without a coating of pus). A broken tooth or gingivitis may predispose to lung abscess or pneumonia. There may be facial plethora or cyanosis if the superior vena cava is obstructed. Some patients with obstructive sleep apnea are obese and have a receding chin, a small pharynx, and a short, thick neck.

Palpation of the chest is performed by first palpating the accessory muscles (i.e., scalene and sternocleidomastoid) of respiration in the patient's neck. Hypertrophy and contraction indicate increased respiratory effort. The trachea should be palpated and should lie in the midline of the neck. Deviation of the trachea may suggest lung collapse or a mass. Neck masses should be documented.

The physician should place both hands on the lower half of the patient's posterior thorax with thumbs touching and fingers spread; the hands should be kept in place while the patient takes several deep inspirations. The physician's thumbs should separate slightly and the hands should move symmetrically apart during the patient's inspiration.

Fremitus is a faint vibration felt best with the edge of the hand against the patient's chest wall while the patient speaks. Fremitus is increased in areas with underlying lung consolidation, and it is decreased over a pleural effusion. Next, the patient's chest should

be percussed. The level of the diaphragms on each side should be observed. The percussion note should be compared on the two sides starting at the apex and moving down, including the posterior, anterior, and lateral aspects. A pleural effusion, consolidation, mass, or elevated diaphragm can cause dullness to percussion; a pneumothorax or hyperinflation can cause hyperresonance.

Auscultation of the lungs is performed to evaluate the quality of the breath sounds and to detect extra sounds not heard in normal lungs. Normal breath sounds have two qualities, vesicular and bronchial. Bronchial breath sounds are heard over the central airways and are louder and coarser than vesicular breath sounds, which are heard at the periphery and base of the lungs. Bronchovesicular sounds are a combination of the two and are heard over medium-sized airways. Bronchial sounds have a longer inhaled component, whereas vesicular sounds have a much longer expiratory component and are much softer. Bronchial breath sounds and bronchovesicular breath sounds at the periphery of the lungs are abnormal and may be caused by underlying consolidation. In the setting of consolidation, increased transmission of vocal sounds, called *whispered pectoriloquy*, occurs; *egophony*, in which the spoken letter *e* sounds like an *a* over the area of consolidation, is heard and sometimes compared with the bleating of a goat.

Abnormal or extrapulmonary sounds are crackles, wheezes, and rubs. Crackles can be coarse rattles or fine, Velcro-like sounds. Mucus in the airways or the opening of large- and medium-sized airways often causes coarse crackles. In bronchiectasis, the crackles are altered with coughing. Fine crackles, heard during inspiration and caused by the opening of collapsed alveoli, are most common at the bases. Crackles are heard in pulmonary edema and interstitial fibrosis.

Wheezing is a higher-pitched sound, and when heard locally, it suggests large airway obstruction. The wheezing of patients with asthma or congestive heart failure is lower in pitch and heard diffusely over all lung fields. Localized wheezing can be heard in conditions such as pulmonary embolism, obstruction of a bronchus by a tumor, and foreign-body aspiration.

A rub is a pleural sound caused by inflamed pleural surfaces rubbing together. A rub has been described as the sound of pieces of leather rubbing against each other. Rubs are often evanescent and depend on the amount of fluid in the pleural space. Often, pleuritic chest pain and a rub develop after large-volume thoracentesis.

A crunching sound timed with the cardiac cycle, called *Hamman's crunch* or *Hamman's sign*, is heard in patients with a pneumomediastinum. The complete absence of breath sounds on one side should cause the examiner to think of pneumothorax, hemothorax, or hydrothorax; obstruction of a main stem bronchus; or surgical or congenital absence of the lung.

EVALUATION

The clinician should be able to develop a differential diagnosis based on a detailed history and a thorough physical examination. The preliminary differential diagnosis is the basis for ordering a battery of tests, recognizing that these tests may reveal disorders not considered in the initial assessment. The objective of this extended evaluation is twofold: to confirm a diagnosis

or discard other disorders and to assess the severity of the lung derangement.

Patients with a suggested lung disorder should undergo pulmonary function testing (see [Chapter 15](#)). Spirometry evaluates airflow and helps to distinguish between the obstructive pattern characteristic of COPD, asthma, and related disorders and the restrictive pattern observed in fibrosing lung disease. Spirometry also provides information regarding the severity of the physiologic derangement.

Lung volume measurements are helpful in assessing hyperinflation or confirming a restrictive process. Measuring the diffusing capacity of the lung for carbon monoxide (DLCO) provides information about alterations in gas-exchanging capability. Further assessment of gas exchange can be obtained by the determination of oxygen saturation using pulse oximetry.

Information regarding oxygenation and acid-base status is obtained from arterial blood gas determination. A 6-minute walk test can evaluate oxygenation during exertion; through this test, patients are often found to require supplemental oxygen for the first time. Other, more specialized tests (e.g., bronchoprovocation, cardiopulmonary stress testing, polysomnography) may be required, depending on the circumstances.

Imaging studies of the chest are extremely useful in evaluating lung structure. The chest radiograph provides information about the lung parenchyma and pleura, the cardiac silhouette, mediastinal structures, and body habitus. Examining old chest radiographic images is essential for assessing progression of disease.

Computed tomography (CT) provides more accurate information about the pulmonary and mediastinal structures, and it is essential in the assessment of interstitial lung disease, lung masses, and other disorders. Together with ventilation-perfusion scanning and pulmonary angiography, CT is one of the many tools available to evaluate the lung vasculature. Positron emission tomography is used to assess metabolic activity of lung masses and can suggest a diagnosis of malignancy.

Standard blood tests such as the blood counts and blood chemistry point to specific disorders or may provide information about the severity of a lung disorder (e.g., polycythemia in chronic hypoxemia, leukocytosis in lung infection). Some specialized tests should be reserved for specific diagnoses such as connective tissue disorders (e.g., rheumatoid factor, antinuclear antibodies) or hypersensitivity pneumonitis (hypersensitivity profile).

Together with the history and physical examination, these tests are useful for narrowing a diagnosis to establish a specific plan of treatment. The plan can often be created in a single visit. However, patients frequently require several visits to a clinician. During these follow-up visits, the physician assesses progression of disease, patient compliance with therapy, and response to management.

If noninvasive tests do not allow a diagnosis of the problem, more invasive tests may be necessary. Fiberoptic or rigid bronchoscopy allows direct visualization of the airways and acquisition of valuable clinical samples for study. Transthoracic percutaneous needle aspiration or navigational bronchoscopy is useful in evaluating peripheral lung lesions. Ultimately, surgery may be required to obtain tissue through open or video-assisted thoracoscopically guided lung biopsy.

 For a deeper discussion on this topic, please see Chapter 84, "Imaging in Pulmonary Disease," and Chapter 101, "Interventional and Surgical Approaches to Lung Disease," in Goldman-Cecil Medicine, 25th Edition.

PROSPECTUS FOR THE FUTURE

The predictive values of various aspects of the history and physical examination need to be clarified. The role of quantitative CT analysis in the diagnosis and assessment of disability from lung diseases should be refined. The role of interventional pulmonary procedures must be ascertained for the diagnosis and treatment of lung diseases.

Evaluating Lung Structure and Function

Jigme M. Sethi and F. Dennis McCool

INTRODUCTION

The satisfactory functioning of all organ systems depends on their capacity to consume oxygen and eliminate carbon dioxide. The primary function of the lung is to deliver oxygen to the pulmonary capillary blood and to excrete carbon dioxide. To accomplish this, the lung must generate a flux of air into and out of the alveoli (ventilation) while absorbing oxygen into the pulmonary blood and eliminating carbon dioxide from alveolar air (gas exchange). This is accomplished in a manner that attempts to optimize gas exchange (ventilation-perfusion matching). This remarkably efficient process allows the human to maintain optimal oxygenation and acid-base balance over a range of activities, from resting breathing to moderately strenuous activity. This chapter provides an overview of the anatomy and physiology that enable the respiratory system to perform its life-sustaining functions as well as a discussion of tests available to evaluate lung structure and function.

ANATOMY

Airway

Inspired air travels through the nose and nasopharynx, where it is warmed to body temperature, humidified, and filtered of airborne particles greater than 10 μm in diameter. Air then enters a complex system of dichotomously branching airways that form a tree occupying the thorax. The first 15 divisions, beginning with the trachea, the mainstem bronchi, segmental and subsegmental bronchi down to the terminal bronchioles, are simply a set of conducting tubes that do not participate in gas exchange. Together, they constitute the *conducting zone* of the lung, also known as the *anatomic dead space* (about 1 mL per pound of ideal body weight, or approximately 150 mL) (Fig. 15-1). Cartilaginous rings help to maintain the patency of these large airways. In the mainstem bronchi, the rings are circumferential, whereas in the trachea, the cartilaginous rings are U-shaped, with the posterior membrane of the trachea sharing a wall with the esophagus.

Airway subdivision	Order No.	Cross-sectional area (cm ²)	Resistance (cm H ₂ O • L ⁻¹ • sec)
Larynx	0		0.5
Trachea	0	2.5	0.5
Bronchi	1	2.0	
Bronchioles	2	5.0	0.2
	16		
Respiratory bronchioles	17	1.8 x 10 ²	
	19		
Alveolar ducts	22	9.4 x 10 ²	
Alveoli	22	5.8 x 10 ³	
	23	5.6 x 10 ⁷	

FIGURE 15-1 The subdivisions of the airways and their nomenclature. (Modified from Weibel ER: Morphometry of the human lung, Berlin, 1963, Springer.)

FIGURE 15-2 **A**, Cast of the right lung demonstrates branching of airways. **B**, The branching airways can be modeled by use of the principles of fractal geometry, which allow for efficient filling of the thoracic space.

The branching pattern of these first 15 divisions of the airways follows the principles of fractal geometry: The reduction of airway diameter and length between each generation is similar, by a factor of 0.79, serving to densely compact the airways into the available space of the thorax (Fig. 15-2A and B). This geometry reduces bronchial path length from the trachea to the periphery and minimizes both dead space volume and resistance to convective airflow.

The remaining eight generations of airways comprise the respiratory bronchioles and alveolar ducts lined with alveolar sacs. This area of the lung is referred to as the *respiratory zone*, and the terminal respiratory unit is called the acinus. Gas exchange commences in the respiratory zone but primarily occurs in the alveoli. Inspired air moves down the conducting zone primarily by bulk convective flow, whereas the movement of oxygen in the respiratory zone is by diffusion.

In total, there are an average of 23 subdivisions of the airway from the trachea to the alveolar ducts. Although it might be suspected that resistance to convective flow would be highest in the small airways because of their small diameter, the opposite is the case. The enormous number of small airways together provide a huge net cross-sectional area for airflow. For example, the cross-sectional area of the trachea is 2.5 cm^2 , compared with a total cross-sectional area of 300 cm^2 for all of the alveolar ducts combined. As a result, 80% of the resistance to airflow occurs in the first seven generations of bronchi, and the remaining “small” airways (diameters $<2 \text{ mm}$) contribute only 20% of the resistance to airflow (Fig. 15-3). As the lung expands during inspiration, the net cross-sectional area of the alveolar ducts doubles, further reducing resistance to airflow.

Alveoli

The alveoli are the grapelike clusters of air sacs that interface with the pulmonary capillaries. There are about 300 million individual alveolar sacs, or 10,000 in each of the 30,000 acini. The alveoli are thin-walled structures with a total surface area of about 130 m^2 . This is roughly half the size of a doubles tennis court. The surface of the alveoli is lined by two types of cells. The flat type I pneumocytes constitute 95% of the cells. Type II pneumocytes, which account for about 5% of the alveolar lining cells, secrete surfactant, a complex lipoprotein whose role in lowering

FIGURE 15-3 Total cross-sectional area of the airways is depicted for several generations of airways. The total cross-sectional area increases dramatically in the respiratory zone. Consequently, the velocity of gas entering the respiratory zone decreases and resistance is low.

surface tension in the alveolar space is critical to reducing the forces needed to expand the lung. Surfactant is also important in preventing alveolar collapse at low lung volumes and thereby promoting normal gas exchange. The capillaries run in the exceedingly thin septa that separate the alveoli and are therefore exposed to the air from surrounding alveoli. The epithelial lining of the alveoli, the endothelial lining of the capillaries, and the intervening fused basement membrane form the alveolar-capillary interface. Normally, this interface is less than $1 \mu\text{m}$ thick and does not significantly interfere with gas exchange.

Blood Vessels

The pulmonary artery arises from the right ventricle and branches until it terminates in a meshwork of capillaries that surround the alveoli. This creates a large surface area that facilitates gas exchange. Blood returns to the heart through pulmonary veins that course through the lungs, coalesce into four main pulmonary veins, and empty into the left atrium. The pulmonary circulation is a low-resistance circuit; pulmonary vascular resistance is about one tenth of the resistance in the systemic circulation. Pulmonary vessels can be easily recruited to accommodate increases in blood flow while maintaining low pressure and resistance. Accordingly, during exercise, any increase in cardiac output can be distributed through the lung without significantly increasing pulmonary arterial pressures.

A separate vascular system, the bronchial system, also supplies the lung. The bronchial arteries originate from the aorta and, in contrast to the pulmonary arteries, are under systemic pressure. These vessels provide nutrients to lung structures proximal to the alveoli. Two thirds of the bronchial circulation drains into the pulmonary veins and then empties into the left atrium. This blood, which has low oxygen content, mixes with the freshly oxygenated blood from the pulmonary veins to lower the oxygen content of the blood that enters the systemic circulation.

PHYSIOLOGY

Ventilation

Ventilation refers to the bulk transport of air from the atmosphere to the alveolus. The product of tidal volume (V_T) and breathing frequency (f) represents the total volume of air delivered to the lung per minute (minute ventilation). However, not all air entering the lung is in contact with gas-exchanging units. The portion of V_T that fills the respiratory zone and alveoli and is available for gas exchange constitutes the alveolar volume (V_A), whereas the portion remaining in the conducting airways is the anatomic dead space volume (V_D) (Fig. 15-4). The ratio of V_D to V_T is called the *dead space ratio* (V_D/V_T). Normally, one third of a breath is dead space ($V_D/V_T = 1/3$). The amount of fresh air reaching the alveoli is $V_A - V_D$. With large breaths, the dead space becomes a smaller fraction of the total tidal volume. Therefore, for a given V_T , slow, deep breathing results in greater V_A and improved gas exchange compared with rapid, shallow breathing.

FIGURE 15-4 Schematic diagram of the inspired volume of air that participates in gas exchange (V_A , 350 mL) and the volume of anatomic dead space (V_D , 150 mL), which together provide a tidal breath (V_T) of 500 mL.

The V_D/V_T ratio can be calculated by the Bohr method, as follows:

$$V_D/V_T = (P_{aCO_2} - P_{ECO_2})/P_{aCO_2}$$

where P_{aCO_2} is the arterial partial pressure of carbon dioxide and P_{ECO_2} is the partial pressure of carbon dioxide in mixed expired gas (i.e., the mixture of CO_2 -rich gas that enters the alveoli from the pulmonary capillaries and dead space gas, which is devoid of CO_2). P_{ECO_2} increases during expiration, reaching a plateau at end-expiration. At end-expiration, the P_{ECO_2} represents exhaled alveolar gas that has been in equilibrium with pulmonary capillary blood. In healthy individuals, the P_{ECO_2} at end-expiration is equivalent to the P_{aCO_2} .

Ventilation of the dead space is wasted ventilation, because only V_A participates in gas exchange. Therefore, as the metabolic rate and carbon dioxide production increase, V_A must increase to maintain an arterial PCO_2 of 40 mm Hg. The relationship among these variables is described by the alveolar carbon dioxide equation:

$$P_{ACO_2} = CO_2 \text{ production}/\dot{V}_A$$

where P_{ACO_2} is the partial pressure of carbon dioxide in the alveolus and \dot{V}_A is alveolar ventilation. From this equation, one appreciates that the partial pressure of carbon dioxide in the alveolus is inversely proportional to alveolar ventilation.

The relationship described by the alveolar oxygen equation is similar:

$$P_{AO_2} = O_2 \text{ consumption}/\dot{V}_A$$

However, this relationship is more complicated because P_{AO_2} also is proportional to the fraction of inspired oxygen, the water vapor pressure, and the partial pressure of carbon dioxide in the alveolus (discussed later). The implications of the alveolar carbon dioxide and oxygen relationships are that (1) maintenance of a constant alveolar gas composition depends on a constant ratio of ventilation to metabolic rate; (2) if ventilation is too high (hyperventilation), alveolar PCO_2 will be low and alveolar PO_2 will be high; and (3) if ventilation is too low (hypoventilation), alveolar PCO_2 will be high and alveolar PO_2 will be low.

Mechanics of Breathing

Respiratory mechanics is the study of forces needed to deliver air to the lung and how these forces govern the volume and flow of gases. Mechanically, the respiratory system consists of two structures: the lungs and the chest wall. The lungs are elastic (spring-like) structures that are situated within another elastic structure, the chest wall. At end-expiration, with absent respiratory muscle activity, the inward recoil of the lung is exactly balanced by the outward recoil of the chest wall, representing the equilibrium position of the lung–chest wall unit. Normally, the recoil of the lung is always inward (favoring lung deflation), and the recoil of the chest wall is outward (favoring inflation); at high lung volumes, however, the chest wall also recoils inward (Fig. 15-5). The energy required to stretch the respiratory system beyond its equilibrium state (end-expiration during quiet breathing) is provided by the inspiratory muscles. With normal quiet breathing, gas flow out of the lung is usually accomplished by passive recoil of the respiratory system.

FIGURE 15-5 Schematic diagram of the lung and chest wall at functional residual capacity (FRC). The arrows show that the expanding elastic force of the chest wall equals the collapsing elastic force of the lung. The intrapleural pressure is -5 at FRC because both forces are tugging on the pleural space in opposite directions.

During a typical breath, inspiratory muscle contraction lowers the intrapleural pressure, which in turn lowers the intra-alveolar pressure. Once alveolar pressure becomes subatmospheric, air can flow from the mouth through the airways to the alveoli. At the end of inspiration, the inspiratory muscles are turned off, and the lungs and chest wall recoil passively back to their equilibrium states. This passive recoil of the respiratory system causes alveolar pressure to become positive throughout expiration until the resting position of the lung and chest wall are reestablished and alveolar pressure once again equals atmospheric pressure. During quiet breathing, pleural pressure is always subatmospheric, whereas alveolar pressure oscillates below and above zero (atmospheric) pressure (Fig. 15-6).

The major inspiratory muscle is the diaphragm. Others include the sternocleidomastoid muscles, the scalenus muscles, the parasternals, and the external intercostals. Diaphragm contraction results in expansion of the lower rib cage and compression of the intra-abdominal contents. The latter action results in expansion of the abdominal wall. The expiratory muscles consist of the internal intercostal muscles and the abdominal muscles. Expiratory flows can be enhanced by recruiting the expiratory muscles; this occurs during exercise or with cough.

To inflate the respiratory system, the inspiratory muscles must overcome two types of forces: the elastic forces imposed by the lung and the chest wall (elastic loads) and the resistive forces related to airflow (resistive loads). The elastic loads on the inspiratory muscles result from the respiratory system's tendency to resist stretch. The elastic forces are volume dependent; that is, the respiratory system becomes more difficult to stretch at volumes greater than the functional residual capacity (FRC) and more difficult to compress at volumes lower than the FRC. The elastic forces can be characterized by examining the relationship between lung volume and recoil pressure (Fig. 15-7). When either deflated or inflated, the lung and chest wall have characteristic recoil pressures. The slope of the relationship between lung volume and elastic recoil pressure of the chest wall or lung represents the *compliance* of each structure. The sum of the chest wall and lung recoil pressures represents the recoil pressure of the total respiratory system.

FIGURE 15-6 Volume, intrapleural pressure, and alveolar pressure during a normal breathing cycle. The letters correspond to the various phases of the cycle: A, end-expiration; B, inspiration; C, end-inspiration; and D, expiration. Alveolar pressure is biphasic, with zero crossings at times of no flow (i.e., end-expiration and end-inspiration). Intrapleural pressure remains subatmospheric throughout.

FIGURE 15-7 Volume-pressure relationship of the respiratory system and its components, the lung and chest wall. Respiratory system recoil pressure at any volume is the sum of the lung and chest wall recoil pressures. Forces creating negative pressures expand the respiratory system, whereas forces creating positive pressures collapse the respiratory system. The slope of the volume-pressure curve represents the compliance of each structure. FRC, Functional residual capacity; RV, residual volume; TLC, total lung capacity.

The elastic properties of the lung are related to two factors: the elastic behavior of collagen and elastin in the lung parenchyma and the surface tension in the alveolus at the air-liquid interface. Both factors contribute equally to lung elastic recoil. A surface-active substance called *surfactant* is produced by type II alveolar cells and lines the alveoli. This substance consists primarily of phospholipids. It lowers the surface tension of the air-liquid interface, making it easier to inflate the lung. The lungs are stiff (less compliant) and difficult to inflate in diseases that

are characterized by a loss of surfactant (e.g., infant respiratory distress syndrome). Diseases such as pulmonary fibrosis, which are characterized by excessive collagen in the lung, can make the lung stiff and difficult to inflate, whereas those such as emphysema, characterized by a loss of elastin and collagen, reduce lung recoil and increase lung compliance (Fig. 15-8). Normally, at FRC, it takes about 1 cm of water pressure (1 cm H₂O) to inflate the lungs 200 mL or to inflate the chest wall 200 mL. The lung and chest wall both need to be inflated to the same volume during inspiration, so 2 cm H₂O of pressure is required to inflate both to 200 mL. Therefore, normal respiratory system compliance is roughly 200/2 or 100 mL/cm H₂O and compliance of the lung or chest wall compliance is 200/1 or 200 mL/cm H₂O at volumes near FRC.

The second set of forces that the inspiratory muscles must overcome to inflate the lungs are flow-dependent forces; namely, tissue viscosity and airway flow resistance, the latter constituting the major component of the flow-dependent forces. Airway resistance during inspiration can be calculated by measuring inspiratory flow and the difference in pressure between the alveolus and the airway opening (ΔP_{A-ao}).

$$\text{Resistance} = \Delta P_{A-ao} / \dot{V}$$

The airflow velocity, the type of airflow (laminar or turbulent), and the physical attributes of the airway (radius and length) are the key determinants of airway resistance. Of the physical properties, the radius of the airways is the major factor. Resistance increases to the fourth power as the diameter decreases under conditions of laminar flow (streamline flow profile) and to the fifth power under conditions of turbulent flow (chaotic flow profile). Because airway diameter increases

FIGURE 15-8 Compliance curves for normal individuals and for patients with emphysema or pulmonary fibrosis. The transpulmonary pressure required to achieve a given lung volume is greatest for the patient with pulmonary fibrosis (notice the horizontal dashed line at 60% of the vital capacity). This increases the work of breathing.

as lung volume increases, airway resistance decreases as lung volume increases (Fig. 15-9). Airway diameter also contributes to regional differences in airway resistance. Although the peripheral airways are narrower than the central airways, their total cross-sectional area is much greater than that of the central airways, as described earlier. Consequently, resistance to airflow of the peripheral airways is low relative to the central airways (see Fig. 15-3).

The type of airflow is another key determinant of airway resistance. Resistance is directly proportional to flow rate when flow is laminar. Resistance is much greater with turbulent flow because it is proportional to the square of the flow rate. The velocity of airflow determines, in part, whether the flow pattern is laminar or turbulent. Clinically, increased airway resistance can be seen in diseases associated with airway obstruction caused by an intrinsic mass, mucus within the airway, airway smooth muscle contraction, or extrinsic compression of the airways.

Lung elastic recoil also influences airway resistance and airflow. Decreased lung recoil increases resistance by promoting collapse of the small airways (E-Fig. 15-1). Normal resistance when breathing at FRC at low flow rates is in the range of 1 to 2 cm H₂O/L per second.

Distribution of Ventilation

The distribution of inhaled volume throughout the lung is unequal. In general, more of the inhaled volume goes to the bases of the lung than to the apex when the individual is inhaling while in an upright body position. This pattern of volume distribution leads to greater ventilation of the bases than at the apices. This inhomogeneity of ventilation results largely from regional differences in lung compliance. The alveoli at the lung apex are relatively more inflated at FRC than the alveoli at the lung base. The difference in alveolar distention from apex to base is related to pleural pressure differences from apex to base. The weight of the lung causes pleural pressure to be more negative at the apex

FIGURE 15-9 As lung volume increases, the airways are dilated, and airways resistance (AWR) decreases. The reciprocal of resistance (conductance) increases as lung volume increases.

E-FIGURE 15-1 Mechanisms of airflow obstruction.

and less negative at the base. The normal difference in pleural pressure from apex to base in an adult is about 8 cm H₂O (Fig. 15-10). Because the apical alveoli are more stretched at FRC, they are operating on a stiffer, less compliant region of their volume-pressure curve than the alveoli at the bases, making them more difficult to inflate than the basilar alveoli. Therefore, at the beginning of inspiration, more volume is directed toward the base than to the apex of the lung.

Control of Ventilation

Maintenance of adequate oxygenation and acid-base balance is accomplished through the respiratory control system. This system consists of the neurologic respiratory control centers, the respiratory effectors (muscles that provide the power to inflate the lungs), and the respiratory sensors. The respiratory center that automatically controls inspiration and expiration is located in the medulla of the brain stem. The respiratory center in the brain stem has an intrinsic rhythm generator (pacemaker) that drives breathing. The output of this center is modulated by inputs from peripheral and central chemoreceptors, from mechanoreceptors in the lungs, and from higher centers in the brain, including conscious control from the cerebral cortex. The respiratory center in the medulla is primarily responsible for determining the level of ventilation.

Carbon dioxide is the primary factor controlling ventilation. Carbon dioxide in the arterial blood diffuses across the blood-brain barrier, thereby reducing the pH of the cerebral spinal fluid and stimulating the central chemoreceptors. A change in PaCO₂ above or below normal will increase or decrease ventilation, respectively. During quiet, resting breathing, the level of PaCO₂ is thought to be the major factor controlling breathing. Only when the PaO₂ (i.e., the partial pressure of oxygen dissolved in the blood that is not bound to hemoglobin) falls substantially does ventilation respond significantly. Typically, PaO₂ needs to fall to

FIGURE 15-10 Transpulmonary pressure and volume for lung units at the base and apex of the lung. Because pleural pressure is more negative at the apex of the lung. Therefore, the alveoli in that region are stretched, placing them on a less compliant part of the volume-pressure curve. For a given change (P) in transpulmonary pressure during inspiration, the more compliant base inflates to a greater degree than the apex (V_1 and V_2 , respectively).

less than 50 mm Hg before ventilation dramatically increases (Fig. 15-11). Low oxygen levels in the blood are not sensed by the respiratory center in the brain but are sensed by receptors in the carotid body. These vascular receptors are located between the internal and external branches of the carotid artery. Changes in PaO₂ are sensed by the carotid sinus nerve. Neural traffic projects to the respiratory center through the glossopharyngeal nerve, which serves to modulate ventilation. The carotid body also senses changes in PaCO₂ and pH. Nonvolatile acids (e.g., ketoacids) stimulate ventilation through their effects on the carotid body.

The outcome of this complex respiratory control system is that variables such as PaO₂, PaCO₂, and pH are held within narrow limits under most circumstances. The respiratory control center also can adjust tidal volume and frequency of breathing to minimize the energetic cost of breathing and can adapt to special circumstances such as speaking, swimming, eating, and exercise. Breathing can be stimulated by artificial manipulation of the PCO₂, PO₂, and pH. For example, ventilation is increased by rebreathing of carbon dioxide, inhalation of a concentration of low oxygen, or infusion of acid into the bloodstream.

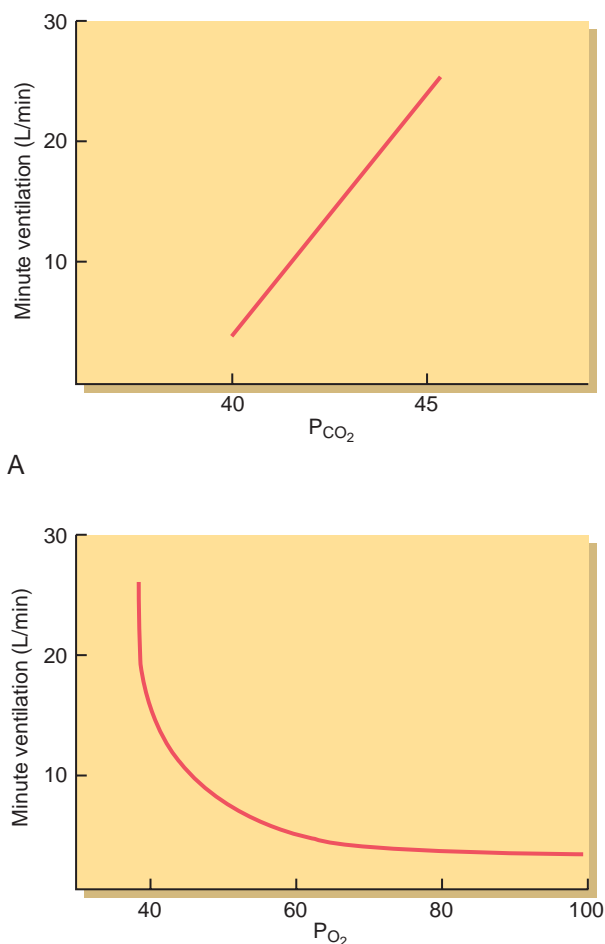

FIGURE 15-11 **A**, A rising partial pressure of carbon dioxide (PCO₂) leads to a linear increase in minute ventilation. **B**, The ventilatory response to hypoxemia is less sensitive and is clinically relevant only when the partial pressure of oxygen (PO₂) has dropped significantly.

Perfusion

The pulmonary vascular bed differs from the systemic circulation in several respects. The pulmonary vascular bed receives the entire cardiac output of the right ventricle, whereas the cardiac output from the left ventricle is dispersed among several organ systems. Despite receiving the entire cardiac output, the pulmonary system is a low-resistance, low-pressure circuit. The normal mean systemic arterial pressure is about 100 mm Hg, whereas the normal mean pulmonary artery pressure is in the range of 15 mm Hg. The vascular bed can passively accommodate an increase in blood flow without raising arterial pressure by recruiting more vessels in the lung. During exercise, for example, there is little increase in pulmonary artery resistance despite a large increase in pulmonary blood flow. Hypoxic vasoconstriction, another feature unique to the pulmonary vascular system, regulates regional blood flow. This regulation aids in matching blood flow to ventilation by reducing flow to poorly ventilated regions of the lung.

Perfusion (\dot{Q}) refers to the blood flow through an organ (i.e., the lung). In the upright individual, there is greater perfusion of the lung bases than of the apices (Fig. 15-12). In a low-pressure system such as the pulmonary circulation, the effects of gravity on blood flow need to be taken into account. The arterial-venous pressure difference usually provides the “driving” pressure for blood flow in the systemic circulation, but this is true only for certain regions of the lung. Pulmonary blood flow also needs to be considered in the context of alveolar pressure. Venous and arterial pressures are importantly affected by gravity, whereas alveolar pressure remains constant throughout the lung, assuming the airways are open. Therefore, as one descends from the apex to the base of the lung, arterial and venous pressures increase because of gravity but alveolar pressure remains constant.

At the apex, alveolar pressure may be greater than arterial pressure. This region of the lung is referred to as *zone 1*, and, in theory,

FIGURE 15-12 Zonal model of blood flow in the lung. Because of the inter-relationship of arterial (P_a) and venous (P_v) vascular pressures and alveolar (P_A) pressures, the lung base receives the most flow (see text for explanation). (From West JB, Dollery CT, Naimark A: Distribution of blood flow in isolated lung: relation to vascular and alveolar pressures, *J Appl Physiol* 19:713–724, 1964.)

it receives no blood flow. The alveolar pressure may be greater than arterial pressure, for example, in special circumstances such as hypovolemic shock, which lowers the arterial pressure, or with very high levels of positive end-expiratory pressure (PEEP), which increases alveolar pressure.

As one descends from the apex toward the midzone of the lung, arterial and venous pressures increase, whereas alveolar pressure remains constant. At some point, arterial pressure becomes greater than alveolar pressure. In this region, the driving pressure for blood flow is the arterial-alveolar pressure difference. This region is referred to as *zone 2* of the lung. Normally, *zone 2* is very small because alveolar pressure is less than venous pressure in most of the lung. However, with high levels of PEEP, alveolar pressure becomes greater than venous pressure in more lung regions.

Further toward the base of the lung, the effects of gravity on arterial and venous pressures are more pronounced, venous pressure becomes greater than alveolar pressure, and the arterial-venous pressure difference provides the driving pressure for blood flow, as in the systemic circulation. This region is referred to as *zone 3* of the lung.

Normally, most of the lung is in *zone 3*, and most of the perfusion is to the lung base. This inequality in perfusion from apex to base is *qualitatively* similar to the inequality of ventilation from apex to base. However, blood flow increases from apex to base *more* than ventilation does, and this accounts for the small amount of ventilation-perfusion inequality that exists in the normal lung.

Gas Transfer

Oxygen and carbon dioxide are easily dissolved in plasma. Nitrogen is much less soluble and is not significantly exchanged across the alveolar-capillary interface. The driving force for the diffusion of a gas across a tissue barrier is the difference in partial pressure of the gas across the barrier. The partial pressure of oxygen in inspired room air entering the trachea is 150 mm Hg; this is derived from the equation, $PO_2 = (P_{atm} - PH_2O) \times FIO_2$, assuming that P_{atm} (atmospheric pressure) is 760 mm Hg, PH_2O (the partial pressure of water vapor) is 47 mm Hg, and FIO_2 (the fraction of oxygen in inspired air) is 20.9%. In the alveolus, however, the partial pressure of oxygen is reduced to 100 mm Hg because the inspired V_T mixes with about 3 L of “oxygen-poor” air already in the lungs and is diluted by carbon dioxide moving into the alveolus from the pulmonary capillaries. The partial pressure of oxygen in the alveolus (PAO_2) is set by the balance of these processes. Increasing minute ventilation increases the amount of oxygen added to the alveolus while lowering the $PACO_2$ —the opposite result from hypoventilation. This reciprocal relationship between alveolar carbon dioxide and alveolar oxygen is described by the *alveolar gas equation*:

$$PAO_2 = [(P_{atm} - PH_2O) \times FIO_2] - (PACO_2 / RER)$$

where RER is the respiratory exchange ratio, usually about 0.8.

The pressure gradient that drives diffusion of oxygen from the alveolus to the capillary is the difference between the alveolar PO_2 (100 mm Hg) and the arterial PO_2 (40 mm Hg) in the capillary blood entering the alveolus. By the time the blood leaves the alveolus, the PO_2 in the capillary blood has risen to 100 mm Hg.

However, because small regions of ventilation-perfusion inequality and shunt exist in the normal lung, the PO_2 in the pulmonary veins from the lungs as a whole is usually about 90 mm Hg. Therefore, the difference between the alveolar and arterial partial pressures of oxygen, known as the *A-a gradient*, is typically about 10 mm Hg in health.

The pressure gradient that drives carbon dioxide from the mixed venous blood into the alveolus is the difference in partial pressure of carbon dioxide (45 mm Hg in mixed venous blood and 40 mm Hg in the alveolus). Despite the lower driving pressure for carbon dioxide compared with oxygen, the greater solubility of carbon dioxide allows complete equilibration between the alveolus and plasma during each respiratory cycle (Fig. 15-13).

Most of the oxygen contained in the blood is bound to hemoglobin; a small fraction is dissolved and measured as the PaO_2 . The amount of oxygen dissolved is about 3 mL/L in arterial blood, whereas the amount of oxygen bound to hemoglobin is about 197 mL/L, assuming a normal hematocrit. Each molecule of hemoglobin is capable of carrying four molecules of oxygen. The shape of the oxyhemoglobin association curve reflects the cooperative binding of oxygen to hemoglobin (Fig. 15-14). In general, the hemoglobin saturation is between 80% and 100% with PaO_2 values greater than 60 mm Hg and drops dramatically when the PaO_2 is less than 60 mm Hg. Factors that decrease the affinity of hemoglobin for oxygen include a reduction in blood pH, an increase in temperature, an increase in $Paco_2$, and an increase in the concentration of 2,3-diphosphoglyceric acid (2,3-DPG) (Fig. 15-15). These factors facilitate unloading of oxygen into tissues, which is seen as a shift of the oxyhemoglobin

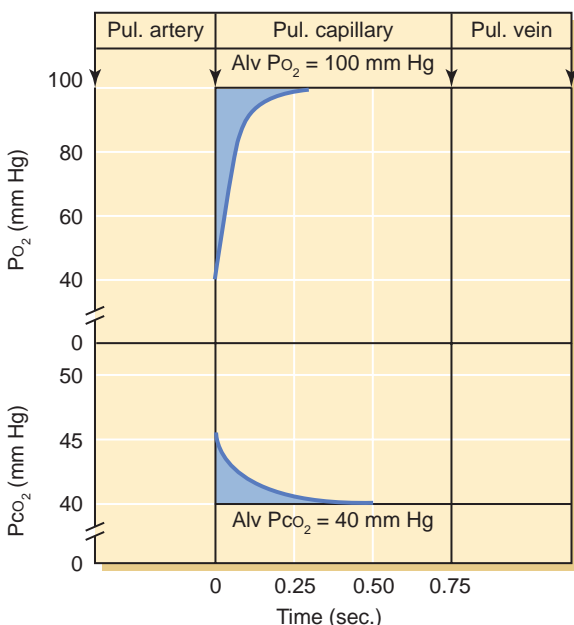

FIGURE 15-13 Changes in the partial pressures of oxygen (PO_2) and carbon dioxide (PCO_2) as blood courses from the pulmonary artery through the capillaries and into the pulmonary veins. The diffusion gradient is greater for O_2 than for CO_2 . However, equilibration of capillary and alveolar gas occurs for both molecules within the 0.75 second it takes for blood to traverse the capillaries. Alv, Alveolar; Pul, pulmonary.

dissociation curve to the right. The oxygen-carrying capacity of hemoglobin is also affected by competitive inhibitors for binding sites, such as carbon monoxide. Carbon monoxide has an affinity for hemoglobin that is 240 times greater than that of oxygen and preferentially binds to the hemoglobin molecule. However, this does not affect the amount of oxygen dissolved in the blood. Someone with carbon monoxide poisoning may have a normal PaO_2 but a very low blood oxygen content because of the high amount of desaturated hemoglobin.

About 5% of carbon dioxide in the blood is dissolved in plasma, and about 10% is bound to hemoglobin. However, carbon dioxide does not exhibit cooperative binding; therefore, the shape of the carbon dioxide-hemoglobin dissociation curve is linear. Carbon dioxide binds to the protein component of the hemoglobin molecule and to the amino groups of the polypeptide chains of plasma proteins to form carbamino compounds. About 10% of carbon dioxide is transported in this fashion. Most of the carbon dioxide is transported as bicarbonate ion: As carbon dioxide diffuses from metabolically active tissue into the blood, it reacts with water to form carbonic acid. This reaction primarily occurs in the red blood cells because it is catalyzed by the enzyme carbonic anhydrase, which resides in those cells. Carbonic acid then dissociates to bicarbonate and hydrogen ion. Although there is more carbon dioxide dissolved in blood than oxygen, it is still a small fraction of the total carbon dioxide transported by blood.

Abnormalities of Pulmonary Gas Exchange

The arterial PO_2 and PCO_2 are determined by the degree of equilibration between the alveolar gas and capillary blood, which depends on four major factors: ventilation, matching of ventilation with perfusion, shunt, and diffusion. *Hypoxemia* refers to a reduction in the oxygen content of the blood and is determined by measuring the PO_2 of arterial blood. In contrast, *hypoxia* refers to a decrease in oxygen content of an organ, for example, myocardial hypoxia. Aberrations in the four factors listed can result in hypoxemia. A fifth cause of hypoxemia is a low inspired PO_2 , which may occur at altitude.

FIGURE 15-14 The oxyhemoglobin dissociation curve. The bulk of the oxygen (O_2) is combined with hemoglobin (Hb). Little is dissolved in plasma. PO_2 , Partial pressure of oxygen.

FIGURE 15-15 **A**, The various factors that decrease the oxygen affinity of hemoglobin are shown shifting the curve to the right. **B**, The carbon dioxide dissociation curve is more linear than the oxyhemoglobin curve throughout the physiologic range. Increased partial pressure of oxygen in the arteries (P_{aO_2}) shifts the curve to the right, decreasing the carbon dioxide content for any given arterial partial pressure of carbon dioxide (P_{aCO_2}) and thereby facilitating carbon dioxide off-loading in the lungs. The shift to the left at a lower P_{aO_2} facilitates carbon dioxide on-loading at the tissues. 2,3-DPG, 2,3-Diphosphoglycerate.

Hypoventilation is defined as ventilation that is inadequate to keep PCO_2 from increasing above normal. Hypoxemia may occur when increased carbon dioxide in the alveoli displaces alveolar oxygen. As alveolar ventilation falls and $PaCO_2$ rises, PAO_2 will have to fall. Administration of supplemental oxygen (i.e., increasing the FIO_2) can reverse hypoventilation-induced hypoxemia. When one is breathing room air, the difference between alveolar oxygen and arterial oxygen (A-a gradient) is normally about 10 mm Hg. Typically, this difference increases when hypoxemia is present. However, if the hypoxemia is caused by hypoventilation, the A-a gradient will be within normal limits. Causes of hypoventilation are varied and range from diseases or drugs that depress the respiratory control center to disorders of the chest wall or respiratory muscles that impair respiratory pump function. Disorders associated with hypoventilation include inflammation, trauma, or hemorrhage in the brain stem; spinal cord pathology; anterior horn cell disease; peripheral neuropathies;

FIGURE 15-16 **A**, The effects of increasing inequality of alveolar ventilation and perfusion (decreasing \dot{V}_A/\dot{Q}) on the arterial partial pressures of oxygen (P_{O_2}) and carbon dioxide (P_{CO_2}) when cardiac output and minute ventilation are held constant. **B**, The gas tensions change when minute ventilation is allowed to increase. Increased ventilation can maintain a normal arterial P_{CO_2} but can only partially correct the hypoxemia. (Modified from Dantzker DR: Gas exchange abnormalities. In Montenegro H, editor: Chronic obstructive pulmonary disease, New York, 1984, Churchill Livingstone, pp 141–160.)

myopathies; abnormalities of the chest wall such as kyphoscoliosis; and upper airway obstruction. Administration of a higher FIO_2 alleviates the hypoxemia but does little to improve the elevated $PaCO_2$.

The most common cause of hypoxemia in disease states is ventilation-perfusion mismatch. In regions where the ratio of ventilation \dot{V} to perfusion \dot{Q} is low, the blood receives little oxygen from the poorly ventilated alveoli. By contrast, in regions where \dot{V}/\dot{Q} is high, the blood is well oxygenated but receives little additional oxygen despite the higher ventilation because the shape of the oxyhemoglobin dissociation curve plateaus at levels of high PAO_2 . As a result, lung units with high \dot{V}/\dot{Q} cannot completely correct for the low oxygen content of blood flowing past units with low \dot{V}/\dot{Q} . Thus, the oxygen uptake of the whole lung is lowered, causing hypoxemia. In the ideal lung, ventilation and perfusion would be perfectly matched (i.e., $\dot{V}/\dot{Q} = 1$). However, the \dot{V}/\dot{Q} normally ranges from 0.5 at the base to 3 at the apex, with an overall value of 0.8. If lung disease develops, ventilation-perfusion inequality may be amplified. If the \dot{V}/\dot{Q} is less than 0.8, the A-a gradient is increased and hypoxia ensues. The $PaCO_2$ is usually within the normal range but increases slightly at extremely low \dot{V}/\dot{Q} ratios (Fig. 15-16). Typically, hypoxemia in diseases that affect the airways, such as chronic obstructive pulmonary disease (COPD), is caused by ventilation-perfusion mismatch. As with hypoxemia due to hypoventilation, administration of a higher FIO_2 improves hypoxemia by improving the PAO_2 in areas of low \dot{V}/\dot{Q} .

The third cause of hypoxemia is shunt. A right-to-left shunt occurs when a portion of blood travels from the right side to the left side of the heart without the opportunity to exchange oxygen and carbon dioxide in the lung. Right-to-left shunts can be classified as anatomic or physiologic. With an anatomic shunt, a portion of the blood bypasses the lung by traversing through an anatomic canal. In all healthy individuals, there is a small fraction of blood in the bronchial circulation that passes to the pulmonary veins and empties into the left atrium, thereby reducing the PaO_2

of the systemic circulation. A smaller portion of the normal shunt is related to the coronary circulation draining through the thebesian veins into the left ventricle. Anatomic shunts found in disease states can be classified as intracardiac or intrapulmonary shunts. Intracardiac shunts occur when right atrial pressures are elevated and deoxygenated blood travels from the right atrium to the left atrium through an atrial septal defect or patent foramen ovale. Intrapulmonary anatomic shunts consist primarily of arteriovenous malformations or telangiectasias. With a physiologic right-to-left shunt, a portion of the pulmonary arterial blood passes through the normal vasculature but does not come into contact with alveolar air. This is an extreme example of ventilation-perfusion mismatch ($\dot{V}/\dot{Q} = 0$). Physiologic shunt can be caused by diffuse flooding of the alveoli with fluid, as seen in congestive heart failure or acute respiratory distress syndrome. Alveolar flooding with inflammatory exudates, as seen in lobar pneumonia, also causes a shunt. The fraction of blood shunted (Q_s/Q_t) can be calculated when the F_{IO_2} is 100% by the following equation:

$$Q_s/Q_t = (C_{CO_2} - C_{aO_2}) / (C_{CO_2} - C_{vO_2})$$

where Q_s is the shunted blood flow, Q_t is the total blood flow, C_{CO_2} is the end-pulmonary capillary oxygen content; C_{aO_2} is the arterial oxygen content; and C_{vO_2} is the mixed venous oxygen content.

If the shunt is severe enough, mechanical ventilation and PEEP are required to improve arterial oxygenation. At values less than 50% of the cardiac output, a shunt has very little effect on P_{aCO_2} (Fig. 15-17). With shunting, the A-a gradient is elevated while the P_{aCO_2} is within normal range or may be low. In contrast to hypoxemia due to hypoventilation or low \dot{V}/\dot{Q} , oxygen administration does not correct hypoxemia due to shunt because the shunted blood has no exposure to oxygen in the alveoli. However, the P_{aO_2} may increase somewhat because the higher

F_{IO_2} improves oxygenation of blood traveling to low \dot{V}/\dot{Q} areas that commonly coexist with shunt.

The fourth cause of hypoxemia is diffusion impairment. With normal cardiopulmonary function, the blood spends, on average, 0.75 second in the pulmonary capillaries. Typically, it takes only 0.25 second for the alveolar oxygen to diffuse across the thin alveolar capillary membrane and equilibrate with pulmonary arterial blood (see Fig. 15-13). However, if there is impairment to diffusion across this membrane, such as thickening of the alveolar capillary membrane by fluid, fibrous tissue, cellular debris, or inflammatory cells, it will take longer for the oxygen in the alveoli to equilibrate with pulmonary arterial blood. If the impediment to diffusion is such that it takes longer than 0.75 second for oxygen to diffuse, hypoxemia ensues, and the A-a gradient widens. Alternatively, if the time a red blood cell spends traversing the pulmonary capillary decreases to 0.25 second or less, hypoxemia may develop. Hypoxemia may be evident only during exercise in individuals with diffusion impairment because of the shortened red cell transit time. In these cases, the A-a gradient may be normal at rest but increases with exercise. With diffusion impairment, the P_{aCO_2} usually is within the normal range. As with hypoxemia due to hypoventilation or ventilation-perfusion mismatch, administration of a higher F_{IO_2} improves hypoxemia due to impaired diffusion by raising the alveolar PO_2 .

An additional cause of hypoxemia is low inspired oxygen. This may occur at high altitude: The F_{IO_2} is normal, but the PO_2 is low because the barometric pressure (P_{atm}) is low. Rarely, circumstances occur in which the F_{IO_2} is low (e.g., rebreathing air). Hypoxemia due to low inspired oxygen is associated with a normal A-a gradient and is usually accompanied by a low P_{aCO_2} . Supplemental oxygen corrects this form of hypoxemia. Finally, a low mixed venous PO_2 predisposes individuals to hypoxia (Fig. 15-18).

FIGURE 15-17 The effects of increasing shunt on the arterial partial pressures of oxygen (PO_2) and carbon dioxide (PCO_2). The minute ventilation has been held constant in this example. Under usual circumstances, the hypoxemia would lead to increased minute ventilation and a fall in the PCO_2 as the shunt increased. (From Dantzker DR: Gas exchange abnormalities. In Montenegro H, editor: Chronic obstructive pulmonary disease, New York, 1984, Churchill Livingstone, pp 141–160.)

FIGURE 15-18 The effects of increasing mixed venous partial pressure of oxygen (PO_2) on the arterial oxygen content under three assumed conditions: a normal lung, severe ventilation-perfusion inequality (\dot{V}/\dot{Q}), and the presence of a 40% shunt. For each situation, the patient is breathing 50% oxygen and the mixed venous PO_2 is altered, keeping all other variables constant. (From Dantzker DR: Gas exchange in the adult respiratory distress syndrome, Clin Chest Med 3:57–67, 1982.)

EVALUATION OF LUNG FUNCTION

Pulmonary function tests evaluate one or more major aspects of the respiratory system. Accurate measurements of lung volumes, airway function, and gas exchange require a pulmonary function testing laboratory. Pulmonary function tests are commonly used to aid in the diagnosis of disease and assess disease severity. In addition, they are helpful in monitoring the course of disease, assessing the risk for surgical procedures, and measuring the effects of varied environmental exposures. The response to bronchodilators or other forms of treatment also can be assessed with serial pulmonary function tests (Table 15-1). Accurate interpretation of pulmonary function tests requires the appropriate reference standards. Variables that affect the predicted standards include age, height, gender, race, and hemoglobin concentration.

Spirometry, the simplest means of measuring lung function, can be performed in an office practice. A spirometer is an apparatus that measures inspiratory and expiratory volumes. Flow rates can be calculated from tracings of volume versus time. Typically, vital capacity (VC) is measured as the difference between a full inspiration to total lung capacity (TLC) and a full exhalation to residual volume (RV) (Fig. 15-19). Flow rates are

measured after the patient is instructed to forcefully exhale from TLC to RV. Such a forced expiratory maneuver allows one to calculate the forced expiratory volume in 1 second (FEV_1) and the forced vital capacity (FVC) (Fig. 15-20). A value that is 80% to 120% of the predicted value is considered normal for FVC. Normally, people can exhale more than 75% to 80% of their FVC in the first second, and the majority of the FVC can be exhaled in 3 seconds. The ratio of FEV_1/FVC is normally greater than 0.80.

Spirometry can reveal abnormalities that are classified into two patterns: obstructive and restrictive. Obstructive impairments are defined by a low FEV_1/FVC ratio. Diseases that are characterized by an obstructive pattern include asthma, chronic bronchitis, emphysema, bronchiectasis, cystic fibrosis, and some central airway lesions. The reduction in FEV_1 (expressed as % predicted FEV_1) is used to determine the severity of airflow obstruction (E-Fig. 15-2). Peak expiratory flow rate (PEFR) can be measured as the maximal expiratory flow rate obtained during spirometry or when using a handheld peak flowmeter. The lower the PEFR, the more significant the obstruction. The peak flowmeter can be used at home or in the emergency department to evaluate the presence of obstruction. Severe attacks of asthma, for example, are usually associated with PEFRs of less than 200 L/minute (normal, 500 to 600 L/minute). A restrictive pattern is characterized by loss of lung volume. With spirometry, both the FVC and the FEV_1 are reduced, so the FEV_1/FVC ratio remains normal. The restrictive pattern must be confirmed by measurements of lung volumes.

Lung volumes are measured by body plethysmography or by dilution of an inert gas such as helium. Lung volumes that can be measured with these techniques include FRC, TLC, and RV (see Fig. 15-19). As described earlier, FRC is the lung volume at which the inward elastic recoil of the lung equals the outward elastic recoil of the chest wall. Changes in FRC reflect abnormalities in lung elastic recoil. Diseases associated with increased elastic recoil (e.g., pulmonary fibrosis) are associated with a reduction in FRC, whereas those with decreased recoil (e.g., emphysema) are associated with an increase in FRC. TLC is the amount of air remaining in the thorax after a maximal inspiration. It is determined by the balance of the forces generated by the respiratory muscles to expand the respiratory system and the elastic recoil of the respiratory system. Restrictive lung disease is defined as a TLC less than 80% predicted, whereas values of TLC greater than 120% predicted are consistent with hyperinflation. The lower the % predicted TLC, the more severe the restrictive impairment.

Restriction may be caused by disorders of the lung, chest wall, respiratory muscles, or pleural space. Lung diseases that cause pulmonary fibrosis cause a restrictive pattern because of the increased elastic recoil of the respiratory system. Diseases of the chest wall, such as kyphoscoliosis, obesity, or ankylosing spondylitis, can also cause restriction by reducing the elasticity of the chest wall. Weakness of the respiratory muscles causes restriction by reducing the force available to inflate the respiratory system. Myasthenia gravis, amyotrophic lateral sclerosis, diaphragm paralysis, and Guillain-Barré syndrome can be associated with weakness sufficient to cause restrictive lung disease. Finally, space-occupying lesions involving the pleural space, such as

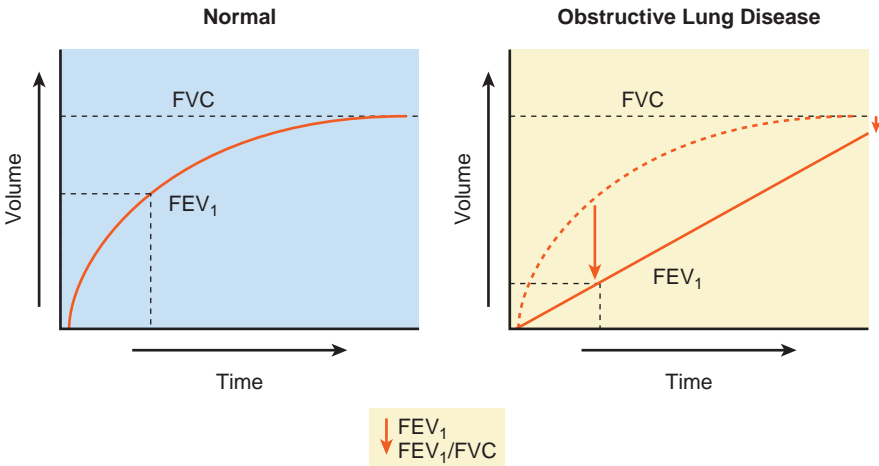

FIGURE 15-19 Lung volumes and capacities. Although spirometry can measure vital capacity and its subdivisions (red circles), calculation of residual volume (RV) requires measurement of functional residual capacity (FRC) by one of the following techniques: body plethysmography, helium dilution, or nitrogen washout. IC, Inspiratory capacity; ERV, expiratory reserve volume; TLC, total lung capacity; VC, vital capacity; VT, tidal volume.

E-FIGURE 15-2 Volume-time curve in the normal lung (*left*) and in obstructive lung disease (*right*). FEV₁, Forced expiratory volume in 1 second; FVC, forced vital capacity.

FIGURE 15-20 Spirometry in a normal individual (A) and in a patient with obstructive lung disease (B). FEV₁ represents the forced expiratory volume in 1 second, and FVC represents the forced vital capacity. The FEV₁/FVC ratio is normally greater than 0.80. With obstruction, the FEV₁/FVC ratio is less than 0.70.

FIGURE 15-21 The maximum expiratory flow and volume curve in a normal individual (A) and in an individual with obstructive lung disease (in this case, COPD) (B). Hyperinflation and air trapping (arrows) push the total lung capacity (TLC) and residual volume (RV) to the left (i.e., toward higher lung volumes). In addition, characteristic scalloping of the expiratory limb of the flow-volume curve develops. IC, Inspiratory capacity.

pleural effusions, pneumothorax, or pleural tumors, can cause restriction. Occasionally, RV and FRC may be elevated with no increase in TLC. This pattern, referred to *air trapping*, and can be seen with COPD or asthma.

The forced expiratory maneuver can be analyzed in terms of flow and volume by construction of a flow-volume loop (Fig. 15-21). Flow-volume loops are useful to identify obstructive and restrictive patterns. The characteristic appearance of obstructive impairment is concavity (“scooping”) of the expiratory loop, whereas with restrictive impairments, the loops have a normal shape but are reduced in size. In addition, flow-volume loops are the primary means of identifying upper airway obstruction. Upper airway obstruction is characterized by a truncated (clipped) inspiratory or expiratory loop. A fixed obstruction

produces clipping of both inspiratory and expiratory loops. Variable intrathoracic upper airway obstruction exhibits clipping of the expiratory loop, whereas variable extrathoracic obstruction exhibits clipping of the inspiratory loop (Fig. 15-22).

Bronchoprovocation Testing

Bronchoprovocation testing is typically used to determine the presence or absence of hyperreactive airways disease. Some individuals with a clinical suspicion of asthma have normal expiratory flow rates and lung volumes. Bronchoprovocation testing in these individuals can be important to identify hyperreactive airways disease and support the diagnosis of asthma. Methacholine is a cholinergic agonist that causes bronchoconstriction. During the bronchoprovocation test, the subject inhales

FIGURE 15-22 The flow-volume loops display different patterns of upper airway obstruction. With fixed obstruction, both inspiratory and expiratory flows are reduced (clipped). With variable extrathoracic obstruction, only the inspiratory flows are clipped. With variable intrathoracic obstruction, only the expiratory flows are clipped. RV, Residual volume; TLC, total lung capacity.

FIGURE 15-23 In bronchoprovocation challenge, patients are exposed to increasing concentrations of an inhaled challenge (e.g., methacholine, histamine), followed by evaluation of the forced expiratory volume in 1 second (percentage of baseline value) or airways conductance. The FEV₁ falls by more than 20% (compared to baseline), and airways conductance by more than 40%, at lower concentrations of the challenge drug in individuals with asthma.

increasing concentrations of methacholine. Measurements of FEV₁, FVC, and specific airways conductance are obtained after the inhalation of each concentration until the maximal dose of methacholine has been administered. If the FEV₁ is reduced by 20% or more or the specific airways conductance is reduced by 40% or more, a diagnosis of hyperreactive airways disease is established. Patients with asthma demonstrate a fall in FEV₁ at considerably smaller doses than in normal individuals (Fig. 15-23).

Lung Diffusion Capacity

The diffusion of oxygen from the alveolus into the capillary can be assessed by measuring the diffusion capacity for carbon monoxide (DLCO). To calculate the diffusion capacity for oxygen, one would need to know the alveolar volume and the partial pressures of oxygen in the alveolus and in the pulmonary capillary. Because it is not practical to measure the oxygen tension of pulmonary

TABLE 15-2 NORMAL VALUES FOR ARTERIAL BLOOD GASES

Partial pressure of oxygen (PaO ₂):	104 – (0.27 × age)
Partial pressure of carbon dioxide (PaCO ₂):	36-44
pH:	7.35-7.45
Alveolar-arterial O ₂ difference =	2.5 + (0.21 × age)

capillary blood, carbon monoxide is used rather than oxygen to assess diffusion capacity. Carbon monoxide diffuses across the alveolar capillary membranes much as oxygen does. However, carbon monoxide has the advantage of binding completely to hemoglobin. Therefore, the partial pressure of carbon monoxide in the pulmonary venous blood is negligible. The DLCO is then measured as the rate of disappearance of carbon monoxide from the alveolus and is used as a surrogate for oxygen diffusion capacity.

The DLCO measurement provides an overall assessment of gas exchange and depends on factors such as the surface area of the lung, the physical properties of the gas, perfusion of ventilated areas, hemoglobin concentration, and the thickness of the alveolar-capillary membrane. Therefore, an abnormal value may not only signify disruption of the alveolar-capillary membrane but may also be related to a reduction in surface area of the lung (pneumonectomy), poor perfusion (pulmonary embolus), or poor ventilation of alveolar units (COPD). A low DLCO may be seen in interstitial lung diseases that alter the alveolar-capillary membrane or in diseases such as emphysema that destroy both alveolar septa and capillaries (E-Fig. 15-3). Anemia lowers the DLCO. Most laboratories provide a hemoglobin correction for diffusion capacity. An increased DLCO may be associated with engorgement of the pulmonary circulation by red blood cells or polycythemia.

Arterial Blood Gases

The measurement of PaO₂ and PaCO₂ provides information about the adequacy of oxygenation and ventilation. This requires arterial blood sampling through arterial puncture or indwelling cannula (Table 15-2). Oxygenation also can be measured through noninvasive devices such as the pulse oximeter, which measures hemoglobin oxygen saturation, and through transcutaneous devices that measure Pao₂ and Paco₂. These devices are particularly useful for measuring oxygenation during exertion or sleep. Often, alterations in oxygenation are not detected at rest but are unveiled during exertion. The 6-minute walk

E-FIGURE 15-3 A photomicrograph of normal and emphysematous lungs. Notice the lack of alveolar septa in the emphysematous lung.

test is a standardized test in which the patient walks for 6 minutes while the oxygen hemoglobin saturation is measured. A decrease in saturation is abnormal and suggests impaired gas exchange capabilities, and a reduction in distance walked is a means of detecting deterioration of overall function due to lung disease.

In summary, pulmonary function tests, in conjunction with the history and physical examination, can be used to diagnose pulmonary disorders and assess severity and response to therapy, as illustrated in the flow diagram (E-Fig. 15-4).

Analysis of Exhaled Breath

Exhaled breath includes monoxides (nitric oxide and carbon monoxide) and volatile organic compounds (VOCs) that are produced endogenously by normal metabolism or in pathologic states such as cancer and inflammation. These compounds can be measured by gas chromatography, spectroscopy or other chemical means and serve as biomarkers of pulmonary inflammation or cancer. Exhaled nitric oxide is elevated in asthma, and clinical use of this biomarker has been approved by the U.S. Food and Drug Administration for diagnosis and evaluation of asthma exacerbation or quiescence. Similarly, unique patterns of exhaled VOCs provide a “fingerprint” that may identify lung cancer. Cytokines and other similar compounds in the condensate phase of exhaled breath are being investigated for possible applications in inflammatory lung diseases (e.g., cystic fibrosis, bronchiectasis). Other nonpulmonary diseases such as malabsorption syndromes and *Helicobacter pylori* infection are also detected by analysis of exhaled breath.

EVALUATION OF LUNG STRUCTURE

Chest Radiography

Generally, the evaluation of a patient with lung disease begins with routine chest radiography and then proceeds to more specialized techniques such as computed tomography (CT) or magnetic resonance imaging (MRI). Ideally, the chest radiograph consists of two different films, a posteroanterior (PA) radiograph and a lateral radiograph (E-Fig. 15-5). Many pathologic processes can be identified on a PA chest radiograph, and the lateral view adds valuable information about areas that are not well seen on the PA projection. In particular, the retrocardiac region, the posterior bases of the lung, and the bony structure of the thorax (e.g., the vertebral column) are better visualized on the lateral radiograph. The PA chest radiograph is obtained with the patient standing with his or her back to the x-ray beam and the anterior chest wall placed against the film cassette. The chest radiograph should be obtained while the patient takes the deepest breath possible. If the patient is too weak to stand or too sick to travel to the radiology department, the cassette is placed behind the patient’s back, and the x-ray beam travels from anterior to posterior (AP film). The quality of a portable film is not that of a standard PA film, but it still provides valuable information.

The examination of a chest radiograph should be systematic so that subtle abnormalities are not missed. It should include evaluation of the lungs and pulmonary vasculature, the bony thorax, the heart and great vessels, the diaphragm and pleura, the

mediastinum, the soft tissues, and the subdiaphragmatic areas. Abnormalities that are visible on a chest radiograph include pulmonary infiltrates, nodules, interstitial disease, vascular disease, masses, pleural effusions and thickening, cavitory lung disease, cardiac enlargement, some airway diseases, and vertebral or rib fractures. In addition to the PA and lateral chest radiographs, the lateral decubitus projection is often used to identify the presence or absence of pleural effusion. The decubitus view is particularly useful in determining whether blunting of the costal phrenic sulcus is caused by freely flowing pleural fluid or related to pleural thickening. Chest radiography, in concert with a good history and physical examination, allows the clinician to diagnose chest disease in many circumstances.

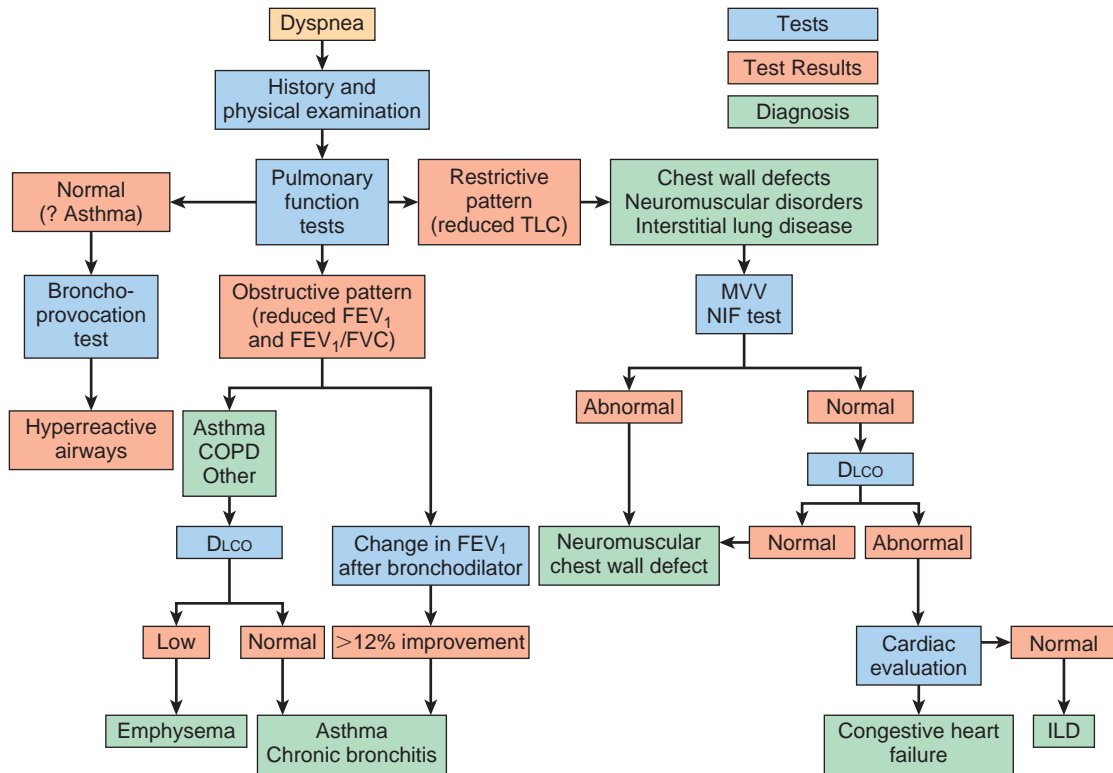

Fluoroscopy

Fluoroscopic examination of the chest is useful for evaluating motion of the diaphragm. This technique is particularly helpful in diagnosing unilateral diaphragm paralysis. A paralyzed hemidiaphragm moves paradoxically when the patient is instructed to inhale or to forcefully sniff. However, fluoroscopy is limited when evaluating for bilateral diaphragm paralysis. Apparently normal descent of the diaphragm during inspiration, caused by compensatory respiratory strategies employed by the patient with bilateral diaphragm paralysis, leads to false-negative results. False-positive results are caused by paradoxical hemidiaphragm motion, which can be seen in as many as 6% of normal subjects during the sniff maneuver. Alternatively, two-dimensional B-mode ultrasound imaging of the diaphragm can be used to visualize diaphragm contraction during inspiration. With this technique, the diaphragm muscle is visualized in the zone of apposition of the diaphragm to the rib cage. Absence of contraction correlates with absence of active transdiaphragmatic pressure and indicates diaphragm paralysis. This technique can be used to diagnose both bilateral and unilateral diaphragm paralysis.

Ultrasonography

In ultrasonographic studies, sound waves in the frequency range of 3 to 10 MHz are reflected off internal tissues to produce images of viscera such as the liver, kidney, and heart. The air-filled lung cannot be imaged directly, but over the last decade, an understanding of various *artifacts* generated by ultrasound beams traversing normal and abnormal lung have led to increased application of ultrasound for imaging of the lung, particularly in the intensive care unit. Ultrasonography can rapidly and reliably detect a pneumothorax, pleural effusion, consolidation, and even pulmonary edema with sensitivity and specificity similar to those of a chest radiograph (Fig 15-24). It is routinely used in real time to direct invasive procedures such as thoracentesis, pericardiocentesis, and placement of a pleural, central venous, or arterial catheter. Other applications of pulmonary ultrasound include assessment of volume status by imaging inferior vena cava collapsibility with respiration and assessment of right ventricular function. Ultrasound can be used to evaluate diaphragm function, as described earlier. Ultrasonic imaging is noninvasive, rapidly and easily applied, relatively low-cost, readily portable to the bedside, and, because it does not use radiation, safe for repeated use on a patient.

E-FIGURE 15-4 The flow diagram shows how pulmonary function tests can be used to evaluate patients with obstructive and restrictive disorders. COPD, Chronic obstructive pulmonary disease; DL_{CO}, diffusing capacity for carbon monoxide; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; ILD, interstitial lung disease; MVV, maximum voluntary ventilation; NIF, negative inspiratory force; TLC, total lung capacity.

E-FIGURE 15-5 Normal posteroanterior (left) and lateral (right) chest radiographs.

Computed Tomography

CT has many applications in pulmonary medicine and provides more detailed information about lung structure than chest radiography. With the use of this technique, cross sections of the entire thorax can be obtained, usually at 1-cm intervals. CT scanning allows visualization of airways up to the seventh generation and delineation of parenchymal anatomy, texture, and density. Image contrast can be adjusted to optimize visualization of the lung parenchyma or pleural and mediastinal structures. The use of intravenous contrast material as part of the examination permits separation of vascular from nonvascular mediastinal structures. CT scans provide tremendous anatomic resolution when compared with chest radiography, but they expose the subject to about 70 times the radiation of a routine chest radiograph.

CT of the chest helps to characterize pulmonary nodules and masses, distinguish between pleural thickening and pleural fluid, estimate the size of the heart and the presence of pericardial fluid, identify patterns of involvement of interstitial lung disease, detect cavities, identify intracavitary processes such as mycetoma, quantify the extent and distribution of emphysema, detect and

FIGURE 15-24 Ultrasound image of the lung depicts the diaphragm, a pleural effusion, and an infiltrate.

measure mediastinal adenopathy for staging of lung cancer, and identify vascular invasion by neoplasm (Fig. 15-25). Newer generations of CT scanners are able to use multiple x-ray beams to create between 4 and 64 images simultaneously at a much faster rate (<10 seconds) than with the older models, which used only a single x-ray beam and detector. Recently, low-dose CT has been recognized as means of screening for lung cancer in high-risk patients.

CT angiography allows for construction of three-dimensional images of the pulmonary vascular system. This imaging technique has emerged as the procedure of choice for identifying pulmonary embolism, supplanting pulmonary ventilation-perfusion scintigraphic lung scanning. The technique also can be used to identify pulmonary vascular abnormalities such as aortic dissection, pulmonary venous malformations, and aortic aneurism.

High-resolution CT is a technique that generates thin (1-mm) anatomic slices to provide a high-contrast image of the pulmonary parenchyma. With high-resolution CT, a special reconstruction algorithm sharpens the soft tissue interfaces to provide superior visualization of the pulmonary parenchyma. This technique is used primarily to identify interstitial lung disease and bronchiectasis. It is extremely useful for identifying interstitial lung disease that may not be apparent on a plain chest radiograph, and it has supplanted bronchography in the diagnosis of bronchiectasis.

Magnetic Resonance Imaging

MRI is a tomographic technique that uses radio waves modified by a strong magnetic field to produce an image resulting from the resonance of protons in tissue water. The chief advantage of MRI is that it does not entail the use of ionizing radiation. Because of the low proton density in air-filled lungs, artifacts arising from multiple air-tissue interfaces and respiratory motion artifacts limit the ability of MRI to image pulmonary parenchyma. However, vascular structures and pulmonary perfusion are well imaged by MRI, especially with the use of intravenous contrast agents such as gadolinium chelates. Therefore, MRI is very useful in the study of aortic dissection and may have a role in the evaluation of pulmonary emboli. Three-directional velocity-encoded MRI allows three-dimensional, time-resolved cine

FIGURE 15-25 Chest radiograph (A) and chest computed tomographic (CT) scan (B) of a patient with severe bronchiectasis. The abnormally dilated airways are better appreciated on the CT scan.

reconstruction of blood flow patterns and pressures and is used in cardiac imaging. It may also have a role in the measurement of pulmonary blood flow. Infiltrative pulmonary diseases and pulmonary edema increase proton density in the lung, allowing better definition by MRI of honeycombing in pulmonary fibrosis and pulmonary edema in acute respiratory distress syndrome (ARDS). The use of inhaled hyperpolarized inert gases such as helium 3 or xenon 129 offers the ability to quantify peripheral airspace size, measure gas flow in lobar and segmental bronchi, and detect regional differences in ventilation. It has promising applications in the evaluation of emphysema and asthma and after lung transplantation, including assessment of bronchodilator responsiveness.

Pulmonary Angiography

Pulmonary angiography entails placement of a catheter in the pulmonary artery, followed by rapid injection of a contrast agent. In the past, this was “gold standard” for diagnosis of pulmonary thromboembolic disease. Pulmonary angiography still can be useful for detection of congenital abnormalities of the pulmonary vascular tree, but CT and MRI have largely supplanted it.

Positron Emission Tomography

Positron emission tomography (PET) detects metabolically active masses greater than 0.8 cm in diameter. It is helpful in assessing whether a pulmonary nodule is benign or malignant. However, it does not distinguish between inflammation and malignancy. Therefore, assessment of multiple pulmonary nodules by PET is limited because of false-positive findings due to active granulomatous disease such as tuberculosis, sarcoidosis, or fungal infections.

Dual-modality integrated PET-CT combines morphologic and functional imaging. The combination of PET and CT is helpful for localizing solitary metastatic lymph nodes in the hilum, allowing better staging of lung cancer. In addition, PET-CT is helpful in planning radiation therapy for patients who have lung cancer associated with atelectasis.

Bronchoscopy

Fiberoptic bronchoscopy is used for diagnostic or therapeutic indications. It is most commonly performed to directly visualize the nasopharynx, larynx, vocal cords, and proximal tracheobronchial tree for diagnostic purposes. The procedure is performed by sedating the patient and providing local anesthesia with inhaled and bronchoscopically instilled lidocaine. The bronchial mucosa is assessed for endobronchial masses, mucosal integrity, extrinsic compression, dynamic compression, and hemorrhage. The bronchoscope is equipped with a channel for passage of biopsy forceps, bronchial brushes, or needles for aspiration and tissue biopsy. Saline also can be instilled through the channel for bronchial washings or bronchoalveolar lavage. Bronchial washings can be analyzed for cytology, culture, and special stains. A bronchial brush is used to scrape the bronchial mucosa and harvest cells for cytology. Bronchoscopes can also be adapted to provide ultrasound images of the airways and neighboring tissues. Endobronchial ultrasound (EBUS) uses high acoustic frequencies, in the range of 20 MHz, to provide high-resolution images of proximal

tissue. EBUS can provide guidance for needle aspiration of mediastinal lymph nodes.

Common therapeutic indications for bronchoscopy include retrieval of foreign bodies, suctioning of secretions, reexpansion of atelectatic lung, treatment of hemoptysis, and assistance with difficult endotracheal intubations. In special centers, bronchoscopy is used to perform yttrium aluminum garnet (YAG) laser therapy for endobronchial lesions, guide placement of catheters for brachytherapy in lung cancer, or guide placement of stents. Lasers produce a beam of light that can induce tissue vaporization, coagulation, and necrosis. Cryotherapy probes induce tissue necrosis through hypothermic cellular crystallization and microthrombosis. Cryotherapy and electrocautery have been used to treat and relieve airway obstruction caused by benign tracheal bronchial tumors, polyps, and granulation tissue. The goal of endobronchial brachytherapy is to relieve airway obstruction from central tumors. This is typically used as an adjunct to conventional external-beam irradiation. Tracheobronchial stenting can be performed to manage airway compression associated with malignant tumors, tracheoesophageal fistulas, or tracheobronchomalacia. Bronchoscopy is generally a safe procedure; major complications, including significant bleeding, pneumothorax, and respiratory failure, occurring in 0.1% to 1.7% of patients.

PROSPECTUS FOR THE FUTURE

Continued refinement and evolution of techniques and methods currently used to assess pulmonary structure and function will enhance the ability to diagnose and treat individuals with lung disease. Although pulmonary function testing has been performed for decades, advances in equipment design and better standardization of methods will improve accuracy and reproducibility. Further development of noninvasive techniques used to measure changes in lung volume from body surface displacements may allow for assessment of pulmonary function in settings outside the pulmonary function laboratory. Analysis of exhaled gas for biomarkers has tremendous potential for early diagnosis of many lung diseases, especially cancer.

Great strides in assessing lung structure will evolve from advances in CT, PET, and MRI technology. CT volume-rendering techniques will provide images of the central airways, enabling “virtual bronchoscopy.” This technique will be useful to guide biopsy site selection in conventional bronchoscopy and to allow visualization of airways distal to an endobronchial obstruction. Volumetric measurements of pulmonary nodules using CT segmentation techniques will allow more accurate calculation of nodule volume and better assessment of tumor doubling times. This, in concert with PET-CT, may provide more accurate means of determining the malignant potential of a solitary pulmonary nodule.

MRI may evolve into the preferred method for evaluating pulmonary emboli, mediastinal disease, and regional ventilation-perfusion matching. Velocity-encoded MRI is a promising modality for assessment of pulmonary vascular blood flow and pressures and may prove to be more accurate than current noninvasive methods. Lymph node-specific magnetic resonance contrast agents and the development of PET molecular tracers targeting tumor proteins and receptors may better differentiate enlarged lymph nodes caused by hyperplasia from those due to

neoplasia. Finally, new insights into the function of the respiratory control centers in the cortex and brain stem may be attained from the use of functional MRI studies of the brain.

Obstructive Lung Diseases

Matthew D. Jankowich

INTRODUCTION

The obstructive lung diseases are a group of pulmonary disorders that result in dyspnea characterized by an obstructive pattern of expiratory airflow limitation on spirometry. These disorders include chronic obstructive pulmonary disease (COPD), asthma, cystic fibrosis (CF), bronchiectasis, and the bronchiolar disorders. In some cases, these disorders overlap clinically (Fig. 16-1), sharing several features aside from the presence of expiratory airflow limitation. These features may include symptoms of wheezing and sputum production, chronic airway-centered inflammation, presence of airway structural changes resulting in remodeling of the airways, and episodic periods of temporarily worsened clinic status, known as exacerbations. However, the causes, locations, and patterns of airway inflammatory changes and remodeling, as well as the treatments, prognoses, and natural histories, are often significantly different, making clinical distinction among these disorders important.

COPD is characterized in general by abnormal airway inflammation and abnormal lung structure in response to an inhaled irritant (typically cigarette smoke); this results in irreversible or incompletely reversible airflow limitation and is typically progressive over time. *Asthma* is distinguished from COPD by characteristic smooth muscle hyperreactivity and reversible airflow

limitation, by its variable clinical course, and by its frequent association with atopy. These disorders are epidemic in the general population worldwide and account for a significant proportion of the morbidity and mortality associated with the obstructive lung diseases. *Bronchiectasis* is a permanent abnormal dilation of the bronchi that results in chronic cough, purulent sputum production, and hemoptysis; it is caused by diverse conditions, including CF, a genetic disorder resulting from mutations in the *CFTR* gene. The *bronchiolar disorders*, also called *small airways disorders*, result from inflammation and/or fibrosis of the small airways of the lung that leads to dyspnea. They may be difficult to diagnose because loss or obstruction of a majority of the small airways must occur before the appearance of expiratory airflow limitation on spirometry.

The basis for expiratory airflow obstruction varies among these disorders. The flow of air through the bronchial tree is directly proportional to the driving pressure and inversely proportional to the resistance. In obstructive lung disease, alterations in one or both of these processes may be present. Loss of lung elastic tissue, frequently present in COPD, results in decreased lung elastic recoil on expiration and therefore decreased driving pressure for expiratory airflow. By contrast, airflow limitation in asthma is primarily caused by smooth muscle contraction resulting in bronchoconstriction that increases airway resistance. Increases in airway resistance are also present in COPD and are related to small airway inflammation and fibrosis as well as small airway collapse due to decreased “tethering” of the airways in the setting of loss of surrounding lung elastic tissue. Mucus obstruction of airway lumens contributes to increased airway resistance in all the obstructive lung diseases.

Obstruction to airflow causes characteristic changes in lung volumes. The residual volume (RV) and functional residual capacity (FRC) are increased, whereas the total lung capacity (TLC) remains normal or is increased. Vital capacity, and particularly inspiratory capacity, is eventually reduced by the increase in RV. Several factors may contribute to the increase in FRC and RV in obstructive lung disease. Decreased lung elastic recoil in COPD increases the FRC because of reduced opposition to the outward force exerted by the chest wall. Loss of airway tone and decreased tethering by the surrounding lung in COPD, as well as bronchoconstriction and mucus plugging in acute asthma, allow airways to collapse at higher lung volumes and trap excessive air. Finally, under demands for increased minute ventilation (e.g., during exercise), the increased resistance to airflow may not allow the lungs to empty completely in the time available for expiration; this leads to so-called dynamic hyperinflation of the lungs as the volume of trapped air progressively increases while

FIGURE 16-1 Classification of obstructive lung diseases. Although most patients with chronic obstructive pulmonary disease (COPD) have small airways disease, the bronchiolar disorders do not overlap with COPD. CF, Cystic fibrosis.

the inspiratory capacity is progressively limited. This phenomenon contributes to symptoms of chest tightness and dyspnea during exercise and results in exercise limitation, especially in COPD.

There are two major consequences of the changes in lung volume in obstructive lung disease. First, breathing at higher lung volumes requires a higher change in pressure for the smaller change in lung volume, and this requirement increases the work of breathing. Second, larger lung volumes place the inspiratory muscles at a mechanical disadvantage. The diaphragms are flattened, decreasing its ability to change intrathoracic volume, and all the inspiratory muscle fibers are shortened, decreasing the tension they are able to exert to effect changes in lung volume. The combination of a higher work of breathing and mechanical disadvantages of the respiratory muscles caused by lung hyperinflation can lead to respiratory muscle fatigue and failure in the setting of an abrupt worsening of airway obstruction, as during an acute exacerbation of COPD or asthma.

In addition to the clinical history and physical examination, spirometry is a key step in the diagnostic work-up for a patient with suspected obstructive lung disease. Although spirometry is readily available and inexpensive, it is often underutilized, and as a consequence, obstructive lung diseases are underdiagnosed. Assessment of the clinical and spirometric response to a bronchodilator is a simple and helpful step in distinguishing asthma from COPD. Measurement of the diffusing capacity of the lungs for carbon monoxide (DLCO) can also be helpful in separating asthma, which is characterized by a normal or elevated diffusing capacity, from COPD, in which the diffusing capacity is often reduced by loss of surface area for gas exchange. More sophisticated testing, such as high-resolution chest computed tomography (HRCT), may be needed to help diagnose less common causes of obstructive lung disease (e.g., bronchiectasis).

The clinical features and laboratory findings associated with the various obstructive lung disorders are summarized in Table 16-1.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Definition and Epidemiology

The Global Initiative for Chronic Obstructive Lung Disease (GOLD) currently defines COPD as a common preventable and treatable disease characterized by persistent airflow limitation that is usually progressive and associated with an enhanced chronic inflammatory response in the airways and lungs to noxious particles and gases. The presence of airflow limitation is established by spirometry: If the ratio of the forced expired volume in 1 second (FEV_1) to the forced vital capacity (FVC) is less than 0.70 after administration of a bronchodilator, airway obstruction is indicated. Although in the past COPD was defined by the presence of either *emphysema* (a pathologic enlargement of the distal air spaces) or *chronic bronchitis* (a clinical syndrome characterized by the presence of cough and sputum production for at least 3 months in each of 2 consecutive years), the current definition is based on the presence of airflow limitation and not on the presence of these entities. Both emphysema and chronic bronchitis may occur with or without the simultaneous presence of expiratory airflow limitation, and therefore these entities overlap with but are not synonymous with COPD (see Fig. 16-1). The current definition of COPD highlights the presence of persistent, reproducible expiratory airflow limitation and emphasizes the progressive nature of COPD and the presence of abnormal inflammation in the lungs and airways.

COPD is a common disorder in populations across the world. The Burden of Obstructive Lung Disease study, in a sample of adults from 12 countries, found that 10.1% had at least moderate airway obstruction ($FEV_1/FVC < 0.70$ and $FEV_1 < 80\%$ predicted) after administration of a bronchodilator. Prevalence rates for COPD are correlated with increasing age, lower socioeconomic status, and smoking. Although COPD is more prevalent in men than in women, the prevalence of COPD in women has been increasing, and annual death rates for COPD have been steadily rising in both white and black women in the United

TABLE 16-1 FEATURES OF OBSTRUCTIVE LUNG DISEASE

DISORDER	CLINICAL FEATURES	LABORATORY FINDINGS
Chronic obstructive pulmonary disease	Chronic progressive dyspnea Cough, sputum production Periodic exacerbations	$FEV_1/FVC < 0.70$ after bronchodilator use Often reduced DLCO
Asthma	Episodic dyspnea, cough, and/or wheezing Nocturnal symptoms May have environmental trigger(s)	Variable airflow obstruction on spirometry Typically significant improvement in FEV_1 with bronchodilator use DLCO normal or elevated Methacholine challenge shows airway hyperreactivity
Bronchiectasis	Chronic cough and purulent sputum production Hemoptysis	Chest radiograph: "tram track" shadows HRCT: dilated bronchi bigger than accompanying vessel, lack of tapering of bronchi, visible bronchi within 1-2 cm of lung border Sputum culture may grow <i>Haemophilus influenzae</i> , <i>Pseudomonas aeruginosa</i> , or atypical mycobacteria Laboratory evaluation may reveal specific etiology (e.g., decreased immunoglobulin levels in CVID)
Cystic fibrosis	Sinusitis, bronchiectasis, meconium ileus, malabsorption, infertility (in males, congenital absence of vas deferens)	Increased sweat chloride concentration, mutation in CFTR chloride channel, elevated fecal fat, abnormal nasal mucosal potential difference
Bronchiolar disorders	Progressive dyspnea Possible history of connective tissue disease, inflammatory bowel disease, lung transplantation, or hematopoietic stem cell transplantation	Fixed airflow obstruction on spirometry HRCT: mosaic attenuation pattern; centrilobular nodules; tree-in-bud opacities

CVID, Common variable immunodeficiency; DLCO, diffusing capacity for carbon monoxide; FEV_1 , forced expiratory volume in 1 second; FVC, forced vital capacity; HRCT, high-resolution computed tomography.

States. COPD results in a significant economic burden in terms of health care expenditures and disability. In 2008, there were more than 820,000 inpatient hospital stays for COPD among U.S. adults, and patients with COPD also frequently utilize acute outpatient and emergency room care. Finally, COPD contributes substantially to mortality from chronic disease. According to the World Health Organization, COPD is the fourth leading cause of death worldwide.

COPD is a complex disorder that results from a susceptibility to environmental factors brought about by a genetic predisposition. Cigarette smoking is the major environmental cause of COPD, although other factors may contribute, including outdoor air pollution, dust and fume exposure in the workplace, and indoor air pollution from use of biomass fuels for cooking and heat. Nonsmokers can and do develop COPD, highlighting the role of non-tobacco-related risk factors. A genetic predisposition is implied by the documentation of familial clusters of COPD. However, the only genetic disorder thus far definitively linked to COPD is α_1 -antitrypsin deficiency resulting from mutations in *SERPINA1*, which accounts for approximately 1% to 2% of all COPD cases. Recent studies have highlighted other areas of the genome that are also associated with COPD susceptibility.

Several longitudinal studies have defined patterns of age-related decline in lung function and have documented the concept of age-related susceptibility to COPD. These studies showed that most adult nonsmoking men exhibit a decline in FEV₁ of 35 to 40 mL/year. This rate is increased to 45 to 60 mL/year in most cigarette smokers. However, the susceptible smoker may demonstrate losses of 70 to 120 mL/year (Fig. 16-2). This information allows the physician to project the rate of decrease of lung function in patients with COPD and to assess the effects of therapeutic interventions.

Pathology

Various structural changes have been observed in the airways and lungs of individuals with COPD. The current definition of COPD emphasizes the central role of chronic inflammation in the

pathogenesis of COPD and in the development of pathologic lung and airway remodeling in the setting of COPD. Structural changes observed in COPD include emphysema and abnormalities of the small and large airways. There is increasing evidence that the small airways are the major site of airflow limitation and a central focus of pathology in COPD.

Emphysema in COPD

Emphysema is defined as a permanent enlargement of the air spaces distal to the terminal bronchioles (E-Fig. 16-1). This is caused by destruction of the lung parenchyma in the absence of significant fibrosis. These changes result in an abnormal acinus with limited capabilities for gas exchange. Based on thin gross lung sections, emphysema can be classified as either centrilobular and panlobular (E-Figs. 16-2 and 16-3). In centrilobular emphysema, the proximal part of the lobule (the respiratory bronchiole) is affected; this is the most common histologic feature observed in emphysema related to smoking. Panlobular emphysema is seen in α_1 -antitrypsin deficiency.

α_1 -Antitrypsin is a serine protease inhibitor that deactivates elastase molecules released by inflammatory cells that are capable of degrading connective tissue matrices. The observations that this enzyme was associated with emphysema and that emphysema could be reproduced in experimental models by the instillation of papain (a protease) into the lungs led to the hypothesis that emphysema is caused by an imbalance between protease and antiprotease systems in the lung. This theorized imbalance would favor proteolytic destruction of lung connective tissue, resulting in emphysema (the protease-antiprotease hypothesis). Research has focused on neutrophil elastase and its role in the destruction of lung elastin. Neutrophil elastase is the main target for inactivation by α_1 -antitrypsin and has relatively unopposed effects. However, evidence for a primary role of this enzyme in cigarette smoke-induced emphysema is less clear, so the focus has broadened to include examination of the role of the matrix metalloproteinases (MMPs), produced by macrophages and other cells, in emphysema. Transgenic mice that are deficient in the *MMP12* gene are resistant to the development of emphysema, and a single nucleotide polymorphism in the *MMP12* gene is associated with a reduced risk for development of COPD, supporting a role for this enzyme in mediating lung connective tissue loss leading to emphysema.

The inflammation induced by cigarette smoke is a trigger of the cycle of protease release and lung destruction resulting in emphysema (E-Fig. 16-4). Macrophages are activated by cigarette smoke and recruit neutrophils and other inflammatory cells to the lung, leading to the release of elastase and MMPs. The destruction of elastin and other connective tissue elements in the lungs by these proteases leads over time to the loss of elastic recoil and destruction of alveolar structures characteristic of emphysema.

Cigarette smoke contains many oxidant molecules capable of inducing oxidative stress in the lung. Oxidative stress has diverse effects, including the oxidative inactivation of antiproteases in the lung and the acetylation of specific histones in the chromatin of lung cells and macrophages, allowing the expression of various pro-inflammatory genes. Histone deacetylase activity is reduced in COPD, and this in turn may result in an inability to control the

FIGURE 16-2 Pattern of decline in forced expiratory volume in 1 second (FEV₁) with risks for morbidity and mortality from respiratory disease in a susceptible smoker compared with a normal patient and with a nonsusceptible smoker. Although cessation of smoking does not replenish the lung function already lost in a susceptible smoker, it decreases the rate of further decline. (Data from Fletcher C, Peto R: The natural history of chronic airflow obstruction, *BMJ* 1:1645–1648, 1977.)

pro-inflammatory response in this condition. Pro-inflammatory gene expression promotes cytokine production and release, contributing to further inflammatory cell recruitment and activation. Systemic inflammation, triggered by ongoing pulmonary inflammation, may lead to nonpulmonary abnormalities associated with emphysema, including cachexia and skeletal muscle alterations. Finally, increased apoptosis of pneumocytes and endothelial cells has been observed in lungs with emphysema and could contribute to the loss of alveoli.

Understanding of emphysema pathogenesis has improved with the recognition that inflammation, oxidative stress, protease-antiprotease balance, and apoptosis are linked in a complex interaction induced by cigarette smoke. This improved understanding has broadened the range of potential therapies that may be effective in ameliorating the destructive process. To date, however, therapies targeted at molecular pathways involved in emphysema pathogenesis have not been successful in altering disease progression, with the possible exception of α_1 -antitrypsin replacement therapy in individuals with α_1 -antitrypsin deficiency.

α_1 -Antitrypsin, an acute phase reactant, is produced primarily in the liver, from which it travels to the lung. By its effect on elastases in the lung, α_1 -antitrypsin prevents the uncontrolled degradation of elastin in the lung parenchyma and protects against the development of emphysema. Individuals with the ZZ genotype of α_1 -antitrypsin deficiency produce mutant forms of α_1 -antitrypsin that have a tendency to inappropriately polymerize within the hepatocyte, leading to a deficiency in secreted α_1 -antitrypsin and, in some cases, collateral damage to the liver caused by accumulation of intracellular misfolded, mutant α_1 -antitrypsin. Patients who develop emphysema at a young age (<40 years) should be evaluated for this condition whether or not they smoke, as should patients with bronchiectasis and unexplained liver disease or cirrhosis. Testing shows reduced α_1 -antitrypsin levels. Genotyping can reveal specific mutations (most commonly ZZ in severe deficiency). Polymorphisms in various other genes (e.g., *MMP12*) that appear to be relevant to susceptibility to COPD have been uncovered, and other factors contributing to COPD heritability and susceptibility are under active investigation. α_1 -Antitrypsin supplementation has been used for patients with α_1 -antitrypsin deficiency and appears to result in a decreased loss of lung density (surrogate for emphysema) by computed tomographic measurement (level 1 evidence).

Large and Small Airways Disease in COPD

Chronic bronchitis often coincides with emphysema in patients with COPD, but it may occur independently from either emphysema or COPD and is defined in clinical terms (described earlier). Cigarette smoking is the major cause, although exposure to pollutants such as dusts and smokes may play a role. Pathologic findings are goblet cell hyperplasia, mucus hypersecretion and plugging, and airway inflammation and fibrosis (Fig. 16-3).

The disease mechanisms involved in the development of emphysema are also important in the pathogenesis of chronic bronchitis. However, in contrast to emphysema, chronic bronchitis is a disease of the large airways and not of the lung parenchyma. Therefore, the relationship of chronic bronchitis to airflow obstruction is less robust than for emphysema, and

FIGURE 16-3 Pathology of chronic bronchitis: Normally, airway submucosal serous glands outnumber mucous glands and the epithelium includes ciliated cells. In chronic bronchitis, mucous glands are more prevalent than serous glands and the epithelium is abnormal. (Courtesy Dr. Charles Kuhn.)

airflow limitation consistent with COPD in a patient with symptoms of chronic bronchitis may be more reflective of concomitant emphysema and small airways disease. Inflammation in chronic bronchitis leads to effects on the airway epithelium, including excess mucus production and impairment in mucociliary clearance.

Neurogenic stimuli are also important in the pathogenesis of airway obstruction in chronic bronchitis. The conducting airways are surrounded by smooth muscle, which contains adrenergic and cholinergic receptors. Stimulation of β_2 -adrenergic receptors by circulating catecholamines dilates airways, whereas stimulation of airway irritant receptors constricts airways through a cholinergic mechanism by means of the vagus nerve. The irritant bronchoconstrictive pathways are normally present to protect against inhalation of noxious agents, but in pathologic states, these pathways may contribute to airway hyperreactivity. A host of endogenous chemical mediators such as proteases, growth factors, and cytokines can also affect airway tone.

By definition, the predominant symptom in chronic bronchitis is sputum production. Bronchospasm may also be prominent. Recurrent bacterial airway infections are typical. As with patients with COPD, the evaluation of patients with chronic bronchitis should include pulmonary function tests and a chest radiograph in addition to standard laboratory testing.

Damage to the small airways (those less than about 2 mm in diameter) is integral to the pathogenesis of COPD. The small airways are the major site of resistance to airflow in COPD. Respiratory bronchiolitis, in which there is an accumulation of pigmented macrophages in and around the bronchioles (E-Fig. 16-5), may be an incidental finding in asymptomatic smokers without COPD. However, as COPD develops, other inflammatory cells are recruited to the small conducting airways, presumably in reaction to ongoing irritation from cigarette smoke or inhaled particles. With inflammation, the small airways in COPD can be affected by remodeling, leading to airway wall thickening and fibrosis, smooth muscle hypertrophy, and airway luminal

narrowing, all of which contribute to airflow obstruction. Mucus plugs and inflammatory exudates can occlude the small airways, leading to increased resistance to airflow.

Recently, demonstration of profound decreases in small airway numbers and cross-sectional area in lungs of individuals with COPD has provided important evidence that loss of the small airways occurs with sufficient severity to result in the spirometrically detectable expiratory airflow limitation that characterizes COPD. Indeed, there is evidence that small airway loss may precede emphysema development in COPD.

Immune-mediated abnormalities are also seen at the level of the small airways in COPD. Lymphoid follicles may form around these airways in response to ongoing antigenic stimulation and bacterial infection, with a prominence of B cells and CD8+ T cells in more advanced COPD. Emphysema is associated with airflow obstruction of the small airways caused by destruction of the alveoli tethered to the airways, which normally provide a force opposing airway closure. These myriad changes at the small airway level contribute significantly to the physiologic abnormalities and altered local immune response in COPD.

Clinical Presentation

COPD related to chronic tobacco exposure is characterized by slowly progressive dyspnea that is first noticed during exertion but progresses over years until it is evident with minimal exertion (e.g., when dressing) or even at rest. Affected individuals complain of exercise intolerance and fatigue, and the disease eventually may lead to weight loss, depression, and anxiety as a result of increased work of breathing. Chronic cough can be present and is productive or dry, depending on the degree of mucus metaplasia (e.g., chronic bronchitis). In general, emphysema caused by chronic cigarette smoking is almost never observed in patients before 40 years of age. If it is, consideration should be given to genetic disorders such as α_1 -antitrypsin deficiency.

During the early stages of COPD, the physical examination may be normal. Normal examination results and the absence of symptoms often delay diagnosis. Inspection of the thorax and palpation may fail to reveal findings. As the disease progresses, the lungs may become hyperresonant to percussion, and auscultation may show diminished breath sounds with rhonchi or wheezes. The chest wall may begin to remodel, giving the patient the appearance of a “barrel chest.” During the late stages of COPD, patients show evidence of increased work of breathing with use of accessory muscles, pursed-lip breathing, and weight loss. Skeletal muscle wasting may also become evident. Despite their respiratory insufficiency, some patients are able to sustain relatively normal oxygen levels in blood until very late in the disease, leading to the classic clinical presentation of the “pink puffer.” Other patients tend to retain carbon dioxide and diminish their work of breathing, resulting in chronic respiratory acidosis and, in extreme cases, polycythemia and cyanosis; this is the prototypical “blue bloater” phenotype. There is also an overlap of COPD with other respiratory disorders, such as obstructive sleep apnea, that may contribute to carbon dioxide retention.

Although COPD results in chronic, progressive dyspnea, periodic acute exacerbations are also characteristic. A rapidly

worsening of pulmonary function and an increased burden of respiratory symptoms such as dyspnea, cough, and sputum production characterize COPD exacerbations. Acute exacerbations are associated with various triggers, most importantly viral or bacterial respiratory infections, air pollution or other environmental factors, pulmonary embolism, and cardiac failure. Exacerbations are more common with increasing severity of COPD, with increasing age, and during the winter months. Exacerbations vary widely in severity. Severe exacerbations may lead to hospitalization, acute respiratory failure, and death. After an exacerbation, it may take weeks for the patient to return to a baseline level of function. Patients with frequent exacerbations of COPD experience an accelerated rate of decline in FEV₁. Patients who have experienced a COPD exacerbation are more likely to experience future exacerbations, suggesting that exacerbation is an important event in the natural history of COPD. On occasion, an exacerbation of COPD leading to acute respiratory failure is the first event leading to the diagnosis of COPD in an individual patient.

COPD is associated with a number of comorbid conditions, such as atherosclerotic heart disease, lung cancer, osteoporosis, and depression. These comorbidities may be related to smoking, to the chronic systemic inflammation present in patients with COPD, to the impaired quality of life resulting from COPD, or to treatments (e.g., corticosteroids) administered during the course of COPD. Monitoring for and appropriate management of these coexisting disorders is an important part of the ongoing assessment of patients with COPD.

As COPD progresses, the lung volumes increase (hyperinflation) and the diaphragms flatten, rendering inspiratory excursions inefficient. Tidal volume decreases and respiratory rate increases in an effort to decrease the work of breathing. In advanced disease, the cardiovascular system becomes affected as a result of the loss of vasculature in destroyed alveolar walls and vasoconstriction and vascular remodeling due to chronic hypoxia. With a limited area for blood flow, pulmonary vascular resistance is increased, leading to increased right ventricular afterload and development of pulmonary hypertension. This accelerates the development of right ventricular failure, which is referred to as cor pulmonale in the setting of lung disease. Right heart gallop, distended neck veins, hepatojugular reflux, and leg edema characterize cor pulmonale.

Diagnosis and Differential Diagnosis

Diagnosis

Pulmonary function tests, especially spirometry, are essential for the diagnosis of COPD. A reduced FEV₁/FVC ratio (<0.70) on spirometry performed after administration of a bronchodilator is diagnostic of COPD. Although some degree of reversibility of the obstruction may be detected with bronchodilators, and airway hyperactivity can be unveiled by bronchoprovocation challenges if performed, the obstructive defect is not entirely reversible in COPD. This characteristic and the consistent and progressive nature of the expiratory flow limitation represent key features that help distinguish COPD from asthma, a major differential diagnostic consideration. The severity of disease and prognosis can be estimated by the FEV₁:

E-FIGURE 16-5 Respiratory bronchiolitis in a young smoker. (Courtesy Dr. Charles Kuhn.)

GOLD 1/mild COPD	FEV ₁ ≥80% predicted
GOLD 2/moderate COPD	FEV ₁ ≥50% but less than 80% predicted
GOLD 3/severe COPD	FEV ₁ ≥30% but less than 50% predicted
GOLD 4/very severe COPD	FEV ₁ <30% predicted

An FEV₁ of about 1 L (usually 50% predicted) suggests severe obstruction and, in the case of COPD, predicts a mean survival rate of 50% at 5 years. For a better predictor of mortality than FEV₁ alone, the BODE index can be used: *body mass index*, degree of obstruction as measured by FEV₁, modified Medical Research Council dyspnea score, and exercise capacity as denoted by 6-minute walk distance.

Lung volumes should be measured along with pulmonary function testing because the limitation to expired airflow and decreased elastic recoil lead to lung hyperinflation, as evidenced by increased RV, FRC, and, ultimately, TLC.

Destruction of alveoli decreases the surface area for gas exchange in emphysema. This loss of surface area, coupled with bronchial obstruction and altered distribution of ventilated air, results in ventilation-perfusion inequality or mismatch, a cause of hypoxemia. Hyperinflation of the lungs increases zone 1 conditions, in which alveolar pressure exceeds pulmonary arterial pressure, and this process decreases perfusion and increases physiologic dead space. Hypercarbia can be avoided by increasing the minute ventilation, even with substantial ventilation-perfusion mismatching. However, eventually, the metabolic costs of breathing become excessive, and respiratory muscles fatigue. Over time, chemoreceptors reset, allowing the level of partial pressure of carbon dioxide in arterial blood (Paco₂) to rise, which increases the efficiency of ventilation by eliminating a higher concentration of carbon dioxide per breath, thereby lowering the metabolic cost of breathing. Significant individual variation is observed in the degree of mechanical impairment and in the magnitude of increase in Paco₂. Derangements in gas exchange can be detected by measuring arterial blood gases, by showing a decrease in DLCO, or by evaluating hemoglobin oxygen desaturation during exertion. The degree of decrease in DLCO correlates well with the radiologic extent of emphysema in COPD.

Chest radiography may fail to reveal abnormalities during the early stages of COPD, but in later stages, radiographic studies show hyperinflation, hyperlucency, flattening of the diaphragms, and bullous changes in lung parenchyma (E-Fig. 16-6). Pleural abnormalities, lymphadenopathy, and mediastinal widening are not characteristic of emphysema and should point to other diagnoses, such as lung cancer. Computed tomography is more sensitive than plain radiography because it allows for a more detailed evaluation of the lung parenchyma and surrounding structures. Computed tomography is useful in assessing the distribution of emphysema (E-Fig. 16-7) in patients for whom operative interventions such as lung volume reduction surgery are being contemplated (see later discussion). HRCT is highly sensitive for the detection of occult emphysema and can reveal the pattern of emphysematous changes. Electrocardiography might show evidence of right ventricular strain. Echocardiography can reveal evidence of right ventricular hypertrophy or dilation and can often provide an estimate of pulmonary arterial pressures in patients with advanced COPD. A high blood hemoglobin level

might reveal erythrocytosis in the setting of chronic hypoxemia, whereas increased white blood cell counts might suggest infection. The arterial blood gas analysis may show hypoxemia, hypercarbia, or both, whereas acidemia due to acute hypercarbia may be present during an exacerbation.

Differential Diagnosis

The differential diagnosis of COPD includes the other major obstructive lung disorders: asthma, bronchiectasis, and the bronchiolar disorders. Asthma can occur at any age and sometimes overlaps with COPD, such as in patients with childhood asthma who smoke as adults. However, patients with COPD are typically older than 40 years of age and have a lengthy smoking history, whereas patients with asthma often have a history of atopy, have more variable symptoms that are often worse at night, and typically have marked improvements in lung function after bronchodilator administration. Patients with asthma may have normal pulmonary function during periods in which their asthma is well controlled, whereas those with COPD demonstrate ongoing airway obstruction even during periods of relative clinical stability.

It can be difficult to distinguish COPD with chronic bronchitis from bronchiectasis, and HRCT is necessary to assess for the abnormal bronchial dilation that is diagnostic of bronchiectasis.

Bronchiolar disorders can also be difficult to distinguish from COPD but should be considered in patients with risk factors, such as connective tissue disease or occupational exposures. Again, more sophisticated testing, such as HRCT with inspiratory and expiratory views to demonstrate peripheral areas of gas trapping and centrilobular nodules consistent with mucus impaction of the small airways, or even lung biopsy, may be needed to diagnose bronchiolitis.

Nonpulmonary causes of dyspnea on exertion, such as congestive heart failure or coronary artery disease, should also be considered in the differential diagnosis of COPD.

Treatment

Prevention

Because a cure for COPD does not exist, the best approach to this condition is prevention. Most cases of COPD in the United States are caused by cigarette smoking. Therefore, an appropriate major emphasis has been placed on the development of community education programs that focus on smoking prevention and promote smoking cessation. Legislative measures banning smoking in various public settings and levying increased taxes on cigarettes have been used to diminish the effects of environmental or second-hand exposure to tobacco smoke and to discourage smoking. Although smoking cessation interventions are effective in only a minority of patients, smoking cessation decreases mortality in patients with COPD who do succeed in quitting (level 1 evidence).

Most patients who are successful at smoking cessation have had at least one prior failed attempt, so physicians should encourage smoking cessation with at least brief interventions at every opportunity, even in patients who have tried but failed to quit in the past. Long-term physician and group support increases the success of cessation attempts, and pharmacologic smoking cessation aides, including nicotine replacement with gum or

E-FIGURE 16-6 Anterior-posterior (*left*) and lateral (*right*) chest radiographs show changes caused by severe chronic obstructive pulmonary disease, including hyperinflation, increased anterior-posterior diameter, flattened diaphragms, and enlarged pulmonary arteries.

E-FIGURE 16-7 Computed tomographic scan shows paraseptal distribution of emphysema.

transdermal patches, bupropion, and varenicline, may provide additional benefit.

Pharmacologic Therapies

After COPD is established, therapy is directed at avoiding complications such as exacerbations, relieving airflow obstruction through use of bronchodilators, and providing supplemental oxygen to patients with hypoxemia. Commonly used inhaled bronchodilators include sympathomimetic agents (β_2 -adrenoreceptor agonists) and anticholinergic agents. Ipratropium bromide, a short-acting anticholinergic agent, is effective at decreasing dyspnea and improving FEV₁ in COPD (level 1 evidence). Albuterol is the most commonly used β_2 -agonist; its bronchodilator effect is rapid in onset and relatively short lived. In practice, a combination of albuterol and ipratropium is frequently prescribed because these agents produce greater benefits when used in combination than individually.

Short-acting agents are typically prescribed for patients with mild disease or intermittent symptoms on an as-needed basis. Short-acting bronchodilators can be delivered by metered-dose inhaler (MDI) or by nebulizer. The MDI offers advantages of portability and ease of administration and convenience. When used correctly with a spacer, MDIs are as effective as nebulizers in delivering the drug. Nebulization has no advantage over the use of MDIs in the long-term management of obstructive lung disease except in patients who are unable to use an MDI properly.

Long-acting bronchodilators are effective for maintenance therapy in patients who have at least moderate COPD. Long-acting agents include the long-acting β_2 -agonists (LABAs), which are available in once- or twice-daily formulations, and the long-acting anticholinergic/muscarinic antagonists (LAMAs), which are administered once daily. Both the LABAs and the LAMAs provide effective bronchodilation with resultant improvements in FEV₁ and symptoms (level 1 evidence). Tiotropium, a LAMA, as well as salmeterol, indacaterol, and formoterol, all LABAs, have been shown to reduce exacerbation rates in COPD (level 1). Initiation of either a LABA or a LAMA is reasonable for patients with COPD who require a long-acting bronchodilator. Tachycardia, hypokalemia, and tremor are potential adverse effects of LABAs, whereas dry mouth and urinary retention may occur with LAMA administration. In more advanced disease, there is some evidence (level 2) of additional benefits from the combination of a LABA and a LAMA.

Current data suggest that the chronic use of inhaled corticosteroids improves symptoms and decreases the frequency of exacerbations (level 1). Inhaled long-acting corticosteroids (e.g., beclomethasone, budesonide, fluticasone propionate) should be considered for individuals with COPD and a history of exacerbations but should not be used as monotherapy. Inhaled corticosteroids are less clearly effective in COPD than in asthma, and pneumonia occurs more frequently in patients with COPD treated with inhaled corticosteroids (level 1). Inhaled corticosteroids can be combined with LABAs; the combination salmeterol with fluticasone in patients with moderate to severe COPD was shown to improve health-related quality of life and to reduce exacerbations to a greater extent than either component alone (level 2).

Systemic use of corticosteroids is indicated during acute exacerbations, and intravenous corticosteroids are useful in the acute setting. Intravenous corticosteroids have also proved effective for the management of acute exacerbations of most obstructive lung diseases, including asthma (Fig. 16-4). Patients with acute exacerbations are usually transitioned from intravenous to oral steroids within 72 hours, with a subsequent tapering of the oral steroid dose over 2 weeks, although shorter courses may also be effective. Other agents with anti-inflammatory capabilities, such as leukotriene inhibitors, are not indicated for treatment of COPD.

Theophylline, a methylxanthine, is a weak systemic sympathomimetic agent with a narrow therapeutic window. It is not a first-line drug in the treatment of COPD, although long-acting derivatives with improved safety profiles have been developed. Theophylline preparations have some anti-inflammatory activity and may provide additional bronchodilation in patients with COPD who do not respond adequately to inhaled β -agonists. When these preparations are used, blood concentrations should be maintained in the lower end of the therapeutic range (between 8 and 12 $\mu\text{g}/\text{mL}$). Toxicity is common at concentrations higher than 20 $\mu\text{g}/\text{mL}$. The metabolism of theophylline is decreased by many commonly used drugs (e.g., erythromycin), and toxic serum concentrations of theophylline can be reached quickly when these other drugs are administered unless the theophylline dose is adjusted appropriately. Toxic effects of theophylline may be observed in the gastrointestinal, cardiac, and neurologic systems. Severe theophylline toxicity can be fatal, and treatment with charcoal hemoperfusion may be required.

Phosphodiesterase type 4 (PDE4) inhibitors have been investigated for the treatment of COPD, and an oral PDE4 inhibitor was recently approved as add-on therapy for treatment of severe COPD with chronic bronchitis and a history of exacerbations. PDE4 inhibitors act to inhibit breakdown of cyclic adenosine monophosphate (cAMP), resulting in a weak bronchodilator effect (approximately 50 mL improvement in FEV₁); they should not be used as acute bronchodilators. However, roflumilast was demonstrated to reduce exacerbation rates in patients who had severe COPD with chronic bronchitis and a history of exacerbation in the prior year and were not using inhaled corticosteroids (level 2 evidence). Adverse effects include weight loss, nausea and loss of appetite, and an increase in psychiatric adverse reactions including suicidality.

Oxygen Therapy and Mechanical Ventilation

Continuous oxygen therapy has been shown to improve survival in patients with COPD and hypoxemia (level 1 evidence). Oxygen supplementation is recommended once the partial pressure of oxygen in arterial blood (PaO_2) drops below 55 mm Hg or the hemoglobin oxygen saturation decreases to 88%. Oxygen supplementation is indicated at higher levels of PaO_2 if end-organ damage, such as pulmonary hypertension, is present.

Oxygen therapy is frequently necessary for treatment of acute exacerbations of obstructive lung disease. In patients who hypoventilate chronically and therefore have an elevated Paco_2 , elevating the inspired oxygen content may acutely worsen hypercarbia by inhibiting the hypoxic ventilatory drive and by promoting the dissociation of carbon dioxide from oxygenated hemoglobin (the Haldane effect). High-flow oxygen has been

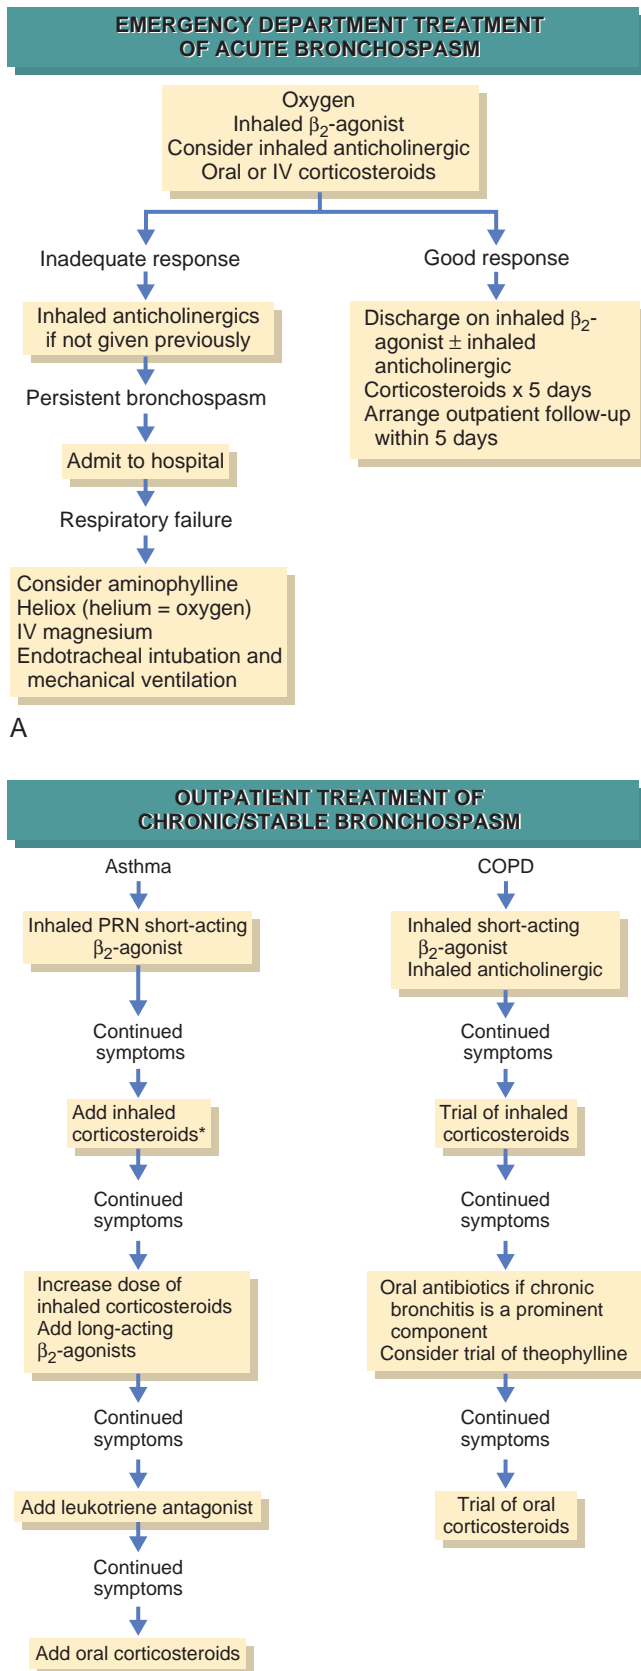

FIGURE 16-4 Algorithms for the treatment of bronchospasm in patients in the emergency department (**A**) and in outpatients with stable disease (**B**). IV, Intravenous; PRN, as needed. *Leukotriene antagonists could be considered.

shown to be harmful in the setting of prehospital emergency treatment for COPD (level 1 evidence). Therefore, oxygen should be closely titrated to maintain normoxia and to avoid either hypoxemia or excessively elevated PaO₂. An oxygen saturation of 90% to 92% is a reasonable target in the absence of further data (level 3). During exacerbations of COPD leading to hypercarbic respiratory failure, noninvasive positive airway pressure ventilation has proved useful in reducing the work of breathing, alleviating diaphragm fatigue, and reducing the need for endotracheal intubation and mechanical ventilation (level 1).

Antibiotics

Exacerbations of airway obstruction may result from viral or bacterial infection. The most common bacterial pathogens in COPD are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. Management of acute exacerbations should include empiric administration of antibiotics, which have been shown to improve the success rate in exacerbation treatment (level 2 evidence). The role of chronic prophylactic antibiotic use in COPD is uncertain, and a trial of oral azithromycin resulted in a reduction in exacerbations but an increased risk of hearing loss (level 2). Immunization with influenza vaccines directed at specific epidemic strains reduces exacerbations of COPD (level 1). Pneumococcal vaccination is also recommended in patients with COPD.

Nonpharmacologic Therapies

Multiple airway clearance techniques aid in clearing of airway secretions, but their effectiveness in the management of emphysema and other obstructive lung diseases in adults is questionable. If needed, chest physiotherapy and postural drainage might be useful in patients with chronic bronchitis and increased sputum production. Few data support the use of specific mucolytics or expectorant agents for patients with COPD.

Patients with pulmonary disease of sufficient severity to compromise normal activities of daily living commonly demonstrate improved quality of life and less subjective dyspnea when enrolled in a comprehensive, high-quality pulmonary rehabilitation program (level 1 evidence). Pulmonary rehabilitation has not been shown to improve objective measures of pulmonary function, to affect the rate of decline in lung function, or to improve survival. However, it has been shown to improve the quality of life in motivated patients. An important part of pulmonary rehabilitation is nutritional assessment and careful attention to maintaining adequate nutrition. Malnutrition and cachexia are common in later stages of obstructive lung disease, and they result in decreased respiratory muscle strength and compromised immune function.

The role of surgery in COPD is generally limited. Bullectomy, lung volume reduction surgery (LVRS), and lung transplantation are all potentially effective surgical options for selected patients. Resection of nonfunctional areas of lung (e.g., bullectomy) may allow for compressed functional areas to expand and may improve symptoms, airflow, and oxygenation by improving ventilation-perfusion matching in a subgroup of patients. In addition, resection of bullae can decrease lung volumes, resulting in enhanced diaphragmatic function and decreased work of breathing. The best candidates for LVRS are those with predominantly upper

lobe disease who have a low exercise tolerance despite rehabilitation and are without other major comorbidities. This subgroup may have reduced mortality after LVRS (level 2 evidence). In general, a high surgical mortality risk exists in patients referred for LVRS who have an FEV₁ or DLCO of less than 20% predicted and in those who have more homogeneous distribution of emphysema. Endoscopic therapies to deflate regions of lung with emphysema are currently under investigation.

Single or bilateral lung transplantation is an option for patients with end-stage airflow obstruction. The average survival after lung transplantation is 4 to 5 years. Rejection, viral infections, transplant-associated lymphoproliferative disease, and late occurrence of bronchiolitis obliterans remain significant problems, but the procedure can improve the quality of life in properly selected patients.

Palliative Care

Although the disease course can be unpredictable, discussion of end-of-life issues with the patient is an important component of longitudinal care as COPD progresses to an advanced stage. Preparation of advance directives regarding use of intensive care measures at the end of life may be desirable. Opioid narcotics can be highly effective for relieving dyspnea in patients with terminal complications of COPD (level 1 evidence).

Prognosis

COPD is a chronic and progressive disease with a variable and typically prolonged clinical course. As discussed previously, measurement of lung function (FEV₁ % predicted) has prognostic significance, and use of the multifactorial BODE index can improve prognostication compared with use of FEV₁ alone. Patients who have frequent exacerbations of COPD appear to have more rapid loss of lung function than those without exacerbations, suggesting that frequent exacerbations result in a worse clinical course.

At present, aside from smoking cessation and the addition of long-term oxygen therapy for patients with hypoxemia, interventions to improve survival in COPD are limited. No pharmacologic therapy for COPD has been definitively demonstrated to improve survival. In mild COPD, mortality is frequently related to comorbidities such as ischemic heart disease and lung cancer; in more advanced stages, a greater proportion of patients die from respiratory causes.

BRONCHIOLAR DISORDERS

Definition and Epidemiology

The bronchioles are defined as the small noncartilaginous airways (<2 mm in diameter). The bronchiolar disorders, or bronchiolitides, encompass a spectrum of diseases of widely varying causes primarily affecting these small airways. Although small airways disease contributes significantly to the syndrome of COPD, and respiratory bronchiolitis may be found incidentally in smokers, bronchiolar disorders with different etiologies than cigarette smoking also exist. These disorders are associated with patchy inflammation and epithelial injury, fibrosis, mucoid impaction, or obliteration of the bronchioles (E-Fig. 16-8). These changes result in airflow limitation due to increased airway resistance.

Acute bronchiolitis related to respiratory syncytial virus infection is epidemic among infants and young children, but primary bronchiolar disorders, including infectious or postinfectious bronchiolitis, are rare in the adult general population and tend to affect certain specific patient populations.

Pathology

The pathology of the bronchiolar disorders is complex. A variety of terms are used to describe or classify the various histopathologic patterns of small airways disease, including *cellular bronchiolitis* (inflammatory cell infiltration of the small airway wall resulting in small airway narrowing), *follicular bronchiolitis* (formation of abundant lymphoid follicles in close apposition to the small airways, resulting in airway compression), *obliterative* or *constrictive bronchiolitis* (fibrosis surrounding the small airways resulting in narrowing of the affected airways), and *bronchiolitis obliterans* (formation of endoluminal fibrous lesions, sometimes called *Masson bodies*, obstructing the small airway lumen). The histopathologic pattern of small airways disease may suggest a likely underlying etiology; for example, follicular bronchiolitis is often, although not exclusively, seen in the context of Sjögren's syndrome.

Clinical Presentation

In general, the bronchiolar disorders manifest nonspecifically with dyspnea, which may be severe or progressive, in some cases accompanied by cough or sputum production. The physical examination may reveal inspiratory squeaks or wheezes but may be surprisingly normal. The possibility of a bronchiolar disorder should be considered in particular settings. For example, bronchiolitis may complicate the course of rheumatoid arthritis, Sjögren's syndrome, or inflammatory bowel disease.

Diffuse panbronchiolitis is a rare idiopathic disorder, most common in Japan, that is characterized by cough with purulent sputum, sinusitis, and dyspnea. Recurrent respiratory infections with bacterial organisms such as *Pseudomonas aeruginosa* complicate the course of diffuse panbronchiolitis. Bronchiolitis obliterans (in this context a clinical, not a histopathologic, term) is seen with the bronchiolitis obliterans syndrome of chronic allograft rejection after lung transplantation, in graft-versus-host disease after allogeneic hematopoietic stem cell transplantation, and after occupational toxin exposures. For example, occupational clusters of bronchiolitis obliterans have been described after exposure to diacetyl, a flavoring chemical used in the manufacture of microwave popcorn.

Diagnosis and Differential Diagnosis

In general, the bronchiolar disorders cause an obstructive pattern of expiratory airflow limitation on pulmonary function testing without evidence of reversibility. The bronchiolitis obliterans syndrome is diagnosed clinically by a decline in FEV₁ of 20% from a stable baseline value on serial testing after lung transplantation. HRCT is valuable in the diagnosis and assessment of the bronchiolar disorders. Characteristic findings on HRCT include centrilobular nodules or tree-in-bud opacities, reflecting impacted inflammatory exudates or sloughed epithelial cells in the bronchioles. A "mosaic attenuation" pattern, with decreased attenuation in geographic regions of lung reflecting areas of air trapping

E-FIGURE 16-8 Arrows point to normal bronchiole (*left*) and bronchiole narrowed by inflammation and remodeling in a patient with bronchiolitis (*right*). (Courtesy Dr. Charles Kuhn.)

distal to obstructed bronchioles, is often seen on inspiration. CT scanning during the expiratory phase can confirm that this finding is caused by air trapping as opposed to decreased perfusion from pulmonary vascular disease. Lung biopsy may be of limited value because of the scattered, patchy nature of the abnormalities present in the bronchiolar disorders. The differential diagnosis includes COPD, which also causes poorly reversible obstruction on spirometry.

Treatment

Treatment of the bronchiolar disorders is challenging. Acute bronchiolitis typically resolves without treatment; bronchodilators and steroids are not clearly beneficial, although they are often prescribed. The bronchiolitis obliterans syndrome responds poorly to increased immunosuppression and is a frequent cause of death after lung transplantation. Azithromycin, a macrolide antibiotic, has been reported to increase FEV₁ in the bronchiolitis obliterans syndrome. Macrolide antibiotics have also been reported to positively affect the clinical course of diffuse pan-bronchiolitis, possibly reflecting immunomodulatory or antifibrotic effects of these medications (level 2 evidence). Lung transplantation may be necessary in progressive bronchiolitis obliterans, and retransplantation has sometimes been performed in patients affected by the bronchiolitis obliterans syndrome after transplant rejection.

Prognosis

These disorders may be self-limited, as in acute bronchiolitis caused by respiratory syncytial virus, or relentlessly progressive and fatal, as in the bronchiolitis obliterans syndrome occurring after lung transplantation.

BRONCHIECTASIS

Definition and Epidemiology

 Bronchiectasis (E-Fig. 16-9) is defined as an abnormal dilation of the bronchi (the large airways containing cartilage within their walls) resulting from inflammation and permanent destructive changes of the bronchial walls. The incidence of bronchiectasis is unknown, but it may affect more than 100,000 individuals in the United States and is more frequent in older age groups. There is likely a higher incidence of bronchiectasis in developing countries where there are lower childhood vaccination rates and a higher prevalence of pulmonary tuberculosis.

Pathology

Bronchiectasis may be localized to a bronchial segment or lobe of the lung, or it may be diffuse. The involved bronchi are abnormally dilated and demonstrate chronic inflammation within the bronchial wall with neutrophilic inflammation and bacterial colonization and infection in the bronchial lumen. The inflammation in bronchiectasis is associated with structural changes in the walls of the bronchi, including destructive changes affecting the elastic fibers, smooth muscle, and cartilage. As with COPD, there is also involvement of the small airways. Small airway obstruction leads to increased resistance to airflow that results in airflow obstruction despite the presence of dilation of the larger airways. The classic pathologic classifications of bronchiectasis are *tubular*

(the most common form, in which there is smooth dilation of the bronchi), *varicose* (dilated bronchi with indentations reminiscent of varicose veins), and *cystic* (end-stage bronchiectasis with dilated bronchi ending in sac-like structures resembling clusters of grapes).

Bronchiectasis is hypothesized to result from an environmental insult leading to bronchial damage in a susceptible host. This in turn leads to impaired infection clearance, bacterial colonization and infection or reinfection, ongoing inflammation of the airways, and further bronchial damage, creating a classic vicious cycle. An inciting infection, sometimes occurring in childhood, is thought to initiate the development of bronchial damage leading to bronchiectasis in many cases (post-infectious bronchiectasis). This may be a viral infection (e.g., measles), a necrotizing pneumonia (e.g., *Staphylococcus aureus* pneumonia), tuberculosis, or infection with an atypical mycobacteria (e.g., *Mycobacterium avium-intracellulare*). Because infections such as *M. avium-intracellulare* also complicate the course of bronchiectasis, determination of whether a mycobacterial infection was an initiator or a consequence of bronchiectasis may be difficult.

Localized bronchiectasis may also result from anatomic obstruction by an endobronchial foreign body, tumor, or broncholith or from extrinsic compression by lymphadenopathy. The right middle lobe syndrome results from narrowing of the right middle lobe bronchial orifice, often by lymph node enlargement in the setting of tuberculosis, which leads to localized bronchiectasis distal to the site of obstruction. Anatomic obstruction results in chronic or recurrent bacterial infections and inflammation leading to bronchial distortion and destruction over time.

Diffuse bronchiectasis can result from various impairments in host defenses that create a vulnerability to persistent or recurrent lung infection leading to bronchial damage. For example, bronchiectasis may occur with congenital defects that impair mucus clearance in the airways such as CF (discussed later) or primary ciliary dyskinesia, a rare inherited abnormality of the ciliary microtubules. The classic triad of sinusitis, situs inversus, and infertility is diagnostic of Kartagener's syndrome, a form of primary ciliary dyskinesia. Immunodeficiency states, such as hypogammaglobulinemia in combined variable immunodeficiency, may also result in bronchiectasis. α_1 -Antitrypsin deficiency results in deficient antiprotease activity in the lung and is also associated with bronchiectasis. Bronchiectasis also complicates certain connective tissue disorders such as rheumatoid arthritis.

Finally, bronchiectasis overlaps with the more common obstructive lung disorders, COPD and asthma. Certain patients with COPD also have bronchiectasis, often in the lower lobes. Allergic bronchopulmonary aspergillosis is a condition that occurs in asthmatics with hypersensitivity to aspergillus fungi. It is associated with central bronchiectasis, high levels of immunoglobulin E (IgE), and precipitins for *Aspergillus* species.

Clinical Presentation

Patients with bronchiectasis exhibit chronic cough and copious, sometimes foul-smelling sputum. The sputum produced may be greater in volume and purulence than with COPD or asthma. Shortness of breath and fatigue may also be present. Blood-streaked sputum is common, and massive hemoptysis may occur during the course of bronchiectasis. Localized crackles and

E-FIGURE 16-9 Cystic bronchiectasis with enlarged airways (*arrow*).

clubbing may be present. Periodic exacerbations due to infection with bacterial pathogens, including *H. influenzae* and *P. aeruginosa*, are common. Nontuberculous mycobacterial colonization or infection may also occur. Pulmonary function tests typically show mild to moderate obstruction. Evidence of bronchial hyperresponsiveness is not infrequent.

Diagnosis and Differential Diagnosis

Chest radiographs may be normal or may show increased interstitial markings. The classic finding is parallel lines in peripheral lung fields, described as “tram tracks,” which represent thickened bronchial walls that do not taper from proximal to distal sites. However, HRCT is more sensitive for the detection of dilated airways and is the diagnostic test of choice in the evaluation of suspected bronchiectasis. Bronchiectasis on HRCT is diagnosed by demonstration of lack of airway tapering, airways that are larger in diameter than their accompanying blood vessel, and the presence of visible bronchi at the lung periphery (outer 1 to 2 cm of the lung). Bronchoscopy may be indicated in localized bronchiectasis to assess for endobronchial abnormalities or foreign body. Sputum can be cultured to assess for fungal or mycobacterial organisms that may be causative or for identification of specific bacterial pathogens during exacerbations. Once the diagnosis of bronchiectasis is established, investigation to determine the underlying cause, such as assessment of immunoglobulin levels to rule out combined variable immunodeficiency, is indicated.

The differential diagnosis includes chronic bronchitis and COPD, asthma, and, in the setting of hemoptysis and clubbing, lung cancer.

Treatment

Treatment of the underlying cause of the bronchiectasis should be undertaken if possible. An anatomic obstruction, such as from a foreign body or benign tumor, should be relieved. Atypical mycobacterial infection should be treated with an appropriate multidrug regimen in symptomatic patients after confirmation of the diagnosis with multiple smears and cultures. Allergic bronchopulmonary aspergillosis is typically treated with corticosteroids; addition of azole antifungals may also be beneficial (level 3 evidence). Bacterial exacerbations of bronchiectasis should be treated with a broad-spectrum antibiotic that is effective against the likely pathogens, such as amoxicillin or, in patients known to be colonized or infected by *Pseudomonas*, a fluoroquinolone (level 2). Aerosolized antibiotics are of benefit to suppress bacterial growth in bronchiectasis associated with CF and may be beneficial in non-CF bronchiectasis if *Pseudomonas* infection is present or if frequent exacerbations occur (level 3). Chronic administration of macrolide antibiotics has been shown to reduce inflammation and exacerbations in bronchiectasis but may also promote development of macrolide-resistant bacteria (level 2).

Immunoglobulin supplementation may aid in the host defense against bacterial infection in individuals with hypogammaglobulinemia. Airway clearance and postural drainage are frequently employed in bronchiectasis. Bronchodilators may provide symptomatic relief. Massive hemoptysis should be managed with airway protection and identification of the bleeding site; bronchial artery angiography with embolization of the causative bleeding vessels can be life-saving (level 3). The role of surgery

is mainly in resection of obstructing lesions that are causing distal bronchiectasis, in removal of a badly damaged isolated segment of bronchiectatic lung, and, on occasion, as a salvage therapy in resection of a site with uncontrolled hemorrhage (level 3).

Prognosis

The prognosis of patients with bronchiectasis is generally thought to be favorable, although deterioration of lung function over time has been shown to occur. Quality of life may be affected adversely, for example by chronic production of copious sputum or frequent exacerbations. Massive hemoptysis is an emergency situation that requires intensive management and may be fatal.

● CYSTIC FIBROSIS

Definition and Epidemiology

CF is an autosomal recessive genetic disorder that results from mutations in the *CFTR* gene. CF affects about 30,000 children and adults in the United States. This disorder affects many organs, including the lungs, pancreas, and reproductive organs, although most mortality related to CF is due to lung disease. It is the most common lethal genetic disorder in the white population, with a carrier frequency of about 1 in 29, affecting 1 in 3300 live births. About 1000 new cases of CF are diagnosed each year. Although most patients are diagnosed in infancy and childhood, some are not diagnosed until adulthood. About 45% of the population with CF in the United States is older than 18 years of age, but before 1940, infants with CF rarely lived to their first birthday. Currently, the median predicted life span for a person with CF is about 37 years.

Pathology

CF results from pathogenic mutations in both alleles of a single gene, *CFTR*, which encodes the cystic fibrosis transmembrane conductance regulator (CFTR), a cAMP-regulated chloride channel that is present on the apical surface of epithelial cells (E-Fig. 16-10). The most common mutation is the $\Delta F508$ mutation, a three-base-pair deletion that results in absence of the phenylalanine residue at the 508 position of the protein. However, more than 1600 mutations in *CFTR* have been identified to date.

The abnormal *CFTR* protein results in defective chloride transport and increased sodium reabsorption in airway and ductal epithelia; this leads to abnormally thick and viscous secretions in the respiratory, hepatobiliary, gastrointestinal, and reproductive tracts. The thick secretions do not easily clear from the airways, resulting in respiratory symptoms, and they cause luminal obstruction and destruction of exocrine ducts in other organs, leading to exocrine organ fibrosis and dysfunction, including pancreatic damage.

In patients with CF, the airways become colonized initially with *S. aureus* or *H. influenzae*, followed by *P. aeruginosa* in ensuing years. Persistent inflammation and infection cause bronchial wall destruction and bronchiectasis. Mucus plugging of small airways results in postobstructive cystic airway dilation and parenchymal destruction; progressive airflow obstruction and eventually hypoxemia ensue. The course of CF may additionally be complicated by the development of allergic bronchopulmonary aspergillosis or by nontuberculous mycobacterial infection.

E-FIGURE 16-10 Proposed structure of the CFTR chloride channel.

Colonization and infection with multidrug-resistant organisms such as the *Burkholderia cepacia* complex may occur in advanced CF, creating challenging management issues. Most patients die of respiratory failure.

Clinical Presentation

Neonatal screening programs for CF exist nationwide in the United States to identify infants with possible CF who should undergo further testing (e.g., genotyping). Infants with CF may have meconium ileus or failure to thrive with steatorrhea. Salty-tasting skin may be noticed by caregivers. Patients with CF typically have chronic cough with thick sputum production, wheezing, and dyspnea. Pancreatic insufficiency and diabetes are common, and male patients have azoospermia. Nasal polyps are often present, and clubbing is typical.

CF should be considered in the differential diagnosis of patients with unexplained chronic sinus disease, bronchiectasis, male infertility associated with absence of the vas deferens, pancreatitis, or malabsorption. Pulmonary function tests demonstrate hyperinflation and obstruction; a bronchodilator response may be present. Chest imaging studies show hyperinflation, bronchial wall thickening, and bronchiectasis.

Diagnosis and Differential Diagnosis

Measurement of the concentration of chloride in sweat (sweat test) is used to diagnose CF. The diagnosis is considered definitive if the clinical picture is consistent with CF and if the chloride concentration measured in a certified laboratory is greater than 60 mEq/L on at least two occasions. Genotyping can also confirm the diagnosis if known mutations are identified in both gene alleles and may be used if sweat testing is equivocal.

Treatment

The treatment of CF currently relies on supportive measures such as aggressive airway hygiene, nutritional support including pancreatic enzyme replacement, antibiotics, and bronchodilators. Aerosolized recombinant human deoxyribonuclease I (Dornase alfa) decreases sputum viscosity, improves lung function, and reduces exacerbations in CF (level 1 evidence). Inhaled hypertonic saline helps to hydrate secretions, allowing them to be coughed out more easily, and also improves pulmonary function, although likely to a lesser extent than Dornase alfa (level 2). Inhaled tobramycin provided twice daily every other month is indicated for patients with moderate to severe CF who have pseudomonas infections (level 1). Inhaled aztreonam also appears to be beneficial in this patient group (level 2). Anti-inflammatory therapy with ibuprofen and azithromycin may be helpful in certain patients with CF (level 2 for both). However, chronic inhaled and oral corticosteroids are not beneficial and should not be used (level 1).

Specific treatments to improve the function of the defective CFTR chloride channel in CF are under investigation. Recent studies have shown ivacaftor to have positive benefits on CFTR function and FEV₁ in patients with a specific CF mutation (G551D) (level 1 evidence). As with other obstructive lung diseases, the ultimate therapy for patients with CF and end-stage lung disease is lung transplantation. Bilateral lung transplantation is preferred in this condition.

Prognosis

CF is ultimately a fatal disease, although supportive care measures have led to considerable improvement in median survival time. There clinical course of may be variable, in part related to the underlying mutations in the *CFTR* gene.

● ASTHMA

Definition and Epidemiology

Asthma is described by the Global Initiative for Asthma as “a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role. The chronic inflammation is associated with airway hyperresponsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread but variable airflow obstruction within the lung that is often reversible either spontaneously or with treatment.”

The incidence of asthma is highest in children, but it affects all ages and occurs worldwide, with a preponderance of the disease in developed industrialized countries. Asthma affects millions of individuals worldwide. In the United States in 2008, 8.2% of the population (approximately 24,000,000 persons) were estimated to have asthma based on survey data, an increase from 7.3% in 2001. The prevalence of asthma has increased markedly over recent decades. Nevertheless, after rising in the late 20th century, the number of deaths from asthma has declined since 2000; in 2010, there were 3404 deaths from asthma in the United States, compared with 5637 deaths in 1995. Asthma death rates are higher in older age groups, females, and blacks.

Pathology

Underlying chronic airway inflammation is considered to be a major pathogenic feature of asthma. Patients with asthma have higher numbers of activated inflammatory cells within the airway wall, and the epithelium is typically infiltrated with eosinophils, mast cells, macrophages, and T lymphocytes, which produce multiple soluble mediators such as cytokines, leukotrienes, and bradykinins. Airway inflammation in asthma is typified by a type 2 helper T-cell (T_H2) response with predominantly eosinophilic inflammation, but some patients with severe asthma exhibit neutrophilic airway inflammation and cytokine production more characteristic of T_H1 inflammation.

The hallmark of asthma is airway hyperresponsiveness—a tendency of the airway smooth muscle to constrict in response to levels of inhaled allergens or irritants that would not typically elicit such a response in normal hosts. Inhaled allergens provoke airway mast cell degranulation by binding to and cross-linking IgE on the mast cell surface. Mast cell degranulation leads to the release of chemical mediators, which cause acute bronchoconstriction and thus increased airway resistance and wheezing as well as mucus hypersecretion (E-Fig. 16-11). Disruption of the continuity of the ciliated columnar epithelium and increased vascularity and edema of the airway wall also follow antigen exposure. In addition to allergens, factors such as stimulation of irritant receptors, respiratory tract infections, and airway cooling can provoke bronchoconstriction in asthmatic individuals.

E-FIGURE 16-11 Mucus in the large airways of a patient with asthma. (Courtesy Dr. Charles Kuhn.)

Airway cooling appears to be responsible for exercise-induced bronchoconstriction as well as some wintertime asthma attacks.

Asthma is associated with airway wall remodeling, which is characterized by hyperplasia and hypertrophy of smooth muscle cells (E-Fig. 16-12), edema, inflammatory infiltration, angiogenesis, and increased deposition of connective tissue components such as type I and type III collagen. This last effect leads not only to a thickening of the subepithelial lamina reticularis (E-Fig. 16-13) but also to an expansion of the entire airway wall. Airway remodeling may begin fairly early in the course of the disease. Whether inflammation leads to remodeling or whether these processes represent two independent manifestations of the disease is unknown. Pulmonary function does seem to decline at an accelerated rate over time in patients with asthma, and airway wall remodeling may play a role in this functional loss. Over time, airway wall remodeling may lead to irreversible airflow limitation, which can worsen the disease by rendering bronchodilator drugs less effective. In this way, airway wall remodeling may make the clinical distinction between asthma and COPD difficult.

The cause of asthma is unknown, but it is likely to be a polygenic disease influenced by environmental factors. Atopy is strongly linked to asthma. Asthma is associated with an allergic-type activation of the immune system, typified by a T_H2 -predominant T-cell response to inhaled antigens with consequent IgE production and allergic airway inflammation. Exposure to indoor allergens such as dust mites, cockroaches, furry pets, and fungi is a significant factor; outdoor pollution and other irritants, including cigarette smoke, are also important.

Current concepts of asthma pathogenesis include a focus on impairment of the shift from a T_H2 -predominant immunity to a T_H1 immune response early in life. Paradoxically, in the developed world, the perpetuation of T_H2 immune responses and the development of inappropriate allergic responses may be related to a relative lack of exposure of the immune system to appropriate infectious antigenic stimuli in childhood, the so-called hygiene hypothesis. Farming, for example, appears to be protective against the development of asthma and allergic disease, possibly in part because of the increased exposure to microbial antigens eliciting a T_H1 response. Increased exposure to other children (as in daycare settings) and less frequent use of antibiotics may also decrease asthma risk, supporting this hypothesis. On the other hand, asthma is common in poor urban settings in which there is heavy exposure to allergic antigens from dust mites and cockroaches. The timing and roles of particular environmental exposures in utero and in early life in the pathogenesis of asthma and allergic diseases remain to be fully elucidated, and there is no current theory that completely explains asthma pathogenesis or the recent increased incidence of asthma. The interplay of other aspects of modern life, such as changes in the microbiome, with regard to asthma propensity continues to be explored.

Several genetic polymorphisms have been associated with asthma, including variations in the β -adrenergic receptor leading to diminished responsiveness to β -agonists. Identification of other genetic polymorphisms that are important in asthma is a subject of ongoing research. Although asthma is more common in male children than in female children, the prevalence of asthma changes after puberty, and it is more common in adult women

than in men. These facts, along with evidence of variation in asthma symptoms during the menstrual cycle and during pregnancy, suggest possible hormonal influences on asthma pathogenesis.

Asthma can be induced by workplace exposures in persons having no previous history of asthma (occupational asthma). Certain substances, such as isocyanates (used in spray paints) and Western red cedar wood dust, are strongly provocative agents for the development of occupational asthma. Obesity has been linked to a higher incidence of asthma. The mechanisms by which obesity may influence asthma development are unclear. Certain infectious agents and other conditions can cause acute bronchospasm even in patients without the diagnosis of asthma. Examples include viral infections, gastroesophageal reflux disease (GERD), and exposure to gases or fumes. These disorders may play a role in the development or control of some cases of asthma.

Clinical Presentation

Major symptoms of asthma are wheezing, episodic dyspnea, chest tightness, and cough. The clinical manifestations vary widely, from mild intermittent symptoms to catastrophic attacks resulting in asphyxiation and death. Although wheezing is not a pathognomonic feature of asthma, in the setting of a compatible clinical picture, asthma is the most common diagnosis. Often symptoms worsen at night or during the early hours of the morning. Other associated symptoms are sputum production and chest pain or tightness. Patients may exhibit only one or a combination of symptoms, such as chronic cough only (cough-variant asthma). Wheezing may occur several minutes after exercise (exercise-induced bronchoconstriction). Physical examination typically shows evidence of wheezing, although findings may be normal in between symptomatic periods. Rhinitis or nasal polyps may be present. In the case of an acute episode of bronchospasm or an exacerbation, the clinician may find that the patient has difficulty talking, is using accessory muscles of inspiration, has *pulsus paradoxus*, is diaphoretic, and has mental status changes ranging from agitation to somnolence. In patients with these findings, treatment should be immediate and aggressive.

Diagnosis and Differential Diagnosis

A diagnosis of asthma requires documentation of bronchial hyperreactivity and reversible airway obstruction. The history may provide sufficient documentation because most patients complain of characteristic periodic episodes of wheezing and other symptoms that respond to use of a bronchodilator. However, spirometry is recommended to assess formally for expiratory flow limitation, and reversibility is demonstrated by repeat spirometry after bronchodilator administration. At least 12% and 200 mL improvement in FEV_1 after bronchodilator use indicates reversibility. Because asthma is episodic, airflow limitation is variable and patients may exhibit symptoms at a time when spirometry cannot be performed. Peak expiratory flow measurements can be performed at home and may be helpful in establishing evidence of variability in expiratory flow.

Depending on the circumstances, formal testing for airway hyperactivity by bronchoprovocation challenge may be necessary. A stimulant with bronchoconstrictor activity, most

E-FIGURE 16-12 Thickening of the airway smooth muscle layer (between black arrows) in asthma. (Courtesy Dr. Charles Kuhn.)

E-FIGURE 16-13 Thickening of the subepithelial basement membrane in asthma (white arrows). (Courtesy Dr. Charles Kuhn.)

commonly methacholine, is applied to the patient's airway. Methacholine, a synthetic form of acetylcholine, is preferred to histamine because there are fewer systemic side effects. Exercise can also be used to trigger an attack. Although most patients with or without asthma develop some degree of airflow limitation during bronchoprovocation testing, those with asthma develop airflow limitation at much lower doses. For methacholine challenge, the concentration of methacholine required to produce a 20% decline in FEV₁ from baseline is reported. Although a positive bronchoprovocation challenge result is not by itself diagnostic of asthma, a negative result is helpful in ruling out asthma as a diagnosis.

Lung volume measurements may show hyperinflation during active disease, but the DLCO is typically normal or even elevated. During acute exacerbations of asthma, analysis of arterial blood gases is useful to determine gas-exchange status. A chest radiograph should be obtained if a concern for pulmonary infection exists, but routine chest radiography is not necessary. Fleeting or migratory infiltrates on chest radiographs in a patient with difficult asthma should suggest the possibility of allergic bronchopulmonary aspergillosis. Blood tests in asthma might reveal eosinophilia and increased levels of IgE. Skin tests might be useful to identify household products or other antigens that could precipitate asthma attacks in a specific patient.

The differential diagnosis includes tracheal disorders, respiratory tract tumors and foreign bodies, COPD, and bronchiectasis. In patients whose primary presenting complaint is chronic cough, the differential diagnosis includes other causes of chronic cough, such as GERD and postnasal drip. A major differential consideration in patients not responding to typical asthma treatment is vocal cord dysfunction.

Treatment

The management of asthma requires education and cooperation on the part of the patient. Simple, inexpensive peak expiratory flow meters can be used at home to monitor airflow obstruction. A diary should be maintained, and a clear written plan should be in place for using symptoms and peak flow information to intervene early in exacerbations and to alter long-term therapy for optimal control of symptoms. Short-acting β -agonists are used for acute relief of symptoms such as wheezing (level 1 evidence). However, the cornerstone of maintenance therapy in all but mild intermittent asthma is administration of inhaled corticosteroids, which are highly effective in improving asthma control (level 1). Long-acting β -agonists may be added for additional symptomatic control as needed (level 1). LABAs should not be used as a monotherapy for asthma control because they do not control airway inflammation and increased mortality has been demonstrated with this therapeutic approach (level 1). However, these medications may be added to inhaled corticosteroids to provide additional symptom control.

Alternatively, leukotriene modifiers can be used in maintenance therapy (level 1 evidence), although they appear to be somewhat less effective than inhaled corticosteroids (see Fig. 16-4). Theophylline preparations may have additional beneficial effects in some patients, but the narrow therapeutic window and modest efficacy of these preparations limit their value. Recent evidence suggests that use of long-acting anticholinergics in

patients with poor control on LABAs and inhaled corticosteroids may increase the time to exacerbation and provide additional bronchodilation (level 2). Oral or intravenous corticosteroids are used during acute asthma exacerbations. Long-term use of oral corticosteroids should be avoided, if possible, given the various side effects associated with chronic glucocorticoid administration.

Allergen avoidance is a reasonable measure in asthma, although the effects of specific interventions, such as mattress barrier protection to reduce dust mite exposure, appear limited. Treatment of associated conditions that may exacerbate asthma, such as allergic rhinitis and GERD, may be clinically beneficial and may aid in achieving asthma control. Use of recombinant human anti-IgE monoclonal antibody may be effective at reducing exacerbations in certain patients with allergic asthma (level 2 evidence). Therapies targeting other specific cytokines involved in asthma remain under active investigation. Bronchial thermoplasty is a new endoscopic technique in which radiofrequency energy delivered in a series of treatments is used to destroy airway smooth muscle. It has been shown to reduce exacerbations and improve quality of life in the months following treatment (level 2).

Acute severe asthma, or status asthmaticus, is an attack of severe bronchospasm that is unresponsive to routine therapy. Such attacks may be sudden (hyperacute asthma) and can be rapidly fatal, often before medical care can be obtained. In most cases, however, patients have a history of progressive dyspnea over hours to days, with increasing bronchodilator use. Treatment of status asthmaticus should be aggressive, including administration of nebulized bronchodilators and intravenous steroids and continuous monitoring of blood oxygen saturation by pulse oximetry, often supplemented by arterial blood gas analysis to evaluate for hypercarbia. A rising PaCO₂ in a patient with asthma is an ominous sign and may portend need for ventilatory support. Noninvasive ventilation has been used successfully to decrease the work of breathing and avoid the need for endotracheal intubation in patients with exacerbations of asthma, but intubation and mechanical ventilation are necessary for the management of respiratory failure in status asthmaticus. Mechanical ventilation of the patient with status asthmaticus can be extremely challenging and may require the use of paralytic agents to control the breathing pattern or even use of inhaled general anesthesia to relieve bronchospasm.

Prognosis

The prognosis in most patients with asthma is excellent. Although there is no cure, most patients can achieve appropriate control of their asthma.

Interstitial Lung Diseases

Matthew D. Jankowich

INTRODUCTION

The interstitial lung diseases (ILDs) are a complex group of dozens of disorders with heterogeneous clinical courses and prognoses. ILDs are characterized by diffuse and typically chronic lung injury occurring in the setting of various degrees of inflammation, which often leads to lung fibrosis. These diseases are daunting for the clinician because the differential diagnosis may be broad, and the work-up required to make the appropriate diagnosis may be extensive.

Understanding of these disorders has been hampered in the past by use of confusing and nonspecific terminology, especially for the idiopathic interstitial pneumonias (IIPs). Current classifications use histopathology and clinical syndromes to categorize them in understandable groups: idiopathic interstitial pneumonitides, granulomatous disorders, connective tissue–related ILDs, drug-induced ILDs, pulmonary vasculitic disorders, and distinct entities of unknown origin that exhibit well-defined syndromes such as pulmonary Langerhans cell histiocytosis (LCH) and lymphangioleiomyomatosis.

ILD manifests with nonspecific, common clinical symptoms, including dyspnea on exertion, dry cough, and sometimes, constitutional symptoms. Pulmonary function tests usually show restriction and gas-exchange abnormalities. Imaging usually demonstrates diffuse lung disease. However, early radiographic changes may be subtle, and other clinical entities such as congestive heart failure or lymphangitic carcinomatosis may manifest with similar clinical, physiologic, and radiographic findings. The diagnosis may sometimes be delayed until other clinical entities are excluded and biopsy is undertaken. High-resolution computed tomography (HRCT) has contributed greatly to the diagnostic work-up of patients with suspected ILD because typical HRCT patterns in appropriate clinical settings may be sufficient for diagnosis.

Most ILDs, including more common entities such as idiopathic pulmonary fibrosis (IPF), manifest with chronic, progressive symptoms. However, some ILDs manifest in an acute fashion. They include acute pneumonitis due to systemic lupus erythematosus, acute hypersensitivity pneumonitis (HP), some drug reactions, and acute interstitial pneumonia. Infection often needs to be ruled out in these cases, and the diagnosis may be challenging for critically ill individuals.

When ILD is suspected in a patient with typical symptoms and diffuse lung disease on identified on imaging, the epidemiologic background, including the age, race, and sex of the patient, is helpful in formulating the diagnostic possibilities. For example, IPF typically occurs in middle-aged or elderly individuals,

whereas sarcoidosis often occurs in young individuals and is most common among African Americans in the United States. Sex is also a consideration because lymphangioleiomyomatosis manifests almost exclusively in women of childbearing age, and pulmonary LCH most often occurs in young male smokers. These background data can help to focus the initial differential diagnosis.

The history can further narrow the differential diagnosis for suspected ILD. Important factors to elicit are rash, dysphagia, arthritis, and Raynaud's phenomenon, which may suggest an underlying connective tissue disorder. If the patient has a diagnosis of connective tissue disease, the work-up may be limited if imaging findings are typical of the pulmonary manifestations of that disease. A history of severe or poorly controlled asthma for a patient with radiographic infiltrates and constitutional symptoms should lead to consideration of Churg-Strauss syndrome, whereas a history of severe sinus disease should raise the possibility of granulomatosis with polyangiitis (formerly called *Wegener's granulomatosis*).

Drug-induced ILD should be considered for all patients with diffuse lung disease seen on imaging, and a careful evaluation of medication use is critical. The smoking history is important because several ILDs are associated with cigarette smoking, including respiratory bronchiolitis–associated interstitial lung disease, desquamative interstitial pneumonitis, and pulmonary LCH.

Environmental exposures should be elicited. For example, an exposure to pet birds or hot tubs may suggest HP. Home visits can be informative, and the occupational history is important. Although the pneumoconioses due to asbestos and silica exposure are becoming much less common with modern safeguards and restrictions, these diseases continue to manifest long after exposure. High-technology manufacturing has particular hazards, such as beryllium exposure leading to berylliosis in susceptible individuals. Nonindustrial professions also carry occupational risks. For example, outbreaks of granulomatous pneumonitis have been described in indoor lifeguards exposed to molds.

The physical examination may reveal only oxygen desaturation with exertion in early ILD. Patients may have evidence of decreased chest expansion during inspection. Auscultation of the lungs typically reveals Velcro-like crackles at the lung bases. The patient may have clubbing. Skin rashes, arthritis with joint deformities, Raynaud's phenomenon, and dysphagia may point to a connective tissue–related ILD such as dermatomyositis or polymyositis, progressive systemic sclerosis, or mixed connective tissue disorder. Evidence of right ventricular heart failure with jugular vein distention, a cardiac gallop, a loud P₂ sound, and leg

edema suggests pulmonary hypertension. Right ventricular heart failure is usually the result of chronic hypoxemia and is often related to end-stage lung disease.

Laboratory studies may be of benefit. For example, eosinophilia suggests the particular group of disorders associated with pulmonary infiltrates and peripheral blood eosinophilia.

A chest radiograph can narrow the diagnosis based on the distribution of the typical reticulonodular changes found in ILD. For example, sarcoidosis, lymphangioleiomyomatosis, silicosis, HP, eosinophilic granuloma, and ankylosing spondylitis most often affect the upper- and mid-level lung fields, whereas IPF, asbestosis, and many connective tissue-related ILDs typically involve the lower-level lung fields.

Disease patterns are best analyzed with the use of HRCT of the chest, a test considered essential in the evaluation of patients thought to have ILD. HRCT can reveal patterns of disease that allow the diagnostic considerations to be significantly narrowed. For example, upper lobe-predominant cystic lung disease on HRCT suggests LCH, sarcoidosis, or lymphangioleiomyomatosis. Lower lobe and peripheral reticular opacities with associated traction bronchiectasis and honeycombing suggest IPF, asbestosis, or certain connective tissue disease-related ILDs. Visualization of abnormalities of the mediastinum or pleura associated with parenchymal lung disease is helpful. Sarcoidosis, for example, typically exhibits hilar and mediastinal

lymphadenopathy associated with beadlike septal nodules, whereas pleural plaques associated with lower lobe fibrosis are consistent with asbestosis. Incorporation of HRCT imaging data with clinical history sometimes may be sufficient for diagnosis.

Pulmonary function tests for ILD typically reveal a restrictive pattern characterized by proportionately decreased airflow with a preserved ratio of forced expiratory volume in 1 second to forced vital capacity (FEV_1/FVC) (i.e., no obstruction to airflow) and decreased lung volumes as highlighted by decreased total lung capacity and functional residual capacity. The diffusion capacity of the lung for carbon dioxide (DLCO) is often decreased and may be the earliest change seen in drug-induced ILD or connective tissue disease-related ILD. The restrictive abnormality found in most forms of ILD results from decreased compliance of the lung in the setting of fibrosis.

Histologically, ILD affects the interstitium of the lung, the space located between the basement membrane of the vascular structures in the distal air spaces and the basement membranes of the epithelial cells that line the alveoli (Fig. 17-1). This space extends proximally toward the alveolar ducts and respiratory bronchioles. Normally, the interstitium of the lung contains a few fibroblasts and connective tissue components within a very thin wall that allows efficient diffusion of gases. In ILD, however, this space expands with the accumulation of fibroblasts or other

Idiopathic pulmonary fibrosis
Asbestosis

FIGURE 17-1 Radiographic manifestations of interstitial lung diseases. Well-preserved lung volumes with bilateral interstitial reticulonodular infiltrates (*left*) are seen in diseases similar to sarcoidosis and hypersensitivity pneumonitis. Reduced lung volumes with bilateral basilar infiltrates (*right*) are seen in idiopathic pulmonary fibrosis.

cells and the deposition of an aberrant matrix that increases the distance between the alveolar space and vascular structures, delaying and sometimes preventing gas exchange. This thickened interstitium accounts for poor oxygenation with exercise, increased lung stiffness exhibited as decreased compliance, small lung volumes, and increased work of breathing.

Because lung involvement by ILD may be sporadic, with areas of normal lung adjacent to areas of fibrosis, local differences in compliance may result in ventilation-perfusion mismatching, contributing to hypoxemia. The processes previously outlined account for the physiologic manifestations seen in disorders such as IPF and asbestosis.

In some ILDs, an obstructive rather than restrictive abnormality or mixed patterns are identified on pulmonary function testing, and lung volumes are relatively preserved on physiologic testing and imaging (Fig. 17-2). In diseases such as lymphangioliomyomatosis, pulmonary LCH, and some cases of HP or sarcoidosis, obstructive or mixed patterns on pulmonary function testing occur with preservation of lung volumes. This pattern of disease is caused by proximal extension of the interstitial disease in the lung parenchyma with consequent involvement of the small airways. For example, in lymphangioliomyomatosis, the small airways are narrowed by the proliferation of surrounding abnormal smooth muscle–like cells. This leads to increased airway resistance and airflow obstruction. Endobronchial disease with direct narrowing of the airways can occur in sarcoidosis, leading to similar effects. The finding of airflow obstruction does not rule out a diagnosis of ILD but may help to focus the differential diagnosis on particular diseases.

In ILD, a synthesis of clinical, functional, and imaging data, often in the context of a multidisciplinary approach, can determine the appropriate diagnosis. In many circumstances, however,

FIGURE 17-2 Interstitial lung disease (ILD) affects the interstitium of the lung at different locations. Depending on the site of disease activity, its consequences may vary. Diseases that affect the interstitium that surrounds the distal part of the alveoli lead to physiologic restrictions with reduced lung volumes. Diseases that preferentially affect the interstitium located near the more proximal parts of the acinus near the distal bronchioles may exhibit predominantly well-preserved lung volumes and physiologic obstruction.

clinical and imaging data are insufficiently specific, and lung biopsy must be undertaken. Surgical lung biopsy, typically using a thoracoscopic approach, is the preferred method of obtaining tissue for examination. Transbronchial lung biopsy through the bronchoscope yields small fragments of tissue, typically too small to allow appropriate examination of the lung architecture, and it is not recommended for the assessment of suspected IPF. However, transbronchial biopsies may be useful for certain ILDs, including sarcoidosis, cryptogenic organizing pneumonia, and HP.

The lung's response to injury is relatively stereotyped, and particular biopsy patterns of injury, such as usual interstitial pneumonia or granulomatous inflammation, are seen in a variety of disorders. Interpretation of lung biopsy results must be done in the appropriate context and with incorporation of clinical and imaging data. For example, a biopsy result of usual interstitial pneumonitis may carry a different prognosis in the setting of rheumatoid arthritis–associated ILD than in the setting of IPF. The typical manifestations of several ILDs are summarized in Table 17-1.

Management of ILD depends on the underlying cause, and treatments appropriate to specific entities are discussed later. Exposure avoidance is critical for HP, smoking-related ILD, and drug-induced ILD. Immunosuppressants are employed in a variety of the ILDs, with results depending on the specific disease. Supplemental oxygen and pulmonary rehabilitation may be helpful in advanced disease. Lung transplantation is performed in patients with limited life expectancy, and early referral is suggested for patients with a poor prognosis, as in IPF.

For a deeper discussion on this topic, please see Chapter 92, "Interstitial Lung Disease," in Goldman-Cecil Medicine, 25th Edition.

IDIOPATHIC INTERSTITIAL PNEUMONIAS

The IIPs are a group of ILDs of unknown origins. In the 1970s, these conditions were considered to be different variations of IPF. However, the distinct clinical presentations, natural courses, and responses to treatment observed in these patients led to their reclassification as IIPs. The classification scheme suggested in a 2002 consensus statement by the American Thoracic and European Respiratory Societies was updated in 2013.

The major IIPs are IPF, idiopathic nonspecific interstitial pneumonia (NSIP), respiratory bronchiolitis–associated interstitial lung disease (RB-ILD), desquamative interstitial pneumonia (DIP), cryptogenic organizing pneumonia (COP), and acute interstitial pneumonia (AIP). Rare IIPs include lymphoid (or lymphocytic) interstitial pneumonia (LIP) and idiopathic pleuroparenchymal fibroelastosis. Some patients have idiopathic interstitial lung disease that does not meet criteria for any of these entities, and they are considered to have unclassifiable IIP.

Idiopathic Pulmonary Fibrosis

Definition and Epidemiology

Of the IIPs, IPF, formerly called *cryptogenic fibrosing alveolitis*, is the most common, affecting 85,000 to 100,000 individuals in the United States. IPF was defined in a consensus statement as a

TABLE 17-1 MANIFESTATIONS OF INTERSTITIAL LUNG DISEASE

DISEASE	PHYSICAL EXAMINATION	RADIOGRAPHS	LABORATORY FINDINGS	HISTOLOGIC FINDINGS
Pneumoconioses				
Silicosis	Various findings	Large nodules Eggshell calcification of hilar nodes PMF, upper lobes Emphysema, nodules PMF	Restrictive PFTs	Silica: inflammation, birefringent crystals, alveolar proteinosis
Coal worker's pneumoconiosis	Normal		FEV1 and FVC may be decreased	Coal: pigmented macules, anthracotic pigment
Asbestosis	Crackles	Pleural plaques, lower lobe fibrosis	Restrictive PFTs	Asbestos: UIP pattern, asbestos bodies, mesothelioma
Beryllium exposure	Nonspecific findings	Lymphadenopathy, lung nodules	Nonspecific except beryllium: lymphocyte transformation test	Beryllium: noncaseating granulomas
Hypersensitivity pneumonitis	Fever, cough, crackles	Centrilobular nodules, air trapping, fibrosis	Serum precipitins to specific proteins CD8>CD4 cells Lymphocytic BAL fluid Obstructive and/or restrictive PFTs	Chronic airway centered inflammation, poorly formed granulomas
Idiopathic interstitial pneumonias				
DIP, RB-ILD	Various findings	Centrilobular nodules, ground-glass infiltrates	Nonspecific	DIP: Intra-alveolar accumulation of pigmented macrophages
IPF	Crackles, clubbing	Basilar predominant fibrosis, honeycombing	Restrictive PFTs	IPF: UIP pattern with heterogeneous areas of fibrosis, fibroblast foci
AIP	Tachypnea, respiratory distress	Bilateral alveolar infiltrates	Nonspecific	AIP: Diffuse alveolar damage
NSIP	Crackles, possible clubbing	Ground-glass, subpleural reticulations	Restrictive PFTs	NSIP: Uniform thickening of interstitium with inflammatory cells and fibrosis
Collagen vascular	Collagen vascular disease, crackles, pleural rub	Pleural effusions Diffuse interstitial infiltrates, nodular infiltrates Occasional cavities	Serologic findings for specific disease Occasionally obstructive, usually restrictive PFTs	Interstitial inflammation Vasculitis Bronchiolar obstruction Organizing pneumonia Fibrosis: UIP, NSIP, LIP
Drug-induced ILD	Fever, crackles, pleural rub	Fibrosis Migratory infiltrates, diffuse interstitial infiltrates Pulmonary edema	Restrictive PFTs	Alveolar macrophages with lamellar bodies in amiodarone Interstitial inflammation Fibrosis Eosinophilic infiltration
Sarcoidosis	Fever, malaise, weight loss Erythema nodosum, lupus pernio, and skin plaques Salivary and lacrimal gland enlargement Arthritis Iritis, uveitis, chorioretinitis; keratoconjunctivitis Cranial nerve palsies Occasional rales or wheezes	Reticulonodular infiltrates Nodules Hilar adenopathy Mediastinal adenopathy Fibrosis	Lymphocytic BAL, T4 > T8 cell subsets Obstructive and/or restrictive PFTs Elevated transaminases with liver involvement Occasional hypercalcemia	Noncaseating granuloma with giant cells and negative acid-fast bacilli and fungal staining Fibrosis
Radiation exposure	Crackles, fever	Focal interstitial infiltrates corresponding to radiation port Occasional diffuse infiltrates Fibrosis	Restrictive PFTs	Acute: endothelial and alveolar lining cell damage Chronic: fibrosis
Pulmonary Langerhans cell histiocytosis	None to cough, dyspnea, chest pain Fatigue, weight loss, occasional fever	Spontaneous pneumothorax Nodules Reticulonodular infiltrates Middle and upper lobe predominance Honeycombing Sparing of costophrenic angle Cysts and nodules on HRCT	Normal lung volumes with decreased DLCO	OKT-6 (CD1) and S100-positive immunostaining Few eosinophils Peribronchiolar inflammation Macrophages filling lumen of bronchioles and intraluminal fibrosis

TABLE 17-1 MANIFESTATIONS OF INTERSTITIAL LUNG DISEASE—cont'd

DISEASE	PHYSICAL EXAMINATION	RADIOGRAPHS	LABORATORY FINDINGS	HISTOLOGIC FINDINGS
Lymphangioleiomyomatosis	Dyspnea, cough, chest pain Decreased breath sounds or rales Hemoptysis, ascites	Spontaneous pneumothorax Pleural effusions Reticulonodular infiltrate Miliary pattern Honeycombing Hyperinflation Diffuse, small, thin-walled cysts on HRCT	Obstructive and/or restrictive PFTs Chylous pleural effusions Chylous ascites	HMB-45–positive immunostaining Atypical smooth muscle cell proliferation around bronchovascular bundles
COP	Fever, chills, malaise, fatigue, cough, dyspnea on exertion, weight loss	Peripheral patchy infiltrates, occasionally migratory CT: patchy consolidation, ground-glass opacities, small nodules	Restrictive and occasionally obstructive PFTs for smokers	Patchy peribronchiolar distribution Foamy macrophages in alveolar spaces Intraluminal buds of granulation tissue

AIP, Acute interstitial pneumonia; BAL, bronchoalveolar lavage; BOOP, bronchiolitis obliterans and organizing pneumonia; COP, cryptogenic organizing pneumonia; CT, computed tomography; DIP, desquamative interstitial pneumonia; DLCO, diffusing capacity of the lung for carbon monoxide; HRCT, high-resolution computed tomography; ILD, interstitial lung disease; IPF, idiopathic pulmonary fibrosis; LIP, lymphoid interstitial pneumonia; NSIP, nonspecific interstitial pneumonia; PFT, pulmonary function test; PME, progressive massive fibrosis; RB, respiratory bronchiolitis; RNP, anti-ribonucleoprotein antibodies; UIP, usual interstitial.

“specific form of chronic, progressive fibrosing interstitial pneumonia of unknown cause, occurring primarily in older adults, limited to the lungs, and associated with the histopathologic and/or radiologic pattern of usual interstitial pneumonitis.”

Although initially thought to be a rare disease, IPF is now considered one of the most common ILDs, with a prevalence in some populations of up to 29 cases per 100,000 people; the prevalence is much higher among patients older than 70 years. Among most patients with IPF, the disease is sporadic. However, IPF has been found in members of certain families and is called *familial IPF*, indicating that genetic alterations predispose some patients to this illness. Genetic abnormalities associated with familial IPF include abnormalities of the telomerase complex and surfactant proteins.

The disease is idiopathic, but risk factors include cigarette smoking and possibly gastroesophageal reflux disease. Many environmental, occupational, and infectious agents can cause lung fibrosis, including asbestos, silica, and tuberculosis. Distinguishing IPF from other lung disorders is important because of the implications for prognosis and therapy.

Pathology

The underlying histopathologic pattern found in the lungs of patients with IPF is called *usual interstitial pneumonia* (UIP). This histologic pattern shows areas of scar tissue deposition and honeycombing interspersed with areas with relatively normal alveolar structures, resulting in a heterogeneous pattern on microscopy (Fig. 17-3). An interesting pathologic feature is the finding of fibroblastic foci, which are areas in which fibroblasts accumulate. They are thought to be sites of disease activity.

The UIP pattern can accompany other disorders (e.g., connective tissue–related ILD in rheumatoid arthritis, asbestosis). The diagnosis of IPF depends on a clinical, radiographic, and histologic picture that includes the syndrome of ILD in the absence of an obvious cause and a histologic manifestation consistent with UIP.

Clinical Presentation

IPF is characterized by progressive fibrosis of the lungs, resulting in nonproductive cough and shortness of breath that worsens

FIGURE 17-3 Pulmonary fibrosis in idiopathic pulmonary fibrosis with usual interstitial pneumonia pathology that is adjacent to normal lung parenchyma. (Courtesy Dr. Charles Kuhn.)

with exertion and ultimately causes hypoxemic respiratory failure. The typical patient with IPF is older than 50 years, and the symptoms frequently develop 1 to 2 years before a diagnosis is confirmed.

Physical examination often reveals inspiratory crackles in the bases of both lungs, indicating the predominant site of scarring. Clubbing may exist, but extrapulmonary findings such as rash or joint arthritis are absent. With increased connective tissue deposition, the lung becomes stiff as evidenced by decreased compliance. Pulmonary function tests show decreased lung volumes consistent with a restrictive process, and the DLCO is reduced. Impaired oxygenation in IPF, initially with exercise and later at rest, often requires long-term oxygen supplementation.

The chest radiograph shows reticular infiltrates that are most predominant at the bases and periphery of the lungs. HRCT allows better visualization of the lung and is useful in evaluating the extent of disease. It delineates the areas of fibrosis and provides information about other structures in the chest. The classic HRCT findings of IPF are bilateral reticulonodular infiltrates, which are more pronounced at the lung bases and have

a peripheral, subpleural distribution, and detection of honeycombing and traction bronchiectasis in the absence of ground-glass opacification, lymphadenopathy, and pleural disease (Fig. 17-4; E-Fig. 17-1). In the setting of a typical clinical presentation and classic HRCT findings, a lung biopsy is unnecessary. A lung biopsy may be required for confirmation in some patients.

Diagnosis and Differential Diagnosis

IPF is diagnosed on the basis of typical clinical, radiographic (HRCT), and if available, pathologic features (e.g., biopsy showing a UIP pattern). Other potential causes of ILD, such as connective tissue disease, hypersensitivity pneumonitis, and asbestosis, must be ruled out by the history, examination, and selected laboratory testing.

HRCT of the chest should show a compatible UIP pattern, with subpleural reticulations, honeycombing, and traction bronchiectasis. If honeycombing is absent on HRCT or atypical features such as ground-glass infiltrates, lymphadenopathy, nodules, or air trapping are found, the radiographic diagnosis becomes less certain. In these cases, a lung biopsy may be needed, and it should show a UIP pattern to confirm a diagnosis of IPF. Multidisciplinary discussion during the diagnostic process, with input from experienced clinicians, radiologists, and pathologists, is ideal.

Treatment

There is insufficient clinical evidence to suggest that any pharmacologic treatment improves survival or the quality of life for patients with IPF. A commonly used immunosuppressive combination of corticosteroids, azathioprine, and *N*-acetylcysteine was shown in a multicenter clinical trial to be more harmful than a placebo or *N*-acetylcysteine alone (level 1 evidence). *N*-acetylcysteine treatment did not show any clear advantage over placebo.

The antifibrotic drug pirfenidone has been approved in some countries based on evidence from a study showing a reduced decline in lung function with this medication, although a parallel study did not show the same results (level 2 evidence). An ongoing clinical trial of this drug showing better preserved lung

function with pirfenidone compared to placebo was recently completed in the United States.

Lung transplantation should be considered for patients with IPF. Because survival of patients with IPF on the lung transplantation waiting list is worse than for patients with other indications for lung transplantation, early referral for transplantation evaluation should be initiated (level 2 evidence). Unfortunately, the 5-year survival rate for lung transplant recipients with IPF is only 40% to 50%.

Some patients with IPF experience acute respiratory deterioration in the absence of any clinically apparent cause (e.g., heart failure, pulmonary embolism, pneumonia). These episodes of idiopathic acute deterioration have been called *acute exacerbations of IPF* and are associated with a poor prognosis. HRCT findings include new ground-glass opacities and consolidation superimposed on a background reticular or honeycomb pattern consistent with UIP. Histologically, evidence of acute lung injury (i.e., diffuse alveolar damage) can be found on the background of UIP. Acute exacerbations of IPF are typically treated with high doses of corticosteroids (level 3 evidence).

Prognosis

The prognosis for IPF is poor. The disease is progressive, ultimately leading to death from respiratory failure or other complications such as lung cancer. Median survival is often reported to be 2 to 3 years from the diagnosis, although this may be an underestimate.

Other Idiopathic Pneumonias

The second most common IIP is NSIP. This condition exhibits a histologic picture that is nonspecific and characterized by diffuse, uniform interstitial inflammation (i.e., cellular NSIP, which is less common) with or without fibrosis (i.e., fibrotic NSIP, which is more common), as distinguished by the heterogeneous pattern seen in UIP or IPF. Patients with NSIP exhibit progressive dyspnea, cough, and bilateral interstitial infiltrates. Affected patients are middle-aged and commonly women.

Although NSIP may be idiopathic, the NSIP pathologic pattern also may occur in conditions such as connective tissue disorders (e.g., systemic lupus erythematosus, rheumatoid arthritis, polymyositis). The association with these disorders is so strong that histologic confirmation of NSIP should prompt a search for these conditions, which occasionally manifest only after the development of NSIP. The differential diagnosis also includes IPF, COP, and HP. Pulmonary function tests most commonly show a restrictive pattern. Ground-glass infiltrates, subpleural reticulation, and traction bronchiectasis are often seen by HRCT, but honeycombing is minimal or absent.

NSIP may be more responsive to immunosuppressants than IPF, and a trial period with immunosuppressive agents should be considered (level 3 evidence). Lung transplantation should be considered in these patients if they exhibit progressive disease. However, the overall prognosis is much better than for IPF, with a 5-year survival rate of more than 82% in one series.

DIP is a rare idiopathic pneumonia usually seen in younger individuals. It is associated in most cases with a history of cigarette smoking. Patients exhibit a progressive shortness of breath

FIGURE 17-4 Computed tomography of the chest of a patient with idiopathic pulmonary fibrosis.

E-FIGURE 17-1 Honeycombing.

and bilateral infiltrates on chest radiographs. The HRCT pattern shows extensive ground-glass infiltrates, and a biopsy is often required for diagnosis. Tissue histologic findings show the accumulation of so-called smoker's macrophages, which contain yellow-brown pigment and fill the alveolar spaces, and some degree of interstitial inflammation and fibrosis.

Treatment of DIP relies on immunosuppressant therapy and the avoidance of tobacco exposure. Prognosis is fair, with some individuals developing progressive lung disease. DIP is considered by some experts to be part of a continuum with RB-ILD, which produces a similar clinical presentation; has a somewhat different pathology, with macrophages centered at the small airways as opposed to the alveolar level; and is associated with tobacco exposure. RB-ILD has a better prognosis. Respiratory bronchiolitis may be found incidentally in asymptomatic smokers, and it does not constitute an ILD if not extensive and associated with clinical symptoms.

AIP is an IIP that manifests acutely. There is no sex predominance in AIP and no association with smoking. Dyspnea and radiographic alveolar lung opacities develop and progress over days to a few weeks, invariably leading to respiratory failure. Patients often have a prior illness suggesting a viral upper respiratory infection with constitutional symptoms such as myalgias, arthralgias, fever, chills, and malaise. The histologic pattern shows diffuse alveolar damage with hyaline membrane formation or with organization. Although a trial of immunosuppressants is recommended (level 3 evidence), this condition is frequently fatal independent of treatment, and relapse may occur even after apparent improvement.

COP manifests over a subacute time course. Patients with COP exhibit dyspnea, cough, and systemic symptoms. Radiographically, patients with COP typically have areas of air space consolidation mimicking a bacterial pneumonia but that do not resolve with antibiotics. The radiographic infiltrates may be unilateral or bilateral and may be migratory. Pulmonary function tests may show restriction or obstruction. Histologically, COP is characterized by distal airway and interstitial inflammation and obliteration of distal small airways and air spaces with plugs of fibroblasts and fibrotic tissue called *Masson bodies*.

Similar to NSIP and DIP, COP is likely to respond to immunosuppressant therapy and is usually treated with prednisone (level 2 evidence). Relapses are typical and may occur when the steroid treatment is tapered. Connective tissue disorders, inhaled irritants, and drugs (e.g., methotrexate) can cause a type of inflammation known as *secondary organizing pneumonia*.

LIP is a rare disease that is seen predominantly in women. Patients have gradual-onset dyspnea and cough and occasionally have fever, weight loss, chest pain, and arthralgias. Cases of apparently idiopathic LIP must be investigated for known causes, such as collagen vascular diseases (especially Sjögren syndrome and rheumatoid arthritis) and immunodeficiency diseases (e.g., acquired immunodeficiency syndrome [AIDS]).

For LIP, HRCT shows interstitial reticulations, centrilobular nodules, ground-glass opacities, and thin-walled cysts. Histologically, infiltration of cells, including lymphocytes, plasma cells, and histiocytes, can be seen within alveolar septa. Type II pneumocyte hyperplasia and an increase in the number of alveolar

macrophages can be seen in cases of LIP. Lymphoid follicles are often identified, usually in the distribution of pulmonary lymphatics.

Corticosteroids are used to treat LIP with various degrees of success (level 3 evidence); however, more than one third of patients progress to diffuse fibrosis. It is unclear whether treatment influences the course of the disease or has a significant effect on lung physiology.

● GRANULOMATOUS DISORDERS

Interstitial Lung Diseases with Granuloma Formation

Several noninfectious ILDs are characterized by granuloma formation in the lungs, including granulomatosis with polyangiitis, HP, and chronic beryllium disease. These disorders are discussed elsewhere in this chapter. Of the ILDs characterized by granulomatous lung inflammation, sarcoidosis is the most common.

Sarcoidosis

Definition and Epidemiology

Sarcoidosis is a multisystem granulomatous disorder of unknown cause. The lungs and thoracic lymph nodes are frequent sites of involvement. Sarcoidosis is relatively common, with a prevalence of 1 to 40 cases per 100,000 people worldwide. A higher incidence of sarcoidosis is reported among Scandinavian, German, and Irish individuals residing in northern Europe. In the United States, the prevalence rates of sarcoidosis are 10.9 cases per 100,000 whites and 35.5 cases per 100,000 African Americans, with women in both groups being more frequently affected. Because sarcoidosis may be asymptomatic, the true prevalence may be higher. Sarcoidosis typically occurs in individuals between 10 and 40 years old.

Pathology

Sarcoidosis is characterized by the formation in tissues of noncaseating granulomas that organize in an inner core of epithelioid histiocytes, CD4⁺ T lymphocytes, and giant cells, which are surrounded by a rim of lymphocytes, fibroblasts, and connective tissue (Fig. 17-5). Granulomas are found in the airways or lung parenchyma in more than 90% of patients with sarcoidosis. Granulomatous angiitis may also be found in the lungs. The upper respiratory system, lymph nodes, skin, and eyes are commonly involved. Virtually any other organ may be affected, including the liver, bone marrow, spleen, musculoskeletal system, heart, salivary glands, and nervous system.

The granulomas may be clinically silent or, if extensive, may disrupt normal organ structure and function. The cause of these lesions is unknown, but given the frequency of lung involvement, inhaled antigens ranging from bacteria (especially mycobacteria and *Propionibacterium*) to environmental substances have been hypothesized to trigger the onset of granulomatous inflammation. This inflammation may be self-limited or may be propagated, possibly by repeated exposure to the unknown antigen or because of defective immune regulation.

Familial susceptibility to sarcoidosis exists, and alleles of human leukocyte antigen (HLA) genes involved in antigen

FIGURE 17-5 Subepithelial noncaseating granuloma, which is characteristic of sarcoidosis, from an endobronchial biopsy.

presentation and a mutation in the butyrophilin-like 2 gene (*BTNL2*), a possible immunoregulatory gene, have been associated with susceptibility to sarcoidosis. A single causative antigen initiating granuloma formation may not exist, and sarcoidosis instead may represent a stereotypical inflammatory reaction to various antigens in a genetically susceptible host.

Sarcoidosis is associated with abnormal immune function as evidenced by cutaneous anergy and as exhibited in lung by an increased ratio of CD4⁺ to CD8⁺ T lymphocytes and increased concentrations of pro-inflammatory cytokines such as interferon- γ , interleukin-12, and tumor necrosis factor- α (TNF- α). These derangements can be detected in the bronchoalveolar lavage (BAL) fluid and are consistent with an imbalance in the production of type 1 (T_H1) and type 2 (T_H2) helper T-cell cytokines, favoring the production of the former and promoting persistent inflammation. Sarcoidosis may occur in the setting of immunomodulatory therapy, especially with interferon alfa, or the immune reconstitution syndrome, occurring after initiation of antiretroviral therapy for human immunodeficiency virus (HIV) infection, highlighting the role of immune imbalances in the disorder.

Clinical Presentation

The clinical presentation of patients with sarcoidosis varies. The disease is frequently detected incidentally on routine chest radiographs of asymptomatic individuals. Others may have diverse acute or chronic symptoms. Patients may develop well-described acute syndromes such as Löfgren syndrome, which includes erythema nodosum, fever, arthritis, and hilar adenopathy, or uveoparotid fever (i.e., Heerfordt's syndrome), which exhibits the triad of uveitis, parotitis, and facial nerve palsy. Both syndromes are associated with better outcomes than for other clinical presentations of sarcoidosis.

In many cases, symptoms are vague and chronic, and they may include systemic symptoms such as low-grade fevers, fatigue, night sweats, or joint pains. Respiratory manifestations, including shortness of breath, wheezing, dry cough, and chest pain, occur in one third to one half of patients. Skin manifestations include erythema nodosum, plaques, nodules, and lupus pernio, a

TABLE 17-2 RADIOGRAPHIC STAGING OF SARCOIDOSIS

STAGE	RADIOGRAPHIC FINDINGS
0	Normal radiograph
I	Adenopathy without parenchymal abnormality
II	Adenopathy and parenchymal disease
III	Parenchymal disease without lymphadenopathy
IV	End-stage fibrosis

violaceous, often disfiguring, nodular lesion of the nose and cheeks. Ocular symptoms are also common, and the onset of uveitis may eventually lead to the diagnosis of sarcoidosis when granulomatous extraocular organ involvement is uncovered. Neurosarcoidosis may manifest with cranial nerve palsies or with headache in the setting of lymphocytic meningitis. Sarcoidosis can involve the heart, resulting in a cardiomyopathy. Arrhythmias and sudden cardiac death can occur as a result of the disruption of the conducting system by granulomatous infiltration. Pulmonary hypertension may result from pulmonary fibrosis or directly from granulomatous vasculitis.

In 90% of patients, the chest radiograph shows abnormalities that include bilateral hilar adenopathy (E-Fig. 17-2), infiltrates (E-Fig. 17-3), and fibrosis. The radiographic changes characteristic of sarcoidosis have been classified as stages 0 through IV (Table 17-2), but this staging system does not imply a typical chronologic progression. However, stage I patients have a better prognosis for resolution than those with more advanced stages of disease.

As in other ILDs, computed tomography (CT) is more sensitive for the detection of parenchymal abnormalities, and it more clearly demonstrates the extent of mediastinal adenopathy. Parenchymal HRCT findings include nodularity along the bronchovascular bundles emanating from the hila (E-Fig. 17-4). Lung parenchyma involvement in sarcoidosis is more prominent in the upper lobes. Positron emission tomography (PET) or gallium-67 scans may reveal other sites of organ involvement.

Pulmonary function tests show restriction or obstruction. Liver involvement may cause mild elevation of transaminase levels, and cirrhosis and liver failure have been reported, although they are rare. Hypercalcemia and hypercalciuria may be detected and are caused by increased intestinal absorption of calcium as a result of increased conversion of vitamin D to its active form in sarcoid granulomas. Kidney stones may result from the abnormal calcium metabolism. Elevated levels of angiotensin-converting enzyme (ACE) are common but are not specific. The use of ACE levels in the diagnosis or management of sarcoidosis is controversial.

Diagnosis

The diagnosis of sarcoidosis depends on a typical clinical, radiographic, and histologic picture and is a diagnosis of exclusion. Patients with classic syndromes such as the Löfgren syndrome or uveoparotid fever may not require biopsy; however, most patients require tissue biopsy of an affected organ. Tissue samples show noncaseating granulomas, but because this finding is nonspecific, careful attention should be given to ruling out other causes of granulomatous inflammation (e.g., mycobacterial infection) through stains and cultures.

E-FIGURE 17-2 Hilar adenopathy in a patient with sarcoidosis (*arrows*). **A**, Chest radiograph. **B**, Chest computed tomography scan. (Courtesy Dr. Rafael L. Perez.)

E-FIGURE 17-3 Sarcoidosis with interstitial infiltrates.

E-FIGURE 17-4 Arrows indicating hilar adenopathy (*left*) and nodularity along the bronchovascular bundles (*right*) in a patient with sarcoidosis.

Necrotizing granulomas have rarely been reported in sarcoidosis, but this finding should prompt an intense search for infection. In contrast to most ILDs, in which tissue diagnosis requires open lung biopsy, the granulomas in sarcoidosis can be identified in skin nodules or in lymph nodes. Due to frequent lung and lymph node involvement, bronchoscopy is commonly used to diagnose sarcoidosis. Results of bronchoscopy with transbronchial lung biopsy are positive for 50% to 60% of patients, but the procedure poses the risks of hemorrhage and pneumothorax. Because airway involvement is common, endobronchial biopsies may also demonstrate granulomas. However, there is increasing evidence that transbronchial needle aspiration of mediastinal and hilar lymph nodes using endobronchial ultrasound guidance may have a higher diagnostic yield for granulomas than conventional bronchoscopic techniques (level 1 evidence).

After the diagnosis is made, all patients should have an ophthalmologic evaluation and a 24-hour collection of urine to assess for hypercalciuria. Electrocardiographic examination and sometimes Holter monitoring should be performed to assess for conduction system abnormalities or arrhythmias resulting from involvement of the heart by sarcoidosis. If cardiac sarcoidosis is suspected, magnetic resonance imaging (MRI) or PET scanning may be helpful.

Treatment

Corticosteroids are the standard therapy, but they should not be used indiscriminately in all patients with the diagnosis of sarcoidosis because sarcoidosis may not cause symptoms or complications and the disease may undergo spontaneous remission. Whether corticosteroids alter the disease course is uncertain. However, corticosteroid therapy should be considered in patients with extrapulmonary organ involvement or progressive pulmonary symptoms. In patients with pulmonary involvement, oral prednisone at a dosage of 20 to 40 mg per day may be initiated (level 2 evidence). Because the duration of treatment may be prolonged, steroid-sparing agents, particularly methotrexate, have been used (level 2). Infliximab, an anti-TNF agent, has resulted in a small improvement in vital capacity compared with placebo in patients with pulmonary sarcoidosis (level 1).

Patients with erythema nodosum in the setting of Löfgren syndrome may be treated with nonsteroidal anti-inflammatory

medications alone. Other skin involvement may respond to hydroxychloroquine or topical corticosteroids. The treatment of lupus pernio is challenging, but it may respond to infliximab (level 3 evidence). Given the role of TNF in T_H1 -type immunity, anti-TNF agents may also have roles in treating other forms of extrapulmonary disease not responding to conventional therapy (level 3).

Anterior uveitis may be treated with topical steroids, but other eye involvement may require systemic corticosteroids. Systemic corticosteroids are also used for the treatment of cardiac sarcoidosis (level 3 evidence). Conduction system disease and arrhythmias may necessitate placement of pacemakers or automatic implantable cardioverter-defibrillators (level 3). Neurosarcoidosis and hypercalcemia are among the other indications for systemic steroid treatment (level 3 for both).

Prognosis

The course of sarcoidosis varies. Spontaneous remission is common, and death and disability occur rarely, making decisions regarding treatment initiation difficult. The acute sarcoidosis syndromes tend to remit and not recur. However, about one third of patients with sarcoidosis have chronic, progressive disease, and some patients develop pulmonary fibrosis or other end-organ damage.

 For a deeper discussion on this topic, please see Chapter 95, "Sarcoidosis," in Goldman-Cecil Medicine, 25th Edition.

INTERSTITIAL LUNG DISEASES RELATED TO CONNECTIVE TISSUE DISORDERS

In patients with ILD, a thorough history and physical examination may reveal abnormalities such as arthritis and hand deformities, rashes, esophageal dysmotility, Raynaud's syndrome, and skin changes suggesting an underlying connective tissue disease. Connective tissue disorders, such as systemic lupus erythematosus, rheumatoid arthritis, mixed connective tissue disorder, systemic sclerosis (i.e., scleroderma), polymyositis or dermatomyositis, and Sjögren syndrome, can cause ILD and a wide variety of other pulmonary manifestations (Table 17-3). Lung disease is a major cause of morbidity and mortality in some of these conditions, especially systemic sclerosis. Although not typical, a connective tissue disorder-related ILD (CTD-ILD)

TABLE 17-3 PULMONARY INVOLVEMENT IN CONNECTIVE TISSUE DISORDERS

DISORDER	RA	LUPUS	SS	PM/DM	SJÖGREN SYNDROME

DM, Dermatomyositis; PM, polymyositis; RA, rheumatoid arthritis; SS, systemic sclerosis.

can develop before other symptoms such as arthritis manifest, making the diagnosis more difficult.

Clinical manifestations of CTD-ILD are nonspecific and include exertional dyspnea and dry cough. Exertional dyspnea may be obscured by disabilities caused by the underlying connective tissue disorder. CTD-ILD may be relatively asymptomatic, manifesting as an incidental finding on imaging. Lung examination in patients with CTD-ILD may reveal bibasilar crackles, and pulmonary function tests often show a restrictive pattern with decreased diffusion capacity. If obstruction is identified on pulmonary function testing, airway manifestations of the connective tissue disorder, such as obliterative bronchiolitis in the setting of rheumatoid arthritis, must be considered.

Chest imaging studies are useful because they may reveal typical patterns associated with the underlying connective tissue disorder, often obviating the need for biopsy. These patterns include apical fibrocavitary disease in ankylosing spondylitis and basilar fibrotic changes in rheumatoid arthritis, polymyositis, and systemic sclerosis. Imaging may also reveal pulmonary nodules in RA or pleural disease in the setting of rheumatoid arthritis or systemic lupus erythematosus.

Pulmonary hypertension in the absence of fibrosis can occur in these patients, especially those with limited scleroderma (e.g., CREST syndrome [calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia]) and systemic lupus erythematosus. Echocardiography may be helpful in patients with these disorders and otherwise unexplained dyspnea.

Drug-induced lung disorders related to immunosuppressant therapy should always be considered in patients with connective tissue disorders. Although CTD-ILD typically is chronic in nature, acute or fulminant pneumonitis that may be difficult to distinguish from opportunistic infection can be seen in systemic lupus erythematosus, Sjögren syndrome, polymyositis, and dermatomyositis.

Bronchoscopy with BAL is often used to rule out infection in acute presentations or when imaging reveals areas of consolidation, as may occur with organizing pneumonia in rheumatoid arthritis. Lung biopsy may be necessary if the clinical presentation or imaging findings are atypical. Biopsies of areas of typical basilar fibrosis in connective tissue disorders frequently reveal patterns consistent with NSIP or UIP. In Sjögren syndrome with ILD, LIP or lymphoma may be found on biopsy. Diffuse alveolar damage is found in the setting of acute lupus pneumonitis.

Immunosuppressants are the mainstay of treatment for CTD-ILD. These disorders are more responsive to this therapy than IPF.

DRUG-INDUCED LUNG DISORDERS

A large number and variety of drugs can induce adverse reactions in the lung, often in the form of an ILD (Table 17-4). These reactions vary in severity from self-limited hypersensitivity reactions (E-Fig. 17-5) to diffuse alveolar damage resulting in respiratory failure and death. A high index of suspicion is needed to make the association between a drug and a pulmonary reaction, and a careful review of medications and other pharmacologic substances used by a patient is necessary in the setting of diffuse lung disease. Illicit drugs such as heroin and cocaine commonly produce adverse pulmonary reactions. Substances

such as talc may be injected or inhaled inadvertently during the use of illicit drugs, resulting in pulmonary vascular or interstitial disease.

The clinical presentation of a drug-induced ILD is often nonspecific, with fever, cough, and dyspnea accompanied by radiographic infiltrates. Eosinophilia is sometimes found. Tests results for antinuclear antibodies are positive, but those for anti-double-stranded DNA antibodies are negative in the setting of drug-induced lupus. Pulmonary function tests, if performed, usually reveal decreases in DLCO and often show a restrictive pattern. ILD caused by medications usually does not produce a unique radiographic or histologic pattern of lung injury but may result in a variety of nonspecific reactions, including pulmonary infiltrates with peripheral eosinophilia, an HP pattern, and interstitial fibrosis. Alveolar filling may also occur in the setting of drug-induced organizing pneumonia and acute lung injury or diffuse alveolar damage. Pleural and pericardial effusions may occur in lupus-like drug reactions. Because the clinical presentation of patients with drug-induced ILDs lacks specificity, ILDs are typically diagnoses of exclusion.

There are settings in which drug-induced lung disease may be especially relevant and should be strongly considered in the differential diagnosis. They include the use of chemotherapeutic agents, the use of illicit drugs, patients with lupus-like illness, and patients using agents known to produce pulmonary toxicity, such as amiodarone or nitrofurantoin. Many chemotherapeutic agents, ranging from the newer tyrosine kinase inhibitors to older agents such as bleomycin and methotrexate, may produce lung injury and ILD. Diagnosis of a drug-induced ILD may be challenging in patients treated with chemotherapy because atypical infections and chemotherapy-induced heart failure may result in similar symptoms and radiographic findings.

Heroin use typically results in pulmonary edema or aspiration injury rather than ILD. Cocaine use can produce a variety of pulmonary effects, including organizing pneumonia, alveolar hemorrhage, and diffuse alveolar damage. "Crack lung" is a clinical diagnosis typified by dyspnea, hemoptysis, and pulmonary infiltrates occurring in the setting of crack cocaine use. Drug-induced lupus occurs with drugs such as procainamide or hydralazine. Amiodarone lung toxicity is a classic drug-induced lung disorder that results in alveolar or interstitial infiltrates accompanied by dyspnea on exertion. Although foamy macrophages can be detected by BAL, they indicate amiodarone use, not toxicity. Nitrofurantoin may cause an acute pulmonary syndrome with fever, dyspnea, and cough soon after initiation of the drug or cause a chronic pulmonary fibrosis with long-standing use. Amiodarone and nitrofurantoin reactions necessitate drug withdrawal and often require corticosteroids for resolution.

Pulmonary toxicity from drugs may be dose dependent, as with bleomycin, for which the risk of lung toxicity increases with cumulative doses exceeding 450 U. Amiodarone lung disease typically occurs with dosages greater than 400 mg per day. Synergistic lung toxicities may occur. For example, exposure to high levels of inspired oxygen may precipitate bleomycin lung injury and should be avoided if possible in exposed patients.

An online drug reference website (<http://www.pneumotox.com>) is available. It tabulates the reported pulmonary

E-FIGURE 17-5 **A**, Poorly formed granulomas (*arrow*) in a patient with hypersensitivity reaction to a chemotherapy drug (low magnification). **B**, Poorly formed granuloma (*arrow*) in a patient with a hypersensitivity reaction to a chemotherapy drug (high magnification).

TABLE 17-4 COMMON DRUG-INDUCED LUNG DISEASES

DRUG	DOSE RELATIONSHIP	MANIFESTATION
CHEMOTHERAPEUTIC		
Bevacizumab	Acute	Hemoptysis, pulmonary hemorrhage
Bleomycin	Acute or delayed, >450 U increases risk	Pneumonitis, fibrosis, OP, lung nodules
Busulfan	Chronic	Fibrosis, alveolar proteinosis
Cyclophosphamide	Chronic	Fibrosis, OP
Cytosine arabinoside	Acute	Pulmonary edema, ARDS
Gefitinib	Acute	Pulmonary fibrosis, interstitial pneumonitis, diffuse alveolar damage
Gemcitabine	Acute	Dyspnea, bronchospasm, capillary leak syndrome with pulmonary edema, ARDS, alveolar hemorrhage
Imatinib	Acute, chronic	Pulmonary edema, pneumonitis
Interferon alfa	Chronic	Sarcoidosis
Irinotecan	Acute	Pneumonitis
Methotrexate	Acute or chronic	Hypersensitivity pneumonitis, resolves with discontinuation, OP
Mitomycin C	Acute or delayed	Pneumonitis, ARDS, OP, hemolytic uremic syndrome
Paclitaxel and docetaxel	Acute	Interstitial and hypersensitivity pneumonitis
ANTIMICROBIAL		
Nitrofurantoin	Acute or chronic	Acute pneumonitis, chronic fibrosis
Sulfasalazine	Acute or chronic	Pulmonary infiltrates with eosinophilia, OP
CARDIOVASCULAR		
Amiodarone	Acute or chronic, >400 mg/day	Pneumonitis, fibrosis
Flecainide	Acute	ARDS, LIP
Tocainide	Weeks or months	Pneumonitis
Procainamide	Subacute or chronic	Drug-induced SLE, pleural effusions, pulmonary infiltrates
ANTI-INFLAMMATORY		
Aspirin	Acute	Pulmonary edema, bronchospasm
ILLICIT		
Opiates	Acute	Pulmonary edema
Cocaine	Acute	Pulmonary edema, diffuse alveolar damage, pulmonary hemorrhage, OP
Talc (in intravenous and inhaled illicit drugs)	Acute or chronic	Granulomatous interstitial fibrosis, granulomatous pulmonary artery occlusion, particulate embolization
TOCOLYTIC		
Terbutaline, albuterol, ritodrine	Acute	Pulmonary edema

ARDS, Acute respiratory distress syndrome; OP, organizing pneumonia; LIP, lymphoid interstitial pneumonia; SLE, systemic lupus erythematosus.

toxicities of various drugs, and it is searchable by drug name and by pattern of lung involvement.

 For a deeper discussion on this topic, please see Chapter 94, "Physical and Chemical Injuries of the Lung," in Goldman-Cecil Medicine, 25th Edition.

PULMONARY VASCULITIS AND DIFFUSE ALVEOLAR HEMORRHAGE

Diffuse Alveolar Hemorrhage

Definition and Epidemiology

Diffuse alveolar hemorrhage (DAH) syndromes encompass a diverse group of entities that are characterized by disruption of the alveolar-capillary membrane, resulting in bleeding into the alveolar spaces from the alveolar capillaries and intra-alveolar accumulation of red blood cells. DAH is a rare condition of uncertain incidence in the general population, but it occurs with increased frequency in specific patient populations, such as those after hematopoietic stem cell transplantation.

Pathology

The DAH syndromes are characterized by three distinct histologic patterns. Bland pulmonary hemorrhage is caused by

alveolar hemorrhage without inflammation or destruction of the alveolar structures. This pattern is seen in conditions with elevated pulmonary capillary hydrostatic pressure, such as congestive heart failure or mitral stenosis, or with the use of anticoagulation medications.

DAH can be seen in diffuse alveolar damage (DAD), which is caused by a variety of pulmonary infections, connective tissue diseases, and medications. DAD is also seen in acute respiratory distress syndrome (ARDS) from any cause. Histologically, alveolar walls appear edematous and are lined with hyaline membranes.

The most common histologic pattern seen on lung biopsy obtained from patients with DAH is pulmonary capillaritis, which is characterized by neutrophilic infiltration of the alveolar septa. It sequentially leads to necrosis, loss of capillary structural integrity, and extravasation of red blood cells into the interstitium and alveolar spaces. This pattern is seen in a variety of connective tissue diseases and in some of the pulmonary vasculitides.

Clinical Presentation

All DAH syndromes are characterized by the abrupt onset of cough and dyspnea. Hemoptysis is common but not universal; it may be absent in up to one third of patients with DAH. Fever may occur in patients with underlying vasculitis. Physical

findings are usually nonspecific, although ocular, nasopharyngeal, or cutaneous abnormalities may suggest systemic vasculitis or collagen vascular disease as a cause. The cardiopulmonary examination is often normal but may reveal inspiratory crackles, a systolic murmur suggesting mitral stenosis, or evidence of pulmonary hypertension.

 Falling hemoglobin levels in the setting of new patchy alveolar infiltrates (E-Fig 17-6) seen on chest imaging favor the diagnosis of DAH, especially in the setting of a predisposing condition such as connective tissue disease. Pertinent laboratory abnormalities may include azotemia, suggesting a pulmonary-renal syndrome. In this setting, an abnormal urinalysis result with proteinuria, hematuria, and red blood cell casts is usually seen.

Some lung disorders characterized by DAH are associated with the production of antineutrophil cytoplasmic antibodies (ANCA) directed against neutrophil cytoplasmic antigens or antibodies directed at the glomerular basement membrane. ANCA testing in particular can play an important role in the work-up of DAH because it is used in the diagnosis and classification of various pulmonary vasculitides that cause DAH. Two major immunofluorescent patterns can be seen in ANCA testing: diffuse staining throughout the cytoplasm (cANCA) or staining around the nucleus (pANCA). Specific antigens that ANCAs are directed against include proteinase 3 (PR3), typically causing the cANCA pattern, and myeloperoxidase (MPO), which typically causes the pANCA pattern. The Goodpasture or antiglomerular basement membrane syndrome is a cause of DAH and pulmonary-renal syndrome characterized by the finding of anti-basement membrane antibodies.

Diagnosis and Differential Diagnosis

Increasingly hemorrhagic fluid seen on sequential BAL studies confirms the diagnosis of DAH, but it does not give insight into the cause. The presence and quantity of hemosiderin-laden macrophages in BAL fluid should be determined. Biopsy of the lung shows accumulation of red blood cells in the alveolar spaces and may show evidence of associated capillaritis or diffuse alveolar damage.

After the diagnosis of DAH is established, the specific cause must be determined based on whether there is apparently bland pulmonary hemorrhage (e.g., mitral stenosis); pulmonary capillaritis with positive ANCA staining (e.g., granulomatosis with polyangiitis, which is typically positive for anti-PR3 ANCA and sometimes for anti-MPO ANCA); microscopic polyangiitis (typically anti-MPO positive); Goodpasture's syndrome with positive anti-basement membrane antibodies; pulmonary capillaritis due to connective tissue disease; or DAH due to diffuse alveolar damage (e.g., ARDS, bone marrow transplantation). Some cases of DAH are associated with idiopathic recurrent bland hemorrhage, resulting in accumulation of hemosiderin-laden macrophages in the lungs, a condition called *idiopathic pulmonary hemosiderosis*. This syndrome is most common in children, who have a worse prognosis than adults.

Treatment

Treatment of DAH is based on the underlying cause. Immunosuppressives are used for capillaritis due to vasculitis or connective tissue disease, such as a combination of cortico-

steroids and cyclophosphamide for the treatment of granulomatosis with polyangiitis (level 1 evidence).

Prognosis

DAH is a serious condition. The underlying illnesses such as granulomatosis with polyangiitis are associated with significant morbidity and mortality rates.

Pulmonary Vasculitides

The pulmonary vasculitides represent a group of entities, many of which are associated with elevated serum ANCA levels. They include granulomatosis with polyangiitis, microscopic polyangiitis, Churg-Strauss syndrome, and certain drug-induced vasculitis syndromes. The conditions are rare.

Granulomatosis with polyangiitis is a systemic necrotizing granulomatous vasculitis that often involves the small and medium-sized vessels of the upper airway, the lower respiratory tract, and the kidney. Although this triad is not always seen at initial presentation because only 40% of those affected have renal disease at that time, 80% to 90% of patients eventually develop glomerulonephritis. The most frequent manifestations of this illness are pulmonary, as highlighted by cough, chest pain, hemoptysis, and dyspnea. Constitutional symptoms such as fever and weight loss and symptoms due to involvement of the skin, eye, heart, nervous system, and musculoskeletal system are also common.

Chest imaging may show bilateral disease and infiltrates that evolve over the course of the illness. Lung nodules are common and may cavitate. Effusions and adenopathy are uncommon. Sinus films or CT scans can diagnose upper airway involvement. The diagnosis of granulomatosis with polyangiitis is supported by clinical findings and by circulating ANCAs, which are seen in 90% of patients. The remaining 10% of patients are ANCA negative. In ANCA-positive patients, antibodies are usually directed against PR3; however, 10% to 20% may have anti-MPO antibodies.

Tissue biopsy at a site of active disease is usually needed to confirm granulomatosis with polyangiitis. Necrotizing granulomatous inflammation is common, but actual vasculitis is seen in only 35% of patients. A renal biopsy is preferred because it is easier to perform and more often diagnostic. In the absence of renal involvement, a lung biopsy should be considered. Pathologically, granulomatosis with polyangiitis is characterized by small and medium-sized vessel necrotizing vasculitis and granulomatous inflammation. Special stains and cultures should be performed to exclude infections that can produce similar findings.

Microscopic polyangiitis is a form of systemic necrotizing small vessel vasculitis that universally affects the kidneys, whereas pulmonary involvement occurs in only 10% to 30% of patients. This rare condition has a prevalence of 1 to 3 cases per 100,000 people, but it is the most common cause of pulmonary-renal syndrome.

Microscopic polyangiitis often is heralded by a long prodromal phase, characterized by constitutional symptoms followed by the development of rapidly progressive glomerulonephritis. In patients who develop lung involvement, DAH due to capillaritis is the most common manifestation. Joint, skin, peripheral

E-FIGURE 17-6 Alveolar infiltrates of diffuse alveolar hemorrhage (arrow).

nervous system, and gastrointestinal involvement also can be seen.

Seventy percent of patients with microscopic polyangiitis are ANCA positive, and most have anti-MPO antibodies. Because anti-MPO and anti-PR3 antibodies can occur in microscopic polyangiitis and granulomatosis with polyangiitis, these diseases cannot be distinguished based on their ANCA pattern. However, they can be distinguished pathologically because microscopic polyangiitis is characterized by a focal, segmental necrotizing vasculitis affecting venules, capillaries, arterioles, and small arteries without clinical or pathologic evidence of necrotizing granulomatous inflammation. The absence or paucity of immunoglobulin localization in vessel walls distinguishes microscopic polyangiitis from immune complex-mediated small vessel vasculitis such as Henoch-Schönlein purpura and cryoglobulinemic vasculitis.

Treatments for granulomatosis with polyangiitis and microscopic polyangiitis are similar. Combination therapy with corticosteroids and cyclophosphamide is the standard of care to induce remission (level 1 evidence). Rituximab is also an option in this setting (level 1). Plasma exchange is added in cases of severe disease and provides better renal outcomes (level 1). Azathioprine (level 1) or methotrexate (level 1) can be substituted for cyclophosphamide if remission is achieved. Rituximab may be used for induction of remission in place of cyclophosphamide (level 1 evidence) or for relapsing disease (level 1). Novel therapies, including co-trimoxazole (sulfamethoxazole/trimethoprim) for remission maintenance (level 1) and TNF inhibitors for persistent disease, have been tried with some success.

Allergic granulomatosis or Churg-Strauss syndrome is characterized by the triad of asthma, hypereosinophilia, and necrotizing vasculitis. Many other organ systems, including the nervous system, skin, heart, and gastrointestinal tract, may be involved. The vasculitis can be associated with skin nodules and purpura. Although DAH and glomerulonephritis may occur, they are much less common than in the other small vessel vasculitides. Morbidity and mortality often result from cardiac or gastrointestinal complications or status asthmaticus and respiratory failure.

ANCA are less helpful in the diagnosis of Churg-Strauss syndrome because only 50% of patients are ANCA positive. Anti-MPO antibodies are more commonly seen in these patients. Pathologically, a necrotizing small vessel vasculitis and an eosinophil-rich inflammatory infiltrate with necrotizing granulomas are seen. Most patients respond well to corticosteroids, but other immunosuppressants such as cyclophosphamide may be required for patients with refractory disorders.

Other well-known causes of pulmonary capillaritis include the collagen vascular disorders, anti-glomerular membrane antibody syndrome (i.e., Goodpasture's syndrome), and Henoch-Schönlein purpura. Goodpasture's syndrome causes DAH associated with glomerulonephritis due to anti-glomerular basement membrane antibodies to the α_3 chain of type IV collagen that is also found in the lung basement membrane. More than 90% of patients with Goodpasture's syndrome have anti-glomerular basement membrane antibodies detectable in the serum. For those without circulating antibodies, the diagnosis may be confirmed by lung biopsy, although the kidney is the preferred site. Up to 40% may also be ANCA positive, primarily with anti-MPO antibodies. Pathologically, linear deposition of

antibody along the alveolar or glomerular basement membrane is visible by direct immunofluorescence.

The treatment of Goodpasture's syndrome is plasmapheresis and immunosuppression. The disease is fatal if left untreated.

ENVIRONMENTAL AND OCCUPATIONAL INTERSTITIAL LUNG DISEASES

Several environmental and occupational exposures may cause ILDs. They include the pneumoconioses, drug-induced ILD (discussed earlier), and HP. Pneumoconioses are lung diseases resulting from the inhalation of mineral dusts, including silica, coal dust, or asbestos. HP is caused by the inhalation of organic dusts.

 For a deeper discussion on this topic, please see Chapter 93, "Occupational Pulmonary Disorders," in Goldman-Cecil Medicine, 25th Edition.

Pneumoconiosis

The pneumoconioses result from the effects of accumulation of mineral dusts in the lungs; the typical reaction is fibrosis. The risk and extent of these diseases are related to the intensity and cumulative amount of exposure over time. Prevention of the pneumoconioses through occupational safeguards or, in the case of asbestos, legislative bans on use, is important because there are no effective treatments for these diseases.

Silicosis is a lung disease caused by exposure to crystalline-free silica, which results in an inflammatory and fibrotic reaction and the formation of the characteristic silicotic nodule. Occupations with a higher likelihood of exposure to silica include mining, stone cutting, carving, polishing, foundry work, and abrasive clearing (e.g., sandblasting). Although exposure is usually chronic (over years), accelerated and acute disease manifestations have been described in the setting of heavier short-term exposures.

Acute silicosis causes a pulmonary alveolar proteinosis and accumulation of surfactant in the alveolar spaces. Chronic silicosis results in simple nodular silicosis, which is usually asymptomatic unless the patient is also exposed to tobacco, and progressive massive fibrosis, which is characterized by extensive bilateral apical fibrosis resulting from the confluence of many silicotic nodules.

Patients with silicosis may have dyspnea or may be relatively asymptomatic but require further evaluation of an abnormal chest radiograph. Chest radiographs in uncomplicated silicosis show upper lobe nodular opacities, which may be subtle, whereas progressive massive fibrosis results in marked architectural distortion of the upper lobes (E-Fig 17-7). Hilar node enlargement may be accompanied by eggshell nodal calcification (E-Fig 17-8). Pulmonary function tests in simple nodular silicosis may be normal or show a mixed obstructive or restrictive pattern, whereas progressive massive fibrosis is typically associated with severe restriction and hypoxemia. Patients with silicosis are at elevated risk for tuberculosis and should be screened for latent tuberculosis infection; there is also an association between silicosis and rheumatoid arthritis.

Coal worker's pneumoconiosis is an uncommon cause of pulmonary fibrosis, occurring in workers exposed to coal dust and graphite. Usually, the patients are exposed while working in underground mines. Coal worker's pneumoconiosis results in the

E-FIGURE 17-7 Architectural distortion of the upper lobes in a patient with silicosis.

E-FIGURE 17-8 Eggshell calcifications (*arrows*) in a patient with silicosis.

formation of pigmented lesions in the lung surrounded by emphysema, called *coal macules*. Progressive massive fibrosis may subsequently occur. Most patients have chronic cough, which is usually productive, resulting from bronchitis related to coal exposure or to tobacco. The chest radiograph shows diffuse, small, rounded opacities. As with silicosis, there is an association with rheumatoid arthritis. Caplan's syndrome is the occurrence of multiple, large, sometimes cavitary lung nodules in association with rheumatoid arthritis after coal dust exposure.

Asbestosis results from chronic exposure to asbestos, which is a fibrous silicate used for insulation, for friction-bearing surfaces, and to strengthen materials. The inhaled asbestos fibers are deposited in the lungs, where the small fibers may be phagocytosed and cleared through lymphatics to the pleural space, but the longer fibers are often retained. Asbestos exposure typically leads to pleural disease characterized by pleural plaques, effusion, and fibrosis, but it does not necessarily affect the lung parenchyma. If it does, it is called *asbestosis*, with interstitial lung fibrosis resulting from asbestos exposure.

Asbestosis is characterized by a gradual onset of dyspnea. As with other pneumoconioses, the risk and severity of disease are related to the extent and duration of exposure. Asbestosis is often diagnosed after exposure has ceased, and disease progression may continue in the absence of ongoing exposure because of the reaction to retained asbestos fibers in the lung.

The clinical presentation, pulmonary function tests, and imaging studies are similar to those for restrictive lung diseases such as IPF. However, the detection of significant pleural disease is useful in distinguishing this illness from other ILDs.

The diagnosis is made from the history of exposure and demonstration of concomitant pleural plaques and lower lobe–predominant fibrotic changes on the chest radiograph or CT scan. In uncertain cases, the demonstration of asbestos in tissue specimens may be necessary. Asbestos bodies are the characteristic finding and consist of asbestos fibers coated by iron-containing (ferruginous) material. Asbestos exposure increases the incidence of malignancy, including lung carcinoma and mesothelioma, especially among people who also smoke. It is uncertain whether asbestosis itself confers a heightened risk of malignancy independent of the effects of asbestos exposure alone. No specific treatment for asbestosis exists.

Berylliosis results from exposure to beryllium, a rare metal useful in modern, high-technology industries. Exposure to beryllium can lead to an acute chemical bronchitis and pneumonitis or chronic beryllium disease. Chronic beryllium disease is characterized by a multisystemic granulomatosis that is difficult to distinguish from sarcoidosis. The diagnosis is made by history of exposure, histologic examination, and laboratory confirmation using the beryllium lymphocyte proliferation test that is available at specialized centers. Corticosteroids may be useful in the treatment of berylliosis, but patients should avoid further exposure to beryllium.

Hypersensitivity Pneumonitis

Definition and Epidemiology

HP (formerly called *extrinsic allergic alveolitis*) is a relatively common ILD resulting from an exaggerated immune reaction in the alveoli and small airways to various small, inhaled organic

antigens in sensitized individuals. Potential sensitizing antigens are diverse, ranging from bacterial, fungal, and animal proteins to low-molecular-weight chemicals (Table 17-5). Although evocative descriptions have been given to occupational forms of this disease (e.g., paprika splitter's lung resulting from sensitivity to inhaled paprika dust contaminated with *Mucor stolonifer*), more prosaic exposures may occur in everyday life, such as to contaminated hot tub water or to antigens from pet birds. The incidence and prevalence of HP are not well known, and underdiagnosis occurs.

Pathology

HP occurs as the result of an abnormally exuberant immune response in the alveoli and small airways to inhaled antigens, typically organic molecules, but also small chemical compounds such as isocyanates, which bind to haptens. This response occurs in a susceptible host; the underlying reasons for susceptibility are unclear but probably include genetic and environmental factors (e.g., pesticide exposure). Smokers are less likely than nonsmokers to develop HP, but they may have a more severe disease course if HP does occur. After exposure to an antigen, a susceptible individual develops an alveolitis with influx of neutrophils and lymphocytes. A T_H1 -type immune response then leads to granuloma formation.

Typical lung biopsy findings include granulomatous inflammation with poorly formed granulomas containing foreign body giant cells, interstitial chronic inflammation with a bronchiolocentric component, and bronchiolitis. In chronic or end-stage disease, fibrosis occurs, and biopsies may feature areas with a UIP or NSIP pattern in addition to areas of granulomatous and airway-centered inflammation.

Clinical Presentation

The disease may manifest in an acute fashion (i.e., acute HP) several hours after intense exposure to a provocative antigen, with

TABLE 17-5 HYPERSENSITIVITY PNEUMONITIS

ANTIGEN	SOURCE	DISEASES
Thermophilic bacteria	Moldy hay, sugar cane, compost	Farmer's lung, bagassosis, mushroom worker's disease
Other bacteria, including atypical mycobacteria	Contaminated water, wood dust, fertilizer, paprika dust	Humidifier, detergent worker's disease, and familial hypersensitivity pneumonitis
Fungi	Moldy cork, contaminated wood dust, barley, maple logs	Suberosis, sequoiosis, and maple bark stripper's disease, malt worker's disease, and paprika splitter's lung
Animal protein	Bird droppings, animal urine, bovine and porcine pituitary powder	Pigeon breeder's lung, duck fever, turkey handler's disease, pituitary snuff-taker's disease, laboratory worker's hypersensitivity pneumonitis
Chemically altered human proteins (e.g., albumin)	Toluene diisocyanate, trimellitic anhydride, diphenylmethane diisocyanate	Hypersensitivity pneumonitis
Phthalic anhydride	Heated epoxy resin	Epoxy resin lung

a flulike illness featuring fever, chills, cough, dyspnea, and malaise that lasts for up to 24 hours (e.g., farmer's lung from exposure to thermophilic actinomycetes). Subacute and chronic HP may occur with repeated or prolonged lower-level antigen exposure, which results in chronic dyspnea and cough with eventual progression to pulmonary fibrosis (e.g., pigeon breeder's lung from exposure to avian droppings and other antigens).

The patient with acute HP may be febrile. Diffuse wheezes are common physical findings in acute HP, whereas crackles may be auscultated in chronic HP. Patients with chronic HP may have clubbing. Hypoxemia with exertion may occur in earlier stages of disease, progressing to hypoxemia at rest in chronic fibrotic HP. Pulmonary function tests usually show a restrictive pattern with abnormal gas exchange in subacute and chronic HP, although obstructive or mixed patterns are sometimes seen.

HP is characterized by nonspecific infiltrates in the middle and upper lung fields on chest radiographs, although chest radiographs may be normal in acute disease. CT scanning is more sensitive than chest radiography, revealing ground-glass opacities, centrilobular nodules, and mosaic attenuation and air trapping patterns resulting from airway obstruction. Chronic HP may have architectural distortion with traction bronchiectasis and honeycombing.

Emphysema occurs in some cases of advanced farmer's lung. BAL may demonstrate a lymphocytic alveolitis, with CD4⁺ T-lymphocyte predominance. Patients with HP may have precipitating antibodies to the offending antigen, but serum precipitins are not sufficiently sensitive or specific for diagnosis, and the specific antigen may not be known or may not be tested for with standard test panels.

Diagnosis and Differential Diagnosis

An appropriate exposure, clinical history, BAL, and HRCT imaging findings can suggest the diagnosis, but a lung biopsy may be necessary for confirmation, especially in subacute and chronic HP. Transbronchial biopsy may be sufficient, but surgical lung biopsy can collect larger samples from different lung regions. The differential diagnosis includes acute viral infection in acute HP; in chronic HP, the differential includes other fibrosing lung diseases such as IPF, NSIP, and sarcoidosis.

Treatment

Clinical improvement often occurs in the hospital setting when patients are isolated from the offending antigen, and relapse may occur after discharge. This pattern of illness can point to the diagnosis of HP. Corticosteroids can relieve symptoms in the acute phase, but their long-term efficacy in chronic forms of the disease is less clear (level 3 evidence). Identification of the cause of HP is important because chronic disease management requires avoidance of exposure to the antigen, which can be financially or psychologically challenging for patients in the setting of occupational, pet, or residential exposures. For advanced HP with fibrosis, lung transplantation may be necessary.

Prognosis

The prognosis for HP varies. Acute HP usually has a good prognosis, but chronic HP can lead to end-stage pulmonary fibrosis and death.

SPECIFIC DISEASES

Pulmonary Langerhans Cell Histiocytosis

Definition and Epidemiology

Pulmonary LCH, formerly called *eosinophilic granuloma*, is a rare disease of young and middle-aged adults. It is characterized by an abnormal infiltration of Langerhans cells, which are dendritic cells, into the lung parenchyma. The disease almost always occurs in smokers.

Pathology

Pulmonary LCH results in the formation of cysts and nodules in the lungs. The accumulation of activated Langerhans cells results in stellate nodular infiltrates around the small airways, with eventual destruction and dilation of the airway walls, resulting in cystic changes in the lung parenchyma. Although a multisystem Langerhans cell disease related to clonal proliferation of Langerhans cells occurs in children, isolated pulmonary LCH in adult smokers does not appear to be a clonal neoplastic disorder.

Smoking may alter local immune signaling, attracting the Langerhans cells to the lungs, or it may cause local proliferation and increased survival of Langerhans cells in the lungs. Biopsy of the lung demonstrates multiple stellate lung nodules that may be cellular or fibrotic, containing Langerhans cells that stain for Cd1a and S100. Electron microscopy may reveal Birbeck granules, distinctive racquet-shaped structures in the Langerhans cells.

Clinical Presentation

Patients may be asymptomatic or may exhibit constitutional symptoms, dyspnea on exertion, and cough, possibly with hemoptysis. Spontaneous pneumothorax may also occur. Chest imaging shows nodules that may be cavitary and cysts that predominate in the middle and upper lung zones. Pulmonary function tests show impaired diffusion capacity, and an obstructive or restrictive pattern may be seen.

Diagnosis and Differential Diagnosis

A specific diagnosis can be made with open lung biopsy. In the right clinical setting and with a typical HRCT, a biopsy may not be needed for a presumptive diagnosis. The differential diagnosis includes other cystic lung diseases, such as lymphangiomyomatosis, sarcoidosis, and smoking-related idiopathic pneumonias such as RB-ILD and DIP complicated by emphysema.

Treatment

The main treatment is tobacco cessation (level 3 evidence). Corticosteroids and cytotoxic agents are sometimes employed as adjunctive therapy (level 3). Lung transplantation may be considered in cases of advanced disease.

Prognosis

In contrast to systemic LCH, pulmonary LCH is not a neoplastic disorder, and spontaneous regression may occur with smoking cessation. Although some patients have a benign course, others develop progressive disease or complications such as pulmonary hypertension, which may be fatal.

Lymphangiomyomatosis

Definition and Epidemiology

Lymphangiomyomatosis is a rare, slowly progressive, neoplastic disorder resulting in cystic lung disease and kidney angiomyolipomas that occurs in association with the tuberous sclerosis complex or sporadically in women of childbearing age.

Pathology

The disease is characterized by extensive infiltration of the lungs and lymphatics with growths of smooth muscle–like lymphangiomyomatosis cells. Mutations in the *TSC1* or *TSC2* gene, which encodes tumor suppressor proteins that normally act as inhibitors of protein synthesis and cell growth, may result in tuberous sclerosis or lymphangiomyomatosis. Mutations in *TSC2* are associated with greater disease severity.

Clinical Presentation

Dyspnea and spontaneous pneumothorax are the most common presentations, with chylous pleural effusions and hemoptysis also occurring. These clinical presentations result from lung parenchymal destruction, airway narrowing, and lymphatic obstruction caused by the abnormal proliferation of the smooth muscle–like cells.

Imaging studies show an interstitial pattern with middle and upper lung predominance; multiple, thin-walled cystic lesions; and characteristically preserved lung volumes. Pleural effusion or pneumothorax may be seen on imaging. CT of the abdomen may reveal fat-containing kidney lesions consistent with angiomyolipomas. Pulmonary function tests typically show a progressive obstructive pattern, although mixed obstruction and restriction may also be seen.

Diagnosis

Although the clinical features coupled with characteristic imaging are often diagnostic, lung biopsy may be necessary in some cases. It demonstrates interstitial nodules composed centrally of spindle-shaped cells that stain for smooth muscle cell actin and for HMB-45, an antibody to the melanocytic glycoprotein 100, with staining involving the alveolar walls, lobular septa, venules, small airways, and pleura.

Treatment

Treatment involves management of pleural complications, including the use of pleurodesis to prevent recurrent pneumothorax or effusion, bronchodilator and oxygen therapy, and avoidance of pharmacologic estrogens, which may exacerbate the disease. Progesterones have been used in an attempt to modulate disease progression, but efficacy data are limited.

Because the products of the *TSC1* and *TSC2* genes normally act as inhibitors of the mammalian target of rapamycin (mTOR), pharmacologic mTOR inhibitors such as sirolimus and everolimus have been studied in lymphangiomyomatosis. Sirolimus stabilized lung function in lymphangiomyomatosis (level 1 evidence), and sirolimus and everolimus treatment resulted in angiomyolipoma shrinkage (level 1). Lung transplantation can be performed in patients with severe pulmonary dysfunction.

Prognosis

Lymphangiomyomatosis is a slowly progressive disease that can result in potentially fatal complications, especially respiratory failure.

Eosinophilic Lung Disease

Eosinophilic lung diseases are characterized by pulmonary infiltrates and eosinophilia of the peripheral blood or lung. Because eosinophilia is a feature of many diseases, distinguishing primary pulmonary eosinophilic lung disorders from lung disorders in which eosinophilia has a specific cause is important.

Eosinophilic lung diseases can be categorized as follows: primary pulmonary eosinophilic disorders (e.g., acute and chronic eosinophilic pneumonia, hypereosinophilic syndrome), pulmonary disorders of known cause associated with eosinophilia (e.g., asthma, allergic bronchopulmonary aspergillosis, drug reactions, parasitic infections), lung diseases associated with eosinophilia (e.g., HP, COP, IPF), malignancies associated with eosinophilia (e.g., lung cancer, leukemia, lymphoma), and systemic disease associated with eosinophilia (e.g., rheumatoid arthritis, sarcoidosis, Sjögren syndrome).

Acute eosinophilic pneumonia is characterized by fever, a non-productive cough, and dyspnea of less than 7 days' duration, often leading to acute respiratory failure. This disease typically affects male smokers between the ages of 20 and 40 years who are otherwise healthy. Chest imaging reveals diffuse bilateral pulmonary infiltrates. Eosinophilia is not found in the peripheral blood initially but may occur 7 to 30 days after onset. Abundant eosinophils can be found in BAL fluid, and a level of greater than 25% of all nucleated cells is helpful in making the correct diagnosis. Although lung biopsy is typically not required to make the diagnosis, it can show eosinophilic infiltration with acute and organizing diffuse alveolar damage. Treatment with corticosteroids typically offers rapid and complete clinical and radiographic resolution without recurrence or residual sequelae (level 3 evidence).

Chronic eosinophilic pneumonia is an idiopathic disease predominantly of middle-aged women with a history of asthma. Also called *prolonged pulmonary eosinophilia*, this illness is characterized by a productive cough, dyspnea, malaise, weight loss, night sweats, and fever associated with progressive peripheral lung infiltrates that have been described as resembling the photographic negative of pulmonary edema on chest radiographs (E-Fig 17-9). On presentation, most patients with chronic eosinophilic pneumonia have a peripheral eosinophilia of greater than 30% and BAL fluid eosinophilia.

Histologic examination shows eosinophils and histiocytes in the lung parenchyma and interstitium, areas of COP, but minimal fibrosis. Spontaneous remissions have been reported, but respiratory failure can develop. Typically, treatment with corticosteroids is rapidly effective. Prolonged therapy is recommended because relapses are common (level 3 evidence), unlike treatment for acute eosinophilic pneumonia.

Simple pulmonary eosinophilia (i.e., Löffler syndrome) is characterized by transient migratory infiltrates that last less than 1 month. Some cases are asymptomatic, but dyspnea and dry cough may occur. Pathologic examination of tissues reveals

E-FIGURE 17-9 Photographic negative of pulmonary edema in chronic eosinophilic pneumonia.

interstitial and intra-alveolar accumulation of eosinophils, macrophages, and edema. The syndrome may be idiopathic or caused by parasitic infections (e.g., *Ascaris* species, *Strongyloides* species, hookworms) or drugs (e.g., nitrofurantoin, minocycline, sulfonamides, penicillin, nonsteroidal anti-inflammatory drugs). Treatment requires removal of the offending agent or treatment of the parasitic infection. In idiopathic cases, corticosteroids may be used.

Allergic bronchopulmonary aspergillosis is a hypersensitivity reaction that occurs when *Aspergillus* species colonizes the airways in patients with asthma or cystic fibrosis. Patients may have fever; malaise; a cough productive of thick, brown mucous plugs; and occasionally hemoptysis. On the chest radiograph, pulmonary infiltrates, which are often transient and migratory, and central bronchiectasis may be seen. Peripheral eosinophilia of greater than 10%, elevated immunoglobulin E (IgE) levels (and *Aspergillus*-specific IgE), and precipitating antibodies to *Aspergillus* are among the laboratory abnormalities seen in allergic bronchopulmonary aspergillosis. Response to corticosteroids is good. Itraconazole can be added to the treatment regimen.

Pulmonary Alveolar Proteinosis

Definition and Epidemiology

Pulmonary alveolar proteinosis (PAP) is a rare disorder in which surfactant accumulates within the alveoli. PAP occurs more frequently in middle-aged patients and in smokers.

Pathology

PAP results from impaired surfactant clearance by alveolar macrophages. PAP has a congenital form, characterized most commonly by mutations of the genes encoding surfactant proteins or for the receptor for granulocyte-macrophage colony-stimulating factor (GM-CSF). Secondary PAP occurs in conditions in which there is a functional impairment or decrease in the number of alveolar macrophages, as seen in various hematologic malignancies (e.g., leukemia), infections (e.g., pneumocystis pneumonia), and inhalation of toxic dusts (e.g., silica, aluminum) or after allogeneic bone marrow transplantation. The acquired or idiopathic form of PAP is an autoimmune disease, with neutralizing antibodies directly targeting GM-CSF, resulting in abnormal surfactant metabolism by alveolar macrophages. Lung biopsy in PAP shows intra-alveolar accumulation of eosinophilic, acellular material staining positive with the periodic acid–Schiff (PAS) stain, which is consistent with surfactant.

Clinical Presentation

Patients with PAP may be asymptomatic, or they may have progressive dyspnea on exertion, malaise, low-grade fever, and cough. Examination may reveal clubbing. The chest radiograph typically shows bilateral perihilar opacities. The CT scan may show thickening of the intralobular and interlobular septa, creating a pattern called *crazy paving*, which is a nonspecific finding because it is seen in many other diseases of the lung. The course of PAP may be complicated by opportunistic lung infection.

Diagnosis

BAL fluid can establish the diagnosis because it has a milky, opaque appearance. The fluid contains large, foamy

alveolar macrophages and extracellular surfactant material that stains positive with PAS. Surgical or transbronchial lung biopsy may also be performed to establish the diagnosis if the BAL is nondiagnostic.

Treatment

Asymptomatic patients and those with mild symptoms require no immediate treatment. Sequential whole lung lavage with warmed saline (level 3 evidence) is indicated for patients with hypoxemia or severe dyspnea, and in up to 40% of patients, it may be required only one time. Limited lobar lavage may be performed in milder disease (level 3). GM-CSF administration in patients with acquired PAP may be beneficial (level 2). Rituximab has been used in refractory PAP (level 2).

Prognosis

The prognosis of autoimmune PAP is good, with excellent survival since the introduction of whole lung lavage.

PROSPECTUS FOR THE FUTURE

IPF, the most common of the IIPs, is usually fatal, and current treatment strategies are ineffective. The National Institutes of Health have established the Idiopathic Pulmonary Fibrosis Clinical Research Network to accelerate clinical research trials. These trials have demonstrated the ineffectiveness or even hazard of proposed or commonly used therapies, such as the triple-therapy regimen of prednisone, azathioprine, and *N*-acetylcysteine. A deeper understanding of the pathogenesis of IPF is needed to implement more effective therapies.

The advent of technology able to evaluate genetic abnormalities related to disease has unveiled mutations associated with IPF, sarcoidosis, and other ILDs, with the prospect for further insights into disease pathogenesis. The use of mTOR inhibitors in lymphangiomyomatosis, which affects women of childbearing age, is an example of the successful translation of the molecular pathobiology of a specific interstitial lung disease into effective therapy.

Further work linking basic science and clinical therapeutics is needed in other ILDs. Until new and effective treatment strategies are generated, lung transplantation represents the only hope for an increasing number of patients with fibrosing ILDs, and efforts to better allocate donors and decrease complications from lung transplantation remain priorities.

Pulmonary Vascular Diseases

Sharon Rounds and Matthew D. Jankowich

INTRODUCTION

Pulmonary vascular diseases are a heterogeneous group of disorders with multiple causes that directly affect the pulmonary vessels, as in idiopathic pulmonary arterial hypertension (PAH), or are caused by other disorders, as in pulmonary hypertension associated with lung disease and hypoxemia. This chapter considers diseases of the pulmonary circulation characterized by vascular remodeling and pulmonary hypertension, followed by pulmonary thromboembolism.

The World Health Organization (WHO) classification of pulmonary hypertensive disorders is presented in [Table 18-1](#). The hallmark of these disorders is pulmonary hypertension, defined by a mean pulmonary artery pressure greater than 25 mm Hg at rest. Factors that increase pulmonary arterial pressure include increases in cardiac output, left atrial pressure, or blood viscosity, and most importantly, loss of cross-sectional area of the vascular bed, which increases vascular resistance. Loss of cross-sectional area may result from mechanical occlusion, loss of vessels, vascular remodeling, or vasoconstriction.

Clinical manifestations of pulmonary hypertension may not be exhibited until late in the course of the disease because the normal pulmonary vasculature is a high-flow, low-resistance, highly compliant system with very high capacitance. The normal pulmonary circulation can accept the entire output of the right ventricle with only slight increases in pressure.

For a deeper discussion on this topic, please see Chapter 68, "Pulmonary Hypertension," in Goldman-Cecil Medicine, 25th Edition.

IDIOPATHIC PULMONARY ARTERIAL HYPERTENSION

Definition and Epidemiology

Idiopathic PAH is an uncommon disorder that is progressive and usually fatal without treatment. The median survival time after diagnosis of the disease is about 3 years without treatment (level 1 evidence). Variables associated with poor survival include heart failure, Raynaud's phenomenon, elevated right atrial pressure, significantly elevated mean pulmonary arterial pressure, and decreased cardiac index.

The peak incidence of idiopathic PAH occurs between the ages of 20 and 45 years, and it affects women more frequently than men. The cause of idiopathic PAH is unknown. However, some cases occur in families, called *heritable pulmonary arterial*

hypertension. Heritable PAH is caused by mutations in the genes for bone morphogenetic protein receptor type 2 (*BMPR2*) and related receptors in the transforming growth factor- β family. PAH may also be associated with other disorders, such as human immunodeficiency virus (HIV) infection, scleroderma, hepatic cirrhosis, and anorectic drug use (see [Table 18-1](#)).

Pathology

The histologic characteristics of PAH include changes in the arterial and venous systems. The arteries are more commonly affected, with changes in the intima, media, and adventitia. There is medial vascular smooth muscle hypertrophy, adventitial thickening, and in situ thromboses of small pulmonary arteries. Plexogenic pulmonary arteriopathy is the classic pathologic finding in PAH, consisting of medial hypertrophy, intimal proliferation and fibroelastosis, and necrotizing arteritis. The plexiform lesion is an abnormal proliferation of pulmonary endothelial cells with slit-like channels seen only in PAH ([E-Fig. 18-1](#)).

Clinical Presentation

The clinical presentation of idiopathic PAH can be subtle. The usual symptoms are dyspnea on exertion or chest pains that are not typical of angina pectoris. In more severe cases, patients may have syncope on exertion caused by the inability of the restricted pulmonary circulation to accommodate increased cardiac output with exercise. The WHO has classified the severity of symptoms in PAH (i.e., dyspnea, fatigue, chest pain, and syncope) in terms of functional ability: class I (symptoms with strenuous activity only), class II (symptoms with normal activity), class III (symptoms with activities of daily living), and class IV (symptoms with any physical activity; right heart failure, dyspnea, or fatigue may occur at rest).

Chest radiographs may reveal prominent pulmonary arteries or right ventricular enlargement ([E-Fig. 18-2](#)). Pulmonary function test results are usually normal, with the exception of diffusing capacity, which is usually decreased, reflecting the restricted circulation and decreased surface area available for gas exchange.

Diagnosis and Differential Diagnosis

The diagnosis of PAH depends on exclusion of other underlying heart or lung diseases that might cause pulmonary hypertension (see [Table 18-1](#)). In cases of PAH (group 1), the echocardiogram may reveal enlarged right atrial and right ventricular cavity size and encroachment of the interventricular septum on the left ventricle ([E-Fig. 18-3](#)). The echocardiogram also may be used to

E-FIGURE 18-1 The plexiform lesion is an abnormal proliferation of pulmonary endothelial cells seen only in the setting of pulmonary arterial hypertension (hematoxylin and eosin stain). (Courtesy Dr. Charles Kuhn.)

E-FIGURE 18-2 The chest radiograph shows an enlarged right main pulmonary artery (*arrow*), which resulted from pulmonary artery hypertension.

E-FIGURE 18-3 In cases of pulmonary artery hypertension, the echocardiogram may show enlarged right atrial and right ventricular cavities. The interventricular septum is deviated to the left. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

TABLE 18-1 WORLD HEALTH ORGANIZATION CLASSIFICATION OF PULMONARY HYPERTENSION**Group 1: pulmonary arterial hypertension (PAH)**

- Idiopathic PAH
- Heritable PAH
 - Bone morphogenic protein receptor type II
 - ALK-1, endoglin, SMAD9, caveolin-1, KCNK3
 - Unknown
- Drug- and Toxin-Induced
- Associated with PAH:
 - Connective tissue disease
 - Human immunodeficiency virus infection
 - Portal hypertension
 - Congenital heart diseases
 - Schistosomiasis

Pulmonary veno-occlusive disease and/or pulmonary capillary hemangiomatosis

Persistent pulmonary hypertension of the newborn

Group 2: pulmonary hypertension due to left heart disease

- Left ventricular systolic dysfunction
- Left ventricular diastolic dysfunction
- Valvular disease
- Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies

Group 3: pulmonary hypertension due to lung diseases and/or hypoxia

- Chronic obstructive pulmonary disease
- Interstitial lung disease
- Other pulmonary diseases with mixed restrictive and obstructive pattern
- Sleep-disordered breathing
- Alveolar hypoventilation disorders
- Chronic exposure to high altitude
- Developmental lung diseases

Group 4: chronic thromboembolic pulmonary hypertension**Group 5: pulmonary hypertension with unclear multifactorial mechanisms**

- Hematologic disorders: chronic hemolytic anemia, myeloproliferative disorders, splenectomy
- Systemic disorders: sarcoidosis, pulmonary histiocytosis, lymphangioleiomyomatosis
- Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
- Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure, segmental PH

Modified from Simonneau G, Gatzoulis MA, Adatia L, et al: Updated clinical classification of pulmonary hypertension, *J Am Coll Cardiol* 62:D34–41, 2013.

estimate the level of pulmonary artery systolic pressure. Echocardiography also is useful for excluding group 2 pulmonary hypertension caused by heart diseases that increase pulmonary venous pressures (e.g., mitral valve stenosis).

Pulmonary function tests, lung imaging, and tests for conditions causing hypoxemia (e.g., obstructive sleep apnea) are important for excluding group 3 pulmonary hypertension. Acute pulmonary thromboembolism rarely causes pulmonary hypertension, but recurrent pulmonary emboli or nonresorbed clots that obstruct proximal pulmonary arteries can cause group 4 pulmonary hypertension. The diagnosis of group 4 disease requires a ventilation-perfusion (\dot{V}/\dot{Q}) scan, computed tomography (CT) angiography, or pulmonary arteriography.

Definitive diagnosis of PAH requires right heart catheterization and documentation of increased pulmonary arterial pressures and resistance with normal left-sided filling pressures as assessed by pulmonary capillary wedge pressure. Left-to-right intracardiac shunts can also cause pulmonary hypertension due to increased blood flow through the lungs. This can be diagnosed

at the time of right heart catheterization by measuring the difference in oxygen content between blood from the superior vena cava and the main pulmonary artery. At the time of right heart catheterization, short-acting vasodilators are usually administered, and hemodynamic responses are recorded. These vasodilator trials are useful in predicting whether patients are likely to respond to calcium-channel blockers (a minority of patients).

Treatment

Modern treatment of PAH includes drugs with vasodilator activity such as calcium-channel blockers, prostacyclin, endothelin receptor antagonists, and phosphodiesterase inhibitors that increase vascular cyclic guanosine monophosphate (cGMP) levels. Continuous intravenous prostacyclin is the only therapy that has been shown to prolong survival and is the recommended treatment for patients with WHO class IV symptoms (level 1 evidence). However, because of the cost and technical challenges of intravenous prostacyclin, oral endothelin receptor antagonists or phosphodiesterase inhibitors, or inhaled or subcutaneous prostacyclin derivatives are preferred for patients with WHO class II or III symptoms.

Most studies of the effects of vasodilator drugs have used the 6-minute walk test as a surrogate for hemodynamic improvement and have demonstrated benefits for exercise tolerance and symptoms (level 1 evidence). Combination therapy may improve symptoms when one agent is not sufficient (level 2-1). In addition to relaxing vascular smooth muscle constriction, vasodilator drugs may stabilize or reverse vascular remodeling in PAH (level 3).

Other interventions include supplemental oxygen, anticoagulation (level 2-1 evidence), and judicious use of diuretic medications. Pulmonary rehabilitation also can improve exercise tolerance (level 1). Heart-lung, double-lung, or single-lung transplantations have been performed in these patients with some success, but the overall 5-year survival rate for PAH patients undergoing lung transplantation is only 50%.

SECONDARY PULMONARY HYPERTENSION

Pulmonary hypertension is associated with many disorders that increase pulmonary venous pressure (e.g., mitral valve stenosis, group 2 pulmonary hypertension) and diseases of the lungs associated with hypoxemia (e.g., sleep apnea, chronic obstructive pulmonary disease, group 3 pulmonary hypertension). These conditions have been called *secondary pulmonary hypertension*.

Vasoconstriction and vascular remodeling contribute to increased pulmonary vascular resistance in secondary pulmonary hypertension. For example, alveolar hypoxia causes intense pulmonary vasoconstriction. Long-standing hypoxia causes vascular remodeling that is similar to plexogenic pulmonary arteriopathy but does not include *in situ* thromboses or formation of plexiform lesions (E-Fig. 18-4).

Treatment of secondary pulmonary hypertension is directed at the underlying heart or lung disease. If the patient has hypoxia, home oxygen therapy should be used. It is not known whether vasodilator therapy is useful in group 2 or 3 diseases. Group 4 pulmonary hypertension caused by proximal, unresolved clot can be improved by pulmonary thromboembolotomy (level 1 evidence).

Normal lung

Emphysema

E-FIGURE 18-4 Hypertrophy of smooth muscle in the media of an artery (*arrow*) in a patient with emphysema is compared with that of a normal artery (*arrow*). (Courtesy Dr. Charles Kuhn.)

COR PULMONALE

The most frequent cause of death of patients with PAH is right ventricular failure, also called *cor pulmonale*. Prolonged increased afterload causes the right ventricle to hypertrophy and then dilate. The interventricular septum shifts to the left, and filling of the left ventricle is decreased, with subsequent decreased cardiac output. Dilation of the right atrium causes atrial tachyarrhythmias and further decreased cardiac output.

Treatment of cor pulmonale is directed at the underlying cause of pulmonary hypertension. The existence of cor pulmonale is a bad prognostic sign in group 1 pulmonary hypertension (level 1 evidence).

PULMONARY THROMBOEMBOLISM

Definition and Epidemiology

Pulmonary thromboembolism refers to the passage of a clot from the venous system or the right ventricle that lodges in a pulmonary artery. Other materials, such as tumor or injected foreign bodies (e.g., talc) can also lodge in the lung circulation, but pulmonary thromboembolism is a complication of venous thrombosis.

Pulmonary thromboembolic disease is a relatively common entity, with an incidence ranging from 400,000 to 650,000 cases per year in the United States. The deep veins of the femoral and popliteal systems of the lower extremities are most often involved, but right atrial, right ventricular, and upper extremity thromboses can also embolize to the lung. The predisposing factors for pulmonary embolism are the same as those for venous thrombosis and include venous stasis, hypercoagulability, and endothelial injury. Congenital or acquired procoagulant disorders (e.g., activated protein C deficiency, factor V Leiden) are also considered predisposing factors.

 For a deeper discussion on this topic, please see Chapter 68, "Pulmonary Hypertension," in Goldman-Cecil Medicine, 25th Edition.

Pathology

After a clot dislodges from the lower extremity circulation, it travels to the pulmonary circulation, where it can obstruct a branch of the pulmonary artery. The affected lung segment develops an increased \dot{V}/\dot{Q} ratio. This increases overall dead space ventilation, which can lead to inefficient excretion of carbon dioxide, potentially raising the partial pressure of carbon dioxide in arterial blood (P_{aCO_2}). Blood flow is shifted from the obstructed site to other areas, which may include areas with a low \dot{V}/\dot{Q} ratio, leading to shunting and hypoxemia.

Infarction of the lung distal to the occlusion is rare because of the redundancy of the pulmonary circulation and because of oxygenation of lung parenchyma by bronchial arteries and by alveolar oxygen. However, pulmonary thromboembolism causes deficiency or inactivation of surfactant and commonly causes collapse of alveolar units perfused by the obstructed vessel.

Clinical Presentation

The most common symptom of pulmonary thromboembolism is shortness of breath (level 1 evidence). Other, less common

symptoms include chest pain, hemoptysis, and syncope. A careful history is paramount when evaluating patients for thromboembolic disease to determine risk factors, such as recent immobilization or surgery, malignancy, or a history of pulmonary embolus or deep vein thrombosis. Using a validated clinical scoring system to assess the pretest probability of pulmonary embolism, such as calculation of the Wells or Geneva score, is helpful in the integration of subsequent laboratory and radiologic testing results.

The most common physical examination findings are tachycardia and tachypnea (level 1 evidence). The physical examination may be normal or may reveal isolated crackles or even diffuse wheezing. Pleural effusions are identified by areas of dullness to percussion. Edema of the extremities, especially if the edema is asymmetrical, may point to venous thrombosis. In deep vein thrombosis, dorsiflexion of the foot may cause calf pain as a result of stretching the calf muscles and deep veins (Homan's sign). Signs of pulmonary hypertension and right ventricular strain, such as increased pulmonary component of the second heart sound or right ventricular heave, are not usually appreciated unless there is a massive pulmonary embolus or preexisting heart or lung disease.

Arterial blood gas determinations usually reveal respiratory alkalosis with a normal P_{aO_2} value (level 1 evidence). However, when the alveolar-arterial oxygen gradient is calculated, it is frequently widened. However, a normal alveolar-arterial gradient in the partial pressure of oxygen does not exclude acute pulmonary embolism. A normal P_{aCO_2} in a patient with tachypnea suggests increased dead space and, in the appropriate setting, may point to the diagnosis. In severe cases, arterial blood gas measurement may show acidemia, hypoxemia, and hypercapnia.

An elevated level of lactate dehydrogenase (LDH) may be the result of tissue infarction, but this test is insensitive and nonspecific. An elevated level of B-type natriuretic peptide (BNP) is useful in assessing the severity and likelihood of complicating right ventricular failure. If the highly sensitive D-dimer level is normal, it effectively excludes pulmonary thromboembolism if the pretest probability is intermediate or low. However, the D-dimer level may be elevated in patients with unrelated medical conditions, such as congestive heart failure, chronic illness, and connective tissue disorders.

The electrocardiogram may show atrial tachyarrhythmias or evidence of right heart strain as shown by a new right bundle branch block, right ventricular strain pattern, and the $S_1 Q_{III} T_{III}$ pattern (i.e., S wave in lead I, Q wave in lead III, T wave inversion in lead III) that mimics inferior myocardial infarction. The chest radiograph is often normal but may show atelectasis, isolated infiltrates, or a small pleural effusion. Oligemia (Westermark's sign), an abrupt cutoff of pulmonary vessels or enlarged central pulmonary arteries (Fleischner's sign), and a pleural-based area of increased opacity (Hampton's hump) may be seen on the radiograph. In most cases, chest radiographs are not sufficiently sensitive to diagnose a pulmonary embolism.

Three major diagnostic methods are used for the diagnosis of pulmonary embolism: the \dot{V}/\dot{Q} scan, chest CT, and pulmonary arteriography (Fig. 18-1). CT angiography provides a noninvasive and sensitive way to detect pulmonary emboli (E-Fig. 18-5).  The Prospective Investigation of Pulmonary Embolism Diagnosis II (PIOPED II) study demonstrated that the best approach is a combination of clinical suspicion, D-dimer determination, CT

E-FIGURE 18-5 Computed tomography angiography shows a saddle embolus entering both right and left (*arrow*) pulmonary arteries. (Courtesy Dr. Charles Kuhn.)

angiography, and assessment of the lower extremities for deep vein thrombosis DVT by CT or ultrasound. The Christopher study showed that the frequency of a subsequent venous thromboembolism diagnosis in the 3 months after a negative CT angiogram is low (level 1 evidence).

However, for pregnant women or individuals with renal insufficiency or iodinated contrast dye allergy, the \dot{V}/\dot{Q} scan provides an alternative approach. The \dot{V}/\dot{Q} scan compares lung ventilation by radiolabeled tracer gas with lung perfusion by radiolabeled micro-occlusive particles. The usefulness of the \dot{V}/\dot{Q} scan depends greatly on the pretest probability of the disease, which depends on the expertise of the clinician and his or her level of certainty. A *high-probability* \dot{V}/\dot{Q} scan is characterized by lobar or multilobar perfusion defects that coincide with areas of normal or relatively normal ventilation, and it is more than 90% accurate in diagnosing pulmonary embolism. A *normal* \dot{V}/\dot{Q} scan shows no perfusion or ventilation defects and excludes pulmonary embolism in essentially all cases. However, the test is less reliable when interpreted as *low*, *intermediate*, or *indeterminate* probability. In these circumstances, pulmonary embolism is likely in 4% to 66% of patients, and further testing is necessary for an accurate diagnosis of pulmonary embolism.

Pulmonary arteriography may be considered in patients without contraindications to the procedure when other tests are inconclusive and a high likelihood of pulmonary embolism exists. Although the rate of complications of pulmonary angiography is low with experienced operators, the complications can be significant, ranging from pulmonary hypertension and sudden death to idiosyncratic hypersensitivity reactions to the dye. Pulmonary angiography is now performed infrequently, and operator experience may be limited in certain care settings.

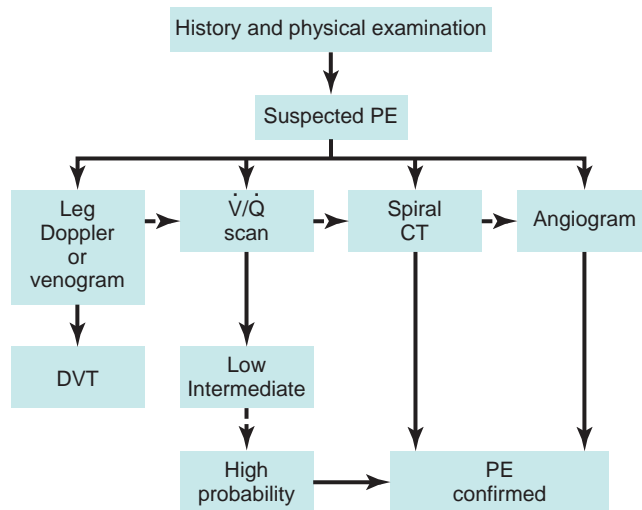

FIGURE 18-1 Tests commonly used in the evaluation of patients who may have pulmonary embolism (PE). Doppler ultrasound or venogram of the leg is useful to evaluate deep vein thrombosis (DVT). Ventilation-perfusion (\dot{V}/\dot{Q}) scans are most useful when they are normal or show lesions that suggest an intravascular clot. Unfortunately, these findings are lacking for many patients, who require further investigation. Spiral computed tomography (CT) has high sensitivity and specificity and allows for evaluation of thoracic structures and the vasculature. Angiography is considered the gold standard, but it often is not needed if other noninvasive tests are used alone or in combination.

Treatment

Pulmonary embolism is treated with supportive measures directed at sustaining organ function, such as fluid replacement for hypotension and mechanical ventilation for respiratory failure. Mechanical dislodgement of a pulmonary artery clot, such as by surgical thromboembolectomy, a procedure with a high mortality rate, requires a high level of expertise. Thromboembolectomy is used only for long-standing proximal clots that are complicated by chronic pulmonary hypertension (e.g., group 4 pulmonary hypertension, chronic thromboembolism syndrome) (level 1 evidence).

For acute pulmonary embolism, medical treatments are preferred, and they are used to prevent further clotting or to dissolve an existing clot. Anticoagulation with regular (intravenous) or low-molecular-weight (subcutaneous) heparin (LMWH) is recommended in the acute setting for patients without major contraindications to anticoagulation (e.g., upper gastrointestinal bleeding, hemorrhagic stroke) (level 1 evidence).

For patients with a contraindication to anticoagulation, an inferior vena cava filter should be placed. These filters have been shown to reduce pulmonary embolism occurrence in the setting of proximal deep vein thrombosis in patients also receiving anticoagulation (level 1 evidence). However, the devices carry a long-term risk of increased rates of deep vein thrombosis (level 1), and they do not clearly affect mortality if anticoagulation is also used. The use of thrombolytic medications (e.g., tissue plasminogen activator) is usually reserved for patients at increased risk for death as a result of circulatory collapse caused by obstruction to the flow in large or multiple pulmonary vessels (level 2-2).

Oral anticoagulation therapy with vitamin K antagonists such as warfarin is initiated, overlapping initially with acute heparin or LMWH treatment, and it is continued for at least 3 months to allow resolution of venous clot and to prevent recurrence (level 1 evidence). However, for venous thromboembolism occurring in the setting of active malignancy, LMWH treatment is superior to warfarin in preventing recurrent events (level 1).

Novel oral anticoagulants (i.e., factor Xa inhibitors) have been shown to be noninferior to the combination of heparin and warfarin therapy and to require less testing for safety (level 1 evidence). Patients who have had an unprovoked pulmonary embolism (i.e., pulmonary embolism not associated with a known temporary risk factor such as surgery) have a high rate of recurrence. For these patients, whether therapy should be routinely extended beyond 3 months is unclear, as is the optimal method of anticoagulation, and decisions regarding extended anticoagulation in this setting may be based on clinical factors such as bleeding risk or risk stratification with D-dimer testing.

PROSPECTUS FOR THE FUTURE

Translational research has markedly enhanced understanding of the pathogenesis of pulmonary hypertensive disorders, and this has resulted in the development of therapies that increase quality of life and improve mortality. There is heightened appreciation of the role of increased vascular cell proliferation in pulmonary vascular remodeling. In particular, abnormal proliferation of pulmonary endothelial cells and development of plexiform lesions have suggested that PAH may be a disease of hyperproliferative pulmonary endothelium.

Little is understood about the adaptive changes of the right ventricle to chronically increased afterload. Future investigations are needed to understand and better treat cor pulmonale. Less information is available about pulmonary thromboembolic disease, although new inhibitors of the coagulation cascade have been developed. Studies are needed in the area of genetic predisposition to thromboembolic disease and vascular dysfunction leading to thrombus formation. The role of thrombolytic therapy outside the setting of shock and the best management strategy after an unprovoked pulmonary embolism need to be clarified.

Disorders of Respiratory Control

Sharon Rounds and Matthew D. Jankowich

INTRODUCTION

During the transition between wakefulness and sleep, input from the behavioral control system decreases, the hypoxic drive to breathe is reduced, and the ventilatory response to partial pressure of carbon dioxide in arterial blood (P_{aCO_2}) is diminished. These changes are most dramatic during rapid eye movement (REM) sleep. *Sleep-disordered breathing* refers to a diverse group of conditions in which these physiologic variations are heightened, resulting in abnormal respiratory function and fragmented sleep.

Of the sleep-related disorders, sleep apnea has received the most attention. *Apnea* is the complete cessation of airflow for 10 seconds or longer. *Hypopnea* is a significant decrease in airflow. Occasional episodes of apnea and hypopnea are expected during normal sleep, and their frequency increases with age. However, in patients with sleep apnea, the frequency and duration of the episodes are increased, leading to sleep fragmentation and to hypoxemia and hypercapnia. Upper airway obstruction (i.e., obstructive sleep apnea [OSA]) or decreased central respiratory drive (i.e., central sleep apnea) may be the cause of sleep apnea. Some patients have both disorders.

Some studies suggest that the prevalence of sleep-disordered breathing may be as high as 9% among women and 24% among men, but prevalence levels depend on the definition used. Sleep-disordered breathing is usually defined as a respiratory disturbance index or frequency of abnormal respiratory events that number at least five episodes per hour of sleep. Prevalence estimates are higher for the older adult population, with some studies finding a more than 80% prevalence among older patients. Children are also affected, although less frequently (about 2%).

For a deeper discussion on this topic, please see Chapter 100, "Obstructive Sleep Apnea," in Goldman-Cecil Medicine, 25th Edition.

OBSTRUCTIVE SLEEP APNEA

Definition and Epidemiology

OSA is the most common of the sleep apnea syndromes. It is thought to affect almost 6% of middle-aged and older men; it is less common among women. In these patients, the upper airway relaxation that occurs during sleep produces complete occlusion of the airway and, consequently, cessation of airflow. After various periods of airway occlusion, the patient arouses, reestablishes muscle tone, and opens the airway. This vicious cycle is repeated many times during the night, resulting in recurring episodes of hypoxemia. During airway occlusion, sympathetic tone is

increased, resulting in vasoconstriction and hypertension, which persists during the waking hours. OSA is the most common identifiable cause of systemic hypertension (level 1 evidence). With airway occlusion, intrathoracic pressure becomes more negative with inspiration. Episodes of hypoxemia can be associated with cardiac arrhythmias, cardiovascular events, and all-cause mortality (level 1). These events are thought to be linked mechanistically to the increased incidence of stroke and coronary artery disease in patients with OSA.

An important physiologic consequence of airway occlusion is arousal from sleep, resulting in fragmented sleep. Because apneas are more frequent during REM sleep, patients complain of lack of refreshing sleep. Patients with OSA have an increased incidence of motor vehicle crashes, presumably related to somnolence while driving. These patients have an increased incidence of diabetes mellitus and other manifestations of the metabolic syndrome. The cardiovascular complications of OSA appear to be at least partially reversible with treatment of OSA with continuous positive airway pressure (CPAP) (level 2-3 evidence).

Clinical Presentation

The diagnosis of OSA is suggested when patients complain of morning headaches, recurrent awakenings, and daytime somnolence that affects daytime activities, including driving. Complaints of snoring and gasping episodes may be elicited from sleeping partners. Difficulties in maintaining sleep as a result of frequent awakenings may lead to mood effects and decreased quality of life. Recent weight gain, use of sedatives and sleeping pills, or alcohol intake may heighten these symptoms.

The primary risk factors for OSA are obesity (variable) and abnormal upper airway anatomy caused by macroglossia, a long soft palate and uvula, enlarged tonsils, or micrognathia. Patients may have an increased neck diameter (>17 inches in men; >16 inches in women). A narrow oropharynx as a result of a small pharyngeal opening or redundant soft tissue is often observed. Patients may be hypertensive and, in extreme cases, may have right-sided heart failure, which results from prolonged episodes of hypoxemia and pulmonary vasoconstriction that lead to pulmonary hypertension.

Diagnosis and Differential Diagnosis

Chest radiographic images and pulmonary function testing are usually not helpful in the evaluation of patients with sleep apnea. In some cases, OSA is associated with the obesity-hypoventilation syndrome, which is characterized by significant obesity associated with chronic hypoventilation and hypercapnia (i.e., Pickwickian syndrome). In these cases, arterial blood gas

determinations show hypoxemia and hypercapnia, and blood cell counts may indicate polycythemia. Although rare, hypothyroidism, acromegaly, and amyloidosis can cause or enhance OSA, and these conditions should be considered.

The diagnosis of OSA requires overnight polysomnography, during which continuous recordings of electrocardiographic and electroencephalographic tracings are made while the patient sleeps. Airflow, oxygen saturation, and respiratory, eye, chin, and limb muscle movements are monitored and recorded. OSA is diagnosed in sleeping patients (confirmed by electroencephalographic tracings) who develop cessations or reductions of airflow despite repeated muscular efforts to breathe (E-Fig. 19-1). These episodes may be accompanied by transient hypoxemia and cardiac arrhythmias. A score (i.e., apnea-hypopnea index) is derived from these data that defines OSA.

Polysomnography can distinguish OSA from central sleep apnea, during which cessation of airflow is associated with halted respiratory movements. Polysomnography is also important to rule out other sleep disturbances caused by insomnia, narcolepsy, parasomnias, and periodic limb movement syndrome. For patients strongly suspected of having OSA, home sleep studies that measure airflow, oxygen saturation, and chest and abdominal muscle movements (with or without an electroencephalogram) are frequently effective in making the diagnosis of OSA (level 1 evidence). However, if the diagnosis is unclear or there is concern about narcolepsy or some other sleep disorder, formal polysomnography in the laboratory is needed.

Treatment

Treatment of sleep apnea includes behavioral and medical approaches. When associated with obesity, significant weight loss (through lifestyle modification or bariatric surgery) results in a reduction in the apnea-hypopnea index (level 1 evidence). Avoidance of sedatives and alcohol are also encouraged (level 3).

Airway obstruction can be prevented with the use of CPAP provided through a tightly fitted mask (level 1 evidence). CPAP maintains positive airway pressure throughout expiration, thereby preventing collapse of the upper airway. The amount of airway pressure can be titrated, and oxygen can be added if necessary. Many patients are begun on autotitrating CPAP; the machine senses apneas and increases CPAP automatically to eliminate them. Autotitrating CPAP is not inferior to a fixed CPAP prescription, based on in laboratory polysomnography (level 1). CPAP is effective in most patients, but compliance with this technique varies.

Surgical removal of obstructing tonsils, adenoids, and polyps or uvulopalatopharyngoplasty may be useful in patients with specific anatomic abnormalities. However, in children with OSA, adenotonsillectomy was not superior to watchful waiting in improving neuropsychological function (level 1 evidence). Mandibular advancement may improve symptoms of OSA in patients who do not tolerate CPAP (level 3). A permanent tracheostomy may be necessary in severe cases after other approaches have failed. However, the surgical approach to this disorder is limited to selected patients only after CPAP has failed. The obesity-hypoventilation syndrome is treated effectively with noninvasive ventilation with bilevel positive airway pressure (level 2-1).

OTHER DISORDERS RELATED TO RESPIRATORY CONTROL

Congenital central hypoventilation syndrome is a rare disorder that usually is diagnosed in infancy. It is caused by mutation in the *PHOX2B* gene (level 1 evidence).

Central sleep apnea is also a rare disorder. It predominates in men and is usually associated with normal body habitus. Patients may complain of daytime sleepiness and insomnia with frequent awakenings. The disorder is caused by apnea or hypopnea resulting from a decreased central respiratory drive. It may be a consequence of central nervous system injury (e.g., structural abnormality of the brain stem), or it may be idiopathic. Affected individuals may hypoventilate even while awake, although they are capable of normal voluntary breaths. During sleep, frequent apnea is common.

In patients with obstructive lung disease, increased work of breathing eventually makes it difficult to maintain sufficient ventilation to maintain normal P_{aCO_2} levels. When ventilatory capacity declines, hypoventilation causes P_{aCO_2} to increase; the kidneys respond by retaining bicarbonate to keep arterial blood pH at normal levels. These patients appear to have normal ventilatory drive, but they lack the ability to increase minute ventilation to meet increased metabolic demands. This characteristic is observed in certain patients with chronic bronchitis who exhibit the classic signs of the “blue bloater.”

Lower brain stem and upper pontine lesions may cause *central hyperventilation*. However, this disorder rarely occurs in the absence of other physiologic or chemical abnormalities. Hepatic cirrhosis and extreme anxiety are causes of central hyperventilation. Pregnancy can also cause hyperventilation due to elevated levels of progesterone and other hormones. *Apneustic breathing* consists of sustained inspiratory pauses, resulting from damage to the midpons, most commonly caused by basilar artery infarction. *Biot respiration* or *ataxic breathing* is a haphazardly random pattern of sleep and is characterized by shallow breaths. A disruption of the respiratory rhythm generator in the medulla causes this sign.

The regular cycling of crescendo-decrescendo tidal volumes, separated by apneic or hypopneic pauses, characterizes Cheyne-Stokes respiration. Patients with this disorder usually have generalized central nervous system disease or congestive heart failure. Heart failure prolongs circulatory times, causing a delay between changes in blood gases at the tissue level and the arrival of those changes at the brain stem chemoreceptors. This delay sets up a cycle of gradual increase to hyperventilation, followed by gradually decreasing ventilation to apnea and then a repetition of the cycle. Studies suggest that OSA and Cheyne-Stokes respiration are consequences of congestive heart failure and contribute to its progression.

For a deeper discussion on this topic, please see Chapter 86, “Disorders of Ventilatory Control,” in Goldman-Cecil Medicine, 25th Edition.

PROSPECTUS FOR THE FUTURE

With more than 5% of the population in the United States suffering from sleep-disordered breathing and with the recognition

E-FIGURE 19-1 Electrocardiogram (ECG) and other tracings for a subject with obstructive sleep apnea. SaO₂, Arterial oxygen saturation.

that these disorders may contribute to systemic illnesses such as hypertension and cardiovascular disorders, interest in the early diagnosis and treatment of disorders of respiratory control is growing. In view of the high incidence and potential health consequences of sleep-disordered breathing, physicians must be on the lookout for this condition. The increased incidence of OSA parallels that of obesity in the United States, a public health problem that has been associated with asthma and increased risk of death. It is highly likely that genetic predisposition to OSA accounts for increased incidence in some families.

Disorders of the Pleura, Mediastinum, and Chest Wall

Eric J. Gartman and F. Dennis McCool

PLEURAL DISEASE

The pleura is a thin membrane that covers the entire surface of the lung, inner surface of the rib cage, diaphragm, and mediastinum. There are two pleural membranes: the visceral pleura, which covers the lung; and the parietal pleura, which lines the rib cage, diaphragm, and mediastinum. A layer of mesothelial cells lines both pleural surfaces. The closed space in between the surface of the lung and the chest cavity is called the *pleural space*. A small amount of fluid normally resides in this space and forms a thin layer between the pleural surfaces. Pleural fluid serves as a lubricant for the visceral and parietal pleurae as they move against each other during inspiration and expiration.

The blood vessels in the visceral pleura are supplied from the pulmonary circulation and have less hydrostatic pressure than the blood vessels in the parietal pleura, which are supplied by the systemic circulation. The pressure in the pleural space is subatmospheric during quiet breathing. Fluid is filtered from the higher-pressure vascular structures into the pleural space. The normal fluid turnover is about 10 to 20 mL per day, with 0.2 to 1 mL remaining in the pleural space. Pleural fluid usually contains a small amount of protein and a small number of cells that are mostly mononuclear cells. Although both parietal and visceral pleurae contribute to pleural fluid formation, most of the fluid results from filtration of the higher-pressure vessels supplying the parietal pleura.

After the fluid enters the pleural space, it is drained from the pleural space by a network of pleural lymphatics located beneath the mesothelial monolayer. The lymphatics originate in stomas on the parietal pleural surface. In abnormal circumstances of increased fluid production or impaired removal, fluid can accumulate in the pleural space. Factors that promote the entry of fluid into the pleural space include an increase in systemic venous pressure, an increase in pulmonary venous pressure, an increase in permeability of pleural vessels, and a reduction in pleural pressure. Conditions that increase hydrostatic pressure can be seen in congestive heart failure; changes in pleural membrane permeability can be seen in various inflammatory states or malignancy; and a reduction in pleural pressure can be seen with atelectasis. Occasionally, microvascular oncotic pressure may be sufficiently reduced to promote fluid entry into the pleural space in patients with hypoalbuminemia. Factors that block lymphatic drainage and interfere with the egress of fluid from the pleural space include central lymphatic obstruction and obstruction of lymphatic channels at the pleural surface by tumor.

Pleural Effusion

Pleural effusion is the accumulation of fluid in the pleural space. Pleural effusions usually are detected by chest radiography; however, the volume of fluid in the pleural space must exceed 250 mL to be visualized on a chest radiograph. When an effusion exists, there is blunting of the costophrenic angle on a posteroanterior chest film, which represents a fluid meniscus that can be detected posteriorly on the lateral chest radiograph, and fluid occasionally can be demonstrated in the minor or major fissures (E-Figs. 20-1 and 20-2). Apparent elevation or changes in the contour of the diaphragm on a posteroanterior chest film may signify a subpulmonic effusion, so called because it retains the general shape of the diaphragm without blunting the costophrenic angle; however, it is evident on the lateral film.

A decubitus chest radiograph can be obtained to determine whether the fluid is free flowing or loculated. Computed tomography (CT) of the chest provides better definition of the pleural space than plain radiography. Chest CT is particularly useful in defining loculated effusions and in differentiating pulmonary parenchymal abnormalities from pleural abnormalities, atelectasis from effusion, and loculated effusion from lung abscess or other parenchymal processes (E-Fig. 20-3). The edge of a parenchymal process usually touches the chest wall and forms an acute angle, whereas that of an empyema is usually an obtuse angle.

Thoracentesis is a procedure in which fluid is aspirated from the pleural space. To help minimize procedural complications and assist in needle placement, ultrasound or CT guidance should be used to direct the thoracentesis catheter into the pleural space.

Classifying pleural effusions as transudates or exudates greatly assists with the differential diagnosis. The approach to pleural effusions is outlined in E-Figure 20-4. Further analysis of pleural fluid may provide a definitive diagnosis (e.g., malignancy); however, even without a definitive diagnosis, pleural fluid analysis can be useful in excluding possible causes of disease such as infection.

Transudates

Effusions that accumulate due to changes in oncotic and hydrostatic forces usually have a low protein content and are called *transudates* (Table 20-1). Congestive heart failure is the most common cause of a transudate, and the effusions are typically bilateral. If the effusion is unilateral, it involves the right hemithorax in most instances. Effusions due to heart failure almost

TABLE 20-1 CAUSES OF PLEURAL EFFUSIONS

CONDITIONS ASSOCIATED WITH TRANSUDATES	
Ascites	Infection
Cirrhosis	Intra-abdominal pathologic abnormalities (abscess)
Congestive heart failure	Lymphedema
Hypoalbuminemia	Malignancy (primary lung cancer, lymphoma, metastatic cancer)
Intra-abdominal fluid	Meigs' syndrome (benign ovarian tumor)
Malnutrition	Myxedema
Nephrotic syndrome	Pancreatitis
Peritoneal dialysis	Parapneumonic causes (pneumonia, lung abscess, bronchiectasis)
CONDITIONS ASSOCIATED WITH EXUDATES	
Asbestosis	Pulmonary embolism and infarction
Chylothorax	Rheumatoid arthritis (pleurisy)
Collagen vascular disease	Ruptured esophagus
Complications of abdominal surgery	Subphrenic abscess
Dressler's syndrome (myocardial infarction, cardiomy)	Systemic lupus erythematosus
Drug-induced lupus	Trauma
Empyema	Uremia
Hemothorax	Urinorhax
	Miscellaneous sources

Modified from Light RW, Macgregor MI, Luchsinger PC, et al: Pleural effusions: the diagnostic separation of transudates and exudates, *Ann Intern Med* 77:507–513, 1972.

universally are related to dysfunction of the left side of the heart, although they rarely can result from right heart failure (e.g., advanced pulmonary arterial hypertension).

Transudative effusions may be seen in cirrhosis, nephrotic syndrome, myxedema, pulmonary embolism, superior vena cava obstruction, and peritoneal dialysis. In patients with cirrhosis, the effusions are often right sided, and the mechanism may be related to flow from the peritoneal space across diaphragmatic defects into the pleural space (i.e., hepatic hydrothorax). Transudative effusions are typically small to moderate sized and rarely require drainage to improve symptoms.

Exudates

Exudative effusions occur when there is an alteration in vascular permeability or pleural fluid resorption. They can be observed in inflammatory, infectious, or neoplastic conditions.

To distinguish an exudate from a transudate, one of three criteria must be fulfilled: (1) An exudate must have a pleural fluid–to–serum protein ratio greater than 0.5; (2) a pleural fluid–to–serum lactate dehydrogenase (LDH) ratio must be greater than 0.6; or (3) a pleural fluid LDH level must be greater than two thirds of the upper limit of normal (Table 20-2). When all three criteria are met, the sensitivity, specificity, and positive predictive value exceed 98% for defining an exudative effusion.

Measuring pleural fluid cholesterol may also help to distinguish an exudate from a transudate. Pleural fluid cholesterol is derived from degenerating cells within the pleural space and from vascular leakage due to increased permeability. A cholesterol level greater than 45 mg/dL is consistent with an exudative effusion.

Exudative effusions are commonly caused by infection. Parapneumonic effusion typically occurs in patients with bacterial pneumonia and can be further classified as an uncomplicated or complicated effusion. Uncomplicated parapneumonic effusions do not require drainage and respond to antibiotic therapy alone

TABLE 20-2 DIFFERENTIATION OF EXUDATIVE AND TRANSUDATIVE PLEURAL EFFUSIONS

CHARACTERISTIC	EXUDATE	TRANSUDATE
Pleural fluid–to–serum protein ratio	>0.5	<0.5
Pleural fluid LDH level	> 2/3 of the upper limit of normal	< 2/3 of the upper limit of normal
Pleural fluid–to–serum LDH ratio	>0.6	<0.6

LDH, Lactate dehydrogenase.

Modified from Light RW, Macgregor MI, Luchsinger PC, et al: Pleural effusions: the diagnostic separation of transudates and exudates, *Ann Intern Med* 77:507–513, 1972.

used for treatment of the underlying pneumonia. In contrast, complicated parapneumonic effusions do not respond to antibiotic therapy alone and require drainage to prevent the formation of an empyema. The transition from uncomplicated to complicated can occur extremely rapidly, within a 24-hour period in some cases.

Typically, an uncomplicated parapneumonic effusion has a pH level greater than 7.3, a glucose level greater than 60 mg/dL, and an LDH level less than 1000 IU/L. A pH level of less than 7.2 usually identifies a complicated effusion. However, this finding is not specific for infection, and the cause may be malignancy, rheumatoid arthritis, or trauma with esophageal disruption causing an associated reduction in pH level.

Complicated exudative effusions require drainage to avoid development of loculation, cutaneous fistulas, bronchopleural fistulas, or fibrothorax. Pus aspirated from the pleural space or cultured or Gram-stained bacteria isolated from the fluid confirm an empyema, which requires immediate drainage. The injection of fibrolytic agents and DNase into the pleural space can augment full drainage of infected pleural effusions; however, treatment of complicated pleural effusions occasionally requires surgical intervention and lung decortication.

Pleural effusions due to primary tuberculosis may be seen in up to 30% of patients in endemic areas. The effusion is caused by increased vascular permeability of the pleural membrane because of a hypersensitivity reaction, not direct infection. Typically, the pleural fluid is lymphocyte predominant and acid-fast stain and culture negative. Adenosine deaminase levels greater than 50 U/L may be helpful in identifying tuberculous pleural effusions. Tuberculous empyema is distinct from a tuberculous pleural effusion and can occur when there is an extension of infection from the thoracic lymph nodes into the pleural space or hematogenous spread of tuberculosis to the pleural space.

Malignant effusions are the second most common cause of exudative pleural effusions and imply a poor prognosis. Seeding of the parietal or visceral pleura with malignant cells can change vascular permeability and impede resorption, resulting in effusion formation. However, the finding of a pleural effusion in an individual with malignancy does not necessarily imply that there is a malignant process in the pleural space. Effusions in these individuals may be caused by atelectasis, postobstructive pneumonia, hypoalbuminemia, pulmonary emboli, or complications from irradiation or chemotherapy.

The most common cause of malignant effusion is lung cancer, followed by breast cancer and lymphoma. An effusion that is

bloody suggests a malignant process; however, other causes of bloody pleural effusions include trauma, tuberculosis, collagen vascular disease, and thromboembolic disease. To confirm the diagnosis of malignancy, cytologic examination of the fluid is needed. Malignant cells can be seen in 60% of malignant effusions on the first thoracentesis. Sensitivity rises to 80% if three separate samples are obtained. If needed, a biopsy of the pleura may be useful in identifying a malignancy. Biopsies may be obtained with video-assisted thoracoscopy or, less optimally, in a blinded fashion through a Cope or Abrams needle.

A low pleural fluid pH has prognostic and therapeutic implications for patients with malignant effusions. Patients with a low pleural fluid pH due to malignancy tend to have shorter survival times and poorer responses to chemical pleurodesis. Recurrent malignant pleural effusions may improve with chemical pleurodesis with talc or tetracycline derivatives, but effectiveness varies, achieving a complete response in little more than 50% of patients. Alternatively, many patients with recurrent malignant effusions have tunneled indwelling pleural catheters placed, allowing intermittent drainage and relief of symptoms.

Systemic inflammatory disorders such as rheumatoid arthritis and lupus erythematosus can be associated with exudative effusions. Rheumatoid pleural effusions are a common intrathoracic manifestation of rheumatoid disease and may be seen in as many as 5% of patients. Rheumatoid factor titers in pleural fluid are often greater than 1 : 320, and the pleural fluid glucose level is less than 60 mg/dL (or the pleural fluid-to-serum glucose ratio is less than 0.5). However, a low glucose level also may be found in complicated parapneumonic effusions or empyema, malignant effusion, tuberculosis pleurisy, lupus pleuritis, and esophageal rupture. In systemic lupus erythematosus, 15% to 50% of patients have pleural effusions, and the pleural fluid antinuclear antibody titer is greater than 1 : 160.

Measuring pleural fluid amylase concentrations may further refine the differential diagnosis for an exudative effusion. Finding a pleural amylase level greater than the upper limit of normal for serum amylase is consistent with acute pancreatitis, chronic pancreatic pleural effusion, esophageal rupture, or malignancy. Pancreatic disease is associated with pancreatic amylase isoenzymes, whereas malignancy and esophageal rupture are characterized by a predominance of salivary isoenzymes.

Pneumothorax

Pneumothorax is the accumulation of air in the pleural space. In this instance, pleural pressure becomes positive, and there is compression of underlying lung. Patients with pneumothorax typically have acute onset of dyspnea. Findings include tachycardia, decreased breath sounds, decreased tactile fremitus, a pleural friction rub, subcutaneous emphysema, hyperresonance, and a tracheal shift to the opposite side.

The diagnosis can be made by obtaining an upright chest radiograph, and rapid assessment can be achieved with point-of-care ultrasound. Typically, the visceral pleura separates from the parietal pleura, and air can be seen between the visceral pleural lining and the rib cage. An end-expiratory radiograph increases the density of lung while reducing its volume, highlighting the difference between the lung parenchyma and the pleural gas.

Management of a significant pneumothorax usually requires insertion of a thoracostomy tube and suction followed by water-seal drainage. However, if the pneumothorax is small and the patient is not in distress, observation alone may be indicated. If there is not a continuing air leak, as from a bronchopleural fistula, the pleural air is reabsorbed into the blood with resolution of the pneumothorax.

A tension pneumothorax is a medical emergency that requires immediate decompression by placement of a chest catheter. A tension pneumothorax occurs when pleural pressure reaches levels sufficient to cause mediastinal shift, compression of the vena cava and heart, and hemodynamic compromise. This physiology implies an ongoing leak of air into the pleural space.

Pneumothorax is often associated with blunt or penetrating trauma. With penetrating trauma, air may leak into the pleural space through the chest wall or the lung. Mechanical ventilation has also been associated with pneumothorax. Patients with underlying lung disease receiving mechanical ventilation may acutely develop a pneumothorax. A sudden rise in peak airway pressures with a reduction in breath sounds can alert the clinician to this complication.

Pneumothorax may occur spontaneously or result from underlying lung disease. Typically, spontaneous pneumothorax occurs in tall, young, thin men, presumably a result of rupture of apical blebs. Underlying lung diseases that can be complicated by pneumothorax include emphysema, cystic fibrosis, granulomatous inflammation, necrotizing pneumonia, pulmonary fibrosis, and lung abscess. Catamenial pneumothorax occurs in women who have subpleural and diaphragmatic endometriosis, with rupture of the endometrial nodules at the time of menstruation causing pneumothorax.

Mesothelioma

Malignant mesotheliomas are neoplasms arising from the serosal membranes of the body cavities. Eighty percent of mesotheliomas originate in the pleura. Individuals usually are older than 55 years, and there is an association with asbestos exposure in the distant past. Symptoms include shortness of breath, chest pain, and weight loss.

The most common radiologic finding is a large, unilateral pleural effusion that may completely opacify the hemithorax. There may be circumferential pleural thickening, usually associated with various amounts of calcified pleural plaque and effusions. CT of the chest is the most accurate noninvasive method for assessing stage and progression of mesothelioma. Pleural fluid cytology frequently is insufficient for diagnosis, and the most efficient way of obtaining tissue is by CT-guided core biopsy or thoracoscopy.

The overall prognosis for patients with malignant mesothelioma is poor. No particular therapy has emerged as superior to supportive therapy alone in terms of survival.

MEDIASTINAL DISEASE

Lesion Location

The mediastinum is the central part of the thoracic cavity between the lungs that contains the heart and aorta, esophagus, trachea, lymph nodes, and thymus. The mediastinum is bordered by the

two pleural cavities laterally, the diaphragm inferiorly, and the thoracic inlet superiorly. The mediastinal space can be divided into three compartments: anterior, middle, and posterior. The localization of mediastinal masses in one of these compartments assists in the differential diagnosis (Fig. 20-1).

The anterior mediastinal compartment is anterior to the pericardium and includes lymphatic tissue, the thymus, and the great veins. Lesions most commonly found in the anterior mediastinum are thymomas, germ cell tumors, lymphomas, intrathoracic thyroid tissue, and parathyroid lesions. Thymomas comprise 20% of mediastinal neoplasms in adults, and they are the most common anterior mediastinal primary neoplasm in adults. Symptoms due to myasthenia gravis may affect one third of patients with thymomas. Middle mediastinal lesions include tracheal masses, bronchogenic and pericardial cysts, enlarged lymph nodes, and proximal aortic disease (i.e., aneurysm or dissection). Posterior mediastinal masses include neurogenic tumors and cysts, meningocele, lymphoma, aneurysm of the descending aorta, and esophageal disorders such as diverticula and neoplasms.

Patients with systemic lymphoma often have involvement of the mediastinum, and 5% to 10% of patients with lymphoma have primary mediastinal lesions at clinical presentation. Mediastinal cysts can arise in the pericardium, bronchi, esophagus or stomach, thymus, and thoracic duct, and although benign, they can produce compressive symptoms. Lung cancer can manifest with mediastinal adenopathy, a sign of advanced stage (see E-Fig. 20-3).

FIGURE 20-1 Masses of the mediastinum and their anatomic locations.

Treatment of a mediastinal mass depends on the underlying pathology. Many require surgical resection, irradiation, chemotherapy, or careful monitoring over time.

Mediastinitis

Inflammation of the mediastinal structures can be acute or chronic. Acute mediastinitis is a rapidly progressive condition due to infection, and it most commonly complicates cardiothoracic surgical procedures or occurs as a result of trauma. Chest imaging studies may show a widening of the mediastinum, pneumothorax, or hydrothorax. Treatment requires antibiotics, pleural drainage, and mediastinal evacuation.

Chronic mediastinitis (i.e., fibrosing mediastinitis) is a progressive illness that results from fungal or granulomatous infections, neoplasms, radiotherapy, or occasionally drugs such as methysergide; it may be idiopathic. Patients usually remain asymptomatic until vascular, respiratory, or neurologic structures are affected; tracheobronchial narrowing is the most common manifestation. Diagnosis and treatment often require surgical intervention, although no treatment is highly successful.

CHEST WALL DISEASE

The chest wall is composed of the bony structures of the rib cage, the articulations between the ribs and the vertebrae, the diaphragm, and other respiratory muscles. Normal function of this ventilatory pump is needed to bring oxygen from the atmosphere into the body. A wide variety of chest wall and neuromuscular disorders can result in dysfunction of the ventilatory pump. These disorders typically result in a restrictive dysfunction characterized by a reduction in total lung capacity and vital capacity with a normal residual volume. Hypoventilation may ensue, resulting in hypercapnia, atelectasis, and hypoxemia.

Skeletal Disease

Kyphoscoliosis and ankylosing spondylitis are disorders that involve the spine and its articulations. Pectus excavatum involves the sternum, flail chest affects the ribs, and obesity adds to the soft tissue mass of the chest wall. These disorders primarily affect the respiratory system by stiffening its tissues. Of these disorders, kyphoscoliosis produces the most severe restrictive impairment, and ankylosing spondylitis and pectus excavatum cause little respiratory compromise.

Kyphoscoliosis refers to a group of disorders characterized by excessive spinal curvature in the lateral plane (i.e., scoliosis) and sagittal plane (i.e., kyphosis). The degree of curvature can be assessed by measuring the Cobb angle (Fig. 20-2). Greater degrees of spinal curvature are associated with greater restriction and an increased risk of respiratory failure (E-Fig. 20-5).

Kyphoscoliosis may be idiopathic, caused by neuromuscular disease, or associated with congenital vertebral malformations. Idiopathic kyphoscoliosis is the most common form, usually manifesting in late childhood or early adolescence and affecting females more than males (ratio of 4 : 1). It is thought to be a multigene condition with an autosomal or sex-linked inheritance pattern and variable phenotypic expression. A defect in the chromatin-remodeling gene (*CHD7*) has been associated with idiopathic kyphoscoliosis.

E-FIGURE 20-5 A patient with post-polio syndrome had severe kyphoscoliosis, and Harrington rods were placed to correct the spinal curvature.

FIGURE 20-2 Schematic depiction of the lines constructed to measure the Cobb angle of scoliosis (A) and kyphosis (B).

For a given degree of spinal deformity, individuals with kyphoscoliosis due to a neuromuscular disease have more respiratory impairment than those with idiopathic kyphoscoliosis. Factors that contribute to respiratory failure in patients with kyphoscoliosis include inspiratory muscle weakness, underlying neuromuscular disease, sleep-disordered breathing, and airway compression due to distortion of lung parenchyma and twisting of airways.

Treatment consists of general supportive measures such as immunizations against influenza and pneumococci, smoking cessation, maintenance of a normal body weight, supplemental oxygen, and treatment of respiratory infections. It is important to recognize nocturnal hypoventilation because it can be treated with noninvasive positive-pressure ventilation. This is typically delivered through a nasal or full face mask. Indications for instituting noninvasive ventilation include symptoms suggesting nocturnal hypoventilation, signs of cor pulmonale, nocturnal oxyhemoglobin desaturation, or an elevated daytime $Paco_2$.

Obesity

Obesity is a major health problem that affects children and adults throughout the world. Body fat usually constitutes 15% to 20% of body mass in healthy men and 25% to 30% of body mass in healthy women. In cases of obesity, the body fat content may increase by as much as 500% in women and 800% in men. The degree of obesity can be assessed by the body mass index, which is the ratio of body weight (BW) in kilograms to the square of the height (Ht) in meters (BW/Ht^2). Individuals with a BMI between 18.5 and 24.9 kg/m^2 are normal, and those with a BMI greater than 40 kg/m^2 are considered severely or morbidly obese.

Reductions in functional residual capacity and expiratory reserve volume are the most common pulmonary function abnormalities in obesity, whereas vital capacity and total lung capacity may be only minimally reduced. Obesity promotes breathing at low lung volumes, which reduces lung compliance and increases the work of breathing. A subgroup of individuals with obesity hypoventilate and become hypercapnic. When obesity is associated with hypoventilation, it is called the *obesity-hypoventilation syndrome* (i.e., pickwickian syndrome). The mechanism underlying hypoventilation is unknown. Obesity-hypoventilation syndrome may result from factors that reduce respiratory center chemosensitivity, such as hypoxia, sleep apnea, or adipokines such as leptin. The most important consequences

FIGURE 20-3 Computed tomography of a patient with unilateral right hemidiaphragm paralysis and associated right lower lobe atelectasis.

of chronic hypoventilation are hypoxemia and pulmonary hypertension.

Nocturnal noninvasive positive-pressure ventilation can help to reverse these abnormalities. Weight loss is the optimal therapy, but it is not always attainable, and long-term weight loss maintenance is even more difficult. Pharmacotherapy or bariatric surgery should be considered for obese individuals who do not achieve weight control with conventional methods (i.e., diet, enhanced physical activity, and behavioral therapy).

Diaphragm Paralysis

The diaphragm separates the thorax from the abdomen and is the major muscle of inspiration. Diaphragm weakness or paralysis can involve one or both hemidiaphragms. Unilateral diaphragm paralysis is more common than bilateral diaphragm paralysis. The most frequent causes of unilateral paralysis include traumatic phrenic nerve injury, herpes zoster infection, cervical spinal disease, and compressive tumors. Patients may be asymptomatic, or the abnormality may be discovered as an incidental finding of an elevated hemidiaphragm on a chest radiograph (Fig 20-3). The diagnosis is confirmed by seeing on fluoroscopy a paradoxical upward motion of the affected diaphragm during a vigorous sniff maneuver. There is no specific treatment for this disorder, but recovery after the initial injury occasionally occurs. When the patient has disabling symptoms and significant elevation of the diaphragm is seen on the chest radiograph, surgical plication of the diaphragm may provide some relief of symptoms.

Bilateral diaphragm paralysis is most often seen in the setting of a disease producing generalized muscle weakness or motor neuron disease such as amyotrophic lateral sclerosis. Pulmonary function test results are associated with severe restrictive impairments. When the patient assumes the supine position, there may be a further reduction ($\leq 50\%$) in vital capacity. It is not surprising that orthopnea is an especially prominent symptom, and patients often have difficulty sleeping in the supine position. Patients also complain of dyspnea when bending or lifting objects.

Bilateral diaphragm paralysis can be difficult to diagnose. Restriction evidenced by pulmonary function test results is non-specific, as is the finding of low lung volumes on chest radiographs. Fluoroscopic sniff testing (i.e., diaphragm fluoroscopy) can yield false-negative and false-positive results. Measurement of transdiaphragmatic pressure is the gold standard, but it is somewhat invasive, requiring placement of catheters in the esophagus and stomach. Alternatively, B-mode ultrasound of the diaphragm in the zone of apposition is a noninvasive means of diagnosing diaphragm paralysis.

Treatment should address the underlying disease, which may or may not be reversible. If paralysis is idiopathic or caused by neuralgic amyotrophy (i.e., brachial plexus neuritis), more than 50% of individuals may recover. Phrenic nerve pacing may be used in patients with spinal cord injuries above C3, and noninvasive positive-pressure ventilation can be used to treat patients with nocturnal hypoventilation. Diaphragm plication is not indicated in patients with bilateral diaphragm paralysis.

PROSPECTUS FOR THE FUTURE

Numerous advances can be expected in treating individuals with pleural, mediastinal, and chest wall diseases. Progress in pleural fluid analysis using novel biomarkers and nucleic acid amplification tests may lead to more rapid and accurate diagnosis of tuberculous pleural effusions. Assays of pleural fluid tumor markers and chromosome analysis are promising developments for the differentiation of malignant from nonmalignant effusions. Mesothelioma remains resistant to traditional therapeutic approaches, but evolving technology centered on gene therapy may produce a new treatment modality.

Better visualization of mediastinal structures can be achieved as magnetic resonance imaging (MRI) evolves and becomes more routinely applied to examination of the chest. Molecular tracers targeting tumor receptors or proteins may be used with MRI and positron emission tomography imaging techniques to better differentiate malignant from benign mediastinal masses.

Noninvasive nocturnal ventilation remains a cornerstone of therapy for patients with chest wall and neuromuscular diseases,

but compliance can be problematic. Continued evolution of techniques to deliver nocturnal noninvasive ventilation may improve compliance with treatment, and application of this technique to patients with obesity-hypoventilation syndrome may reduce morbidity and mortality for them.

Patients with diaphragm paralysis due to high cervical spinal cord lesions may benefit from advances in intramuscular diaphragm pacing. This technique may provide an alternative means of treating respiratory failure in these individuals and others with diaphragm paralysis.

For a deeper discussion on this topic, please see Chapter 99, "Diseases of the Diaphragm, Chest Wall, Pleura, and Mediastinum," in Goldman-Cecil Medicine, 25th Edition.

Infectious Diseases of the Lung

Narendran Selvakumar, Brian Casserly, and Sharon Rounds

PNEUMONIA

Definition and Epidemiology

Pneumonia is an infection of the lower respiratory tract parenchyma by bacteria, viruses, fungi, or parasites. It should be distinguished from pneumonitis, which is inflammation of the lungs caused by noninfectious causes, including chemicals, blood, radiation, and autoimmune processes. Pneumonia, the leading cause of death of children worldwide and the eighth leading cause of death in the United States, is responsible for 4 to 10 million respiratory infections each year.

Pathology

Microbial agents can be introduced to the lungs through several sources, including normal flora from the sinuses, nasopharynx, or oropharynx and inhalation of dust, liquid, or gases from environmental sources. The most common route is by aspiration of oropharyngeal secretions. Direct inhalation of organisms such as *Legionella* species, mycobacteria, endemic fungi, *Mycoplasma pneumoniae*, *Chlamydomphila pneumoniae*, and most viruses can cause pneumonia, resulting in geographic and seasonal clustering of cases.

Much less commonly, pneumonia can arise from hematogenous or embolic spread of infection from infected heart valves or venous clots. The small vessels of the pulmonary circulation act as filters for venous blood carrying small clusters of bacteria from the source. Hematogenous pneumonias are often multifocal with peripheral lesions susceptible to rapid cavitation.

Clinical Presentation

Patients usually exhibit respiratory symptoms, including productive cough, dyspnea, chest pain, and occasionally hemoptysis. Less specific symptoms include fever, general malaise, myalgias, and weight loss. The presentation may be acute (days to weeks), as observed in bacterial pneumonia, or subacute or chronic (weeks to years), as observed with tuberculosis (TB). Immunocompromised patients (e.g., with human immunodeficiency virus [HIV] infection) may be predisposed to specific illnesses, and knowledge of the specific impairment in host defense mechanisms may help to determine the cause of the infection.

The chest radiograph plays an important role. A parenchymal opacity is observed in the patient with pneumonia (E-Fig. 21-1) However, noninfectious disorders can mimic pneumonia, and no radiographic finding is specific for infection.

The initial antibiotic choice may be guided by Gram stain of respiratory secretions. This requires the demonstration

of a satisfactory sputum sample (i.e., >25 polymorphonuclear leukocytes and <10 epithelial cells per low-power field) and the presence of a predominant organism (>8 to 10 organisms per high-power field), particularly if the same bacteria are found in white blood cells. However, despite extensive laboratory testing, a causative organism can be identified in only about 50% of all pneumonia cases. Reasons include poor Gram-staining bacteria such as *Legionella pneumophila*, *C. pneumoniae*, absence of a peptidoglycan wall in *M. pneumoniae*, and various difficult-to-culture organisms that give inconclusive results. Table 21-1 lists the most common causative agents of pulmonary infections.

Clinical guidelines have been developed to provide a systematic approach to the diagnosis and management of pneumonia. The initial evaluation should determine whether the pneumonia is community acquired or health care associated.

Differential Diagnosis, Treatment, and Prognosis

Community-Acquired Pneumonia

Community-acquired pneumonia occurs twice as frequently during winter, and those at the extremes of age (<5 years and >65 years) are at increased risk. *Streptococcus pneumoniae* is the most common causative agent. *S. pneumoniae* is a gram-positive, diplococcal bacterium whose encapsulated structure and immunoglobulin A (IgA) protease protects it from host defense.

TABLE 21-1 ORGANISMS CAUSING PULMONARY INFECTIONS

PATHOGEN	COMMUNITY ACQUIRED INFECTIONS	NOSOCOMIAL INFECTIONS
Bacteria	70-80%	90%
<i>Streptococcus pneumoniae</i>	60-75%	3-9%
<i>Haemophilus influenzae</i>	4-5%	—
<i>Legionella</i> spp.	2-5%	Up to 25%
<i>Staphylococcus aureus</i>	1-5%	10-20%
Gram-negative bacilli	Rare	50
Atypical bacteria	10-20%	Rare
<i>Mycoplasma pneumoniae</i>	5-18%	—
<i>Chlamydia psittaci</i>	2-3%	—
<i>Coxiella burnetii</i>	1%	—
Viruses	10-20%	Rare
Influenza virus	—	8%
Hantavirus	—	Rare

Modified from Modaj J: Empiric therapy of severe infections in adults, Am J Med 88:12S-17S, 1990.

E-FIGURE 21-1 Anteroposterior and lateral views of left lower lobe retrocardiac infiltrate and atelectasis.

Patients may have an antecedent upper respiratory tract infection followed by the sudden onset of fever, shaking chills, dyspnea, and pleurisy. Cough productive of purulent, rust-colored sputum is common. Imaging studies show lobar consolidation. Sputum is gram positive in only 45% of bacteremic cases. The diagnosis is confirmed by culture of the organism from a normally sterile site, such as blood, pleural fluid, or cerebrospinal fluid. In many cases, the diagnosis is presumptive, and recommended antibiotic coverage for community-acquired pneumonia is designed to cover this organism (discussed later).

M. pneumoniae is a slow-growing, facultative anaerobic organism that accounts for 25% to 60% of all atypical pneumonias. *M. pneumoniae* is a common cause of pneumonia in patients between the ages of 5 and 35 years who may initially exhibit upper respiratory tract symptoms, pharyngitis, and bullous myringitis. The clinical presentation includes dry cough and gastrointestinal symptoms in addition to fever, headache, and myalgias. Uncommon complications include cold agglutinin–induced hemolysis, hepatitis, erythema multiforme, hyponatremia caused by the syndrome of inappropriate antidiuretic hormone, pericarditis, myocarditis, and neurologic abnormalities. The chest radiograph may show fine interstitial reticulonodular infiltrates in patients. The diagnosis is based on clinical and epidemiologic features. Acute and convalescent serologic findings are required to confirm the diagnosis, but they are not helpful during the acute illness.

Other common causes of community-acquired pneumonia are *C. pneumoniae* and *Haemophilus influenzae*. Patients with comorbid conditions and those older than 65 years are also at risk for pneumonia from *Legionella* species, *Staphylococcus aureus*, and gram-negative organisms. Anaerobic infection should be considered when large amounts of oropharyngeal secretions are aspirated and in patients with chronic gingivitis.

Viral causes may encompass up to 65% of cases of community-acquired pneumonia in infants and preschool-age children (<5 years). The most common causes include rhinovirus, parainfluenza virus, adenovirus, enterovirus, coronavirus, human metapneumovirus (hMPV), and respiratory syncytial virus (RSV), the most commonly identified pathogen. HMPV is a recent addition to the long list of viral causes that mostly affect the upper and lower respiratory tracts in young children and older adults. It is common in late winter and early spring, when RSV is common, and co-infection with RSV causes severe bronchiolitis in children younger than 2 years of age.

In September 2012, a novel betacoronavirus was isolated from a man in Saudi Arabia. This Middle East respiratory syndrome coronavirus (MERS-CoV) causes severe acute pneumonia, acute respiratory distress syndrome (ARDS), and acute kidney injury. It has since been identified in Europe and other parts of the Middle East. Patients also may have gastrointestinal symptoms, pericarditis, and disseminated intravascular coagulation (DIC). Diagnosis is made by polymerase chain reaction (PCR) assay, and its infectivity is based on antagonizing endogenous interferon (IFN) production in cells. Treatment is supportive with mechanical ventilation or extracorporeal membrane oxygenation (ECMO), but exogenous interferon alfa-2b administration has reduced viral replication in vitro. MERS-CoV has a high mortality rate of 48%, with a median time of survival from clinical presentation of 14 days.

Diagnostic tests for community-acquired pneumonia include a chest radiograph and complete blood count. The role of routine sputum and blood cultures in this setting is controversial. Studies have advocated the use of C-reactive protein and procalcitonin as markers of the inflammatory response to bacterial infection. However, further studies are needed.

The recommended treatment for community-acquired pneumonia is a 7- to 10-day course of a macrolide antibiotic (i.e., erythromycin, clarithromycin, or azithromycin). Azithromycin has been linked to increased risk of cardiovascular death, especially in patients with a high baseline risk of cardiovascular disease. If there are comorbidities such as chronic heart or lung disease, an extended-spectrum fluoroquinolone (i.e., levofloxacin, moxifloxacin, or gemifloxacin) or a β -lactam (e.g., amoxicillin) plus a macrolide should be used. The choice of treatment should be influenced by local antibiotic resistance patterns.

An important decision in the care of community-acquired pneumonia is whether the patient requires hospital admission. This decision should take into consideration the known risk factors of increased mortality from pneumonia, including age 65 years or older; the presence of comorbidities such as diabetes mellitus, renal, or congestive heart failure; altered mental status; tachycardia (>125 beats per minute); tachypnea (>30 breaths per minute); high fever (>38.3° to 40° C); hypotension (systolic blood pressure <90 mm Hg); hypoxia (SaO₂ <90% or PaO₂ <60 mm Hg); multilobar involvement seen on the chest radiograph; and identification of high-risk pathogens such as gram-negative organisms and *S. aureus*.

For hospitalized patients, initial therapy for community-acquired pneumonia usually includes a cephalosporin such as ceftriaxone or cefuroxime with or without a macrolide. Antibiotic treatment should be given as soon as possible because the likelihood of death can increase even after a short delay (>8 hours) in receiving appropriate antibiotics. Sputum and blood cultures should be obtained before instituting antibiotic therapy.

 For a deeper discussion on this topic, please see Chapter 289, “*Streptococcus Pneumoniae* Infections,” and Chapter 317, “*Mycoplasma* Infection,” in Goldman-Cecil Medicine, 25th Edition.

Nosocomial Pneumonia

Nosocomial pneumonia is categorized as hospital-acquired pneumonia (HAP), ventilator-associated pneumonia (VAP), and health care–associated pneumonia (HCAP). HAP is pneumonia that occurs 48 hours or more after admission. VAP is a type of HAP that develops more than 48 to 72 hours after endotracheal intubation. HCAP is pneumonia that occurs in a nonhospitalized patient with extensive health care contact. This includes recent hospitalization, residence in a nursing home or other long-term care facility, and recent intravenous therapy. These patients should be considered at high risk for resistant organisms and therefore inappropriate for routine, empirical therapy for community-acquired pneumonia.

Nosocomial pneumonia is the second most common infection among hospitalized patients and the most common infection in the intensive care unit. The pathogenesis of nosocomial pneumonia is based on colonization of the oropharynx and stomach with

virulent pathogens and the subsequent aspiration of these organisms into the lower respiratory tract. Gastric colonization by gram-negative organisms is enhanced by neutralization of gastric acidity. In the first 5 days of hospitalization, *H. influenzae*, *S. pneumoniae*, and *S. aureus* are often isolated. After this time, *Pseudomonas aeruginosa*, *S. aureus*, anaerobic microbes, *Acinetobacter* species, and various gram-negative enteric bacilli often are the cause of pneumonia. This finding has important therapeutic implications because these organisms are more commonly associated with multidrug antibiotic resistance.

Treatment depends on combined chemotherapy with β -lactam antipseudomonal penicillin or cephalosporin, together with an aminoglycoside or a quinolone. Vancomycin is added if methicillin-resistant *S. aureus* is suspected. A more definitive identification of organisms and their sensitivity to antibiotics is often sought for these patients using more invasive measures, including endotracheal aspirate in intubated patients or flexible fiberoptic bronchoscopy. However, the best predictor of patient outcome with nosocomial pneumonia appears to be adequacy of the initial empirical antibiotic regimen.

 For a deeper discussion on this topic, please see Chapter 282, "Prevention and Control of Health Care–Associated Infections," in Goldman-Cecil Medicine, 25th Edition.

COMPLICATIONS OF PNEUMONIA

 Parapneumonic effusion is a neutrophilic exudative effusion adjacent to a lung with pneumonia (E-Fig. 21-2). It has exudative, fibrinopurulent, and organized stages. Depending on the stage, the effusion can resolve with antibiotics alone or may require drainage in addition to antibiotics. As pneumonia progresses, inflammatory edema leaks into the pleural space, first appearing as an uncomplicated effusion (i.e., exudative stage). At this point, the effusion can resolve with antibiotic therapy alone. During the fibrinopurulent and organized stages, the inflammatory process is marked by anaerobic metabolism, cytokine production, fibrin deposition in the pleural space, and thickening of the pleura.

There is no universally accepted definition of *empyema*, but most clinicians include all pleural effusions that are grossly purulent or contain microorganisms identified by a positive Gram stain or culture. Empyema must always be treated with pleural drainage, usually by a chest thoracostomy tube. Highly inflammatory parapneumonic effusions may behave as if they are infected, although microorganisms are never identified. Effusions described as "complicated" parapneumonic effusions are identified clinically by a pH of less than 7.1, a high serum lactate dehydrogenase (LDH) level, and a glucose level of less than 40 mg/dL. Complicated effusions usually require drainage in addition to antibiotic therapy.

The major risk factor for the development of lung abscess is aspiration resulting in a more indolent, polymicrobial infection, usually involving both aerobes and anaerobes. Conditions predisposing patients to aspiration, such as alcoholism, seizures, or stroke, are associated with an increased incidence of lung abscess. Poor dentition increases the anaerobic bacterial load in the mouth and the likelihood of infection after an aspiration event. In trials of empirical therapy for lung abscess, clindamycin showed superiority over penicillin, probably because the

incidence of penicillin-resistant anaerobes in lung abscesses is 15% to 20%. Antibiotics should be continued for 6 weeks, and drainage should be reserved for very large abscesses or failure to resolve with antibiotics.

MYCOBACTERIUM TUBERCULOSIS INFECTION

Infection with *M. tuberculosis*, an aerobic, nonmotile, acid-fast rod with niacin production, causes TB. In 2011, the World Health Organization (WHO) Global Surveillance and Monitoring Project estimated 8.7 million new cases of TB per year, 13% of whom are co-infected with HIV. Twelve million cases of the disease existed predominately in Asia and Africa. An estimated 1.4 million individuals die of TB each year, and the global case-fatality rate was 23%, with a rate of 50% in some African countries with high HIV rates. In the United States, TB increased at an alarming rate in the early 1990s as a result of the surge of HIV infection, drug abuse, inner-city poverty, and homelessness.

TB infection occurs when aerosolized, contaminated droplets (expectorated by a diseased person) are inhaled by another individual and droplet nuclei reach an alveolus. This is almost always a latent infection, called *latent tuberculosis infection* (LTBI). If the innate immune system of the host fails to eliminate the latent infection, the bacilli proliferate inside alveolar macrophages and kill the cells.

The infected macrophages produce cytokines and chemokines that attract other phagocytic cells, including monocytes, other alveolar macrophages, and neutrophils, which eventually form a nodular granulomatous structure called the *tubercle*. If the bacterial replication is not controlled, the tubercle enlarges, and the bacilli enter the local draining lymph nodes. This leads to lymphadenopathy, a characteristic manifestation of primary TB. The lesion produced by the expansion of the tubercle into the lung parenchyma and lymph node involvement is called the *Ghon complex*.

The bacilli continue to proliferate until an effective cell-mediated immune response develops, usually 2 to 6 weeks after infection. Failure by the host to mount an effective cell-mediated immune response and tissue repair leads to progressive lung injury. Bacterial products, tumor necrosis factor- α , reactive oxygen intermediates, reactive nitrogen intermediates, and the contents of cytotoxic cells (e.g., granzymes, perforin) can contribute to the development of caseating necrosis that characterizes a tuberculous granuloma (E-Fig. 21-3).

 If mycobacterial growth is unchecked, the bacilli may spread hematogenously to produce disseminated TB. Miliary TB is a disseminated form with lesions resembling millet seeds. Bacilli can also spread mechanically by erosion of the caseating lesions into the lung airways. It is at this point that the host becomes infectious to others.

Untreated disseminated TB has a mortality rate of 80%, with the remainder developing chronic disease or recovering spontaneously. The chronic disease is characterized by repeated episodes of spontaneous healing with fibrotic changes around the lesions and tissue breakdown. Healing by complete spontaneous eradication of the bacilli is rare.

Reactivation TB results when the persistent bacteria in a host suddenly proliferate. Only 5% to 10% of patients with no underlying medical problems who become infected develop

E-FIGURE 21-2 Bilateral lower lobe infiltrates with predominant right-sided pneumonia and parapneumonic effusion (*arrow*).

E-FIGURE 21-3 Necrotizing granuloma in a lung infected with *Mycobacterium tuberculosis*.

reactivation disease in their lifetimes. Although immunosuppression is clearly associated with reactivation TB, it is not clear what host factors specifically maintain the infection in a latent state for many years and what triggers the latent infection to become overt.

The diagnosis of latent TB infection depends on a positive tuberculin test result, which indicates previous infection but not necessarily active disease. The standard Mantoux test is an intradermal injection of 0.1 mL (5 tuberculin units) of purified protein derivative (PPD) tuberculin in the skin of the forearm. The injection site is evaluated 48 to 72 hours later. The reading is based on the diameter of the indurated or swollen area.

Patients are at high risk for active TB early after tuberculin conversion, and treatment is recommended for LTBI. QuantiFERON-TB Gold (QFT-G) has been approved by the U.S. Food and Drug Administration (FDA) for the diagnosis of LTBI and TB. It uses the enzyme-linked immunosorbent assay (ELISA) for two proteins in *M. tuberculosis* (i.e., ESAT6 and CFP10). Because these proteins are absent from all bacillus Calmette-Guérin (BCG) vaccine strains, this test does not produce false-positive results in people with previous BCG vaccinations. Other advantages to QFT-G are that the results are available within 24 hours without the need for a second visit and without reading biases or errors. However, QFT-G sensitivity for LTBI may be less than the tuberculin skin test (TST). It is also limited in differentiating infection associated with TB disease or LTBI, similar to the TST. Differentiation is based on suggestive symptoms, radiographs, and sputum samples. Negative QFT-G results cannot exclude the absence of infection in patients with TB signs and symptoms, patients who are HIV positive, or those who are severely immunosuppressed.

The risk for active disease is 5% within 2 years of exposure and another 5% per year thereafter. HIV-infected patients are an exception and have a 40% risk for active disease within several months of conversion. The current recommendations about what constitutes a positive PPD test result take into account the degree of clinical suspicion for LTBI (Table 21-2). Typical treatment of LTBI is 5 mg/kg/day to a maximum dose of 300 mg/day of isoniazid for 9 months (Adult).

Treatment of patients suspected of having active disease includes at least four drugs: 5 mg/kg/day of isoniazid, 10 mg/kg/day of rifampin; 15 to 20 mg/kg/day ethambutol; and 15 to 30 mg/kg/day of pyrazinamide. Treatment should be considered before a formal diagnosis is made. Factors suggesting active disease include exposure to active TB, pulmonary symptoms, and cavitary disease seen on imaging studies. If the diagnosis of TB is confirmed, the drugs are continued for 2 months, barring adverse reactions to drug therapy. After 2 months, the regimen can be tailored, depending on drug-sensitivity studies, and continued for another 4 months with at least two active drugs. Rates of drug-resistant TB are increased in certain populations (e.g., recent immigrants from high-prevalence TB areas, homeless people).

Resistance is detected in 9% of patients who have not received previous therapy and in 22.8% of those with prior treatment. In patients with drug-resistant TB, treatment should include at least three drugs that have not been administered before and to which the organism is susceptible in vitro. Treatment should continue

TABLE 21-2 PROPHYLAXIS AGAINST TUBERCULOSIS IN ADULTS

PPD TEST RESULT*	PROPHYLAXIS INDICATED REGARDLESS OF AGE	OTHER INDICATIONS FOR PROPHYLAXIS
≥5 mm	Close contacts recently diagnosed with TB HIV positive or HIV risk factors Fibrotic changes on chest radiograph Patients with organ transplants	No risk factors

● PNEUMOCYSTIS PNEUMONIA

Pneumocystis jirovecii pneumonia (PCP), formerly called *Pneumocystis carinii* pneumonia, is an opportunistic fungus that occurs mainly in malnourished, premature infants and in adults with hematologic malignancy undergoing chemotherapy in the era before acquired immunodeficiency syndrome (AIDS). However, its incidence rose significantly in the late 1980s and 1990s in patients with AIDS with low CD4⁺ lymphocyte counts (<250 cells/mm³).

Patients may complain of nonproductive cough, fever, dyspnea, and weight loss. The symptoms are slowly progressive over weeks in patients infected with HIV. Oral candidiasis, an increased serum LDH level, an increased A-a oxygen gradient, and a decreased CD4⁺ count are independent predictors of HIV-related PCP.

The chest radiograph may show diffuse, bilateral interstitial infiltrates, but the chest radiograph may be clear for up to 15% of patients (E-Fig. 21-4). High-resolution computed tomography (HRCT) is more sensitive, with a diagnostic accuracy of 94% for PCP. Other findings include isolated infiltrates, cavitary lesions, nodular masses, pneumothorax, and a miliary pattern. Hilar and mediastinal adenopathy are rare. Identifying the organism in sputum, which is effective in 60% to 85% of patients, helps with diagnosis. Bronchoscopy with bronchoalveolar lavage can increase the yield (86%), especially if a transbronchial biopsy is included (98% to 100%).

Prophylaxis can be provided by oral sulfamethoxazole-trimethoprim or aerosolized pentamidine. For pneumonia, the

E-FIGURE 21-4 Bilateral diffuse infiltrates.

therapy of choice is sulfamethoxazole-trimethoprim. However, significant adverse effects, including leukopenia, nausea, vomiting, and elevation of liver transaminase levels, are associated with this therapy. Intravenous pentamidine is a reasonable alternative to sulfamethoxazole-trimethoprim, but this therapy may be complicated by hypoglycemia. Less toxic drug regimens are available (e.g., trimethoprim and dapson, clindamycin and primaquine), but they are recommended only after failure of other medications. Corticosteroids should be considered in patients with severe disease as demonstrated by significant hypoxemia (e.g., PaO₂ <70 mm Hg). Corticosteroids decrease the likelihood of progression to respiratory failure.

 For a deeper discussion on this topic, please see Chapter 341, "Pneumocystis Pneumonia," in Goldman-Cecil Medicine, 25th Edition.

PROSPECTUS FOR THE FUTURE

Lung infections cause high morbidity and mortality rates in the community and in health care settings. A significant portion of these infections affects the extremes of age—young children and older adults. The judicious use of antimicrobial agents helps to prevent emergence of drug resistance. Continued efforts are needed to reinforce vaccination against infectious agents, including influenza and *S. pneumoniae*.

Co-infection with HIV and TB are significant problems in Africa, where effective HIV therapy is less available. This was highlighted by the identification of extensively drug-resistant TB (XDR-TB), which is caused by a strain of *M. tuberculosis* that is resistant to many available antimycobacterial agents and is difficult to cure. The potential adverse effects of vaccinations are another area of concern.

New and devastating epidemic infections continue to be recognized. Examples include MERS-CoV and severe acute respiratory syndrome (SARS), a rapidly progressive respiratory illness identified in the Guangdong province of China, Hong Kong, Vietnam, Singapore, and Canada.

There have been four influenza pandemics during the past century, each caused by a novel influenza virus and recently caused by viruses containing components of previous human and avian influenza viruses. Estimates of potential global mortality related to pandemic avian influenza are as high as 62 million deaths, and there is no specific treatment available. In 2009, the H1N1 ("swine") influenza virus emerged in Mexico. It has spread

worldwide and has been designated a pandemic by the WHO. At least initially, H1N1 had a relatively low mortality rate, but it may mutate to produce more severe disease in humans. The most recent outbreak of avian influenza A H7N9 in 2013 was limited to China, and most infected patients reported contact with poultry with no evidence of sustained human-to-human transmission.

PCR assay of 16S rRNA genes may provide species-specific signature sequences useful for bacteria identification. The dysbiosis hypothesis states that alterations to microbial communities in terms of structure and stability may result in human disease. Pertinent to the lung, which was previously thought to be sterile, 16S rRNA gene sequencing provides a glimpse into the normal respiratory microbiome. Based on changes in these normal microbial communities, the cause, identification, and management of various diseases may be inferred.

Essentials in Critical Care Medicine

Narendran Selvakumar, Brian Casserly, and Sharon Rounds

INTRODUCTION

Critical care medicine has evolved dramatically with development of new technologies, and clinical trials have established standards for the management of the critically ill. Since the poliomyelitis epidemic in the 1950s, intensive care units have proved beneficial in treating acute, reversible disorders. However, because of the innovative nature of the technology used and the need for close monitoring and intensive management, the delivery of critical care medicine is expensive, accounting for up to 30% of total hospital costs.

Patients in intensive care units (ICUs) are a heterogeneous population treated for diverse conditions ranging from septic shock and respiratory failure to diabetic ketoacidosis and upper gastrointestinal bleeding. This chapter discusses a few of the most common conditions encountered in the ICU setting. Topics include acute respiratory failure and mechanical ventilation, acute lung injury, and shock.

ACUTE RESPIRATORY FAILURE

Acute respiratory failure results when the lung can no longer accomplish adequate gas exchange, a condition that is fatal if left untreated. Hypoxemic respiratory failure refers to respiratory failure associated with failure to oxygenate (type 1), whereas hypercarbic respiratory failure is the failure to ventilate (type 2). These disorders result from alterations in the arterial partial pressures of oxygen (P_{aO_2}) and carbon dioxide (P_{aCO_2}), respectively.

Type 1 respiratory failure is hypoxia without hypercarbia that may result from interstitial lung diseases (e.g., pneumonia, emphysema), parenchymal diseases due to ventilation-perfusion (\dot{V}/\dot{Q}) mismatch or diseases of vasculature such as pulmonary embolism. Type 2 respiratory failure is the result of inadequate ventilation from various causes, including airway diseases, decreased respiratory drive, and disorders of the chest wall. Inadequate ventilation results in hypoxia and hypercarbia.

The values of P_{aO_2} and P_{aCO_2} that define respiratory failure are somewhat arbitrary, but respiratory compromise is usually evident when the P_{aO_2} is less than 60 mm Hg or the P_{aCO_2} is higher than 45 mm Hg. These values are not synonymous with the need for mechanical ventilation, and they do not preclude the need for mechanical ventilation.

The management of respiratory failure depends on the clinical presentation. Patients with respiratory failure who are awake, cooperative, and hemodynamically stable may tolerate aggressive

respiratory therapy without intubation and mechanical ventilation, as long as gas exchange and overall status are continually monitored. Examples include patients with chronic obstructive pulmonary disease (COPD) who can tolerate P_{aCO_2} levels as high as 85 mm Hg without severe respiratory acidosis. In contrast, patients in respiratory failure with evidence of severe respiratory distress (e.g., respiratory rate >30 breaths/min), mental deterioration (e.g., impaired judgment, confusion, hallucinations, somnolence), or hemodynamic instability (e.g., bradyarrhythmias, tachyarrhythmias, hypotension) usually require intubation and mechanical ventilation. In the latter circumstances, waiting for arterial blood gas determinations is unnecessary and may dangerously delay therapy. Although arterial blood gas evaluation is crucial when determining the need for mechanical ventilation in the patient with respiratory failure, the patient's clinical status ultimately dictates the course of action.

For a deeper discussion on this topic, please see Chapter 104, "Acute Respiratory Failure," in Goldman-Cecil Medicine, 25th Edition.

MECHANICAL VENTILATION

Modern mechanical ventilation is positive-pressure ventilation. Air is forced into the central airways, increasing central airway pressure. Air follows the pressure gradient from the central airways to the alveoli, inflating the lungs. As the lungs inflate and the device stops forcing air into the central airways, the intra-alveolar pressure increases, and central airway pressure decreases. Exhalation occurs when the air follows the newly reversed pressure gradient from the alveoli to the central airways.

The principal benefits of mechanical ventilation during respiratory failure are improved gas exchange and decreased work of breathing. Mechanical ventilation improves gas exchange by improving \dot{V}/\dot{Q} matching. Improved matching of the \dot{V}/\dot{Q} ratio is primarily a consequence of decreased physiologic shunting. Altered lung mechanics (e.g., increased airway resistance, decreased compliance) and increased respiratory demand (e.g., metabolic acidosis) increase the work of breathing. The ventilatory muscles and diaphragm can tire while trying to maintain the elevated work of breathing, resulting in respiratory failure. Mechanical ventilation can alleviate some or all of the increased work of breathing, allowing recovery of fatigued ventilatory muscles. Deteriorating gas exchange, unresponsive to conservative measures, and respiratory distress are the most common

reasons for mechanical ventilation in patients with acute respiratory failure.

Immediate complications of mechanical ventilation include barotrauma causing pneumothorax, pneumomediastinum, or subcutaneous emphysema. Atrophy of the diaphragm and impairment of mucociliary motility may also occur.

Noninvasive Mechanical Ventilation

Although intubation and mechanical ventilation are usually the preferred options in respiratory failure that is considered reversible, noninvasive positive-pressure ventilation (NPPV) is useful in selected patients. NPPV is ventilation delivered through a noninvasive interface (i.e., nasal mask, face mask, or nasal plugs), rather than through an endotracheal tube or tracheostomy. Selecting patients for NPPV requires careful consideration of its indications and contraindications. A trial of NPPV is worthwhile in patients with acute cardiogenic pulmonary edema or hypercapnic respiratory failure due to COPD who do not require emergent intubation and who do not have contraindications to NPPV.

Contraindications to NPPV include cardiac or respiratory arrest; inability to cooperate, protect the airway, or clear secretions; uncontrolled vomiting, hematemesis or hemoptysis; severely impaired consciousness; facial surgery, trauma, or deformity; anticipated prolonged duration of mechanical ventilation; and recent esophageal anastomosis. Early predictors of success include a significant correction in pH (i.e., respiratory acidosis) and a decrease in PaCO₂ of more than 8 mm Hg.

Invasive Mechanical Ventilation

After the decision to intubate is made, an experienced operator should expeditiously perform intubation. Complications of intubation include prolonged hypoxemia due to delays in the procedure, vomiting and aspiration of gastric contents, trauma to the vocal cords, bleeding, pneumothorax, cardiac arrhythmias, and cardiac arrest. Immediately after insertion, endotracheal location should be confirmed by assessing exhaled carbon dioxide. The endotracheal tube should be secured and its position assessed by examining for breath sounds, followed by chest radiography for confirmation. Direct visualization, such as by bronchoscopy, is occasionally needed for successful intubation.

Initial ventilator settings may vary, but orders should include ventilator mode, fraction of inspired oxygen (FIO₂) of 1.0 (or 100%), respiratory rate set, and tidal volume (discussed later). The adequacy of the ventilator settings is determined with arterial blood gas measurement and clinical evaluation of the patient. After the settings are adjusted to maintain relatively normal levels of arterial blood gases (i.e., pH of 7.3 to 7.45, PaO₂ >60 mm Hg, and PaCO₂ of 30 to 45 mm Hg), attention should be given to developing a maintenance plan to ensure adequate oxygenation and ventilation until the cause of the respiratory failure is treated and reversed. This plan should include assessment of the need for sedation, appropriate strategy of mechanical ventilation, supportive measures to achieve hemodynamic stability, nutritional assessment, and therapies targeting the initial injurious process that triggered the respiratory failure. Most patients require sedation to diminish discomfort and to decrease the work of breathing, but it should be administered carefully

because sedation is often accompanied by a decrease in blood pressure.

Commonly used modes of ventilation are determined by the duration of inspiration, which can be limited by volume, pressure, flow, or time. During volume-limited ventilation, inspiration ends after delivery of a preset tidal volume. Airway pressure varies during volume-limited ventilation and is related to respiratory system compliance, airway resistance, and tubing resistance. Assist control ventilation (ACV), continuous mandatory ventilation (CMV), and synchronized intermittent mandatory ventilation (SIMV) are examples of volume-limited modes of ventilation. CMV has a set rate and set tidal volume that do not allow spontaneous breathing by the patient. Because patient-ventilator asynchrony is a serious problem, CMV is rarely used. ACV is similar to CMV in that there is a set rate and set tidal volume, but this mode allows the patient to initiate machine-delivered breaths. When the machine senses that the patient is attempting to take a breath, it delivers the selected tidal volume. SIMV is similar to ACV in that a set rate and set tidal volume are selected. The patient is also able to generate a spontaneous breath. However, this spontaneous breath may have a very small tidal volume and thereby increase work of breathing. Consequently, this mode of mechanical ventilation is seldom used except when weaning patients from mechanical ventilation.

The pressure control mode of ventilation (PCV) uses machine breaths that are pressure cycled, not volume cycled. With PCV, the pressure to be used for each breath is ordered. If the patient attempts a spontaneous breath, a machine breath at the designated pressure is delivered. This may be helpful in limiting airway pressures in patients with bronchospasm or stiff lungs because it limits the risk for pneumothorax (i.e., barotrauma). Because tidal volumes may vary, PCV must be titrated carefully at the bedside to determine the proper pressure settings. The physician should order the desired minimal tidal volume.

Pressure support ventilation (PSV) is used only for spontaneously breathing patients. The inspiratory and expiratory pressures are selected, and there are no mandatory machine-delivered breaths. Patients find this to be a more comfortable mode of mechanical ventilation. However, PSV should be used only for patients with a stable respiratory drive (i.e., not sedated heavily) and stable lung compliance. PSV is typically used for patients who are weaning from mechanical ventilator support.

Pressure-regulated volume control, airway pressure–release ventilation, and high-frequency ventilation are newer modalities. They are increasingly used in clinical practice.

Settings

Numerous settings need to be considered when mechanical ventilation is initiated. They include tidal volume, respiratory rate, trigger mode and sensitivity, fraction of inspired oxygen, positive end-expiratory pressure (PEEP), flow rate, and flow pattern.

The appropriate initial tidal volume depends on numerous factors, most notably the disease for which the patient requires mechanical ventilation. The tidal volume can then be increased or decreased incrementally to achieve the desired pH and PaCO₂. Large tidal volumes can cause barotrauma or volutrauma, which

increases the risk of ventilator-associated lung injury. The tidal volume should not be increased without considering its effects on airway pressure or the likelihood of ventilator-induced lung injury. In acute respiratory distress syndrome (ARDS), tidal volumes of about 6 mL/kg of ideal body weight are associated with improved mortality (level I evidence).

An optimal method for setting the respiratory rate has not been determined. After the tidal volume has been established, the respiratory rate can be incrementally increased or decreased to achieve the desired pH and PaCO₂ while monitoring auto-PEEP. Patients who are breathing spontaneously set their own respiratory rates in all modes of ventilation except CMV.

The lowest possible fraction of inspired oxygen (FIO₂) necessary to meet oxygenation goals should be used. This decreases the likelihood that adverse consequences of supplemental oxygen, such as absorption atelectasis, accentuation of hypercapnia, airway injury, and parenchymal lung injury, will develop.

PEEP usually is added to prevent end-expiratory alveolar collapse. This can improve \dot{V}/Q matching and arterial oxygenation, and it allows reduction in FIO₂, reducing the risk for oxygen toxicity. However, elevated levels of applied PEEP can have adverse consequences, such as reduced preload (i.e., decreased cardiac output), elevated plateau airway pressure (i.e., increased risk of barotrauma), and impaired cerebral venous outflow (i.e., increased intracranial pressure). The optimal PEEP value enhances oxygenation without lung hyperinflation and decreased blood pressure.

Respiratory therapists typically adjust the inspiratory flow rate, flow pattern, and amount of negative pressure required to trigger a mechanical ventilator breath. If these ventilator settings are not adjusted with due consideration of the patient's respiratory mechanics, two common problems can occur: asynchrony and auto-PEEP.

Patient-ventilator asynchrony occurs if the phases of breaths delivered by the ventilator do not match the breathing pattern of the patient. This can lead to dyspnea, increased work of breathing, and prolonged duration of mechanical ventilation. It is detected by careful observation of the patient and examination of the ventilator waveforms. The abnormality that is most readily apparent is failure of the ventilator to trigger a breath when the patient makes an inspiratory effort.

Auto-PEEP is usually seen when patients do not fully empty their lungs during expiration before the initiation of the next breath. This is called *stacking breaths* or *generating auto-PEEP*. It is particularly worrisome in patients who have exacerbations of COPD or status asthmaticus requiring mechanical ventilation. In ventilated patients, auto-PEEP may cause barotrauma or hemodynamic collapse because of high intrathoracic pressures that prevent blood return to the right ventricle.

Weaning from Mechanical Ventilation

The complications of endotracheal intubation and mechanical ventilation include barotrauma, volutrauma (i.e., acute lung injury caused by high tidal volumes), and ventilator-associated pneumonia. Weaning from mechanical ventilation should be considered on a daily basis, particularly when the original insult that caused respiratory failure has improved. Weaning is most

likely to be successful in the awake and cooperative patient without respiratory or hemodynamic instability. Weaning is usually not attempted if requirements for oxygen supplementation remain high (FIO₂ > 0.5).

Conventional parameters that determine whether weaning is possible include negative inspiratory force, vital capacity, tidal volume, respiratory rate, and minute ventilation (Table 22-1). However, the strength of these parameters lies in the ability to predict failure to wean rather than in the ability to predict successful spontaneous breathing. A better way to assess weaning capability is to engage the patient in a short weaning trial during which support from the ventilator is diminished. Another strategy is to decrease the pressure generated by the ventilator during a trial of continuous positive airway pressure (CPAP). The patient is monitored for signs of distress or hemodynamic instability, and arterial blood gas levels are measured to determine the effectiveness of spontaneous ventilation. If the patient tolerates the trial, extubation may be indicated, depending on the patient's clinical status, ability to protect the airway, and underlying medical condition.

If the patient fails the weaning trial, attempts should be made to identify the factors responsible for the failure to wean. For very sick patients, all obvious contributory factors might have been identified and corrected, but the patient still requires a more prolonged weaning trial before extubation. The first of two recommended weaning strategies is to engage the patient in spontaneous ventilation trials without positive pressure for 1 hour once or twice each day, with total ventilatory support between trials usually supplied by ACV or PCV. The length of the spontaneous breathing trials can be progressively increased until the patient no longer requires mechanical support. The second strategy uses PSV. The inspiratory pressure is progressively decreased until the patient can breathe spontaneously without ventilatory support.

Both strategies appear to be equally effective, although weaning through PSV may be preferred in patients with chronic lung disease who have been mechanically ventilated for prolonged periods. For patients with prolonged mechanical ventilation, studies have shown that early tracheostomy is beneficial for weaning purposes and facilitates trials of unassisted breathing exercises because it can be easily and repeatedly removed (level II-1 evidence).

 For a deeper discussion on this topic, please see Chapter 105, "Mechanical Ventilation," in Goldman-Cecil Medicine, 25th Edition.

TABLE 22-1 CONVENTIONAL WEANING PARAMETERS

PARAMETERS	WEANABLE VALUES	NORMAL VALUES
NIF (cm H ₂ O)	≤20	≤50
VC (mL/kg)	>10	>65-75
V _T (mL/kg)	<5	>5-7
RR (breaths/min)	<32	12-20
V _E (L/min)	>10	>10
RSBI (RR/V _T)	<105	<40

NIF, Negative inspiratory force; RR, respiratory rate; RSBI, rapid shallow breathing index; VC, vital capacity; V_E, minute ventilation; V_T, tidal volume.

ACUTE LUNG INJURY

Acute lung injury in its most severe form is called *acute respiratory distress syndrome* (ARDS). It typically manifests with dyspnea, cyanosis, tachypnea, tachycardia, diaphoresis, and diffuse crackles detected on examination. ARDS is characterized by increased permeability of the alveolar-capillary membrane, leading to flooding of the alveolar spaces with proteinaceous edema fluid. It is defined by clinical measures of the severity of lung dysfunction (e.g., PaO₂/FIO₂ ratio).

Based on the 2012 revised Berlin definition of ARDS, the severity can be separated into mild, moderate, and severe forms. Mild ARDS requires the PaO₂/FIO₂ ratio to be between 200 and 300 mm Hg on ventilator settings (PEEP or CPAP ≥5 cm H₂O). Moderate or severe ARDS occurs when the PaO₂/FIO₂ ratio is between 100 and 200 mm Hg or 100 mm Hg or less on ventilator settings (PEEP or CPAP ≥5 cm H₂O). Respiratory failure must not be caused by cardiac failure or fluid overload; bilateral opacities representing pulmonary edema on the chest radiograph or CT must be evident; and respiratory symptoms must be of sudden onset due to a known clinical insult (<1 week). Additional criteria include exclusion of cardiogenic pulmonary edema and other causes of acute hypoxemic respiratory failure such as idiopathic pulmonary fibrosis, chronic interstitial lung disease, and diffuse alveolar hemorrhage.

ARDS is triggered by direct injury to the lung, as observed in aspiration pneumonia, smoke inhalation, and near-drowning, or by systemic injury, such as trauma, surgery, sepsis, burns, long bone fractures, pancreatitis, uremia, transfusion therapy, shock, drug intoxication, and cardiopulmonary bypass. About 150,000 cases of ARDS are reported each year in the United States, and aspiration pneumonia and sepsis are the most common associated conditions. The morbidity rate associated with ARDS is high, and 30% to 50% of patients die.

ARDS is the pulmonary manifestation of a systemic disorder that triggers a dysregulated inflammatory response. Uncontrolled inflammation injures the pulmonary vascular endothelium, resulting in increased permeability and allowing extravasation of proteinaceous edema fluid from the intravascular space and its accumulation in the lung interstitium and alveolar spaces (E-Fig. 22-1). Injury to the lung epithelium decreases absorption of water from the alveolar space and causes secretion of abnormal or inadequate quantities of surfactant.

ARDS is often referred to as noncardiogenic or increased permeability pulmonary edema. In the lung, these processes cause right-to-left intrapulmonary shunting of blood that results in refractory hypoxemia and decreased lung compliance that increases the work of breathing. The chest radiograph reveals diffuse bilateral alveolar infiltrates (E-Fig. 22-2). Failure of other organs occurs frequently, and multiorgan failure is common, especially in the setting of sepsis.

Histologically, ARDS is characterized by diffuse alveolar damage with hyaline membranes (E-Fig. 22-3). The damage is further exaggerated by reductions in the quantity and quality of the synthesized surfactant, leading to atelectasis. After a few days, the tissue shows hyperplasia of type II pneumocytes (E-Fig. 22-4) and deposition of connective tissue resulting in fibrosis. These events can be worsened by mechanical

ventilation through high tidal volumes, hyperdistention, and hyperoxia.

The diagnosis of ARDS should be considered in patients with a predisposing condition (e.g., sepsis), bilateral pulmonary infiltrates on the chest radiograph, and refractory hypoxemia (i.e., usually a PaO₂/FIO₂ ratio of 200 mm Hg or less) in the absence of significant cardiac dysfunction. Treatment of ARDS relies on supportive measures directed at eradicating the triggering event, sustaining the cardiovascular system, providing nutrition, and avoiding fluid overload. The Fluid and Catheter Treatment Trial (FACTT) conducted by the National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network showed that conservative fluid strategy resulted in more ventilator-free (2.5 days) and ICU-free days (2.2 days) than a more liberal fluid management approach (level I evidence). A ventilatory management strategy delivering low tidal volumes (about 6 mL/kg of body weight) increased survival (level I).

Advances in extracorporeal membrane oxygenation (ECMO) and pumpless extracorporeal lung assist (PECLA) have been reported, questioning the previous failures of these devices in patients with acute lung injury. The CESAR trial, which compared conventional ventilatory support with ECMO for severe respiratory failure, showed a significant improvement in survival with decreased disability at 6 months for the patients receiving ECMO (level I evidence). ECMO improved mortality for younger patients with H1N1-induced ARDS (level II-2). Several observational and uncontrolled clinical trials have shown similar improvements in survival rates. However, hemolysis and anticoagulation complications have restricted the use of ECMO.

High-frequency oscillatory ventilation (HFOV) has also been tried in patients with moderate to severe ARDS, but the mortality rate was not reduced, and there were worse outcomes than with conventional positive-pressure ventilation. Corticosteroids, surfactant replacement, and extracorporeal oxygenation have not proved beneficial and are not recommended. Oxygenation can be improved by PEEP and prone ventilation, but these interventions do not improve mortality rates. There was no difference in the 60-day mortality rate or improvement in ventilator-free days between initial trophic and full enteral feeding (EDEN trial, level I evidence). Early and late enteral feeding also showed no difference in mortality rates. Antioxidants, omega-3 fatty acids, and γ -linolenic acid did not improve clinical outcomes in patients with acute lung injury. Because there is no available therapy that lessens acute lung injury or hastens repair, the key to care of patients with ARDS is meticulous supportive care and avoidance of complications such as ventilator-associated pneumonia or catheter-related sepsis.

The lung injury prediction score (LIPS) encompasses various predisposing conditions and risk modifiers that have been found useful as a screening tool (negative predictive value -0.97) in clinical trials (level A evidence). As a result, such prognostic measures in identifying patients at risk of acute lung injury or ARDS on admission may lead to interventions that prevent disease progression or allow for close monitoring of patients for disease progression.

Most patients who survive ARDS do not have significant pulmonary function abnormalities in 12 months. The most common

E-FIGURE 22-1 Alveolar edema and acute and chronic inflammation in acute respiratory distress syndrome.

long-term complications in survivors are neuromuscular and psychosocial (level A evidence).

SHOCK

Shock is systemic organ hypoperfusion, usually caused by hypotension, that leads to cell injury and death. Four classifications are provided: cardiogenic shock (i.e., decreased cardiac output as a result of dysfunction), hypovolemic shock (i.e., decreased intravascular volume), septic or redistributive shock (i.e., decreased systemic vascular resistance), and obstructive shock (i.e., decreased cardiac output as a result of obstruction to flow). Anaphylactic shock caused by allergic reaction to a drug or a related insult is not discussed in this textbook.

For a deeper discussion on this topic, please see Chapter 106, "Approach to the Patient with Shock," 107, "Cardiogenic Shock," and 108, "Shock Syndromes Related to Sepsis," in Goldman-Cecil Medicine, 25th Edition.

When encountering a patient in shock, the strategy is to gain vascular access quickly and to replace volume aggressively while making a careful assessment of the situation. This strategy is particularly appropriate when shock is thought to result from hypovolemia or sepsis. In the case of cardiogenic shock, strategies designed to improve cardiac function should be implemented, including administration of inotropic drugs or, in severe and unresponsive cases, cardiac bypass or cardiac-assist devices. In the case of severe hypovolemia, administration of saline is usually sufficient. Fluid replacement, antibiotic therapy, and drainage of infected spaces are paramount in treating sepsis.

Obstructive shock is the result of obstruction to blood flow, as observed in massive pulmonary embolism or saddle embolus lodged at the bifurcation of the right and left pulmonary arteries. In this setting, it is important to relieve the obstruction mechanically or through other methods (e.g., thrombolysis) or support the patient's circulation until the obstruction subsides.

The management of shock entails monitoring of blood pressure and organ perfusion. A central venous line facilitates the delivery of fluids and assessment of central volume status, and an arterial line allows accurate monitoring of blood pressure. Although the placement of a pulmonary artery catheter (i.e., Swan-Ganz catheter) showed favorable results in initial trials for a selected group of patients, recent studies have shown no beneficial effects (e.g., FACTT study, level I evidence). The catheter allows direct assessment of pressures in the right atrium, right ventricle, and pulmonary artery; measurement of the pulmonary capillary wedge pressure; and assessment of cardiac output.

Concerns have been raised about the true usefulness and benefit-risk ratio associated with catheter placement. Pulmonary artery catheters have been shown to increase complications, primarily nonlethal cardiac dysrhythmias, and to be poor predictors of fluid responsiveness in sepsis. The central venous oxygen saturation ($ScvO_2$) measured from a central venous catheter was shown to be similar to the mixed venous oxygen saturation ($S\bar{v}O_2$). Significant expertise is required for the insertion of these catheters and for adequate interpretation of the data generated.

For a deeper discussion on this topic, please see Chapters 106, "Approach to the Patient with Shock," and 107, "Cardiogenic Shock," in Goldman-Cecil Medicine, 25th Edition.

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

The systemic inflammatory response syndrome (SIRS) is a constellation of clinical signs and symptoms triggered by the host response to diverse insults. The most common cause of SIRS is infection, which is called *sepsis*, but SIRS also can be triggered by noninfectious disorders such as pancreatitis and drug intoxication.

The diagnosis of SIRS requires at least two of the following criteria: temperature higher than 38°C or less than 36°C; tachycardia greater than 90 beats per minute; tachypnea greater than 20 breaths per minute; $Paco_2$ less than 32 mm Hg; and white blood cell count greater than 12,000 cells/ μ L or less than 4000 cells/ μ L. This systemic response may result in dysfunction of many organs, including the lung, liver, kidneys, heart, and central nervous system, which is called *multiple-organ dysfunction syndrome* or *multiple-organ system failure*. The prognosis worsens as more organs become involved, with mortality rates ranging from 30% for less severe cases to more than 90% for five or more failing organs. Treatment includes aggressive fluid replacement or vasopressors to improve blood pressure and prompt administration of antibiotics after blood and other cultures have been obtained.

For a deeper discussion on this topic, please see Chapter 108, "Shock Syndromes Related to Sepsis," in Goldman-Cecil Medicine, 25th Edition.

NOXIOUS GASES, FUMES, AND SMOKE INHALATION

Inhalation of certain gases and fumes may cause asphyxia or cellular and metabolic injury (Table 22-2). Carbon monoxide poisoning is a common and frequently unsuspected cause of inhalational injury. It results in tissue hypoxia by competitively displacing oxygen from hemoglobin. Affinity of carbon monoxide for hemoglobin is about 250 times greater than that of oxygen.

The correlation between carbon monoxide levels and symptoms is weak, but patients with levels greater than 30% are usually

TABLE 22-2 TOXIC GASES AND FUMES

INJURIES	AGENTS	OCCUPATIONAL EXPOSURES
Simple asphyxia	Carbon dioxide	Mining, foundries
	Nitrogen	Mining, diving
	Methane	Mining
Cellular hypoxia and oxygen transport	Carbon monoxide	Mining, combustion in closed spaces
	Cyanide	Smoke inhalation
Direct tissue injury	Hydrogen sulfide	Petroleum refining
	Ammonia	Fertilizer, cleaning agents
	Chlorine	Bleaches, swimming pools
	Nitrogen dioxide	Farming, fertilizer, combustion in closed spaces
	Phosgene	Welding, paint removal
	Cadmium, mercury	Welding

symptomatic. Symptoms may range from confusion or fatigue to nausea, headache, tachycardia, and profound coma. The diagnosis is based on clinical grounds and supported by laboratory data. Carbon monoxide intoxication can occur from vehicle exhaust in enclosed automobiles, methylene chloride–based paint strippers, and by exposure to kerosene heaters or charcoal fires in closed spaces.

In suggested cases, arterial blood gas levels should be obtained with measured (not calculated) hemoglobin-oxygen saturation. A carbon monoxide level should be measured in patients with a measured systemic arterial oxygen saturation (SaO_2) lower than the calculated SaO_2 obtained from the arterial oxygen tension. Carbon monoxide does not alter PaO_2 , which is a measure of the partial pressure of oxygen dissolved in plasma. Treatment of carbon monoxide poisoning is breathing 100% oxygen. Hyperbaric oxygen may be useful, but this therapy may not be readily available.

Inhalation of caustic substances such as ammonia, chlorine, and hydrogen fluoride causes acute symptoms of eye and upper airway inflammation. Pain, lacrimation, rhinorrhea, and upper airway symptoms usually prompt the individual to flee the environment. Inhalation of nitrogen dioxide (i.e., silo filler's disease) occurs in farmers who work in silos where fermentation of grain produces large quantities of the gas. Most patients recover without sequelae, but a few may develop bronchiolitis obliterans, an irreversible obstruction of small airways.

Metal fume fever causes influenza-like symptoms as a result of the inhalation of metal oxides generated by welding. Inhalation of platinum, formalin, and isocyanates may precipitate asthma. Pneumonitis can be induced by high-intensity inhalation of cadmium and mercury vapors.

Smoke inhalation may cause direct thermal injury that is usually confined to the upper airways, but it may also produce

injury to the lower airways if exposure to sufficient steam occurs as a result of the high thermal content of water. Laryngeal edema, airway inflammation, and mucus can lead to airway obstruction, which requires intubation. Anoxia occurs from consumption of oxygen by fire and from cytotoxic injury from gases such as carbon monoxide, cyanide, and oxidants liberated during combustion. The combustion of natural and synthetic polymers often produces aldehydes, acetaldehyde, and acrolein, which also have a high irritant potential.

Cyanide poisoning uncouples oxygen from energy production by binding to cytochrome a, a_3 (i.e., cytochrome c oxidase), preventing electron transfer to oxygen, and it requires prompt treatment with 100% oxygen and sodium thiosulfate. Sodium thiosulfate facilitates the conversion of cyanide to thiocyanate. Recently, the U.S. Food and Drug Administration (FDA) has also approved the use of hydroxocobalamin, which combines with cyanide to form cyanocobalamin (vitamin B_{12}).

The treatment of inhalation injuries is supportive, with close attention to the airway. Oxygen should be provided, and continuous monitoring of cardiac and hemodynamic status is necessary. Sometimes, intubation and mechanical ventilation are needed to overcome airway obstruction and the development of respiratory failure.

For a deeper discussion on this topic, please see Chapter 110, "Acute Poisoning," in Goldman-Cecil Medicine, 25th Edition.

DRUG OVERDOSES

Drug overdoses are common causes of admission to the ICU. The presenting complaints and management of the more common overdoses that result in medical emergencies are summarized in Table 22-3.

TABLE 22-3 COMMON DRUG OVERDOSES

DRUG OVERDOSE	CLINICAL SYNDROME	TREATMENT
Acetaminophen (paracetamol)	0.5-24 hr: nausea, vomiting 24-72 hr: nausea, vomiting, right upper quadrant pain; abnormal liver function tests and prothrombin time 72-96 hr: liver necrosis, coagulation, defects, jaundice, renal failure, hepatic encephalopathy 4 days-2 wk: resolution of liver dysfunction	Elimination: gastric lavage (if <1 hr after ingestion); activated charcoal (if <4 hr after ingestion); both longer if sustained-release product Treatment: <i>N</i> -acetylcysteine for toxic ingestion
Amphetamines	Hypertension, tachycardia, arrhythmias, myocardial infarction, vasospasm, seizures, paranoid psychosis, diaphoresis, tachypnea	Elimination: activated charcoal for oral ingestion Agitation or seizures: benzodiazepines Hypertension: control agitation, α -antagonists (phentolamine), vasodilators (nitroglycerin, nitroprusside, nifedipine) Hyperthermia: control agitation, external cooling
Iron	0.5-6 hr: nausea, vomiting, gastrointestinal discomfort, gastrointestinal bleed, drowsiness, hypoglycemia, hypotension 6-24 hr: latency, quiescence (may not occur in severe ingestions) 6-48 hr: shock, coma, seizures, coagulopathy, acidosis, cardiac failure 2-7 days: hepatotoxicity, coagulopathy, metabolic acidosis, renal insufficiency 1-8 wk: gastrointestinal disorders, achlorhydria	Elimination: gastric lavage and/or whole bowel irrigation with polyethylene glycol electrolyte solution, especially after ingestion of tablets containing radiopaque iodinated dye for kidney-ureter-bladder radiography Shock: intravenous fluids and blood (for hemorrhage); vasopressors if needed Antidote: deferoxamine to chelate iron, when iron levels >500 $\mu\text{g}/\text{dL}$ or severe ingestion suspected
Tricyclic antidepressants	Wide-complex tachyarrhythmias, hypotension, seizures	Tachyarrhythmias: alkalinize blood (pH 7.5-7.55) with intravenous bicarbonate Seizures: benzodiazepines
Salicylate	Respiratory alkalosis (initially), metabolic acidosis (after substantial absorption), pulmonary edema, platelet dysfunction, nausea, vomiting, hearing loss, agitation, delirium	Hypotension: fluid resuscitation, vasopressors Elimination: activated charcoal, hemodialysis (for severe poisoning), alkalization of urine Agitation or delirium: alkalinize blood with intravenous bicarbonate

Neoplastic Disorders of the Lung

Lauren M. Catalano and Jason M. Aliotta

DEFINITION

Lung cancer is the leading cause of cancer death for men and women in the United States. An estimated 1.3 million people die worldwide of lung cancer each year. Lung cancer causes 28% of all cancer deaths in the United States, more than the next three most common cancers (i.e., colon, breast and prostate) combined.

Most lung cancers are classified as two major types: *small cell lung carcinoma* (SCLC) (E-Fig. 23-1) and *non-small cell lung carcinoma* (NSCLC). NSCLCs are more common and include squamous cell carcinoma (E-Fig. 23-2), adenocarcinoma (E-Fig. 23-3), and large cell carcinoma (E-Fig. 23-4). SCLCs account for less than 20% of all lung cancers.

EPIDEMIOLOGY

Smoking is the leading cause of lung cancer, a cause-effect relationship that was recognized as early as the 1940s. The risk of lung cancer is proportionate to cigarette pack-years smoked (i.e., packs per day multiplied by years smoked), with a peak incidence in the sixth and seventh decades. Compared with never-smokers, men who smoke are 23 times more likely and women 13 times more likely to develop lung cancer. Ex-smokers show a persistent risk of lung cancer throughout life.

Passive smoking is thought to be the cause of lung cancer for a significant percentage of nonsmokers who develop the disease. Nonsmokers who live with smokers have a more than 20% to 30% increased risk of developing lung cancer. However, nonsmokers do develop lung cancer that is thought to be unrelated to environmental tobacco exposure; the cause of this phenomenon is poorly understood.

Other risk factors for lung cancer include environmental hazards such as asbestos exposure. Tobacco smoking in the setting of asbestos exposure is thought to have a multiplicative effect on risk. Radon exposure, such as that seen in miners, also increases the risk of lung cancer by approximately 10%. Radon exposure in the home is less significant, but home radon testing is recommended and legally mandated in some states.

PATHOLOGY

The exact mechanisms by which risk factors promote lung cancer remain unclear, but if unopposed, they are likely to cause genetic abnormalities that promote oncogenic transformation of lung epithelial cells. Because of the inherent redundant repair mechanisms available to the lung, however, many genetic insults appear necessary to irreversibly mutate and activate genes such as the *RAS* gene family, *ERBB* gene family, *RBI*, *MYC*, *SRC*, suppressor

genes such as *CDKN1A* and *TP53*, and genes encoding growth factors such as gastrin-releasing peptide, insulin-like growth factor, and epidermal growth factor. Epidermal growth factor receptor mutations are prominent in nonsmokers who develop lung cancer and may indicate a unique molecular basis for lung cancer in those patients.

Non-Small Cell Lung Carcinomas

Squamous cell carcinomas arise from the epithelial layer of the bronchial wall as normal columnar epithelial cells undergo metaplasia, eventually being replaced by increasingly atypical squamous epithelial cells. A localized carcinoma, called *carcinoma in situ*, forms and later extends beyond the bronchial mucosa as it becomes invasive. Histologically, squamous cell carcinomas can be distinguished from other NSCLCs by the presence of keratinization, pearl formation, and intercellular bridging.

Adenocarcinomas can form glandlike structures and produce mucus. The tumor cells stain positive for carcinoembryonic antigen (CEA), mucin, and surfactant apoprotein. Slower-growing forms appear to grow and spread along preexisting alveolar walls.

Large cell carcinomas lack the glandular and squamous features typical of other NSCLCs and cytologic features typical of SCLCs. In this respect, it is considered a diagnosis of exclusion.

Small Cell Lung Carcinoma

Small cell carcinoma is strongly associated with cigarette smoking. Tumor cells are of pulmonary neuroendocrine cell origin. Released factors are often associated with paraneoplastic syndromes.

CLINICAL PRESENTATION

Patients may complain of mild cough, dyspnea, increased sputum production, chest pain, and weight loss. Hemoptysis may indicate local airway inflammation or erosion of the neoplasm into surrounding vascular structures. Localized pleuritic chest pain suggests pleural involvement or chest wall invasion (E-Fig. 23-5). Hoarseness is caused by involvement or compression of the left recurrent laryngeal nerve and suggests a mediastinal or hilar mass or significant lymphadenopathy. Dysphagia suggests esophageal involvement or compression by lymph nodes.

A pleural effusion is observed in 9% of patients, is often unilateral, and can be related to direct tumor involvement of the pleura or obstruction of lymph flow from the mediastinal nodes (E-Fig. 23-6). The superior vena cava is involved in less than 5% of patients, but obstruction may result in superior vena cava syndrome, which is characterized by edema of the face and upper

E-FIGURE 23-6 Massive malignant pleural effusion from lung cancer.

extremities due to impaired venous return. Despite its aesthetic and prognostic implications, its involvement typically does not represent a medical emergency.

The physical examination may be normal or may reveal changes in the lung, such as crackles (e.g., postobstructive pneumonia) (E-Fig. 23-7), inspiratory wheeze suggesting airway obstruction, or dullness to percussion as a result of underlying pleural effusion. Lymph node enlargement in the neck or axillary areas suggests metastatic disease (E-Fig. 23-8).

Lung cancers that occur in the apex of the chest and invade apical chest wall structures are known as *superior sulcus* or *Pancoast tumors* (E-Fig. 23-9). The classic description involves a syndrome of radicular-type pain or paresthesias radiating down the arm due to tumor erosion into the brachial plexus. Tumor erosion into the cervical sympathetic chain can result in Horner's syndrome, which is characterized by a triad of physical findings: ptosis, miosis, and anhidrosis over the face and forehead.

Paraneoplastic syndromes are usually neurologic syndromes that are rare and are elicited by a patient's own immune response to neoplastic processes, often originating in the lung. Neurologic symptoms develop over weeks and may include difficulties in walking or swallowing, loss of muscle tone, loss of fine motor coordination, slurred speech, memory loss, vision problems, dementia, sleep disturbances, seizures, and vertigo. Neurologic paraneoplastic syndromes include stiff-person syndrome, encephalomyelitis, cerebellar degeneration, neuromyotonia, and sensory neuropathy. Neuromuscular junction disorders can occur, as observed in the Lambert-Eaton myasthenic syndrome. Myopathies, electrolyte disturbances, and certain visual loss syndromes can also be manifestations of a paraneoplastic syndrome.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Non–Small Cell Lung Carcinomas

Between 60% and 80% of squamous cell carcinomas tend to be located in central airways (E-Fig. 23-10). The airway lumen may become obstructed, leading to collapse of the lung (i.e., atelectasis) or postobstructive pneumonia. Although necrosis and cavity formation may occur in any lung tumor, this feature is more common with squamous cell carcinomas. Because of their slow rate of growth, these tumors have the lowest propensity for metastasis of all types of lung cancer.

Adenocarcinomas represent the most common type of lung cancer and the most common type in nonsmokers (almost 20% of cases). Adenocarcinomas are most often found in the periphery of the lung (75%) (E-Fig. 23-11). This tumor is frequently associated with malignant pleural effusions (60%) and has a high propensity for distant metastasis.

Previously called *bronchoalveolar cell carcinomas*, it is now understood that these more insidious forms of adenocarcinoma likely exist as a spectrum of disease. In its most benign form, atypical adenomatous hyperplasia (AAH) exhibits mild to moderate nuclear atypia without stromal invasion. A stepwise progression of classification, including adenocarcinoma in situ (AIS), minimally invasive adenocarcinoma, and lepidic pattern adenocarcinoma, describes a gradual progression of invasion. This is the most common form of lung cancer found in

nonsmokers and young patients. It can develop as a lung infiltrate or as a solitary nodule, and it can be accompanied by excessive production of secretions.

Large cell carcinomas (giant cell and clear cell subtypes) frequently develop as a peripheral lesion and may be associated with pneumonitis and hilar adenopathy. Patients usually have cough and weight loss. Given the aggressive nature of these tumors, symptoms (e.g., bone pain) are often the consequence of metastatic disease.

Small Cell Lung Carcinomas

SCLC is strongly associated with cigarette smoking. SCLCs typically are found in perihilar locations, frequently originating in the main bronchi, and they often have associated lymphadenopathy (E-Fig. 23-12). These tumors metastasize rapidly, most commonly to the thoracic lymph nodes, bones, liver, adrenal glands, and brain. Approximately 70% of patients have metastatic disease at the time of clinical presentation.

Diagnostic Evaluation

Because lung cancer typically is diagnosed at an advanced stage, when cure is not possible, an effective strategy for detection of lung cancer at an early stage is desirable. Results from the National Lung Screening Trial, sponsored by the National Cancer Institute, have started to support the formation of lung cancer screening guidelines. This was a randomized trial that compared two ways of detecting lung cancer in smokers: low-dose helical computed tomography (CT) and standard chest radiography. More than 50,000 patients were enrolled in this study over a period of 2 years, with a follow-up time of 5 years. Subjects enrolled were between 55 and 74 years old and smoked for a minimum of 30 pack-years. Former smokers enrolled in this study had quit within the preceding 15 years. There was a 20% relative reduction in mortality from lung cancer with low-dose helical CT screening. However, formal recommendations have not been made for the application of these data to larger cohorts given the rate of false positives and concurrent increased rate of invasive procedures (with potential negative outcomes).

When a suspected lung cancer is identified, a tissue diagnosis is essential for most patients. If imaging reveals sites of suspected metastasis, the site of biopsy should be chosen to determine the greatest extent of spread or highest stage of the tumor to prevent patients from undergoing multiple invasive procedures. If the apparent tumor is confined to the chest, bronchoscopy (potentially with endoscopic ultrasound-guided lymph node biopsies) is appropriate for central masses, whereas transthoracic needle aspiration can be performed for more peripheral lesions. An identified pleural effusion should be sampled to assess for malignant cells. In some cases, if the pretest probability is very high that the lung lesion is a primary lung cancer and there is no imaging evidence of disease spread, direct referral for surgical resection may be appropriate. In these cases, equivocal biopsy results should not hamper attempts to remove the lesion. If patients are too debilitated to undergo treatment or insightfully refuse interventions, tissue diagnosis may be deferred with the intention of palliative measures.

After a lung cancer is diagnosed, staging is necessary to determine the treatment and prognosis. For NSCLCs, staging can

E-FIGURE 23-7 Postobstructive pneumonia.

determine whether the patient may benefit from surgical resection for curative intent or from other treatment modalities such as chemotherapy. Chest CT is useful to delineate the location and size of the primary tumor and to examine for involved mediastinal lymph nodes, pleural disease, and adrenal or liver metastases. However, CT has limited ability to distinguish benign versus malignant lymphadenopathy in the mediastinum. Positron emission tomography (PET) using 18-fluorodeoxyglucose (FDG) is more sensitive and specific than CT for the detection of mediastinal lymph node metastases and may detect unexpected metastases elsewhere in the body. Suspected mediastinal or extrathoracic metastases demonstrated by imaging should be confirmed with tissue sampling before determining whether a patient is an operative candidate. Although rare, multiple primary lung cancers can occur, especially in patients with many cancer risk factors.

Invasive techniques for staging of the mediastinal lymph nodes include endoscopic transbronchial needle aspiration, endoscopic ultrasound-guided needle aspiration, and mediastinoscopy. Mediastinoscopy is frequently performed to exclude mediastinal spread of disease in patients without definite imaging evidence of lymph node involvement before definitive resection of the lung cancer. Head CT with intravenous contrast or magnetic resonance imaging (MRI) is the preferred radiologic study if the clinical history or examination suggests brain metastasis. Bone scans are useful for the investigation of suspected bony metastases if there are corresponding clinical symptoms.

The increased use of CT scan for the work-up of other intrathoracic and extrathoracic conditions has led to a marked increase in the incidental diagnosis of solitary and multiple pulmonary nodules. These nodules may be described by their appearance: solid, partially solid, and ground glass. Radiographically, solid nodules demonstrate a soft tissue density. Ground-glass nodules represent alveolar wall inflammation or thickening, with partial air space filling. Radiographically, the nodules appear hazy but do not obscure underlying bronchial and vascular markings of the lung. Mixed nodules contain some combination of the two patterns. These incidental findings pose a conundrum for practitioners when evaluating patients without any other clinical symptoms who may or may not have a smoking history.

Current recommendations were created in 2005 by the Fleischner Society, a multidisciplinary panel of experts in lung cancer. These recommendations provide guidance for radiologic follow-up of incidentally encountered nodules. Patients with these findings are stratified as low risk (i.e., minimal or no history of smoking and other known risk factors) or high risk (i.e., history of smoking with other known risk factors). The recommendations state that nodules less than 4 mm in the greatest dimension require no follow-up in low-risk patients, and if they remain unchanged on a 12-month follow-up CT scan in high-risk patients, no additional scans are warranted. Nodules 4 to 6 mm in the greatest dimension in low-risk patients require a follow-up CT scan at 12 months, and if unchanged, no additional scans are warranted. However, high-risk patients should have a repeat CT scan 6 to 12 months after discovery and then at 18 to 24 months if the situation remains unchanged. This recommendation applies to low-risk patients with nodules between 6 and 8 mm in the greatest dimension. Closer follow-up is recommended for high-risk patients with 6- to 8-mm nodules and all patients with

nodules greater than 8 mm in diameter. These patients should have CT scans at 3 to 6, 9 to 12, and 24 months, respectively.

Ground-glass nodules 5 mm or larger seen on thin-slice (1-mm section) chest CT do not warrant further follow-up. Although multiple ground-glass nodules are less likely to represent a neoplastic process, they should be followed to ensure resolution. Ground-glass nodules larger than 5 mm in diameter that persist on a 3-month follow-up CT scan should be monitored by CT scans at 12, 24, and 36 months. If there has been no increase in size after 36 months of observation, follow-up CT scans can be discontinued. Mixed solid and ground-glass nodules that persist on a 3-month follow-up CT scan and have a solid component less than 5 mm in diameter should be followed in a similar fashion. However, nodules with a solid component of 5 mm or larger that persist on a 3-month follow-up CT scan should be biopsied or surgically resected. PET scanning is not helpful in characterizing ground-glass nodules because of the wide variation in radiotracer uptake (from nil to positive). The diagnostic yield of needle biopsy for these lesions varies because operator inexperience and sampling error can affect results.

TREATMENT

Evidence-based clinical practice guidelines for lung cancer were published by the American College of Chest Physicians (ACCP) in May 2013. These guidelines are based on a comprehensive review of the literature and systematic interpretation of the data to provide management recommendations in a graded fashion.

Management of lung cancer includes preventive strategies, early detection, and treatment. Of these, the most effective approach is prevention. Smoking prevention and cessation strategies are paramount. Individuals who are successful at quitting smoking have a lower long-term rate of lung cancer death than individuals who continue to smoke. Survival differences are seen as early as 5 to 10 years after removal of tobacco exposure. Although cancer risk remains higher in previous smokers than never-smokers, the survival benefit continues to increase as exposure becomes more remote. A diet rich in fruits and vegetables may protect against the development of lung cancer in smokers. Animal studies have suggested that antioxidants contained in these foods might block free radical-induced cell injury, preventing the development of various cancers. However, high-dose supplemental β -carotene, vitamin E, retinoids, and *N*-acetylcysteine should not be advocated for smokers and former smokers (grade 1A recommendation).

The treatment of lung cancer depends on the stage of disease at the time of presentation. The 7th edition of the International Staging System for Lung Cancer was proposed in 2009 by the International Association for the Study of Lung Cancer and accepted into use in January 2010. Neoplasms of the chest are classified by standardized tumor, node, metastasis (TNM) nomenclature that has been accepted throughout the field of oncology (Table 23-1). The Veterans Administration system of limited-stage versus extensive-stage disease (see Table 23-1) may be used in conjunction with the TNM staging system in the description of SCLC (grade 1B recommendation).

A timely, efficient, multidisciplinary approach using the expertise of a thoracic surgeon, medical and radiation oncologists, and a pulmonologist should be employed to evaluate patients with

TABLE 23-1 LUNG CANCER STAGING SYSTEMS

STAGE	DESCRIPTION
TUMOR, NODE, METASTASIS STAGING SYSTEM FOR NSCLC	
Primary Tumor (T)	
TX	Primary tumor cannot be assessed, or tumor proved by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor <3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)
T1a	Tumor <2 cm in greatest dimension
T1b	Tumor >2 cm but <3 cm in greatest dimension
T2	Tumor >3 cm but <7 cm or tumor with any of the following features (T2 tumors with these features are classified T2a if <5 cm): involves main bronchus, >2 cm distal to the carina or invades visceral pleura; associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T2a	Tumor >3 cm but <5 cm in greatest dimension
T2b	Tumor >5 cm but <7 cm in greatest dimension
T3	Tumor >7 cm or one that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; tumor in the main bronchus <2 cm distal to the carina but without involvement of the carina; associated atelectasis or obstructive pneumonitis of the entire lung; separate tumor nodule(s) in the same lobe
T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina; separate tumor nodule(s) in a different ipsilateral lobe
Nodal Involvement (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural/pericardial effusion
M1b	Distant metastasis
VALG STAGING SYSTEM	
Limited-stage disease (LD)	Tumor confined to the ipsilateral hemithorax and regional lymph nodes, including ipsilateral supraclavicular nodes; can be encompassed within a tolerable radiation therapy port
Extensive-stage disease (ED)	Tumor has spread beyond the boundaries of LD, including malignant pleural or pericardial effusions, contralateral hilar or supraclavicular involvement or distant metastases

lung cancer for surgical resection, regardless of age (grade 1C recommendation). The presurgical evaluation of patients with lung cancer involves staging, the determination of resectability, and the evaluation of lung function to determine pulmonary reserve. Given the high occurrence of comorbid conditions that increase the likelihood of an adverse perioperative cardiovascular event, a preoperative cardiologic evaluation may be warranted (grade 1C).

A comprehensive respiratory assessment can estimate the preoperative risk from underlying pulmonary disease, such as chronic obstructive pulmonary disease (COPD). Spirometry to ascertain pulmonary function (i.e., forced expiratory volume in 1 second [FEV₁]) is commonly used to assess the suitability of patients with lung cancer for surgery. Patients with an FEV₁ value greater than 2 L (for pneumonectomy), greater than 1.5 L (for lobectomy), or greater than 80% predicted have an average preoperative risk (grade 1C).

Measurement of the lung's carbon monoxide diffusion capacity (DLCO) is necessary for patients with an acceptable FEV₁ value but who have unexplained dyspnea on exertion or evidence

of interstitial lung disease on chest imaging. If the measured DLCO is greater than 80% predicted, the patient is still considered to have an average preoperative risk. Radionuclide perfusion scanning and cardiopulmonary exercise testing may be performed when spirometry and DLCO are borderline, conflicting, or otherwise difficult to interpret and apply to the patient's functional status (grade 1B recommendation).

Non-Small Cell Lung Carcinomas

Surgery is the only curative therapy for NSCLCs, and it is indicated for patients with stage I or II disease who are operative candidates (grade 1B recommendation). Lobectomy is considered superior to wedge resection (grade 1B). Pathologic stage IA or IB disease does not require additional therapies (grade 1B). Adjuvant chemotherapy is appropriate for patients with stage II or greater disease (grade 1A).

For patients with stage IIIA disease, the optimal treatment strategy remains unclear. These patients usually are not candidates for surgery or radiation therapy alone (grade 1A recommendation), and a treatment plan should be individualized in a

multidisciplinary setting. For stage IIIB disease, surgery may rarely be indicated for some T4N0-1M0 tumors. A malignant pleural effusion precludes resection. Combined and ideally concurrent chemotherapy and radiation therapy is preferable to radiation therapy alone for patients with stage IIIB disease (grade 1A). For stage IV disease, chemotherapy is recommended because it improves survival and provides palliation for symptoms (grade 1A).

Targeted molecular therapies are emerging as effective lung cancer treatment. Bevacizumab, a humanized monoclonal antibody against vascular endothelial growth factor (VEGF), improves survival when added to a standard platinum-based chemotherapeutic regimen for patients with nonsquamous NSCLC (grade 1A recommendation). However, it was associated with hemoptysis, which was sometimes fatal, in patients with squamous cell carcinoma in an early-stage trial. Erlotinib and gefitinib, tyrosine kinase inhibitors that target the activity of the epidermal growth factor receptor (EGFR), are approved for the first-line treatment of metastatic NSCLCs that have EGFR mutations (grade 1A). Targeting the EGFR seems to have benefit in particular patient groups, such as women, never-smokers, and Asians who harbor these particular receptor mutations.

Small Cell Lung Carcinoma

Most SCLCs are treated with chemotherapy, and common regimens are four to six cycles of platinum-based chemotherapy (cisplatin or carboplatin) plus etoposide or irinotecan (grade 1A recommendation). Thoracic external beam radiation therapy may be useful if disease is limited (grade 2C). Occasionally, SCLCs can be resected if no evidence of metastasis is found (grade 2C). Although chemotherapy and radiation therapy often produce a dramatic response and sometimes are curative for limited disease, relapse is typical, and subsequent treatments usually are less effective.

PROGNOSIS

The Surveillance, Epidemiology, and End Results (SEER) database, which contains more than 31,000 cases, was used to validate the 2010 TNM staging system, and it provides the most robust prognostic information for lung cancer. Despite persistent

advances in the understanding of the biology of lung cancer and the introduction of novel chemotherapeutic agents for its treatment, the overall 5-year survival rate for patients with lung cancer is 15%. Most patients with lung cancer are diagnosed during the advanced stages of the disease, when surgical resection is less likely to be curative.

Non-Small Cell Lung Carcinomas

Patients with stage IA NSCLC have a median survival of 59 months. The median survival for stage IV disease is only 4 months. Approximately 40% of patients experience a recurrence, with a median time to recurrence after surgery of 11.5 months. Average survival after recurrence is about 8 months.

Small Cell Lung Carcinoma

Patients with limited-stage SCLC at the time of presentation have a median survival of 15 to 20 months and a 5-year survival rate of 10% to 13%. Unfortunately, most patients are diagnosed with extensive disease at the time of clinical presentation. Median survival for these patients is only 8 to 13 months, and the 5-year survival rate is 1% to 2%.

Preoperative and Postoperative Care

Prashant Vaishnava and Kim A. Eagle

INTRODUCTION

More than 40 million people undergo noncardiac surgical procedures in the United States annually. It is estimated that the incidence of cardiac complications after noncardiac surgical procedures is between 0.5% and 1%. In other words, 200,000 to 400,000 people will experience perioperative cardiac complications annually. Moreover, more than 25% of these patients will die. Patients who survive a postoperative myocardial infarction (MI) are twice as likely to die in the following 2 years as are patients with uneventful surgical procedures. Emerging evidence-based practices dictate that the physician should thoughtfully perform an individualized evaluation of the surgical patient to provide an accurate preoperative risk assessment, risk stratification, and modification of risk parameters that can then provide the framework for optimal perioperative risk reduction strategies. This chapter reviews preoperative and postoperative cardiovascular risk assessment that targets intermediate- to high-risk patients to strategically guide perioperative preventive therapies for optimal outcome.

EVALUATION OF PATIENTS WITH ELEVATED RISK

The preoperative evaluation includes an assessment of the risk associated with the planned surgery or procedure. Historically the risk of procedures has been categorized as low, intermediate, or high. The most recent guidelines from the American College of Cardiology/American Heart Association (ACC/AHA) on perioperative cardiovascular evaluation, however, have simplified the approach by categorizing planned procedures as low or elevated perioperative risk. Low-risk procedures (e.g., colonoscopy, cataract surgery) are associated with a less than 1% risk of major adverse cardiovascular events (MACE) of death or myocardial infarction. Those procedures with a MACE risk of $\geq 1\%$ are classified as conferring escalated risk. Simple standardized preoperative screening questionnaires have been developed for the purpose of identifying patients at intermediate to high risk who may benefit from a more detailed clinical evaluation (Table 24-1).

Evaluation of such surgical patients should always begin with a thorough history and physical examination including a 12-lead resting electrocardiogram (ECG) in accordance with the ACC/AHA guidelines. A determination of the urgency of the surgery should be included in the history because truly emergent procedures are associated with unavoidably higher rates of morbidity and mortality.

Perioperative risk assessment begins with an assessment of the urgency of the noncardiac surgery; emergency surgery should not be delayed and may not allow for risk stratification. Preoperative testing should be done only for specific clinical conditions based on the history. Healthy patients of any age who are undergoing elective surgical procedures and have no coexisting medical conditions should not need any testing unless the degree of surgical stress could result in unusual changes from the baseline state. The history should focus on symptoms of occult cardiac disease.

PREOPERATIVE CARDIAC RISK ASSESSMENT

During the perioperative risk assessment of patients undergoing noncardiac surgery, there are active cardiac conditions that should be evaluated and treated in accordance with the ACC/AHA guidelines. These conditions include unstable coronary artery disease (CAD), decompensated heart failure, severe

TABLE 24-1 STANDARDIZED PREOPERATIVE QUESTIONNAIRE*

1. Age, weight, and height
2. Are you
 - a. Female and 55 years of age or older or male and 45 years of age or older?
 - b. If yes, are you also 70 years of age or older?
3. Do you take anticoagulant medications (“blood thinners”)?
4. Do you have or have you had any of the following heart-related conditions?
 - a. Heart disease
 - b. Heart attack within the last 6 months
 - c. Angina (chest pain)
 - d. Irregular heartbeat
 - e. Heart failure
5. Do you have or have you ever had any of the following?
 - a. Rheumatoid arthritis
 - b. Kidney disease
 - c. Liver disease
 - d. Diabetes
6. Do you get short of breath when you lie flat?
7. Are you currently on oxygen treatment?
8. Do you have a chronic cough that produces any discharge or fluid?
9. Do you have lung problems or diseases?
10. Have you or any blood member of your family ever had a problem with any anesthesia other than nausea?
 - a. If yes, describe
11. If female, is it possible that you could be pregnant?
 - a. Perform pregnancy test
 - b. Please list date of last menstrual period

arrhythmia, and severe valvular disease (including severe aortic stenosis and symptomatic mitral stenosis).

Assessment of exercise tolerance in preoperative risk stratification and precise prediction of in-hospital perioperative risk is most applicable in patients who self-report worsening exercise-induced cardiopulmonary symptoms, patients who may benefit from noninvasive or invasive cardiac testing regardless of the scheduled surgical procedure, and patients with known CAD or with multiple risk factors and the ability to exercise. For the prediction of perioperative events, “poor” exercise tolerance has been defined as inability to walk four blocks and climb two flights of stairs or as inability to meet a metabolic equivalent (MET) level of 4 (Table 24-2). Highly functional symptomatic patients (i.e., those who are able to achieve a functional capacity ≥ 4 METS without symptoms, as when climbing a flight of stairs or running a short distance) rarely require noninvasive testing or intervention to lower the risk of noncardiac surgery.

If the patient has poor functional capacity or is symptomatic, physicians often use risk indices derived from empirical multivariable predictive models based on clinical assessment of risk factors to identify patients with elevated perioperative cardiac risk. Based on prospective comparison studies, the Revised Cardiac Risk Index (RCRI) is favored by many given its accuracy and simplicity (Table 24-3). A newer predictive model is the National Surgical Quality Improvement Program (NSQIP) risk calculator and is based on multiple clinical predictors. The RCRI relies on the presence or absence of six identifiable predictive factors: high-risk surgery (suprainguinal vascular, intrathoracic, or intraperitoneal surgery), ischemic heart disease, congestive heart failure (CHF), cerebrovascular disease, diabetes mellitus (requiring insulin therapy), and renal failure (with a serum creatinine concentration >2.0 mg/dL). Each of the RCRI clinical predictors, if present, is assigned 1 point. The risk for cardiac events (i.e., MI, pulmonary edema, ventricular fibrillation or primary cardiac arrest, and complete heart block) can then be predicted. A patient with an RCRI score of 0 has an estimated risk of 0.4% to 0.5% for major cardiac complications; the risk is 0.9% to 1.3% for someone with a score of 1, 4% to 6.6% with a score of 2, and 9% to 11% with a score of 3 (Fig. 24-1). Cardiac

risk particularly increases with the presence of two or more predictors and is greatest with three or more. The clinical utility of the RCRI is that it identifies patients who are at higher risk for cardiac complications and helps determine whether they may benefit from further risk stratification with noninvasive cardiac testing or from initiation of preoperative preventive medical management.

Preoperative Noninvasive Cardiac Testing for Risk Stratification

Evidence discourages widespread application of preoperative noninvasive cardiac testing for all patients. Rather, a selective approach based on clinical risk categorization appears to be both effective and cost-effective. No testing is recommended if it might delay surgical intervention for urgent or emergent conditions.

Coronary revascularization offers the potential benefit of identifying asymptomatic but high-risk patients—that is, patients

TABLE 24-3 REVISED CARDIAC RISK INDEX: CLINICAL MARKERS

- High-risk surgical procedures
- Ischemic heart disease
 - History of myocardial infarction
 - Current angina considered to be ischemic
 - Requirement for sublingual nitroglycerin
 - Positive exercise test
 - Pathologic Q waves on ECG
 - History of PTCA and/or CABG with current angina considered to be ischemic
- Congestive heart failure
 - Left ventricular failure by physical examination
 - History of paroxysmal nocturnal dyspnea
 - History of pulmonary edema
 - S_3 gallop on cardiac auscultation
 - Bilateral rales on pulmonary auscultation
 - Pulmonary edema on chest radiography
- Cerebrovascular disease
 - History of transient ischemic attack
 - History of cerebrovascular accident
- Diabetes mellitus
 - Treatment with insulin
- Chronic renal insufficiency
 - Serum creatinine concentration >2 mg/dL

FIGURE 24-1 Bar graph shows the predicted risk for cardiac events during surgery according to a patient’s Revised Cardiac Risk Index score.

with acute coronary syndromes, those with left main disease, those with two-vessel coronary disease who have significant proximal left anterior descending artery stenosis and either ischemia on noninvasive testing or reduced left ventricular ejection fraction, and those with three-vessel coronary vessel disease and an ejection fraction of less than 50%. Routine prophylactic coronary revascularization should not be performed in patients with stable CAD before noncardiac surgery. An RCRI score of 3 or higher in a patient with severe myocardial ischemia suggestive of left main or three-vessel disease should lead to consideration of coronary revascularization before noncardiac surgery in appropriate patients.

Noninvasive cardiac testing is most appropriate if it is anticipated that the patient will meet guidelines for initiation of additional medical therapy or coronary angiography and coronary revascularization in the event of a positive test. Noninvasive stress testing of patients with three or more clinical risk factors and poor functional capacity (<4 METS) who require vascular surgery is reasonable, provided that the result might change future management. When feasible, exercise stress testing is the modality of choice and offers the benefit of an objective assessment of functional capacity. Pharmacologic stress tests may be performed instead of exercise tests; they are typically reserved for patients with functional limitations.

Dobutamine echocardiography and nuclear perfusion testing for purposes of identifying patients at risk for perioperative MI or death have excellent negative predictive values (near 100%) but poor positive predictive values (<20%). Therefore, a negative study is reassuring, but a positive study is still only a weak predictor of a “hard” perioperative cardiac event. Which higher-risk patients are most likely to benefit from preoperative noninvasive cardiac testing and treatment strategies to improve outcomes is not well defined.

Choices of Noninvasive Cardiac Testing

The choice among noninvasive tests should be based on the need to assess valvular or ventricular function and on which test is most reliable and available locally. Dobutamine stress echocardiography is often used because it has excellent overall predictive performance and can provide additional information about valvular and left ventricular dysfunction.

In general, poor functional capacity associated with exercise-induced ischemia indicates a higher risk for perioperative cardiac events, and achievement of an excellent workload indicates a lower risk. The ability to attain 75% to 85% of the maximal age-predicted heart rate is predictive of a lower rate of perioperative cardiac events. In patients with baseline ECG abnormalities (e.g., left bundle branch block, left ventricular hypertrophy with repolarization abnormalities, Wolff-Parkinson-White pattern, changes secondary to digoxin therapy, paced rhythms) and in those with an inability to exercise due to comorbid conditions, pharmacologic stress echocardiography or nuclear imaging is preferred.

Studies of myocardial perfusion imaging methods (with thallium 201 and technetium 99m) have shown that reversible perfusion defects, which reflect jeopardized viable myocardium, confer the greatest risk for adverse perioperative outcomes. The uniformly high negative predictive value of a normal myocardial perfusion scan may make this technique particularly useful when

noninvasive testing is pursued. In most studies, fixed perfusion defects do not have significant predictive value for perioperative cardiac events. Coronary vasodilators (e.g., intravenous dipyridamole, adenosine, regadenoson), which induce a “coronary steal” phenomenon, are the preferred pharmacologic agents to use with radionuclide myocardial perfusion imaging.

With dobutamine stress echocardiography, the number of myocardial segments demonstrating wall motion abnormalities or wall motion changes at low dobutamine infusion rates identifies patients who are at higher risk for perioperative cardiac events. Dobutamine should be avoided in patients with significant arrhythmias, and coronary vasodilators are best avoided in those with significant bronchospasm.

Preoperative Invasive Cardiac Testing for Risk Stratification

Recommendations for perioperative coronary angiography are similar to those for patients with suspected or known CAD in general and should conform to the ACC/AHA guidelines for coronary angiography. This procedure should be considered for patients who are at high risk for adverse outcomes based on the presence of unstable angina, angina refractory to medical treatment, high-risk results on noninvasive testing, or a nondiagnostic test in a high-risk patient undergoing high-risk noncardiac surgery. It should be considered on an individual basis for those with extensive ischemia revealed during noninvasive testing, for those at intermediate risk undergoing high-risk surgery for whom test results are nondiagnostic, for those convalescing from MI who require urgent noncardiac surgery, and for those with perioperative MI. In patients who have a high clinical risk (RCRI >3) and high-risk features on noninvasive cardiac testing, diagnostic cardiac catheterization should be considered (see Fig. 24-1).

PREOPERATIVE RISK MODIFICATION TO REDUCE PERIOPERATIVE CARDIAC RISK

Coronary Revascularization

Retrospective analyses of the Coronary Artery Surgery Study (CASS) registry and the Bypass Angioplasty Revascularization Investigation (BARI), along with prospective study of patients enrolled in the Coronary Artery Revascularization Prophylaxis (CARP) trial, have shown that prophylactic coronary revascularization with either coronary artery bypass grafting (CABG) or percutaneous coronary intervention (PCI) provides no short-term or mid-term benefit for patients without left main disease or multivessel CAD in the presence of poor left ventricular systolic function. Although high-risk patients who have successfully undergone PCI or CABG before elective noncardiac surgery do experience fewer adverse perioperative cardiovascular events compared with similar patients treated with medications alone, the mortality and morbidity associated with PCI or CABG appear to offset the potential benefit of coronary revascularization before any high-risk cardiac surgery (e.g., major vascular surgery). Therefore, evidence is lacking to support elective coronary revascularization as a primary strategy for perioperative risk reduction in intermediate-risk patients undergoing major noncardiac surgery.

Recommendations for PCI are similar to those for patients with suspected or known CAD and should conform to the ACC/AHA guidelines. Recommendations by the AHA/ACC Society for Cardiovascular Angiography and Intervention, the American College of Surgeons, and the American Dental Association Science Advisory Committee are for a 30- to 45-day delay of surgery in patients taking thienopyridine dual antiplatelet therapy after bare-metal coronary stent placement and a 365-day wait after placement of a drug-eluting stent. Some studies indicate that the duration of dual antiplatelet therapy may be shortened to less than 1 year in selected patients receiving newer-generation stents (such as everolimus- or zotarolimus-eluting stents). Individualized decisions about the duration of dual antiplatelet therapy are important, given that recommended timeframes for the use of such therapy are based primarily on expert opinion. If a patient needs to undergo noncardiac surgery within 2 to 6 weeks, drug-eluting stents should not be implanted; balloon angioplasty appears to be a reasonable alternative. If the noncardiac surgery is urgent or emergent, CABG combined with the noncardiac surgery may be considered; however, cardiac risks, the risk for bleeding, and the long-term benefit of coronary revascularization must be weighed.

Currently, studies suggest that optimal medical therapy is the preferred strategy for intermediate- to high-risk patients with RCRI scores of 2 or higher who are without documented severe myocardial ischemia. As stated previously, the CARP trial demonstrated that preoperative coronary revascularization strategies to reduce perioperative cardiovascular risk did not offer significant benefit compared with excellent medical treatment in intermediate- to high-risk patients undergoing vascular surgery. However, high-risk patients with left main coronary stenosis, severe aortic stenosis, left ventricular ejection fraction of 20% or less, or unstable coronary symptoms were excluded from that trial. In many of these patients, coronary or valve surgery may be indicated on its own merit, without factoring in the noncardiac surgery. Therefore, coronary revascularization may be appropriate if diagnostic catheterization reveals left main disease or multivessel disease and depressed ejection fraction.

Using the information obtained from the composite algorithm (Fig. 24-2), a key decision is whether the risk for perioperative cardiac events is sufficiently low to proceed with surgery. For patients identified to be at high cardiac risk who are not candidates for coronary revascularization, the physician may decide to perform a less extensive major plastic reconstruction, consider laparoscopic versus open procedures or alternative palliative procedures, or attempt to modify cardiac risk by additional intraoperative and perioperative therapies.

β-Adrenergic Antagonists

There is uncertainty about the effectiveness and safety of perioperative β-blockade in patients undergoing noncardiac surgery. The ACC/AHA guidelines focusing on recommendations for perioperative β-blocker therapy limit class I recommendations to patients undergoing surgery who are already receiving β-blockers to treat angina, symptomatic arrhythmias, or hypertension. Class IIb recommendations are given for the initiation of β-blocker therapy prior to surgery in those with intermediate- or high-risk myocardial ischemia noted on preoperative noninvasive

stress testing (level of evidence C) and patients with 3 or more RCRI risk factors (level of evidence B). European guidelines make explicit recommendations for the use of atenolol or bisoprolol when oral β-blockade is first introduced in patients undergoing noncardiac surgery.

The Perioperative Ischemic Evaluation (POISE) trial addressed the limitations of perioperative β-blockade. The POISE trial randomized 8351 intermediate- to high-risk patients older than 45 years of age to receive either a long-acting oral metoprolol succinate (metoprolol CR) or placebo. A high starting dose of metoprolol CR was administered: 100 mg was started orally 2 to 4 hours before surgery and continued for up to 6 hours after surgery and then daily for 30 days; alternatively, a slow intravenous infusion of 15 mg every 6 hours was administered until patients were able to receive the drug orally, after which oral administration was continued daily for 30 days. The medication was withheld if systolic blood pressure fell to less than 100 mm Hg or heart rate to less than 50 beats per minute. The results showed that the incidence of cardiac death, nonfatal MI, or cardiac arrest was reduced in the metoprolol group compared with placebo (5.8% versus 6.9%; hazard ratio = 0.84; 95% confidence interval [CI], 0.70 to 0.99; $P = .04$). However, there was an increased incidence of mortality and stroke in the metoprolol group compared with the placebo group (3.1% versus 2.3% [$P = .03$] and 1% versus 0.5% [$P = .005$], respectively). Therefore, for every 1000 patients treated, metoprolol CR would prevent 11 MIs in intermediate- to high-risk patients undergoing major noncardiac surgery, but at a cost of 8 deaths and 5 disabling strokes. Stroke was associated with perioperative hypotension, bleeding, atrial fibrillation, and a history of stroke or transient ischemic attack. The POISE trialists highlighted the importance of a clear risk and benefit assessment for the initiation of preoperative β-blockers (see Fig. 24-2).

There remains a need for more precise, unambiguous practice recommendations for perioperative β-blockade. Preexisting β-blockade should be continued because withdrawal might increase perioperative mortality. If β-blockers are newly initiated in appropriately selected higher-risk patients undergoing noncardiac surgery, they should be carefully titrated and not abruptly initiated on a high-dose regimen to achieve the desired heart rate.

HMG-CoA Reductase Inhibitors (Statins)

Prospective and retrospective evidence supports the perioperative prophylactic use of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) for reduction of perioperative cardiac complications in patients with established atherosclerosis. Statins should be continued in patients who are already on statin therapy and undergoing noncardiac surgery. A class IIa indication is assigned to the use of statins for patients undergoing vascular surgery with or without clinical risk factors.

Calcium Channel Blockers

Evidence is lacking to support the use of calcium channel blockers as a prophylactic strategy to decrease perioperative risk in patients undergoing major noncardiac surgery.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II-receptor antagonists are frequently prescribed for the

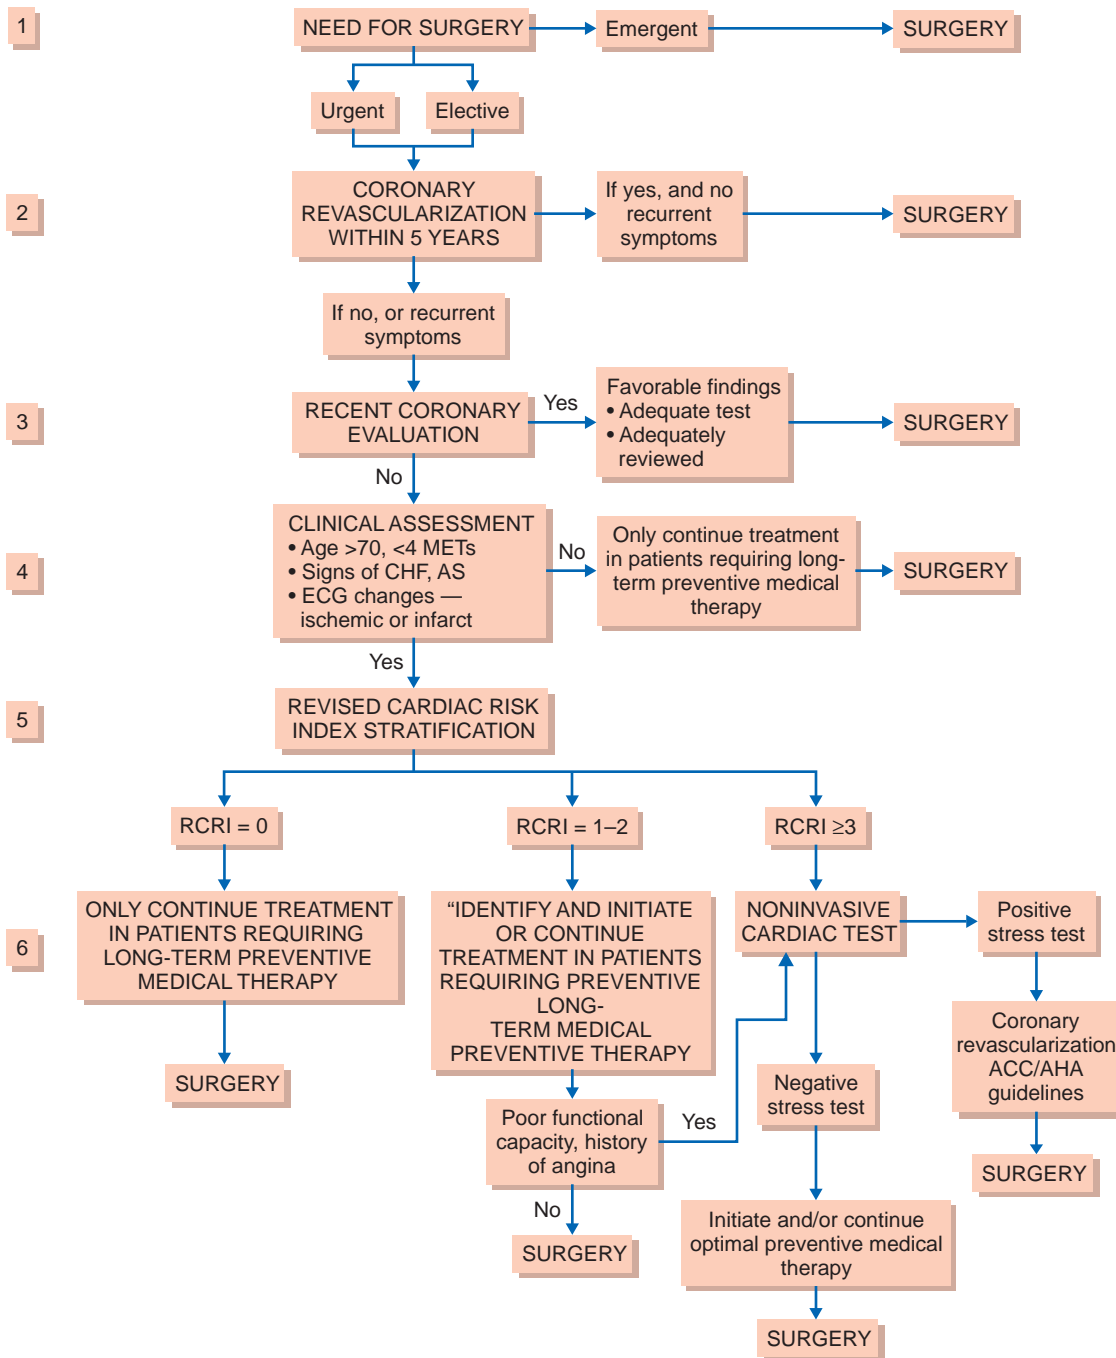

FIGURE 24-2 Stepwise clinical evaluation algorithm for diagnostic cardiac catheterization: (1) emergency surgery; (2) prior coronary revascularization; (3) prior coronary evaluation; (4) clinical assessment; (5) revised cardiac risk index; (6) risk modification strategies. Preventive medical therapy includes β -blocker and statin therapy. ACC, American College of Cardiology; AHA, American Heart Association; AS, aortic stenosis; CHF, congestive heart failure; ECG, electrocardiogram; MET, metabolic equivalent; RCRI, Revised Cardiac Risk Index.

management of hypertension, CHF, chronic renal failure, and ischemic heart disease. Evidence supports the discontinuation of these agents for 24 hours before noncardiac surgery because of adverse circulatory effects after induction of anesthesia in patients on a chronic ACE inhibitor regimen and use of vasopressin agonists for refractory hypotension after induction of anesthesia.

Oral Antithrombotic Agents

Evidence-based recommendations regarding perioperative use of aspirin, clopidogrel, or both to reduce cardiac risk currently lack

clarity. A substantial increase in perioperative bleeding and transfusion requirement in patients receiving dual antiplatelet therapy has been observed. The discontinuation of clopidogrel for 5 days and aspirin for 5 to 7 days before major surgery to minimize the risk of perioperative bleeding and transfusion must be balanced with the potentially increased risk for an acute coronary syndrome, especially in high-risk patients with recent coronary stent implantation. If clinicians elect to withhold aspirin before surgery, it should be restarted as soon as possible postoperatively, especially after vascular graft procedures.

INTRAOPERATIVE STRATEGIES FOR REDUCING PERIOPERATIVE RISK

Anesthetic Management

Epidural anesthesia and analgesia may improve the outcome of major noncardiac surgery through better suppression of surgical stress, a positive effect on postoperative nitrogen balance, more stable cardiovascular hemodynamic response, reduced blood loss, better peripheral vascular circulation, and better postoperative pain control. Overall, there is no preferred myocardium-protective agent, and decisions about anesthetic management should be part of a multidisciplinary effort led by an anesthesiologist. Whereas neuraxial anesthesia (epidural and spinal) may reduce pulmonary and thrombotic complications, its role in lowering cardiac complications is unclear. A technique of combined neuraxial blockade and general anesthesia has merit when indicated to reduce the intraoperative general anesthesia requirements.

Studies have demonstrated that pain management in the perioperative period is crucial for reducing cardiac risk. Adequate pain control reduces catecholamine surges, which are probably responsible for increased myocardial oxygen demand, induction of coronary vasospasm, increased tendency for plaque rupture, and development of a hypercoagulable state.

Intraoperative Pulmonary Artery Catheter

The current evidence on whether the use of a pulmonary artery catheter (PAC) is beneficial for high-risk patients undergoing major noncardiac surgery is controversial. Catheter-guided volume optimization has no clear benefit perioperatively. In a large multicenter randomized trial, Sandham and associates found no benefit for therapy directed by a PAC compared with standard care in elderly, high-risk surgical patients. Nonetheless, a PAC may be considered for patients with signs and symptoms of heart failure preoperatively, who have a very high postoperative incidence of heart failure, and for high-risk patients with limited ventricular reserve who are undergoing procedures that are likely to cause major hemodynamic shifts. Guideline recommendations advocate for evaluation of three parameters—patient disease, surgical procedure (and anticipated intraoperative and postoperative fluid shifts), and practice setting (experience in PAC use)—when considering the intraoperative and postoperative use of a PAC. Regarding practice setting, there is variability in provider understanding of invasive hemodynamic data, and incorrect interpretation of data from a PAC may lead to harm.

Intraoperative Transesophageal Echocardiography

Because ischemia-induced myocardial wall motion abnormalities appear earlier than ischemia-induced electric abnormalities, intraoperative transesophageal echocardiography (TEE) was proposed to be a more sensitive monitor of ischemia than conventional intraoperative 2-lead ECG. Similarly, 12-lead ECG monitoring was also proposed to have greater sensitivity than conventional intraoperative ECG. However, a comparison of intraoperative monitoring using 2-lead ECG versus routine monitoring for myocardial ischemia with TEE or 12-lead ECG during noncardiac surgery failed to provide robust evidence for

incremental value in identifying patients at high risk for perioperative ischemic outcomes. Therefore, the routine use of intraoperative TEE is not recommended for monitoring and guiding therapy during noncardiac surgery, except in emergent scenarios in which the cause of an acute persistent and life-threatening hemodynamic instability needs to be determined.

Maintenance of Body Temperature during Noncardiac Surgery

Current ACC/AHA guidelines recommend maintenance of the patient's body temperature in a normothermic range rather than use of hypothermia to provide organ protection during surgical procedures. A retrospective analysis of a prospective randomized controlled trial demonstrated that hypothermia (core temperature $<35^{\circ}\text{C}$) was associated with an increased risk for myocardial ischemia compared with a core temperature greater than or equal to 35°C . A randomized controlled trial involving 300 high-risk patients undergoing noncardiac surgery in which patients were randomized to active warming or routine care demonstrated that adverse cardiac events (unstable angina, myocardial ischemia, cardiac arrest, and MI) occurred less frequently in the normothermic group than in the hypothermic group (1.4% versus 6.3%; $P = .02$). Furthermore, hypothermia was an independent predictor of adverse cardiac events by multivariable analysis (RR, 2.2; 95% CI, 1.1 to 4.7; $P = .04$), indicating a 55% reduction in risk when normothermia was maintained.

POSTOPERATIVE CARDIAC RISK ASSESSMENT

Monitoring for Myocardial Infarction

Although there are no standard criteria for their diagnosis, most perioperative MIs occur within the first 3 days after noncardiac surgery. A protocol involving ECG evaluation immediately after surgery and on postoperative days 1 and 2 has the highest sensitivity for detection of postoperative MI; routine serial measurements of creatine kinase and its CK-MB fraction led to high false-positive rates and did not increase the sensitivity. Myocardium-specific biomarkers such as troponin I and troponin T have emerged as the most sensitive and specific biochemical markers of myocardial injury and infarction and have been associated with increased risk for cardiac events if elevated in the postoperative period.

While EKG is recommended in the setting of signs or symptoms suggestive of myocardial ischemia, MI, or arrhythmia in the postoperative period, the usefulness of postoperative screening with ECGs is uncertain. Measurement of cardiac biomarkers should be reserved for patients at high risk and for those who demonstrate ECG changes, angina typical of acute coronary syndrome, or hemodynamic evidence of cardiovascular dysfunction.

Postoperative Risk Stratification and Management Strategies

Postoperative patient care involves assessment and treatment of modifiable cardiac risk factors, including hypertension, hyperlipidemia, smoking, obesity, hyperglycemia, and physical inactivity. Patients who sustain a perioperative MI or develop evidence of myocardial ischemia should be carefully investigated because

they are at substantial cardiac risk over the subsequent 5 to 10 years. Noninvasive testing to assess left ventricular function and inducible ischemia should be undertaken to identify patients who may benefit from revascularization or optimization of medical therapy. Postoperative heart failure and pulmonary edema should be treated similar to pulmonary edema in the non-operative setting.

NONCARDIAC SURGERY IN PATIENTS WITH SPECIFIC CARDIOVASCULAR CONDITIONS

Valvular Heart Disease

Special consideration has to be given in preoperative risk assessment for patients with valvular heart disease. All patients undergoing noncardiac surgery should be assessed especially for aortic stenosis by physical examination and by two-dimensional echocardiography for any suspicious murmur. One recent study demonstrated that patients with aortic stenosis have a fivefold increased risk for perioperative mortality and nonfatal MI compared to patients without aortic stenosis. Symptomatic severe represents an active cardiovascular condition that should be evaluated and managed before elective surgery is undertaken. Appropriately selected cases can be managed with valve replacement or valvuloplasty as a bridge to noncardiac surgery.

Less is known about the perioperative risks associated with mitral stenosis and mitral regurgitation in patients undergoing noncardiac surgery. Usually, a preoperative history and physical examination, chest radiograph, or ECG provides clues to the diagnosis, which can be confirmed by echocardiography. Accurate diagnosis may help optimize intraoperative anesthetic strategies, choice of pharmacologic interventions and invasive monitoring, and postoperative medical management. Heart rate should be controlled to ensure a sufficient diastolic filling period and to avoid pulmonary congestion in patients with mild to moderate mitral stenosis. Patients with severe mitral stenosis are likely to benefit from balloon mitral valvuloplasty or surgical intervention before high-risk surgery.

Patients with aortic or mitral valvular regurgitation benefit from volume control and afterload reduction. In aortic insufficiency, it is thought that faster heart rates are better tolerated than slow ones because slow heart rates lead to increased diastolic filling and can exacerbate left ventricular volume overload.

Except for perioperative antibiotic prophylaxis to prevent bacterial endocarditis and the need for effective anticoagulation strategies, perioperative complications in patients with prosthetic heart valves are probably similar to those in patients with comparable degrees of native valvular heart disease. In patients with a mechanical valve prosthesis, the recommendations for anticoagulation are as follows. For patients requiring minimally invasive procedures (i.e., dental procedures, superficial plastic surgery, and biopsies), the international normalized ratio (INR) should be reduced briefly to the low or subtherapeutic range, with the normal dose of oral anticoagulation resumed promptly after the procedure. For those patients in whom the risk of bleeding with oral anticoagulation is high and the risk for thromboembolism without anticoagulation is also high (e.g., mechanical valve in the mitral position, history of thromboembolism while not on anticoagulation, Bjork-Shiley or Starr-Edwards valve, known

hypercoagulability, atrial fibrillation), perioperative unfractionated heparin is recommended. Patients between these two extremes should undergo individual assessment for the risk and benefit of reduced anticoagulation with warfarin versus perioperative heparin initiation and brief interruption perioperatively. The use of low-molecular-weight heparin may be a feasible alternative in appropriately selected patients who require heparin conversion, although there is still controversy about its use for this indication.

Arrhythmias and Conduction Defects

Ventricular and atrial arrhythmias historically are recognized as predictors of perioperative cardiac complications. Therefore, identification of a preoperative arrhythmia warrants a careful evaluation for the presence and severity of underlying ischemic heart disease, cardiomyopathy, or other conditions that may contribute to perioperative complications. In general, asymptomatic arrhythmias or conduction defects warrant only observation and maintenance of an optimal metabolic state. Although new-onset atrial fibrillation raises embolic risk, most cases of postoperative atrial fibrillation resolve within 36 to 48 hours. Short-term rhythm management and anticoagulation may be justified for postoperative atrial fibrillation. Electrical cardioversion is the procedure of choice for supraventricular tachycardia associated with hemodynamic compromise.

Congestive Heart Failure and Left Ventricular Dysfunction

CHF has been identified as a significant marker of cardiac risk in noncardiac surgery. Every effort should be made to identify the etiology of CHF and optimally control it preoperatively because it is a known risk factor for postoperative cardiac complications. However, there are no evidence-based recommendations for optimal perioperative strategy in patients with heart failure undergoing intermediate- to high-risk noncardiac surgery other than making sure that they are taking medications known to improve heart failure in the long-term. Because proper treatment of heart failure depends greatly on its underlying etiology (especially systolic dysfunction versus diastolic dysfunction), characterization of this etiology before elective noncardiac surgery can help in tailoring therapy to each patient. Close monitoring of volume status is needed to avoid perioperative decompensation. Intravenous inotropic agents, vasodilators, or both may be useful for a short duration in the perioperative period to prevent or treat CHF, depending on the situation.

Hypertrophic Cardiomyopathy

Patients with echocardiographically documented hypertrophic cardiomyopathy (HCM) are at risk for exacerbation of dynamic left ventricular outflow tract (LVOT) obstruction during periods of tachycardia, hypotension, or increased inotropy. General anesthesia or neuraxial block can lead to peripheral vasodilation and sympathetic autonomic blockade that may decrease venous return and further exacerbate LVOT obstruction. Observational studies of patients with HCM undergoing noncardiac surgery suggest that for most operations, patients with compensated HCM tolerate the perioperative period well. Perioperative cardiac risk reduction strategies should include avoidance of

hypovolemia, vasodilators, phosphodiesterase inhibitors, and β -adrenergic agonists as well as diligent attention to volume repletion and selective use of α -adrenergic agonists. Patients with HCM are at significant risk for development of perioperative hypotension, CHF, and arrhythmias and should be monitored closely.

Congenital Heart Disease

Studies have demonstrated that patients who have left-to-right cardiac shunts with residual hemodynamic abnormalities after surgical repair experience decreased cardiac output in response to stress. Vigorous treatment of ongoing CHF is required for such patients before noncardiac surgery. Patients with a large left-to-right shunt but only a slight increase in pulmonary artery resistance should undergo cardiac repair before noncardiac surgery. Patients with irreversible pulmonary artery hypertension have an extremely high risk associated with noncardiac procedures and should not undergo such procedures unless there is absolutely no alternative. Patients with prior repair of coarctation of the aorta have a significant risk for sudden death during follow-up, caused by residual cardiac defects with CHF, rupture of a major vessel, dissecting aneurysm, or complications arising from severe atherosclerosis. Such patients also have a high incidence of residual hypertension. Therefore, these patients require careful preoperative assessment and close hemodynamic monitoring during the intraoperative and postoperative periods. Patients with tetralogy of Fallot are also prone to sudden cardiac death. Monitoring and aggressive prevention and treatment of life-threatening arrhythmias such as ventricular tachycardia or atrioventricular block are needed for such patients in the perioperative period.

Surgery in patients with cyanotic congenital heart disease and right-to-left shunts poses several unique problems. Most cyanotic patients are polycythemic and therefore prone to thrombotic complications. Use of diuretics should be avoided in such patients because dehydration may increase blood viscosity, which increases the tendency for thrombosis, particularly cerebral thrombosis. Patients with a hematocrit greater than 70% should be considered for plasmapheresis before noncardiac surgery. Phlebotomy is not advisable in this circumstance because it can decrease intravascular blood volume and thus increase cyanosis. Patients with a hematocrit between 55% and 65% should receive intravenous fluids starting the night before the surgery. Patients with congenital heart disease should also receive appropriate prophylaxis for bacterial endocarditis. One retrospective report suggested that, with careful monitoring and precautions as outlined previously, and with careful attention not to introduce air into the vascular system, patients with right-to-left shunts can undergo noncardiac surgery with relatively few complications.

SUMMARY

CAD accounts for most deaths in patients undergoing noncardiac surgery, and perioperative MI is associated with high mortality rates in these patients. The success of standardized evidence-based preoperative and postoperative cardiac risk reduction strategies in patients undergoing noncardiac surgery depends on collaborative teamwork and sound communication

among surgeons, the anesthesiologist, the patient's primary care physician, and the consultant.

The risk for a perioperative cardiac complication varies with the severity of the surgical procedure and with RCRI stratification. A systematic, stepwise approach for preoperative cardiac risk assessment in patients undergoing noncardiac surgery facilitates a decision as to whether the risk for perioperative cardiac events is sufficiently low to proceed with the surgery. Active cardiovascular conditions, including severe aortic stenosis and symptomatic mitral stenosis, may need to be addressed preoperatively. Preoperative noninvasive cardiac testing should be based on a discrete clinical risk categorization, and the choice among noninvasive tests should be based on the need for coronary, valvular, or ventricular function assessment and which test is most reliable and available locally. Preoperative noninvasive cardiac testing should be considered if the results of such testing could inform the decision for angiography or modify management, regardless of the planned surgery.

Although unambiguous practice recommendations for the use of perioperative β -blockade are lacking, preexisting therapy with β -blockers should not be withdrawn, and newly initiated and titrated therapy may be beneficial in appropriately selected higher-risk patients.

Optimal postoperative patient care involves assessment and treatment of modifiable cardiac risk factors, including pain, hypertension, hyperlipidemia, smoking, obesity, hyperglycemia, and physical inactivity. Finally, patients who sustain a nonfatal perioperative MI or develop evidence of ischemia should be carefully investigated because they are at substantial cardiac risk over the subsequent months and years.

 For a deeper discussion on this topic, please see Chapters 431, "Preoperative Evaluation," and 433, "Postoperative Care and Complications," in Goldman-Cecil Medicine, 25th Edition.

Renal Structure and Function

Orson W. Moe and Javier A. Neyra

INTRODUCTION

The kidney maintains the composition and quantity of body fluids, and its failure is manifested by dysfunction of multiple organs. Chronic kidney disease is approaching epidemic proportions worldwide, and acute kidney injury in the inpatient setting affects a very high percentage of hospital admissions with a high mortality rate. The etiologies of these conditions are very diverse. In addition to loss of glomerular filtration, kidney diseases include hypertension, urolithiasis, and a host of electrolyte disorders that do not affect the glomerular filtration rate (GFR) but nonetheless cause significant morbidity and mortality. To understand these conditions, a thorough knowledge of the anatomy and function of the kidney is requisite.

Approximately 25% of the cardiac output is distributed to the kidneys, where the blood is continuously cleansed. In addition to excretion, the kidney is an important metabolic organ and a source of endocrine molecules. Renal failure represents a disruption of all three of these functions. Selected aspects of renal structure and function are reviewed briefly in this chapter to set the foundation for the subsequent chapters that deal with specific renal diseases.

RENAL STRUCTURE

Macroscopic Anatomy

The kidneys are seated against the posterior wall of the abdomen in the retroperitoneal space, making them readily accessible for percutaneous biopsy. The lower poles may be palpable on deep inspiration in a lean individual. Each human kidney weighs about 120 to 170 g; is about 11 cm long, 6 cm wide, and 3 cm thick; and is endowed with approximately 1 million nephrons. There are interindividual variations. The “kidney size” commonly referred to in clinical sonographic reports is actually the cephalocaudal renal length, which is not a perfect surrogate for renal volume and mass.

The kidney is surrounded by a fibrous capsule. The renal arteries enter the kidney and the renal vein and ureters leave the kidney in the renal pelvis. The bisected surface consists of the lighter-colored outer *cortex* and the darker inner *medulla* (Fig. 25-1). A sample from a clinical biopsy typically originates from the cortex in the lower pole. The medulla is divided into outer and inner regions, and the outer medulla is subdivided into outer and inner stripes. The medulla has multiple conical contours, called *pyramids*, with their apices abutting on the renal pelvis as papillae. The contact points of the renal pelvis with the renal papillae are cup-like structures called *calyces*. Interpolated

between the pyramids are centripetal extensions of cortical tissue called *columns of Bertin*.

Renal Circulation

Each kidney receives blood from a single renal artery, although supernumerary arteries are present in up to one third of individuals. Just before or after the renal artery enters the kidney, it divides into interlobar arteries that pass between the pyramids of the kidney radially up the columns of Bertin (see Fig. 25-1A). The interlobar arteries further divide into arcuate arteries which arch along the corticomedullary junction (see Fig. 25-1B). Arcuate arteries give rise to cortical ascending arteries, which bring blood to the glomeruli. Afferent arterioles ramify into glomerular capillaries, distributing blood to individual glomeruli. Features of the renal circulation are summarized in Table 25-1.

The glomerular capillary is the site for glomerular ultrafiltration. Even though the efferent arteriole is downstream from the glomerular capillary, it is not a venule because it has arteriolar walls and is upstream of the second capillary system surrounding the tubules. The peritubular capillaries provide oxygen and nutrients for the kidney, collect the fluid and solutes reabsorbed by tubules to return into the circulation, and deliver the solutes to be secreted by tubule into the tubule fluid. The peritubular capillaries surrounding the cortical and juxtamedullary nephrons originate from the efferent arterioles of cortical and juxtamedullary glomeruli, respectively.

The vessels that run parallel to loops of Henle are called *vasa recta* (see Fig. 25-1D) because of their long, straight structures. Blood from the peritubular capillaries is returned to the circulation by a venous system that mirrors the architectural structure of the arterial supply: interlobular vein, arcuate vein, interlobar vein, and renal vein. The parallel countercurrent nature of the vasculature provides the basis for the very high medullar tonicity, which allows urine concentration but also direct arteriovenous diffusion of oxygen, giving rise to the very low oxygen tension in the medulla. This low oxygen tension renders the kidney prone to ischemic injury, which is one of the most common causes of acute kidney injury (see Chapter 31).

Renal Nerves

The capsules of the kidney and the ureters have pain fibers derived from splanchnic nerves. This explains the costovertebral angle pain that occurs when the kidneys are inflamed and during renal colic. The renal parenchyma does not have pain fibers but is richly innervated with sympathetic nerves that enter the renal parenchyma with the renal artery. The sympathetic nerves abut on the arterioles (see Fig. 25-1C), stimulate renin release,

FIGURE 25-1 **A**, Gross anatomy of the kidney. **B**, Schematic representation of the vasculature within a column of Bertin. **C**, Structural components of the glomerulus. **D**, Schematic representation of a superficial and a juxtamedullary nephron based on the location of their glomeruli. The tubules are intimately intertwined with the capillary system. The peritubular capillaries come off the efferent arteriole leaving the glomerular capillary. The capillaries that bathe the long descending and ascending limbs of Henle's loop are called the vasa recta due to their straight nature. The tubular segments are named axially: CCD, Cortical collecting duct; CNT, connecting tubule; DCT, distal convoluted tubule; IMCD, inner medullary collecting duct; LOH, loop of Henle; OMCD, outer medullary collecting duct; PCT, proximal convoluted tubule; PST, proximal straight tubule; TAL, thick ascending limb; tAL, thin ascending limb; tDL, thin descending limb.

TABLE 25-1 CHARACTERISTICS OF THE RENAL CIRCULATION

FEATURE	IMPLICATIONS
Few or no anastomoses	Very prone to regional disruption of blood supply
Among the highest blood flow rates per gram of tissue	Lowest oxygen extraction (lowest arteriovenous O ₂ difference)
Functional arteriovenous shunts	Solutes and gases (e.g., O ₂) can diffuse directly from artery to vein without passing through capillaries
Two capillary systems in tandem	The two capillaries serve completely different functions, in the glomeruli and tubules in sequence

decrease renal blood flow, and promote renal retention of sodium (Na⁺). Renal sympathetic denervation has been proposed as a novel treatment of resistant hypertension using radiofrequency energy delivered via an intrarenal arterial catheter radially to disrupt the nerve fibers on the renal artery.

Walk the Nephron

The functional unit of the kidney is the nephron. Each human kidney has approximately 1 million nephrons. Approximately 30% of these have their glomeruli situated deep in the cortex and are referred to as *juxtamedullary nephrons*; the rest are in the outer cortex and are referred to as *superficial nephrons*. Each nephron is

a glomerulus followed by a tubule. The surrounding capillaries and the interstitial space are also important functional components of the nephron.

Glomerulus

The glomerulus consists of the glomerular vasculature (arterioles and capillaries) supported by the mesangium (mesangial cells and matrix) inside Bowman's capsule (parietal and visceral epithelial cells) (see Fig. 25-1C). The visceral cells of Bowman's capsule are the podocytes, so named because of their numerous "foot processes." The smooth muscle layers of the afferent and efferent arterioles are critical in determining arteriolar tone. The glomerular capillary contacts the mesangium on one side and is separated from the foot processes of the podocyte on the opposite side by the glomerular basement membrane (GBM). The glomerulus filters large volumes of water and solutes while retaining most of the proteins and all of the cells in the blood. The glomerular filtration barrier is composed of the capillary endothelium, the GBM, and the podocyte slit diaphragm.

Lining the inside of the GBM is a single layer of fenestrated endothelial cells. The fenestrations (50 to 100 nm in diameter) provide a barrier to negatively charged large molecules in the blood. The GBM contains laminin, type IV collagen, nidogen, and proteoglycans that restrict movement of large molecules (e.g., albumin) from the capillary into Bowman's space. The GBM contains dense negative charges due to glycoproteins with sialic acid residues that restrict the passage of anionic plasma solutes. It can be the site of deposition of immunocomplexes that cause glomerulonephritis (e.g., membranous glomerulonephritis, lupus nephritis). Autoantibodies to the GBM cause severe inflammation and loss of filtration. The epithelial layer consists of podocytes and the parietal epithelium, which is flat and squamous with very few organelles. At the vascular pole, the parietal epithelium is contiguous with a completely different epithelium—the proximal convoluted tubule.

On the visceral side of Bowman's space are the podocytes, which constitute the outermost layer of the filtration barrier. These cells have a highly interdigitating system of foot processes that rest against the basement membrane. The podocyte cell bodies lie within the extracellular matrix. The spaces between foot processes are filtration slits approximately 40 nm in diameter; they are bridged by slit diaphragms, which are also negatively charged, contributing to the containment of middle-size negatively charged particles in the capillary. In the last decade, there have been momentous advances in identifying the components of the slit diaphragm complex and understanding their functions. A full discussion is not possible here, but major slit diaphragm-associated proteins include nephrin, podocin, neph-1/2/3, FAT-1, R-cadherin, catenin, CD2AP, ZO-1, and α -actinin 4. Mutations of many of these genes cause congenital nephrotic syndrome (see Chapter 28).

Tubules

The parietal epithelium of Bowman's capsule becomes the renal tubule (see Fig. 25-1D) as it leaves the glomerulus. The renal tubule is a prototypical polarized epithelium. Its salient characteristics are summarized in Figure 25-2. A simple cylinder would not suffice in terms of surface area for transport. In the

luminal apical membrane, surface amplification is achieved either by protrusions or by a more extensive form of protrusions called the *brush border* in the proximal tubule. Between cells are structures called *tight junctions*. Although they are called tight junctions, some are truly tight (with high resistance to solute and charge movement), whereas others can be quite leaky to solutes. In addition to resistance, these complexes also regulate whether the junction is more permeable to one ion type compared with another (relative and selective permeability). On the other side of the tight junction is the intercellular space, which is contiguous with the interstitial space. The basolateral cell membrane on the interstitial-capillary side amplifies its surface area by infoldings into the cell and interdigitations between two cells.

The movement of a solute can be through a cell (transcellular transport) or around the cell (paracellular transport) (see Fig. 25-2A). Solute transport is an energy-consuming process that requires metabolic fuels. There are many kinds of transport proteins (see Fig. 25-2B). ATPases directly couple hydrolysis of adenosine triphosphate (ATP) to transport. Cotransporters (symporters) move two solutes in the same direction, and countertransporters (antiporters) move two different solutes in opposite directions. Channels function as protein-lined "holes" that allows specific solutes to permeate. Different transporters can also be coupled together to form a new transport system. Finally, there are proteins that protrude outside the cell in the junctional area to provide a conduit for paracellular transport.

Specialized Structures Interstitial

The space between the tubules and peritubular capillaries constitutes about 5% to 10% of renal volume and harbors interstitial fibroblasts and dendritic cells. In diseases such as interstitial nephritis (see Chapter 29), the interstitium is full of inflammatory cells, which elaborate cytokines and chemokines that profoundly affect filtration and tubular function. The resident fibroblasts are stellate cells with projections that physically contact tubules and capillaries, provide scaffold support, and secrete and maintain matrix. In pathologic conditions, these cells, when stimulated by cytokines, can transform into myofibroblasts and contribute to interstitial fibrosis. Some specialized fibroblasts in the deep cortex are sensors of oxygen and producers of circulating erythropoietin. The dendritic cells are antigen-presenting cells that express major histocompatibility complex (MHC) class II molecules. They are in intimate communication with the renal parenchyma, constantly sampling and responding to the local antigenic environment. Dendritic cells are involved with innate and adaptive immunity and are major players in immunologic homeostasis and diseases of the renal parenchyma.

Juxtaglomerular Apparatus

A unique feature of the nephron is that each thick ascending limb traverses back to and engages in physical contact with its parent glomerulus. The tubular cell at the point of contact is different from the rest of the thick ascending limb and is called the *macula densa*. The tripartite structure comprising the macula densa, the afferent and efferent glomerular arterioles, and the extraglomerular mesangium, a special part of the mesangium that protrudes

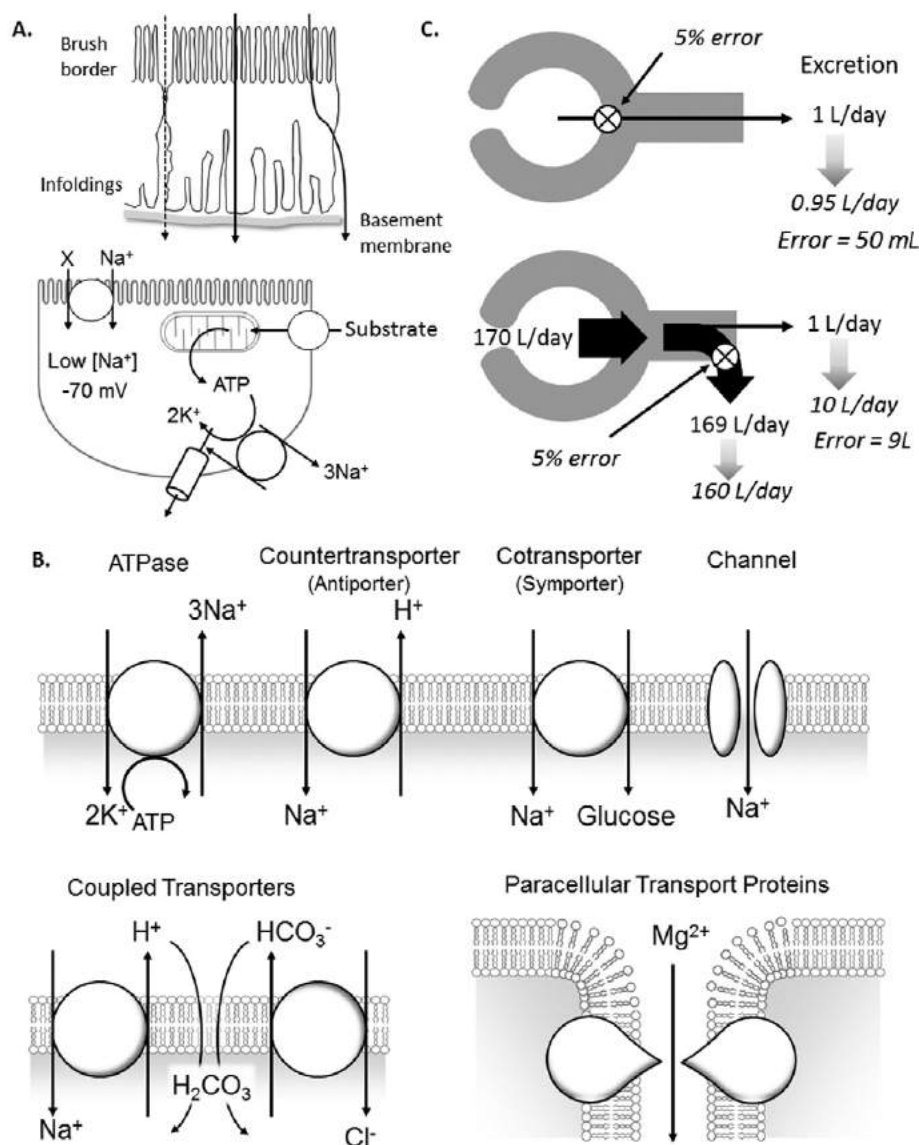

FIGURE 25-2 **A**, Top, Transcellular and paracellular transport of solutes. Solute transport is an energy-consuming process that requires metabolic fuels; a sodium cotransporter and a sodium-potassium countertransporter are shown. **B**, Transport proteins. Top, Adenosine triphosphatases (ATPases) directly couple ATP hydrolysis to transport. Cotransporters (symporters) move two solutes in the same direction, and countertransporters (antiporters) move two different solutes in opposite directions. Channels function as protein-lined “holes” that allow specific solutes to permeate. Lower left, Different transporters can be coupled together to form a new transport system. See text for details.

outside the glomerulus, is called the *juxtaglomerular apparatus* (JGA) (see Fig. 25-1C). The JGA is an important structure in the maintenance of GFR by tubuloglomerular feedback and is the site of endocrine renin production.

RENAL FUNCTION

Excretory Function

Renal excretion of a substance can be mediated and modified by one or a combination of three processes: filtration, secretion, and reabsorption. Figure 25-2C compares two designs—pure filtration (or secretion) and filtration-reabsorption—and their implications in terms of demands on regulation. The

filtration-reabsorption mechanism allows high filtration rates to be achieved, and the coupling with reabsorption prevents loss of valuable fluid and electrolytes. This design also enables economy in transport mechanisms through adaptive targeting of key solutes while allowing the rest to be excreted. However, there is a metabolic price to be paid for this configuration. Consider the excretion of 1 L/day by pure filtration (or secretion). If there is a 5% error (reduction in filtration or secretion), only 0.95 L/day will be excreted—a difference of 50 mL. Compare this to a filtration-reabsorption mechanism wherein 170 L/day is filtered and 169 L/day is reabsorbed, resulting in 1 L/day excretion. A 5% error (reduction) in reabsorption would result in reabsorption of 160 L/day and excretion of 10 L/day, with an absolute

error of 9 L. One consequence of a filtration-reabsorption design is that regulation has to have exquisite fidelity, and even small errors are not tolerated.

Filtration

Filtration occurs exclusively at the glomerulus. The GFR, measured as volume per unit time, has been the standard quantitative surrogate for overall kidney function, although there are many disturbances of renal function that are not associated with a decrease in GFR (e.g., nephrotic syndrome, tubulointerstitial disorders, kidney stones). Numerically, GFR can be conceptualized as an equation:

$$\text{GFR} = K_f \times (\Delta P - \Delta \Pi)$$

where the ultrafiltration coefficient, K_f , is equal to the surface area for filtration multiplied by the hydraulic permeability; the hydrostatic driving force, ΔP , is the pressure gradient between the glomerular capillary and Bowman's space, which drives fluid to go into Bowman's space to form urine; and the osmotic driving force, $\Delta \Pi$, is the osmotic pressure gradient between the glomerular capillary and Bowman's space, which holds fluid back in the capillary and slows down filtration.

Many renal diseases affect the determinants of GFR. Glomerular disease (see [Chapter 28](#)) decreases K_f by affecting both the surface area for filtration and the hydraulic permeability.

Changes in ΔP are commonly involved in diseases that reduce GFR. Changes in renal blood flow and more importantly in afferent and efferent arteriolar resistances can drastically affect ΔP and GFR. Functional changes in ΔP , such as prerenal failure from hypoperfusion or hepatorenal syndrome (see [Chapter 31](#)), can radically lower GFR simply by hemodynamic changes without any structural glomerular lesions. Changes in $\Delta \Pi$ also can affect GFR but have not been studied in as much detail.

Reabsorption

High GFR, which is required to maintain a high metabolic rate, can be sustained only if there is high reclamation to maintain intravascular volume and prevent circulatory collapse. Tubular reabsorption thwarts the loss of valuable solutes and allows for finer tuning of the water and solutes not reabsorbed. The resulting tubular contents are excreted. In the mammalian kidney, tubular reabsorption assumes critical roles in the regulation of excretion of many solutes ([Table 25-2](#)). A universal mechanism of reabsorption is energy-dependent transepithelial transport, which is mostly Na^+ dependent but can be Na^+ independent. The proximal tubules participate in the reabsorption of all solutes, but some solutes are sequentially reabsorbed by the proximal and distal segments; in these cases, the generic design tends to be high-capacity reabsorption proximally and more of a high-gradient reabsorption for fine tuning distally. The axial difference

TABLE 25-2 SOLUTE EXCRETION

SOLUTE	FILTRATION	REABSORPTION	SECRETION	FE (%)	REGULATION
Water	Yes	Yes	No	0.3-6.0	Responds primarily to body tonicity but also EABV. ADH is the major regulator of collecting duct water permeability.
Na^+	Yes	Yes	No	0.2-2.0	Responds to EABV. Reabsorption is stimulated by sympathetic nerves, angiotensin II, aldosterone; inhibited by atrial natriuretic peptides, dopamine, uroguanylin.
K^+	Yes	Yes	Yes	5-20	Responds to total body potassium status. Secretion is controlled primarily by aldosterone and distal Na^+ delivery.
Ca^{2+}	Yes	Yes	No	2-10	Responds to serum ionized $[\text{Ca}^{2+}]$ and body need for calcium. Major calciotropic hormones include parathyroid hormone, vitamin D, and calcitonin. Renal epithelia directly respond to ionized calcium via the calcium sensing receptor.
Mg^{2+}	Yes	Yes	No	3-5	Responds to total body magnesium status and requirements. Paracrine regulation is via epidermal growth factor.
HCO_3^-	Yes	Yes	Yes	0.1-0.5	Most bicarbonate reabsorption is to reclaim the filtered load. Responds to systemic acid-base status which can be mediated by direct sensing by the renal epithelia or via hormonal actions (e.g., angiotensin II, endothelin). Bicarbonate can also be secreted in the collecting duct when alkali excretion is required.
Phosphate	Yes	Yes	No	5-20	Responds to serum phosphate concentration and body phosphate status. Reabsorption primarily resides in the proximal tubule and is regulated by parathyroid hormone and fibroblast growth factor-23.
Glucose	Yes	Yes	No	0.2-0.5	The proximal tubule reclaims almost all filtered glucose except when the filtered load exceeds reabsorptive capacity. The cortical proximal tubule performs gluconeogenesis from other organic substrates.
Uric acid	Yes	Yes	Yes	10-50	Major routes of uric acid clearance are (1) renal excretion and (2) intestinal secretion and uricolysis. Handling of both secretion and reabsorption in the proximal tubule is complex, and regulatory mechanisms are unclear.
Creatinine	Yes	No	Yes	1.0-1.2	Filtered at the glomerulus and secreted by the proximal tubule. The contribution of the tubules to creatinine clearance increases when GFR declines.

ADH, Antidiuretic hormone; EABV, effective arterial blood volume; FE, fractional excretion under normal physiology.

can occur within the same nephron segment (e.g., early vs. late proximal tubule) or across different segments (e.g., proximal vs. distal nephron segments).

Secretion

Secretion is an ancient mode of excretion that is found in lower-order organisms. Although the human nephron is not primarily secretory in nature, a number of solutes are still handled by secretion. For example, the renal excretion of potassium (K^+) and hydrogen (H^+) ions is largely achieved by secretion. Many organic cations and anions are secreted by the proximal tubule, and so are many exogenous toxins such as xenobiotics. The secretion of creatinine by organic cation transporters in the proximal tubule is the reason why creatinine clearance overestimates GFR.

Integrated Models of Excretion

The modes of excretion are well coordinated in a precise, complex, and concerted fashion to effect excretion with exquisite accuracy (see [Table 25-2](#)). The kidney is capable of a large range of urinary tonicity (<50 to 1200 mOsm), depending on the need of the organism to excrete or conserve electrolyte-free water. Water is filtered at the glomerulus and is handled isotonicity in the proximal tubule. At the lumen of the distal convoluted tubule, urine is maximally dilute as a consequence of low water permeability throughout the thick ascending limb of Henle. The subsequent fate of the urine determines whether there is electrolyte-free water excretion (dilute urine), achieved by low water permeability of the collecting duct, or electrolyte-free water conservation (concentrated urine), effected by the action of antidiuretic hormone (ADH), which renders the collecting tubule permeable to water.

Na^+ homeostasis basically occurs via filtration-reabsorption; it is regulated by changes in effective arterial blood volume (EABV) mediated by neurohormonal afferent signals that act directly on tubules. In the proximal tubule, Na^+ reabsorption is also regulated by peritubular physical factors. K^+ undergoes an interesting sequence in which the filtered load is largely reabsorbed in the proximal tubule and the thick ascending limb; the final determinant of excretion is secretion by the collecting duct, for which aldosterone and distal Na^+ delivery are major regulators.

Only Ca^{2+} that is not bound to plasma protein is filtered; it is reabsorbed largely via paracellular pathways in the proximal tubule and thick ascending limb and via transcellular pathways in the distal convoluted tubule.

A massive amount of bicarbonate (HCO_3^-) is filtered and must be reclaimed to forestall catastrophic acidosis. H^+ secretion provides the mechanism for HCO_3^- reclamation as well as acid excretion, with the H^+ being carried by urinary buffers such as ammonia.

Metabolic Function

The kidney is a major metabolic organ. It consumes a wide range of fuels, regulates plasma levels of metabolic substrates, and is a major source of gluconeogenesis. Metabolic substrates such as amino acids, glucose, organic anions, and fatty acids are converted to ATP, the universal energy unit for all cells (see [Fig. 25-2A](#)). ATP is directly hydrolyzed by transport proteins such as Na^+/K^+ -ATPase to create a low intracellular Na^+ concentration

($[Na^+]$) and a negative interior cell voltage, thus translating the energy into chemical gradients. About 80% to 90% of the oxygen consumption of the kidney can be attributed to Na^+ transport. For example, a protein such as the Na^+ -glucose cotransporter (see [Fig. 25-2B](#)) on the luminal membrane couples the movement of one Na^+ ion to one glucose molecule (carrying a net positive charge). The low cell $[Na^+]$ and negative voltage energize glucose uptake, allowing the proximal tubule to capture most of the filtered glucose that otherwise would be lost in the urine. In normal physiology, this glucose reclamation is beneficial.

The amount of filtered organic molecules far exceeds the metabolic consumption by the kidney. Very large amounts of organic metabolic substrates are passively filtered daily; these substrates are not meant to be excreted, but the high GFR and lack of retention at the glomerular capillaries obligate their presence in the glomerular urine. In the proximal tubule, the bulk of the filtered organic molecules are reclaimed from the urine and returned to the systemic circulation. Several thousands of millimoles of amino acids, glucose, and organic cations and anions are retrieved each day by the kidney from the urine.

The kidney rivals the liver as a gluconeogenic organ that sustains circulating blood glucose levels. Although there is no doubt that this is an critical physiologic function, there are no clinical examples of hypoglycemia stemming purely from lack of renal gluconeogenesis.

Endocrine Function

In addition to the prominent and more obvious roles in solute and water balance, the kidney also is an important endocrine organ. The autocrine and paracrine substances elaborated by the kidney are important for both intrarenal and systemic regulation. Although this subject is not addressed fully here, three of these substances are highlighted because they represent important pharmacologic targets ([Table 25-3](#)).

Renin

As the initiating component of the renin-angiotensin-aldosterone system (RAAS), renin is important for maintenance of the integrity of the circulation. The RAAS permits the kidney to have a constant GFR in the face of low and fluctuating salt intake, a property that is vital for terrestrial existence. Renin is produced by the JGA (see earlier discussion). Despite the benefits and importance of the RAAS in physiology, its activation in many disease states appears to be maladaptive and contributes to kidney and cardiovascular injury. Pharmacologic blockade of RAAS pathways at various levels has proved beneficial in animal disease models and human clinical studies, and agents to block RAAS signaling are now in clinical use, with others under development (see [Table 25-3](#)).

Vitamin D

1α -Hydroxylase (cytochrome P-450 isoenzyme 27B1) is found in the proximal tubule, where the major body defense for maintaining phosphate homeostasis is localized. Lesser expression of the same enzyme is also found in the rest of the nephron segments. The kidney is one of the most important organs for maintaining calcium and phosphate homeostasis, not just as the major controller of external balance but as an elaborator of systemic

**TABLE 25-3** SOME ENDOCRINE HORMONES ELABORATED BY THE KIDNEY

HORMONE	SOURCE	FUNCTION	DRUGS

factors such as vitamin D and the Klotho protein. Conversion of the precursor 25(OH)-hydroxyvitamin D to its active form, 1,25(OH)₂dihydroxyvitamin D, is achieved not exclusively but substantially in the kidney and is mediated by 1 α -hydroxylase. Vitamin D deficiency is an important complication in chronic kidney disease. Replacement of vitamin D is efficacious in reducing the complications of chronic kidney disease and may even improve survival.

Erythropoietin

Erythropoietin, which is produced mainly in the kidney, stimulates erythropoiesis. The erythropoietin-producing cells are strategically located in the cortical interstitium to sense the balance between oxygen delivery and consumption. The current model suggests that upregulation of renal erythropoietin production (mainly by anemia and hypoxia) occurs via an increase in the number of latent erythropoietin-producing cells. The mechanism of erythropoietin deficiency in kidney disease is not definitively known, although it does not involve destruction of renal erythropoietin-producing interstitial cells. One possible mechanism is decreased renal oxygen consumption as a consequence of reduced GFR; this results in higher renal tissue oxygen tension and suppression of erythropoietin production. Resetting of the

oxygen-sensing mechanism has also been conjectured. Another theory is direct inhibition of the erythropoietin-producing cells by inflammatory cytokines. Others have proposed transdifferentiation of erythropoietin-producing cells into myofibroblasts and a decrease in the number of interstitial cells that can be recruited to produce erythropoietin.

The use of erythropoiesis-stimulating agents (ESAs) has revolutionized the treatment of anemia associated with chronic kidney disease, but because of incomplete understanding of erythropoietin and erythropoietin receptor biology, the clinical outcome is far from ideal due to inability to tailor the optimal hematocrit for individual patients and uncertainty about possible extra-erythropoietic effects of erythropoietin.

Approach to the Patient with Renal Disease

Rajiv Agarwal

INTRODUCTION

Chronic kidney disease (CKD) may be defined as having an estimated glomerular filtration rate (GFR) of less than 60 mL/min/1.73 m² for at least 3 months. Most of these patients are seen in the outpatient setting, and the focus of their care is on determination of the cause of renal injury, preservation of kidney and cardiovascular function, prevention of the long-term complications of kidney disease, and provision of renal replacement therapy once kidney function deteriorates to the extent that it can no longer sustain an appropriate quality of life. In contrast, most patients with acute kidney injury (AKI) are hospitalized. The focus of their care also starts with accurate determination of the cause of renal failure, but over a period of days to weeks it is important to reverse the kidney failure if possible, replace kidney function if needed, and manage the many potential adverse consequences of AKI.

Because of the widespread use of automated systems for serum chemistry analysis, an elevated serum creatinine concentration is the most common initial manifestation of kidney disease. This test is performed as a screen for renal function abnormalities in most metabolic panels; in most cases, an elevated serum creatinine concentration reflects reduced filtration function of the kidney. After ensuring that intravascular volume is appropriate, the approach to the patient depends on whether renal insufficiency is thought to be acute or chronic. Accordingly, the initial step in evaluating an elevated serum creatinine level is to assess the time course and duration of the changes so as to distinguish AKI from CKD.

A careful history, physical examination, and laboratory evaluation, including imaging studies, are all fundamental to this process. The highest priority is to address acute dehydration, bleeding, and other causes of intravascular volume loss. Evidence of preceding kidney disease may be discovered by searching the records for prior abnormalities of serum creatinine, proteinuria, abnormal urine sediment, or anatomic features such as the presence of multiple cysts in both kidneys. Similarly, a call to the primary care doctor may provide clues to suggest the presence of kidney disease at an earlier time.

Small kidney size, as assessed by ultrasound, can be highly suggestive of CKD. The size of the kidney depends on the height of the patient, but in general, a kidney length on ultrasound images of less than 9 cm in an adult male is considered small. The presence of normal-sized or even large kidneys does not exclude the diagnosis of CKD. In fact, it is common in patients

with diabetic nephropathy for kidneys to be 11 or 12 cm long. Radiography of clavicles or hands is not commonly performed but may demonstrate renal osteodystrophy and suggest the presence of CKD.

Anemia is common in both AKI and CKD and therefore is not a differentiating feature. Rarely, if the initial evaluation is unrevealing, a kidney biopsy may be required to distinguish AKI from CKD and to define the etiology of injury.

APPROACH TO THE PATIENT WITH CHRONIC KIDNEY DISEASE

If the elevated creatinine concentration is thought to be chronic in nature, the history and physical examination should focus initially on detection of diabetes (e.g., diabetic retinopathy) and hypertension, the two most common causes of CKD. In all cases, the evaluation also includes laboratory testing of renal function, serum electrolytes, complete blood count, testing for albuminuria, and microscopic urine sediment analysis. Kidney ultrasound is almost always obtained early in the evaluation to eliminate ureteral or bladder obstruction, a cause of reversible renal failure. In addition, the ultrasound provides important information about kidney size, symmetry, and echogenicity. Kidney biopsy may be needed in some patients, but parenchymal scarring is common in many forms of CKD so the biopsy may not be diagnostic.

Because diabetes and hypertension are common causes of kidney disease, it is important to recognize the associated presentations. To establish a likely diagnosis of diabetic nephropathy, a long-standing history of documented diabetes mellitus is typical, and the presence of diabetic retinopathy, albuminuria, and large kidneys on ultrasound is expected. The urinary sediment is usually unremarkable, so the presence of red blood cell (RBC) casts or a significant number of dysmorphic erythrocytes should initiate a careful evaluation for other causes of CKD. In cases of hypertensive nephrosclerosis, established hypertension typically antedates the diagnosis of renal failure for many years, and the presence of hypertensive retinopathy or cardiovascular disease (e.g., left ventricular hypertrophy) is common. Proteinuria is typically minimal or absent (<2 g/day), and the kidneys are symmetrically small on ultrasound.

In patients with chronic renal failure, it is important not to assume that diabetes and hypertension are the cause. The implication, rather, is that no other identifiable cause of kidney disease is apparent after a thorough evaluation. Notably, in individuals

with hypertension, several genes have been identified that appear to be associated with a greater risk of renal disease, and genetic analysis may emerge as one approach to identify those most at risk so that strategies for prevention can be tested in the future.

Once a diagnosis of CKD is established, ongoing evaluation is required, because those with CKD are at increased risk for complications such as hypertension, metabolic bone disease, anemia, hyperkalemia, and metabolic acidosis. Accordingly, the initial diagnosis of CKD may be modified over time, such as by the discovery of RBC casts in a patient with diabetes mellitus. Similarly, if hypertension or volume overload becomes difficult to manage, the dietary intake of sodium can be estimated by 24-hour urine collection as a clue toward more effective management as CKD evolves over time.

History and Examination

The signs and symptoms of CKD depend on the stage at presentation. Early in the clinical course, nonspecific fatigue is typical, and there may be no discernable clues on examination, highlighting the need for laboratory screening. As filtration rate declines, the signs and symptoms of CKD become more common and may include pedal edema, facial puffiness, flank pain, polyuria, nocturia, and hypertension. Symptoms referable to uremia, such as nausea, dysgeusia, and vomiting, tend to occur late and should not be relied on to make a diagnosis of early CKD.

Sometimes the manifestations of the primary disease predominate. For example, the presence of fever, arthralgia, and rash in a young woman with renal failure and active urinary sediment is highly suggestive of lupus nephritis; or a recent history of skin infection or pharyngitis may reveal the presence of postinfectious glomerulonephritis. A family history of deafness can point to the diagnosis of Alport's syndrome; or a history of cerebral hemorrhage due to a ruptured aneurysm may suggest underlying polycystic kidney disease.

Medication history should focus on exposure to nephrotoxins, including long-term use of nonsteroidal anti-inflammatory drugs (NSAIDs), lithium, exposure to cisplatin, and recent escalation of the dose of diuretics. Some nonprescription drugs can lead to CKD (e.g., cocaine-induced glomerulonephritis, Ma Huang-induced ephedrine stones).

Past medical history may reveal diabetes mellitus and its complications (e.g., retinopathy); recurrent urinary tract infection in a patient with renal calculi; or ongoing hepatitis C, infective endocarditis, or Wegner's granulomatosis in patients with glomerular disease. Therefore, knowledge of the past history is important.

Physical examination can reveal the presence of anemia, skin rash (such as in endocarditis, Fabry's disease, Henoch-Schönlein purpura, or cryoglobulinemia), rales, pericardial or pleural friction rub, pedal edema, abdominal bruit, or enlarged kidneys. Retinal examination is of particular importance and may reveal diabetic retinopathy or changes associated with hypertension; in a patient with rapid deterioration of renal function, retinal examination may show cholesterol emboli or septic emboli, pointing to the existence of cholesterol emboli or bacterial endocarditis as possible causes. Rectal examination, and pelvic examination in female patients, may point to clues to urinary tract obstruction such as a tumor or neurogenic bladder. Examination of the

muscle mass is important when interpreting serum creatinine concentration (see later discussion).

The assessment of blood pressure is particularly important. Often, blood pressure is elevated in the clinic but normal at home (*white coat hypertension*). Occasionally, the blood pressure is elevated at home but not in the clinic (*masked hypertension*). In patients who complain of orthostatic symptoms but appear to have normal or high blood pressure in the clinic, home blood pressure measurements or 24-hour ambulatory blood pressure monitoring may be required. The latter may reveal very low blood pressure with orthostatic symptoms, and antihypertensive therapy may need to be modified.

The overall condition of the patient and level of functional status is important in deciding therapies. For example, transplantation may be an option for a patient with correctable cardiovascular disease and dialysis for someone without correctable cardiovascular disease. However, the physician and the patient's family may share the decision to forego renal replacement in an elderly person with advanced dementia and poor functional status.

Assessment of Kidney Function

Knowledge of both the degree and the rate of change in renal function is important in managing CKD. Rapid deterioration of kidney function over a few weeks to a few months may not reflect intrinsic renal function *per se*; rather, it may reflect superimposed volume depletion (e.g., escalation in the dose of diuretics), exposure to nephrotoxins (e.g., NSAID use), or urinary tract obstruction. Alternatively, progressive renal injury may be associated with malignant hypertension, crescentic glomerulonephritis, microangiopathic hemolytic anemia (thrombotic thrombocytopenic purpura, scleroderma), vasculitides (lupus nephritis, Wegener's granulomatosis), atheroembolic renal disease, or multiple myeloma. In general, a slower course of progression is anticipated in patients with CKD caused by polycystic kidney disease, hypertension, or diabetes mellitus.

Serum creatinine is the standard measure of kidney function. Along with the assessment of albuminuria, it is an important component for staging CKD (Fig. 26-1). If estimated GFR is less than 60 mL/min/1.73 m² for 3 months or longer, kidney disease is said to be chronic.

Notably, serum creatinine concentration does not rise to above the population threshold of normal (about 1.3 mg/dL in men and 1.1 mg/dL in women) until approximately 40% of kidney function is lost. In earlier stages of kidney disease, serum creatinine is maintained in the normal range by enhanced tubular secretion of creatinine. This process of creatinine secretion requires cationic transporters; and drugs that compete with creatinine (e.g., cimetidine, triamterene, trimethoprim) may cause elevation of serum creatinine without depressing true GFR. A clue to impaired cationic transport of creatinine is the lack of rise in blood urea nitrogen despite an increase in serum creatinine.

With advanced kidney failure, the changes in serum creatinine may be more rapid. The relationship between serum creatinine and GFR is nonlinear, accelerating as the GFR declines. This means, for example, that an increase in serum creatinine concentration from 3 to 3.5 mg/dL is associated with a lesser decline in GFR than is a change from 1 to 1.5 mg/dL. Specific knowledge

Prognosis of CKD by GFR and Albuminuria Categories: KDIGO 2012				Persistent albuminuria categories		
				Description and range		
				A1	A2	A3
				Normal to mildly increased	Moderately increased	Severely increased
				<30 mg/g <3 mg/mmol	30–300 mg/g 3–30 mg/mmol	>300 mg/g >30 mg/mmol
GFR categories (mL/min/1.73 m ²) Description and range	G1	Normal or high	≥90			
	G2	Mildly decreased	60–89			
	G3a	Mildly to moderately decreased	45–59			
	G3b	Moderately to severely decreased	30–44			
	G4	Severely decreased	15–29			
	G5	Kidney failure	<15			

Green: Low risk (if no other markers of kidney disease, no CKD); Yellow: moderately increased risk; Orange: high risk; Red: very high risk.

FIGURE 26-1 Chronic kidney disease (CKD) nomenclature used by the Kidney Disease Improving Global Outcomes (KDIGO) consortium. CKD is defined as abnormalities of kidney structure or function, present for 3 months or longer, with implications for health. CKD is classified on the bases of cause, glomerular filtration rate (GFR), and albuminuria. (From KDIGO: 2012 clinical practice guideline for the evaluation and management of chronic kidney disease, *Kid Intl Suppl* 3:18, 2013. Available at http://www.kdigo.org/clinical_practice_guidelines/pdf/CKD/KDIGO_2012_CKD_GL.pdf. Accessed June 1, 2014.)

of the baseline level of serum creatinine is important; for example, change from 0.6 to 1.2 mg/dL is still within the normal range in an adult man but actually reflects an approximately 50% loss of GFR.

The relationship between GFR and serum creatinine is best interpreted at steady state and not when the GFR is changing rapidly. For example, bilateral nephrectomy in a patient with previously normal kidney function (as might occur in a patient with renal cell carcinoma) results in drop in GFR from 100 to 0 mL/min. However, serum creatinine would be expected to increase by only about 1 mg/dL/day, and a plateau may not be achieved before 1 week. This delay reflects the fact that the generation of creatinine is insufficient to saturate the volume of distribution of creatinine. A plateau will be reached more rapidly if the rate of creatinine generation is increased, the volume of distribution of creatinine is small, or residual renal function is substantial. Given these variables, it is important to be aware that serum creatinine may be a poor marker of GFR in non-steady-state conditions.

There also are several conditions in which serum creatinine may be falsely low in relation to the GFR. Because creatinine generation is dependent on muscle mass, low creatinine generation occurs in diseases associated with sarcopenia, such as motor neuron diseases (amyotrophic lateral sclerosis), wasting illnesses (advanced cancer, tuberculosis, cardiac cachexia), and even malnutrition. Visual examination of muscle mass (thighs, arms, temporal muscles) may therefore be important in the interpretation of serum creatinine concentrations. Other conditions associated with low creatinine generation include cirrhosis and advanced age. Creatinine generation is reduced in sepsis, and kidney

function may be worse than is detectable by estimation of GFR through measurement of serum creatinine.

At very advanced levels of kidney disease (e.g., GFR <20 mL/min), creatinine is secreted and urea is absorbed by the tubule. Tubular secretion is balanced by tubular reabsorption, making measurements of urea clearance and creatinine clearance useful in estimating true GFR. An average of creatinine and urea clearance closely approximates true GFR in such situations.

At steady state—that is, when the patient is neither gaining or losing weight—the 24-hour urine urea nitrogen measurement can be used to estimate dietary protein intake. In addition to its excretion in urine, nitrogen is lost through the gut, through the skin, and, as non-urea nitrogen, through the kidney in proportion to body weight. It is estimated that 31 mg/kg/day of non-urea nitrogen is excreted in this fashion. Dietary protein intake can be calculated as 6.25 g protein per gram of total daily nitrogen excretion. Accordingly, the formula for dietary protein intake in grams per day is (urine urea nitrogen + 0.031 × body weight in kg) × 6.25.

Although urea by itself is less useful to assess kidney function, it can be helpful in conjunction with the serum creatinine measurement. Urea is reabsorbed by the tubule in sodium-avid states. The normal ratio of urea to creatinine is 10 : 1. In states of volume depletion such as diuretic use, diarrhea, sweat losses, or third spacing (e.g., ascites), the urea-to-creatinine ratio may be greater than 20 : 1. Sometimes, ratios greater than 20 : 1 are also seen in catabolic states (e.g., long-bone fracture, corticosteroid use, burns, sepsis), increased gut protein load (upper gastrointestinal bleeding, high-protein diet), or obstructive uropathy. In contrast,

creatinine may rise disproportionately more than urea, for example in advanced cirrhosis, low-protein diets, or states associated with the use of cationic transport inhibitors (e.g., cimetidine).

For many decades, the assessment of creatinine clearance by a 24-hour urine collection has been the mainstay of assessing renal function. However, given that creatinine may be secreted (and not just filtered), this test may overestimate GFR. Furthermore, voiding outside the collection jug is common and may lead to errors in estimating GFR. Although a 24-hour urine collection is not routinely recommended to assess renal function, it may still be useful for estimating GFR in sarcopenic individuals and in those with advanced liver disease. Creatinine clearance can be easily calculated as the urinary flow rate (in mL/min) times the ratio of urinary creatinine to plasma creatinine. A timed collection is needed. Creatinine excretion approximates 15 mg/kg/day. Although this rate is variable (the coefficient of variation from day to day over 28 days on a standard diet varies from 6% to 22%) and depends on meat intake, it can be used to estimate whether urine has been grossly undercollected or overcollected.

Usually, GFR is estimated through the use of equations that account for age in years, race, sex, and serum creatinine. The Modification of Diet in Renal Disease (MDRD) equation uses a creatinine measurement (Scr) that has been calibrated to an isotope dilution mass spectrometry standard:

$$\text{GFR [in mL/min/1.73 m}^2\text{]} = 175 \times (\text{Scr})^{-1.154} \times (\text{Age})^{-0.203} \times 0.742 \text{ [if female]} \times 1.212 \text{ [if black]}$$

A newer equation, called the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation, is less likely to estimate GFR as low if the GFR is higher than 60 mL/min/1.73 m². This equation is more complicated:

$$\text{GFR [60 mL/min/1.73 m}^2\text{]} = 141 \times \min(\text{Scr}/\kappa, 1)^\alpha \times \max(\text{Scr}/\kappa, 1)^{-1.209} \times 0.993^{\text{Age}} \times 1.018 \text{ [if female]} \times 1.159 \text{ [if black]}$$

where Scr is serum creatinine (in mg/dL), κ is 0.7 for females and 0.9 for males, α is -0.329 for females and -0.411 for males, *min* indicates the minimum of Scr/κ or 1, and *max* indicates the maximum of Scr/κ or 1. Several calculators to estimate GFR using the CKD-EPI equation or the MDRD equation are available on the World Wide Web or as applications for personal devices.

Assessment of Albuminuria

The assessment of albuminuria is fundamental because it may point to the cause of the CKD. Furthermore, greater albuminuria is associated with an accelerated progression of CKD and cardiovascular disease. As a result, albuminuria is now used to stage CKD (see Fig. 26-1).

Albumin excretion rate is normally less than 10 mg/24 hr, and an excretion rate of 30 mg/24 hr or higher is considered abnormal and moderately increased. An albumin excretion rate of 300 mg/24 hr or higher is considered severely increased. Albuminuria can be more conveniently assessed by measuring the ratio of urine albumin and urine creatinine concentrations in a spontaneously voided specimen. Given that the creatinine excretion rate averages 1 g/day, an albumin-to-creatinine ratio of

30 mg/g creatinine or higher is considered abnormal and moderately increased; a ratio of 300 mg/g creatinine is considered severely increased.

An albumin excretion rate higher than 2200 mg/24 hr (corresponding to 3000 mg protein/24 hr) is considered nephrotic. Such a degree of albuminuria/proteinuria is often accompanied by edema, hypoalbuminemia, and hyperlipidemia. The combination of these disorders is referred to as the *nephrotic syndrome*, and the severe proteinuria reflects a profound disorder of glomerular permselectivity. Common causes of nephrotic syndrome in adults are diabetic nephropathy, focal segmental glomerulosclerosis, membranous nephropathy, and amyloidosis. Among children, minimal change nephropathy and focal segmental glomerulosclerosis are important causes of nephrotic syndrome.

Assessment of Blood Pressure

Hypertension is a common accompaniment of CKD, yet the evaluation of hypertension often is performed poorly. Current management of hypertension is directed most often to management of blood pressure measurements obtained during clinic visits. However, blood pressure may be falsely higher in the clinic (*white coat hypertension*) or lower in the clinic (*masked hypertension*) compared with 24-hour ambulatory blood pressure measurements. The latter technique is mostly limited to research or to management in a few difficult cases. However, home blood pressure recordings self-measured by the patient twice daily for about 1 week every month can help diagnose and manage hypertension more effectively. Self-performance of these measurements may promote adoption of a healthier diet and better medication adherence by the patient, as well as reducing therapeutic inertia on the part of the physician.

Assessment of Dietary Sodium Intake

At steady state, when body weight is neither increasing nor decreasing, the dietary sodium intake can be judged by 24-hour urine collection. To establish adequacy of urine collection, the measurement of urine creatinine in 24-hour urine sample is important. The creatinine excretion rate in an adequately collected specimen should approach 1 g/day for women and 1.5 g/day for men. Dietary potassium and protein intake can be monitored similarly. Measurement of urine urea nitrogen in the 24-hour urine sample can reveal the adequacy of dietary protein intake. Dietary sodium restriction can improve blood pressure, can enhance the biologic actions of inhibitors of the renin-angiotensin system, and may protect the heart, blood vessels, and kidneys independent of improvement in blood pressure.

Microscopic Urinalysis

Microscopic urinalysis at initial evaluation and on an ongoing basis can reveal vital information about the health of the kidney. Evaluation should be performed by centrifugation of at least 12 mL of a freshly voided specimen. Cells, casts, crystals, and other elements can corroborate the diagnosis of the cause of CKD. Examples are shown in Figures 26-2 through 26-5.

Renal Imaging

Bladder ultrasonography is a tool that can be used to assess residual urine volume. The wide availability of this tool allows

FIGURE 26-2 Cells often found in urine of patients with kidney disease. **A**, Sternheimer-Malbin–stained urine sediment (100× objective) in a patient with urinary tract infection. *Solid line* shows a leukocyte and *hollow line* indicates bacteria. **B**, Sternheimer-Malbin–stained urine sediment (40×) in a patient with fungal urinary tract infection. *Solid line* shows a pseudohypha and *hollow lines* indicate leukocytes. **C**, Unstained urine sediment (40×) shows an oval fat body in a patient with nephrotic syndrome. **D**, Sternheimer-Malbin–stained urine sediment (100×) in a patient with immunoglobulin A (IgA) nephropathy. *Solid line* shows an acanthocyte characterized by outpouching of the red blood cell (RBC) membrane. **E**, Sternheimer-Malbin–stained urine sediment (40×) in a patient with IgA nephropathy shows many acanthocytes (*solid line*). When acanthocytes constitute more than 5% of the RBCs, their presence is considered significant. **F**, Sternheimer-Malbin–stained urine sediment (100×) in a patient with recovering acute tubular necrosis (ATN). *Solid lines* indicate glitter cells. The granules of these leukocytes have a Brownian motion and appear to glitter under the microscope. These cells can be seen in large numbers during the recovery stage of ATN and in patients with urinary tract infection. **G**, Sternheimer-Malbin–stained urine sediment (40×) shows numerous squamous cells, indicating poor collection technique. **H**, Hansel–stained urine sediment (100×) shows eosinophils that can be seen in patients with allergic interstitial nephritis, cholesterol emboli, or, sometimes, urinary tract infection.

FIGURE 26-3 Tubular cells often found in urine of patients with acute kidney injury. **A**, Unstained urine sediment (40× objective) in a patient recovering from acute tubular necrosis (ATN). *Solid lines* show intact renal tubular epithelial cells. **B**, Same specimen as in **A** but stained with acridine orange-propidium iodide and viewed with a triple excitation band fluorescence filter (triple-cube). Red cells are dead and green cells are live. Both tubular cells appear viable. Smaller cells are leukocytes. **C**, Unstained urine sediment (40×) shows several renal tubular cells that appear monomorphic (as in images **A** and **B**), indicating acute tubular injury. The *arrow* indicates a binucleate tubular cell. **D**, Unstained urine sediment (40×) shows several renal tubular cells (*solid lines*) that appear dysmorphic. Instead of being round, the cells are angular. Furthermore, these cells are multinucleated, indicating failure of the cell to divide. Large numbers of dysmorphic renal tubular cells are often seen if the acute tubular injury is substantial. **E**, Unstained urine sediment (100×) shows two teardrop-shaped dysmorphic renal tubular epithelial cells (*solid lines*). Because the patient had jaundice, the cells appear to have a color despite lack of staining. **F**, Unstained urine sediment (100×) shows one dysmorphic, binucleate renal tubular epithelial cell (*line*). This is the same patient as in **E**. **G**, Unstained urine sediment (40×) shows severe ATN. No dirty-brown granular casts were seen, but the tubular cells were dysmorphic (*lines*). The large amount of granular debris and absence of casts suggests failure to form Tamm-Horsfall protein and more severe tubular injury. This patient also had jaundice, as is evident from the yellow hue. **H**, Unstained urine sediment (40×) shows dysmorphic renal tubular epithelial cells (triangular, cigar-shaped, and polygonous), often multinucleated as denoted by *lines*.

FIGURE 26-4 Crystals commonly found in urine sediment. All images were made with the use of polarized light and a diffusion interference contrast microscope. **A**, Uric acid crystals (40× objective). **B**, Calcium oxalate dihydrate crystals (*white lines*) (40×). Large numbers are seen in patients with ethylene glycol poisoning. **C**, Calcium oxalate monohydrate crystals (*solid line*) (40×). **D**, Magnesium ammonium phosphate crystals, or triple phosphate crystals, are often found in patients with a complicated urinary tract infection (40×). **E**, Coffin-lid appearance of magnesium ammonium phosphate crystals (100×). **F**, Bilirubin crystals in a patient with acute tubular necrosis and obstructive jaundice (100×). Inset shows 40× view of the bilirubin crystals. **G**, Calcium phosphate crystals (40×) in a patient with tumor lysis syndrome. Sequential images (*left to right, top to bottom*) show dissolution of the crystals within a few minutes after urine was acidified by adding 2% perchloric acid. **H**, Fiber artifact in the urine is of no clinical significance.

FIGURE 26-5 Casts in urine. **A**, Unstained urine sediment (40× objective) in a patient with glomerulonephritis. *Solid line* shows a granular cast, and *hollow line* shows a hyaline cast. **B**, Sternheimer-Malbin–stained urine sediment (40×). The *solid line* points to an erythrocyte cast in a patient with immunoglobulin A nephropathy. **C**, Unstained urine sediment (40×) shows several renal tubular cells and an epithelial cell cast (*solid line*) indicating acute tubular injury. **D**, Papanicolaou–stained urine sediment (*solid line*) (100×) shows an epithelial cell cast in an otherwise stable patient with diabetic nephropathy. **E**, Unstained urine sediment (40×) shows bilirubin-stained granular cast (*solid line*) indicating renal inflammation in a patient with liver disease. **F**, Unstained urine sediment (10×) shows dirty-brown granular casts (*solid line*) indicative of acute tubular necrosis (ATN). **G**, Unstained urine sediment (40×) shows severe ATN. No dirty-brown granular casts were seen, but the tubular cells (*solid lines*) were dysmorphic and multinucleated. **H**, Sternheimer-Malbin–stained urine sediment (40×) shows a fatty cast (*solid line*) in a patient with nephrotic syndrome.

diagnosis of bladder outlet obstruction without the need to catheterize the patient.

Renal ultrasonography is the most accurate way of determining kidney size. It is commonly performed to detect renal masses, cysts, and evidence of obstruction characterized by dilatation of the pelvicalyceal system and to evaluate the size and shape of the

kidneys. The presence of small kidneys (i.e., <9 cm on both sides) suggests the presence of scarring and therefore CKD. However, kidneys that are larger, typically in the range of 11 to 13 cm, are often seen in conjunction with CKD due to diabetes mellitus, amyloidosis, and multiple myeloma. Therefore, the presence of small kidneys is not needed to make a diagnosis of CKD.

The echogenicity of the kidneys is compared with that of liver parenchyma. Typically, the kidneys are less echogenic than the liver. Increased echogenicity of the kidneys suggests the presence of scarring and therefore CKD. Renal ultrasonography can also easily detect the presence of cysts in the kidneys and therefore is a useful technique to detect polycystic kidney disease. Pulsed Doppler imaging is often used to calculate the resistive index by estimating the systolic and diastolic Doppler velocities in the renal cortex. A resistive index greater than 0.8 suggests that interventional procedures to revascularize the kidney would be unlikely to benefit the patient in terms of improving blood pressure or protecting the long-term decline in kidney function. If the two kidneys differ in size by 1.5 cm, it suggests the presence of renovascular disease in an adult. In children, reflux nephropathy or congenital abnormalities are more common causes.

Computed tomography (CT) of the kidney is often helpful to evaluate complex cysts. In contrast to simple cysts, complex cysts are suspicious for the presence of malignancy, and CT can evaluate them better than ultrasonography. Likewise, CT is important for evaluating renal masses, stones, retroperitoneal conditions (e.g., hemorrhage, tumor, abscess), and renal vein thrombosis. In morbidly obese people, CT is often used to guide kidney biopsy. The use of contrast agents to assess vascular lesions of the kidney may not be possible if kidney function is compromised due to fear of precipitating AKI. Limiting the volume of the contrast agent and volume repletion before radiocontrast administration may minimize renal injury.

Although intravenous pyelography can image the structures in the kidney, contrast CT has taken the place of classic intravenous pyelography in many centers because of the risk of inducing nephrotoxicity in patients with CKD. In contrast, retrograde pyelography is often used by urologists to define the site and nature of obstruction within the ureter and the pelvis. In addition, during the procedure, ureteric stones can be removed with the use of a basket device.

Magnetic resonance imaging (MRI) is useful for imaging of the vasculature and therefore for the diagnosis of renal vein thrombosis and renal artery stenosis. Gadolinium-based contrast agents are often used for MRI because of their paramagnetic properties. These agents should be avoided if the GFR is less than 30 mL/min/1.73 m², because in such patients they have been implicated in causing a disabling and untreatable condition called *nephrogenic systemic fibrosis*. Two other MRI contrast agents (one containing iron and another containing manganese) may be used in such patients but are approved by the U.S. Food and Drug Administration only for the evaluation of lesions in the liver. MRI cannot be performed in patients who have metallic implanted devices such as pacemakers, artificial joints, or aneurysmal clips.

After injection of a small amount of radioactive substance, radionuclide imaging can be performed to assess renal perfusion and function of the kidneys. One advantage of this technique is that it can assess kidney function and perfusion simultaneously for each kidney. It therefore allows diagnosis of renal artery stenosis, especially when it is performed before and after administration of angiotensin-converting enzyme (ACE) inhibitors.

Renal arteriography is the reference standard for the diagnosis of renal artery stenosis. It involves direct injection of a radiocontrast dye into the renal arteries. In patients with CKD, contrast

injection can be limited and carbon dioxide can be injected to avoid nephrotoxicity. This technique is also useful for assessing vascular malformations in the kidney and for making a diagnosis of polyarteritis nodosa. In the latter condition, renal arteriography can detect the presence of microaneurysms.

APPROACH TO THE PATIENT WITH ACUTE KIDNEY INJURY

The approach to patients with AKI depends on four major factors: (1) the evaluation of risk or susceptibility to renal injury, (2) the nature of the AKI, (3) the severity of injury, and (4) the presence of distant organ effects or consequences. In all cases, it is important to evaluate and optimize intravascular volume early in the course, because this is a readily addressable factor that can prevent or minimize further injury.

The risk factors for AKI include, first and foremost, prior existence of CKD; CKD can easily be detected by a low estimated GFR or the presence of albuminuria. Other common risk factors for AKI include advanced age, diabetes mellitus, hypertension (especially when treated with inhibitors of the renin-angiotensin system), chronic liver disease or cirrhosis, and multiple myeloma.

AKI is a challenging medical problem, and a careful and stepwise approach to evaluation is essential. This approach is guided by knowledge of the causes of injury, which can be divided into five major groups: ischemia, toxins, obstruction, inflammation, and infection.

Ischemia can be caused by volume loss from the gastrointestinal system (vomiting or diarrhea), the skin (sweating, burns), or the kidneys (diuretics, Addison's disease, and solute diuresis). Comparing the body weight of the patient with those weights recorded in the medical record can be valuable. A substantial decrease in body weight may point toward volume depletion as a possible cause of AKI. Third-space fluid losses, as observed in patients with ascites, pancreatitis, or ileus, can make the diagnosis of volume depletion challenging because such patients may not have an overall loss in body weight. Ischemia is a common cause of AKI due to poor perfusion associated with significant blood loss or sepsis or both. In the setting of ischemia, glomerular hypoperfusion is aggravated when patients are taking inhibitors of the renin-angiotensin system.

Nephrotoxins can be divided into two major groups: endogenous and exogenous. The endogenous toxins include paraproteins, myoglobin, hemoglobin, uric acid (e.g., in tumor lysis syndrome), and bile acids. Exogenous toxins include contrast dyes, aminoglycosides, chemotherapeutic agents such as cisplatin, and NSAIDs.

Inflammation can involve the glomerular, interstitial, and vascular compartments. Inflammation of these structures produces glomerulonephritis, interstitial nephritis, and vasculitis, respectively.

Infection is an important cause of injury to the nephron. Most often it happens in the intensive care unit, where early sepsis can manifest as a fall in urine output followed by an increase in serum creatinine, confirming AKI. The causes of AKI in the setting of sepsis are multifactorial and include ischemia, direct tubular dysfunction due to sepsis, and concomitant administration of drugs such as nephrotoxic antibiotics (commonly, high doses of vancomycin) and procedures (radiocontrast imaging), often performed

to reverse sepsis. Therefore, declines in urine volume, especially in the intensive care unit, should lead to a diligent search for a focus of infection.

Urinary tract obstruction is often a reversible cause of renal injury and therefore important to diagnose. Although urine output is frequently reduced with obstruction, partial obstruction may be associated with an increase in urine output. Renal ultrasound is useful to diagnose hydronephrosis; urinalysis may reveal hematuria, infection, or may be bland. Left untreated renal atrophy may ensue.

In many ways, the severity of injury is best assessed at the bedside. Oliguric renal failure (100–400 mL urine/24 hr) or anuric renal failure (<100 mL urine/24 hr) has a worse prognosis than non-oliguric renal failure (>400 mL urine/24 hr). A low fractional excretion of sodium or, if the patient is taking diuretics, a low fractional excretion of urea may suggest volume depletion as the likely cause. Fractional excretion of any substance is simply calculated as the ratio of the clearance of the analyte in question to the clearance of creatinine. However, a low fractional excretion of urea or sodium may have causes other than volume depletion. For example, because of the heterogeneous nature of nephron injury, contrast-induced injury, sepsis, or burns often result in a low fractional excretion of sodium despite intrinsic renal failure.

Intrinsic renal injury can be detected by examining the urine sediment. The classic manifestation of acute tubular necrosis (ATN) is the presence of dirty-brown granular casts. However, in severe AKI, there may be a large amount of amorphous granular material without cast formation (see Figs. 26-3 and 26-5). This occurs because severe AKI may result in failure to produce the Tamm-Horsfall protein, leading to no formation of casts. In the absence of dirty-brown granular casts, a diagnosis of acute tubular injury can still be made based on the presence of dysmorphic epithelial cells in the urine. These epithelial cells, under hypoxic conditions, transform from the round, fried-egg appearance of the tubular cell to angular cells taking the shape of triangles or teardrops (see Fig. 26-3). A normal sediment, on the other hand, suggests minimal or no kidney injury.

The severity of injury needs to be assessed, as well as its relationship to the preexisting state of kidney health. Severe injury is required for AKI to be manifested when the kidney is otherwise healthy. Little damage is needed to produce a severe injury if CKD preexists. More important, however, is the response to injury. It remains unclear why do certain individuals have low GFR and others with the same extent of injury do not, but this reflects the protective nature of responses that can result in poor or better GFR.

End-organ manifestations of AKI include pulmonary edema or acute respiratory distress syndrome; uremic encephalopathy

as alteration of mental status or asterixis; and uremic pericarditis or pleuritis manifested as pericardial or pleural friction rub. Although pulmonary edema is still a common manifestation of uremia, uremic serositis and encephalopathy are now rare.

The individual elements that can be seen in the urine and may be of diagnostic importance are as follows: dysmorphic RBCs, sterile pyuria manifested by white blood cells (WBCs) in the urine without bacteria, urinary tract infection characterized by both WBCs and bacteria in the urine, dysmorphic tubular cells suggesting ATN, intact renal tubular cells suggesting recovery from AKI, bubble cells, glitter cells, and oval fat bodies (see Figs. 26-2 and 26-3).

Budding yeast in a patient with diabetes may suggest the need to remove a long-standing indwelling catheter. Uric acid crystals in large amount suggest tumor lysis syndrome; calcium oxalate crystals may suggest ethylene glycol poisoning; and magnesium ammonium phosphate (triple phosphate) crystals may suggest infection with urease-positive organisms (see Fig. 26-4).

Casts can occur in various forms, such as RBC, WBC, epithelial cell, granular, hyaline, and dirty-brown granular casts. They can also occur in various shapes, such as broad and narrow casts. Examples of these are demonstrated in Figure 26-5.

For a deeper discussion on this topic, see Chapter 114, “Approach to the Patient with Renal Disease,” in Goldman-Cecil Medicine, 25th Edition.

Fluid and Electrolyte Disorders

Biff F. Palmer

NORMAL VOLUME HOMEOSTASIS

Body Water

In the average adult, total body water is equal to 50% to 60% of body weight: 60% for men and 50% for women because of extra body fat, which is water free. In an average 70-kg man, total body water is 42 kg or 42 L, and for an average 70-kg woman, total body water is 35 kg or 35 L.

Approximately two thirds of total body water is located intracellularly and one third is located extracellularly. One fourth of the extracellular fluid volume (ECF) resides in the intravascular space. In a 70-kg man with 42 L of total body water, 28 L are located intracellularly, 14 L are located in the ECF, and 3.5 L are located in the extracellular intravascular compartment.

ECF volume is determined by the balance between sodium intake and excretion. Under normal circumstances, wide variations in salt intake lead to parallel changes in renal salt excretion, such that ECF volume and total body salt are maintained within narrow limits. This relative constancy of ECF volume is achieved by a series of afferent sensing systems, central integrative pathways, and renal and extrarenal effector mechanisms acting in concert to modulate sodium excretion by the kidney (Table 27-1).

The concentration of salt (i.e., sodium chloride [NaCl]) in the plasma is regulated by renal water handling. Plasma tonicity is maintained by sensing and effector mechanisms that are different from those that regulate volume, although the systems that regulate volume and plasma tonicity do work in concert. For example, if the baroreceptors of the body detect that the ECF volume is low, the kidney responds by retaining NaCl. This transiently leads to an increase in the tonicity of the ECF that stimulates release of arginine vasopressin (AVP), causing renal water retention and expansion of the ECF volume.

TABLE 27-1 SENSORS AND EFFECTORS THAT DETERMINE OSMOREGULATION AND VOLUME REGULATION

FACTOR	OSMOREGULATION	VOLUME REGULATION
Sensors	Hypothalamic osmoreceptors	Low- and high-pressure baroreceptors
What is sensed	Plasma osmolality	Effective arterial blood volume
Effectors	Arginine vasopressin (AVP), thirst	Aldosterone, angiotensin II, sympathetic nerves
What is effected	Urine osmolality, thirst	Urine sodium (Na ⁺) excretion

Osmolality and Tonicity

Osmolality is the number of particles per kilogram of solution. Plasma osmolality can be directly measured with the use of an osmometer or can be calculated by the following equation:

$$\text{Calculated osmolality} = (\text{Na}^+ \times 2) + \text{glucose}/18 + \text{BUN}/2.8$$

where Na⁺ is the sodium ion concentration and BUN is the blood urea nitrogen level.

The osmolar gap is the difference between the measured and calculated osmolality and is normally less than 10 mOsm/L. A higher value indicates accumulation of an unmeasured substance such as ethanol, methanol, ethylene glycol, or acetone.

It is important to differentiate osmolality from tonicity. *Osmolality* refers to all particles in solution, and *tonicity* describes whether the particles are effective or ineffective osmoles. Effective osmoles such as Na⁺, glucose, or mannitol cannot penetrate cell membranes and can lead to changes in cell volume. Ineffective osmoles such as urea and alcohols pass freely into and out of cells and are unable to effect changes in cell volume. As an example, chronic kidney disease patients with BUN levels greater than 100 mg/dL have no cellular shifts of fluid due to the urea. The plasma osmolality is high, but plasma tonicity is normal.

HYPONATREMIA

Definition

Hyponatremia is one the most common electrolyte abnormalities encountered in clinical practice. Increasing age, medications, various disease states, and administration of hypotonic fluids are among the established risk factors for the disorder. Although hyponatremia is most commonly a marker of hypo-osmolality, three causes of hyponatremia are not associated with a hypo-osmolar state (Fig. 27-1). The first is pseudohyponatremia. This condition occurs in the setting of hyperglobulinemia or hypertriglyceridemia, in which plasma water relative to plasma solids is decreased in blood, decreasing the Na⁺ concentration in a given volume of blood.

The second cause involves true hyponatremia with elevations in the concentration of an effective osmole. Clinical examples include hyperglycemia as seen in uncontrolled diabetes and infusion of mannitol for the treatment of cerebral edema. Increased plasma glucose concentration raises serum osmolality, which pulls water out of cells and dilutes the serum Na⁺ concentration. For every 100-mg/dL rise in glucose or mannitol, the serum Na⁺ level quickly falls by 1.6 mEq/L. The increased

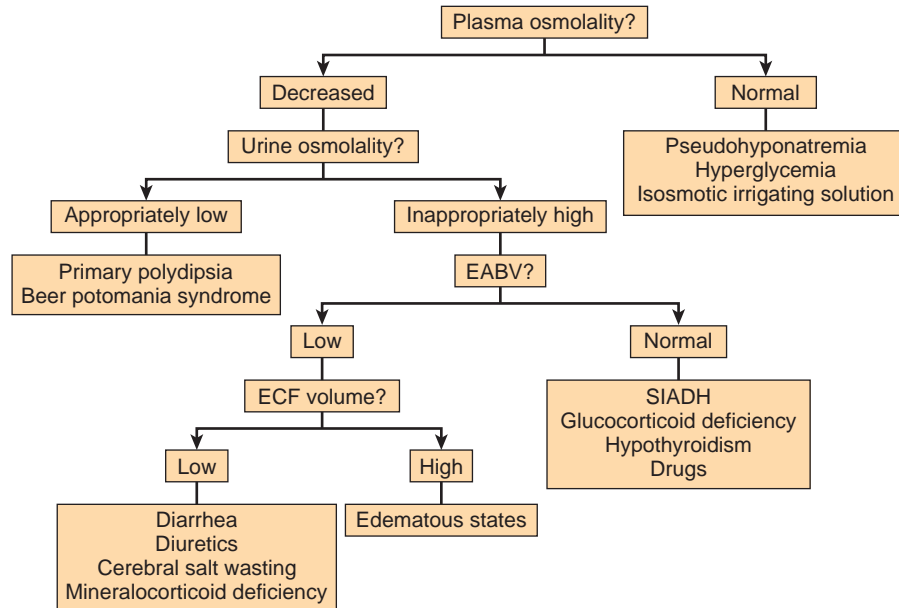

FIGURE 27-1 Approach to the patient with hyponatremia. Assessment of effective arterial blood volume (EABV) is key to understanding the mechanism of renal NaCl retention and whether it is primary or a response to a low EABV. The EABV is the arterial volume sensed by the kidney. If the kidney is working normally and is retaining NaCl, the EABV must be low, and if a normally functioning kidney is excreting large amounts of NaCl, the EABV is large. The physical examination is the most reliable way to assess EABV. Useful findings include the presence or absence of edema and orthostatic changes in blood pressure and pulse. Laboratory tests include collection of a spot urinary sample for sodium (Na^+), chloride (Cl^-), and creatinine to calculate the fractional excretion of Na^+ or fractional excretion of Cl^- using the following equations: $\text{FE}_{\text{Na}} (\%) = \frac{[\text{urine } \text{Na}^+ \times \text{plasma creatinine}]}{[\text{plasma } \text{Na}^+ \times \text{urine creatinine}]} \times 100$ and $\text{FE}_{\text{Cl}} (\%) = \frac{[\text{urine } \text{Cl}^- \times \text{plasma creatinine}]}{[\text{plasma } \text{Cl}^- \times \text{urine creatinine}]} \times 100$. If these parameters are low ($<0.5\text{--}1\%$), a low EABV is indicated. Other findings suggesting a low EABV include an increase in the blood urea nitrogen (BUN)/creatinine ratio ($>20:1$), increased serum uric acid concentration (due to increased proximal tubular reabsorption), and increased hematocrit and serum albumin concentration due to hemoconcentration. SIADH, Syndrome of inappropriate secretion of antidiuretic hormone.

tonicity also stimulates thirst and AVP secretion, both of which contribute to water retention. As the plasma osmolality returns toward normal, the decline in the serum Na^+ level is 2.8 mEq/L for every 100-mg/dL rise in glucose. The net result is a normal plasma osmolality but a low serum Na^+ concentration.

The third cause of hyponatremia in the absence of a hypo-osmolar state is the addition of an isosmotic or near-isosmotic, non- Na^+ -containing fluid to the extracellular space. This situation typically occurs during transurethral resection of the prostate or during laparoscopic surgery, when large amounts of a nonconducting flushing solution containing glycine or sorbitol are reabsorbed systemically.

Despite these exceptions, hypotonic hyponatremia in most cases implies that water intake exceeds the ability of the kidney to excrete water. Because the normal kidney can excrete 20 to 30 L of water per day, hyponatremia with normal renal water excretion implies that the patient is drinking at least this volume of water. This condition is referred to as *primary polydipsia*. Urine osmolality is less than 100 mOsm/L in this setting. Hyponatremia associated with a maximally dilute urine can also result from more moderate fluid intake combined with extremely limited solute intake, a condition often referred to as *beer potomania syndrome*.

In the absence of primary polydipsia, hypotonic hyponatremia results when water intake exceeds the renal capacity for water excretion due to an inappropriately concentrated urine (>100 mOsm/L). The effective arterial blood volume (EABV) is defined in this setting. Decreased EABV causes baroreceptor

stimulation of AVP secretion and decreases distal delivery of filtrate to the tip of the loop of Henle, accounting for the inability to maximally dilute the urine. If the EABV is low, ECF volume can be low in the volume-depleted patient (i.e., hypovolemic hyponatremia) or can be high in the edematous patient (i.e., hypervolemic hyponatremia). A normal EABV points to the euvolemic causes of hyponatremia (e.g., isovolemic hyponatremia).

Approximately two thirds of diagnosed hyponatremia cases are acquired in the hospital, where the common practices of monitoring daily fluid intake, patient weight, and Na^+ levels normally allow prompt diagnosis. Administration of hypotonic fluids in the postoperative period is a risk factor for acute iatrogenic hyponatremia, especially because AVP levels remain increased several days after surgical procedures. Iatrogenic cases can be prevented by close monitoring of electrolytes and urine output and by fluid restriction and avoidance of solutions with low- Na^+ content; this approach applies particularly to elderly patients.

In neurosurgical patients, the syndrome of inappropriate antidiuretic hormone (SIADH) secretion and cerebral salt wasting are two causes of hyponatremia. Differentiating these disorders can be challenging because there is considerable overlap in the clinical presentation. The primary distinction lies in the EABV assessment. SIADH is a volume-expanded state due to AVP-mediated renal water retention. Cerebral salt wasting is characterized by a contracted EABV resulting from renal salt wasting. Making an accurate diagnosis is important because

therapy for these conditions is different. Vigorous salt replacement is indicated for patients with cerebral salt wasting, and fluid restriction is the treatment of choice for patients with SIADH.

Common causes of hyponatremia outside the hospital setting include overhydration, diarrhea, vomiting, central nervous system infection, extreme exercise, liver failure, renal failure, congestive heart failure, drugs, SIADH, and combinations of these and other factors. Thiazide diuretics are the most common cause of drug-induced hyponatremia. Hyponatremia typically develops in the first 2 weeks of drug initiation and is most likely to occur in elderly women and during the summer months because of the increased ingestion of hypotonic fluids when it is hot. Concomitant use of nonsteroidal anti-inflammatory drugs (NSAIDs) and selective serotonin reuptake inhibitors (SSRIs) can further increase the risk of thiazide-induced hyponatremia.

Treatment

Symptoms of hyponatremia include nausea and malaise, which can be followed by headache, lethargy, muscle cramps, disorientation, restlessness, and obtundation. When treating a patient with hyponatremia, the Na^+ concentration should be raised at the rate at which it fell. In patients with chronic hyponatremia (>48 hours' duration), the serum Na^+ concentration has fallen slowly. Neurologic symptoms are minimal, brain size is normal, and the number of intracellular osmoles is decreased. Sudden return of ECF osmolality to normal values produces cell shrinkage and possibly precipitates osmotic demyelination. This complication can be avoided by limiting correction to between 10 and 12 mEq/L in 24 hours and to less than 18 mEq/L in 48 hours. In a patient whose serum Na^+ concentration has decreased rapidly (<48 hours), neurologic symptoms are common, and cerebral edema occurs. In this case, there has not been sufficient time to remove osmoles from the brain, and rapid return to normal ECF osmolality merely returns brain size to normal.

Development of hyponatremia in the outpatient setting is commonly chronic in duration and should be corrected slowly. In contrast, hyponatremia of short duration is more likely to be encountered in hospitalized patients receiving intravenous free

water. Use of the illicit drug ecstasy, exercise-induced hyponatremia, or primary polydipsia can cause patients to develop acute hyponatremia, and if symptomatic, they may require rapid correction.

● HYPERNATREMIA

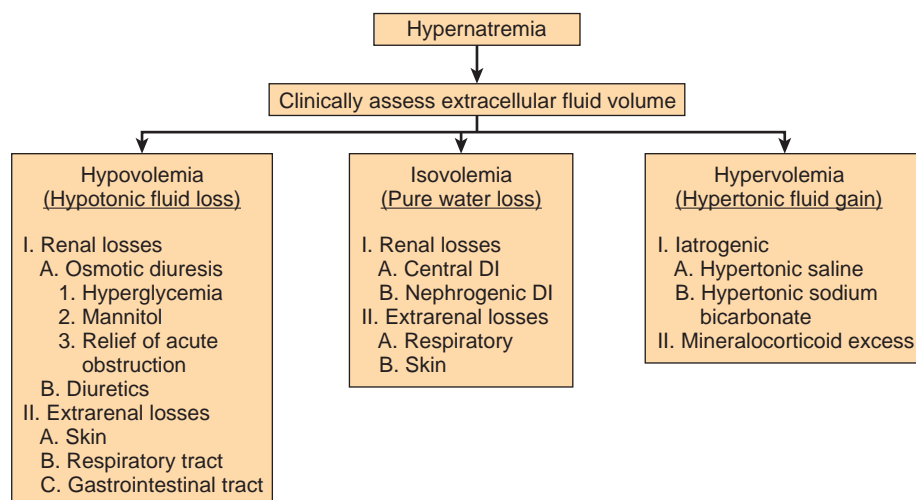

Definition

Hypernatremia is a relatively common problem, particularly among the elderly and critically ill. Hypernatremia always indicates hypertonicity and is associated with shrinkage of cells. It is an independent risk factor for mortality in the intensive care unit setting.

The initial approach to any patient with hypernatremia is to determine why there has been inadequate intake of water (Fig. 27-2). Hypernatremia is rare in conscious patients who have free access to water because of the extreme sensitivity of the thirst mechanism. Usually, there is inadequate water intake due to an alteration in the level of consciousness. Patients become unaware of thirst or cannot adequately communicate the need for water, or there is restricted access to water. Rarely, there is a specific lesion of the thirst center. A reduced sensation of thirst occurs in otherwise normal individuals as a feature of increasing age.

The next step is to search for accelerated water loss or Na^+ gain, both of which increase the likelihood of a patient developing hypernatremia. This can best be accomplished by clinical assessment of the EABV. Hypovolemic hypernatremia results from fluid losses in which the Na^+ concentration is less than the plasma concentration. Hypervolemic hypernatremia can result from iatrogenic administration of hypertonic NaCl or hypertonic sodium bicarbonate (NaHCO_3) or from mineralocorticoid excess.

Pure water loss, whether from mucocutaneous routes or from the kidneys, causes isovolemic hypernatremia. Because two thirds of pure water loss is sustained from within cells, patients do not become clinically volume depleted unless the water deficit becomes substantial. Insensible losses from the respiratory tract or skin result in concentrated urine. Inappropriate water loss by the kidney, whether from central or nephrogenic diabetes

*All are associated with impairment of thirst or access to water.

FIGURE 27-2 Approach to the patient with hypernatremia. DI, Diabetes insipidus.

insipidus, results in dilute urine. Although renal water loss can lead to hypernatremia in patients with impaired thirst or access to water, most patients with diabetes insipidus have neither defect, and they typically have polyuria, polydipsia, and a normal serum sodium concentration at clinical presentation.

Evaluation of Polyuria and Polydipsia

Polyuria can result from osmotic diuresis or water diuresis. Water diuresis may result from inappropriate water loss, as in central or nephrogenic diabetes insipidus, or it may represent appropriate water loss, as in primary polydipsia. The clinical setting and urine osmolality help to differentiate these processes (Fig. 27-3).

Osmotic diuresis causing polyuria is often evident in the clinical setting. Poorly controlled glucose levels in a diabetic, administration of mannitol to a patient with increased intracranial pressure, and high-protein enteral feedings (i.e., urea diuresis) are examples in which polyuria is the result of osmotic diuresis. A urine osmolality value greater than 300 mOsm/L in a polyuric patient suggests a solute or osmotic diuresis.

After excluding osmotic diuresis, the clinician must discriminate between the causes of water diuresis. In patients with central diabetes insipidus, the onset of symptoms is characteristically abrupt, whereas patients with nephrogenic diabetes insipidus usually have a gradual onset of symptoms. Patients with primary polydipsia typically are vague in dating the onset of their symptoms. Nephrogenic and central forms of diabetes insipidus are characterized by severe and frequent nocturia, a feature that is typically absent in patients with primary polydipsia. Patients with central diabetes insipidus seem to have a predilection for ice water, which is not typically described in the other two conditions. A serum Na^+ concentration of less than 140 mEq/L suggests primary polydipsia because the patients tend to have a mildly positive water balance. A value greater than 140 mEq/L suggests central or nephrogenic diabetes insipidus because the patients tend to have a mildly negative water balance.

Urine osmolality increases in response to water deprivation in primary polydipsia but shows no response in diabetes insipidus.

Both central and nephrogenic diabetes insipidus are distinguished by the change in urine osmolality after subcutaneous administration of AVP. It is increased in the central type but does not change in nephrogenic diabetes insipidus.

Treatment

Signs and symptoms of hypernatremia include lethargy, weakness, fasciculation, seizures, and coma. Increased ECF osmolality initially causes cell shrinkage in the brain. In response, cells generate intracellular osmoles, which balance the transmembrane osmotic gradient and pull water back into the cells, returning brain size to normal. After this adaptation, if extracellular osmolality is returned rapidly to normal, the additional intracellular osmoles pull water into the brain cells, resulting in cerebral edema. Hypernatremia should be corrected slowly by water administration at a rate that leads to one-half correction in 24 hours. The water deficit can be estimated in men from the following formula:

$$\text{Water deficit} = \text{Current body water} (0.6 \times \text{body weight}) \times \left(\frac{\text{Na}^+_{\text{plasma}}}{140} - 1 \right)$$

where $[\text{Na}^+]_{\text{plasma}}$ is the sodium ion concentration in plasma. The calculation for women uses 0.5 instead of 0.6 as the multiplication factor.

Calculation of the amount of water to give must add insensible losses and ongoing losses from the urinary and gastrointestinal tracts. This formula does not include the volume of isotonic saline required in patients who may be concomitantly volume depleted. Careful monitoring of the serum Na^+ level is required to ensure the rate of correction is appropriate.

HYPOKALEMIA

Definition

Hypokalemia is a common clinical disorder. Decreases in total body potassium ions (K^+) usually result from gastrointestinal or renal losses, whereas hypokalemia in the setting of normal total body K^+ results from net movement of K^+ into cells. In most cases, the cause can be readily determined by the history, measurement of blood pressure, examination of the acid-base balance, and measurement of urinary K^+ levels.

Cellular Potassium Shift with Normal Total Body Potassium

In the absence of physical and historical evidence of gastrointestinal or renal K^+ losses, a redistribution of K^+ at the cellular level or laboratory error can account for a low serum K^+ concentration. Spurious causes of hypokalemia can be seen in leukemia patients with leukocyte counts of 100,000 to 250,000/ m^3 , in which the leukocytes extract K^+ from the serum.

The regulation of K^+ distribution between the intracellular and extracellular spaces is referred to as *internal K^+ balance*. Although the kidney is ultimately responsible for maintenance of total body K^+ , factors that modulate internal balance are important in the disposal of acute K^+ loads. A large potassium meal, for example, could double extracellular K^+ were it not for the rapid shift of the K^+ load into cells. The kidney cannot excrete

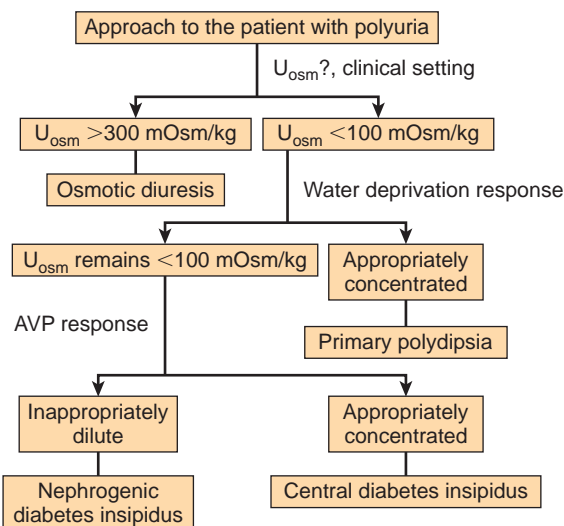

FIGURE 27-3 Approach to the patient with polyuria. AVP, Arginine vasopressin; U, urinary.

K^+ rapidly enough in this setting to prevent life-threatening hyperkalemia. This excess K^+ must be rapidly shifted and stored in cells until the kidney has successfully excreted the K^+ load. The major regulators of K^+ shift into cells are insulin and catecholamines.

Insulin excess can lower the serum K^+ level when given exogenously to a diabetic patient or when it occurs as an endogenous secretion in a normal person given a high-glucose load. β -Adrenergic agonists used in the treatment of bronchospasm or in treating premature labor can effect similar K^+ shifts. In the setting of an acute myocardial infarction, hypokalemia may result as a sequela of high circulating epinephrine levels and may predispose patients to arrhythmias. Other clinical disorders resulting in an intracellular sequestration of K^+ are treatment of megaloblastic anemia with vitamin B_{12} , hypothermia, and barium poisoning. Hypokalemic periodic paralysis is inherited in an autosomal dominant pattern and is characterized by episodic hypokalemia resulting in muscle weakness. An acquired form of the disorder is seen in thyrotoxic patients, who are often of Japanese or Mexican descent.

Decreased Total Body Potassium

In the absence of a cellular shift, a low serum K^+ level can result from inadequate dietary intake, extrarenal losses through the gastrointestinal tract or skin, or renal losses. The urinary K^+ concentration is a useful guide for deciding among these possibilities. A urine K^+ concentration of less than 20 mEq/L suggests extrarenal losses, whereas a concentration of more than 20 mEq/L suggests renal K^+ losses. Calculation of the transtubular K^+ gradient has also been used for this purpose.

Inadequate dietary intake is an unusual cause of hypokalemia. Clinical situations associated with extreme K^+ -deficient diets include anorexia nervosa, crash diets, alcoholism, and intestinal malabsorption. Increased renal K^+ excretion due to magnesium deficiency (which occurs often in these clinical situations) may contribute to the observed hypokalemia.

Extrarenal Potassium Losses

Sweat has a low K^+ concentration and is an unusual cause of K^+ depletion. However, during physical training, sweat losses can

become substantial, and K^+ depletion may result. Gastrointestinal syndromes are the most common clinical sources of extrarenal K^+ losses. Diarrhea leads to fecal K^+ wastage and is associated with a normal anion gap acidosis. Acidosis results in K^+ redistribution out of cells, leading to a degree of hypokalemia that is not as severe as the degree of K^+ depletion.

Renal Potassium Losses

Increased distal delivery of Na^+ and water and increased mineralocorticoid activity can each stimulate renal K^+ secretion. Under normal physiologic conditions, these two determinants are inversely regulated by the EABV (Fig. 27-4). Decreased EABV is associated with increased aldosterone secretion but with lower distal delivery of Na^+ and water due to enhancement of reabsorption in the proximal nephron. Renal K^+ excretion is relatively independent of volume status. It is only under pathophysiologic conditions that distal Na^+ delivery and aldosterone become coupled, and in this setting, renal K^+ wasting occurs. The coupling can result from a primary increase in mineralocorticoid activity or a primary increase in distal Na^+ delivery. The term *primary* means that the changes do not depend on changes in the EABV. The causes of hypokalemia, grouped according to the physiologic determinants of renal K^+ excretion, are given in Figure 27-5.

Primary Increase in Mineralocorticoid Activity

Increases in mineralocorticoid activity can result from primary increases in renin or aldosterone secretion, increases in a nonaldosterone mineralocorticoid, or an increased mineralocorticoid-like effect. In these conditions, ECF volume is expanded, and hypertension typically occurs. The differential diagnosis for the patient with hypertension, hypokalemia, and metabolic alkalosis rests on the measurement of plasma renin activity and plasma aldosterone levels.

Primary Increase in Distal Sodium Delivery

Conditions that give rise to primary increases in distal Na^+ delivery are characterized by normal or low ECF volume. Blood pressure is typically normal.

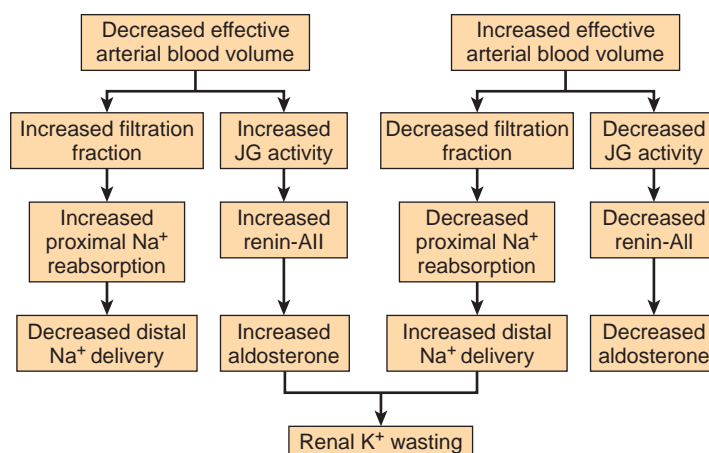

FIGURE 27-4 The relationship between effective arterial volume and distal sodium (Na^+) delivery in determining renal potassium (K^+) excretion. All, Angiotensin II; JG, Juxtaglomerular.

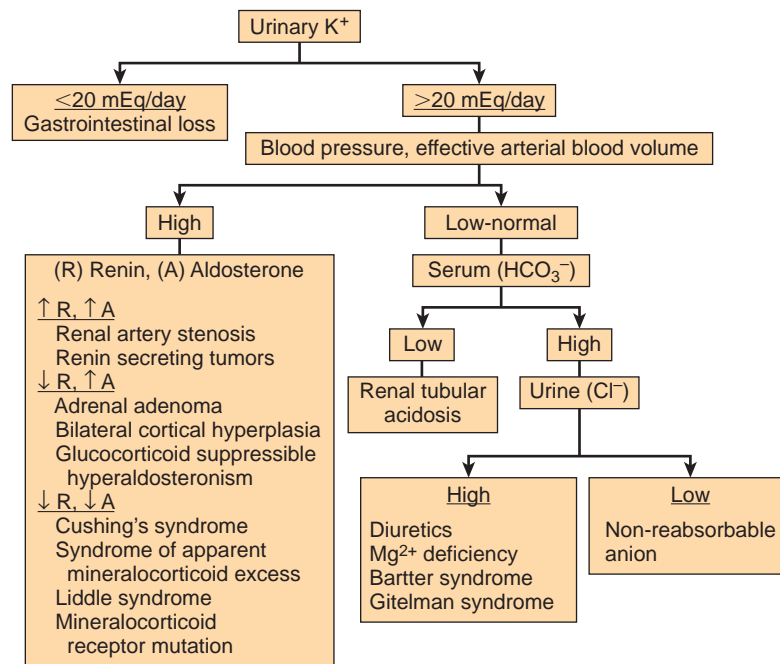

FIGURE 27-5 Approach to the hypokalemic patient. HCO_3^- , Bicarbonate; ↓, decreased; ↑, increased.

Increases in distal Na^+ delivery most frequently result from diuretics that act proximal to the cortical collecting duct. Increased delivery can also be the result of non-reabsorbed anions such as bicarbonate (HCO_3^-), as occurs with active vomiting, or of type II proximal renal tubular acidosis. Ketoanions (i.e., β -hydroxybutyrate and acetoacetate) and the Na^+ salts of penicillin are other examples. The inability to reabsorb these anions in the proximal tubule results in increased delivery of Na^+ to the distal nephron. Because these anions also escape reabsorption in the distal nephron, a more lumen-negative trans-epithelial voltage develops, and the driving force for K^+ excretion into the tubular fluid is enhanced. Disorders of hypokalemia due to primary increases in distal Na^+ delivery can best be categorized by the finding of metabolic acidosis or metabolic alkalosis.

Clinical Presentation

The most important clinical manifestations of hypokalemia occur in the neuromuscular system. A low serum K^+ concentration leads to cell hyperpolarization, which impedes impulse conduction and muscle contraction. Typically, a flaccid paralysis develops in the hands and feet that moves proximally to include the trunk and respiratory muscles. Death may occur from respiratory insufficiency. Myopathy may also occur, which in its most severe form can lead to frank rhabdomyolysis (i.e., muscle cell lysis) and renal failure. Hypokalemia can also lead to smooth muscle dysfunction, including paralytic ileus.

Changes in the electrocardiogram (ECG) include ST depression, T-wave flattening, and an increase in the amplitude of the U wave. Patients treated with cardiac glycosides are at increased risk for premature ventricular contractions and for supraventricular and ventricular tachyarrhythmia when hypokalemic.

Hypokalemia causes a renal concentrating defect due to a decrease in the medullary gradient and resistance of the cortical

collecting tubule to AVP. This leads to polyuria and polydipsia. Prolonged hypokalemia can also lead to tubulointerstitial nephritis and renal failure. Because insulin release is regulated partially by the serum K^+ concentration, hypokalemia can lead to glucose intolerance.

Treatment

The serum K^+ levels can sometimes be misleading about the degree of deficit because a normal or increased K^+ level can occur with significant total body K^+ depletion. In the absence of significant K^+ shifts, a decline in the serum K^+ level from 4 to 3 mEq/L usually is associated with a deficit of 300 to 400 mEq of intracellular K^+ per 70 kg of body weight. A serum K^+ concentration of 2 mEq/L reflects a deficit of roughly 600 mEq. Along with these guidelines, the serum K^+ level should be monitored frequently during replacement therapy.

Supplemental K^+ can be given orally or intravenously as the potassium chloride (KCl) salt. Potassium bicarbonate or citrate can be given if there is concomitant metabolic acidosis. The safest way to administer KCl is orally. KCl can be given in doses of 100 to 150 mEq/day. Liquid KCl is bitter tasting and, like the tablet, can irritate the gastric mucosa. The microencapsulated or wax-matrix forms of KCl are better tolerated.

Intravenous administration of K^+ may be necessary if the patient cannot take oral medications or the K^+ deficit is large and is causing cardiac arrhythmias, respiratory paralysis, or rhabdomyolysis. Intravenous KCl should be given at a maximum rate of 20 mEq/hour and maximum concentration of 40 mEq/L. Higher concentrations result in phlebitis. Replacement of KCl in dextrose-containing solutions can lower the serum K^+ further due to insulin release. Saline solutions are preferred.

Depending on the specific cause, additional therapy for chronic hypokalemia involves the use of K^+ -sparing diuretics such as amiloride, spironolactone, or triamterene. Caution is

warranted when using these agents in patients with renal insufficiency or other disorders that impair renal K^+ excretion.

● HYPERKALEMIA

Definition

As in the hypokalemic disorders, a high serum K^+ concentration can occur in the setting of normal or altered body stores of K^+ . The body has a marked ability to protect against hyperkalemia. This includes regulatory mechanisms that excrete excess K^+ quickly and mechanisms that redistribute excess K^+ into cells until it is excreted. All causes of hyperkalemia involve abnormalities in these mechanisms.

Pseudohyperkalemia is an in vitro phenomenon caused by the mechanical release of K^+ from cells during a phlebotomy procedure, specimen processing, or in the setting of marked leukocytosis and thrombocytosis.

Excessive Dietary Potassium Intake

In the setting of normal renal and adrenal function, it is difficult to ingest sufficient K^+ in the diet to produce hyperkalemia. Dietary intake of K^+ as a contributor to hyperkalemia is usually observed in patients with impaired kidney function. Dietary sources particularly enriched with K^+ include melons, citrus juice, and commercial salt substitutes containing KCl.

Cellular Redistribution

Cellular redistribution is a more important cause of hyperkalemia than as a cause of hypokalemia. Tissue damage is probably the most important cause of hyperkalemia due to redistribution of K^+ out of cells. This can be caused by rhabdomyolysis, trauma, burns, massive intravascular coagulation, and tumor lysis (spontaneous or after treatment).

The effect of metabolic acidosis in causing K^+ to exit from cells depends on the type of acid. Mineral acidosis (i.e., ammonium chloride [NH_4Cl] or hydrogen chloride [HCl]), by virtue of the relative impermeability of the chloride anion, results in the greatest efflux of K^+ from cells. In contrast, organic acidosis (lactic or β -hydroxybutyric) results in no significant efflux of K^+ .

Increased osmolality, as occurs in uncontrolled diabetes, causes K^+ to move out of cells. The hypertonic state and insulin deficiency account for hyperkalemia often seen in patients with diabetic ketoacidosis who are total body K^+ depleted. β -Adrenergic blocking agents can interfere with the disposal of acute K^+ loads. Other drugs that can result in hyperkalemia include the depolarizing muscle relaxant succinylcholine and digitalis in cases of severe poisoning.

Decreased Renal Excretion of Potassium

Decreased renal excretion of K^+ can occur because of three abnormalities: a primary decrease in distal delivery of salt and water, abnormal cortical collecting duct function, and a primary decrease in mineralocorticoid levels.

Primary Decrease in Distal Delivery of Salt and Water

Acute decreases in the glomerular filtration rate (GFR), as occur in acute kidney injury, may lead to marked decreases in the distal

delivery of salt and water, which may secondarily decrease distal K^+ secretion. When acute kidney injury is oliguric, distal delivery of NaCl and volume are low, and hyperkalemia is a frequent problem. When acute kidney injury is nonoliguric, distal delivery is usually sufficient, and hyperkalemia is unusual.

In chronic kidney disease patients, hyperkalemia is unusual until the GFR falls to less than 10 mL/min. Hyperkalemia with a GFR of more than 10 mL/min raises the question of decreased aldosterone levels or a specific lesion of the cortical collecting duct.

Primary Decrease in Mineralocorticoid Activity

Decreased mineralocorticoid activity can result from disturbances that originate at any point along the renin-angiotensin-aldosterone system. These disturbances can be the result of a disease state or various drugs. Hyperkalemia most commonly develops when one or more of these drugs are administered when the renin-angiotensin-aldosterone system is already impaired. A common example is the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin-receptor blockers (ARBs) in diabetics with hyporeninemic hypoaldosteronism.

Distal Tubular Defects

Certain interstitial renal diseases can affect the distal nephron specifically and lead to hyperkalemia despite mild decreases in the GFR and normal aldosterone levels. Amiloride and triamterene inhibit Na^+ transport, which makes the luminal potential more positive and secondarily inhibits K^+ secretion. A similar effect occurs with trimethoprim and accounts for the development of hyperkalemia after the administration of the antibiotic sulfamethoxazole-trimethoprim. Spironolactone and eplerenone compete with aldosterone and block the mineralocorticoid effect.

Clinical Presentation

Hyperkalemia leads to depolarization of the resting membrane because the potential across cell membranes is in part determined by the ratio of intracellular to extracellular K^+ . The heart is particularly sensitive to this depolarizing effect. The progressive changes of hyperkalemia on the electrocardiogram are peaking of T waves, widening of the PR and QRS interval, development of a sine wave pattern, and eventually, ventricular fibrillation and asystole.

ECG changes appear at a serum K^+ level of 6 mEq/L with acute onset of hyperkalemia, whereas the ECG may remain normal up to a concentration of 8 to 9 mEq/L with chronic hyperkalemia. Hyperkalemia can also cause neuromuscular manifestations such as ascending paralysis and flaccid quadriplegia.

Treatment

Acute Hyperkalemia

The immediate treatment for life-threatening hyperkalemia is the administration of calcium usually in the form of calcium gluconate or calcium chloride. ECG changes such as an increasing PR interval or a widening QRS complex warrant treatment with calcium. Glucose and insulin therapy shift K^+ into cells. Acute administration of glucose without insulin can potentially worsen

hyperkalemia in diabetics by raising extracellular osmolality and causing K^+ to shift into the extracellular space. Through expansion of the ECF space, $NaHCO_3$ administration results in dilution of the serum K^+ concentration. K^+ also is shifted into cells whenever concomitant metabolic acidosis is corrected. Inhalation of β_2 -agonists such as albuterol or parenteral use of salbutamol can effect significant K^+ shifts into cells.

The administration of calcium, HCO_3^- , glucose and insulin, and β_2 -agonist therapy provides immediate relief of acute toxicity but does not decrease total body K^+ . Measures to reduce total body K^+ include the administration of Na^+ polystyrene sulfonate (Kayexalate) and dialysis.

Chronic Hyperkalemia

After a review the patient's medication profile, drugs that can impair renal K^+ excretion should be discontinued if possible. Prescription or over-the-counter NSAIDs are common offenders. Patients should be placed on a low- K^+ diet with specific counseling against the use of K^+ -containing salt substitutes.

Diuretics are particularly effective in minimizing hyperkalemia. In patients with an eGFR >30 mL/min, thiazide diuretics can be used, but for more severe renal insufficiency, loop diuretics are required. In chronic kidney disease patients with metabolic acidosis (HCO_3^- concentration <20 mEq/L), $NaHCO_3$ should be given. Intermittent use of a K^+ -binding resin can be tried, but this drug is poorly tolerated when used on a chronic basis and has been associated with gastrointestinal ulceration.

METABOLIC ACIDOSIS

Metabolic acidosis is diagnosed by a low serum pH, a reduced plasma HCO_3^- concentration, and respiratory compensation resulting in a decrease in the partial pressure of carbon dioxide (P_{CO_2}). A low HCO_3^- concentration alone is not diagnostic of metabolic acidosis because it also results from renal compensation to chronic respiratory alkalosis. Measurement of the arterial pH differentiates these two possibilities. The pH is low in hyperchloremic metabolic acidosis and high in chronic respiratory alkalosis. The clinical approach to a patient with a low serum HCO_3^- concentration is given in Figure 27-6.

After confirming metabolic acidosis, calculation of the serum anion gap is a useful step in determining the differential diagnosis of the disorder. The anion gap is equal to the difference between the plasma concentrations of the major cation (Na^+) and the major measured anions ($Cl^- + HCO_3^-$).

$$\text{Anion gap} = [Na^+] - [Cl^-] - [HCO_3^-]$$

The normal value of the anion gap is approximately 12 ± 2 mEq/L. Most of the unmeasured anions consist of albumin, and the normal anion gap therefore changes in the setting of hypoalbuminemia (i.e., normal anion gap is approximately three times the serum albumin [in g/dL]).

Because the total number of cations must equal the total number of anions, a fall in the serum HCO_3^- concentration must be offset by a rise in the concentration of other anions. If the anion accompanying excess hydrogen ions (H^+) is Cl^- , the decrease in the serum HCO_3^- concentration is matched by an equal increase in the serum Cl^- concentration. The acidosis is

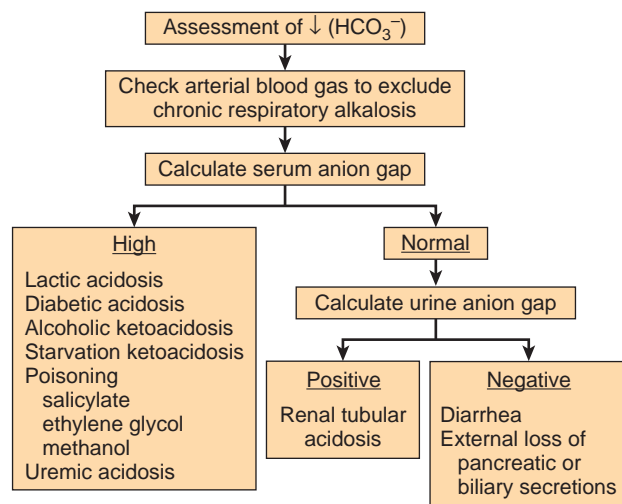

FIGURE 27-6 Approach to the patient with a reduced (\downarrow) serum bicarbonate (HCO_3^-) concentration.

classified as a normal anion gap or hyperchloremic metabolic acidosis. If excess H^+ is accompanied by an anion other than Cl^- , the decrease in HCO_3^- is balanced by an increase in the concentration of the unmeasured anion. The Cl^- concentration remains the same. In this setting, the acidosis is a high anion gap metabolic acidosis.

A useful method for differentiating extrarenal from renal causes of metabolic acidosis is measurement of urinary ammonium ion (NH_4^+) excretion. Extrarenal causes of metabolic acidosis are associated with an appropriate increase in net acid excretion, which is primarily reflected by high levels of urinary NH_4^+ excretion. In contrast, net acid excretion and urinary NH_4^+ levels are low in metabolic acidosis of renal origin. Unfortunately, measurement of urinary NH_4^+ is not a test that is commonly available in clinical medicine. However, the amount of urinary NH_4^+ can be indirectly assessed by calculating the urine anion gap (UAG).

$$UAG = (UNa^+ + UK^+) - UCl^-$$

Under normal circumstances, the UAG is positive, with values ranging from 30 to 50 mEq/L. Metabolic acidosis of extrarenal origin is associated with a marked increase in urinary NH_4^+ excretion, and a large negative value is therefore obtained for the UAG. If the acidosis is of renal origin, urinary NH_4^+ excretion is minimal, and the UAG value usually is positive.

Urine pH cannot reliably differentiate acidosis of renal origin from that of extrarenal origin. For example, an acidic urine pH does not necessarily indicate an appropriate increase in net acid excretion. With a significant reduction in the availability of NH_4^+ to serve as a buffer, only a small amount of distal H^+ secretion leads to a maximal reduction in urine pH. In this setting, the pH of the urine is acidic, but the quantity of H^+ secretion is insufficient to meet daily acid production. Alkaline urine does not necessarily imply a renal acidification defect. In conditions in which availability of NH_4^+ is not limiting, distal H^+ secretion can be massive, but the urine remains relatively alkaline because of the buffering effects of NH_4^+ .

Hyperchloremic or Normal Anion Gap Metabolic Acidosis

Hyperchloremic (normal anion gap) metabolic acidosis can have a renal or extrarenal origin. Metabolic acidosis of renal origin is the result of abnormalities in tubular H^+ transport. Metabolic acidosis of extrarenal origin is most commonly caused by gastrointestinal losses of HCO_3^- . Other causes include the external loss of biliary and pancreatic secretions and ureteral diversion procedures. [Figure 27-7](#) provides a clinical approach to metabolic acidosis of renal origin.

Renal Origin of Metabolic Acidosis

Proximal Renal Tubular Acidosis

The diagnosis of proximal renal tubular acidosis (type II RTA) is suspected in a patient with a normal anion gap acidosis, hypokalemia, and an intact ability to acidify the urine to a pH of less than 5.5 while in a steady state. In the steady state, the serum HCO_3^- concentration is usually in the range of 16 to 18 mmol/L. Proximal RTA can be an isolated finding but most commonly is accompanied by generalized dysfunction of the proximal tubule (i.e., Fanconi's syndrome). The UAG is normal.

Proximal RTA is not associated with nephrolithiasis or nephrocalcinosis. However, osteomalacia can develop as a result of chronic hypophosphatemia or deficiency of the active form of vitamin D. Osteopenia may occur as a result of acidosis-induced demineralization of bone.

Treatment of patients with proximal RTA is difficult. Correction of the acidosis is often not possible, even with large amounts of HCO_3^- (3 to 5 mmol/kg/day), because exogenous alkali is rapidly excreted in the urine. This therapy also leads to accelerated renal K^+ losses. Use of a thiazide diuretic to induce sufficient volume depletion to lower the GFR and decrease the filtered load of HCO_3^- may increase the effectiveness of alkali therapy. Potassium-sparing diuretics may limit the degree of renal K^+ wasting. After therapy is initiated, close monitoring is required to guard against severe electrolyte derangements. Topiramate can

cause metabolic acidosis due to its inhibitory effects on carbonic anhydrase.

Hypokalemic Distal Renal Tubular Acidosis

The diagnosis of hypokalemic distal RTA (type I RTA) should be considered in a patient with hyperchloremic or normal anion gap acidosis, hypokalemia, and an inability to lower the urine pH maximally. A urine pH greater than 5.5 in the setting of systemic acidosis is consistent with distal RTA. The UAG value is positive. The systemic acidosis tends to be more severe than in patients with a proximal RTA with serum HCO_3^- concentrations as low as 10 mmol/L.

Hypokalemia can be severe and cause musculoskeletal weakness and symptoms of nephrogenic diabetes insipidus. Patients frequently have nephrolithiasis and nephrocalcinosis. The predisposition to renal calcification results from the combined effects of increased urinary calcium ion (Ca^{2+}) excretion due to acidosis-induced bone mineral dissolution, a persistently alkaline urine pH, and low rate of urinary citrate excretion.

Correction of the metabolic acidosis in distal RTA can be achieved by administration of alkali in an amount equal to daily acid production (usually 1 to 2 mmol/kg/day). In patients with severe K^+ deficits, correction of the acidosis with HCO_3^- can transiently cause further lowering of the extracellular K^+ concentration and result in symptomatic hypokalemia. In this setting, the K^+ deficit should be corrected before correcting the acidosis. Potassium citrate is the preferred form of alkali for patients with persistent hypokalemia or with calcium stone disease.

Hyperkalemic Distal Renal Tubular Acidosis

Hyperkalemic distal RTA (type IV RTA) should be suspected in a patient with a normal anion gap (hyperchloremic) metabolic acidosis associated with hyperkalemia. The UAG is slightly positive, indicating little to no NH_4^+ excretion in the urine. Patients in which the disorder is caused by a defect in mineralocorticoid activity typically have a urine pH of less than 5.5, reflecting a

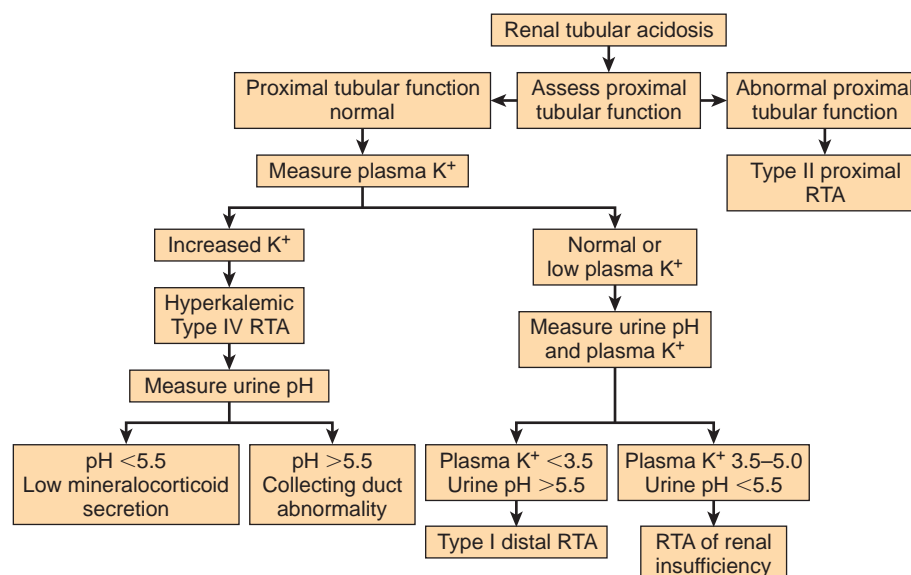

FIGURE 27-7 Approach to the patient with acidosis of renal origin. K^+ , Potassium ion; RTA, renal tubular acidosis.

more severe defect in ammonia (NH_3) availability than in H^+ secretion. In patients with structural damage to the collecting duct, the urine pH may be alkaline, reflecting impaired H^+ secretion and decreased urinary NH_4^+ excretion.

The syndrome is most often associated with mild or moderate renal insufficiency. However, the magnitudes of hyperkalemia and acidosis are disproportionately severe for the observed degree of renal insufficiency (Table 27-2).

The primary goal of therapy is to correct the hyperkalemia. In many instances, lowering the serum K^+ level simultaneously corrects the acidosis by restoring renal NH_4^+ production, increasing the buffer supply for distal acidification.

Renal Tubular Acidosis of Renal Insufficiency

Patients with chronic kidney disease initially develop a normal anion gap (hyperchloremic) metabolic acidosis associated with normokalemia as the GFR falls below 30 mL/min. With more advanced chronic kidney disease (GFR < 15 mL/min), the acidosis changes to predominately an anion gap metabolic acidosis, reflecting a progressive inability to excrete phosphate, sulfate, and the Na^+ salts of various organic acids. At this stage, the acidosis is commonly referred to as *uremic acidosis*.

Correction of the metabolic acidosis in patients with chronic kidney disease is achieved by treatment with NaHCO_3 (0.5 to 1.5 mmol/kg/day), beginning when the HCO_3^- level is less than 22 mmol/L. Metabolic acidosis should be aggressively treated because it can contribute to metabolic bone disease and increase catabolism in chronic kidney disease patients.

Extrarenal Origin of Metabolic Acidosis

Diarrhea

Loss of HCO_3^- in intestinal secretions beyond the stomach leads to development of metabolic acidosis. Volume loss signals the kidney to increase reabsorption of salt. Renal retention of NaCl combined with the intestinal loss of NaHCO_3 generates a normal

anion gap (hyperchloremic) metabolic acidosis. Net acid excretion markedly increases due to increases in urinary excretion of NH_4^+ . Hypokalemia as a result of gastrointestinal losses and the low serum pH stimulate the synthesis of NH_3 in the proximal tubule. Increased availability of NH_3 to act as a urinary buffer allows a maximal increase in H^+ secretion by the distal nephron. Urine pH during chronic diarrheal states may be persistently greater than 6.0 due to the large increase in buffer capacity.

A patient who has hypokalemic hyperchloremic metabolic acidosis with a urine pH greater than 5.5 may have a diarrheal condition or hypokalemic distal RTA (type I RTA). Although the clinical history would be the easiest way to distinguish between these two possibilities, in a patient with surreptitious laxative abuse, it may not be helpful. Determination of the UAG is the best way to differentiate them. In diarrhea, the urine pH is high because of the large amount of NH_4^+ in the urine. This is reflected by a negative UAG value because most of the NH_4^+ is excreted in the urine as NH_4Cl . In hypokalemic distal RTA, the urine pH is high because of the inability to secrete H^+ in the distal nephron. Urinary excretion of NH_3 is very low, and the UAG is positive.

Ileal Conduits

Surgical diversion of the ureter into the intestine may lead to development of a normal anion gap (hyperchloremic) metabolic acidosis due to systemic reabsorption of NH_4^+ and Cl^- from the urinary fluid and exchange of Cl^- for HCO_3^- through activation of the $\text{Cl}^-/\text{HCO}_3^-$ exchanger in the intestinal lumen. The main determinants for this complication are the length of time urine is in contact with the bowel and the total surface area of bowel exposed to urine.

Anion Gap Metabolic Acidosis

Lactic Acidosis

Lactic acidosis is generated when an imbalance develops between the production and use of lactic acid. Accumulation of a nonchloride anion accounts for the increase in the anion gap. In severe exercise and grand mal seizures, lactic acidosis can develop as a result of increased production. The short-lived nature of the acidosis in these conditions suggests that a concomitant defect in lactic acid use occurs in most conditions of sustained and severe lactic acidosis.

Type A lactic acidosis is characterized by disorders in which there is tissue hypoperfusion or acute hypoxia. These disorders include cardiopulmonary failure, severe anemia, hemorrhage, hypotension, sepsis, and carbon monoxide poisoning. Type B lactic acidosis occurs in patients with a variety of disorders that have in common the development of lactic acidosis in the absence of overt hypoperfusion or hypoxia (Table 27-3).

D-Lactic Acidosis

D-Lactic acidosis is a unique form of metabolic acidosis that can occur in the setting of small bowel resections or in patients with a jejunoileal bypass. These short-bowel syndromes create a situation in which carbohydrates that are normally extensively reabsorbed in the small intestine are delivered in large amounts to the colon. In the setting of colonic bacterial overgrowth, these

substrates are metabolized to D-lactate and absorbed into the systemic circulation. Accumulation of D-lactate produces an anion gap metabolic acidosis in which the serum lactate level appears to be normal because the standard test for lactate is specific for L-lactate.

These patients typically seek medical attention after ingestion of a large carbohydrate meal that causes neurologic abnormalities consisting of confusion, slurred speech, and ataxia. Ingestion of low-carbohydrate meals and antimicrobial agents to decrease the degree of bacterial overgrowth are the principal treatments.

Diabetic Ketoacidosis

Diabetic ketoacidosis is a metabolic condition characterized by the accumulation of acetoacetic acid and β -hydroxybutyric acid resulting from insulin deficiency and a relative or absolute increase in the glucagon concentration. The degree to which the anion gap is elevated depends on the rapidity, severity, and duration of the ketoacidosis and the status of the ECF volume. Although an anion gap acidosis is the dominant disturbance in diabetic ketoacidosis, a normal anion gap (hyperchloremic) acidosis often occurs in the earliest stages of ketoacidosis, when the ECF volume is near normal.

Confirmation of ketoacids can be achieved with the use of nitroprusside tablets or reagent strips. However, this test can be misleading in assessing the severity of ketoacidosis because it detects only acetone and acetoacetate, and it does not permit reaction with β -hydroxybutyrate.

Treatment of diabetic ketoacidosis involves the use of insulin and intravenous fluids to correct volume depletion. Deficiencies in K^+ , magnesium (Mg^{2+}), and phosphate (PO_4^{3-}) are common, and these electrolytes are typically added to intravenous solutions.

Alcoholic Ketoacidosis

Ketoacidosis develops in patients with a history of chronic ethanol abuse, decreased food intake, and often a history of nausea and vomiting. Alcohol withdrawal, volume depletion, and starvation markedly increase the levels of circulating

catecholamines and result in peripheral mobilization of fatty acids that is much larger in magnitude than that typically found with starvation alone. The metabolism of alcohol leads to an increase in the NADH/NAD⁺ (i.e., balance between the reduced and oxidized forms of nicotinamide adenine dinucleotide), causing a higher ratio of β -hydroxybutyrate to acetoacetate. The nitroprusside reaction may be diminished by this redox shift despite severe ketoacidosis.

Glucose administration leads to the rapid resolution of the acidosis. Stimulation of insulin release leads to diminished fatty acid mobilization from adipose tissue and decreased hepatic output of ketoacids.

Ethylene Glycol and Methanol Poisoning

Ethylene glycol and methanol poisoning are characteristically associated with the development of a severe anion gap metabolic acidosis. Together with the appearance of the anion gap, an osmolar gap manifests and is an important clue to the diagnosis of ethylene glycol and methanol poisoning.

Metabolism of ethylene glycol by alcohol dehydrogenase generates various acids, including glycolic, oxalic, and formic acids. Ethylene glycol is a component of antifreeze and solvents and is ingested by accident or as a suicide attempt. The initial effects of intoxication are neurologic and begin with drunkenness, but they can quickly progress to seizures and coma. If left untreated, cardiopulmonary symptoms such as tachypnea, noncardiogenic pulmonary edema, and cardiovascular collapse may appear. Between 24 and 48 hours after ingestion, patients may develop flank pain and renal failure, which are often accompanied by abundant calcium oxalate crystals in the urine.

Methanol is also metabolized by alcohol dehydrogenase and forms formaldehyde, which is then converted to formic acid. Methanol is found in a variety of commercial preparations such as shellac, varnish, and de-icing solutions. As with ethylene glycol ingestion, methanol is ingested by accident or as a suicide attempt.

Methanol ingestion is associated with an acute inebriation, followed by an asymptomatic period lasting 24 to 36 hours. At this point, abdominal pain is caused by pancreatitis. Seizures, blindness, and coma may develop. The blindness results from the direct toxic effects of formic acid on the retina. Methanol intoxication is also associated with hemorrhage in the white matter and putamen, which can lead to the delayed onset of a Parkinson-like syndrome. Lactic acidosis, which is a feature of methanol and ethylene glycol poisoning, contributes to the elevated anion gap.

In addition to supportive measures, the therapy for ethylene glycol and methanol poisoning centers on reducing the metabolism of the parent compound and accelerating removal of the alcohol from the body. Fomepizole (4-methylpyrazole) is the agent of choice to inhibit the enzyme alcohol dehydrogenase and prevent formation of toxic metabolites.

Salicylate Poisoning

Aspirin (acetylsalicylic acid) poisoning leads to increased lactic acid production. The accumulation of lactic, salicylic, keto, and other organic acids leads to development of an anion gap metabolic acidosis. At the same time, salicylate has a direct stimulatory effect on the respiratory center. Increased ventilation

lowers the PCO_2 , contributing to the development of respiratory alkalosis. Children primarily have an anion gap metabolic acidosis with toxic salicylate levels, whereas respiratory alkalosis is most evident in adults.

In addition to conservative management, the initial goal of therapy is to correct systemic acidemia and to increase the urine pH. By increasing the systemic pH, the ionized fraction of salicylic acid increases, and there is less accumulation of the drug in the central nervous system. Similarly, an alkaline urine pH favors increased urinary excretion because the ionized fraction of the drug is poorly reabsorbed by the tubule. At serum concentrations greater than 80 mg/dL or in the setting of severe clinical toxicity, hemodialysis can be used to accelerate removal of the drug from the body.

Pyroglutamic Acidosis

Pyroglutamic acidosis is a cause of anion gap metabolic acidosis accompanied by alterations in mental status ranging from confusion to coma. Pyroglutamic acidosis occurs in critically ill patients receiving therapeutic doses of acetaminophen, a setting in which glutathione levels are reduced as a result of acetaminophen metabolism and oxidative stress associated with critical illness. The diagnosis of pyroglutamic acidosis should be considered for patients with unexplained anion gap metabolic acidosis and recent acetaminophen ingestion.

METABOLIC ALKALOSIS

Definition

The pathogenesis of metabolic alkalosis involves generation and maintenance of the disorder. Metabolic alkalosis is caused by the addition of new HCO_3^- ions to the blood as a result of loss of acid or gain of alkali. New HCO_3^- ions may be generated by renal or extrarenal mechanisms. Because the kidneys have an enormous capacity to excrete HCO_3^- , even vigorous HCO_3^- generation may not be sufficient to produce sustained metabolic alkalosis. To maintain a metabolic alkalosis, the kidney's capacity to correct the alkalosis must be impaired, or the capacity to reclaim HCO_3^- ions must be enhanced.

Metabolic alkalosis is considered by most physicians to be a benign condition. However, a high blood pH can result in a number of effects that decrease tissue perfusion. Increases in blood pH (i.e., alkalemia) cause respiratory depression and decrease tissue oxygen delivery through the Bohr effect and vasoconstriction. Alkalosis should be aggressively corrected in critically ill patients in whom perfusion of the heart and brain is essential.

Treatment

The treatment of metabolic alkalosis is best approached according to the mechanism of maintenance because correction of the mechanism remedies the metabolic alkalosis. If the EABV can be restored with saline, the metabolic alkalosis is easily corrected. Several conditions are poorly responsive to the administration of NaCl. Metabolic alkalosis in these conditions usually is maintained by a combination of increased mineralocorticoid levels along with high distal Na^+ delivery and hypokalemia. The distinction between these entities relies on assessment of the EABV (Table 27-4).

Decreased Effective Arterial Blood Volume and Saline-Responsive Metabolic Alkalosis

Gastrointestinal Acid Loss

Loss of acid, as occurs with vomiting or nasogastric suction, is a common cause of metabolic alkalosis that is maintained by volume contraction. The loss of gastric acid generates a metabolic alkalosis, and the loss of NaCl in the gastric fluid leads to volume contraction. During active vomiting, the plasma HCO_3^- concentration tends to be higher than the threshold for reabsorption in the proximal nephron. The resultant bicarbonaturia leads to increased excretion of NaHCO_3 and KHCO_3 , resulting in further total body Na^+ depletion and development of K^+ depletion. During this active phase, urine Cl^- concentration is less than 15 mEq/L in the setting of high levels of urine Na^+ and K^+ and a urine pH of 7 to 8.

When the patient stops vomiting, equilibrium is established such that bicarbonaturia disappears but a metabolic alkalosis is maintained by volume contraction, K^+ depletion, and reduction

TABLE 27-4 METABOLIC ALKALOSIS CLASSIFICATION

CLASSIFICATION CHARACTERISTIC	TYPES OF METABOLIC ALKALOSIS		
	Decreased EABV, Saline Responsive	Decreased EABV, Saline Resistant	Increased EABV, Saline Resistant
EABV	Low	Low	High
Urine Cl^- concentration (mEq/L)	<15	>15	>15
Response to saline	Corrects (saline responsive)	No correction (saline resistant)	No correction (saline resistant)
Maintenance	Low EABV	Low EABV + high distal Na^+ delivery and mineralocorticoid effect	High distal Na^+ delivery and mineralocorticoid effect
Cause	Gastrointestinal acid loss: Vomiting or nasogastric suction Congenital chloridorrhea Villous adenoma Post-hypercapneic alkalosis Diuretics Non-reabsorbable anions	Primary increase in distal delivery of Na^+ : Active diuretic use (loop and thiazide) Mg^{2+} deficiency Bartter syndrome Gitelman syndrome	Primary increase in mineralocorticoid or mineralocorticoid-like effect: Conn syndrome Liddle syndrome Glucocorticoid-suppressible hyperaldosteronism

EABV, Effective arterial blood volume.

in the GFR. Decreased EABV is the main factor in the maintenance of metabolic alkalosis. At this point, urine Na^+ and Cl^- levels are low. Administration of NaCl results in bicarbonaturia, and the metabolic alkalosis is corrected.

Diuretics

Thiazide and loop diuretics are another common cause of metabolic alkalosis. The diuretics produce a metabolic alkalosis that is generated in the distal nephron by the combination of high aldosterone levels and enhanced distal delivery of Na^+ . If diuretics are stopped and the patient is maintained on a low-salt diet, the alkalosis is maintained despite the fact that distal delivery is no longer increased. In this setting, patients tend to be volume contracted and K^+ deficient. Contraction of the EABV is the major factor in the maintenance of metabolic alkalosis. Saline infusion in this setting corrects the metabolic alkalosis.

Decreased Effective Arterial Blood Volume and Saline-Resistant Metabolic Alkalosis

In some forms of metabolic alkalosis, the alkalosis is maintained by decreased EABV, but because of other maintenance factors, the alkalosis is not completely saline responsive. In these patients, saline infusions may improve the metabolic alkalosis but do not completely correct it. Patients may have a low EABV but typically do not have a low urine Cl^- level.

Continued use of thiazide or loop diuretics, magnesium deficiency, Gitelman syndrome, and Bartter syndrome can produce this condition. Treatment of the various causes of metabolic alkalosis is summarized in Table 27-5.

Increased Effective Arterial Blood Volume and Saline-Resistant Metabolic Alkalosis

One type of metabolic alkalosis is not maintained by decreased EABV but instead is maintained by K^+ deficiency and high mineralocorticoid levels in the setting of continued distal delivery of Na^+ . The most common cause of this saline-resistant alkalosis is a primary increase in mineralocorticoid levels not related to volume contraction. The mechanism of generation of the alkalosis—enhanced Na^+ delivery with high mineralocorticoid activity—is also responsible for maintenance of metabolic alkalosis. The K^+ deficiency that occurs in this setting exacerbates the tendency to produce alkalosis.

The preferred treatment of metabolic alkalosis in patients with volume expansion and primary mineralocorticoid excess is to remove the underlying cause of the persistent mineralocorticoid activity. When this is not possible, therapy is directed

at blocking the actions of the mineralocorticoid at the level of the kidney.

RESPIRATORY ALKALOSIS

Definition

Primary respiratory alkalosis results from hypocapnia and is defined by an arterial partial pressure of carbon dioxide (PaCO_2) of less than 35 mm Hg in the setting of alkalemia. Primary respiratory alkalosis should be differentiated from secondary hypocapnia, which is a compensatory mechanism in the setting of primary metabolic acidosis.

Respiratory alkalosis is the most frequent acid-base disturbance encountered. It is particularly common in hospitalized patients, for whom it can be the initial clue to gram-negative sepsis. Hepatic failure is a common and important cause of primary hypocapnia. The severity of hypocapnia correlates with the level of blood ammonia and has prognostic significance. Respiratory alkalosis can be an important clue to the existence of salicylate intoxication. High progesterone levels (in pregnancy) can also cause respiratory alkalosis.

Clinical Presentation

Mild respiratory alkalosis causes lightheadedness, palpitations, and paresthesia of the extremities and the circumoral area. Acute hypocapnia decreases cerebral blood flow and causes binding of free calcium to albumin in the blood. At clinical presentation, patients with acute respiratory alkalosis may appear similar to patients with hypocalcemia and have positive Chvostek and Trousseau signs. Patients with ischemic heart disease may occasionally develop cardiac arrhythmias, ischemic electrocardiographic changes, and angina pectoris during acute hypocapnia.

Diagnosis

The diagnosis of respiratory alkalosis is made by evaluating the patient's history, performing a physical examination, and obtaining laboratory data, including a blood gas analysis. Tachypnea or Kussmaul breathing can be detected on physical examination, and it may be the first clue to a primary respiratory alkalosis or a compensatory respiratory mechanism in the setting of primary metabolic acidosis.

Changes in serum electrolytes can aid in the diagnosis of respiratory alkalosis. An acute fall in PCO_2 causes an HCO_3^- - Cl^- shift in red blood cells and accounts for the small initial compensatory response in acute respiratory alkalosis in which the

TABLE 27-5 TREATMENT OF SALINE-RESISTANT METABOLIC ALKALOSIS

DECREASED EABV		INCREASED EABV	
Cause	Treatment	Cause	Treatment
Thiazide and loop diuretics	Discontinue drug, replete EABV	Renin secreting tumor	Remove tumor

TABLE 27-6 COMPENSATION IN ACID-BASE DISORDERS

DISORDER	COMPENSATORY CHANGES
Acute respiratory acidosis	For every 10 mm Hg rise in PCO_2 , the HCO_3^- increases by 1 mEq/L
Chronic respiratory acidosis	For every 10 mm Hg rise in PCO_2 , the HCO_3^- increases by 3.5 mEq/L
Acute respiratory alkalosis	For every 10 mm Hg fall in PCO_2 , the HCO_3^- decreases by 2 mEq/L
Chronic respiratory alkalosis	For every 10 mm Hg decrease in PCO_2 , the HCO_3^- decreases by 5 mEq/L
Metabolic acidosis	1.2 mm Hg decrease in PCO_2 for each 1 mEq/L fall in HCO_3^- $\text{PCO}_2 = \text{HCO}_3^- + 15$ PCO_2 resembles last two digits of pH
Metabolic alkalosis	PCO_2 increases by 0.7 mm Hg for each mEq/L HCO_3^-

HCO_3^- concentration falls by 2 mEq/L for every 10 mm Hg decrease in PCO_2 . Table 27-6 provides the expected compensatory responses for acid-base disorders.

In chronic respiratory alkalosis, the renal HCO_3^- reabsorptive capacity decreases, and there is a transient HCO_3^- diuresis. This process takes 2 to 3 days to fully manifest. After the new steady state is achieved, the HCO_3^- concentration has decreased by 5 mEq/L for each 10 mm Hg fall in the PCO_2 . A higher or lower value for the plasma HCO_3^- concentration suggests an additional metabolic disorder.

To defend ECF volume in the setting of increased urinary loss of NaHCO_3 , the kidney retains NaCl . These changes are reflected in the serum electrolyte levels of patients with chronic respiratory alkalosis, in whom the Cl^- level is typically increased with respect to the serum Na^+ concentration. Another characteristic finding is an increase of 3 to 5 mEq/L in the serum anion gap. The increased gap results from the greater fixed negative charge on serum albumin and an increase in the serum lactate concentration. Lactate production is increased due to a stimulatory effect of high pH on phosphofructokinase, the rate-limiting step in the glycolytic pathway.

Treatment

Primary respiratory alkalosis is treated by correcting the underlying cause. A patient with anxiety-hyperventilation syndrome should be treated by providing reassurance. Rebreathing into a paper bag or any other closed system causes the PCO_2 to increase with each breath taken and leads to partial correction of hypocapnia and improvement of symptoms. In the rare case when there is no response to conservative management, sedatives can be used. In mechanically ventilated patients, the PCO_2 can be increased by raising the inspired carbon dioxide tension or by increasing the dead space of the ventilator circuit.

Correction of respiratory alkalosis may prove helpful in correcting arrhythmias in patients with underlying coronary disease. In contrast, caution is warranted in raising the PCO_2 in patients with brain injury because cerebral perfusion may increase and worsen intracranial pressure. Respiratory alkalosis frequently develops as a complication of hypoxia. Administration of oxygen or return to lower altitudes can reverse the respiratory alkalosis that develops in this setting.

RESPIRATORY ACIDOSIS

Definition

Respiratory acidosis develops as a result of ineffective alveolar ventilation. This acid-base disorder, which is also called *primary hypercapnia*, should be differentiated from secondary hypercapnia, which develops as a compensatory mechanism in the setting of primary metabolic alkalosis. Primary hypercapnia is clinically recognized by PaCO_2 levels greater than 45 mm Hg on arterial blood gas analysis. However, PaCO_2 levels of less than 45 mm Hg may still indicate respiratory acidosis if a primary metabolic acidosis is not adequately compensated by alveolar ventilation.

The development of respiratory acidosis is usually multifactorial. Major causes of carbon dioxide retention include diseases of or malfunction in any element of the respiratory system, including the central and peripheral nervous systems, respiratory muscles, thoracic cage, pleural space, airways, and lung parenchyma. Six factors should be considered in the differential diagnosis of acute and chronic respiratory acidosis: inhibition of the medullary respiratory center, disorders of the chest wall and respiratory muscles, airway obstruction, disorders affecting gas exchange across the pulmonary capillary, increased carbon dioxide production, and mechanical ventilation.

Clinical Presentation

Hypercapnic encephalopathy is a clinical syndrome that usually starts with irritability, headache, mental cloudiness, apathy, confusion, anxiety, and restlessness. It can progress to asterixis, transient psychosis, delirium, somnolence, and coma. Papilledema and other manifestations of increased intracranial pressure that are collectively named *pseudotumor cerebri* are occasionally observed in patients with acute or chronic hypercapnia. The increase in intracranial pressure is caused in part due by cerebral vasodilation resulting from acidemia.

Acute respiratory acidosis is typically much more symptomatic than acute metabolic acidosis because carbon dioxide diffuses and equilibrates across the blood-brain barrier much more rapidly than does HCO_3^- , resulting in a more rapid fall in cerebral spinal fluid and cerebral interstitial pH. Severe hypercapnia also can lead to decreased myocardial contractility, arrhythmias, and peripheral vasodilatation, particularly when the blood pH falls to less than 7.1.

Diagnosis

The diagnosis of primary respiratory acidosis is based on the finding of acidemia and hypercapnia on arterial blood gas analysis. Changes in the serum chemistries can aid in the diagnosis of respiratory acidosis.

Acute hypercapnia is associated with a shift of HCO_3^- out of red blood cells in exchange for Cl^- , a process called *red cell HCO_3^- - Cl^- shift*. Acutely, the plasma HCO_3^- concentration increases by 1 mmol/L for each 10 mm Hg of elevation in the PaCO_2 . After 24 to 48 hours of hypercapnia, proximal tubular cells increase H^+ secretion, resulting in accelerated HCO_3^- reabsorption. The retention of NaHCO_3 leads to slight expansion of the ECF compartment and increases renal excretion of NaCl to return the volume level to normal. The net effect is increased

serum HCO_3^- and decreased Cl^- concentrations. In chronic respiratory acidosis, there is a 3.5 mEq/L increase in HCO_3^- for each 10 mm Hg elevation in the PaCO_2 . Higher or lower plasma HCO_3^- concentrations suggest mixed respiratory and metabolic acid-base disorders.

Treatment

The mainstay of treatment in respiratory acidosis is to recognize and treat the underlying cause when possible. Patients with acute respiratory acidosis are primarily at risk for hypoxemia rather than hypercapnia or acidemia. Immediate therapeutic efforts should focus on establishing and securing a patent airway to provide adequate oxygenation. In patients with status asthmaticus, a lower ventilatory rate and peak inspiratory pressure may be required to minimize barotrauma to the lung, but it is achieved at the expense of a persistently higher PCO_2 . Small amounts of NaHCO_3 can help to prevent excessive decreases in blood pH in this setting. The downside of this therapy is that infusion of NaHCO_3 can result in increased carbon dioxide production, causing a further increase in PCO_2 when ventilation cannot be increased.

Excessive oxygen should be avoided in patients with chronic respiratory acidosis because it may lead to worsening hypoventilation. When mechanical ventilation is required, care should be taken to lower the PaCO_2 carefully and slowly because there is the risk of overshoot alkalemia due to a high HCO_3^- (i.e., post-hypercapnic metabolic alkalosis). The kidneys must excrete the HCO_3^- to normalize the acid-base status. This excretion does not occur when the EABV is reduced because of salt depletion due

to restricted intake or diuretic therapy or because of a salt-retentive state such as heart failure or cirrhosis. Correction of the superimposed metabolic alkalosis can usually be achieved with saline and discontinuation of loop diuretics. In edematous patients with heart failure, this is not possible, and acetazolamide may be needed to correct the alkalosis.

Glomerular Diseases

Sanjeev Sethi, An De Vriese, and Fernando C. Fervenza

INTRODUCTION

The glomerulus can be injured in a variety of disorders, and glomerular injury or disease can manifest as hematuria, proteinuria, hypertension, fluid retention, and a reduction in the glomerular filtration rate. Traditionally, glomerular diseases have been classified according to clinical presentation, including asymptomatic microscopic hematuria, the nephritic syndrome, the nephrotic syndrome, and rapidly progressive glomerulonephritis (RPGN). However, great progress has been made in unraveling the molecular causes of glomerular diseases. For instance, autoantibodies against the phospholipase A₂ receptor have been associated with membranous nephropathy, a disease that manifests clinically as nephrotic syndrome. Many glomerular diseases can manifest with more than one constellation of signs and symptoms and show more than one histologic pattern on renal biopsy. In the future, the etiologic approach to the classification of glomerular diseases will undoubtedly be expanded.

CLINICAL PRESENTATION

A detailed history and careful physical examination, with particular attention to the time of symptom onset, help to clarify the differential diagnosis of suspected glomerular disease. Blood pressure and fluid status should be recorded. Urine microscopy is a critical element of this assessment, and it may reveal hematuria, typically with dysmorphic red blood cells and casts. Hematuria due to glomerular disease is painless and often associated with brown or cola-colored urine rather than bright red; clots are rare. Other causes of brown urine include hemoglobinuria, myoglobinuria, and food or drug dyes (e.g., beetroot).

Quantitative evaluation of the degree of urinary protein excretion is essential. In adults, urine total protein excretion is less than 150 mg/24h, and urinary albumin excretion is less than 20 mg/24h. Persistent albumin excretion of 30 to 300 mg/24h reflects high albuminuria (i.e., microalbuminuria), and albumin excretion above 300 mg/24h, the level at which the standard dipstick becomes positive, reflects overt proteinuria. Levels above 3.5 g/24h are considered to be nephrotic-range proteinuria. The principal constituent of the protein excreted by these patients is albumin (up to 98% in some cases).

A 24-hour urine collection remains the gold standard, but it is cumbersome, is often collected incorrectly, and does not provide a rapid result. A protein-to-creatinine ratio measured on a spot urine sample has emerged as a useful alternative. The urine protein concentration (in mg/dL) divided by the urine creatinine concentration (in mg/dL) yields a dimensionless number that

approximates the 24-hour protein excretion (in g/24h). The reliability of the protein-to-creatinine ratio is limited in patients who excrete approximately 1 g/24h of creatinine, such as in those who are severely catabolic.

Glomerular proteinuria can be classified as transient or hemodynamic (functional) (e.g., fever, exercise induced, orthostatic) or as persistent (fixed). Although functional proteinuria is benign, fixed nephrotic-range proteinuria is usually results from glomerular diseases. Total proteinuria greater than 1 g/24h in a patient with a negative urine dipstick test result (which detects only albumin) suggests that the proteinuria may be caused by light chains or low-molecular-weight proteins (e.g., retinol-binding protein, α_1 -microglobulin).

CLINICAL SYNDROMES

The major clinical syndromes associated with glomerular injury are discussed in this section. In each case, general recognition and management should be pursued in parallel with efforts to define the specific mechanisms of injury.

Nephrotic Syndrome

Nephrotic syndrome is defined as persistent urinary total protein excretion greater than 3.5 g/24h, accompanied by a serum albumin concentration less than 3.5 g/dL. Edema, hyperlipidemia, and lipiduria (i.e., doubly refractile fat bodies) are common but are not required for the diagnosis.

Complications of the nephrotic syndrome include hypogammaglobulinemia, vitamin D deficiency due to loss of vitamin D-binding protein, and iron deficiency anemia due to hypotransferrinemia. Thrombotic complications such as renal vein thrombosis are more common, especially in patients with greater protein loss (>10 g/24h) and serum albumin levels less than 2 g/dL. Patients with severe nephrotic syndrome may also have acute renal failure when there is superimposed volume depletion, sepsis, interstitial nephritis, or use of nephrotoxic agents such as nonsteroidal anti-inflammatory drugs (NSAIDs).

Management of patients with nephrotic syndrome includes diuretics to control edema, regulation of blood pressure (angiotensin-converting enzyme inhibitors [ACEIs] and angiotensin-receptor blockers [ARBs] are preferred), limitation of the intake of protein to between 0.8 and 1 g/kg/day and sodium to less than 4 g/day, and control of lipid levels. Anticoagulation should be considered for patients at increased risk, especially if the nephrotic syndrome is caused by membranous nephropathy or amyloidosis.

Nephritic Syndrome

The nephritic syndrome is defined by oliguria, edema, hypertension, proteinuria (usually <3.5 g/24h), and abnormal urinalysis with dysmorphic red blood cells or casts on microscopic examination.

Rapidly Progressive Glomerulonephritis

RPGN is a clinical syndrome characterized by progressive loss of kidney function with a time course of days to months in a patient with active urinary sediment such as red blood cell casts. Patients may have oliguria. Most of the pulmonary-renal syndromes manifest in this fashion, and the pathologic corollary is often a focal, necrotizing, crescentic glomerulonephritis. When RPGN is suspected, renal biopsy with immunofluorescence studies is extremely helpful.

Linear deposition of immunoglobulin G (IgG) points to Goodpasture disease or anti-glomerular basement membrane (anti-GBM)-mediated glomerulonephritis. Immunoglobulins and complement suggest systemic lupus erythematosus (SLE), cryoglobulinemia, immunoglobulin A nephropathy (IgAN), or postinfectious glomerulonephritis. Negative or weak immunofluorescence (pauci-immune) findings usually indicate an antineutrophil cytoplasmic autoantibody (ANCA) vasculitis (Fig. 28-1).

GLOMERULAR DISEASES MANIFESTING WITH NEPHROTIC SYNDROME

Minimal Change Disease

In a patient with nephrotic syndrome, minimal change disease (MCD) is defined by a renal biopsy with no significant glomerular abnormalities on light microscopy, negative immunoglobulin and complement deposition on immunofluorescence, and widespread foot process effacement on electron microscopy (Fig. 28-2). MCD is the most common cause of nephrotic syndrome in children and accounts for up to 20% of adults with primary nephrotic syndrome.

The pathogenesis of MCD is unknown. The association with Hodgkin's lymphoma suggests that MCD may be a consequence of T-lymphocyte abnormalities, with T cells producing a lymphokine that is toxic to glomerular epithelial cells. Most cases of MCD are idiopathic, although drugs (e.g., NSAIDs), hematologic malignancies (mainly Hodgkin's lymphoma), and thymoma are well-recognized causes of secondary MCD. Concomitant interstitial nephritis suggests drugs (e.g., NSAIDs) as the likely cause of MCD.

In children, MCD usually manifests with nephrotic syndrome of acute onset. Hematuria, hypertension, or impaired renal function is unusual and suggests another diagnosis. When nephrotic syndrome occurs in a child with normal urinalysis results, the

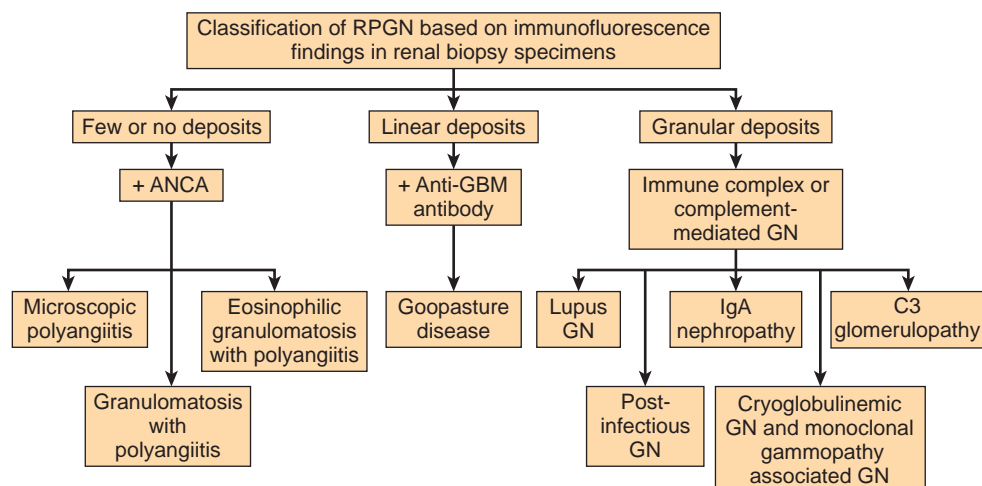

FIGURE 28-1 Rapidly progressive glomerulonephritis (RPGN) is classified according to immunofluorescence microscopy findings in renal biopsy specimens. ANCA, Antineutrophil cytoplasmic autoantibody; GBM, glomerular basement membrane; GN, glomerulonephritis; IgA, immunoglobulin A.

FIGURE 28-2 Minimal change disease. **A**, Light microscopy shows a normal-appearing glomerulus (periodic acid-Schiff, $\times 40$). **B** and **C**, Electron microscopy shows diffuse foot process effacement (arrows) (**B**, $\times 2500$; **C**, $\times 4200$). Immunofluorescence studies were negative for immune deposits.

diagnosis is MCD until proved otherwise, and treatment with high-dose corticosteroid therapy can be started, often without the need of a renal biopsy.

More than 90% of children achieve complete remission after 4 to 8 weeks of treatment. Children who do not respond to corticosteroid therapy should undergo a renal biopsy. Adolescents and adults also respond to high-dose corticosteroids (>80%), but the response is slower, and treatment for 16 weeks or more may be required to achieve remission. Therapy usually is continued for 4 to 8 weeks after remission.

Among patients who have a response to corticosteroids, about 25% have a long-term remission. However, up to 25% of the patients have frequent relapses, and up to 30% become steroid dependent. For these patients, alternative therapies aiming to minimize corticosteroid toxicity include the use of alkylating agents, antimetabolites, and calcineurin inhibitors. Although these agents may allow a lower corticosteroid dose, some patients respond poorly or not all, and use of an agent may be complicated by development of significant side effects. Noncompliance is always a concern, especially in young patients. Rituximab is a chimeric human-murine monoclonal antibody that targets the CD20 antigen expressed on B cells. It has been efficacious in a number of autoimmune diseases and has promise in the treatment of MCD.

Focal Segmental Glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS) is a clinicopathologic syndrome, and the common pathophysiologic element is podocyte injury and depletion leading to glomerular scarring (Fig. 28-3). FSGS accounts for less than 15% of cases of idiopathic nephrotic syndrome in children and up to 25% in adults. FSGS is thought to be the most common form of idiopathic nephrotic syndrome in African Americans; it most likely represents a different disease from FSGS in Caucasians. Hypertension is found in 30% to 50% of patients with FSGS, and microscopic hematuria occurs in 25% to 75% of cases. Up to 30% of those with FSGS have impaired renal function.

The pathogenesis of idiopathic or primary FSGS is unknown. A circulating permeability factor has been demonstrated in some patients. More recently, the soluble urokinase-type plasminogen activator receptor (suPAR) has been identified as a potential marker because levels are elevated in two thirds of cases of

primary FSGS and levels are higher in renal transplant recipients with recurrent FSGS. However, suPAR levels do not distinguish primary from secondary FSGS, and serum levels increase with reductions in the glomerular filtration rate. Further research is needed to define the role of serum suPAR in idiopathic FSGS.

Secondary causes of FSGS include genetic mutations in podocyte genes, human immunodeficiency virus (HIV) infection, sickle cell disease, vesicoureteral reflux, obesity, unilateral renal agenesis, remnant kidneys, and aging (Table 28-1). Four histologic variants of FSGS have been described. The cellular or collapsing variant, which has the worst prognosis, is more common in African Americans and patients with HIV infection.

Spontaneous remission of proteinuria is uncommon (<5% of cases). Treatment of the primary forms consists of prolonged (>4 months), high-dose corticosteroid therapy (prednisone, 1 mg/kg/day), but there is no study comparing this approach with other forms of therapy. If patients are going to respond to corticosteroids, proteinuria starts to decrease soon after the start of treatment, and those who show no reduction in proteinuria after 2 to 3 months of prednisone at 1 mg/kg/day are unlikely to respond. For patients who respond to corticosteroids but undergo relapse, alternative therapy includes the use of cytotoxic drugs alone or in combination with corticosteroids, calcineurin inhibitors, and possibly rituximab. For patients with secondary forms of FSGS, treatment should target the cause.

TABLE 28-1 CAUSES OF FOCAL SEGMENTAL GLOMERULOSCLEROSIS

PRIMARY (IDIOPATHIC) FSGS

- Attributed to a circulating permeability factor

SECONDARY FSGS

- Genetic mutations in podocyte genes
- Viral: HIV-associated nephropathy, parvovirus B19, simian virus 40, cytomegalovirus
- Drug induced: heroin, interferon (α , β , γ), pamidronate, sirolimus, calcineurin inhibitors
- Adaptive: reduced nephron mass or glomerular adaptation, unilateral renal agenesis, obesity-related glomerulopathy, basement membrane defects healing phase of focal proliferative glomerulonephritis, body building, sickle cell anemia, hypertensive nephrosclerosis, thrombotic microangiopathy, aging kidney
- Other causes: hemophagocytic syndrome

FSGS, Focal segmental glomerulosclerosis; HIV, human immunodeficiency virus.

FIGURE 28-3 Focal segmental glomerulosclerosis. **A**, Light microscopy shows segmental sclerosis (arrow) with segmental consolidation of the glomerular capillary tufts and visceral epithelial cell hypertrophy over the segmentally sclerosed tufts (silver methenamine, $\times 40$). **B**, Electron microscopy shows diffuse foot process effacement (arrows) of the visceral epithelial cells ($\times 1850$). Immunofluorescence studies were negative for immune deposits.

In all patients, treatment with an ACEI or ARB, alone or in combination, may substantially reduce proteinuria and prolong renal survival. Patients who have a non-nephrotic-range proteinuria have the best renal survival (>80% at 10 years). In patients who continue to have a high degree of proteinuria (>10 g/day), end-stage renal disease (ESRD) typically develops over 5 to 20 years. Idiopathic FSGS may recur in a transplanted kidney.

HIV-Associated Nephropathy

Patients with HIV infection can have many forms of kidney injury due to sepsis, co-infection with hepatitis B or C virus (HBV or HCV), nephrotoxic drugs, and use of antiretroviral agents. HIV-associated nephropathy (HIVAN) is a clinicopathologic entity characterized by nephrotic-range proteinuria and a collapsing form of FSGS, often with microcystic tubular dilation. On electron microscopy, tubuloreticular inclusions (i.e., interferon fingerprints) may be seen within the glomerular and vascular endothelial cells.

HIVAN occurs almost exclusively in patients of African descent when CD4 levels are low. It is thought to be caused by infection and subsequent expression of HIV viral genes in podocytes. The onset of proteinuria is typically acute. Proteinuria can be greater than 10 g/day, and renal insufficiency can progress rapidly.

Membranous Nephropathy

Membranous nephropathy is the leading cause of nephrotic syndrome in whites. It occurs in persons of all ages and races but is most often diagnosed in middle age, with the incidence peaking during the fourth and fifth decades of life. The male-to-female ratio is about 2 : 1.

Autoantibodies against the phospholipase A₂ receptor in podocytes are found in about 70% of patients with the primary form of the disease. Most patients have nephrotic syndrome, normal renal function, and no hypertension. Microscopic hematuria may be detected in about one third of patients. Secondary membranous nephropathy is caused by autoimmune diseases (e.g., SLE, autoimmune thyroiditis), infection (e.g., HBV, HCV), drugs (e.g., penicillamine, NSAIDs), and solid malignancies (e.g., colon cancer, lung cancer).

On light microscopy, capillary walls may appear thickened, and methenamine silver stain shows subepithelial projections (“spikes”) along the capillary walls. Immunofluorescence

microscopy shows marked granular deposition of IgG and C3 along the capillary walls, and subepithelial deposits are seen on electron microscopy (Fig. 28-4).

Up to one third of the patients with membranous nephropathy undergo spontaneous remission, and another one third of patients undergo partial remission. Initial therapy should include angiotensin II receptor blockade, a low-salt diet (<4 g/day), a low-protein diet (0.8 to 1 g/kg/day), and lipid control. If spontaneous remission occurs, it usually does so within the first 12 to 24 months.

Patients who remain nephrotic or those with declining renal function are candidates for immunosuppressive therapy, including a combination of corticosteroids and cytotoxic agents or calcineurin inhibitor monotherapy. Rituximab has recently garnered attention as a potential breakthrough in the treatment of membranous nephropathy, and studies are being conducted. The probability of renal survival is more than 80% at 5 years and about 60% at 15 years. Patients with an accelerated course should be evaluated for superimposed anti-GBM disease, acute interstitial nephritis, or renal vein thrombosis.

GLOMERULAR DISEASES MANIFESTING WITH NEPHRITIC SYNDROME

Infection-Associated Glomerulonephritis

Poststreptococcal glomerulonephritis (PSGN) is a classic form of acute glomerulonephritis that develops 1 to 4 weeks after a pharyngitis or skin infection with specific (nephritogenic) strains of group A β-hemolytic streptococci. It typically occurs in children and usually has a benign course. More recently, however, infection-associated glomerulonephritis has been recognized to have a broader spectrum, including affecting elderly and immunocompromised patients and being associated with different bacteria, particularly staphylococci. Unlike classic PSGN, the variant occurs when the infection is still active and has an unfavorable prognosis.

Infection-associated glomerulonephritis manifests clinically with the abrupt onset of nephritic syndrome. In patients with PSGN, cultures are usually negative, but elevated titers of antistreptolysin O (ASO), antistreptokinase, antihyaluronidase, and anti-deoxyribonuclease (anti-DNAse B) antibodies may provide evidence of recent streptococcal infection. Activation of the alternative complement pathway is reflected by low C3 complement

FIGURE 28-4 Membranous nephropathy. **A**, Light microscopy shows thickened glomerular basement membranes ($\times 60$). **B**, Immunofluorescence study shows granular immunoglobulin G deposition along the capillary walls ($\times 20$). **C**, Electron microscopy shows subepithelial electron-dense deposits (arrows) ($\times 15,000$).

levels. C4 levels are usually normal or mildly decreased. Other nephrologic conditions associated with low complement are C3 glomerulopathy, lupus nephritis, cryoglobulinemic glomerulonephritis, and cholesterol emboli (Table 28-2).

Renal biopsy typically shows diffuse glomerular hypercellularity and infiltration of polymorphonuclear leukocytes, monocytes, or macrophages on light microscopy. Immunofluorescence shows granular deposition of IgG, C3, and occasionally immunoglobulin M (IgM). On electron microscopy, characteristic dome-shaped subepithelial deposits (“humps”) can be seen along the GBM (Fig. 28-5).

Treatment is supportive and aims to minimize fluid overload, optimize blood pressure control, and eradicate ongoing infection. For children, the prognosis is excellent, with most patients recovering renal function in 1 to 2 months. Some patients have persistent microscopic hematuria, proteinuria, hypertension, and renal dysfunction and are said to have *atypical*, *persistent*, or *resolving* PSGN. Some of these patients have mutations or autoantibodies to proteins in the alternative complement cascade.

Immunoglobulin A Nephropathy

IgAN (i.e., Berger disease) is the most common form of a primary glomerulopathy. On light microscopy, mesangial proliferation is

seen along with mesangial deposition of IgA on immunofluorescence and electron-dense deposits in the mesangial cells on electron microscopy (Fig. 28-6).

Patients may have episodes of macroscopic hematuria accompanying an intercurrent upper respiratory tract infection (sympathetic) or have asymptomatic hematuria, with or without proteinuria, detected on routine urinalysis. Proteinuria is common, but nephrotic syndrome occurs in less than 10% of cases and raises the possibility of a podocytopathy (e.g., MCD) superimposed on IgAN.

The pathogenesis of IgA nephropathy has been linked to galactose-deficient IgA1 (GD-IgA1) molecules and increased formation of anti-GD-IgA1 autoantibodies, with deposition of IgG or IgA anti-GD-IgA1 immune complexes in the mesangium, resulting in activation of complement and cytokine cascades. Secondary causes of IgAN include chronic liver disease, celiac disease, dermatitis herpetiformis, and ankylosing spondylitis.

In up to 60% of the patients, IgA nephropathy has a benign clinical course, and patients maintain proteinuria of less than 500 mg/24h and preserve renal function. However, progression to ESRD occurs in up to 40% of patients over 10 to 25 years. Clinical predictors of progression include proteinuria greater than 1 g/24h, hypertension, and impaired renal function at diagnosis. Any degree of proteinuria carries a worse prognosis for a patient with IgAN. IgAN frequently recurs after renal transplantation, but loss of the allograft from recurrent disease is uncommon.

The use of angiotensin II system blockade and high-dose corticosteroids has been beneficial in slowing or halting progression of renal disease. Henoch-Schönlein purpura is the systemic form of IgAN. The prognosis is generally good for children but varies for adults.

TABLE 28-2 GLOMERULAR DISEASES ASSOCIATED WITH HYPOCOMPLEMENTEMIA

Acute lupus nephritis
C3 glomerulopathy (C3 glomerulonephritis and dense deposit disease)
Cholesterol emboli
Cryoglobulinemic glomerulonephritis
Postinfectious glomerulonephritis

FIGURE 28-5 Postinfectious glomerulonephritis. **A** and **B**, Light microscopy shows diffuse endocapillary proliferative glomerulonephritis. Notice the prominent neutrophil infiltration in the glomerular capillaries (**A**, hematoxylin and eosin; **B**, silver methenamine; both $\times 40$). **C** and **D**, Immunofluorescence studies show granular immunoglobulin G and C3 deposition along the capillary walls (both $\times 20$). **E** and **F**, Electron microscopy shows subendothelial deposits (*white arrows*) and subepithelial humplike deposits (*black arrows*). The subendothelial deposits likely result from circulating immune complexes that are deposited along the glomerular capillary walls and drive the inflammatory response (**E**, $\times 5800$). The subepithelial deposits likely represent in situ immune complex formation (**F**, $\times 2850$).

FIGURE 28-6 Immunoglobulin A (IgA) nephropathy. **A**, Light microscopy shows mesangial hypercellularity (*black arrow*) (silver methenamine, $\times 40$). **B**, Immunofluorescence microscopy shows bright mesangial IgA staining. **C**, Electron microscopy shows large mesangial electron-dense deposits (*arrow*) ($\times 7860$)

FIGURE 28-7 Immune complex-mediated membranoproliferative glomerulonephritis due to hepatitis C virus infection. **A**, Light microscopy shows a membranoproliferative pattern of injury with mesangial expansion, endocapillary proliferation, double-contour formation along the capillary walls, and lobular accentuation of the glomerular tufts (silver methenamine, $\times 40$). **B** and **C**, Immunofluorescence microscopy shows bright capillary wall staining for immunoglobulin M (**B**, $\times 40$) and for C3 (**C**, $\times 40$). **D**, Electron microscopy shows capillary wall thickening and a double-contour formation due to accumulation of subendothelial electron-dense deposits (*black arrows*), cellular elements, and new basement membrane formation (i.e., duplication) (*yellow arrow*) that produces the double contour. The *thick white arrow* indicates the old basement membrane, and fibrin tactoids (*white arrows*) in glomerular capillary loops indicate a prothrombotic state ($\times 1350$).

In patients with normal renal function, treatment is supportive only. Patients with persistent proteinuria >1 g/24h and/or progressive renal failure should be considered for treatment with high-dose corticosteroids with or without cytotoxic medication.

Membranoproliferative Glomerulonephritis

Membranoproliferative glomerulonephritis (MPGN) is a pattern of glomerular injury resulting from predominantly subendothelial and mesangial deposition of immune complexes or complement factors and their products. On light microscopy, mesangial hypercellularity, endocapillary proliferation, and capillary wall remodeling with double-contour formation are characteristic, and they result in a lobular accentuation of the glomerular tufts.

Immunofluorescence microscopy shows immunoglobulins or complement factors, depending on the underlying cause of MPGN. Electron microscopy typically shows mesangial and sub-endothelial deposits, and, less commonly, intramembranous and subepithelial deposits (Fig. 28-7).

Based on a recent proposal, MPGN can be classified as immune complex mediated or complement mediated. Immune complex-mediated MPGN shows immunoglobulin and complement factors on immunofluorescence microscopy. Complement-mediated MPGN shows complement factors and a lack of significant immunoglobulin on immunofluorescence microscopy (Fig. 28-8). Immune complex-mediated MPGN results from chronic infections, autoimmune diseases, and monoclonal gammopathies. Complement-mediated MPGN is caused by genetic

FIGURE 28-8 C3 glomerulonephritis. Light microscopy shows features of mesangial proliferative glomerulonephritis (A, periodic acid–Schiff, $\times 40$) and membranoproliferative glomerulonephritis (B, silver methenamine stain, $\times 40$) in the same biopsy. Immunofluorescence microscopy shows bright granular mesangial and capillary wall staining for C3 (C) and negative staining for immunoglobulin G (D). E, Electron microscopy shows a large accumulation of smudgy mesangial deposits (arrow) ($\times 10,000$). F, Electron microscopy shows subendothelial deposits (black arrow) and subepithelial humplike deposits (white arrows) ($\times 150,000$). The subepithelial deposits sometimes make it difficult to distinguish C3 glomerulonephritis from postinfectious glomerulonephritis. However, C3 glomerulonephritis may not show Ig (as in this case), and the term *atypical postinfectious glomerulonephritis* sometimes is applied in cases of C3 glomerulonephritis with subepithelial humplike deposits.

or acquired dysregulation of the alternative pathway of complement (C3 glomerulopathy) and can be further sub-classified as C3 glomerulonephritis and dense deposit disease (DDD) based on electron microscopy examination.

Immune complex–mediated MPGN precipitated by an infection is most commonly caused by HCV (i.e., cryoglobulinemic glomerulonephritis). The clinical presentation varies and can include nephrotic and nephritic features. In patients with cryoglobulinemic MPGN, the levels of C3, C4, and CH50 are persistently low, reflecting activation of both complement pathways. Patients with C3 glomerulonephritis or DDD may have a persistently low level of C3 but a normal level of C4. A C3 nephritic factor is found in many cases. C3 nephritic factor is an autoantibody to alternative pathway C3 convertase, resulting in persistent breakdown of C3.

The absence of well-designed studies based on current knowledge of the multiple pathogenic processes that impart a MPGN pattern of injury to the kidney make it impossible to give strong treatment recommendations. From a practical point of view, patients with MPGN due to chronic infections (e.g., HCV, endocarditis), autoimmune disease, and plasma cell dyscrasias should undergo treatment of the underlying disease. Patients with normal kidney function, no active urinary sediment, and non–nephritic-range proteinuria can be treated conservatively with angiotensin II blockade to control blood pressure and reduce proteinuria, because the long-term outcome is relatively benign in this setting. Follow-up is required to detect early deterioration in kidney function. Patients who have advanced renal insufficiency and severe tubulointerstitial fibrosis of renal biopsy are unlikely to benefit from immunosuppressive therapy.

GLOMERULAR DISEASES MANIFESTING WITH RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Antineutrophil Cytoplasmic Antibody–Associated Vasculitides

The ANCA-associated vasculitides (AAVs) are a group of three heterogeneous syndromes: granulomatosis with polyangiitis (GPA, formerly Wegener’s granulomatosis), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg–Strauss syndrome). The unifying feature is a necrotizing small vessel vasculitis with a predilection for the kidneys, lungs, and peripheral nervous system that occurs in association with autoantibodies against antigens in the cytoplasm of neutrophils (i.e., myeloperoxidase [MPO] and proteinase 3 [PR3]).

Approximately 75% of the patients with GPA are PR3-ANCA positive, and 20% are MPO-ANCA positive, whereas about 50% of patients with MPA are MPO-ANCA positive and about 40% are PR3-ANCA positive. Necrotizing granulomatous inflammation, which affects the upper and lower respiratory tract and frequently precedes other disease manifestations, separates GPA from MPA. EGPA is characterized by asthma and eosinophilia in addition to features of small vessel vasculitis such as mononeuritis multiplex. AAV is the most common cause of a RPGN in patients older than 60 years. AAV is associated with signs and symptoms ranging from limited renal disease to RPGN and pulmonary–renal syndrome (Table 28-3). Renal biopsy is characterized by a focal, necrotizing, and crescentic glomerulonephritis with pauci-immune immunofluorescence (Fig. 28-9).

FIGURE 28-9 Crescentic glomerulonephritis. **A** and **B**, Light microscopy and silver methenamine staining show a large cellular crescent (*black arrow*) with fibrinoid necrosis (*blue arrow*), hemorrhage into Bowman's capsule (*yellow arrow*), and collapse of capillary tufts (**A**, $\times 20$; **B**, $\times 40$). **C** and **D**, Electron microscopy shows fibrinoid necrosis (i.e., necrotizing lesion) in Bowman's space (*white arrow*) and capillary loops (*short white arrow*) (both, $\times 11100$).

TABLE 28-3 SIGNS AND SYMPTOMS OF ANTINEUTROPHIL CYTOPLASMIC AUTOANTIBODY VASCULITIS

Abdominal pain and gastrointestinal bleeding
Cutaneous purpura, petechiae, nodules, ulcerations, and necrosis
Facial pain, necrotizing (hemorrhagic) sinusitis, and septal perforation
Hematuria, proteinuria, and renal failure
Hemoptysis and pulmonary infiltrates or nodules
Muscle and pancreatic enzymes in blood
Myalgias and arthralgias
Peripheral neuropathy (mononeuritis multiplex)

Patients with newly diagnosed severe AAV vasculitis can be treated with a combination of high-dose corticosteroids and cyclophosphamide or high-dose corticosteroids and rituximab. Those with pulmonary hemorrhage, respiratory compromise, or severe renal failure (i.e., serum creatinine >5.5 mg/dL) also should undergo plasma exchange. The prognosis for AAV varies. Those with severe renal failure have the worst prognosis; and after successful therapy, AAVs have a relapse rate of 30% to 50% in the first 5 years. In some patients, rising ANCA titers are predictors of relapse. Patients with GPA or who are PR3-ANCA positive or presenting with relapsing disease are at higher risk for future relapses.

Goodpasture Disease: Anti-Glomerular Basement Membrane Antibody-Mediated Glomerulonephritis

Goodpasture disease is a pulmonary-renal syndrome (i.e., Goodpasture syndrome) caused by circulating anti-GBM

antibodies. On immunofluorescence staining of biopsy specimens, a linear pattern is seen along the GBM and alveolar basement membrane (Fig. 28-10) using antibodies directed against the $\alpha 3$ chain of type IV collagen (COL4A3 protein). Patients usually have RPGN and various degrees of pulmonary hemorrhage.

The treatment of Goodpasture disease is based on high-dose pulse methylprednisolone (1 g/day for 1 to 3 days) followed by corticosteroids (prednisone, 1 mg/kg/day up to 80 mg daily) in combination with oral cyclophosphamide (2 to 3 mg/kg/day up to 200 mg daily, adjusted for age and creatinine level) and plasma exchange. The prognosis is predicted in part by the percentage of circumferential crescents on the renal biopsy specimen, oliguria, and the need for dialysis. Those with an initial serum creatinine level less than 5.0 mg/dL have a 90% probability of renal survival at 5 years; but those with 100% circumferential crescents and on dialysis do not recover renal function, and immunosuppressive regimens should be avoided except in the case of pulmonary hemorrhage.

Goodpasture disease rarely recurs. Patients with ESRD are candidates for renal transplantation after the antibody has disappeared (6 to 12 months).

Lupus Nephritis

Lupus nephritis occurs in up to 50% to 70% of patients with SLE and is associated with a poor prognosis. Proteinuria is the most common initial manifestation, and it is often in the nephritic range and accompanied by a decline in renal function. Urinalysis does not always reflect the severity of the glomerular lesion, and kidney biopsy is indicated in those with proteinuria or active urinary sediment, or both, because the type of renal lesion

FIGURE 28-10 Anti–glomerular basement membrane–mediated disease. **A**, Light microscopy shows a large, circumferential crescent (*arrow*), with collapse of the glomerular capillary tufts and many infiltrating neutrophils in the crescent (periodic acid–Schiff, $\times 20$). Immunofluorescence microscopy shows linear staining for anti–immunoglobulin G antibody (**B**) along the glomerular capillary walls and bright staining for fibrinogen in the Bowman's tuft (**C**), indicating crescent formation and fibrinoid necrosis (both, $\times 40$).

TABLE 28-4 ABBREVIATED INTERNATIONAL SOCIETY OF NEPHROLOGY/RENAL PATHOLOGY SOCIETY 2003 CLASSIFICATION OF LUPUS NEPHRITIS

TYPE	MORPHOLOGIC CLASS	RENAL MANIFESTATION
I	Minimal mesangial lupus nephritis	Normal urinary sediment
I	Mesangial proliferative lupus nephritis	Low-grade hematuria and/or proteinuria Normal renal function
III	Focal lupus nephritis	Active sediment, proteinuria <3 g/1.73 m ² /day
IV	Diffuse segmental (IV-S) or global (IV-G) lupus nephritis	Nephritic and nephrotic syndromes Hypertension; progressive renal failure
V	Membranous lupus nephritis	Nephrotic syndrome
VI	Advanced sclerosing lupus nephritis	Inactive urinary sediment Chronic renal failure

Modified from Weening JJ, D'Agati VD, Schwartz MM, et al: The classification of glomerulonephritis in systemic lupus erythematosus revisited, *J Am Soc Nephrol* 15:241–250, 2004.

influences the therapeutic decisions. The International Society of Nephrology/Renal Pathology Society (ISN/RPS) classification of lupus nephritis recognizes six morphologic classes of renal involvement (Table 28-4). However, patients may migrate from one class to another spontaneously or after treatment.

Immunofluorescence typically shows glomerular deposition of IgG, IgM, IgA, C1q, and C3 (i.e., full-house pattern). On electron microscopy, tubuloreticular inclusions are common within glomerular and vascular endothelial cells. Electron-dense deposits sometimes show fingerprint-like substructures (Fig. 28-11). Histologic lesions correlate with the prognosis; classes III and IV have the worst prognosis (see Fig. 28-11). Other manifestations of SLE include acute and chronic tubulointerstitial nephritis and glomerular capillary thrombi in patients with antiphospholipid antibodies.

Three guidelines for the management of lupus nephritis have been published recently by the American College of Rheumatology, the Kidney Disease-Improving Global Outcomes (KDIGO) working group, and the Joint European League Against Rheumatism and European Renal Association–European Dialysis and Transplant Association (EULAR/ERA-EDTA). For class I lupus

nephritis, the prognosis is excellent, and no immunosuppression is required. Patients with class II lupus nephritis and proteinuria less than 1 g/24h should be treated as dictated by the extrarenal clinical manifestations of lupus. Patients with class II lupus nephritis and proteinuria greater than 3 g/24h should be treated with corticosteroids or calcineurin inhibitors.

Patients with class III or IV lupus nephritis should undergo induction therapy with corticosteroids plus cyclophosphamide or mycophenolate mofetil because both are considered equivalent. Pure class V (membranous) lupus nephritis usually has a benign prognosis, and initial therapy should be supportive. However, patients with progressive or persistent nephrotic-range proteinuria should be treated with corticosteroids plus an additional immunosuppressive agent (e.g., cyclosporine, mycophenolate mofetil). Patients with ESRD should be considered for renal transplantation because there is a low rate of recurrence in the transplanted kidney.

Cryoglobulinemic Glomerulonephritis

Cryoglobulins are immunoglobulins that precipitate at low temperatures and redissolve on rewarming. Cryoglobulinemia usually leads to a systemic inflammatory syndrome with weakness, arthralgias or arthritis, palpable purpura, peripheral neuropathy, and glomerulonephritis. Serum levels of C4 are typically low due to activation of complement by the classic pathway. The disease mainly involves small to medium-sized blood vessels and causes vasculitis due to cryoglobulin-containing immune complexes.

Cryoglobulinemia is classified as type I, II, or III on the basis of immunoglobulin composition. It can be idiopathic or occur in association with autoimmune diseases (see Fig. 26-11B), malignancy, or infection (Table 28-5). Cryoglobulinemia may be associated with chronic HCV infection.

Renal disease occurs in 20% to 60% of patients with cryoglobulinemia and manifests as proteinuria, microscopic hematuria, nephrotic syndrome, or renal impairment. Hypertension is common and may be severe, particularly in the setting of acute nephritic syndrome. The cryocrit values correlate poorly with disease activity. On light microscopy, renal biopsy specimens show an immune complex–mediated membranoproliferative pattern of injury, and on electron microscopy, diffuse, dense sub-endothelial deposits with a microtubular or crystalline appearance may be seen occluding the capillary loops.

FIGURE 28-11 Light microscopy (**A** to **C**) and electron microscopy (**D**) are used to identify lupus nephritis. **A**, Mild mesangial proliferative glomerulonephritis (International Society of Nephrology/Renal Pathology Society [ISN/RPS] class II) has mesangial hypercellularity (arrows) (periodic acid–Schiff, $\times 40$). **B**, Diffuse endocapillary proliferation with cryoglobulins in the glomerular capillaries, identified as pale, silver-negative material (arrow) (silver methenamine, $\times 20$). **C**, In diffuse proliferative glomerulonephritis (ISN/RPS class IV), the glomerulus on top shows a large cellular crescent (black arrows), and the glomerulus at the bottom shows diffuse endocapillary proliferation (white arrows) (silver methenamine, $\times 20$). **D**, Electron-dense deposits have fingerprint substructures (arrow) ($\times 46,000$).

TABLE 28-5 CRYOGLOBULINS AND ASSOCIATED DISEASES

CRYOGLOBULINEMIA TYPE	IMMUNOGLOBULIN CLASS	ASSOCIATED DISEASES
I. Monoclonal immunoglobulins	M > G > A > BJP	Myeloma, Waldenström macroglobulinemia
II. Mixed cryoglobulins with monoclonal immunoglobulins	M/G \gg G/G	Sjögren syndrome, Waldenström macroglobulinemia, lymphoma, essential cryoglobulinemia
III. Mixed polyclonal immunoglobulins	M/G	Infection, SLE, vasculitis, neoplasia, essential cryoglobulinemia

BJP, Bence Jones protein (κ light chain); SLE, systemic lupus erythematosus.

Treatment targets the underlying pathologic process to minimize or eliminate the associated cryoglobulinemia. Patients with active HCV infection, for example, should receive antiviral therapy when possible, and those with a monoclonal gammopathy should receive appropriate antimyeloma therapy. Immunosuppressive therapy (including the use of rituximab) with or without plasmapheresis should be considered for patients with a rapidly progressive, organ- or life-threatening course, regardless of the cause of the mixed cryoglobulinemia. Overall, the renal prognosis is usually good, with few patients progressing to ESRD. The long-term outcome reflects the underlying process.

GLOMERULAR DISEASES CAUSED BY PLASMA CELL DYSCRASIAS

Amyloidosis

Amyloidosis is characterized by systemic extracellular deposition of randomly arranged fibrils 8 to 12 nm in diameter that stain positive with Congo red (i.e., green birefringence with polarized light) or thioflavin T. Several processes, including malignancy, genetic mutations, and aging, can produce at least 24

amyloidogenic proteins. With renal deposition, amyloid in biopsy specimens appears as pale, amorphous, extracellular deposits that are periodic acid–Schiff (PAS) and methenamine silver stain negative (Fig. 28-12).

The affinity for kidney compared with other target organs varies according to the type of amyloid protein. Renal manifestations include proteinuria, nephrotic syndrome, and renal failure. Affected patients typically have large kidneys on ultrasound, but the diagnosis depends on demonstration of amyloid deposits. After amyloid is detected, typing should be performed when possible because treatments vary according to the protein involved. The most common approach to amyloid typing involves immunofluorescence or immunohistochemistry, but genetic testing and liquid chromatography mass spectrometry are also helpful for high-resolution amyloid typing.

Treatment of amyloidosis depends on the origin of the amyloidogenic protein. In patients with amyloid light chain (AL) amyloidosis, antimyeloma therapy with high-dose melphalan and autologous stem cell transplantation can be beneficial. In selected cases, bone marrow transplantation has led to resolution of the disease. Secondary amyloid A (AA) amyloidosis is most

FIGURE 28-12 Amyloidosis. **A**, Light microscopy shows amyloid deposits characterized by mesangial expansion (*small arrows*) with material negative for staining. The material is also seen in vessel walls, where the *arrow* points to vascular deposits (periodic acid–Schiff stain, $\times 20$). **B**, Congo red staining is positive for amyloid and shows reddish brown material in the glomeruli, interstitium, and vessel walls ($\times 10$). **C**, Amyloid deposits show apple green to orange-yellow birefringence under polarized light ($\times 20$). **D**, Electron microscopy shows randomly oriented amyloid fibrils. The fibrils measured 9 nm thick ($\times 49,000$).

common in patients with rheumatoid arthritis, inflammatory bowel disease, chronic infection, or familial Mediterranean fever. Treatment of AA amyloidosis is directed at the underlying inflammatory process with antimicrobials or anti-inflammatory medications.

Light Chain Deposition Disease

Light chain deposition disease is a paraprotein-associated disorder. The peak incidence is in the sixth decade of life, and men are affected more commonly than women. Approximately 30% to 50% of patients with light chain deposition disease have multiple myeloma. Most have a detectable monoclonal protein (usually κ light chain) in the serum or urine, but no hematologic abnormality is identified in about 10% of cases. Renal involvement manifests as proteinuria, and renal insufficiency is the most common initial presentation. Immunoglobulin deposits in other organs may result in myriad associated clinical symptoms.

Renal biopsy specimens show acellular, eosinophilic mesangial nodules that stain strongly positive with PAS, often mimicking diabetes mellitus. The deposited monoclonal proteins do not form fibrils and are Congo red negative. Immunofluorescence microscopic findings are diagnostic, with diffuse linear immunoglobulin light chain deposition (κ in 80% of cases) along the GBM and tubular basement membranes. On electron microscopy, amorphous, nonconglomerate, monoclonal immunoglobulin proteins can be seen along the GBM (Fig. 28-13).

Encouraging results have emerged with the use of bortezomib and dexamethasone and with high-dose chemotherapy and autologous stem cell transplantation. Unless remission is achieved after chemotherapy, the disease will recur in the kidney allograft.

● GLOMERULONEPHRITIS ASSOCIATED WITH HEPATITIS B VIRUS INFECTION

HBV-mediated glomerular disease usually manifests as membranous nephropathy, especially in children. The diagnosis of HBV-mediated glomerular disease requires detection of the virus in the blood and the exclusion of other causes of glomerular diseases.

HBV-mediated glomerular disease usually has a favorable prognosis, with a high spontaneous remission rate in children, but it is often progressive in adults. Patients with HBV infection and glomerulonephritis should receive treatment with interferon- α and/or with nucleoside analogues as recommended by standard clinical practice guidelines for management of HBV infection. Those with severe vasculitis or RPGN may be candidates for immunosuppressive therapy in combination with antiviral therapy. Rituximab treatment of patients who are positive for HBV has been associated with fatal acute hepatitis.

● THROMBOTIC MICROANGIOPATHIES

Thrombotic microangiopathy is characterized by thrombocytopenia, microangiopathic hemolytic anemia, and microvascular occlusion, resulting in various degrees of organ dysfunction. Markers of hemolysis include low haptoglobin levels, increased levels of lactate dehydrogenase and unconjugated bilirubin, and a high reticulocyte count. Schistocytes are seen in peripheral blood smears.

The quintessential forms of thrombotic microangiopathy include hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). Although previously thought to represent different manifestations of the same disease, these disorders are distinct clinically and mechanistically. In adults,

FIGURE 28-13 Light chain deposition disease. **A**, Light microscopy shows glomeruli with silver-positive mesangial nodules (*arrow*) and thickened tubular basement membranes (silver methenamine, $\times 10$). **B**, Periodic acid–Schiff staining shows thickened, wavy tubular basement membranes (*arrow*) ($\times 10$). Immunofluorescence studies found negative staining for λ light chains (**C**) and bright staining for κ light chains (**D**) along the tubular basement membranes (both $\times 10$). **E**, Electron microscopy shows granular, punctate, electron-dense deposits (*arrows*) along the tubular basement membranes ($\times 5800$).

predominant neurologic involvement suggests a diagnosis of TTP, and predominant renal involvement points to HUS. In most cases, the clinical presentations are very similar, making it difficult to distinguish between HUS and TTP on clinical grounds alone. Other causes of thrombotic microangiopathy include malignant hypertension, drugs (e.g., cocaine, quinidine, ticlopidine), autoimmune diseases (e.g., SLE, scleroderma, antiphospholipid antibody syndrome), malignancy, HIV infection, and antibody-mediated rejection.

Kidney biopsy in HUS and TTP reveals microthrombi in glomerular capillaries and arterioles, and mesangial expansion with loose granular material, called *mesangiolysis*, may be seen in HUS and TTP and in malignant hypertension or autoimmune diseases (Fig. 28-14). Malignant hypertension and autoimmune diseases may also show thickening and intimal fibrosis of arteries and onion-skinning (i.e., laminated deposition of basement membrane–type material) of the vessel walls. Thrombi are common and may occlude the vascular lumen.

Hemolytic Uremic Syndrome

Two subtypes of HUS are recognized: a sporadic or diarrhea-associated form (D+ HUS) and an atypical or non-

diarrhea-associated form (D– HUS). D+ HUS is the most frequently encountered form, and it is linked strongly to ingestion of meat contaminated with enterohemorrhagic *Escherichia coli* or other infectious agents. The bacterium produces a Shiga-like toxin that binds to a glycolipid receptor on renal endothelial cells and triggers activation of the alternative complement cascade, leading to endothelial damage. Therapy for D+ HUS is supportive. Children with D+ HUS have a good prognosis (90% recover renal function), but older patients have increased mortality rates and unfavorable long-term renal survival.

Atypical or D– HUS represents 10% to 15% of the cases of HUS and is more common in adults. The disease results from genetic mutations or autoantibodies against complement factors or complement factors regulating proteins (i.e., C3, factor B, factor H, factor I, MCP, CFHR1, and CFHR3) that control the activity of C3 convertase of the alternative complement pathway. The resulting defective control of C3 convertase leads to widespread activation of the complement cascade.

The complement inhibitor eculizumab has been approved for the treatment of patients with atypical HUS. Eculizumab and plasma infusion may also be considered in the treatment of

children with D+ HUS and severe central nervous system involvement such as seizures, stroke, or coma.

Thrombotic Thrombocytopenic Purpura

TTP results from mutations in the von Willebrand factor (vWF)–cleaving protease (ADAMTS13) or development of an autoantibody against ADAMTS13. ADAMTS13 cleaves large multimers of vWF, and abnormalities or deficiency of ADAMTS13 activity affects vWF function. Patients can have acute or chronic (i.e., relapsing) TTP. Microthrombi rich in large vWF multimers develop in the arterioles and capillaries of the brain and other organs.

Genetic or acquired forms of ADAMTS13 deficiency can be treated by plasma infusion or exchange to supply functional protease. Plasma exchange should be initiated promptly, based on findings of microangiopathic hemolytic anemia and thrombocytopenia without evidence of other causes of thrombotic microangiopathy (e.g., scleroderma, malignancy, antiphospholipid syndrome). Treatment should not await test results for the levels or activity of ADAMTS13.

DISEASES WITH GLOMERULAR BASEMENT MEMBRANE ABNORMALITIES

Alport Syndrome

Alport syndrome is an inherited disorder of basement membranes. In more than one half of patients, the disease results from

a mutation in the *COL4A5* gene that codes for the $\alpha 5$ chain of type IV collagen ($\alpha 5[IV]$). The mutation in *COL4A5* disables a developmental switch in the GBM collagen that retains its embryonic phenotype and results in a friable GBM.

Alport syndrome is frequently associated with sensorineural hearing loss and ocular abnormalities (e.g., lenticonus of the anterior lens capsule). Patients characteristically have persistent or intermittent hematuria and usually have mild proteinuria, which progresses with age and may reach nephrotic range in up to 30%. The disease is X-linked in approximately 85% of patients, but autosomal recessive and autosomal dominant patterns of inheritance have been described.

In virtually all male patients, the syndrome progresses to ESRD, often before the age of 30 years. The disease is usually mild in heterozygous women, but some develop ESRD, usually after the age of 50 years. The rate of progression to ESRD is fairly constant among affected men within individual families, but it varies markedly from family to family. The degree of deafness correlates with the rate of progression to ESRD.

On light microscopy, the glomerular changes are nonspecific. Diagnostic features are usually seen on electron microscopy. At an early stage, thinning of the GBM may be the only visible abnormality and may suggest thin basement membrane disease. With time, the GBM thickens, and the lamina densa splits into several irregular layers that may branch and rejoin, producing a characteristic basket-weave appearance (Fig. 28-15).

Immunohistochemical studies of type IV collagen show the absence of $\alpha 3(\text{IV})$, $\alpha 4(\text{IV})$, and $\alpha 5(\text{IV})$ chains from the GBM and distal tubular basement membrane. This abnormality occurs only in patients with Alport syndrome and is diagnostic. In families with an unquestionable diagnosis, evaluation of patients with newly diagnosed hematuria can be limited to kidney ultrasound and urinary tract examination in most cases. If a defined mutation has been previously identified, molecular diagnosis of affected men or gene-carrying women is possible. In other cases, confirmation of the diagnosis can be obtained by examination of skin biopsy by immunofluorescence for the expression of the $\alpha 5(\text{IV})$ chain. Absence of the $\alpha 5(\text{IV})$ chain from epidermal basement membrane is diagnostic of X-linked Alport syndrome and may avoid a renal biopsy. Direct sequencing of the *COL4A5* gene can help to diagnosis patients in whom a clear diagnosis cannot be made based on clinical findings and histologic methods or to identify the carrier state in asymptomatic female members of X-linked Alport syndrome families.

No specific treatment is available for Alport syndrome. Tight control of blood pressure and moderate protein restriction are recommended to retard the progression of renal disease, but the benefit is unproved. Patients with Alport syndrome are phenotypic knockouts for the $\alpha 3(\text{IV})$ chain. Consequently, kidney transplantation carries a 5% to 10% risk of subsequent Goodpasture's disease due to the $\alpha 3(\text{IV})$ chain (i.e., the Goodpasture antigen) in the transplanted kidney.

Thin Glomerular Basement Membrane Nephropathy

Thin glomerular basement membrane nephropathy, also known as benign familial hematuria, is a relatively common condition characterized by isolated glomerular hematuria and associated with the renal biopsy finding of an excessively thin GBM. It is usually transmitted as an autosomal dominant disease. Heterozygous mutations in the *COL4A3* or *COL4A4* genes have been described in numerous patients with thin glomerular basement membrane nephropathy, indicating a genetically heterogeneous condition.

The usual clinical presentation is isolated, persistent hematuria that is first detected in childhood. In some patients, hematuria is intermittent and may not manifest until adulthood. On light microscopy, glomeruli appear normal, and immunofluorescence microscopy shows no immunoglobulin or complement deposition. Electron microscopy shows diffuse thinning of the

GBM (Fig. 28-16). In adults, a GBM thickness less than 250 nm strongly suggests thin GBM disease.

The condition is usually benign and requires no specific treatment. However, a few patients have progressive renal disease that leads to ESRD.

FABRY DISEASE

Fabry disease is an X-linked recessive inborn error of glycosphingolipid metabolism caused by deficient activity of the lysosomal enzyme α -galactosidase A, which results in the progressive accumulation of neutral glycosphingolipids (predominately globotriaosylceramide, particularly in the vascular endothelial cells of the kidney and heart.

Early manifestations of the disease include angiokeratoma, episodic pain crises, and hypohidrosis. With time, progressive globotriaosylceramide accumulation in the microvasculature in the kidney, heart, and brain leads to clinical manifestations such as proteinuria, renal failure, cardiac arrhythmias, and strokes, resulting in early death during the fourth and fifth decades of life of affected men.

Light microscopy reveals vacuolated glomerular cells, especially podocytes. Electron microscopy shows enlarged podocytes lysosomes filled with osmiophilic, granular to lamellated membrane structures (i.e., zebra bodies) (Fig. 28-17). Enzyme replacement therapy can lead to significant improvement of neuropathic

FIGURE 28-17 Fabry's disease. Electron microscopy shows visceral epithelial cells (i.e., podocytes) with numerous multilamellated structures called *myelin bodies* or *zebra bodies* (arrows) that are made of glycosphingolipids ($\times 4800$).

FIGURE 28-16 **A**, In thin glomerular basement membrane nephropathy, electron microscopy shows glomerular basement membranes (arrows) that are 198 nm thick ($\times 5800$). **B**, In Alport syndrome, electron microscopy shows thickened glomerular capillary walls with lamellations and disorganization of the glomerular basement membranes (arrows) and extensive foot process effacement of the visceral epithelial cells ($\times 6000$).

FIGURE 28-18 Light microscopy shows diabetic glomerulosclerosis. **A** and **B**, Early diabetic nodule formation (arrows). **C** and **D**, Well-formed Kimmelstiel-Wilson lesions result from mesangial expansion (thin black arrows). The nodules are periodic acid-Schiff and silver methenamine positive. The glomerular capillary lumen is distended by formation of small microaneurysms (thick black arrows). pain, but the beneficial effects on the severity or progression of other disease manifestations are less clear.

DIABETIC NEPHROPATHY

Diabetic nephropathy accounts for more than 50% of patients on dialysis in the United States. In type 1 diabetes mellitus, nephropathy usually manifests 10 to 15 years after the initial diagnosis; and a similar natural history is likely for patients with type 2 diabetes mellitus. The main risk factors include a positive family history of diabetic nephropathy, hypertension, and poor glycemic control. The risk may be greater in some racial groups (e.g., Pima Indians, African Americans).

The pathogenesis is complex. Increased glycosylation of proteins with accumulation of advanced glycosylation end products that cross-link with collagen and glomerular hyperfiltration with hypertension are important. High albuminuria (i.e., urinary albumin excretion >30 but <300 mg/24h) is the initial manifestation of diabetic nephropathy. With time, high albuminuria may evolve into overt proteinuria (>300 mg/24h), with the degree of proteinuria correlating roughly with the renal prognosis.

After overt proteinuria develops, progression to ESRD is relentless, although rates of decline vary among patients. For patients with type 1 diabetes, there is a strong correlation (95%)

between the development of nephropathy and other signs of diabetic microvascular compromise (e.g., diabetic retinopathy), but the correlation is weaker for patients with type 2 diabetes. Hypertension is almost universal among patients with proteinuria. It is difficult to control and usually requires at least three antihypertensive agents.

On renal biopsy, early signs of diabetic nephropathy include glomerular hypertrophy and thickening of the GBM. As the disease progresses, arteriolar hyalinosis, arteriosclerosis, and progressive mesangial expansion (i.e., diffuse diabetic glomerulosclerosis) and nodular formations (i.e., Kimmelstiel-Wilson nodules) develop (Fig. 28-18). For patients with a history of diabetes longer than 10 years and retinopathy, a renal biopsy may not be necessary. However, renal biopsy is indicated for patients with an atypical course of the disease (e.g., nephrotic syndrome), those with less than 10 years of type 1 diabetes, or patients with rapid loss of renal function.

Treatment with ACEIs or ARBs slows progression of diabetic nephropathy and should be used in all patients with albuminuria, even if normotensive. Tight glycemic control (i.e., glycated hemoglobin $<7.0\%$) may also retard progression of diabetic nephropathy. Target systolic blood pressure should be less than 125 mm Hg, but this may be difficult to achieve and may require multiple medications and a strict low-salt diet.

Major Nonglomerular Disorders of the Kidney

Nilum Rajora, Shani Shastri, and Ramesh Saxena

INTRODUCTION

The tubulointerstitial compartment comprises 80% of renal parenchyma, with most of the volume accounted for by renal tubules, interstitial cells, and collagenous matrix. Tubulointerstitial disorders have two common clinical presentations: acute tubulointerstitial nephritis, characterized by sudden onset and a rapid decline in renal function, and chronic tubulointerstitial nephropathy, characterized by a more protracted clinical course. Although primary glomerular and vascular diseases are associated with significant tubulointerstitial changes, the clinical presentations are dominated primarily by injury (see [Chapters 28 and 30](#)). Acute tubular injuries are discussed in [Chapter 31](#).

ACUTE INTERSTITIAL NEPHRITIS

Acute interstitial nephritis (AIN), also called *tubulointerstitial nephritis*, is characterized by inflammation and edema of the renal interstitium; glomeruli and vessels are distinctly normal. AIN is associated with an acute, rapid decline in renal function and is a common cause of acute kidney injury, accounting for 15% to 27% of acute kidney injury cases confirmed on biopsy.

On gross examination, the kidneys are pale and swollen. Histologically, the hallmarks of AIN include interstitial edema and infiltration of the interstitium with inflammatory cells comprising lymphocytes, monocytes, plasma cells, eosinophils, and macrophages ([E-Figs. 29-1 and 29-2](#)). This inflammation can result in fibrotic changes in 7 to 10 days. Immunofluorescence studies typically are unrevealing, except in cases in which linear or granular immunoglobulin G (IgG) or complement deposits along basement membrane are observed.

In most cases, AIN begins abruptly with a decrease in kidney function within days of exposure to the offending agent. However, AIN may ensue after several weeks of the exposure in some cases. Characteristic clinical manifestations include rash, fever, and eosinophilia. Modest proteinuria (usually <1g/day) or hematuria may be observed, and oliguria is uncommon. A high index of suspicion is required for diagnosis because these features may be absent.

The most common causes of AIN are shown [Table 29-1](#). Frequently used therapeutic drugs merit particular emphasis. They include antibiotics, allopurinol, mesalamine, nonsteroidal anti-inflammatory drugs (NSAIDs), and proton pump inhibitors (PPIs). Other causes of AIN include infections, autoimmune disorders, tubulointerstitial nephritis and uveitis syndrome, snakebite, and herbal supplements.

When evaluating a patient with a recent decline in renal function, the diagnosis of AIN is suggested by a history of exposure to known offending agents coupled with typical clinical features. In addition to identifying elevated serum creatinine levels, a urinalysis can detect the characteristic findings of white blood cells, red blood cells, and white blood cell casts in urine. Identification of eosinophils in urine with Hansel or Wright stains is highly suggestive, but their absence does not rule out AIN. Moreover, eosinophils in urine can be observed in other diseases, including cholesterol embolism, urinary tract infections, parasitic disorders, and glomerulonephritis.

A definitive diagnosis of AIN requires a kidney biopsy, although it is not necessary for management when clinical features are highly suggestive. Treatment of the patients with AIN consists of removal of the offending drug and management of the underlying infection or autoimmune process. Kidney biopsy should be considered when the diagnosis is not obvious. The role of steroids in limiting the inflammatory process is controversial, but early use (within 7 to 14 days) may decrease the duration of

TABLE 29-1 CAUSES OF ACUTE INTERSTITIAL NEPHRITIS

CAUSE	EXAMPLES
Antibiotics	Penicillin Cephalosporin Sulfa drugs Ciprofloxacin Acyclovir
Nonsteroidal anti-inflammatory drugs	Naproxen Ibuprofen Diclofenac Celecoxib
Diuretics	Thiazides Furosemide Triamterene
Other drugs	Cimetidine Omeprazole Phenytoin Allopurinol
Systemic infections	Legionnaires disease Leptospirosis Streptococcal infection Cytomegalovirus infection
Primary kidney infections	Acute bacterial pyelonephritis
Autoimmune disorders	Sarcoidosis Sjögren syndrome

E-FIGURE 29-1 Acute interstitial nephritis. Interstitial inflammatory cell infiltrate (*arrows*) with tubular atrophy and interstitial edema (*double arrows*) (hematoxylin and eosin, $\times 200$).

E-FIGURE 29-2 Acute interstitial nephritis. Interstitial inflammatory cell infiltrate (*arrows*) with numerous eosinophils (*double arrows*) (hematoxylin and eosin, $\times 200$).

AIN and protect renal function. When indicated, the usual approach includes high-dose intravenous methylprednisolone (250 mg consecutively for 3 days), followed by oral prednisone (1 mg/kg) and tapering over 4 to 6 weeks. Patients who are intolerant or resistant to steroids may benefit from mycophenolate mofetil (500 to 1000 mg twice daily).

Most cases of drug-related AIN resolve after removal of the offending drug. The overall prognosis depends on the duration of the AIN; a longer interval between onset of AIN and drug withdrawal can lead to irreversible kidney damage. Because of the rapid transformation of interstitial cellular infiltrates into fibrosis, up to 40% of patients may not fully recover baseline renal function, and about 10% of the patients may become dialysis dependent.

CHRONIC INTERSTITIAL NEPHRITIS

Chronic interstitial nephritis (CIN) is a clinicopathologic diagnosis. Prolonged exposure to a causative agent initiates an indolent inflammatory process, and chronic interstitial nephritis can lead to permanent renal damage over months to years before it manifests clinically. Patients usually have a gradual decline in renal function. CIN is common and accounts for 15% to 30% of all cases of end-stage renal disease (ESRD).

Histologically, CIN shows tubular atrophy, flattened epithelial cells, tubule dilation, interstitial fibrosis, and areas of mononuclear cell infiltration within the interstitial compartment (E-Fig 29-3). The infiltrates are typically less conspicuous compared with AIN, and there is more interstitial fibrosis. In earlier stages of CIN, glomeruli are usually spared, but with progression, glomerular abnormalities such as segmental and global sclerosis can develop.

Patients with CIN usually have no renal symptoms until they develop overt chronic kidney disease. The features are nonspecific and include fatigue, lack of appetite, nausea, vomiting, hypertension, and sleep disturbances, and other laboratory and clinical findings may develop as listed in Table 29-2. CIN also can cause proximal or distal tubular dysfunction, which can lead to defects in acidification of the urine, partial or complete Fanconi's syndrome, and decreased concentrating ability. Laboratory data for these patients may show elevated levels of creatinine, proteinuria, hematuria, glycosuria, and pyuria. Due to the destruction of erythropoietin-producing interstitial cells, anemia, associated fatigue, and decreased exercise tolerance are common as CIN progresses.

The histologic findings of CIN are nonspecific, and the differential diagnosis can be extensive, as shown in Table 29-3. Repeated injuries from drugs, toxins, radiation nephritis, and

TABLE 29-2 CLINICAL FINDINGS THAT SUGGEST CHRONIC INTERSTITIAL NEPHRITIS

Hyperchloremic metabolic acidosis (out of proportion to the degree of renal insufficiency)
Hyperkalemia (out of proportion to the degree of renal insufficiency)
Reduced maximal urinary concentrating ability (e.g., polyuria, nocturia)
Partial or complete Fanconi's syndrome (e.g., phosphaturia, bicarbonaturia, aminoaciduria, uricosuria, glycosuria)
Modest proteinuria (<2 g/day)
Anemia
Hypertension

reflux nephropathy can result in a similar histologic picture. The most common cause of CIN is chronic NSAID use. Other causes of include infections, immune-mediated disorders, drug reactions, hematologic disorders, chronic urinary tract obstruction, and urinary reflux. Some metabolic disorders and exposure to heavy metals can also lead to CIN. The clinical importance, distinguishing features, causes, and management of several forms of CIN are discussed in the following sections.

Analgesic Nephropathy

Analgesic nephropathy is the prototype CIN, and it occurs commonly worldwide. This disorder is caused by long-term ingestion of aspirin in various combinations with phenacetin, caffeine, or acetaminophen. In its most severe form, analgesic nephropathy is associated with papillary necrosis.

The cumulative amount of phenacetin-acetaminophen combination required to cause chronic interstitial nephritis is estimated to be at least 2 to 3 kg. Although initially thought to be exclusively associated with phenacetin-containing combinations, all analgesics, including acetaminophen, aspirin, and NSAIDs, are capable of inducing CIN.

Analgesic nephropathy is most commonly detected in women in the sixth and seventh decades of life. Patients with analgesic nephropathy have renal insufficiency, modest proteinuria, sterile pyuria, and anemia. Occasionally, patients may have flank pain

TABLE 29-3 CONDITIONS ASSOCIATED WITH CHRONIC INTERSTITIAL NEPHRITIS

ASSOCIATED CONDITIONS	EXAMPLES
Hereditary diseases	Autosomal dominant polycystic kidney disease
Metabolic disturbances	Hypercalcemia, nephrocalcinosis Hyperuricemia Hyperoxaluria Hypokalemia Cystinosis
Drugs and toxins	Analgesics, nonsteroidal anti-inflammatory drugs Lead Nitrosoureas Cisplatin Cyclosporine Tacrolimus Lithium Chinese herbs Olanzapine
Immune-mediated diseases	Granulomatosis with polyangiitis (Wegener's granulomatosis) Sjögren syndrome Systemic lupus erythematosus Vasculitis Sarcoidosis Crohn's disease
Hematologic disease or malignancy	Multiple myeloma Sickle cell disease Lymphoma
Infection	Chronic pyelonephritis Xanthogranulomatous pyelonephritis
Obstruction	Tumors Stones Bladder outlet obstruction Vesicoureteral reflux
Miscellaneous disorders	Radiation nephritis Hypertensive arterionephrosclerosis Renal ischemic disease

E-FIGURE 29-3 Chronic interstitial nephritis. Interstitial chronic inflammatory cell infiltrate (*arrows*) with tubular atrophy (*double arrows*) (periodic acid-Schiff, $\times 200$).

and gross hematuria, suggesting papillary necrosis. Diagnosis is supported by a history of heavy analgesic use, and computed tomography (CT) may reveal microcalcifications at the papillary tips.

Treatment of analgesic nephropathy is supportive and includes discontinuation of analgesic use. Long-term follow-up studies are characterized by progression to ESRD requiring dialysis. A high incidence of uroepithelial cancers is also observed in patients with long-term analgesic use.

Chinese Herb Nephropathy and Balkan Endemic Nephropathy

Chinese herb nephropathy (CHN) and Balkan endemic nephropathy (BEN), also called *aristolochic acid nephropathy*, are chronic tubulointerstitial renal diseases associated with urothelial carcinoma. The clinical expression and pathologic lesions observed at different stages of CHN and BEN are strikingly similar except for the higher prevalence of CHN among women and familial clustering of BEN. Both have been linked to exposure to the nephrotoxin and carcinogen aristolochic acid. It has been suggested that CHN and BEN should be abandoned and replaced by the term *aristolochic acid nephropathy* (AAN).

Aristolochic acid is a major component of *Aristolochia*-containing herbal remedies and is commonly prescribed in China and other Asian countries. AAN was first reported in 1993 in Belgium in young women taking aristolochic acid-containing Chinese herbs for weight reduction, and the finding has been confirmed by many others. BEN was described 50 years ago in farming villages in the Balkan area, where there is dietary exposure to aristolochic acid through the contamination of flour prepared from locally grown wheat.

Unique features of AAN include clustering of the cases among adults in endemic areas and close association with upper urinary tract carcinomas. About 50% of the affected patients develop transitional cell carcinomas; aristolochic acid induces DNA damage with a distinct molecular signature. Unfortunately, no effective specific treatment for AAN is available. Management is supportive with regular monitoring for urothelial malignancy.

Heavy Metals

Heavy metals such as cadmium, lead, and chromium can cause CIN, and exposure usually represents an environmental toxin. Cadmium exposure occurs with tobacco smoke and contaminated water and food. Lead exposure occurs from contact with lead-based paint and lead-contaminated dust and soil. Chromium is used to increase the hardness and corrosion resistance of alloy steel, and chromium exposure can occur when industrial plant employees work with alloy steels, dyes, paints, inks, and plastics. Renal proximal tubules are the principal site of accumulation and injury, but other nephron segments also can be injured.

Heavy metal nephrotoxicity ranges from mild tubular dysfunction to severe renal failure. The extent of renal damage depends on the nature, dose, route, and duration of exposure. With chronic exposure, changes consistent with CIN are observed on kidney biopsy. The best characterized clinical feature of heavy metal renal toxicity is the Fanconi syndrome, which results from proximal tubule damage. These patients have low-molecular-weight

proteinuria, aminoaciduria, bicarbonaturia, glycosuria, and phosphaturia. Other clinical findings for lead toxicity include gout from decreased urate excretion in proximal tubules, hemolytic anemia, encephalopathy, and neuropathy.

Other than supportive care, no specific treatment is available for heavy metal-associated renal disease. Chelating agents may be used in acute poisoning, but no randomized clinical trials have proved the efficacy of chelation on clinical outcomes.

Sarcoidosis

Sarcoidosis is a chronic, multisystem, inflammatory disease of unknown origin. It is characterized by noncaseating, epithelioid granulomas in affected organs, leading to organ dysfunction. The severity and diversity of the clinical manifestations related to sarcoidosis depend on the extent of the infiltrating granulomatous lesions. Granulomatous tubulointerstitial nephritis is observed in approximately 20% of patients with sarcoidosis and responds well to steroid therapy. Sarcoidosis is described in details elsewhere.

Steroid therapy is effective in the acute setting and in advanced tubulointerstitial nephritis. Some patients with granulomatous tubulointerstitial nephritis may require long-term treatment with steroids to preserve renal function, although the side effects of steroids limit their use in advanced renal disease. The efficacy of steroid-sparing agents such as mycophenolate mofetil or azathioprine requires further investigation.

Radiation Nephritis

Radiation exposure is a significant cause of chronic kidney disease, and radiation nephritis develops in most patients if they are exposed to more than 2300 cGy. Ionizing radiation directly damages all molecules, including DNA, and initiates cellular synthesis of reactive oxygen species (ROS), which cause secondary tissue damage. Hydroxyl radicals are generated within milliseconds of tissue exposure. Oxidative stress and other factors may play additional roles over time, and patients may develop severe renal injury and impaired function 6 to 12 months (or longer) after exposure.

The diagnosis is based on a history of radiation exposure and the clinical findings of renal injury. Treatment is supportive.

Sickle Cell Disease

Chronic renal insufficiency is relatively common in patients with sickle cell disease, an inherited hematologic disorder characterized by hemolytic anemia and vascular occlusion by sickled red cells. Under normal conditions, the renal medullary zone is characterized by low oxygen tension, acidic pH, and high osmolality, which can predispose to increased blood viscosity and red blood cell sickling. This increases the likelihood of local ischemia and infarction of the renal microcirculation. In the vasa recta, vascular occlusion can interfere with the countercurrent exchange system in the inner medulla, resulting in a defect in the urine-concentrating mechanism.

Patients may have nocturia or polyuria and can develop gross hematuria due to papillary necrosis resulting from medullary ischemia and infarction. The sloughed papillae can obstruct urinary tract outflow, leading to obstructive nephropathy and renal failure. Another renal abnormality associated with sickle

cell disease is proteinuria, a consequence of glomerular hyperfiltration that results from reduction in nephron mass.

The treatment of sickle cell nephropathy focuses on primary management of the hematologic disorder. Tubular dysfunction may require potassium and bicarbonate supplementation to treat hypokalemia and acidosis, and those with ESRD are treated with dialysis and renal transplantation.

Lithium

Lithium is a monovalent cation, which is freely filtered through the glomeruli. Up to 80% of filtered lithium is reabsorbed in the proximal tubule, and a small fraction is reabsorbed in the distal nephron through the epithelial sodium channel ($E_{Na}C$). Lithium causes dysregulation of the aquaporin water channel and $E_{Na}C$ expression in the cortical collecting duct. The most common manifestation of renal disease associated with lithium is CIN manifesting as a chronic, insidious decline in renal function. The course of renal disease after discontinuation of lithium is highly unpredictable, with no reliable clinical clues to identify those destined for recovery or progression.

Lithium also is associated with nephrogenic diabetes insipidus, which can occur in up to 40% of patients as early as 8 weeks after lithium initiation. Other tubular dysfunctions associated with lithium include water diuresis, natriuresis, and metabolic acidosis. Lithium-associated nephrogenic diabetes insipidus can be treated with $E_{Na}C$ blockade by amiloride.

Urinary Tract Obstruction

Urinary tract obstruction is a common cause of acute kidney injury and chronic kidney disease. When renal function is normal at baseline, unilateral or partial obstruction anywhere along the urinary tract may be asymptomatic, with no discernable change in renal function or urine output. Bilateral urinary tract obstruction, however, can lead to acute and chronic kidney injury and ESRD. It is important to address this possibility early in the clinical course of unexplained renal insufficiency or uremia.

Obstruction to urine flow causes an increase in ureteral intraluminal pressure. Over time, nephron tubules are injured, and the resulting changes in thromboxane A_2 and angiotensin levels decrease renal blood flow. Tubular damage leads to urinary concentrating defects, renal tubular acidosis, and hyperkalemia. If complete obstruction is not relieved, ischemia and nephron loss decrease the glomerular filtration rate.

The most common causes of obstructive nephropathy are shown in Table 29-4. Among elderly men, benign prostatic hypertrophy is a particular concern. Overall, the clinical presentation depends on the cause, site, and time course of obstruction. Patients with obstructive nephropathy have decreased urine output and are at risk for suprapubic pain (i.e., bladder distention from ureteral obstruction), renal colic (i.e., nephrolithiasis), urinary tract infections, fever, acute kidney injury, hypertension, and hematuria. Pain resulting from stretching of the urinary collecting system is the most common presenting symptom. Acute ureteral obstruction usually results in severe flank pain that typically radiates to the groin and is referred to as *renal colic*. Patients with complete bladder outlet obstruction have acute kidney injury and anuria. Patients with incomplete or intermittent bladder outlet obstruction have urinary hesitancy, dribbling,

TABLE 29-4 CAUSES OF URINARY OBSTRUCTION

CAUSE	EXAMPLES
Congenital urinary tract malformation	Meatal stenosis Ureterocele Posterior urethral valves Urethral atresia Phimosis Megaureter–prune belly syndrome
Intraluminal obstruction (urethra and bladder outlet)	Phimosis Urethral strictures Benign prostatic hyperplasia Pelvic tumor Anticholinergic drugs Neurogenic bladder Tuberculosis Radiation Trauma Calculi Blood clots Papillary necrosis (sickle cell disease, diabetes mellitus)
Extrinsic compression	Pelvic tumors Prostatic hypertrophy Retroperitoneal fibrosis or tumors
Acquired anomalies	Urethral strictures Neurogenic bladder Intratubular precipitates Bladder mass or stones

urgency, decreased urine stream, nocturia, and polyuria. These patients are usually pain free. Tubular injury from obstruction causes decreased urinary concentrating capability leading to polyuria.

The physical examination should include palpation of the kidney and bladder, as well as a rectal, pelvic, and prostate assessment. The patient may have an enlarged and palpable bladder, enlarged prostate, costovertebral tenderness, groin pain, hypertension, or gross hematuria. The mainstays of the initial evaluation include measurement of the postvoid residual volume of the bladder (>125 mL is considered significant and may indicate obstruction) and renal ultrasound to evaluate the kidneys, ureters, and bladder for distention or other abnormalities.

The initial goals of therapy are to manage volume status, electrolyte abnormalities, infection, and other complications of obstructive nephropathy and to relieve the obstruction as soon as possible to prevent further damage to renal parenchyma. If urinary obstruction is suspected, a catheter should be placed in the bladder to address possible bladder outlet obstruction. If a large postvoid residual volume (>125 mL) is detected, the urinary catheter should remain in place while the cause is ascertained. Occasionally, relief of obstruction is associated with a large postobstructive diuresis that may be sufficient in degree to cause volume depletion and hypotension.

If the obstruction is acute, complete recovery of renal function can be expected. If the anatomic site of the urinary tract obstruction is above the bladder, more sophisticated approaches to drainage (e.g., percutaneous nephrostomy tube placement) may be required to relieve obstruction.

CYSTIC KIDNEY DISEASES

Renal cysts are lined by a polarized epithelium and filled with fluid. They result from defects in the structure and the function

of renal tubular epithelial cells. Several of the cellular and molecular mechanisms involved in cystogenesis have been identified.

Renal cysts can be acquired, hereditary, or developmental. Acquired conditions include cystic kidney disease that develops in patients with existing ESRD. Cystic kidney diseases also are important causes of ESRD.

The most common inherited cystic kidney diseases are the polycystic kidney diseases (PKDs), including autosomal dominant and autosomal recessive forms of PKD. Other hereditary cystic renal diseases include medullary cystic kidney disease (MCKD), Von Hippel–Lindau disease (VHL), and tuberous sclerosis. Developmental cystic diseases of the adult kidney include localized renal cystic disease, multicystic dysplastic kidney, and medullary sponge kidney.

In the inherited disorders, several mutations have been associated with cyst formation. Mutation of any of the tubular epithelial–related genes such as *PKD1*, *PKD2*, *MUC1* (formerly *MCKD1*), and *MCKD2* can result in disruption of normal ciliary function, resulting in cyst formation from overproliferation of tubular epithelium and increased fluid secretion. In PKD, the cysts are not connected to the urinary drainage system, and cellular secretion results in cyst enlargement.

Simple Cysts

Widespread use of ultrasonography and CT has resulted in frequent detection of kidney cysts. Simple cysts are most common. They are usually unilateral, solitary, well-defined structures, but they can be multiple and bilateral. They tend to be more common among older adults and are often benign, incidental findings on radiographic imaging. Sonography reveals a thin-walled, fluid-filled cavity with no septations or calcifications. The diameter varies between 0.5 and 1.0 cm, but a few may be as large as 3 to 4 cm in diameter.

Simple cysts are usually asymptomatic but occasionally may result in a palpable abdominal mass, infection, back pain, or hematuria. Differentiation of simple cysts from cysts associated with genetic disorders is based on the cystic pattern, age at detection, and family history.

In the absence of symptoms, no treatment is required for simple cysts. If the kidney cyst becomes infected, causes pain, or leads to renin-mediated hypertension, percutaneous drainage is often the first step in further evaluation and management.

Complex Cysts

Differentiation of simple from complex cysts is usually made radiographically. When in doubt, histologic examination is required to exclude malignancy, but imaging is sensitive and specific, and it suffices in most cases. The distinction between complex and simple cysts is important in monitoring the need for intervention because simple cysts are usually benign, whereas complex cysts have a higher risk of malignancy and other complications.

Initial evaluation includes ultrasonography and triphasic CT to characterize the cyst. If the cyst characteristics of size, nodularity, mural enhancement, or septations change over time, the likelihood of malignancy increases. In a simple cyst, complications resulting from hemorrhage or infection can result in the features

of more complex cysts, including calcification, septa, irregular borders, and multilobularity.

To help with diagnosis and management, the Bosniak classification of renal cyst was introduced in 1996 and revised in 2003. This classification, which includes four categories based on triphasic CT findings, is described in Table 29-5. Category 1 cysts are benign, and category II cysts have a 0% to 5% risk of malignancy. The risk increases to almost 50% for category III cysts. There are also several important subcategories. Category III and IV renal cysts are considered to be renal carcinoma unless proved otherwise, and they should be surgically resected.

POLYCYSTIC KIDNEY DISEASE

Autosomal dominant polycystic kidney disease (ADPKD) is a common cause of cystic renal disease and an important cause of ESRD. The monogenetic, progressive disorder is characterized by multiple cysts in kidneys and other organs, including the liver and pancreas. The incidence of ADPKD is 1 case in 400 to 1000 live births, and between 300,000 and 600,000 Americans are affected by the disease.

Mutations in the *PKD1* and *PKD2* genes are responsible for about 85% and 15% of ADPKD cases, respectively, and there is evidence for important modifier genes. *PKD1* is located on chromosome 14 and encodes the protein polycystin 1 (PC1), which functions as a membrane receptor. *PKD2* is located on chromosome 4 and encodes polycystin 2 (PC2), which functions as a calcium permeable cation channel (E-Fig 29-4). PC1 and PC2 regulate intracellular calcium homeostasis and signaling pathways involved in tubular morphogenesis and cell-cell

TABLE 29-5 BOSNIAK RENAL CYST CLASSIFICATION SCHEME

CATEGORY	DESCRIPTION
I. Simple cyst	A benign simple cyst with a thin wall and no septa, calcifications, or solid components.
II. Minimally complicated	A benign cystic lesion with a few thin septa. The wall or septa may contain fine calcifications or short segment of a slightly thickened calcification. (This category also includes uniformly high-attenuating lesions that are less than 3 cm in diameter, well margined, and nonenhancing.)
IIIF. Complicated	Well-margined cysts but more complicated than category II. They have multiple thin septa or minimal smooth thickening of the septa or wall and may contain calcifications that may be thick and nodular. (This category also includes totally intrarenal, nonenhancing high-attenuating lesions that are more than 3 cm in diameter.)
III. Indeterminate	Indeterminate cystic masses that have thickened, irregular, or smooth walls or septa. These lesions are enhancing on computed tomography. Between 40% and 60% of lesions are malignant (e.g., cystic renal cell carcinoma, multiloculated cystic renal cell carcinoma). The remaining lesions are hemorrhagic, chronic, infected cysts or multiloculated cystic nephroma and are benign.
IV. Malignancy	On computed tomography, they have characteristics of category III cysts and contain enhancing soft tissue components that are adjacent to and independent of the wall or septum on the cyst. Between 85% and 100% of lesions are malignant; evaluation and surgical excision are recommended.

E-FIGURE 29-4 Structure of polycystic kidney disease proteins. (Modified from Igarashi P, Somlo S: Genetics and pathogenesis of polycystic kidney disease, *J Am Soc Nephrol* 13:2384–2398, 2002.)

interactions. PC1 and PC2 also are integral membrane proteins of cilia, including the primary cilia of renal tubular cells. ADPKD is now classified under the new class of diseases called *ciliopathies*.

In the kidney, increases in cyst size and number over time damage adjacent renal architecture and cause renal insufficiency and renin-mediated hypertension. Total kidney volume increases continuously and is associated with progressive decline of renal function. Higher rates of kidney enlargement are associated with a more rapid decrease in renal function.

ADPKD is a multisystem disease. The clinical presentation may range from no symptoms to an array of multiple renal and extrarenal manifestations. In addition to renal tubules, PC1 and PC2 proteins are found in diverse cell types, including bile ducts, endothelial cells, and neurons. ADPKD patients with mutated PC1 or PC2 proteins often have extrarenal manifestations, including polycystic liver disease, which is detected in about 80% of adults. Cardiac valvular abnormalities and cerebral aneurysms are key noncystic features of ADPKD, and familial clustering of cases occurs. Cerebral aneurysms are observed in about 8% of patients with ADPKD, but the incidence increases to 20% among those with a positive family history of cerebral aneurysm or subarachnoid hemorrhage.

Most patients with ADPKD develop cysts before the age of 30, but renal insufficiency can be delayed to beyond the fourth decade. Patients with the *PKD2* mutation have later onset and slower progression of the disease than patients with the *PKD1* mutation. Renal survival associated with *PKD2* mutations is about 20 years longer than that associated with *PKD1* mutations. Twenty percent of patients with ADPKD can develop uric acid and calcium oxalate nephrolithiasis and may have renal colic, obstructive nephropathy, or urinary tract infection.

ADPKD is usually diagnosed by imaging of the kidneys. The finding of three or more cysts (unilateral or bilateral) in those younger than age 30, two or more cysts in each kidney in those between 40 and 59 years of age, and four or more cysts in each kidney in patients older than 60 years is sufficient to make diagnosis of ADPKD. The absence of more than two cysts in individuals older than 40 years of age makes ADPKD very unlikely. Genetic testing is usually not required for an individual with a positive family history if other diagnostic criteria for ADPKD are met, but other family members should be screened.

No specific treatment is available to prevent the growth of renal or liver cysts. Renin-mediated hypertension is a common complication of ADPKD, and it contributes to an increased incidence of cardiovascular mortality and faster progression to ESRD. The main and most effective therapy remains control of hypertension by angiotensin-converting enzyme inhibitors or angiotensin-receptor blockers to achieve a target blood pressure of less than 125/75 mm Hg.

Renal cyst enlargement can cause pain, and cysts can be complicated by infection or bleeding that warrants specific intervention. Surgical decompression is usually reserved for patients who fail conservative management. If ESRD occurs, patients are treated with renal replacement therapy, including dialysis and renal transplantation. Preemptive management of intracranial aneurysms is important but controversial.

The time of onset and rate of progression of ADPKD varies from patient to patient, even within the same family. Risk factors for progressive renal failure include increases in renal cyst volume, a *PKD1* gene mutation, and uncontrolled hypertension. Other risk factors include male gender, diagnosis of ADPKD before 30 years of age, hypertension before 35 years of age, concurrent diabetes mellitus, and hematuria. About 45% of the patients with ADPKD develop ESRD by 60 years of age, but they have a better prognosis than patients with ESRD from other causes.

● AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY

Autosomal recessive polycystic kidney disease (ARPKD) also is classified under the *ciliopathies*. ARPKD is characterized by dif-fused dilation of the collecting ducts and congenital hepatic fibrosis. The estimated incidence of ARPKD is 1 case in 20,000 live births.

Mutations in the polycystic kidney and hepatic disease 1 gene (*PKHD1*) are responsible for ARPKD. *PKHD1* is a large gene located on chromosome 6. More than 300 mutations have been identified at different loci of the *PKHD1* gene. Fibrocystin (i.e., polyductin) is the product of *PKHD1* gene and is expressed in the primary cilia of the thick ascending limb, in cortical and medullary ducts in the kidney, and in hepatic bile ducts. It has an important role in the terminal differentiation of renal and biliary ductules.

Patients with ARPKD may be diagnosed at different ages, but most are identified in utero or at birth because those with more severe phenotypes develop enlarged kidneys, oligohydramnios, pulmonary hypoplasia, Potter's facies, and deformities of the spine and limb. Neonates usually have renal enlargement and renal failure, and older patients have liver disease, including portal hypertension, hepatosplenomegaly, variceal bleeding, and hepatic fibrosis.

The initial diagnosis is usually suspected on the basis of renal imaging with antenatal ultrasound or after birth. Abdominal ultrasound shows bilateral renal cysts and enlarged kidneys. Fetal imaging shows oligohydramnios, pulmonary hypoplasia, and Potter's syndrome.

No treatment is available for ARPKD, and genetic testing is usually not performed outside of research scenarios. Most deaths occur in utero or at the time of birth, and of those with ARPKD who survive birth, 20% to 30% die within the first year of life. Neonates have more renal manifestations, and older patients have more liver disease manifesting as portal hypertension, hepatosplenomegaly, and bleeding esophageal or gastric varices. The likelihood of patients being alive without ESRD increases with older age at presentation due to their more benign phenotypes.

● JUVENILE NEPHRONOPHTHISIS-MEDULLARY CYSTIC KIDNEY DISEASE COMPLEX

Nephronophthysis and medullary cystic kidney disease (MCKD) are hereditary forms of renal cystic disease. Both produce bilateral cysts at the corticomedullary junction of the kidney and early-onset ESRD. They are clinically and pathologically indistinguishable, and they are separated only by the age of onset and mode of inheritance.

Nephronophthysis is an autosomal recessive cystic kidney disease, and the median age of onset of renal disease is 11.5 years.

MCKD has an autosomal dominant pattern of inheritance, and the median age of onset of renal disease is 28.5 years. Nephronophthisis is more common than MCKD and is the most common cause of ESRD in first 3 decades of life.

Several genes are associated with the nephronophthisis and MCKD phenotypes. Mutations in at least two genes (*MUC1*, *Uromodulin*) can lead to MCKD. Nephronophthisis is caused by mutations in at least 18 genes: *NPHP1*, *NPHP2* (now called *INVS*), *NPHP3*, *NPHP4*, *NPHP5* (now *IQCB1*), *NPHP6* (now *CEP290*), *NPHP7* (now *GLIS2*), *NPHP8* (now *RPGRIP1L*), *NPHP9* (now *NEK8*), *NPHP10* (now *SDCCAG8*), *NPHP11* (now *TMEM67*), *NPHP12* (now *TTC21B*), *NPHP13* (now *WDR1*), and *NPHP14-18*. Functional defects of any of the proteins associated with these genes can lead to ciliary dysfunction and development of multiple cysts.

The three clinical forms of nephronophthisis are based on the onset of ESRD: an infantile form with a median onset at 1 year of age, a juvenile form with a median onset at 13 years of age, and an adolescent form with a median onset at 19 years of age. In patients with MCKD, ESRD develops between the ages of 50 and 70 years.

The diagnosis of nephronophthisis or MCKD is based mainly on clinical features. Medullary cysts, a low urinary specific gravity, and absence of significant proteinuria may suggest either disease. Genetic testing is available for several gene mutations and can be applied based on the age at presentation. Siblings can be screened by renal ultrasound and urine concentration test results. Renal biopsy is usually not indicated because the findings of interstitial fibrosis and tubular atrophy are nonspecific.

No specific treatment is available for nephronophthisis or MCKD, and treatment is mainly supportive. Sodium supplementation for salt wasting, allopurinol for gout, and dialysis or renal transplantation for ESRD are part of supportive care. The time of onset of ESRD varies between 30 and 60 years, depending on the type of mutation. Nephronophthisis or MCKD does not recur after renal transplantation.

MEDULLARY SPONGE KIDNEY

Medullary sponge kidney (MSK), also known as Lenarduzzi-Cacchi-Ricci disease, is a relatively uncommon congenital disorder. It usually occurs sporadically, but familial cases have been reported. MSK is characterized by ectasia and cystic dilation of medullary and papillary collecting ducts, resulting in a spongy appearance of the kidney on imaging. MSK is associated with urinary acidification and concentration defects, a high risk of nephrocalcinosis and renal stones, and a moderate risk of urinary infections and renal failure. The prevalence of MSK is 1 case in 5000 persons in the general population, and 15% to 20% of patients with nephrolithiasis have MSK.

No clear genetic basis for MSK has been established. MSK is usually detected between the ages of 30 and 50 years. Most patients with MSK are asymptomatic and may have incidental finding on imaging. The clinical course is benign and is not associated with ESRD.

When suspected, CT urography has replaced intravenous urography as the imaging study of choice for the diagnosis of MSK. There is retention of contrast media in renal pyramids and cystic collecting ducts, giving the appearance of blush or diffused

linear striations. Nephrocalcinosis is common in patients with MSK but is not required to make the diagnosis of MSK. CT imaging may help in excluding papillary necrosis, ADPKD, obstruction, or pyelonephritis.

RENAL TUMORS

Each year, approximately 65,000 new cases of renal cancer are diagnosed, and 14,000 deaths from renal cell carcinoma (RCC) are reported in the United States. Most cases are sporadic, but there is an association between RCC and VHLD and tuberous sclerosis that has helped to explain the cellular mechanisms involved.

RCC originates from renal epithelial cells and accounts for 85% of renal cancers. Based on histology, the five subtypes are clear cell, papillary (chromophilic), oncocytoma, collecting duct (Bellini's duct), and chromophobe RCC. Clear cell carcinoma is the most common subtype and accounts for about 75% to 80% of all cases.

The classic triad of symptoms of flank pain, hematuria, and a palpable flank mass is uncommon (10%). About 50% of cases are identified as a result of an incidental finding on radiographic imaging. Other clinical symptoms are nonspecific and include fatigue, anemia, and weight loss. Paraneoplastic syndromes associated with RCC include erythrocytosis (i.e., overproduction of erythropoietin), hypercalcemia (i.e., excess parathyroid hormone-related peptide), hepatic dysfunction (i.e., Stauffer's syndrome), and cachexia.

The initial diagnosis of RCC is usually made by imaging. Unlike simple cysts, which are anechoic, round, and smooth walled, RCC is more likely to be septate, irregular, thick-walled mass. When RCC is suspected, additional evaluation by CT urography or magnetic resonance imaging (MRI) is usually required, along with complete staging and evaluation for metastases (Table 29-6).

When possible, the primary treatment of localized RCC is surgical resection, which usually includes complete or partial nephrectomy. Locally advanced or metastatic RCC is treated medically with chemotherapy and immunomodulatory therapy with interleukin-2. Newer therapies based on molecular targeting of the mammalian target of rapamycin (mTOR), which regulates vascular endothelial growth factor (VEGF), and several tyrosine kinases are promising.

The prognosis for RCC depends primarily on the clinical stage at the time of presentation as assessed by the tumor-node-metastasis (TNM) criteria. TNM stages I through III have a better prognosis than TNM stage IV (metastatic) RCC. With documented metastases, the 1-year survival rate is 12% to 71%, and the 3-year survival rate is 0% to 31%. Other poor prognostic factors include a lower Karnofsky performance status, elevated lactate dehydrogenase level, low hemoglobin level, and hypercalcemia.

ACQUIRED CYSTIC KIDNEY DISEASE IN RENAL FAILURE

Acquired cystic kidney disease (ACKD) is not associated with hereditary causes of cyst formation but occurs in the setting of chronic kidney disease of many causes. It is defined by three or more cysts per kidney in a patient with chronic kidney disease or

TABLE 29-6 TNM STAGING SYSTEM OF RENAL CELL CARCINOMA

PRIMARY TUMOR (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
T1	Tumor <7 cm and limited to the kidney		
T1a	Tumor <4 cm and limited to the kidney		
T1b	Tumor >4 cm but <7 cm and limited to the kidney		
T2	Tumor >7 cm and limited to the kidney		
T2a	Tumor >7 cm but <10 cm and limited to the kidney		
T2b	Tumor >10 cm and limited to the kidney		
T3	Tumor extends into major veins or perinephric tissues but not into the ipsilateral adrenal gland and not beyond Gerota's fascia		
T3a	Tumor grossly extends into the renal vein or its segmental branches, or tumor invades perirenal and/or renal sinus fat but not beyond Gerota's fascia		
T3b	Tumor grossly extends into the vena cava below the diaphragm		
T3c	Tumor grossly extends into the vena cava above the diaphragm or invades the wall of the vena cava		
T4	Tumor invades beyond Gerota's fascia, including contiguous extension into the ipsilateral adrenal gland		
REGIONAL LYMPH NODES (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastasis in regional lymph node(s)		
DISTANT METASTASIS (M)			
M0	No distant metastasis		
M1	Distant Metastasis		
ANATOMIC STAGE/PROGNOSIS GROUPS			
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T1 or T2	N1	M0
	T3	N0 or N1	M0
Stage IV	T4	Any N	M0
	Any T	Any N	M1

From Edge SB, Byrd DR, Compton CC, et al: AJCC cancer staging manual, ed 7, New York, 2010, Springer Verlag, pp 482–487.

ESRD. The prevalence of ACKD varies from 10% to 100%, and it increases with the duration of dialysis, reaching 87% after 10 years of dialysis. Patients with risk factors of male gender, older age, and a history of heart disease, larger kidneys, and kidney calcifications are more likely to develop ACKD.

Neither the cause of the underlying ESRD nor the mode of dialysis influences the progression of ACKD. It has been postulated that damage to the renal parenchyma in chronic kidney disease increases local growth factors levels that promote hypertrophy and cyst generation in the remaining nephrons. In some cases, increased levels of growth factors and mutated genes (e.g. *ERBB2*) may cause the malignant transformation of cysts, the primary clinical concern for 3% to 7% of ACKD patients.

ACKD-related cyst formation is limited to the kidneys and is an incidental finding on radiographic imaging. Patients with ACKD are usually asymptomatic but may develop infectious or bleeding complications. ACKD can be differentiated from hereditary causes of cystic renal disease by presence of chronic kidney disease or ESRD and the absence of any other clinical findings. Routine screening for ACKD among dialysis patients is contentious but is recommended for patients during their pre-transplantation evaluation and after kidney transplantation because of the potential for malignancy.

Patients with ACKD do not require specific treatment. Tumors larger than 3 cm may be considered for nephrectomy. Bilateral nephrectomy is suggested in renal transplant candidates due to the higher risk of subsequent malignant transformation with immunosuppression.

TUBEROUS SCLEROSIS

Tuberous sclerosis complex (TSC) (i.e., Bourneville's disease) is an autosomal dominant genetic disorder that affects adults and children. TSC causes benign tumors to form in multiple organ systems, including the skin, brain, and kidneys. TSC is often characterized by related neurologic disorders such as epilepsy and mental retardation.

The prevalence of TSC in the general population is approximately 1 in 10,000, and 50% to 65% of cases are sporadic. Because TSC has an autosomal dominant pattern of inheritance, there is a 50% risk of siblings being affected. Genetic counseling is important for affected families. The overall diagnosis and management of TSC is discussed in [Chapter 115](#).

TSC is caused by inactivating mutations in the *TSC1* or *TSC2* genes. *TSC1* is located on chromosome 9, and *TSC2* is on chromosome 16, adjacent to the *PKD1* gene. They, respectively, encode the hamartin and tuberlin proteins, which together form a complex that regulates specific cellular growth, motility, and migration of cells. Inactivating mutations of the *TSC1* or *TSC2* genes result in disruption of these processes and may cause unrestricted growth of cells and tumorigenesis.

TSC conveys a lifetime risk of 2% to 3% for RCC. Renal tumors are usually bilateral and occur at an early age. More commonly, the tumors are benign. Angiomyolipomas, composed of abnormal, thick-walled vessels, smooth muscle cells, and adipose tissue, are seen in about 80% of patients with TSC by the age of 10 years. These benign renal tumors often require no treatment. However, they can grow, become locally invasive, and cause bleeding, pain, and hypertension.

Conclusive guidelines for surveillance are unavailable, but annual MRI of renal and brain lesions is suggested until the age of 21 years and then every 2 to 3 years to monitor their growth. Patients with progressive lesions should have yearly imaging, and those with tumors larger than 4 cm in diameter are at high risk for spontaneous bleeding and life-threatening hemorrhage. If the angiomyolipomas become locally invasive or cause bleeding, surgical intervention is needed.

Mutations in the *TSC1* or *TSC2* gene cause constitutive activation of mTOR. Everolimus, an inhibitor of mTOR, has been approved for the treatment of patients with TSC-associated subependymal giant cell astrocytomas.

VON HIPPEL-LINDAU DISEASE

VHLD is an autosomal dominant disease that affects multiple organ systems. It is caused by germline mutations in *VHL*, a tumor suppressor gene located on chromosome 3. This mutation predisposes to renal cell carcinoma and to tumor formation in other organs, including the eyes, cerebellum, spinal cord, adrenal glands, epididymis, and pancreas. VHLD affects approximately 1 in 40,000 births, and about 7000 patients are affected in the United States. There is an important association with pheochromocytoma in some patients with VHLD that warrants consideration.

RCC occurs in up to 70% of patients with VHL. It is usually bilateral and the clear cell type. RCC affects younger patients with a mean age at presentation of 26 years. For a high-risk patient, the diagnosis of VHL is suggested by central nervous system or retinal hemangioblastoma, RCC, or pheochromocytoma. These patients should be referred for detailed assessment. When indicated, genetic testing can be performed to assess possible mutations of the *VHL* gene.

NEPHROLITHIASIS

Epidemiology and Pathogenesis

Nephrolithiasis is a common clinical disorder that imposes a substantial burden on human health and resource use. Calcium-containing stones are the most common types, and stones composed of cystine, struvite, and pure uric acid are less common but have high recurrence rates. Based on National Health and Nutrition Examination Survey, the prevalence of kidney stones has increased from 3.2% in the 1976-1980 period to 8.8% in the 2007-2010 period. Diet and lifestyle factors likely play significant roles in the changing epidemiology.

Nephrolithiasis increases with age and is more common in men than in women, except after menopause, when the incidence tends to equalize. The prevalence is higher among white males, intermediate among Hispanics and Asians, and rare among blacks. After the first manifestation, there is a high rate of stone recurrence, approaching about 50% in 5 to 10 years. The risk factors for recurrence include a younger age at initial presentation, a family history of urolithiasis, underlying medical conditions, and recurrent urinary infections.

Stone formation occurs as a result of supersaturation of urinary solutes, expressed as the ratio of solute concentration in urine to its known solubility. A ratio greater than 1 indicates that urine is supersaturated, promoting crystallization. In all cases, low urine volumes increase the probability of urine solute supersaturation and promote stone formation.

Additional factors are involved. Higher urinary calcium and oxalate concentrations promote calcium oxalate stones, whereas alkaline urine and high urinary calcium concentrations promote calcium phosphate crystal formation. Acidic urine is a major determinant of uric acid crystal formation. Normal urine contains substances such as citrate, pyrophosphate, magnesium, Tamm-Horsfall glycoprotein, glycosaminoglycan, osteopontin, and calgranulin that can inhibit aggregation of crystals in urine. Citrate is the only inhibitor that can be modified in clinical settings.

Clinical Presentation and Diagnosis

Patients with nephrolithiasis are often asymptomatic, and calculi are detected as incidental findings on imaging studies. When symptoms occur, flank pain with or without gross hematuria is characteristic. The pain can vary in intensity from mild to severe and is classically abrupt in onset, paroxysmal, and follows a waxing and waning course over hours. Other associated symptoms include dysuria, urgency, nausea, and vomiting. Some patients may pass “gravel” in their urine, a finding more characteristic of uric acid stones. Complications associated with nephrolithiasis include urinary tract obstruction, hydronephrosis, infection, and acute kidney injury from obstructive uropathy in

the setting of bilateral obstruction or unilateral obstruction in the setting of solitary kidney.

A detailed history is crucial for patients with kidney stones and should include age at the first episode, number of stones, bilateral or unilateral occurrence, frequency of stone formation, type of stone if known, type and number of surgical interventions, family history of stone disease, and associated infections. Certain clues elucidated by the history may point toward a systemic cause of nephrolithiasis; for example, patients with malabsorptive states may be predisposed to calcium oxalate stones. The history should include detailed dietary habits, including the amount of fluid intake and dietary levels of sodium, protein, oxalate, and calcium, to determine the potential cause of or contributors to stone formation. Medications that can potentiate stone formation are shown in Table 29-7.

Except during an acute episode of stone passing, most patients have normal physical examination. However, physical examination may sometimes reveal findings suggesting systemic condition such as tophi in patients with hyperuricosuria and uric acid stones.

Laboratory testing includes a complete metabolic profile with attention to calcium, phosphate, and uric acid levels. Hypokalemia and metabolic acidosis suggest renal tubular acidosis, which is associated with a higher incidence of stone formation. A careful urinalysis may identify crystals, and other findings may indicate a specific cause (Table 29-8). When possible, it is important to retrieve stones for chemical analysis. Identification of stone type can guide therapy.

A 24-hour urine collection is the cornerstone of evaluation of most patients with nephrolithiasis and includes quantitation of

TABLE 29-7 MEDICATIONS ASSOCIATED WITH STONE FORMATION

MEDICATION	MECHANISM
Acetazolamide	Hypocitraturia
Vitamin C	Hypocitraturia
Vitamin D	Hypercalciuria
Antacids	Hypercalciuria
Theophylline	Hypercalciuria
Nifedipine	Hypercalciuria
Probenecid, aspirin	Hyperuricosuria
Topamax	Hypocitraturia
Indinavir	Precipitation within the tubule
Acyclovir	Precipitation within the tubule

TABLE 29-8 URINALYSIS AND RADIOGRAPHIC FINDINGS OF RENAL CALCULI

STONE TYPE	URINE MICROSCOPIC FINDINGS	RADIOLOGIC FINDINGS
Calcium oxalate monohydrate	Dumbbell shaped; under polarized light, appear coarse and needle shaped	Opaque, round, multiple calculi
Calcium oxalate dihydrate	Envelope shaped	Opaque
Struvite, magnesium ammonium phosphate	Coffin lid	Opaque, may be staghorn
Uric acid	Pleomorphic, often rhombic plates or rosettes	Radiolucent
Cystine	Hexagonal	Opaque

urine volume, pH, and levels of calcium, uric acid, citrate, oxalate, sodium, urea nitrogen, phosphate, and creatinine to assess the completeness of the collection. Preferably, two collections are performed in outpatient settings while consuming a usual diet. The findings are important for prevention of recurrence.

In the acute setting, noncontrast helical CT has replaced intravenous urography as the test of choice for the diagnosis of renal stones. CT can detect opaque and radiolucent stones with high sensitivity and specificity. Ultrasound can also detect radiolucent and radiopaque stones in kidneys but may miss ureteral stones. Ultrasound has a role in evaluating stones in pediatric and pregnant patients.

Treatment and Prevention

In most cases, small (<4 mm), nonobstructive stones can be managed conservatively because they have a good chance of spontaneous passage. With increases in stone size, the spontaneous passage rate decreases from 55% for stones less than 4 mm in diameter to 35% for stones 4 to 6 mm in diameter and 8% or less for stones greater than 6 mm in diameter.

During an acute episode of renal colic, pain management is essential, and it can be controlled with the use of NSAIDs or narcotics. Patients should be instructed to increase their fluid intake to increase their urine output to at least 2 L/day to hasten stone passage. α_1 -Adrenergic receptor blockers and calcium-channel blockers can be used to facilitate stone passage. The α_1 -adrenergic receptor blockers decrease ureteral smooth muscle tone and decrease the frequency and force of peristalsis, whereas calcium-channel blockers suppress smooth muscle contraction and reduce ureteral spasm.

Signs of urinary tract infection, inability to take oral fluids, or obstruction of a single functioning kidney warrants hospitalization. In acute kidney injury, anuria, or sepsis with an obstructive stone, urgent urologic consultation should be obtained. Similarly, a urology consultation should be obtained for stones greater than 10 mm in diameter due to the low probability of spontaneous clearance, for failure of conservative management, or for anatomic abnormalities that would prevent passage of the stone.

The type of surgical intervention is determined by stone size, type, and location and by the existence of infection. Shock wave lithotripsy is often recommended as the first-line therapy for non-lower pole renal calculi less than 2 cm in diameter and for lower pole renal calculi less than 1 cm in diameter. Percutaneous nephrolithotomy is suggested for larger stones.

General measures to prevent recurrent stone formation include increases in oral fluid intake to between 2 and 2.5 L/day and limitation of dietary sodium intake to less than 2 g/day and protein intake to 0.8 to 1 g/day. Dietary calcium restriction is not recommended because calcium in food binds to oxalate in the bowel and reduces urinary excretion of the highly lithogenic oxalate. However, calcium supplementation between meals should be avoided in patients with calcium stones.

Types of Renal Stones

Specific treatment modalities can be implemented when the metabolic risk factors for stone formation are identified (Table 29-9).

TABLE 29-9 TREATMENT MODALITIES FOR NEPHROLITHIASIS RISK FACTORS

URINARY ABNORMALITY	DIETARY CHANGE	MEDICATION
High calcium	Adequate dietary calcium intake Reduce animal protein intake Reduce sodium intake to <3 g/day	Thiazide
High oxalate	Avoid high oxalate foods Adequate dietary calcium intake	Consider vitamin B ₆
High uric acid	Reduce purine intake	Allopurinol
Low citrate	Increase fruit and vegetable intake Reduce animal protein intake	Alkali (potassium citrate)
Low volume	Increase total fluid intake Goal urine output >2 L/day	—

TABLE 29-10 PRINCIPAL RISK FACTORS FOR CALCIUM STONE FORMATION

Low urinary volume
High urinary oxalate
High urinary calcium
Low urinary citrate
Dietary factors
Low dietary intake of fluids, calcium, phytates, potassium
High intake of oxalates, sodium, protein, sucrose
Medical conditions: obesity, metabolic syndrome, diabetes mellitus, primary hyperparathyroidism, gout, medullary sponge kidneys

Calcium Stones

Approximately 80% of stones are calcium stones, most of which are composed primarily of calcium oxalate, mixed oxalate, and phosphate, and less often, they are pure calcium phosphate. Calcium oxalate supersaturation is not pH dependent in the physiologic range, whereas alkaline urine promotes calcium phosphate supersaturation. The pathophysiologic mechanisms for calcium kidney stone formation are complex and are associated with several metabolic derangements (Table 29-10).

Hypercalciuria is the most common metabolic abnormality found in recurrent calcium stones formers and is detected in 30% to 60% of adults with nephrolithiasis. It is most often familial or idiopathic. One pathophysiologic mechanism for hypercalciuria is increased intestinal calcium absorption (i.e., absorptive hypercalciuria), which is the most common abnormality. Gut calcium absorption is increased in persons with idiopathic hypercalciuria, but serum calcium values remain unchanged because the absorbed calcium is promptly excreted. A second mechanism is enhanced calcium mobilization from bone (i.e., resorptive hypercalciuria), which leads to urinary loss of bone calcium. This is seen in patients with primary hyperparathyroidism, immobilization, and metastatic tumors. A third mechanism is decreased renal calcium reabsorption (i.e., renal leak), the pathogenesis of which is unclear. It is thought to result from a primary defect in renal tubular of calcium. High-sodium intake decreases proximal sodium reabsorption, and the ensuing urinary sodium excretion causes physiologic increases in calcium excretion, promoting stone formation. Consumption of large amounts of animal protein can increase the acid load, causing calcium release from bones and increased urinary calcium excretion. Acidosis results

in decreased tubular calcium reabsorption and depletion of urinary citrate.

Thiazide diuretics are commonly used to decrease urine calcium excretion in recurrent calcium stone formers. They reduce hypercalciuria and stone recurrence regardless of the underlying pathophysiologic mechanism because they promote increased proximal tubule calcium absorption. Thiazides can cause hypokalemia-induced hypocitraturia, and thiazide use should be supplemented with potassium. Potassium citrate has an advantage over other agents because it provides both potassium and citrate.

Hyperoxaluria

Hyperoxaluria (>45 mg/day in women and 55 mg/day in men) is detected in 10% to 50% of calcium stone formers. Hyperoxaluria increases calcium oxalate supersaturation and promotes calcium oxalate stone formation. Hyperoxaluria can result from increased dietary intake, increased gastrointestinal absorption of oxalate, or overproduction of oxalate caused by an inborn error in metabolism.

Dietary issues can be important. Foods known to increase urinary oxalate excretion include rhubarb, spinach, beets, most nuts, chocolate, tea, raspberries, figs, and plums. Enteric hyperoxaluria occurs in patients with malabsorption of fat. Dietary calcium binds to fatty acids in the enteric lumen. The released free oxalate is then available for augmented absorption. Enteric hyperoxaluria is commonly seen in patients with chronic diarrhea, inflammatory bowel diseases, celiac disease, and intestinal resection or after bariatric surgery.

Concomitant risk factors for stone formation include low urine volume, acidic urine, and hypocitraturia. Rarely, hyperoxaluria is caused by inborn errors in metabolism such as primary hyperoxaluria, a rare autosomal recessive genetic disorder of oxalate synthesis. Patients should be advised to avoid excessive vitamin C (>500 mg/day). For patients with enteric hyperoxaluria, measures should be instituted to reduce steatorrhea, such as a low-fat diet, cholestyramine, and administration of medium-chain triglycerides.

Hypocitraturia

Citrate, an endogenous inhibitor of calcium stone formation, is the only inhibitor that is measured and can be modified in clinical settings. Citrate binds to urinary calcium to form a soluble complex and prevent precipitation of calcium with oxalates or phosphates. Citrate also directly inhibits crystal agglomeration. Hypocitraturia can be a consequence of metabolic acidosis, high-protein intake, carbonic anhydrase inhibitors, or hypokalemia, or it may be an idiopathic disorder. Decreases in tubular fluid pH result in conversion of the trivalent citrate anion into the divalent anion, which is more easily reabsorbed by the sodium citrate cotransporter in the luminal membrane. Acidosis results in increased cell citrate use and upregulation of proximal renal tubular reabsorption of citrate, leading to hypocitraturia.

Potassium citrate is more effective in preventing calcium stone formation compared with sodium citrate because the sodium load can worsen hypercalciuria. The usual dose for potassium citrate is 15 to 25 mmol two or three times per day. A potential concern with alkali therapy is the risk of calcium phosphate stone

formation. Among patients with reduced kidney function, serum potassium needs to be monitored closely because of the risk of hyperkalemia.

Calcium Phosphate Stones

Calcium phosphate stone formation is a result of hypercalciuria, hypocitraturia, and persistently alkaline urine. Calcium phosphate stones can be seen in patients with distal renal tubular acidosis, with use of carbonic anhydrase inhibitors such as acetazolamide (which inhibit bicarbonate reabsorption in the proximal tubule), and with use of antiepileptic drugs such topiramate that can inhibit carbonic anhydrase.

Uric Acid Stones

Three major urinary abnormalities causing uric acid precipitation are low urinary pH (urine pH <5.5), low urine volume, and hyperuricosuria. When urinary pH is acidic, changes in physical chemistry result in conversion of more soluble urate into less soluble uric acid, thereby facilitating lithogenesis. Excessive acid loads (e.g., diet high in animal protein) or chronic bicarbonate loss in patients with chronic diarrhea can result in low urinary pH, increasing the propensity for uric acid stone formation. The increased incidence of uric acid stones among patients with insulin resistance and type 2 diabetes mellitus has been linked to impaired ammonia synthesis resulting in reduced urinary pH. Hyperuricosuria also may be seen in certain clinical conditions such as myeloproliferative disorders, tumor lysis syndrome, rare genetic disorders linked to the uric acid synthetic pathway, and mutations in renal uric acid transporters.

Alkaline therapy along with increasing urine volume is the most effective treatment of uric acid stones. Potassium citrate, given as 30 to 80 mmol in divided doses, is prescribed to maintain a urine pH of 6.5 to 7. Further increases in urinary pH to above 7 may result in calcium phosphate precipitation and should be avoided. When marked hyperuricosuria persists (urinary uric acid excretion >600 mg/day in women and 700 mg/day in men) despite dietary animal protein limitation and other measures, xanthine oxidase inhibitors such as allopurinol can be used at doses of 100 to 300 mg/day.

Struvite Stones

Struvite or triple phosphate stones are composed of magnesium ammonium phosphate and calcium carbonate apatite. They can grow rapidly and, if untreated, can fill the entire pelvis, resulting in staghorn calculi. They also can cause chronic kidney disease, including ESRD. Struvite stones result from chronic urinary tract infections with urea-splitting organisms (Table 29-11), which increase urine pH by generating ammonium to produce stones composed of ammonium-magnesium-phosphate.

The mainstay of treatment for struvite stones includes early surgical removal of bacteria-laden stones and eradication of

TABLE 29-11 UREASE-PRODUCING BACTERIA

<i>Corynebacterium</i>	<i>Providencia</i> (most species)
<i>Haemophilus</i>	<i>Pseudomonas</i>
<i>Klebsiella</i>	<i>Serratia</i>
<i>Proteus</i> (most species)	<i>Staphylococcus</i>

associated infection with antibiotics. If other measures are ineffective, acetohydroxamic acid, a urease inhibitor, can be considered, but its use is limited by significant side effects.

Cystine Stones

Cystinuria is the most common of the rare hereditary kidney stone diseases. It is caused by inherited defects of dibasic amino acid transport in the kidney and intestine. Mutations of one of the two subunits of the amino acid transporter in the kidney leads to defective renal tubular reabsorption of dibasic amino acids such as cystine, arginine, lysine, and ornithine. Cystine stones are the main complication of this defect due to the low solubility of cystine in urine. Characteristic hexagonal cystine crystals can be seen on urine sediment analysis.

The diagnosis of cystinuria is based on a family history of stones, stone formation at a young age, mildly radiopaque stones, and measurement of urinary cystine excretion. Patients with cystinuria excrete 250 to 1000 mg of cystine per day (normal is about 30 mg/day).

Treatment must be aimed at decreasing the urinary cystine concentration by increasing urine volume to more than 4 L/day, alkalization of urine (urine pH >6.5) with potassium citrate or sodium bicarbonate, reducing urine cystine excretion by reducing sodium intake and raising urinary pH by decreasing animal protein intake. Thiol derivatives such as D-penicillamine and

α -mercaptopyropionylglycine split cystine molecules into two cysteines and produce a highly soluble disulfide compound. However, their use may be limited by their side effects.

Vascular Disorders of the Kidney

Jeffrey S. Berns

INTRODUCTION

The spectrum of vascular disorders of the kidneys is broad as a result of high renal blood flow and the intimate relationship between blood supply and fundamental glomerular and tubular functions. In this chapter, emphasis is placed on the clinical manifestations of hypertension, chronic kidney disease (CKD), end-stage kidney failure, and the many other causes of acute kidney injury (AKI).

RENAL VASCULAR ANATOMY

The renal arteries arise directly from the aorta and enter the renal hilum. The right renal artery passes anterior to the inferior vena cava (IVC) and is longer than the left renal artery. In up to 30% of the population, accessory renal arteries arise from the aorta to provide blood to portions of one or both kidneys, which may become important when evaluating patients for renovascular hypertension.

The renal arteries give rise to segmental, interlobar, and arcuate arteries (Fig. 30-1). Arcuate arteries course along the corticomedullary junction and give rise to interlobular arterioles, which extend outward into the cortex before branching into afferent arterioles, from which the glomerular capillary tufts arise. The postglomerular efferent arterioles from more superficial glomeruli form a capillary network in the renal cortex, and those extending from glomeruli nearer the cortical-medullary junction (i.e., juxtamedullary glomeruli) form capillaries that extend deeper into the medulla in association with thin, descending and ascending loops of Henle as the vasa recta. The vasa recta provide the sole blood supply for the renal medulla, making this portion of the kidney particularly susceptible to ischemic injury. Venules from the ascending vasa recta and the cortical capillary network empty into the renal veins.

The left renal vein returns to the IVC anterior to the aorta and inferior to the inferior mesenteric artery, which may rarely cause compression of this vein. The left gonadal vein also empties into the left renal vein, and a left varicocele may be evident if the renal vein is occluded by thrombosis or tumor involvement. The right renal vein is much shorter and empties directly into the IVC. The right gonadal vein empties directly into the IVC rather than into the right renal vein.

RENOVASCULAR DISEASE

Any process that narrows the lumen of the main or branch renal arteries sufficiently can elicit a humoral response mediated by increased renin release from the ipsilateral kidney, which leads to increases in circulating angiotensin II and aldosterone levels.

Activation of the renin-angiotensin-aldosterone system increases systemic blood pressure and renal arterial perfusion pressure, renal blood flow, and the glomerular filtration rate (GFR) beyond the stenosis. Hemodynamically significant renal artery stenosis (RAS) requires a reduction in lumen diameter of at least 50% to 60%. The resulting renin-angiotensin-aldosterone system activation leads initially to systemic vasoconstriction mediated by angiotensin II and increased renal sodium and fluid reabsorption, resulting in elevation of systemic blood pressure. If the contralateral kidney has no stenosis, the increased systemic blood pressure increases sodium excretion by that kidney (i.e., pressure natriuresis).

Because hypertension in this setting is maintained by increased vasoconstriction due to angiotensin II, treatment is aimed at blocking the synthesis or effect of the elevated angiotensin II levels with an angiotensin-converting enzyme (ACE) inhibitor

FIGURE 30-1 Section of the human kidney shows the renal arteries and a schematic of the microcirculation of each nephron. (From Guyton AC, Hall JE: Textbook of medical physiology, ed 11, Philadelphia, 2006, Saunders, p 309.)

or angiotensin-receptor blocker (ARB). If the arteries to both kidneys are narrowed, pressure natriuresis does not occur, and hypertension is maintained chronically by the resulting intravascular volume expansion rather than by increased total peripheral resistance. Treatment with diuretics becomes more important in this circumstance. The latter situation also occurs when there is only a single functioning kidney that has stenosis or when an initially normal contralateral kidney suffers microvascular damage from long-standing hypertension (Fig. 30-2).

The pathophysiology of hypertension with RAS is such that its treatment may also compromise kidney function and reduce the GFR. If the kidney contralateral to one with hemodynamically significant RAS is normal, lowering the systemic blood pressure maintains the kidney with the stenosis in a vascularly compromised state. However, this may not be detectable by measurement of the serum creatinine level because of the normally functioning contralateral kidney. A decline in the GFR may be evident if there is underlying renal dysfunction in the contralateral kidney, as is often the case in long-standing hypertension, diabetes, or vascular disease. When a solitary functioning kidney or both kidneys are affected (i.e., bilateral RAS), AKI may result when ACE inhibitor or ARB treatment is initiated.

Atherosclerotic Renovascular Disease

Clinical Presentation

Atherosclerosis is the primary cause of RAS, although any process that narrows one or both renal arteries may cause renal ischemia;

FIGURE 30-2 Anatomy of renal artery stenosis. Renal artery stenosis may be unilateral (A), bilateral (B), or unilateral with a solitary kidney (C). Aortic disease may serve functionally as bilateral renal artery stenosis (D).

others are discussed later in this chapter. Atherosclerotic renovascular disease is a common form of secondary hypertension, affecting up to 5% of patients with hypertension. Atherosclerotic RAS rarely occurs in patients younger than 40 years, and it is more common in men, whites, smokers, diabetics, and patients with atherosclerotic disease in other arterial systems.

RAS should be suspected in patients with refractory hypertension or new-onset hypertension in patients older than 50 years, particularly if they have overt risk factors for atherosclerotic RAS (Table 30-1). Evaluation should always begin with a thorough history and physical examination, including attention to blood pressure and pulse amplitude in each extremity. A significant discrepancy between extremities may indicate peripheral vascular disease and increase the likelihood of RAS. An abdominal bruit is detected in about 50% of subjects but is not specific for RAS. Edema is not typically found unless significant CKD or another edematous condition also exists.

Laboratory evaluation may reveal hypokalemia ($K^+ < 3.5$ mEq/L) or metabolic alkalosis ($HCO_3^- > 28$ mEq/L) due to secondary hyperaldosteronism. A reduced GFR with an elevated serum creatinine concentration may be found, but a normal serum creatinine level does not rule out hemodynamically significant RAS. Plasma renin activity and aldosterone concentrations may be elevated, but their measurement is of limited clinical utility in assessing hypertensive patients for RAS or in making therapeutic decisions. Urinalysis results are usually normal, although low-grade proteinuria (usually < 1 g/day) from long-standing hypertension may be seen.

Diagnosis

Standard renal ultrasound imaging provides a limited window into the detection of RAS by revealing a discrepancy in kidney size, which develops only after prolonged ischemia and irreversible renal injury. However, a change in kidney size over time on serial imaging in the setting of known RAS may prompt the clinician to consider treatment with angioplasty and stenting or with surgical revascularization.

Renal ultrasound with pulsed Doppler analysis provides information about flow velocity in the renal arteries that may be helpful in detecting hemodynamically significant RAS. However, renal duplex ultrasonography is technically demanding, particularly in obese patients, and it is best performed by an experienced ultrasonographer at a high-volume center with a proven track record of high diagnostic accuracy. At most centers, the sensitivity, specificity, and positive and negative predictive values of renal

TABLE 30-1 CLINICAL FINDINGS SUGGESTING ATHEROSCLEROTIC RENOVASCULAR DISEASE

Onset of new, severe hypertension or sudden worsening of chronic hypertension at > 55 years of age
Accelerated, resistant, or malignant hypertension

Development of acute kidney injury or worsening of chronic kidney disease after starting an ACE inhibitor or ARB

ACE, Angiotensin-converting enzyme; ARB, angiotensin II-receptor blocker.

duplex ultrasonography are unknown, and its clinical utility is probably limited.

Computed tomography (CT) with intravenous iodinated contrast (i.e., CT angiography [CTA]) permits high-resolution evaluation of the arterial vasculature and can be a very useful diagnostic imaging study, particularly in patients with normal or near-normal kidney function. Its use is limited in patients with more significantly impaired kidney function due to the risk of contrast-induced AKI. Magnetic resonance angiography (MRA) with intravenous contrast is also useful for detecting RAS. Gadolinium administration to patients with advanced kidney disease (GFR <30 mL/min) may be contraindicated because of the risk of nephrogenic fibrosing dermopathy, although this appears to be much less of a concern or contradiction with the newer gadolinium-containing contrast agents. Overall, CTA and MRA appear to have similarly high sensitivity and specificity in the assessment of patients with possible atherosclerotic RAS.

Nuclear imaging using technetium-99m diethylene triamine pentaacetic acid (^{99m}Tc-DTPA) or technetium-99m mercaptoacetyltriglycine (^{99m}Tc-MAG3) to assess isotopic uptake and excretion in each kidney before and after the administration of a short-acting ACE inhibitor has been used in the past but has fallen out of favor due to limited specificity and lack of sensitivity in patients with bilateral RAS. The most sensitive and specific test—but also the most invasive—is renal arteriography, which remains the gold standard for the detection of RAS.

At some centers, flow measurements can be obtained at the time of arteriography. An added advantage of arteriography is that angioplasty and stenting can be performed during the procedure (discussed later) if appropriate. Because of the frequent occurrence of accessory renal arteries, an aortogram must be performed rather than selective renal angiography to ensure that all vessels are visualized.

Treatment

Patients with atherosclerotic RAS typically have coexistent cerebrovascular, coronary, and peripheral vascular disease as the result of a long history of multiple risk factors such as cigarette smoking and hyperlipidemia. Clinicians should recognize this high cardiovascular risk and understand that long-term outcomes for patients with atherosclerotic RAS are often determined by coexisting nonrenal atherosclerotic disease. The absolute risk of developing end-stage renal disease (ESRD) is increased for patients with atherosclerotic RAS compared with those without RAS, but the risk is much less than the risk of clinically significant coronary artery disease, symptomatic peripheral vascular disease, heart failure, or stroke. As with atherosclerotic disease in other arterial circulations, atherosclerotic RAS should prompt efforts for intensive lipid lowering, use of aspirin, smoking cessation, and control of hypertension and diabetes mellitus.

Intervention for atherosclerotic RAS remains controversial despite several randomized clinical trials designed to investigate the benefits and risks of medical management compared with angioplasty and renal artery stenting. Small clinical studies have suggested that renal artery angioplasty and stenting may improve blood pressure control in selected cases of atherosclerotic RAS, but identifying which patients may benefit has been problematic, and many have little or no improvement in blood pressure or are

not able to significantly reduce the number of required antihypertensive medications. Randomized, controlled clinical trials have not demonstrated significant clinical benefit in terms of blood pressure control, kidney function, or mortality for most patients with atherosclerotic RAS.

Renal artery angioplasty and stenting carry a risk of acute worsening of kidney function due to atheroembolic disease, contrast nephropathy, or in-stent thrombosis, among other technical complications, and the procedures may lead to irreversible, progressive kidney dysfunction and ESRD. Decisions to correct atherosclerotic RAS with angioplasty and stenting or surgery must be made on a case-by-case basis, considering underlying kidney function, severity of hypertension, tolerance to antihypertensive medications, unilateral or bilateral RAS, atherosclerotic disease in other vascular beds, and life expectancy based on age and other comorbid conditions. There is no role for angioplasty alone without stenting in most patients with atherosclerotic RAS due to the high risk of recurrent stenosis.

Medical management of hypertension in patients with atherosclerotic RAS must take into consideration other comorbid conditions. Use of ACE inhibitors, ARBs, and diuretics is often very effective, but patients treated with these agents must be monitored closely for further compromise of their kidney function.

Fibromuscular Dysplasia

Fibromuscular dysplasia (FMD) is a nonatherosclerotic, noninflammatory disease that causes RAS. FMD typically affects young women more than other groups. The cause is not established, but it is thought to be a developmental defect. Depending on the population, FMD is responsible for 10% to 25% of all renovascular hypertension and is therefore much less common than atherosclerotic RAS.

FMD most commonly affects the renal arteries (bilaterally in about 35% of affected patients), but carotid and vertebral arteries can also be affected. Although FMD is often thought of as a disease of young women, men and older patients can be affected.

Classification of FMD is based on the histologic layer of the artery involved (i.e., intima, media, or adventitia) (Table 30-2). Medial fibroplasia with a mural aneurysm is the most common cause of FMD in adults (70% of cases). It consists of alternating fibromuscular ridges and aneurysmal segments in the distal two thirds of the renal artery and has a classic string-of-beads appearance on angiography (Fig. 30-3). Perimedial fibroplasia of the outer one half of the media produces severe multifocal stenosis and causes about 15% of FMD in adults.

TABLE 30-2 HISTOLOGIC CLASSIFICATION OF FIBROMUSCULAR DYSPLASIA

SUBTYPE	PERCENTAGE OF CASES (%)	RADIOLOGIC APPEARANCE
Medial fibroplasia	60-70	String of beads with aneurysms
Perimedial fibroplasia	15	String of beads without large aneurysms
Medial hyperplasia	5-15	Smooth tubular stenosis
Intimal fibroplasia	1-2	Focal or smooth stenosis
Adventitial fibroplasia	<1	Focal or smooth tubular stenosis

FIGURE 30-3 **A**, Typical medial fibroplasia (i.e., string-of-beads appearance) on an angiogram of a right renal artery. **B**, Gadolinium-enhanced magnetic resonance angiography in the same patient, revealing bilateral medial fibroplasia of the renal arteries and a large marginal artery of Drummond (*arrow*), indicates that there is disease of the superior mesenteric artery. (From Slovut DP, Olin JW: Fibromuscular dysplasia, *N Engl J Med* 350:1862–1871, 2004.)

Medial subtypes of FMD usually have a benign course and are responsive to angioplasty. The intimal subtype may have a higher likelihood of ischemic events and multiorgan system involvement. Symptoms are usually precipitated by stenoses, but FMD may rarely cause dissection or macroaneurysms that require intervention. Although CTA or MRA may be useful in the detection of FMD in the main renal arteries and main branch arteries, arteriography is necessary for detection of stenoses in smaller arteries.

Treatment for FMD depends on the severity of complications. Pharmacologic treatment alone may be adequate to control hypertension in many patients. Intervention with angioplasty (with or without stenting) or surgery should be considered for patients with severe or difficult to control hypertension or declining kidney function. Angioplasty without stenting is successful in many patients, but recurrent stenosis is not uncommon, and new stenoses from FMD may develop at other sites. For this reason, regular monitoring of blood pressure and serum creatinine levels is essential, and many patients require imaging studies to detect new or recurrent lesions.

Aortic Dissection

Aortic dissection occurs after disruption of the intimal layer of the aorta and propagation of blood flow that dissects along the wall of the aorta, producing a false lumen and compression of the true aortic lumen. Aortic dissection is classified by the site of origin (i.e., DeBakey classification) or the segment of the aorta involved (i.e., Stanford classification). DeBakey type I and II dissections originate in the ascending aorta, and type III dissections originate in the descending aorta. Stanford type A refers to dissections involving the ascending aorta, and type B refers to all others not involving the ascending aorta.

Major branch vessels of the aorta, including the renal arteries, may become obstructed or occluded as a result of extension of the dissection. Aortic dissection frequently compromises the renal arteries (the left more commonly than the right) when it extends into the abdominal aorta and causes renal failure in approximately 20% of patients with type B dissections. When disease is extensive enough to cause AKI, vascular compromise

to the intestinal and cerebral vasculature and severe aortic regurgitation often contribute to the high mortality rate.

Aortic dissection most frequently affects older patients (>50 years of age) with coexistent vascular risk factors such as hypertension, smoking, and atherosclerosis. Men are affected more commonly than women. Occasionally, a genetic connective tissue defect such as Marfan syndrome or Ehlers-Danlos syndrome type IV (about 5% of cases) causes aortic dissection, and these conditions should be considered in younger patients (<40 years of age).

AKI occurs in about 20% of patients diagnosed with acute type B aortic dissection and is an independent predictor of in-hospital mortality. Trauma or procedures (e.g., aortic catheterization) can also cause dissection of the aorta or renal artery. Isolated, spontaneous renal artery dissection may rarely occur, most commonly in the setting of polyarteritis nodosa or FMD. Segmental arterial mediolysis is another uncommon condition of unknown origin that is characterized by vacuolar degeneration of smooth muscle cells in the arterial media, which leads to disruption of the arterial medial layer, vessel dissection, hemorrhage, and ischemia. Segmental arterial mediolysis can affect abdominal visceral arteries and virtually any other arterial system.

The most frequent symptom during aortic dissection is chest pain, which may be described as a ripping sensation. Isolated loss of pulse in one or more extremities may provide a clinical clue, and the number of arteries involved correlates with the severity of dissection. A common clue to the diagnosis on a routine chest radiograph is a widened mediastinum, with or without a pleural effusion (most often on the left).

After the diagnosis of aortic dissection is established, evaluation of renal artery involvement is best undertaken noninvasively to minimize further vascular injury. Contrast-enhanced CT, magnetic resonance imaging (MRI), or MRA usually provide images capable of confirming or excluding renal involvement, although each modality carries the same limitations as outlined for the evaluation of RAS. Transesophageal echocardiography is useful for establishing the diagnosis of aortic dissection, but it does not provide information about the aorta below the diaphragm. Renal duplex ultrasonography may be useful for evaluating renal

perfusion in the setting of aortic dissection, but it is not recommended for the initial investigation of aortic dissection.

Aortic dissection is a hypertensive emergency that requires aggressive reduction of blood pressure; systolic blood pressure should be maintained between 100 and 120 mm Hg. Antihypertensive medications that reduce the rate of increase in blood pressure during the cardiac cycle (dP/dt), such as β -adrenergic receptor blockers, have a theoretical benefit in managing aortic dissection by reducing the rate of progression.

Surgical treatment options for renal involvement due to aortic dissection depend on individual circumstances, and careful evaluation by an experienced vascular surgeon is recommended. Thoracic aortic dissection requires surgical repair due to the high mortality rate if left untreated, but isolated abdominal aortic disease may be medically managed.

Thromboembolic Disease

Systemic arterial emboli, typically originating from the left atrium or left ventricle in patients with atrial fibrillation, infectious endocarditis, cardiac valvular disease, or atrial myxoma, may cause acute obstruction of the renal arteries. Rarely, a paradoxical embolus may occur from the venous system through an atrial septal defect.

Symptoms of acute renal ischemia and infarction include flank pain, gross hematuria, and fever. Laboratory findings are nonspecific but include an elevated level of lactate dehydrogenase (LDH), hematuria, and leukocytosis. A definitive diagnosis can be based on the finding of a focal nonenhancing region on contrast-enhanced CT. Imaging studies are necessary to differentiate renal artery embolic disease from renal artery dissection.

The renal mass affected by a renal artery embolus is usually not large enough to necessitate dialysis, although some worsening of kidney function may be observed. The diagnosis of renal infarction is rarely made early enough to initiate treatment with intra-arterial thrombolysis or thrombectomy, and it is questionable whether the risks and marginal benefit of these procedures warrant aggressive treatment. Therapy should instead address the underlying source of renal emboli with symptomatic treatment of pain as necessary. Systemic anticoagulation may be indicated to reduce the risk of further thromboembolic events.

Large and Medium-Sized Vessel Vasculitis

Systemic vasculitides such as temporal (giant cell) arteritis and Takayasu's arteritis affect primarily large and medium-sized arteries. Polyarteritis nodosa and Kawasaki disease affect primarily medium-sized and smaller arteries. These vasculitides are not associated with antineutrophil cytoplasmic antibodies (ANCA) and do not typically cause glomerulonephritis. They are distinguished from ANCA-associated vasculitides that involve smaller blood vessels and more commonly cause glomerulonephritis.

Takayasu's arteritis and giant cell arteritis are typically associated with a granulomatous vasculitis of the aorta and its branches. Giant cell arteritis typically involves the carotid, vertebral, and temporal arteries, and renal involvement is rare. Both occur much more commonly in women than men. Takayasu's arteritis is usually diagnosed in patients younger than 50 years of age, whereas giant cell arteritis is diagnosed in those 50 years of age or older.

Involvement of the main renal arteries occurs in about 40% of patients with Takayasu's arteritis, producing areas of stenosis with renal ischemia or renal infarction. Common clinical features are constitutional symptoms, claudication, bruits, and hypertension. Pulses are often diminished or absent in one or more extremities, and a blood pressure discrepancy more than 10 mm Hg in the limbs is common. The diagnosis of Takayasu's arteritis is most often made on clinical grounds along with typical angiographic or other imaging findings. Corticosteroids are the primary treatment modality.

Polyarteritis nodosa is a medium-sized or small vessel vasculitis with no gender predilection that predominantly occurs in patients between 40 and 60 years of age. It affects the main renal arteries and renal interlobar arteries (less commonly, the arcuate and interlobular arteries) with a necrotizing vasculitis that typically produces microaneurysms of the intrarenal arteries. They can be seen on arteriograms in 40% to 90% of patients with renal involvement. Renal ischemia leads to loss of kidney function and renin-mediated hypertension. Low-grade proteinuria and hematuria may be seen, but the finding of acute glomerulonephritis indicates some other disorder. Renal infarction may occur, and rarely, a renal artery aneurysm may cause renal artery dissection or rupture.

The diagnosis is made on clinical grounds and by arteriography. There are no confirmatory serologic tests; polyarteritis nodosa is not an ANCA-associated vasculitis. Arteriography appears to be superior for diagnosis compared with CT and MRA. Progressive renal disease is not typical but may occur. Treatment with corticosteroids and immunosuppressive drugs is effective in reducing disease severity and mortality.

Kawasaki disease is an arteritis associated with the mucocutaneous lymph node syndrome that affects mostly medium-sized and small arteries, although the aorta may also be involved. It is primarily a self-limited disease of infants and young children. Renal involvement is extremely rare.

Hypertensive Nephrosclerosis

Chronic hypertension in susceptible individuals may lead to development of proteinuria, CKD, and ESRD. Hypertensive nephrosclerosis is cited as a cause of CKD and ESRD in African Americans at a much higher rate than whites, even with similar levels of blood pressure control and despite good control.

The renal manifestations of chronic hypertension include renal arterial and arteriolar intimal thickening and luminal narrowing with medial hypertrophy and fibroblastic intimal thickening of arteries and deposition of hyaline-like material in the walls of arterioles. Glomeruli show global and focal glomerulosclerosis; the former likely results from glomerular ischemia and the latter from increased intracapillary pressure and compensatory hypertrophy and injury in response to nephron loss. Wrinkled glomerular basement membranes due to glomerular ischemia are seen on electron microscopy. Chronic interstitial nephritis with tubular atrophy and interstitial fibrosis also occurs. These histopathologic changes of hypertensive nephrosclerosis are often found on renal biopsy for patients with other disorders, such as diabetes mellitus, atheroembolic disease, and RAS.

The overall risk of hypertensive nephrosclerosis with progressive CKD is low in the general hypertensive population, and most

patients with hypertensive nephrosclerosis have mild hypertension. The risk is greater for those who have had poorly controlled hypertension and for those of African descent, who are at particularly high risk for hypertensive nephrosclerosis. Polymorphisms in the genes that encode for apolipoprotein L1 (*APOL1*) and podocyte nonmuscle myosin heavy chain 9 (*MYH9*) are found more commonly in African Americans compared with European Americans and strongly associate with the risk of hypertensive nephrosclerosis. A diagnosis of hypertensive nephrosclerosis as the cause of otherwise unexplained CKD is much less likely to be made in white patients compared with black patients, particularly in the absence of long-standing, severe hypertension or a history of malignant hypertension.

The diagnosis of hypertensive nephrosclerosis is typically based on a history of long-standing hypertension that precedes development of proteinuria and CKD in the absence of other causes. The urinary sediment is typically bland, with only low-grade proteinuria (<1 g/day). Symmetrical loss of renal cortical thickness is commonly found on renal ultrasound.

Pharmacologic treatment of severe hypertension reduces the risk for progression of CKD to ESRD in many patient populations, providing further evidence for the causative role of hypertension. The optimal blood pressure for patients with hypertensive nephrosclerosis has not been determined. For black patients, this was best addressed by the African American Study of Kidney Disease (AASK) trial, which examined more than 1000 African Americans with long-standing hypertension, slowly progressive CKD, and low-grade proteinuria. Subjects were allocated to treatment with ramipril, metoprolol, or amlodipine to a blood pressure goal of 125/75 mm Hg or 140/90 mm Hg. The mean rate of change in GFR and the rate of other secondary outcomes were similar in the two groups, suggesting that lowering blood pressure to less than 140/90 mmHg does not provide further benefit in slowing CKD progression in black patients with hypertensive nephrosclerosis. However, there was a trend favoring the lower blood pressure goal for patients with higher baseline proteinuria.

Lower blood pressure goals may also be appropriate for patients with other comorbid conditions such as diabetes mellitus. Besides affecting CKD progression, blood pressure control reduces the risk of heart failure and stroke. Most patients with hypertensive nephrosclerosis and CKD require multiple antihypertensive medications to control blood pressure, typically including a thiazide or thiazide-like diuretic (when GFR is well preserved) and a loop diuretic (as the GFR declines to less than 25 to 30 mL/min), along with an ACE inhibitor or ARB, calcium-channel blocker, and β -blocker.

Atheroembolic Disease

Atheroembolic disease is the result of cholesterol embolization from atherosclerotic plaques, most commonly from the aorta and typically dislodged during an invasive arterial procedure such as cardiac catheterization, aortic angiography, cardiac surgery, or surgery on the aorta. Cholesterol emboli may occur spontaneously or may be precipitated by systemic anticoagulation, such as with heparin, or during systemic administration of thrombolytic agents. Because patients must have underlying atherosclerosis, the incidence increases with age,

and atheroembolic disease rarely occurs before 40 years of age.

As the result of systemic embolization from atheromatous plaques, cholesterol crystals lodge in small arterial vessels, including the arcuate or interlobular arteries of the kidneys. Cholesterol emboli frequently involve other organs, and the pattern of organ involvement depends in part on whether disrupted plaque is in the ascending or descending aorta. The extremities are commonly affected with digital ischemia and gangrene, the skin with livedo reticularis, and the gastrointestinal tract with intestinal ischemia, but any organ can be affected. Embolization from the ascending aorta can cause cardiac ischemia, and emboli arising from the ascending aorta or carotid arteries (e.g., after carotid endarterectomy) can cause stroke.

Cholesterol embolization to the eye may be recognized by finding Hollenhorst plaques on fundoscopic examination, which are whitish yellow flecks at retinal arteriole bifurcations. They are often asymptomatic but may cause retinal ischemia with usually transient visual field defects.

Patients with atheroembolic disease may have fever, eosinophilia, eosinophiluria, and hypocomplementemia, particularly acutely. Laboratory findings include an elevated erythrocyte sedimentation rate and elevated levels of amylase or liver enzymes. The widespread systemic clinical and laboratory manifestations of atheroemboli can lead to a clinical picture suggesting systemic vasculitis.

The typical pattern of renal atheroembolic disease is a decline in kidney function that first becomes apparent 3 or more days after an inciting procedure or other event. The degree of acute and chronic kidney injury that follows is determined by the magnitude of the embolic burden, whether atheroembolism is a one-time or ongoing process, and the degree of inflammation induced by the plaque material. Many patients have stabilization of the process after the initial insult, whereas others progress with various patterns and tempos to advanced CKD and ESRD. Cholesterol embolization also may cause severe hypertension due to acute renal ischemia leading to renin release.

Diagnosis of renal atheroembolic disease is usually made clinically in the appropriate setting, but for some patients, a kidney biopsy is needed to confirm the diagnosis and exclude others. Because the fixation process washes out the cholesterol crystals from the renal biopsy sample, the pathologic examination reveals a typical needle-shaped disruption in the arterial lumen surrounded by reactive endovascular cells.

There is no specific treatment for cholesterol emboli. Because an inflammatory reaction typically results from the emboli, some physicians advocate corticosteroids, but their use is unproved for preventing further atheroembolism or progression of kidney failure. Avoidance of anticoagulation has been recommended to prevent dissolution and embolization of thrombus that may overlie an atheromatous plaque. Statin therapy is appropriate for most patients for treatment of their underlying atherosclerotic disease, but it has not been shown to influence the renal manifestation of atheroemboli. Treatment with ACE inhibitors or ARBs may be effective for hypertension control in the acute setting, but worsening kidney function may limit their use. Dialysis may be necessary if AKI and ESRD develop.

Preeclampsia

Preeclampsia is characterized by the new onset of sustained hypertension (blood pressure $\geq 140/90$ mm Hg) and proteinuria (>300 mg/day) that develops after 20 weeks' gestation in a previously normotensive woman. Although hypertension and proteinuria are the principal features of preeclampsia, it is a systemic vascular disease that may also cause central nervous system symptoms (e.g., visual disturbances, headache, altered mental status), abdominal pain, nausea and vomiting, liver dysfunction, thrombocytopenia, pulmonary dysfunction, impaired fetal growth, nephrotic-range proteinuria, and AKI. If grand mal seizures develop without other explanation, a diagnosis of eclampsia is made. The HELLP syndrome, characterized by hemolysis, elevated liver enzymes, and a low platelet count, may be a manifestation of severe preeclampsia, although some consider it to be a separate disorder. It is also associated with increased maternal and fetal mortality.

Preeclampsia should be distinguished from other hypertensive conditions that can occur during pregnancy, including preexisting hypertension that occurs before 20 weeks' gestation and persists after delivery, preeclampsia superimposed on preexisting chronic hypertension, and gestational hypertension (i.e., new-onset hypertension after 20 weeks' gestation without proteinuria or other related manifestations).

Progress has been made in understanding the pathogenesis of preeclampsia, and maternal and placental or fetal factors have been implicated. Abnormal development of placental vasculature in early pregnancy is thought to lead to some degree of placental hypoperfusion that releases antiangiogenic factors into the maternal circulation, disturbing the delicate balance of angiogenic and antiangiogenic factors. This causes systemic endothelial dysfunction in the mother that leads to hypertension, proteinuria, and other manifestations of the disease.

Soluble FMS-related tyrosine kinase 1 (sFLT1) is a placenta-derived circulating antiangiogenic factor that appears to play a central role in the pathogenesis of preeclampsia. It antagonizes the proangiogenic effects of vascular endothelial growth factor (VEGF) and placental growth factor (PGF) by binding to them and preventing interaction with their receptors. Soluble endoglin (sENG), another antiangiogenic factor that is widely expressed on vascular endothelium, is thought to be an important mediator of preeclampsia. Endothelial dysfunction in preeclampsia is associated with increased sensitivity to vasopressor agents, including angiotensin II, systemic vasoconstriction, and reduced fibrinolytic function.

Kidney biopsy findings include glomerular endothelial cell swelling (i.e., endotheliosis) and occlusion of the capillary lumen with ischemia. These findings are also seen with other microangiopathic disorders, although fibrin thrombi in glomerular capillaries are less commonly seen than with other causes. Foot process effacement is not usually seen.

The only effective treatment for preeclampsia is delivery of the fetus and placenta. The timing of delivery must take into account gestational age, severity of preeclampsia, presence or absence of systemic features, and status of the fetus and mother. Proper obstetric care is essential to balance the risk to the mother against the risk for prematurity of the fetus.

Treatment of mild hypertension in women with preeclampsia should be avoided because it does not treat the underlying disease process, alter the course of disease, or reduce clinical sequelae. In the absence of clinical manifestations other than proteinuria, it is usually unnecessary to start antihypertensive medications unless the systolic blood pressure is greater than 150 mm Hg or the diastolic blood pressure is higher than 100 mm Hg. Labetalol and hydralazine, both of which can be given intravenously or orally, are often recommended as first-line therapy for acute management. For chronic treatment, methyldopa or labetalol are often recommended initially, with extended-release nifedipine added if necessary. Diuretics and dietary sodium restriction usually are avoided unless the patient has pulmonary edema.

The risk profile of these medications is poorly defined in pregnancy. ACE inhibitors, ARBs, and direct renin inhibitors are contraindicated during pregnancy because of the risk of fetal abnormalities. Magnesium sulfate is used in severe cases of preeclampsia to reduce the risk of seizures, but it does not treat other manifestations of the disease or reduce maternal or fetal mortality rates.

Most manifestations of preeclampsia begin to improve shortly after delivery, but in some women, hypertension, proteinuria, and other manifestations may persist for several weeks or months before resolving completely. Because preeclampsia is a risk factor for future hypertension, kidney disease, and cardiovascular events, continued medical follow-up is essential.

Scleroderma Renal Crisis

Systemic sclerosis (i.e., scleroderma) is an idiopathic connective tissue disorder associated with deposition of collagen and other extracellular matrix proteins that produces inflammation and fibrosis of the skin and internal organs. Proliferative endovascular lesions may lead to obliteration of the vascular internal lumina and renal ischemia, with hypertension, increased renin activity, and elevated levels of angiotensin II and aldosterone.

AKI and rapidly worsening hypertension in patients with scleroderma is called *scleroderma renal crisis*. It occurs in approximately 5% to 10% of patients with scleroderma, typically within the first few years after onset and primarily in those with systemic rather than localized cutaneous scleroderma who also have progressive skin and cardiac involvement. Subclinical renal involvement occurs much more frequently. Scleroderma renal crisis occasionally develops before the clinical diagnosis of scleroderma has been made.

Scleroderma renal crisis is often associated with rapid and severe loss of kidney function, oliguria, hypertensive encephalopathy, and heart failure. Microangiopathic hemolytic anemia may also occur. About 10% of patients with scleroderma renal crisis do not have hypertension. This occurs more commonly among patients being treated with ACE inhibitors or high-dose corticosteroids.

Anti-RNA polymerase III antibodies are strongly associated with the risk of scleroderma renal crisis and have been suggested as markers for scleroderma renal crisis. Renal biopsy may reveal interlobular artery involvement with intimal thickening, endothelial cell proliferation, and edema with obliteration of the vessel lumen with concentric onion-skinning of the wall of arterioles. Fibrinoid necrosis occurs in afferent arterioles with intravascular

fibrin accumulation extending into the glomeruli, often with ischemic collapse, but without features of glomerulonephritis.

Activation of the renin-angiotensin-aldosterone system appears to play an important role in the progression of the disease. Before the advent of ACE inhibitors and hemodialysis, scleroderma renal crisis was fatal in about 75% of patients at 1 year. ACE inhibitor therapy has reduced this 1-year mortality rate to less than 15%. Captopril is often recommended as the ACE inhibitor of choice due to its short half-life and ease of dose titration. If the diagnosis of scleroderma renal crisis is made before advanced renal failure is established, ACE inhibition may halt or reverse the decline in renal function. Some experts recommend continuing ACE inhibitors even if kidney function declines and temporary dialysis is necessary, citing an increased chance of renal recovery. ACE inhibitors are not useful for prevention of scleroderma renal crisis, and their use in this setting has been associated with a poorer outcome, including greater risk of requiring permanent dialysis if renal crisis occurs. Use of ACE inhibitors rather than ARBs is recommended because of the long track record of success with ACE inhibitors in this disease.

THROMBOTIC THROMBOCYTOPENIC PURPURA AND HEMOLYTIC-UREMIC SYNDROME

Thrombotic thrombocytopenic purpura (TTP) and hemolytic-uremic syndrome (HUS) manifest with microangiopathic hemolytic anemia (MAHA) and organ dysfunction due to microvascular thrombosis, but each syndrome has distinct clinical, pathophysiologic, and epidemiologic features (Table 30-3).

Although many processes cause microvascular endothelial injury (Table 30-4), renal involvement from these disorders affect the vasculature at different levels. Renal involvement by HUS and TTP primarily affects the glomeruli, whereas scleroderma often extends to the interlobular arteries, and malignant hypertension more often affects the afferent arterioles. However, there is significant overlap and similar histologic features among these diseases, making careful clinical evaluation essential for accurate determination of the cause.

Thrombotic Thrombocytopenic Purpura

TTP is characterized by MAHA and thrombocytopenia. Patients may also have fever, AKI, and neurologic impairment. Purpura is only rarely observed, and it is not necessary to make the diagnosis. TTP occurs with a female-to-male ratio of 3:2 and a peak incidence in the third and fourth decades of life. MAHA and thrombocytopenia manifesting similar to TTP may occur in response to some drugs (e.g., ticlopidine, cyclosporine, tacrolimus), after stem cell transplantation, in association with human immunodeficiency virus (HIV) infection, and in patients with malignant hypertension, sepsis, disseminated intravascular coagulation, or advanced cancers.

TTP may be caused by a deficiency or reduced activity of ADAMTS13 (a disintegrin-like and metalloproteinase with thrombospondin-1-like domains). ADAMTS13 is a plasma protease that normally cleaves von Willebrand factor (vWF) and limits the extent of intravascular thrombosis (Fig. 30-4). Microthrombi composed primarily of platelets and vWF accumulate in the vascular bed of multiple organs, leading to a MAHA. Deficiency in ADAMTS13 may be acquired, caused by

TABLE 30-3 DIFFERENTIATION OF SHIGA TOXIN-RELATED HEMOLYTIC-UREMIC SYNDROME FROM THROMBOTIC THROMBOCYTOPENIC PURPURA

FEATURE	SHIGA TOXIN-RELATED HUS	TTP
Epidemiology	Endemic areas (commonly but not exclusively)	Endemic regions not reported
Similar cases in family	If yes, synchronous	If yes, separated in time and space
Recurrences	Rare	Common
Gastrointestinal prodrome	Painful diarrhea, frequently bloody	Nondiarrheal abdominal symptoms predominate, but not as prodrome
von Willebrand factor profile	Increased degradation to smaller multimers	Ultra-large forms (assay not universally available); depletion of large and ultra-large forms in advanced stage
ADAMTS13 expression	Normal or slightly decreased	Deficient (<0.1 U/mL)
Characteristics of intravascular thrombi	Fibrin predominates	von Willebrand factor predominates
Endothelial cell appearance	Swollen	Not swollen
Response to plasma therapy	Not demonstrated	Yes
Diagnosis	Isolation of STEC; antibody response to <i>Escherichia coli</i> O157:H7 LPS antigen	ADAMTS13 activity; inhibitors of ADAMTS13 activity; genetic analysis for mutations of ADAMTS13 gene

Data from Tarr PI, Gordon CA, Chandler WL: Shiga toxin-producing *Escherichia coli* and haemolytic uremic syndrome, *Lancet* 365:1073–1086, 2005.

ADAMTS3, A disintegrin and metalloproteinase with thrombospondin-1-like domains; HUS, hemolytic-uremic syndrome; LPS, lipopolysaccharide; STEC, Shiga-toxigenic *E. coli*; TTP, thrombotic thrombocytopenic purpura.

TABLE 30-4 DISORDERS ASSOCIATED WITH THROMBOTIC MICROANGIOPATHY

CONDITIONS	EXAMPLES
TTP	ADAMTS13 protease deficiency, acquired (autoantibody), genetic
HUS	Shiga toxin-associated (<i>E. coli</i> , others); D+ (typical HUS)
Pregnancy	Complement dysregulation; D- (atypical HUS)
Medications	Preeclampsia, HELLP syndrome Cyclosporine, tacrolimus, VEGF inhibitors, chemotherapeutic agents (e.g., mitomycin C), quinine, cocaine, ticlopidine (with anti-ADAMTS13 antibodies), muromonab-CD3 (OKT3), clopidogrel
Transplantation	Allogeneic bone marrow and stem cell transplants, solid organ
Neoplastic diseases	Metastatic cancers
Prothrombotic disorders	Antiphospholipid antibody syndrome
Infectious diseases	Rocky Mountain spotted fever, anthrax, HIV
Other conditions	Malignant hypertension, SLE, scleroderma renal crisis, radiation therapy, DIC, cardiovascular surgery

Data from Tsai HM: Advances in the pathogenesis, diagnosis, and treatment of thrombotic thrombocytopenic purpura. *J Am Soc Nephrol* 14:1072–1081, 2003.

D+, Positive for diarrhea; D-, negative for diarrhea; DIC, disseminated intravascular coagulation; HIV, human immunodeficiency virus; HELLP, hemolysis, elevated liver enzyme levels, and a low platelet count; HUS, hemolytic uremic syndrome; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura; VEGF, vascular endothelial growth factor.

FIGURE 30-4 Relation between ADAMTS13 activity, excessive adhesion and activation of platelets, and thrombotic thrombocytopenic purpura. **A**, In normal subjects, ADAMTS13 (i.e., von Willebrand factor–cleaving metalloprotease) molecules attach to binding sites on endothelial cell surfaces and cleave unusually large multimers of von Willebrand factor as they are secreted by stimulated endothelial cells. The smaller von Willebrand factor forms that circulate after cleavage do not induce the adhesion and aggregation of platelets during normal blood flow. **B**, Absent or severely reduced activity of ADAMTS13 in patients with thrombotic thrombocytopenic purpura prevents timely cleavage of unusually large multimers of von Willebrand factor as they are secreted by endothelial cells. The uncleaved multimers induce the adhesion and aggregation of platelets in flowing blood. (From Moake JL: Thrombotic microangiopathies, *N Engl J Med* 347:589–600, 2002.)

anti-ADAMTS13 autoantibodies (mostly immunoglobulin G [IgG]), or, much less commonly, genetic.

Other laboratory abnormalities are manifestations of the MAHA and include thrombocytopenia; an elevated LDH concentration, indirect bilirubin concentration, and reticulocyte count; and a low haptoglobin concentration. Coagulation laboratory test results (e.g., prothrombin time, activated partial thromboplastin time, fibrinogen level) are typically normal, although levels of fibrin split products may be elevated. AKI, microscopic hematuria, and low-grade proteinuria are frequently detected.

Without treatment, TTP has a mortality rate of about 90%, with most deaths occurring within 3 months of the onset of symptoms. Treatment with plasma infusion can normalize ADAMTS13 levels, reducing intravascular hemolysis and mortality rates. Plasmapheresis and replacement with fresh-frozen plasma has the advantage of removing inhibitory autoantibodies in addition to normalizing ADAMTS13 levels because of the large volume of plasma that can be infused.

ADAMTS13 activity must be assayed before therapy is initiated to obtain accurate results, but treatment should not be delayed for the results to return. The severity of ADAMTS13 deficiency (<5%) predicts future relapse, although those with severe deficiency are just as likely to respond initially to plasmapheresis as those with a mild deficiency. Patients with MAHA due to other causes not associated with ADAMTS13 deficiency usually do not respond to plasmapheresis or plasma infusion. Patients with HUS do not have abnormalities in ADAMTS13 levels or function.

Hemolytic-Uremic Syndrome

Gastrointestinal tract infection with the Shiga-toxigenic *Escherichia coli* strain O157:H7 produces a diarrheal illness that is complicated in about 15% of cases by a MAHA with intraglomerular thrombosis and AKI, a condition referred to as diarrheal (D+) HUS. *Shigella dysenteriae* serotype 1 or other Shiga toxin-producing strains of *E. coli* may also cause D+ HUS. D+ HUS most commonly affects infants and children, although adults may also be affected. Cases of D+ HUS often cluster because of outbreaks of *E. coli* O157:H7, with peaks occurring in summer and autumn. *E. coli* is endemic in the gastrointestinal tract of cattle, and cases are often tracked to undercooked meat, exposure to bovine fecal matter, animal exposure, or other contaminated food products.

Shiga-toxigenic bacterial strains commonly produce a prodrome of painful, bloody diarrhea, which precedes the development of HUS by 2 to 12 days (median, 3 days). Shiga toxin is directly thrombogenic in the renal vasculature. Although intravascular coagulation in D+ HUS is usually limited to the kidney, the heart, gastrointestinal tract, and central nervous system may also be affected.

Laboratory abnormalities in HUS include elevated creatinine levels, anemia, schistocytes on the peripheral smear, elevated reticulocyte count, and thrombocytopenia. In contrast to disseminated intravascular coagulation, fibrinogen levels are normal or high, and the prothrombin time is normal or only slightly prolonged. Fresh stool should be sent for culture of *E. coli* O157:H7, which can aid in tracing the source of an outbreak.

Stool studies should also be performed for patients without diarrhea because *E. coli* O157:H7 may rarely cause HUS in the absence of intestinal symptoms. If *E. coli* O157:H7 is not detected, culture for other Shiga-toxigenic organisms should be pursued.

The pathologic renal lesions of HUS include vessel wall thickening with endothelial cell swelling and intraglomerular thrombosis with platelet- and fibrin-rich thrombi. Fragmentation of red blood cells may be seen in the renal vasculature and within the vessel wall.

Treatment of D+ HUS is supportive, including adequate volume repletion with isotonic intravenous fluids, transfusion for severe anemia, and avoidance of other nephrotoxic agents (e.g., nonsteroidal anti-inflammatory drugs, aminoglycoside antibiotics, iodinated contrast). Platelet transfusion is not recommended because it may worsen the ongoing microvascular thrombosis. Antibiotic treatment of patients with bloody diarrhea is not recommended because it is not effective in reducing the incidence of HUS and may increase the risk. Corticosteroids, anticoagulation (e.g., aspirin, heparin), thrombolytic agents, and plasma administration have proved ineffective for the treatment of HUS.

With supportive care alone, most patients with D+ HUS recover with normalization of renal function or only mild residual CKD, although about 25% may develop advanced CKD or ESRD over the next 1 to 2 decades of life. Risk for CKD is increased with cortical necrosis and involvement of more than 50% of glomeruli identified on renal biopsy. The risk for complications and death increases with age, with the mortality rate increasing from about 5% to 10% for children to about 30% for adults.

D– HUS (atypical HUS) accounts for about 5% of cases and has a higher likelihood of recurrence, ESRD, or death. Many cases are caused by genetic defects in the complement pathway (e.g., C3, C5, complement H, factor I, CD46). Testing for ADAMTS13 levels, which are normal in D– HUS, can be useful in differentiating atypical HUS from TTP. Specialty laboratories can test for complement cascade abnormalities. Eculizumab is a humanized monoclonal antibody that binds with high affinity to complement protein C5 and prevents the generation of C5a, C5b, and the terminal complement complex C5b-9. In patients with atypical HUS, eculizumab inhibits complement-mediated thrombotic microangiopathy.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

Antiphospholipid antibodies (APAs) refer to autoantibodies such as lupus anticoagulants or IgG or immunoglobulin M (IgM) anticardiolipin antibodies that interfere with phospholipid-binding proteins and in vitro phospholipid-dependent clotting assays such as the partial thromboplastin time. Because not all lupus anticoagulants cause prolongation of the partial thromboplastin time, other tests of the coagulation system, such as the dilute Russell viper venom time, may need to be obtained. The diagnosis of antiphospholipid antibody syndrome (APS) is based on the occurrence of arterial or venous clotting events or fetal loss during pregnancy after 10 or more weeks' gestation in the setting of laboratory detection of an APA. Lupus anticoagulant and anticardiolipin antibodies are detectable in up to 10% of healthy populations, and their presence alone is insufficient

for a diagnosis of APS. Apolipoprotein H (apo H, formerly β_2 -glycoprotein 1) is the main antigenic target of anticardiolipin antibodies.

In the absence of an underlying autoimmune disease, the syndrome is referred to as primary APS. Secondary APS occurs when associated with other diseases such as systemic lupus erythematosus (SLE). APAs are detectable in 30% to 50% of patients with SLE, and renal involvement is often observed in this setting.

The procoagulant effect of APAs may result from interference with the anticoagulant apo H, inhibition of fibrinolysis, direct endothelial injury, accelerated atherosclerosis, and activation of platelet, monocyte, and endothelial cells. Renal involvement occurs in about 25% of patients with primary APS and can occur in patients with SLE or other causes of APS. Thrombosis may occur throughout the renal vasculature, including main or branch renal arteries, arterioles, glomeruli, and veins. These findings resemble those found in other diseases associated with a thrombotic microangiopathy. Focal atrophy of the cortex in association with interstitial fibrosis may be observed due to resulting ischemia.

The RENAL manifestations of APS vary. Some patients have mild proteinuria with preserved kidney function, and others develop severe hypertension, nephrotic-range proteinuria, and AKI or CKD. Renal arterial thrombosis can cause infarction, acute onset of flank pain, hematuria, and decreased kidney function. Renal vein thrombosis may be silent or, if acute and complete, may manifest with sudden flank pain and reduced kidney function. Pathologic changes seen on renal biopsy of patients with primary APS are small vessel vaso-occlusive disease with fibrous intimal hyperplasia of interlobular arteries, recanalizing thrombi in arteries and arterioles, focal cortical atrophy, and thrombotic microangiopathy. Other manifestations of APS include thrombocytopenia, hemolytic anemia, and a prolonged activated partial thromboplastin time in the absence of heparin therapy.

Long-term warfarin anticoagulation with a target international normalized ratio (INR) between 2 and 3 is indicated for patients with primary or secondary APS and prior deep vein thrombosis, arterial thrombosis, or recurrent spontaneous abortion. Because warfarin is contraindicated during pregnancy, heparin with or without low-dose aspirin (81 mg) is necessary until the end of pregnancy.

Treatment of APA-positive patients in the absence of prior clinical events is controversial because of the high false-positive rate for the tests. Aspirin therapy for primary prevention in patients persistently positive for APAs has been advocated but not proved. Plasmapheresis, prednisone, and hydroxychloroquine have been advocated for the treatment of thrombotic microangiopathy due to APS and should be considered in severe cases.

RENAL VEIN THROMBOSIS

Renal vein thrombosis (RVT) is uncommon, occurring mostly in association with malignancy, but it also is a consequence of nephrotic syndrome, abdominal surgery or trauma, pancreatitis, and genetic or acquired hypercoagulable states. Most malignancy-associated RVT is caused by renal cell carcinoma with venous

invasion, often with spreading to the contralateral kidney, which may cause bilateral renal vein occlusion.

The nephrotic syndrome is associated with a risk for venous thrombosis throughout the circulation, including RVT. The RVT risk in patients with nephrotic syndrome correlates with severity of proteinuria and hypoalbuminemia; patients with a serum albumin concentration of less than 2 g/dL are at particular risk. Some studies have documented an incidence of RVT as high as 30% among patients with nephrotic syndrome, but most cases are not clinically apparent. Patients with membranous nephropathy seem to be at greatest risk for RVT for reasons that are not known, but RVT can also occur with focal segmental glomerular sclerosis, membranoproliferative glomerulonephritis, minimal change disease, and diabetic kidney disease. Hypercoagulability is thought to result from loss of the antithrombotic protein antithrombin III in urine, although other factors such as increased procoagulant factors and platelet activation may also be involved.

RVT may manifest with symptoms attributable to renal cell carcinoma, such as flank pain, gross hematuria, nausea, anorexia, or lower extremity swelling. In male patients, left renal vein occlusion may cause a left varicocele, a result of the venous drainage of the left gonadal vein. In patients without a malignancy, symptoms of RVT depend on the acuity of the thrombosis. Acute, complete thrombosis may manifest with hematuria, flank pain, abdominal distention, and acute renal failure. RVT in adults usually occurs gradually because of collateral venous drainage return; in this setting, symptoms of AKI are uncommon, although proteinuria and creatinine levels may be mildly elevated/

Because patients often do not have symptoms, RVT is likely more common than reported in the literature. Some have suggested CT screening of asymptomatic, high-risk patients, particularly those with membranous nephropathy and severe proteinuria and hypoalbuminemia.

The standard method for diagnosis is renal venography, but because it has a risk of clot dislodgment, bleeding, and iodinated contrast, less invasive methods are commonly used. Contrast-enhanced CT venography appears to have a relatively high sensitivity and specificity, although it carries some risk for contrast nephropathy. MRI using gadolinium-based contrast or time-of-flight sequencing without contrast may also be useful. Renal Doppler ultrasound is useful, but it is operator dependent and has lower sensitivity than CT venography.

Treatment with systemic anticoagulation is recommended in the absence of contraindications. Most clinicians maintain anticoagulation for 6 to 9 months, similar to the approach for non-renal deep vein thrombosis and pulmonary embolism. The long-term recurrence risk is low if the underlying predisposition is successfully treated, and patients are unlikely to require indefinite anticoagulation. Direct intravenous thrombolysis or operative thrombectomy may be considered in severe cases, particularly if the RVT is a source of pulmonary emboli or is causing AKI. Prophylactic anticoagulation in high-risk patients, such as those with severe membranous nephropathy (serum albumin concentration <2.5 g/dL) should be considered for appropriate candidates.

 For a deeper discussion on this topic, please see Chapter 125, "Vascular Disorders of the Kidney," in Goldman-Cecil Medicine, 25th Edition.

Acute Kidney Injury

Mark A. Perazella and Jeffrey M. Turner

DEFINITION

Acute kidney injury (AKI) is a syndrome defined as an abrupt decrease in glomerular filtration rate (GFR) sufficient to promote the retention of nitrogenous waste products (blood urea nitrogen [BUN] and creatinine); disturb the regulation of extracellular fluid volume, electrolyte balance, and acid-base homeostasis; and impair drug excretion. Importantly, even mild abnormalities in kidney structure and function are associated with other end-organ complications and increased mortality.

AKI includes a spectrum of clinical conditions. The numerous causes of AKI vary based on individual comorbidities (and risk for AKI) and whether kidney injury develops in the outpatient setting or in hospital. The incidence of AKI is rising, and its complications include progression to more severe kidney failure, need for renal replacement therapy (RRT), chronic kidney disease (CKD), and death. Several consensus groups have produced definitions and diagnostic criteria for AKI. [Table 31-1](#) describes the diagnostic criteria for the Risk, Injury, Failure, Loss, and End-stage renal disease (ESRD) (RIFLE); Acute Kidney Injury Network (AKIN); and Kidney Disease: Improving Global Outcomes (KDIGO) classifications.

In 2004, the RIFLE classification was put forth to standardize the definition of AKI. Changes in serum creatinine concentration (over 7 days), reductions in estimated glomerular filtration rate (eGFR), and urine output parameters were used in this diagnostic system. The Risk (R), Injury (I), and Failure (F) categories were applicable to AKI, whereas the Loss (L) and ESRD (E) categories were CKD stages. In 2007, the AKIN group modified the RIFLE criteria definition of AKI by adding an absolute increase in serum creatinine of only 0.3 mg/dL, eliminating the eGFR criteria, and changing the time frame for AKI to develop (to 48 hours, compared with the 7 days for RIFLE diagnosis). Focusing on AKI, the AKIN criteria replaced the R, I, and F categories from the RIFLE criteria with stages 1, 2, and 3 and eliminated the L and E categories. In 2012, the KDIGO group combined parts of the RIFLE and AKIN criteria to capture AKI with increased sensitivity.

Understanding of the pathophysiology underlying development of AKI has advanced, and better diagnostic tools have moved the field forward. However, specific directed therapies remain limited for the most common forms of AKI. Although technical advances in RRT and supportive care have improved, patients commonly develop other end-organ disease in the setting of AKI. More concerning is the relatively high mortality rate associated with AKI, particularly when it develops in the hospital setting and requires RRT. [E-Table 31-1](#) shows some of the clinically important outcomes associated with AKI.

ETIOLOGY

In most cases, more than one process contributes to AKI, but for ease of classification, three broad categories ([Fig 31-1](#)) are used: (1) *prerenal AKI*, the result of a decrease in renal blood flow and perfusion of the kidney; (2) *intrinsic AKI*, the result of disease affecting one of the renal parenchymal compartments; and (3) *postrenal AKI*, the result of obstruction to urinary flow anywhere along the urinary tract starting from the renal calyces/pelves and involving the ureters, bladder, or urethra.

The most common form of AKI is due to prerenal physiology, particularly in the outpatient setting, but also in the hospital. Postrenal AKI is more common in elderly men with prostatic

TABLE 31-1 CLASSIFICATION OF ACUTE KIDNEY INJURY

STAGE	SERUM CREATININE INCREASE WITHIN 7 DAYS		URINE OUTPUT
	URINE OUTPUT		
KIDNEY DISEASE: IMPROVING GLOBAL OUTCOMES (KDIGO) CLASSIFICATION (2012)			
1	1.5-1.9 times baseline <i>or</i> ≥ 0.3 mg/dL within 48 hr	<0.5 mL/kg/hr \times 6-12 hr	
2	2-2.9 times baseline	<0.5 mL/kg/hr \times ≥ 12 hr	
3	3 times baseline <i>or</i> an increase in the serum creatinine to ≥ 4 mg/dL with an absolute increase ≥ 0.3 mg/dL within 48 hr <i>or</i> 1.5 times baseline within 7 days <i>or</i> initiation of RRT <i>or</i> in patients aged <18 yr, eGFR decreased to <35 mL/min/1.73 m ²	<0.3 mL/kg/hr \times ≥ 24 hr	
ACUTE KIDNEY INJURY NETWORK (AKIN) CLASSIFICATION (2007)			
1	1.5-1.9 times baseline <i>or</i> ≥ 0.3 mg/dL within 48 hr	<0.5 mL/kg/hr \times 6-12 hr	
2	2-2.9 times baseline	<0.5 mL/kg/hr \times ≥ 12 hr	
3	3 times baseline <i>or</i> increase in serum creatinine ≥ 4 mg/dL with an increase ≥ 0.5 mg/dL <i>or</i> initiation of RRT	<0.3 mL/kg/hr \times ≥ 24 hr <i>or</i> anuria ≥ 12 hr	
RIFLE CLASSIFICATION (2004)			
Risk	1.5-1.9 times baseline <i>or</i> GFR decrease $>25\%$	<0.5 mL/kg/hr \times 6 hr	
Injury	2-2.9 times baseline <i>or</i> GFR decrease $>50\%$	<0.5 mL/kg/hr \times 12 hr	
Failure	3 times baseline <i>or</i> GFR decrease $>75\%$ <i>or</i> serum creatinine ≥ 4 mg/dL with an increase ≥ 0.5 mg/dL	<0.3 mL/kg/hr \times 24 hr <i>or</i> anuria \times 12 hr	
Loss	Complete loss of renal function for >4 wk		
ESRD	End-stage renal disease >3 mo		

eGFR, Estimated glomerular filtration rate; GFR, glomerular filtration rate; RRT, renal replacement therapy.

E-TABLE 31-1 CLINICAL IMPORTANCE OF ACUTE KIDNEY INJURY

Elevations in serum creatinine as minimal as 0.3 mg/dL are associated with increased in-hospital mortality.

Hospitalized patients with AKI have up to a 30% higher risk for mortality.

Patients in the ICU with AKI who require RRT have up to a 60% higher risk for mortality.

Patients who develop AKI and recover have an increased risk for subsequently developing CKD and ESRD.

AKI has been associated with an increased risk for cardiovascular events.

Hospitalized patients with AKI are likely to have longer lengths of stay with higher costs.

AKI, Acute kidney injury; CKD, chronic kidney disease; ESRD, end-stage renal disease; ICU, intensive care unit; RRT, renal replacement therapy.

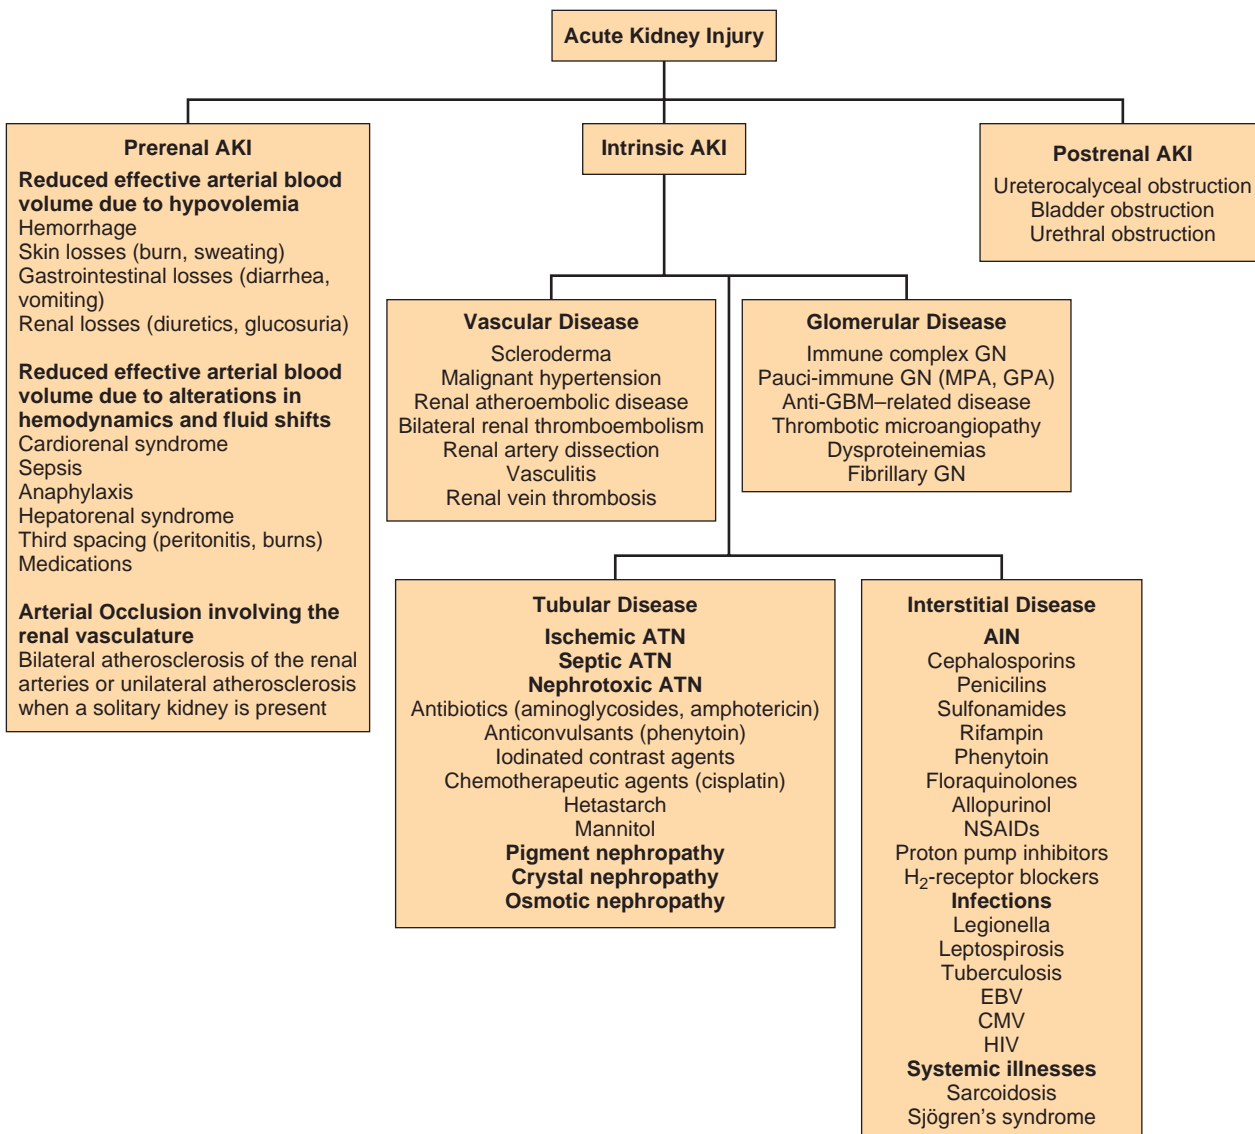

FIGURE 31-1 Common causes of acute kidney injury (AKI). AIN, Acute interstitial nephritis; ATN, acute tubular necrosis; CMV, cytomegalovirus; EBV, Epstein-Barr virus; GBM, glomerular basement membrane; GN, glomerulonephritis; GPA, granulomatosis with polyangiitis; H₂, histamine 2; HIV, human immunodeficiency virus; HUS, hemolytic uremic syndrome; MPA, microscopic polyangiitis; NSAIDs, nonsteroidal anti-inflammatory drugs; TTP, thrombotic thrombocytopenic purpura.

hyperplasia, patients with bladder dysfunction and certain malignancies. Intrinsic AKI may be due to a vascular process, glomerular disease, interstitial disease, or tubular injury. The most common intrinsic AKI is an entity known as *acute tubular necrosis* (ATN), or more recently *acute tubular injury* (ATI), which is histologically more accurate. This is a clinical syndrome characterized by an abrupt and sustained decline in GFR due to an acute ischemic injury, nephrotoxic insult, or a combination of both. The clinical recognition of ATN is based primarily on exclusion of prerenal and postrenal causes of AKI, as well as other causes of intrinsic AKI (glomerulonephritis [GN], acute interstitial nephritis [AIN], and vasculitis). Once other intrinsic causes of AKI are excluded, it is reasonable to conclude ATN is the cause or major contributor to AKI. Although the name *acute tubular necrosis* is not an entirely valid histologic description of the lesion,

the term will be utilized as it is part of the language of clinical medicine.

EPIDEMIOLOGY

AKI occurs more commonly in hospitalized patients as compared to the community setting. Community-acquired AKI defined by various step-wise increases in serum creatinine has an incidence of approximately 1%. Nearly half of the patients involve AKI superimposed on CKD. Prerenal AKI accounts for ~70% of cases, obstructive uropathy ~17%, and intrinsic AKI from various etiologies ~11% of the AKI cases. In contrast, hospital-acquired AKI has an incidence ranging from 4.9% to 7.2%. The incidence of AKI is higher in intensive care unit (ICU) admissions approximating 30%. CKD; older age and other co-morbidities are important risk factors for AKI. Prerenal AKI remains the most common

cause, followed by intrinsic AKI from nephrotoxic medications and ischemic ATN.

DIAGNOSTIC EVALUATION

History and Physical Examination

Evaluation of the patient with AKI should be methodical and systematic to ensure that potentially reversible causes are diagnosed and treated expeditiously to preserve kidney function and limit development of permanent kidney injury, as depicted in [Table 31-2](#). Part of the difficulty in arriving at a correct diagnosis is that several potential causes of AKI often coexist. Emphasis is placed on thorough analysis of available data and examination of the sequence of deterioration in kidney function and urine volume in relation to the chronologies of the potential causes of AKI.

Knowledge of the natural history of the various causes of AKI also is critical. The evaluation should include a thorough patient history and chart review to identify risk factors for prerenal AKI (e.g., vomiting, diuretics, diarrhea, heart failure, cirrhosis); potential nephrotoxic drugs (prescribed or over-the-counter); risk factors for prostate disease, cervical cancer, or bladder cancer; and symptoms of urinary tract obstruction (e.g., prostatism, overflow incontinence, anuria). Some of the important chart review data are presented in [E-Table 31-2](#). The urine volume is less than 400 mL/day with oliguric AKI, less than 100 mL/day with oligoanuric AKI, and less than 50 mL/day with anuric AKI. Normal urine output does not exclude the diagnosis of AKI: Nonoliguric AKI (>400 mL/day) can be associated with nephrotoxic AKI and partial urinary obstruction. Wide variation in daily urine output also suggests AKI due to partial urinary tract obstruction. Anuria has a limited differential diagnosis, suggesting complete urinary obstruction, a vascular catastrophe, or severe cortical necrosis.

The physical examination should focus on volume status to allow initial classification into one of the broad categories of AKI. Reduced body weight, hypotension, an orthostatic fall in blood pressure (BP), or flat neck veins may be present in patients with prerenal AKI (ischemic AKI) caused by true volume depletion. The presence of edema, pulmonary rales, or an S_3 gallop signals effective volume depletion due to cardiac dysfunction, whereas edema, ascites, and asterixis suggest liver dysfunction

TABLE 31-2 DIAGNOSTIC APPROACH TO THE PATIENT WITH ACUTE KIDNEY INJURY

1. Record review (see [E-Table 31-2](#)); special attention to evidence of recent reduction in glomerular filtration rate and sequence of events leading to deterioration of kidney function to determine possible causative factors
2. Physical examination, including evaluation of hemodynamic status
3. Urinalysis and urine microscopy with thorough sediment examination
4. Determination of urinary indices, including fractional excretion of sodium and urine output
5. Catheterization and measurement of postvoid residual urine volume if outlet obstruction is suspected
6. Fluid challenge in cases of suspected prerenal AKI
7. Radiologic studies, particular as dictated by the clinical setting (e.g., ultrasonography to look for obstruction)
8. Kidney biopsy

AKI, Acute kidney injury.

or cirrhosis. If the intravascular volume status is uncertain, measurement of cardiac filling pressures with an indwelling catheter may be useful, but this technique is not commonly used. More often, central venous pressure is measured. Although central venous pressure measurement has limitations, even in monitoring of trends and response to fluid administration or removal, it remains an important tool to guide fluid management. New, noninvasive monitoring tools that more accurately measure volume status are under investigation.

Evidence of systemic disease also should be sought. Findings may include signs of pulmonary hemorrhage indicative of a vasculitis or Goodpasture's disease, skin rash as a manifestation of systemic lupus erythematosus, atheroemboli, vasculitis, cryoglobulins, or AIN, as well as joint disease making lupus or rheumatoid arthritis a consideration.

Basic Laboratory Tests

Laboratory tests are directed by the differential diagnosis that is postulated after a complete history, chart review, and physical examination have been performed. Basic tests include a complete blood count to assess for anemia (microangiopathic or immune-mediated) and thrombocytopenia (thrombotic thrombocytopenic purpura [TTP], hemolytic-uremic syndrome [HUS], and disseminated intravascular coagulation [DIC]). Other tests to evaluate the cause of AKI include various serologic measurements (antinuclear antibody [ANA], antineutrophil cytoplasmic antibodies [ANCA], anti-glomerular basement membrane antibody [anti-GBM], anti-double-stranded DNA antibodies [anti-dsDNA], and hepatitis B and C viral serologies), complement levels, cryoglobulin levels, blood cultures, serum lactate dehydrogenase (LDH) and haptoglobin measurements, serum and urine immunoelectrophoresis, and serum free light chain assay.

Urinalysis and Urine Microscopy

Urinalysis is a key component of the diagnostic evaluation of AKI, as summarized in [Table 31-3](#). It is important to evaluate urine specific gravity (SG), as well as the presence of blood (or heme), protein, or leukocyte esterase.

A very high urine SG typically suggests prerenal AKI, whereas isosthenuria (SG = 1.010) indicates intrinsic AKI (e.g., ATN). A thorough microscopic examination of the spun urine sediment, with quantification of the urinary elements, adds essential information to the case. Bland urine with no blood or protein and few to no cells or casts favors a diagnosis of prerenal AKI. Vascular causes of AKI have a variable urine tonicity and sometimes hematuria (isomorphic or dysmorphic red blood cells [RBCs]) and granular casts. GN exhibits variable urine tonicity, positive blood and protein on the dipstick, RBCs, and RBC casts. ATN shows isotonic urine with variable protein and variable heme on urine dipstick (heme is positive with rhabdomyolysis and hemolysis), Renal tubular epithelial cells (RTECs), RTEC casts, and fine or coarse pigmented granular casts (sometime muddy brown [E-Fig. 31-1](#)) may be present on the sediment examination.

Urine in patients with postrenal AKI is typically isotonic and bland unless there is associated infection (pyuria), nephrolithiasis (hematuria), or concomitant ATN (RTECs, RTEC casts, granular casts).

E-TABLE 31-2 RECORD REVIEW IN A HOSPITALIZED PATIENT WHO DEVELOPS ACUTE KIDNEY INJURY

FINDING	COMMENTS
Prior kidney function	Determination of whether the azotemia is acute; patients with prior kidney disease are particularly susceptible to AKI due to use of contrast dyes
Presence of infection	Sepsis is a possible cause of AKI, even in the absence of hypotension
Nephrotoxic agents	Aminoglycosides (e.g., gentamicin) are an important cause of ATN in hospitalized patients, typically nonoliguric ATN during first 2 wk of therapy; antibiotics are a possible cause of AIN; cytotoxic drugs (e.g., cisplatin) are a possible cause of AKI
Contrast studies including oral cholecystography, IVP, angiography	Important cause of ATN in hospitalized patients; typically causes oliguric ATN within 24-48 hr after study
Episodes of hypotension	Suggestion of prerenal AKI or ischemic ATN
History of blood transfusions	Incompatible blood transfusion is an unusual cause of ATN
History of loss or sequestration of extracellular fluid volume, intake and output, serial weights	Important clues to the possibility of prerenal AKI
Type of surgery	Patients with prior cardiac or vascular surgery or with obstructive jaundice are particularly susceptible to ATN
Type of anesthesia	Methoxyflurane and the related, less toxic enflurane are causes of nonoliguric ATN
Amount of blood loss during surgery and whether associated with hypotension	Suggestion of prerenal AKI or ischemic ATN

AIN, Acute interstitial nephritis; AKI, acute kidney injury; ATN, acute tubular necrosis; IVP, intravenous pyelography.

E-FIGURE 31-1 The presence of muddy brown casts in the urine sediment of a patient with acute kidney injury often points to acute tubular necrosis or apoptosis from ischemic or nephrotoxic tubular injury.

TABLE 31-3 URINALYSIS AND MICROSCOPIC EXAMINATION OF THE URINE SEDIMENT

TEST	PRERENAL	VASCULITIS	GN	ATN	AIN	POSTRENAL
Specific gravity	High	Normal/high	Normal/high	Isosmotic	Isosmotic	Isosmotic
Dipstick blood	Negative	Positive	Positive	±	±	Negative
Dipstick protein	Negative	Positive	Positive	Negative	±	Negative
Urine sediment examination	Negative, hyaline casts	RBC casts, dysmorphic RBCs	RBC casts, dysmorphic RBCs	Granular casts, RTECs	WBC casts, eosinophils	Negative, sometimes WBCs/RBCs

AIN, Acute interstitial nephritis; ATN, acute tubular necrosis; GN, glomerulonephritis; RBCs, red blood cells; RTECs, renal tubular epithelial cells; WBCs, white blood cells.

With certain processes, crystals may be indicative of the underlying cause of AKI. For example, calcium oxalate crystals may suggest enteric hyperoxaluria or ethylene glycol intoxication, uric acid crystals may point to acute urate nephropathy, and various other crystals may indicate a drug-induced form of AKI.

Urinary Indices

Spot urine chemistry testing (sodium, creatinine, and urea), along with plasma samples (sodium, creatinine, and BUN), has been used to evaluate renal tubular function in the setting of AKI, primarily to distinguish prerenal AKI from ATN. These measures allow the clinician to calculate fractional excretion of sodium (FE_{Na}) and fractional excretion of urea (FE_{Urea}); they are thought to be more accurate indicators than urine sodium concentration, which is less than 10 to 20 mEq/L with prerenal AKI and greater than 20 mEq/L with ATN.

The ratio of the clearance of sodium (Na) to that of creatinine (Cr) is calculated as a percentage:

$$FE_{Na} = (U_{Na}/P_{Na}) \times (P_{Cr}/U_{Cr}) \times 100$$

where U and P are the concentrations in urine and plasma, respectively. Likewise, the ratio of urea clearance to creatinine clearance is

$$FE_{Urea} = (U_{Urea}/P_{Urea}) \times (P_{Cr}/U_{Cr}) \times 100$$

The rationale for the use of these indices is that the ratio of urine to plasma creatinine concentrations (U_{Cr}/P_{Cr}) provides an index of the fraction of filtered water excreted. Assuming that all of the creatinine filtered at the glomerulus is excreted into the urine, any increment in the concentration of creatinine in urine over that in plasma must result from the removal of water.

In prerenal AKI, because the increased stimulus for salt and water retention, U_{Cr}/P_{Cr} typically is considerably greater than it is in ATN; moreover, FE_{Na} is <1%, and urine sodium concentrations are characteristically low. In contrast, in AKI due to ATN, the nephrons excrete a large fraction of their filtered sodium and water, resulting in a lower U_{Cr}/P_{Cr} , higher urine sodium concentrations, and a higher FE_{Na} (E-Table 31-3). An important clinical exception to this finding is that FE_{Na} can be high (>1 to 2%) with prerenal AKI in the setting of diuretic therapy. To counter this effect, calculation of FE_{Urea} has been used: An FE_{Urea} greater than 35% favors a diagnosis of prerenal AKI, and an FE_{Urea} greater than 50% favors ATN.

Interpretations of these tests, therefore, must be made in conjunction with other assessments of the patient, because clinically important exceptions to these generalizations exist. As an example, prerenal AKI can manifest with an elevated FE_{Na} or

FE_{Urea} in the setting of glycosuria, metabolic alkalosis, bicarbonaturia, salt-wasting disorders, or CKD. Similarly, ATN with low FE_{Na} and FE_{Urea} occurs with pigmenturia, sepsis, radiocontrast injury, severe heart or liver failure, and nonoliguric ATN.

Renal Imaging

If either prerenal AKI or ATN is the likely cause of AKI, and if the clinical setting does not require the exclusion of another cause, then no further diagnostic evaluation is required. Further assessment may be necessary if the diagnosis is uncertain, especially if the clinical setting suggests other possibilities (e.g., obstruction, vascular accident); if clinical findings make the diagnosis of prerenal AKI or ATN unlikely; or if oliguria persists without a good reason. When indicated, diagnostic renal imaging is important in the evaluation of AKI. Retroperitoneal ultrasonography of the kidneys, ureters, and bladder is the first test used because it is readily available, noninvasive, free of radiation exposure, and fairly accurate.

Ultrasonography provides information about kidney size (large, normal, or small) and the parenchyma (normal or increased echogenicity), the status of the pelvis and urinary collecting system (normal or hydronephrotic), and the presence of structural abnormalities (e.g., stones, masses, enlarged lymph nodes). In the setting of AKI, this test can rapidly confirm or exclude the presence of hydronephrosis (E-Fig. 31-2) and a diagnosis of obstructive uropathy. Interrogation of the renal arteries by Doppler ultrasonography provides important information about renal blood flow and renal artery stenosis; however, this test is highly operator dependent.

Computed tomography (CT) of the retroperitoneum provides important information about the cause of postrenal AKI (e.g., tumor, stones, retroperitoneal fibrosis) when ultrasound findings are negative or inconclusive. CT angiography can also accurately diagnose renal artery disease and renal infarction, but there is a risk of nephrotoxicity in those patients with underlying acute or chronic kidney disease. Magnetic resonance (MR) imaging does not add much to CT scanning except in the diagnosis of retroperitoneal fibrosis. Gadolinium MR angiography can safely provide important information about renal artery stenosis or thrombosis, but it should be avoided in patients with AKI or stage 4 or greater CKD. Nephrogenic systemic fibrosis can develop in these patients, especially with nonionic or linear gadolinium contrast agents and in the setting of inflammation.

Radionuclide tests are used to assess the presence or absence of renal blood flow, differences in flow to the two kidneys, and excretory (secretory) function. However, these studies have limited utility in AKI and have reduced accuracy in quantitating absolute rates of flow.

E-TABLE 31-3 URINE CHEMISTRY VALUES

LABORATORY TEST	PRERENAL AKI	ATN
Specific gravity	>1.020	<1.010
Urine osmolality (mOsm/kg)	>500	<400
Urine Na ⁺ (mEq/L)	<20	>20
FE _{Na} (%)	<1	>2
FE _{Urea} (%)	<35	>50

AKI, Acute kidney injury; ATN, acute tubular necrosis; FE_{Urea}, fractional excretion of urea; FE_{Na}, fractional excretion of sodium; Na⁺, sodium ion concentration; U, urine.

E-FIGURE 31-2 Hydronephrosis. Dilatation of the urinary pelvis and calyces is a fairly sensitive and specific finding for obstruction as the cause of acute kidney injury.

Kidney Biopsy

When prerenal AKI, ATN, and obstructive uropathy are unlikely, percutaneous kidney biopsy is sometimes required to determine the cause of AKI and to direct appropriate therapy. Reasonable criteria to support use of kidney biopsy include absence of an obvious cause of AKI such as hypotension or nephrotoxin exposure and prolonged oliguria, usually for more than 2 to 3 weeks. Other potential indications include evaluation for myeloma-related kidney disease in an elderly patient with unexplained AKI; extrarenal manifestations of systemic diseases such as systemic lupus erythematosus, rheumatoid arthritis, or vasculitis; and determination of whether AIN is present in patients receiving a potential culprit drug.

Kidney tissue should be thoroughly examined with the use of light microscopy, immunofluorescence staining, and electron microscopy to facilitate an accurate diagnosis. This ensures a diagnosis of the cause of AKI in most patients. However, kidney biopsy should be employed judiciously to avoid complications such as traumatic renal arteriovenous malformation, severe bleeding requiring transfusion or embolization, other organ injury (liver, spleen, bowel), and nephrectomy for intractable bleeding.

Future Tests for AKI

The limitations of currently available tests to estimate GFR and kidney injury have led to proteomics-based studies to identify novel biomarkers of AKI. The hope is that novel biomarkers will improve the diagnosis and prognosis of AKI. For example, early AKI diagnosis would permit implementation of appropriate preventive strategies and treatment regimens to abrogate permanent loss of kidney function. In patients who develop AKI, biomarker concentrations demonstrate changes earlier than serum creatinine concentrations and appear to distinguish between prerenal AKI, ATN, and other glomerular disorders, which may allow directed interventions and avoidance of potentially harmful therapies. One such example is aggressive intravenous fluid therapy in patients with ATN, which risks volume overload and other end-organ consequences. Finally, biomarkers may allow clinicians to better predict outcomes such as worsening kidney function, RRT requirement, and mortality in patients with hospital-acquired AKI.

CLINICAL PRESENTATION, DIFFERENTIAL DIAGNOSIS, AND MANAGEMENT OF AKI

Prerenal AKI

Prerenal AKI is primarily the result of inadequate blood flow to the kidneys. Renal blood flow approximates more than 1 L/minute, which is necessary to maintain GFR, preserve oxygen delivery, and sustain ion transport and other energy-requiring processes. Therefore, normal kidney function depends on adequate perfusion; a significant reduction in renal perfusion diminishes filtration pressure and lowers GFR.

Volume Depletion

Both “true” and “effective” hypovolemia activate several neurohormonal vasoconstrictor systems as mechanisms to

protect circulatory stability. The substances released include catecholamines from the sympathetic nervous system, endothelin from the vasculature, angiotensin II from the renin-angiotensin system (RAS), and vasopressin. They raise BP through arterial and venous constriction but also can constrict afferent arterioles and reduce GFR, especially when systemic BP is inadequate to maintain renal perfusion pressure.

Structural lesions in the renal arterial and arteriolar tree can also reduce perfusion and promote prerenal AKI. Kidney adaptive responses are stimulated to counterbalance diminished renal perfusion in these circumstances. These adaptive processes include the myogenic reflex, which is activated by low distending pressures sensed in the renal baroreceptors and causes afferent arteriolar vasodilatation. Prostaglandins (e.g., PGE₂, PGI₂), nitric oxide, and products from the kallikrein-kinin system modify the effects of these vasoconstrictors on the afferent arteriole. Importantly, disturbance of the balance between afferent vasodilatation and efferent vasoconstriction can disrupt intrarenal hemodynamics and precipitate AKI.

Medications

The balance of vasoconstricting and vasodilating processes may be altered by medications such as nonsteroidal anti-inflammatory drugs (NSAIDs) and selective cyclooxygenase 2 (COX2) inhibitors. These drugs act to cause prerenal AKI through inhibition of vasodilatory prostaglandins in patients who require prostaglandin effects to maintain renal perfusion. Despite its vasoconstrictor properties, angiotensin II acutely preserves glomerular filtration pressure and GFR in states of reduced renal perfusion by constricting the efferent arteriole more than the afferent arteriole. This salutary effect in part explains the GFR reduction that occurs when a patient who is dependent on angiotensin II to constrict the efferent arteriole is treated with an ACE inhibitor or an angiotensin II receptor blocker (ARB).

Cardiorenal Syndrome

The cardiorenal syndrome (CRS) is an umbrella term that encompasses a number of coexistent cardiac or kidney derangements. Although there are five subtypes of CRS, hospital-acquired AKI due to CRS is most often of the type 1 variety. Reduced cardiac output, arterial underfilling, elevated atrial pressures, and venous congestion, independently or in combination, can impair the renal circulation and reduce GFR, thereby causing a form of prerenal AKI. These processes stimulate neurohumoral adaptations such as activation of the sympathetic nervous system and RAS and increases in vasopressin and endothelin-1, in an attempt to preserve perfusion to vital organs. However, these adaptations enhance salt and water retention and systemic vasoconstriction, which ultimately promote or exacerbate prerenal AKI by two mechanisms: (1) They increase cardiac afterload and further reduce cardiac output and renal perfusion, and (2) they increase central venous pressure, renal venous pressure, and/or intra-abdominal pressure, ultimately lowering GFR.

AKI in patients with heart failure is often caused by CRS type 1, but certainly these patients can also suffer true prerenal AKI from overzealous diuresis or from ischemic or nephrotoxic ATN. Prerenal AKI from true volume depletion is responsive

to judicious administration of intravenous fluids and diuretic withdrawal, making it easy to recognize. It is sometimes more difficult to distinguish CRS type 1 from ATN, because the processes often coexist.

Identification of AKI in the setting of heart failure is clinically relevant because reduced GFR is generally associated with a worse prognosis. Therapy is directed at improving cardiac function, especially in patients with low cardiac output, and relieving pulmonary and renal congestion. Loop diuretics are part of the central treatment strategy for relieving venous congestion; however, these agents can directly stimulate maladaptive neurohormonal responses, transiently worsening kidney function after their introduction. Patients with congestive heart failure often have some degree of diuretic resistance. Strategies to overcome this resistance include combination therapy with thiazide diuretics and sometimes device-driven ultrafiltration. With advanced AKI, RRT is required to treat uremia, metabolic complications, and volume overload. Therapies for end-stage cardiac failure include cardiac transplantation and placement of a left ventricular assist device for long-term destination therapy or as a bridge to transplantation.

Hepatorenal Syndrome

A strong physiologic interplay also occurs between liver disease and kidney impairment. Patients with advanced, decompensated cirrhosis or fulminant acute hepatic failure develop a unique form of prerenal AKI called hepatorenal syndrome (HRS). The International Ascites Club diagnostic criteria for HRS include (1) the presence of cirrhosis and ascites, (2) serum creatinine levels higher than 1.5 mg/dL, (3) no improvement in kidney function after at least 48 hours of diuretic withdrawal and volume expansion with albumin, (4) absence of shock, (5) no nephrotoxic drug exposure, and (6) absence of parenchymal kidney disease. There are two subtypes of HRS based on rapidity and severity of kidney impairment. Type 1 HRS is characterized by rapidly progressive renal failure, defined by doubling of the initial serum creatinine concentration (to >2.5 mg/dL in <2 weeks). Type 2 HRS is characterized by moderate kidney failure (serum creatinine increase from 1.5 to 2.5 mg/dL). The hallmark of HRS is profound renal vasoconstriction in the setting of systemic and splanchnic arterial vasodilatation. The hemodynamic changes that occur in HRS are summarized in

E-Figure 31-3.

There is no test that is specific for the diagnosis of HRS, and diagnosis requires exclusion of other causes of AKI. The main differential diagnoses of type 1 HRS are prerenal AKI and ATN, which have an acute onset with progressive deterioration of kidney function. Recognition of prerenal AKI is typically easier, because it responds to intravenous fluids (albumin and saline), whereas HRS type 1 and ATN are more difficult to differentiate. Distinguishing ATN from HRS is crucial, because therapies for these two forms of AKI are very different, as are their prognoses and outcomes. For HRS, midodrine and octreotide, vasopressin (or its analogue terlipressin outside of the United States), or norepinephrine is used, whereas ATN requires primarily supportive therapy with initiation of RRT if necessary. Liver (or combined liver-kidney) transplantation is the definitive therapy for HRS.

Intrinsic AKI

Intrinsic AKI reflects kidney injury that arises from a process that damages one of the compartments of the renal parenchyma. To simplify the approach, kidney disease is organized into anatomic sites of injury in the vasculature, glomerulus, tubules, and interstitium.

Vascular Disease

Intrinsic AKI may result from vascular disease in large or medium-sized arteries, small arteries, and arterioles within the renal parenchyma and veins draining the kidneys. Bilateral renal artery thrombosis superimposed on underlying high-grade stenoses, significant cardiac or aortic thromboembolism occluding the renal arteries, or dissection of the renal arteries may cause AKI. With acute presentations, the clinical features often include flank or abdominal pain, fever, hematuria, and oligo-anuria or anuria. Therapy with thrombolytics may reverse acute thrombosis and thromboembolism and restore renal blood flow with early diagnosis. Percutaneous angioplasty with stent placement can noninvasively correct significant underlying renal artery stenosis. Renal artery dissection often requires surgical repair, but at times stent placement may suffice. Vasculitis of large renal vessels (e.g., Takayasu's arteritis, giant cell arteritis) is an extremely rare cause of AKI.

Induction of AKI by renal atheroemboli occurs less commonly than before, perhaps because of improved techniques and use of softer wires during vascular procedures. Cholesterol crystal embolization is caused most often by invasive vascular procedures in patients with atherosclerotic disease that disrupt the fibrous cap on the ulcerated plaque. However, thrombolytic therapy and therapeutic anticoagulation can also precipitate embolization in patients who have a significant burden of renal artery or aortic plaque. When it occurs, atheromatous material may lodge in interlobar, arcuate, or interlobular arteries in the kidneys. In addition to AKI, clinical manifestations include abrupt onset of severe hypertension, livedo reticularis, digital or limb ischemia, abdominal pain from pancreatitis or bowel ischemia, gastrointestinal bleeding, muscle pain, central nervous system symptoms such as focal neurologic deficits, confusion, amaurosis fugax, and retinal ischemic symptoms. Peripheral eosinophilia, hypocomplementemia, elevated sedimentation rate, and eosinophiluria variably accompany the syndrome. Treatment is primarily preventive by avoiding the factors known to precipitate atheroembolization. BP control, treatment with statins, amputation of necrotic limbs, aggressive nutrition, avoidance of anticoagulation (to reduce the risk for further embolization), and RRT for severe AKI may improve the dismal prognosis associated with this syndrome. Steroids and iloprost are sometimes used, but their therapeutic role is uncertain.

AKI from vasculitis involving the medium and small vessels has been described with classic polyarteritis nodosa. It is either idiopathic or secondary to hepatitis B antigenemia and manifests with severe hypertension and AKI. Renal arteriography demonstrating beading in the arterial tree of the kidney (and other organs) is diagnostic. Scleroderma is a disorder characterized by arterial and arteriolar narrowing due to deposition of mucinous material. Scleroderma renal crisis manifests as AKI and

E-FIGURE 31-3 Decompensated cirrhosis is associated with hemodynamic changes that result in the development of acute kidney injury from hepatorenal syndrome.

severe hypertension, often malignant, in a patient with a disease flare. Urinalysis and urine microscopy may be bland or may show cellular activity. Fibrinoid necrosis with ischemic injury occurs in the kidney. ACE inhibitors effectively control BP and improve AKI.

Rarely, AKI may develop in the setting of renal vein thrombosis, a well-known complication of nephrotic syndrome. Imbalance of anticoagulant substances lost in the urine and procoagulant substances produced by the liver leads to a hypercoagulable state and renal vein thrombosis. AKI is thought to develop from raised intrarenal pressures and reduced kidney perfusion. Therapy includes acute thrombolysis and chronic anticoagulation as well as treatment of the underlying glomerular lesion (often membranous nephropathy) and reduction in proteinuria.

Glomerular Disease

A number of glomerular diseases can cause AKI, and the more common entities are reviewed here. Acute proliferative GN may be broadly classified as (1) immune complex disease, (2) pauci-immune disease, or (3) anti-GBM-related disease. They are all characterized by glomerular cell proliferation and necrosis, polymorphonuclear cell infiltration, and, with severe injury, epithelial crescent formation (E-Fig. 31-4). Acute proliferative GN manifests with hypertension and edema formation and with laboratory results pertinent for hematuria and proteinuria, described as *nephritic sediment*. Examination of the urine sediment classically reveals dysmorphic RBCs and RBC casts. Therapy is directed at the underlying cause, with supportive measures and RRT as necessary.

TTP and HUS are two of the more common causes of thrombotic microangiopathy, which is marked by platelet deposition and endothelial injury with thrombosis of arterioles and glomerular capillaries. AKI results from severe glomerular damage with profound ischemia and necrosis. The thrombotic microangiopathies may manifest with nephritic sediment. Patients with HUS may have severe AKI, or it may be mild, as in patients with TTP. Microangiopathic hemolytic anemia and thrombocytopenia are key features. Therapy often includes modulation of the immune system with plasma exchange or eculizumab, in addition to supportive measures.

The dysproteinemias, which deposit monoclonal immunoglobulin light or heavy chains (or both) in the kidney, may also promote glomerular lesions. The type, metabolism, and packaging of the immunoglobulin determine which type of glomerular lesion develops: light or heavy chain deposition disease, amyloidosis, or one of the fibrillary GNs. The immunoglobulin deposition diseases often manifest with nephrotic proteinuria and AKI, rarely with hematuria.

Light chain deposition disease, heavy chain deposition disease, and light/heavy chain deposition disease cause nodular glomerular lesions. Amyloidosis is also associated with the formation of acellular glomerular nodules. The fibrillary GNs (fibrillary and immunotactoid) may be associated with mesangial expansion or glomerular nodules. More commonly, they appear as a mesangial proliferative, mesangiocapillary, or membranous lesion, sometimes with formation of epithelial crescents. These diseases can be distinguished by electron microscopy. Light and heavy chain

diseases produce granular deposits, whereas amyloidosis appears as haphazard fibrils in the 8- to 12-nm size range. Fibrillary GN has fibrils in 20- to 30-nm range, and immunotactoid GN shows fibrils in the 30- to 50-nm range with organized microtubular fibrils.

Tubular Disease

Acute Tubular Necrosis

ATN is the most common form of hospital-acquired intrinsic AKI, accounting for more than 80% of AKI episodes. It is classically divided into ischemic ATN, which makes up almost 50% of the cases, nephrotoxic ATN, and combinations of both. In many instances, ATN results from multiple insults acting together to injure the kidney. The end result of either ischemic or toxic insult is tubular cell injury and death. E-Table 31-4 outlines the important factors underlying the pathogenesis of ATN.

Ischemic ATN

Ischemic ATN is, for the most part, an extension of severe and uncorrected prerenal AKI. Prolonged renal hypoperfusion causes tubular cell injury, which persists even after the underlying hemodynamic insult resolves and may be associated with ischemia-reperfusion injury. Intraoperative and postoperative hypotension impairs renal perfusion and occurs relatively frequently after cardiac and vascular surgical procedures. Ischemic, nephrotoxic, and multifactorial ATN are common on the medical wards and in the ICU. Risk for ischemic ATN is increased by the comorbidities these patients possess. Sepsis and septic shock, severe intravascular volume depletion, cirrhotic physiology, and cardiogenic shock are examples of situations that confer high risk for development of ischemic ATN. Employment of vasopressors to restore BP may further reduce renal perfusion and exacerbate ischemia. In some cases, ischemic ATN is so profound that cortical necrosis (ischemic atrophy of the renal cortex) develops.

Nephrotoxic ATN

Nephrotoxic ATN occurs when exogenous substances injure the tubules, primarily through direct toxic effects but also through perturbations in intrarenal hemodynamics or a combination of these factors. In the past, organic solvents and heavy metals (e.g., mercury, cadmium, lead) were a frequent cause of ATN. Since then, many potentially toxic medications have been synthesized and observed to cause tubular injury by multiple mechanisms.

Aminoglycosides cause proximal tubular injury. AKI rarely develops within the first week of therapy, and injury initially manifests with subtle changes in urine concentrating ability and increased RTECs and granular casts in the urine sediment. The antifungal agent amphotericin B induces AKI through two distinct mechanisms: destruction of cellular membranes through sterol interactions and vasoconstriction-induced tubular ischemia. ATN develops in a dose-dependent fashion and manifests with increasing serum creatinine levels and RTECs and granular casts in the urine. Liposomal and lipid complex formulations are less nephrotoxic but can precipitate AKI in high-risk patients.

Radiocontrast material is a common cause of AKI because it is so widely used with imaging procedures. AKI develops in patients with underlying risk factors such as CKD, especially diabetic nephropathy, “true” or “effective” intravascular volume

E-FIGURE 31-4 Crescentic glomerulonephritis is often a biopsy finding in patients with rapidly progressive glomerulonephritis.

depletion, advanced age, and exposure to other nephrotoxins. The incidence of AKI may be 25% and approaches 50% in patients with underlying risk factors. ATN occurs from both ischemic tubular injury (prolonged decrease in renal blood flow) and direct toxicity (osmotic cellular injury, oxidative stress, inflammation). Large radiocontrast volumes increase risk, whereas low-osmolar and iso-osmolar radiocontrast agents are less nephrotoxic than high-osmolar material.

The antiviral agents cidofovir and tenofovir, once they have entered the cell from the peritubular blood via the human organic anion transporter 1 on the basolateral membrane, cause AKI through disruption of mitochondrial and other cellular functions. Several chemotherapeutic agents, including the platinum-based drugs, ifosfamide, mithramycin, imatinib, pentostatin, and pemetrexed, cause ATN through direct toxic effects. As with other nephrotoxins, part of their ability to induce ATN resides in the renal handling by the kidneys (transport through tubular cells) as they are being excreted. In addition, zoledronate, the polymyxins, high-dose vancomycin, foscarnet, and deferasirox also cause nephrotoxic ATN. AKI prevention is best achieved by judicious prescription of these drugs to high-risk patients, appropriate dose adjustments, avoidance of superimposed volume depletion, and close monitoring with early markers of injury such as urine microscopy.

Pigment Nephropathy

Pigment nephropathy represents the nephrotoxic renal tubular effects of endogenously produced substances. The most common examples are overproduction of heme moieties in serum that are eventually filtered at the glomerulus and excreted in urine. With severe rhabdomyolysis, the heme pigment released from muscle is myoglobin. AKI develops in the setting of myoglobinuria from the combination of direct myoglobin tubular toxicity (in an acid urine), volume depletion, and obstructing myoglobin casts. Therapy includes intravenous fluids (the addition of bicarbonate is questionable), supportive care, and sometimes RRT. Most patients recover kidney function to near-baseline.

Massive intravascular hemolysis from various causes (e.g., immune-mediated, microangiopathic) is associated with hemoglobinuria, which induces tubular injury by promoting the formation of reactive oxygen species and by reducing renal perfusion through inhibition of nitric oxide synthesis. Therapy is directed at the primary cause, with intravenous fluids and supportive care. Most patients ultimately recover kidney function.

Crystal Nephropathy

AKI may result from crystal deposition in distal tubular lumens after massive rises in uric acid or therapy with certain medications. Risk factors for AKI due to crystal deposition are underlying kidney disease and intravascular volume depletion. Acute uric acid nephropathy from urate crystal deposition and tubular obstruction develops in patients with massive tumor lysis syndrome.

Drugs such as sulfadiazine promote intratubular deposition of sulfa crystals in acid urine, whereas acyclovir crystal deposition occurs after large, rapid intravenous doses of the drug, and atazanavir and indinavir crystal deposition occurs in the setting of volume contraction and urine pH higher than 5.5. Ciprofloxacin

can cause AKI due to intratubular crystal deposition when administered in excessive doses, primarily in patients with unrecognized kidney disease and those with alkaline urine. In addition, methotrexate or large doses of intravenous vitamin C (producing oxalate) can cause AKI due to intratubular crystal deposition.

Weight loss therapies such as bariatric surgery with small bowel bypass and orlistat, through induction of malabsorption, cause enteric hyperoxaluria and calcium oxalate crystal deposition, an entity known as acute oxalate nephropathy (E-Fig. 31-5). Sodium phosphate-containing bowel purgatives have also been associated with AKI due to acute phosphate nephropathy, an entity characterized by calcium phosphate intratubular crystal deposition.

Diagnosis of crystal nephropathy is based on a history of exposure to a culprit agent or an underlying disease state associated with excessive crystal production.

Osmotic Nephropathy

Osmotic nephropathy is a little known entity that can promote AKI through the induction of proximal tubular swelling, cell injury, and occlusion of intratubular lumens. The hyperosmolar and unmetabolizable nature of substances such as sucrose, dextran, mannitol, the sucrose excipient of intravenous immune globulin, and hydroxyethylstarch underlies the pathophysiology of this kidney lesion. Cells develop severe swelling with cytoplasmic vacuoles, disturbing cellular integrity and occluding tubular lumens. AKI results from this abnormal tubular process when patients with underlying kidney disease or other risk factors for kidney injury (e.g., intravascular volume depletion, older age) receive these hyperosmolar substances. AKI is dose related and may require RRT. Although most patients recover from AKI, CKD can result. Therapy is primarily supportive, along with avoidance of further exposure to these agents.

Interstitial Disease

Interstitial disease develops in the setting of infection with certain agents, systemic diseases, infiltrative malignancies, and exposure to some medications. Of these, drug-induced disease is by far the most common entity, especially in the hospitalized patient. The syndrome of AIN is characterized by AKI and a variety of clinical findings. The clinical presentation varies based on the offending agent and the host response. As an example, β -lactam antibiotics frequently cause the classic triad of fever, maculopapular skin rash, and eosinophilia. Arthralgias, myalgias, and flank pain may also occur. Aside from causing AKI, NSAIDs can rarely lead to allergic or extrarenal manifestations such as fever, rash, or eosinophilia.

Urinalysis may reveal dipstick-positive (trace to 1+) protein, blood, and leukocyte esterase. Urine microscopy may be bland (~20%), but more often, the urine sediment demonstrates white blood cells (WBCs), RBCs, WBC casts, and granular casts. Wright or Hansel stain may reveal eosinophils in the urine, but neither of these tests is sensitive or specific for AIN.

The diagnosis is best confirmed by kidney biopsy. A cellular infiltrate consisting of lymphocytes, monocytes, eosinophils, and plasma cells is typically present; interstitial edema and fibrosis vary based on the time of drug exposure (E-Fig. 31-6). Tubulitis, or invasion of lymphocytes into the tubular cells, is frequently

E-FIGURE 31-5 Oxalate nephropathy. Calcium oxalate crystal deposition in the renal tubules can cause acute kidney injury. The crystals are strongly birefringent crystals on polarized light microscopy.

E-FIGURE 31-6 Acute kidney injury can result from acute interstitial nephritis, which is characterized by an inflammatory infiltrate consisting of lymphocytes, eosinophils, plasma cells, and monocytes with interstitial edema or fibrosis or both.

part of AIN. Granuloma formation and interstitial inflammation occur with certain drugs such as anticonvulsants and sulfonamides, systemic diseases such as sarcoidosis, tubulointerstitial nephritis with uveitis, and idiopathic granulomatous interstitial nephritis. The glomeruli and vasculature are spared until very late in the disease. If kidney biopsy is not possible, gallium scanning or positron emission tomography of the kidneys may help with diagnosis, especially when the differential diagnosis is primarily between AIN and ATN.

Early diagnosis of AIN, coupled with rapid drug withdrawal before advanced tubulointerstitial fibrosis develops, maximizes successful renal recovery. Steroid therapy is controversial but may reduce the duration of AKI and perhaps improve recovery of kidney function in patients with severe AKI if it is used early (within 2 weeks of diagnosis).

Before development of antibiotics and other drugs that have been associated with AIN, interstitial infection was the major cause of tubulointerstitial nephritis. Microbial agents such as staphylococci, streptococci, mycoplasma, diphtheroids, and legionella are well-described causes of AIN. Several viral agents including cytomegalovirus, Epstein-Barr virus, human immunodeficiency virus (HIV), Hantaan virus, parvovirus, and rubeola also are associated with AIN. In addition, infectious agents that cause rickettsial diseases, leptospirosis, and tuberculosis also invade the renal interstitium.

The renal interstitium is the target of a number of systemic illnesses. Sarcoidosis causes a lymphocyte-dominant AIN, which can be associated with noncaseating granulomas. AKI and urine sediment containing WBCs and WBC casts point to this disease, along with other systemic findings. Steroids reduce the severity of AIN, but CKD is a potential long-term complication. Systemic lupus erythematosus is more commonly associated with various forms of proliferative GN; AIN may coexist with glomerular disease, or, in rare instances, it may be present in isolation. The interstitial inflammatory lesion is caused by immune complex deposition in the tubulointerstitium. AIN usually responds to the cytotoxic therapy given for lupus nephritis. Sjögren's syndrome also causes a lymphocyte-dominant AIN; it appears to be another immune complex-mediated disease of the renal interstitium.

Patients with HIV infection may develop interstitial disease that appears immune related. Diffuse infiltrative lymphocytosis syndrome (DILS) is a Sjögren-like syndrome associated with multivisceral infiltration of CD8-positive T lymphocytes. DILS appears to be a host-determined response to HIV. Immune reconstitution inflammatory syndrome (IRIS) is another multivisceral disease characterized by an interstitial infiltrate. This disease occurs when combination antiretroviral therapy reconstitutes the immune system in the setting of a previous or occult opportunistic infection. An exuberant immune reaction results in T cell infiltration of several organs, including the kidneys, which develop AIN. Therapy involves treatment of the opportunistic infection. Occasionally, steroids are required to suppress the inflammatory response.

Infiltration of the kidney by cancer is an uncommon cause of AKI. Autopsy studies confirm a high rate of asymptomatic renal infiltration. The malignancies most often associated with interstitial infiltration are the lymphomas and leukemias.

Lymphomatous infiltration of the kidney parenchyma can occur in the form of discrete nodules or diffuse interstitial infiltration. Lymphoma may cause massive kidney enlargement (nephromegaly) and AKI. Leukemic infiltration also causes nephromegaly, AKI, and, rarely, renal potassium wasting from either tubulointerstitial damage or lysozyme production. Successful treatment of the underlying malignancy typically improves the infiltrative lesion; however, irradiation of the kidneys may provide additional benefit. Exclusion of obstructive uropathy from bulky retroperitoneal lymph node disease is also required.

Postrenal AKI

AKI can develop when obstruction to urine flow occurs along the genitourinary system (E-Table 31-5). The process causing postrenal AKI is called *obstructive uropathy*, whereas the dilated urinary collecting system identified on imaging is termed *hydronephrosis*. Tubular defects with AKI that results from urinary obstruction is called *obstructive nephropathy*. AKI can develop only when obstruction is bilateral, involving both ureters or the bladder, or unilateral in a person with a single functioning kidney. Importantly, either complete or partial obstruction can cause AKI. In general, complete obstruction is associated with more severe AKI and hypertension, intravascular volume overload, hyperkalemia, metabolic acidosis, and hyponatremia.

A wide variety of disorders, originating anywhere from the renal calyces to the urethra, can cause AKI due to urinary obstruction. The most common causes of obstructive uropathy in the upper urinary tract are stones and retroperitoneal disease; in the lower tract, at the level of the bladder and below, prostatic hyperplasia and bladder dysfunction most often obstruct urinary flow. Obstructive uropathy should be considered in many patients with AKI, especially those with a history suggesting risk. A history of nephrolithiasis or certain cancers, along with flank pain, suggests upper tract disease; a history of prostate or bladder disease, together with symptoms of prostatism and urinary retention, points to lower tract obstruction. A directed physical examination of the flanks, suprapubic area, and prostate for flank tenderness, a palpable bladder, or prostatic enlargement is required. Large residual urine demonstrated on straight catheterization of the bladder bespeaks lower tract obstruction.

Ultrasonography of the kidneys and retroperitoneum is the most appropriate initial test to evaluate the patient with AKI and possible urinary tract obstruction. The sensitivity and specificity of renal ultrasonography for the detection of urinary obstruction are approximately 90%. Several processes blunt dilatation of the collecting system and the formation of hydronephrosis, including acute obstruction of less than 48 to 72 hours' duration, severe intravascular volume depletion superimposed on obstruction, and retroperitoneal disease involving the kidneys and ureters that encases the collecting system. If ultrasonographic findings are equivocal or negative but high suspicion for urinary obstruction persists, a CT scan may provide more information. One of the major benefits of CT imaging is the ability to detect stones, tumor, enlarged lymph nodes, and other processes causing obstruction despite the absence of hydronephrosis. As last resort, if obstruction as the cause of AKI is still considered likely, retrograde pyelography may provide a diagnosis of upper tract obstruction.

- Blood clots

Therapy for AKI due to obstructive uropathy requires rapid diagnosis and intervention to relieve the obstructive process. Delayed interventions, especially in patients with complete obstruction, compromise recovery of kidney function. Upper urinary tract obstruction requires either retrograde ureteral stent placement or nephrostomy tube insertion when it is caused by severe retroperitoneal disease such as ureteral or bladder cancer. Relief of lower tract obstruction with a bladder catheter, a suprapubic tube (rarely), or a nephrostomy tube is the first step in treatment. Electrolyte and fluid management also are required to ensure patient safety in developing postobstructive diuresis. It is a phenomenon that occurs primarily in patients with bilateral, complete obstruction and is characterized by large urine volumes after relief of obstruction. Postobstructive diuresis is physiologic in that excess sodium and water are being excreted from the hypervolemic patient, but impaired tubular function (sodium and water) may lead to excessive diuresis and volume depletion. In this setting, judicious fluid repletion is required to avoid iatrogenic postobstructive diuresis as well as underresuscitation and hypotension.

COMPLICATIONS OF AKI

Considering the normal functions of the kidneys, it is not surprising that a number of metabolic complications develop in the setting of AKI. Hyperkalemia is a potentially life-threatening complication that often requires urgent intervention. Hyperkalemia disturbs the magnitude of the action potential in response to a depolarizing stimulus. The electrocardiogram (ECG) is a better guide to therapy than a single measurement of potassium concentration. The sequential ECG changes observed in hyperkalemia are peaked T waves, PR prolongation, QRS widening, and a sine wave pattern. The presence of any of these ECG changes mandates prompt therapy.

Metabolic acidosis is common in AKI. However, it is usually well tolerated and does not require therapy unless arterial pH declines to less than 7.1. Hyperkalemia and severe metabolic acidosis not responsive to medical therapy are indications for initiation of RRT. Hypocalcemia is a common but asymptomatic finding and usually does not require therapy. Significant hyperphosphatemia may occur but often can be managed with oral phosphate binders. Anemia typically does not require treatment unless it is severe, is symptomatic, or contributes to cardiac dysfunction. Uremic manifestations of AKI are listed in [E-Table 31-6](#). They may be subtle findings, or they may be obvious and life-threatening, requiring urgent RRT.

Importantly, infectious complications are the main cause of death because of the immune compromise, edema with end-organ dysfunction and skin breakdown, and numerous indwelling catheters in these patients.

GENERAL MANAGEMENT OF AKI

Management of AKI begins with identification of the cause and pathogenesis of the inciting process. In addition, the complications associated with AKI need to be recognized and rapidly treated to avoid serious adverse events. Prerenal AKI requires optimization of renal perfusion by repletion of intravascular volume in those who are volume depleted and correction of heart failure, liver failure, and other “effective” causes of reduced

intravascular volume. Intrinsic AKI requires directed therapy of the disturbed kidney compartment. Management of postrenal AKI mandates early intervention to relieve obstruction and preserve kidney function.

Most consequences of AKI are managed initially with conservative measures. These include interventions to correct hypovolemia or hypervolemia, improvement of hemodynamics, and correction of hyponatremia, hyperkalemia, metabolic acidosis, and hyperphosphatemia. Conversion of patients from oliguric to nonoliguric AKI makes management easier but does not improve outcomes in terms of morbidity or mortality. Manifestations of severe uremia and the other consequences of AKI, as listed in [E-Table 31-6](#), may necessitate RRT if conservative measures are unsuccessful or incompletely reverse the complication.

Hospital-based RRT, which includes primarily acute hemodialysis and continuous renal replacement therapies (CRRTs), is required in certain patients with AKI. Continuous therapies, which can be employed only in the ICU, include continuous venovenous hemofiltration, hemodialysis, hemodiafiltration, slow low-efficiency dialysis, and extended daily dialysis. Emergent indications include severe hyperkalemia, uremic end-organ damage (e.g., pericarditis, seizure), refractory metabolic acidosis, and severe volume overload including pulmonary edema. Although the data do not support a cutoff BUN value to initiate RRT, it is sensible to initiate therapy before severe uremic complications develop. Intractable volume overload with anasarca complicated by skin breakdown is another potential indication. Acute hemodialysis is the modality most commonly employed to treat the consequences of AKI. However, critically ill patients who are hemodynamically unstable benefit most from continuous therapies. CRRT allows more precise control of volume, uremia, acid-base disturbances, and electrolyte disorders with less hemodynamic instability. CRRT also allows aggressive nutritional support. Peritoneal dialysis is rarely used for AKI but is a reasonable modality.

OUTCOME AND PROGNOSIS OF AKI

Despite the significant advances in supportive care and RRT technology, acute and long-term complications, including mortality, remain common. The mortality associated with AKI in the hospital setting depends on the patient’s severity of illness and burden of organ dysfunction. As the number of failed organs increases from 0 to 4, the mortality rate associated with AKI increases from less than 40% to more than 90%. Also, in-hospital mortality increases with AKI that develops in the medical or surgical ICU. Long-term outcomes for patients with AKI include increased risk for death (compared with hospitalized patients without AKI). Furthermore, patients with CKD who have a pre-hospitalization eGFR lower than 45 mL/min/1.73 m² who develop RRT-requiring AKI have a much higher mortality rate than patients with CKD not complicated by AKI. On the whole, all forms of AKI, including the RRT-requiring forms, appear to be associated with an increased risk for development of new CKD, progression of CKD, ESRD, and death.

For a deeper discussion on this topic, please see Chapter 120, “Acute Kidney Injury,” in Goldman-Cecil Medicine, 25th Edition.

Chronic Kidney Disease

Kerri L. Cavanaugh and T. Alp Ikizler

DEFINITION AND EPIDEMIOLOGY

Chronic kidney disease (CKD) is defined as persistent, progressive, and irreversible loss of renal function. The spectrum of CKD includes earlier stages of kidney damage (characterized by proteinuria, electrolyte abnormalities, and elevated serum creatinine) that represent a decrease in the glomerular filtration rate (GFR) and extends to complete loss of kidney function—that is, kidney failure or end-stage renal disease (ESRD). Markers of kidney damage or GFR less than 60 mL/min/1.73 m² must be present to meet the diagnostic criteria of CKD. In addition, these must be present and persistent for at least 3 months to differentiate CKD from acute kidney injury. According to the Kidney Disease: Improving Global Outcomes (KDIGO) 2012 clinical practice guideline, CKD is classified based on the underlying cause of kidney disease, GFR category, and degree of albuminuria. There are six GFR categories, ranging from normal or high (G1, ≥ 90 mL/min/1.73 m²) to kidney failure (G5, < 15 mL/min/1.73 m²), and three albuminuria categories based on severity (Table 32-1).

CKD is a worldwide public health problem of increasing magnitude; in the United States, CKD is estimated to affect 20 million people. Although some have mildly decreased GFR with mild to

moderate albuminuria (Fig. 32-1), many people with CKD progress to ESRD and require dialysis or kidney transplantation. The rate of new ESRD patients in the United States has been relatively stable since 2000; however, it was 4% lower (357 per million population) in 2011, as reported by the United States Renal Data System (USRDS) in 2013 (E-Fig. 32-1). Trends in overall prevalence of ESRD suggest a continuing increase in the numbers of patients requiring care, although in 2011 the increase was only 3.4%—the lowest in 30 years (E-Fig. 32-2). Care of the ESRD patient is costly, accounting for \$34 billion (6.3%) of the U.S. Medicare budget in 2011. In addition to concern about progression to ESRD, decreased GFR and proteinuria have each been recognized as independent risk factors for cardiovascular disease and death. Therefore, diagnosis of CKD confers risk not only for progressive loss of kidney function but also for decreased survival.

The most common causes of ESRD are diabetes mellitus (45%), hypertension (28%), glomerulonephritis (6-7%), and cystic or congenital conditions (2-3%). During the evaluation of CKD, every attempt should be made to arrive at the specific cause of kidney disease. Renal biopsy is the most specific approach to definitive diagnosis; it also can guide treatment and help to determine suitability for kidney transplantation. However, the procedure has potential complications, and clinical and imaging information may be sufficient to provide a conclusive diagnosis.

PATHOLOGY

After renal injury, surviving nephrons must adjust by increasing their filtration and excretion rates to ensure adequate solute, water, and acid-base balances. Patients with CKD are vulnerable to edema formation and severe volume overload, hyperkalemia, hyponatremia, and azotemia. Initially, sodium balance is maintained by increasing fractional excretion of sodium by the nephrons. Acid excretion is maintained until late stages of CKD (when the GFR falls to less than 30 mL/minute) by increased tubular ammonia synthesis, which provides an adequate buffer for hydrogen in the distal nephron. Later, a significant decrease in distal bicarbonate regeneration results in hyperchloremic metabolic acidosis. Further nephron loss leads to retention of organic ions such as sulfates, which results in an anion gap metabolic acidosis. There is active research to determine whether metabolic acidosis is itself a contributor to progression of CKD and whether its correction by base supplementation is a potential treatment.

Once GFR has decreased below a critical level, CKD tends to progress to ESRD, regardless of the initial insult. Figure 32-2 shows how risk factors may interact with pathophysiologic

TABLE 32-1 CATEGORIES OF GLOMERULAR FILTRATION RATE AND ALBUMINURIA IN CHRONIC KIDNEY DISEASE

CATEGORY	GFR (mL/min/1.73 m ²)		TERMS	
G1*	≥ 90		Normal or high	
G2*	60-89		Mildly decreased	
G3a	45-59		Mildly to moderately decreased	
G3b	30-44		Moderately to severely decreased	
G4	15-29		Severely decreased	
G5	< 15		Kidney failure	

CATEGORY	AER		ACR		Terms
	(mg/24 hr)	(mg/g)	(mg/mmol)		
A1	< 30	< 30	< 3		Normal to mildly increased
A2	30-300	30-300	3-30		Moderately increased
A3	> 300	> 300	> 30		Severely increased

Modified from Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group: KDIGO 2012 clinical practice guideline for the evaluation and management of chronic kidney disease, *Kid Intl Suppl* 3:1–150, 2013.

ACR, Albumin-to-creatinine ratio; AER, albumin excretion rate; GFR, glomerular filtration rate.

*G1 and G2 alone, without other evidence of kidney damage, do not meet the criteria for chronic kidney disease.

FIGURE 32-1 Distribution of chronic kidney disease in the United States by glomerular filtration rate (GFR) and albuminuria categories.

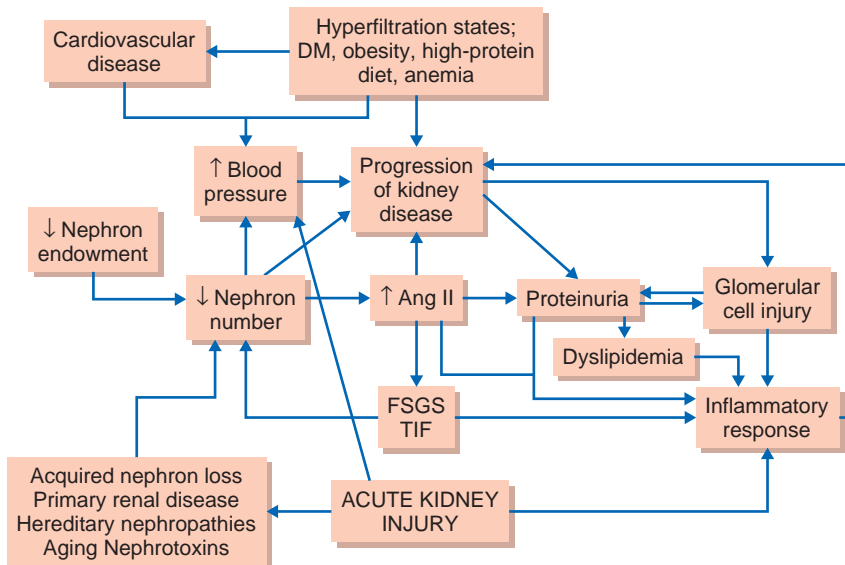

FIGURE 32-2 A simplified depiction of risk factors interacting with pathophysiologic mechanisms to accelerate progression of chronic kidney disease. Ang II, Angiotensin II; DM, diabetes mellitus; FSGS, focal segmental glomerulosclerosis; TIF, tubulointerstitial fibrosis. (Modified from Taal MW, Brenner BM: Predicting initiation and progression of chronic kidney disease: developing renal risk scores, *Kidney Int* 70:1694–1705, 2006.)

mechanisms to accelerate CKD progression. Detailed studies have elucidated interrelated mechanisms, including glomerular hemodynamic responses to nephron loss, proteinuria, and pro-inflammatory responses. Activation of the renin-angiotensin-aldosterone system (RAAS) pathway and increased production of transforming growth factor- β (TGF- β) also contribute to renal fibrosis. Interventions that reduce intraglomerular pressure, such as protein restriction and the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin-receptor blockers (ARBs), help attenuate progression of renal disease and further support the importance of glomerular hemodynamics and RAAS in progressive kidney disease.

CLINICAL PRESENTATION

General Features of Uremic Syndrome

Kidney disease commonly manifests first as abnormalities on laboratory or other diagnostic tests. Patients with CKD may not have symptoms until advanced stages, in which the GFR is less than 15 mL/minute. *Uremia* is a systemic syndrome that negatively affects every organ system. Uremic syndrome is likely the consequence of many factors, including retained molecules, deficiencies of important hormones, and metabolic abnormalities, rather than the effect of a single uremic toxin (E-Fig. 32-3). Excess urea can cause symptoms of fatigue, nausea, 

E-FIGURE 32-3 Etiologic factors of uremia. PTH, Parathyroid hormone; 1,25 Vit. D, 1,25-dihydroxyvitamin D.

vomiting, and headaches. Its breakdown product (cyanate) can result in carbamylation of lipoproteins and peptides, leading to multiple organ dysfunctions. Guanidines, byproducts of protein metabolism, are increased and can inhibit α_1 -hydroxylase activity within the kidney, leading to secondary hyperparathyroidism. β_2 -Microglobulin accumulation in patients with ESRD has been associated with neuropathy, carpal tunnel syndrome, and amyloid infiltration of the joints. Specific roles for other accumulated metabolites are under investigation. The major manifestations of uremia are summarized in [Figure 32-3](#).

Cardiovascular

In addition to hypertension, cardiovascular disorders are common in patients with CKD. More than 60% of patients with ESRD who start dialysis have echocardiographic manifestations of left ventricular hypertrophy, dilation, and systolic or diastolic dysfunction. Metabolic consequences of CKD, including accelerated atherogenesis, contribute to metastatic calcification in the myocardium, cardiac valves, and arteries. Arrhythmias, including those resulting in sudden death, may be caused by electrolyte abnormalities, cardiac structural changes, or ischemic cardiovascular disease. Pericarditis can occur in patients with uremia before they start dialysis or in ESRD patients receiving inadequate dialysis.

Gastrointestinal

Gastrointestinal disturbances are among the earliest and most common signs of the uremic syndrome. Patients describe a metallic taste and loss of appetite. Later, they experience nausea, vomiting, and weight loss, and those with severe uremia may also experience stomatitis and enteritis. Gastrointestinal

bleeding caused by gastritis, peptic ulceration, and arterial venous malformations in the setting of platelet dysfunction may be present.

Neurologic

Central nervous system manifestations are frequent in advanced CKD and are characterized predominantly by changes in cognitive function and sleep disturbances. Lethargy, irritability, asterixis, seizures, and frank encephalopathy with coma are late manifestations of uremia and are usually avoided by timely initiation of renal replacement therapy (RRT). Peripheral neurologic manifestations appear as a progressive, symmetrical sensory neuropathy in a glove-and-stocking distribution. Patients have decreased distal tendon reflexes and loss of vibratory perception. Peripheral motor impairment can result in restless legs, footdrop, or wristdrop. Most of these neurologic manifestations reverse with adequate dialysis or kidney transplantation.

Musculoskeletal

Alterations in calcium and phosphate homeostasis, with hyperparathyroidism and disturbance of vitamin D metabolism, also are common. Hypocalcemia and secondary hyperparathyroidism are the result of phosphate retention and lack of α_1 -hydroxylase activity in the failing kidney, with consequent deficiency of the most active form of vitamin D. Over time, maladaptive parathyroid hypertrophy leads to bone disease and tissue calcification.

Hematologic and Immunologic

Erythropoietin (EPO), a hormone produced by the kidney that regulates erythrocyte production, becomes progressively

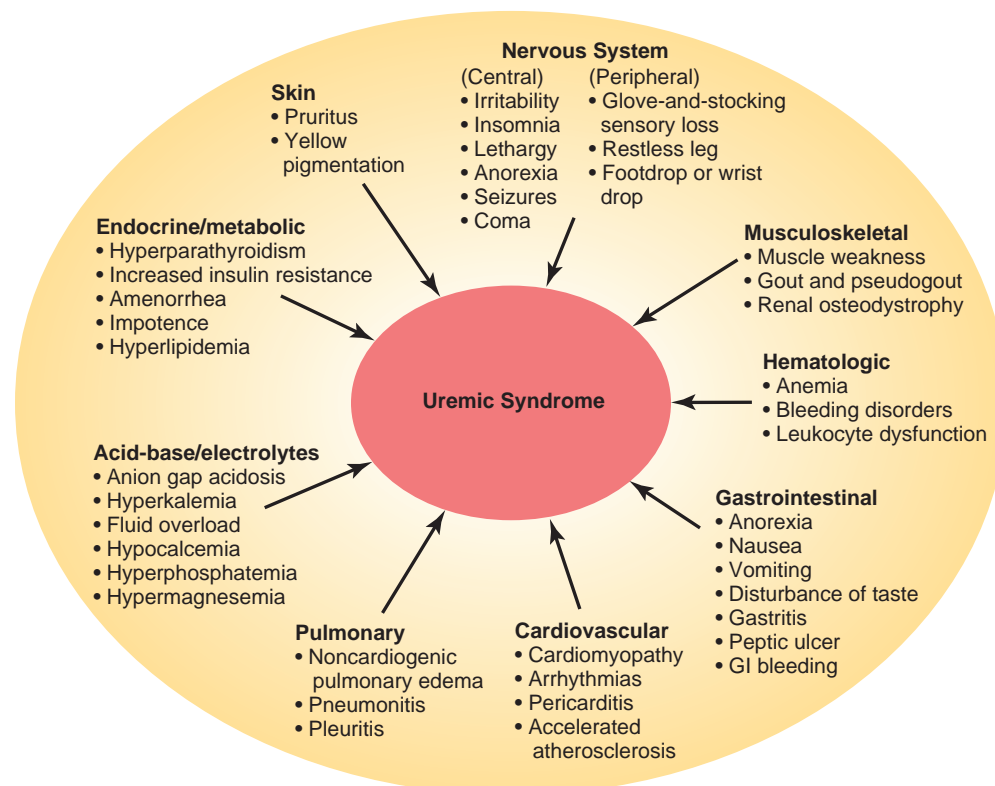

FIGURE 32-3 Diagrammatic summary of the major manifestations of the uremic syndrome. GI, Gastrointestinal.

deficient as CKD progresses. EPO and iron deficiency are common causes of anemia in CKD. Administration of synthetic EPO results in correction of anemia, improved quality of life and anemia-related symptoms, and decreased dependence on blood transfusions. Caution must be exercised, because higher doses of EPO that result in elevations of the serum hemoglobin to more than 12 g/dL may be associated with a higher risk for adverse cardiovascular events. Bleeding disorders, primarily from defects in platelet adherence and aggregation, are common. Bleeding in uremic patients usually can be controlled with cryoprecipitate, 1-deamino-(8-D-arginine)-vasopressin (DDAVP), conjugated estrogens, and dialysis.

Defects occur in both humoral and cellular immune systems in patients with CKD. Although the leukocyte count is typically normal and appropriately responsive in advanced CKD, patients are generally immunosuppressed and susceptible to infections. This may be the result of functional abnormalities of polymorphonuclear leukocytes, lymphocytes, and other cellular host defenses. Additionally, patients with CKD may have a variable immune response to vaccination.

Endocrine and Metabolic

Thyroid function testing may be less reliable in patients with uremia. Common laboratory findings include an increased triiodothyronine (T_3) resin uptake, a low T_3 level resulting from the impaired conversion of thyroxine to T_3 peripherally, and normal thyroxine levels. Thyroid-stimulating hormone levels are usually normal.

A deranged pituitary-gonadal axis can result in sexual dysfunction manifested by impotence, decreased libido, amenorrhea, sterility, and uterine bleeding. Patients have decreased plasma levels of testosterone, estrogen, and progesterone, with normal or increased levels of follicle-stimulating hormone, luteinizing hormones, and prolactin. Pregnancy is uncommon in female patients who have a GFR of less than 30 mL/minute.

Lipid abnormalities are also common in CKD. They are most consistent with type IV hyperlipoproteinemia, with a marked increase in plasma triglycerides and less of an increase in total cholesterol. The activity of lipoprotein lipase is decreased in uremia, resulting in reduced conversion of very-low-density lipoprotein to low-density lipoprotein and thus hypertriglyceridemia. The treatment of choice is the hydroxymethylglutaryl-coenzyme A reductase (HMG-CoA) inhibitor class of drugs because of their pluripotent effects on inflammation and atherosclerosis.

Electrolytes

Hyperkalemia occurs in patients with CKD as a result of decreased renal clearance of potassium, intracellular-to-extracellular shifts of potassium in the setting of metabolic acidosis related to kidney failure, and also the concomitant use of medications such as RAAS blockers. The primary method of treatment is dietary reduction of potassium but may also include use of loop diuretics or potassium-binding medications. Hypokalemia is much less common in CKD but may occur in the setting of very poor nutritional intake or use of high-dose potassium-wasting diuretic medications.

Skin

Uremic hue, a yellowish skin color, is likely the result of retained liposoluble pigments, such as lipochromes and carotenoids. Uremic hue usually responds to dialysis, control of hyperparathyroidism, improved calcium and phosphate balance, and, occasionally, ultraviolet radiation. Calciphylaxis, or calcific uremic arteriolopathy, results in painful skin calcification and is often seen in patients with uncontrolled hyperparathyroidism. Use of warfarin is a risk factor for this condition. Nail findings include the half-and-half nail, characterized by red, pink, or brownish discoloration of the distal nail bed, pale nails, and splinter hemorrhages. Other common signs and symptoms are pruritus and ecchymoses due to disorders of bleeding.

DIAGNOSIS

Comprehensive care for the patient with kidney disease includes screening, diagnosis, and treatment of CKD to manage complications and prevent further progression (E-Fig 32-4). Screening for CKD is recommended for patients with high-risk comorbid conditions, including diabetes mellitus and hypertension, and also for those with a family history of kidney disease. The diagnosis of CKD requires evidence of kidney damage that has persisted for at least 3 months. Imaging abnormalities are important, but more commonly CKD is detected by the presence of albuminuria or by reductions in the clearance of toxins by the kidney (i.e., elevated serum creatinine or blood urea nitrogen). Albuminuria may be detected in a spot collection of urine and is best reported as an albumin-to-creatinine ratio (ACR). In general, an ACR greater than 30 mg/g confirmed on several samples and without evidence of urinary infection raises concern for a diagnosis of CKD and warrants additional investigation.

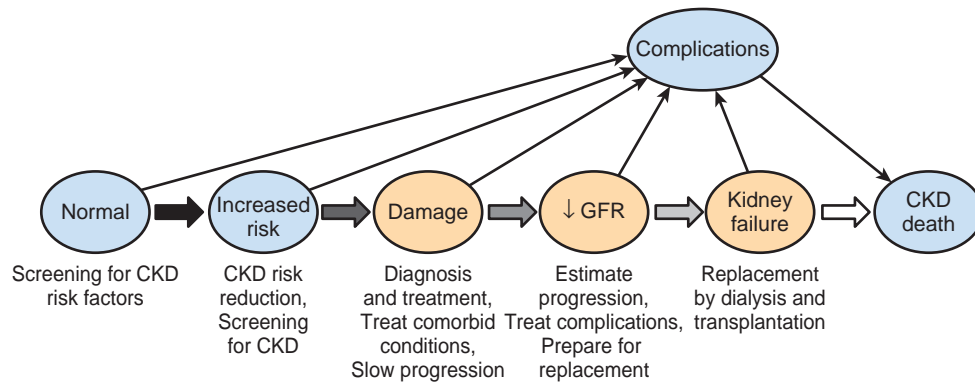

Clearance of toxins by the kidney is most often assessed by the estimated glomerular filtration rate (eGFR). Initial assessment should be performed using a serum creatinine–based estimating equation such as the Modification of Diet in Renal Disease (MDRD) study equation or the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation. Each of these has limitations and cautions regarding application of its results, and a detailed overview can be found in the KDIGO 2012 Clinical Practice Guidelines. The serum biomarker cystatin C may be considered and integrated into another estimating equation for patients who have an eGFR between 45 and 59 mL/min/1.73 m² and may not have albuminuria or kidney imaging abnormalities to confirm evidence of CKD.

Once a diagnosis of CKD is established, management goals include (1) prevention of progression of CKD, (2) identification and treatment of symptoms and complications of CKD, and (3) preparation of patients for RRT if appropriate.

TREATMENT

Prevention of Progression

In addition to treatment of the specific underlying cause of kidney disease, it is important to consider methods to slow the progression of CKD once it is diagnosed. These methods include optimal control of hypertension, diabetes, and other

E-FIGURE 32-4 Approach to care for patients with chronic kidney disease (CKD) and its complications: screening, diagnosis, and treatment. GFR, Glomerular filtration rate. (From National Kidney Foundation: K/DOQI clinical practice guidelines for chronic kidney disease: evaluation, classification, and stratification, Am J Kidney Dis 39[2 Suppl 1]:S1–S266, 2002.)

cardiovascular disease risk factors (e.g., tobacco cessation); use of medications that block the RAAS pathway; diet modifications; avoidance of nephrotoxins; and identification of reversible causes of acute kidney injury in the setting of CKD.

Management of Hypertension and Diabetes

Several controlled trials have demonstrated that treatment of hypertension attenuates the rate of progression of kidney disease. The present recommendation is to target blood pressure to lower than 140/90 mm Hg in patients with diabetes or kidney disease. However, the evidence supporting this recommendation in CKD is limited, and there is debate as to whether a higher target may be acceptable. Medications that block the production or effect of angiotensin II further prevent progression of CKD, beyond control of hypertension, in patients with proteinuria. Dihydropyridine calcium channel blockers have not been shown to be as beneficial as ACE inhibitors or ARBs in slowing CKD progression.

For patients with diabetes mellitus, adequate glycemic control also slows progression of CKD. The recommended goal is to maintain glycosylated hemoglobin (hemoglobin A_{1c}) values less than 7%, irrespective of a concurrent diagnosis of CKD, although this level of glycemic control warrants caution due to hypoglycemic risk (see [Chapter 66](#)). ACE inhibitors and ARBs may be considered, in patients with diabetes and proteinuria who do not have hypertension, to slow CKD progression.

Diet

Dietary protein restriction is advocated to slow progression of CKD. Several meta-analyses have indicated that reduced-protein diets are modestly beneficial to slow CKD progression, but the largest clinical trial, the MDRD study, did not show a significant benefit. The recommended dietary protein intake in advanced CKD is 0.60 g/kg/day with at least 50% of the protein being of high biologic value. The present consensus is that aggressive dietary management in patients with CKD, including proper restriction of sodium, potassium, phosphorus, and protein intake under the supervision of a dietician, may reduce progression of CKD, albeit to a small extent.

Avoidance of Toxic Drug Effects

Many drugs that are excreted by the kidney should be avoided, or their doses should be reduced, as shown in [Table 32-2](#). Drugs may injure the kidney in many ways, including direct toxicity leading to acute tubular necrosis, induction of interstitial nephritis, and development of urinary crystals that obstruct the kidney. Common classes of medications that injure the kidney include antibiotics, specifically aminoglycosides; nonsteroidal anti-inflammatory drugs, including cyclooxygenase 2 (COX2) inhibitors; and antiretroviral medications. Certain over-the-counter herbal medications, including aristolochic acids, can cause CKD. Others, such as St. John's wort, may interact with kidney transplant medications and should be avoided.

Iodinated radiocontrast agents can cause acute worsening of kidney function, especially in patients with CKD. Iso-osmolar contrast agents are less toxic than high-osmolar agents. Patients who are at high risk for contrast-induced kidney injury should

NSAIDs, Nonsteroidal anti-inflammatory drugs.

receive adequate hydration, and the volume of the contrast agent should be minimized. The magnetic resonance imaging contrast agent gadolinium has been associated with the severe fibrotic skin condition of nephrogenic systemic fibrosis in patients with advanced CKD.

Reversible Causes of Acute Deterioration in Kidney Function

The rate of decline in GFR for individual patients is generally log-linear over time. Accordingly, a plot of the reciprocal of the plasma creatinine concentration against time usually predicts the rate at which a specific patient will reach ESRD ([E-Fig. 32-5](#)). When such a patient suddenly shows acute worsening of kidney function, the differential diagnosis should be considered and investigated, as described in [Chapter 31](#) (Acute Kidney Injury).

Care for the Patient with End-Stage Renal Disease

As CKD progresses to kidney failure, preparation is needed for RRT. Patients with moderate CKD should be referred to a nephrologist for comanagement, including evaluation of risk for CKD progression, estimation of timing until kidney failure, and education related to RRT. Late referral (<3 months before ESRD) is associated with a higher risk for death after initiation of RRT.

Renal Replacement Therapies

For those progressing to ESRD, discussions about available RRT options should occur early and should be paired with an assessment of the expectations and values of the patient and other family members. Options include kidney transplantation, dialysis, and medical management without dialysis, sometimes referred to as conservative care. In medically eligible patients, kidney transplantation is encouraged because it allows a better

E-FIGURE 32-5 Use of the reciprocal of plasma creatinine concentration ($1/P_{cr}$) to follow the progress of glomerular disease in a patient. C_{cr} , Creatinine clearance rate. (Data from Sullivan LP, Grantham JJ: Physiology of the kidney, ed 2, Philadelphia, 1982, Lea & Febiger.)

quality of life, increased survival rate, and greater chance for rehabilitation. Kidney transplants may be obtained from deceased or living donors. In the United States in 2011, new kidney transplantations were performed in 15,652 people, although most of these patients (83%) received dialysis before transplantation.

There are two types of dialysis, hemodialysis and peritoneal dialysis. In the United States in 2011, 103,744 patients began hemodialysis, whereas only 7438 (7%) elected peritoneal dialysis. The distribution of patients receiving various modalities differs in other countries. Chronic dialysis is initiated when the patient displays signs of uremia, usually when eGFR is 10 mL/minute or less and there are no apparent reversible causes of kidney failure. However, chronic dialysis may be started at any time when complications of ESRD (e.g., fluid balance, potassium levels) cannot be controlled medically.

Hemodialysis

As illustrated in Figure 32-4, blood is pumped from a vascular access into tubing that leads to a large number of capillary fibers bundled together in a dialyzer (E-Fig. 32-6). These capillaries are made up of semisynthetic materials that are semipermeable and therefore capable of allowing exchange of small molecules between blood and a dialysate solution, permitting countercurrent exchange. The solution contains sodium chloride, bicarbonate, and varying concentrations of potassium. Diffusion through the membrane allows low-molecular-weight substances such as urea and organic acids to move across according to the concentration gradient. Fluid is removed by *ultrafiltration*, which is achieved by applying transmembrane hydrostatic pressure across the dialyzer.

FIGURE 32-4 Essential components of a dialysis delivery system that, together with the dialyzer, make up an *artificial kidney*. In isolated ultrafiltration, no dialysis fluid is used (bypass mode). Also shown is the apparatus for using a single needle for inflow and outflow of blood from the patient. (From Keshaviah PR: Hemodialysis monitors and monitoring. In Maher JF, editor: Replacement of renal Function by dialysis, ed 3, Boston, 1989, Kluwer Academic Publishers.)

In the setting of ESRD, an average patient undergoing *intermittent* chronic hemodialysis requires 4 hours of dialysis three times a week. Common complications include hypotension and muscle cramping. Avoiding excessive fluid weight gain can minimize these complications.

An arteriovenous fistula (AVF) or arteriovenous graft (AVG) is recommended for permanent vascular access for hemodialysis, rather than an indwelling catheter. Although the goal is for more than 74% of prevalent hemodialysis patients to use an AVF or AVG for dialysis access (<http://www.healthypeople.gov/2020/>), many patients continue to use catheters, especially at the time of initiation of chronic hemodialysis. Temporary catheters are placed into the internal jugular, subclavian, or femoral vein, similar to other central venous lines. Permanent catheters have a cuff around the outer wall of the tubing and tunnel under the chest wall skin for some distance before entering the internal jugular vein. Catheters have a higher rate of infection and a higher risk for mortality compared with AVF or AVG.

Peritoneal Dialysis

In peritoneal dialysis, the peritoneal capillaries act as a semipermeable membrane similar to a hemodialysis dialyzer. This technique has several advantages over hemodialysis: it allows independence from the long time spent in dialysis units; it may not require as stringent dietary restrictions compared with hemodialysis; and it allows more patients to return to full-time employment. In *continuous ambulatory peritoneal dialysis*, dialysate of 2- to 3-L volumes is instilled through a peritoneal catheter (E-Fig. 32-7) into the peritoneal cavity for varying amounts of time and exchanged four to six times daily. In *continuous cyclic peritoneal dialysis*, the patient is connected to a machine, referred to as a *cycler*, that allows inflow of smaller volumes of dialysate with shorter dwell time overnight while the patient sleeps. Modifications to this regimen can be made to fit a patient's lifestyle and still achieve adequate clearance of toxins and removal of fluid. Ultrafiltration is achieved through increasing the dextrose concentration in the dialysate.

Two major drawbacks of peritoneal dialysis are peritonitis and difficulty in achieving adequate clearances in patients with excess body mass. Peritonitis can be treated with intraperitoneal antibiotics. Additionally, a slow deterioration occurs in the permeability of the peritoneal membrane, especially after one or more peritonitis episodes, leading to inadequate dialysis and, ultimately, the need to change the modality of RRT.

Kidney Transplantation

Kidney transplantation is the preferred modality of RRT. The variety of available immunosuppressive drugs, including rapamycin, mycophenolate mofetil, anti-interleukin-2 receptor antibodies, and novel agents such as belatacept have resulted in excellent graft survival.

Types of Kidney Transplants

Kidney transplant donors may be deceased or living and related or unrelated to the patient. The 1-year and 5-year graft survival rates are 91% and 71% with a deceased donor, and 97% and 85%, respectively, with a living donor.

E-FIGURE 32-6 Dialyzers for hemodialysis.

E-FIGURE 32-7 Figure demonstrating basic peritoneal dialysis. (Courtesy David Schlosser.)

Advantages and disadvantages of deceased versus living donors are listed in Table 32-3. There is an effort to increase living donation because the deceased donor supply is inadequate. The main advantages of a living related donor transplant are less ischemic injury and better histocompatibility matching (Fig. 32-5). However, with procedures to reduce antibodies, including plasmapheresis and pretransplantation immunosuppressive therapy, it is possible to successfully perform kidney transplantations in patients with high levels of antibodies or even ABO blood group incompatibility with the donor.

TABLE 32-3 COMPARISON OF DONOR SOURCES FOR KIDNEY TRANSPLANTATION

ADVANTAGES	DISADVANTAGES
LIVING DONOR	
Better tissue match with less likelihood of rejection	Small potential risk of operation to donor
Smaller doses of drugs for immunosuppression	Requirement of willing, medically suitable family member or other person
Waiting time for transplant reduced	
Sequelae of long-term dialysis avoided	
Elective surgical procedure	
Better early graft function with shorter hospitalization	
Better short-term and long-term success	
DECEASED DONOR	
Availability to any recipient	Tissue match not as similar
Availability of other organs for combined transplants (i.e., kidney-pancreas transplant)	Waiting time variable
Availability of vascular conduits for complex vascular reconstruction	Operation performed urgently
	Early graft function possibly compromised
	Short-term and long-term success not as good as from living donor

Immunosuppressant Drug Therapy

Prophylaxis against and treatment of graft rejection are at the heart of the success of kidney transplantation. All protocols for immunosuppression aim to disrupt the lymphocyte cell cycle, and many include some period of exposure to corticosteroids. The mechanisms of action of commonly used immunosuppressants are illustrated in Figure 32-6.

The hepatic cytochrome P-450 system is essential for metabolism of cyclosporine, tacrolimus, and rapamycin. Significant changes in the levels of these drugs may occur when patients start or discontinue taking any of several drugs that can induce or inhibit this system. Therefore, evaluation for drug-drug interactions is critical to prevent toxic or even subtherapeutic effects of either the immunosuppressant drug or the other prescribed therapy.

Cyclosporine exerts its activity by inhibiting immunocompetent lymphocytes in the G₀ and G₁ phases of the cell cycle. Side effects of cyclosporine include hematologic suppression,

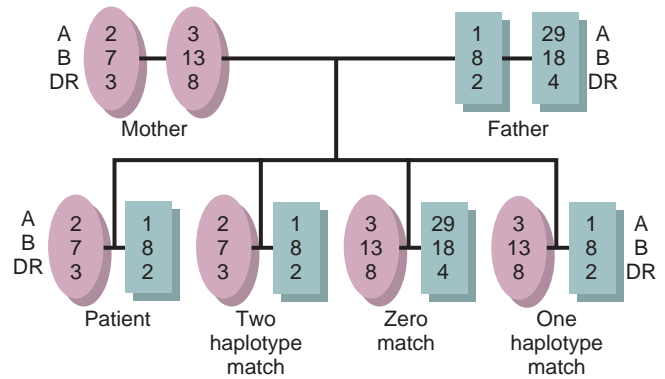

FIGURE 32-5 Diagrammatic representation of possible inheritance of human leukocyte antigen tissue types (A, B, DR) in a family with four siblings.

FIGURE 32-6 Pathways of T-cell activation and sites of action of various immunosuppressive agents. ATG, Antithymocyte globulin; AZA, azathioprine; IL, interleukin; MHC, major histocompatibility complex; MMF, mycophenolate mofetil; mTOR, mammalian target of rapamycin; NFAT, nuclear factor of activated T cells; NF- κ B, nuclear factor- κ B; OKT3, anti-CD3 antibody; TCR, T-cell receptor. G₁, S, and M are phases of the cell cycle.

hyperkalemia, seizures, exacerbation of gout, dyslipidemia, and gingival hypertrophy. The most significant of these effects is nephrotoxicity, and this is often related to decreased glomerular blood flow. *Tacrolimus* has a mechanism of action and side-effect profile similar to those of cyclosporine but with the additional problems of hyperglycemia and an increased tendency toward neurotoxicity. Both cyclosporine and tacrolimus can cause calcineurin inhibitor nephrotoxicity, which may contribute to chronic allograft nephropathy and, ultimately, graft loss.

Mycophenolate mofetil (also called *mycophenolic acid*) specifically inhibits proliferation of T and B lymphocytes by interfering with purine synthesis and thus DNA synthesis. Side effects include anemia and leucopenia as well as gastrointestinal symptoms.

Rapamycin is a macrolide antibiotic produced by the fungus *Streptomyces hygroscopicus*. Rapamycin binds to the mTOR (mammalian target of rapamycin) receptor, thus blocking the phosphorylation of p70 S6 kinase (RBS6KB1) and the eukaryotic initiation factor 4E-binding protein 1 (EIF4EBP1, also known as phosphorylated heat- and acid-stable protein regulated by insulin 1 [PHAS-1]). This action leads to the dampening of cytokine and growth factor activity on T, B, and nonimmune cells. The major side effects are thrombocytopenia and dyslipidemia.

Because of the persistence of episodes of rejection and graft loss over time, novel immunosuppressive agents continue to be developed. Most recently, *belatacept*, a fusion protein that inhibits T-cell activation by blocking the CD80 and CD86 sites on antigen-presenting cells. Clinical trials have established its efficacy and demonstrated a side effect profile similar to those of existing immunosuppression options, leading to its approval for use in the United States and other regions.

Acute Rejection

T lymphocytes recognize foreign antigens, especially when they are presented in association with class II major histocompatibility complex (MHC) antigens. This prompts lymphocyte activation. Activated cytotoxic lymphocytes invade the tubular interstitial region of the transplanted kidney, with resulting tubulitis. Clinically, acute rejection is detected by graft tenderness, a rise in serum creatinine levels, oliguria, and, in some instances, fever. Acute humoral rejection involves the intrarenal arteries and leads to vasculitis, carrying a poor prognosis. This type of rejection is often resistant to steroids, necessitating antilymphocyte and possibly plasmapheresis therapy.

Post-transplantation Infection

Infection is second only to cardiovascular disease as the leading cause of mortality in kidney transplant recipients. Prophylaxis therapies are often used immediately after kidney transplantation to prevent infectious diseases that are of particularly high risk, including *Pneumocystis jirovecii* pneumonia, urinary tract infections, and cytomegalovirus infection. In addition to common community-acquired bacterial and viral infections, kidney transplant recipients are susceptible to numerous viral, fungal, and

other opportunistic infections that usually do not cause severe illness in an immunocompetent host.

Post-transplantation Malignant Disease

Immunosuppression increases the risk of developing malignant disease; this is thought to be, in part, the result of impaired immune surveillance. Skin cancer (mostly squamous cell) has the highest incidence of any type of malignancy among transplant recipients. With continuous surveillance and aggressive management, metastasis from skin cancers is rare. Transplant recipients are also at high risk for development of non-Hodgkin's lymphoma and Kaposi's sarcoma. In addition to age-appropriate screening, cancer surveillance should be an essential part of post-transplantation care.

PROGNOSIS

The prognosis of CKD varies depending on the underlying cause, severity at presentation, and response to therapy. Moreover, CKD in general is a significant risk factor for cardiovascular disease and death. Mortality from cardiovascular disease in CKD patients, especially those with stage 3 to stage 5 disease, is 3.5 times that of an age-matched population (E-Fig. 32-8), accounting for more than 50% of the deaths in ESRD patients. Research to understand the underlying mechanisms and final pathway, as well as those effects specific to patients with unique characteristics, are necessary to advance efforts to reduce related risks and cure kidney disease.

 For a deeper discussion on this topic, please see Chapter 130, "Chronic Kidney Disease," in Goldman-Cecil Medicine, 25th Edition.

Common Clinical Manifestations of Gastrointestinal Disease

M. Michael Wolfe

A. Abdominal Pain

Charles M. Bliss, Jr. and M. Michael Wolfe

DEFINITION AND EPIDEMIOLOGY

Abdominal pain is a frequent manifestation of intra-abdominal disease. However, abdominal pain is difficult to localize or grade because the sensation of pain often is colored by emotional and physical factors. Abdominal pain may be classified as acute or chronic. Acute pain occurs suddenly and more often suggests serious physiologic alterations. Chronic pain may be present for several months; although it does not mandate immediate attention, chronic pain may lead to prolonged evaluation. According to a recent report, abdominal pain is the most common symptom in patients presenting to gastroenterology clinics in the U.S., with almost 16 million estimated visits in 2009 alone. Appropriate evaluation of abdominal pain requires knowledge of pain mechanisms, close attention to history and physical examination findings, and recognition of important accompanying symptoms as well as awareness of the strengths and weaknesses of the tests that might be used.

PHYSIOLOGY

Abdominal pain results from stimulation of receptors specific for thermal, mechanical, or chemical stimuli. Once these receptors are excited, pain impulses travel through sympathetic fibers. Abdominal pain can be characterized as somatic or visceral. Somatic pain originates from the abdominal wall and parietal peritoneum, whereas visceral pain originates in internal organs and from the visceral peritoneum. Two types of neurons carry pain: A fibers, which have rapid conduction, and C fibers, which have slow conduction. Most visceral neurons are of the C type, and the pain resulting from their stimulation tends to be variable with regard to sensation and localization. In contrast, both A and C fibers originate from the parietal peritoneum and abdominal wall, and somatic pain tends to be sharp and distinctly localized.

Because of this pattern of innervation, abdominal viscera are not sensitive to cutting, tearing, burning, or crushing. However, visceral pain results from stretching of the walls of hollow organs or of the capsule of solid organs, as well as from inflammation or ischemia.

CAUSES OF ABDOMINAL PAIN

Multiple intra-abdominal and extra-abdominal disorders can produce abdominal pain. Distinguishing acute from chronic

symptoms is helpful. The approach varies with each specific cause, but acute abdominal pain usually demands prompt intervention.

CLINICAL PRESENTATION

History

The differential diagnosis of abdominal pain, whether acute or chronic, requires thorough history taking with regard to pain characteristics, location and radiation, timing, and the presence of any accompanying symptoms. Recognition of characteristic patterns is essential to narrowing the differential diagnosis.

Pain location often indicates the organ responsible for the problem. For instance, epigastric pain is usually typical of peptic ulcer or dyspepsia, whereas right upper quadrant pain is more suggestive of cholecystitis and other biliary disorders. Early in the course of illness, pain may be perceived in one location and subsequently felt in another; this pattern of progression may be suggestive of specific pain syndromes. In acute cases, abdominal pain tends to be sharp and severe. The pain of a perforated viscus is intense, and the pain from a dissecting aneurysm may be described as tearing or crushing. Chronic pain may be less severe; pain from irritable bowel or dyspepsia is constant and dull, and the pain of chronic peptic ulcer is described as gnawing or hunger pain. The pattern of pain relief is helpful for diagnosing some conditions. The physician should also inquire about whether the pain is steady or intermittent and whether it occurs at night. For nocturnal pain, a distinction should be made between pain that awakens the patient and pain that is felt when the patient wakes up for other reasons.

Table 33-1 outlines characteristics, location, and radiation of pain for a few common acute and chronic abdominal conditions.

Physical Examination

Examination of the abdomen provides valuable clues to the diagnosis, but the examination should start with the general appearance of the patient. A patient who is writhing in bed and unable to find a comfortable position may be suffering from obstruction. In contrast, a patient lying with the lower extremities flexed and

TABLE 33-1 KEY ABDOMINAL PAIN SYNDROMES

CONDITION	TYPE	LOCATION	RADIATION
ACUTE ABDOMINAL PAIN			
Appendicitis	Crampy, steady	Periumbilical, RLQ	Back
Cholecystitis	Intermittent, steady	Epigastric, RUQ	Right scapula
Pancreatitis	Steady	Epigastric, periumbilical	Back
Perforation	Sudden, severe	Epigastric	Entire abdomen
Obstruction	Crampy	Periumbilical	Back
Infarction	Severe, diffuse	Periumbilical	Entire abdomen
CHRONIC ABDOMINAL PAIN			
Esophagitis	Burning	Retrosternal	Left arm, back
Peptic ulcer	Gnawing	Epigastric	Back
Dyspepsia	Bloating, dull	Epigastric	None
IBS	Crampy	LLQ, RLQ	None

IBS, Irritable bowel syndrome; LLQ, left lower quadrant; RLQ, right lower quadrant; RUQ, right upper quadrant.

avoiding any motion may be suffering from peritonitis because movement makes peritoneal pain worse. Abdominal distention indicates obstruction or ascites. Visual inspection for peristalsis is helpful for the diagnosis of small bowel obstruction, but this sign is present only in the early stages. Focal areas of distention may indicate hernias; notice should also be taken of any scars from prior surgeries.

Auscultation should be performed in several areas to evaluate the timbre and pattern of bowel sounds and to search for bruits or hums. Absence of bowel sounds suggests ileus, whereas the presence of hyperactive, high-pitched sounds may indicate obstruction. Multiple bruits alert the examiner to the possibility of significant vascular disease, suggesting ischemia.

The abdomen should be palpated gently, starting in an area away from the pain. The examiner searches for areas of localized tenderness and rebound as well as for masses and enlarged organs. Percussion is performed to identify the size of organs or to determine the presence of ascites. Pain on percussion of the abdomen indicates peritoneal reaction, as does severe rebound tenderness.

A rectal examination is important for identifying a rectal tumor in the case of colon obstruction or tenderness high in the rectum in acute appendicitis. A pelvic examination should be performed in women to rule out pelvic inflammatory disease.

ACUTE ABDOMEN

The evaluation of a patient with an acute abdomen is a challenge in medical practice. The acute abdomen is caused by sudden inflammation, perforation, obstruction, or infarction of an intra-abdominal organ. The urgent question to be answered is whether immediate surgery is needed; a quick but complete evaluation is necessary to avoid undue delay in intervention for patients who require surgery. The physician must assess for abdominal tenderness, rebound, and guarding. Early surgical consultation should be obtained, even in doubtful cases, rather than awaiting confirmation of the diagnosis via laboratory or radiologic studies. However, many extra-abdominal conditions such as pneumonia, myocardial infarction, nephrolithiasis, and metabolic disorders can cause acute abdominal pain.

In some instances of the acute abdomen in its early stages, there are few findings. The examiner should be aware that patients with benign chronic conditions may have severe pain at presentation that is out of proportion to any physical findings. The context provided by the medical history, particularly previous abdominal surgery, is very valuable. Indeed, a patient with sudden crampy pain and abdominal distention may have an intestinal obstruction caused by adhesions or an incarcerated hernia. Therefore, examination of the entire patient, looking for jaundice, skin lesions, evidence of prior surgery, or evidence of chronic liver disease, is important.

In evaluating a patient with acute abdominal symptoms, a complete blood cell count with differential, a urinalysis, and measurements of serum amylase, lipase, bilirubin, and electrolytes are necessary components of the laboratory examination. Additional studies may be done but usually do not aid in the rapid decision making required. An elevated white blood cell count may indicate inflammatory disease, and extremely high values are typical of acute intestinal ischemia. An elevated serum amylase concentration usually indicates acute pancreatitis, although a perforated ulcer or mesenteric thrombosis can also cause hyperamylasemia.

Radiographic examination with an abdominal film is important to reveal the intra-abdominal gas pattern, and an upright film that includes the diaphragm or a left lateral decubitus film may identify intra-abdominal air suggesting perforation of a hollow viscus. Ultrasonography can be helpful in the diagnosis of acute cholecystitis or appendicitis. Computed tomography (CT) scans have become more helpful with technologic improvements in scanners; early CT scans allow prompt diagnosis of sometimes unsuspected abdominal diseases. Examination with a radiopaque medium should be used judiciously, especially if surgery is anticipated. **E-Figures 33-1 through 33-4** are CT images of appendicitis, diverticulitis, pancreatitis, and ulcerative colitis, respectively.

CHRONIC ABDOMINAL PAIN

In the evaluation of chronic abdominal pain, it can be challenging to distinguish between organic pain resulting from a specific pathologic process and functional pain. The location and characteristics of pain, as already discussed, serve as important guides, as do other accompanying symptoms. The presence of postprandial nausea and vomiting suggests chronic peptic ulcer, disorders of gastric emptying, or outlet obstruction. Documentation of weight loss mandates the search for an organic cause, such as inflammatory bowel disease or celiac disease. If anorexia accompanies weight loss, particularly in elderly patients, cancer must be excluded. If no cancer can be found and all objective tests are normal, the possibility of chronic depression must be entertained.

The most frequent causes of chronic abdominal pain are functional. Dyspepsia is characterized by chronic intermittent epigastric discomfort, sometimes accompanied by nausea or bloating. These symptoms are not always relieved by acid suppression and may be the result of an underlying motor disorder. Furthermore, when *Helicobacter pylori* is found in a patient with dyspeptic symptoms, its eradication may not necessarily lead to the resolution of symptoms. Controversy exists regarding the most

effective strategy for the treatment of dyspepsia when *H. pylori* organisms are found in the absence of peptic ulcer disease.

Irritable bowel syndrome (IBS) is a very common disorder. Estimates are that 15% of Americans suffer from IBS on a regular basis and that 40% to 50% of referrals to gastroenterologists are related to IBS. The syndrome consists of abdominal distention, flatulence, and disordered bowel function. The abdominal pain of IBS tends to be in the left lower quadrant, but it can be located elsewhere or be more generalized. Any patient with weight loss, anemia, nocturnal symptoms, steatorrhea, or onset of symptoms after age 50 years should be evaluated carefully for organic disease because these symptoms are not associated with IBS.

The Rome criteria, developed for research studies, may be helpful in the diagnosis of IBS. These criteria include pain that is associated with change in bowel habits, relieved with defecation, or accompanied by distention or bloating. Patients are reassured, counseled, and treated with anticholinergic agents and stool softeners. Although serotonin (5-HT) agonists such as alosetron and tegaserod showed promise initially, they have been relegated to limited use due to unacceptable side effects. Linaclotide is a new agent for chronic constipation and IBS with constipation (IBS-C). This medication causes increased secretion of chloride and bicarbonate into the intestinal lumen via a cyclic guanosine monophosphate (cGMP) pathway. This pathway also may be responsible for relief of visceral pain in patients with IBS-C.

The more challenging clinical problem is *functional abdominal pain syndrome*. This term describes a condition in which the pain has been present for months or years. The complaints of pain often are not related to eating, defecation, or menses, unlike other

causes of chronic pain. The patient is most likely to be a woman who has undergone numerous examinations and diagnostic studies with negative findings and, in many cases, surgical operations without any relief. Lengthy or repeated diagnostic work-ups are counterproductive and only convince the patient that one more test is what is needed to determine the source of the pain. The physician must establish that organic disease is not present and must also realize that the pain is real. These patients are not malingers despite the fact that the pain does not fit any familiar pattern. Depression may be the result rather than the cause of the pain.

Management of chronic abdominal pain is demanding and requires as much tact, diplomacy, and compassion as scientific knowledge. An effort should be made to inquire about social factors, including history of physical and sexual abuse, particularly in women. Psychiatric evaluation may be necessary, but the suggestion for such a consultation may be interpreted by the patient as evidence that the physician believes “the pain is in my head.” Referral to a competent pain management specialist is helpful in some cases. This approach offers the possibility of providing relief with nerve blocks if the pain is localized or with other pain-relieving devices. If this approach fails, referral to a psychologist or psychiatrist may be acceptable to the patient.

The algorithm in [Figure 33-1](#) presents a practical approach to chronic abdominal pain.

B. Gastrointestinal Hemorrhage

D. Roy Ferguson and M. Michael Wolfe

ACUTE GASTROINTESTINAL HEMORRHAGE

Acute gastrointestinal (GI) bleeding remains a common major medical problem despite recent advances in diagnosis and treatment. Bleeding occurs as a complication of many diverse disease processes, and adequate treatment depends on careful assessment and management that focuses on ensuring hemodynamic stability, determining blood loss, and identifying sources of bleeding. Although advances in medical and surgical intensive care, pharmacologic therapy, and the prompt deployment of endoscopic therapies have significantly decreased the rate of rebleeding, the overall mortality rate from acute bleeding episodes has remained essentially unchanged during the past half-century, at about 5% to 10%, owing to an aging population and an increased prevalence of serious concomitant illnesses.

Clinical Presentation

Significant GI bleeding typically manifests with some combination of weakness, dizziness, lightheadedness, shortness of breath, postural changes in blood pressure or pulse, cramping abdominal pain, and diarrhea. The characteristics of the bleeding may help to localize its source to the upper or lower GI tract. Patients with acute bleeding commonly have one of the following symptoms at presentation.

1. *Hematemesis*: The patient vomits bright red blood or material that resembles coffee grounds, representing partially digested blood. After exclusion of swallowed blood from the nasopharynx or the respiratory tract (hemoptysis), the source of bleeding is likely to be proximal to the ligament of Treitz.
2. *Melena*: Black, tarry, usually foul-smelling stools are most often a manifestation of upper GI bleeding; however, a small bowel or proximal colonic source of bleeding may on occasion lead to melanic stools. Volumes as little as 50 to 100 mL of blood in the stomach can result in melena.
3. *Hematochezia*: The passage of bright-red blood or maroon stools per rectum frequently indicates a lower GI source of bleeding. However, 10% to 15% of patients with acute severe hematochezia have an upper GI source of brisk bleeding. This group of patients commonly displays signs of hemodynamic instability.

Etiology

A major early goal is to distinguish between upper and lower GI sources because the management strategies are different. In addition to the symptoms already described, certain aspects of the history and physical examination, the age of the patient, and results of laboratory studies may be suggestive. However, in many patients, the site of bleeding frequently remains uncertain after the initial evaluation. Common sources of acute GI hemorrhage are listed in [Table 33-2](#).

Approach to the Patient with Acute Gastrointestinal Bleeding

Assessment of Vital Signs and Resuscitation

A simple mnemonic for the approach to gastrointestinal bleeding is *SET*: Stabilization, Evaluation (endoscopy), and Treatment. The first goal in management is to *stabilize the patient* and determine the severity of blood loss ([Fig. 33-2](#)). Vital signs with postural changes should be recorded immediately. If the systolic blood pressure drops more than 10 mm Hg or the pulse increases more than 10 beats per minute as the patient changes position from supine to standing, it is likely the patient has lost at least 800 mL (15%) of circulating blood volume. Hypotension, tachycardia, tachypnea, and mental status changes in the setting of acute GI hemorrhage suggest the loss of at least 1500 mL (30%) of circulating blood volume.

The goals of resuscitation are to restore the normal circulatory volume and to prevent complications from red blood cell loss, such as cardiac, pulmonary, renal, or neurologic consequences. Initially, at least two large-bore intravenous catheters are used to administer isotonic solutions (e.g., lactated Ringer's solution, 0.9% NaCl), and blood products if indicated. If the patient is in shock, central venous access should be established. Although the amount of blood to be infused must be individually determined in each case, recent randomized trials and a retrospective review suggest that use of a lower hemoglobin threshold of 7 g/dL, rather than a more liberal level of 9 g/dL, results in improved mortality rates, lower total transfusion requirements, and lower rates of rebleeding in both peptic ulcer bleeding and variceal bleeding in patients in whom early endoscopy (<5 hours) is available. In view of the costs and potential risks of blood transfusion, it is not appropriate to simply transfuse until an arbitrary target hematocrit is achieved. If coagulation studies are abnormal, as is commonly observed in cirrhotic patients, fresh-frozen plasma, platelets, or both may be required to control ongoing hemorrhage.

Initial Evaluation

While resuscitation is underway, the following information should be obtained by history and physical examination to determine the source of bleeding:

1. The nature of the bleeding: melena, hematemesis, hematochezia, or occult blood. A digital rectal examination is essential for determination of stool color and identification of anal fissures or rectal neoplasms.
2. The duration of GI bleeding, which helps dictate the appropriate pace of the evaluation to determine the bleeding source
3. The presence or absence of abdominal pain; for example, hematochezia caused by diverticula or angiodysplasia typically is painless, but hematochezia due to intestinal ischemia it is often accompanied by abdominal pain.

TABLE 33-2 COMMON SOURCES OF ACUTE GASTROINTESTINAL HEMORRHAGE

SOURCE	ASSOCIATED CLINICAL FEATURES	TREATMENTS
UPPER GASTROINTESTINAL TRACT		
Esophagitis	Heartburn, dysphagia, odynophagia	Medication* Antireflux surgery or procedures
Esophageal cancer	Progressive dysphagia, weight loss	Chemoradiotherapy, surgery Palliative endoscopy procedures
Gastritis, gastric ulcer Duodenitis, duodenal ulcer	Aspirin, NSAID use Abdominal pain, dyspepsia, <i>Helicobacter pylori</i> infection	Withdraw NSAIDs Medication [†] Endoscopic therapy for acute bleeding
Gastric cancer Esophagogastric varices	Early satiety, weight loss, abdominal pain History of CLD Stigmata of CLD on examination	Surgery, chemotherapy Variceal banding, sclerotherapy Vasopressin, octreotide TIPS or decompressive surgery
Mallory-Weiss tear	History of retching before hematemesis	Supportive (usually self-limited) Endoscopic therapy
LOWER GASTROINTESTINAL TRACT		
Infection	History of exposure, diarrhea, fever	Supportive, antibiotics
Inflammatory bowel diseases	History of colitis, diarrhea, abdominal pain, fever	Steroids, 5-ASA, immunotherapy Surgery if unresponsive to medication
Diverticula	Painless hematochezia	Supportive Surgery for recurrent disease
Angiodysplasia	Painless hematochezia Often in ascending colon Commonly involves stomach and small bowel as well	Endoscopic therapy Supportive Surgery for localized disease
Colon cancer Colon polyp Ischemic colitis	Change in bowel habit, anemia, weight loss Usually asymptomatic Typically elderly patients History of vascular disease May produce abdominal pain	Surgery Endoscopic or surgical removal Supportive (self-limited)
Meckel's diverticulum Hemorrhoids	Painless hematochezia in young patient Located at distal ileum Rectal bleeding associated with bowel movement	Surgery Supportive Surgery, banding

CLD, Chronic liver disease; NSAIDs, nonsteroidal anti-inflammatory drugs; TIPS, transjugular intrahepatic shunt; 5-ASA, 5-aminosalicylic acid compounds.

*Proton pump inhibitors or histamine-2 receptor antagonists.

[†]Proton pump inhibitors or histamine-2 receptor antagonists in the absence of *H. pylori* infection; various combinations of antibiotics, proton pump inhibitors, and bismuth products in the presence of *H. pylori* infection.

- Other associated symptoms, including fever, urgency or tenesmus, recent change in bowel habits, and weight loss
- Current or recent medication use, particularly nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, which may predispose to ulceration or gastritis (see Chapter 37), anticoagulants, and alcohol. Many over-the-counter products may contain aspirin or NSAIDs.
- Relevant past medical and surgical history, including a history of prior GI bleeding, abdominal surgery (prior abdominal aorta repair should raise suspicion for an aortoenteric fistula), radiation therapy (radiation proctitis), major organ diseases (including cardiopulmonary, hepatic, or renal disease), inflammatory bowel diseases, and recent polypectomy (post-polypectomy bleeding).

The physical examination must include an assessment of vital signs, cardiac and pulmonary examinations, and abdominal and digital rectal examinations. The initial laboratory examination should include a complete blood cell count, blood typing and cross-matching, and measurements of serum electrolytes, blood urea nitrogen, creatinine, and coagulation factors. The first hematocrit measurement may not reflect the degree of blood loss, but it will decrease gradually to a stable level over 24 to 48 hours.

The initial disposition of the patient must also be considered. Patients older than 60 years of age, those with severe blood loss

or continued bleeding (as reflected by a significant decrease in hematocrit or postural changes in blood pressure or pulse rate), and those with significant comorbid illness are at the greatest risk for complications of GI hemorrhage and are best managed in an intensive care setting until stabilized.

Identification of the Bleeding Source

In 80% to 90% of cases, acute GI hemorrhage resolves spontaneously without recurrence. Nevertheless, it is prudent to localize the bleeding source, especially in those with significant bleeding or comorbidities. Proper identification allows for direct treatment if the bleeding does not spontaneously resolve and for recognition of those patient who are at risk for further bleeding. For example, in a patient with a bleeding gastric or duodenal ulcer, acid suppression with an intravenous proton pump inhibitor may maximize clot stability and enhance platelet aggregation. Proton pump inhibitors, in combination with appropriate endoscopic management, decrease the risks for ulcer rebleeding, need for urgent surgery, and death. Direct visualization of the bleeding site by endoscopy can alter patient management.

Classification systems, such as the Forrest Ulcer Description or the Rockall Scoring System, rely heavily on endoscopic criteria for rebleeding risk stratification. Various stigmata of hemorrhage may be identified within the ulcer crater. Stigmata that carry a high risk for rebleeding include active bleeding (Forrest 1) and the visible presence of a pigmented protuberance (artery) within

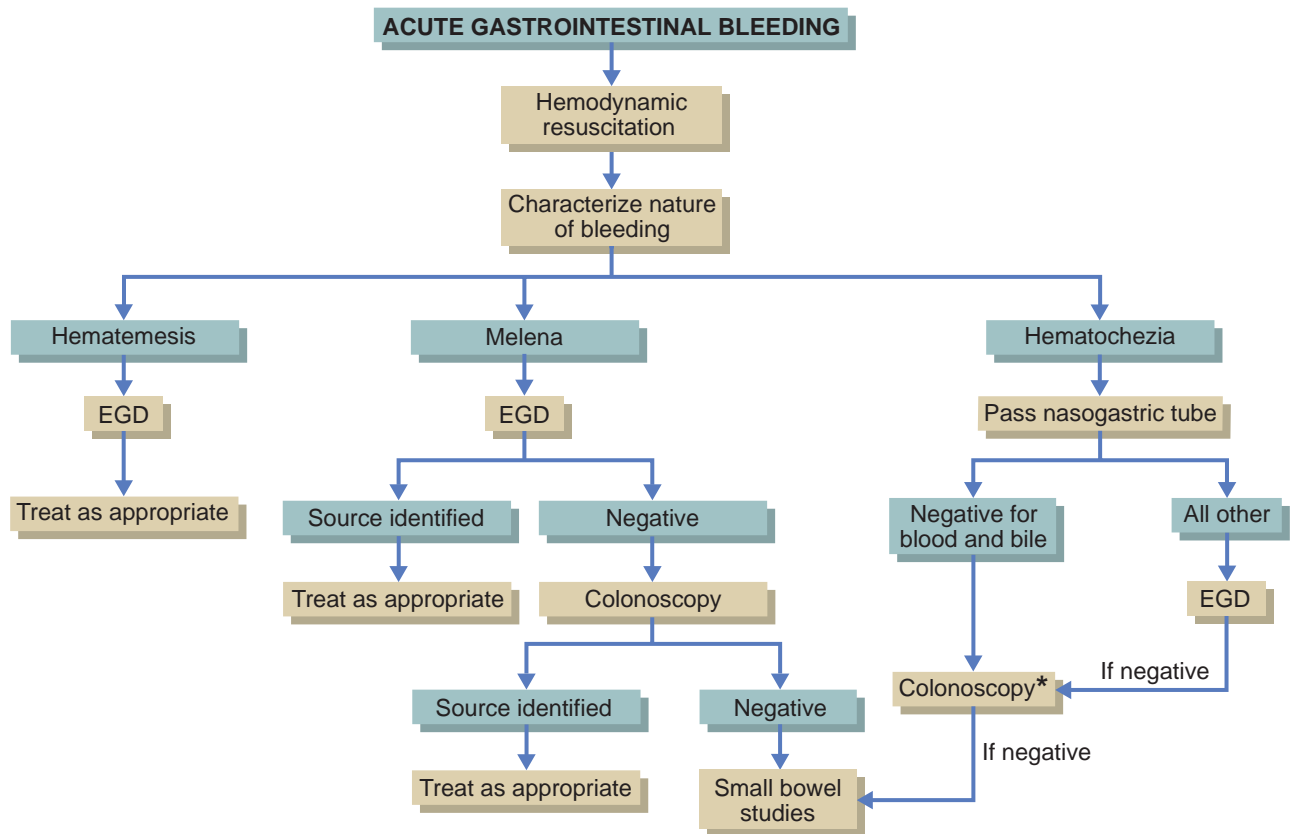

FIGURE 33-2 Approach to the patient with acute gastrointestinal bleeding. EGD, Esophagogastroduodenoscopy. *If severe bleeding prevents endoscopic visualization, arteriography may be performed.

the ulcer crater (Forrest 2). The patient with a “clean base” ulcer exhibiting no such stigmata has an excellent prognosis for cessation of bleeding. Patients found to have high-risk stigmata are likely (~50%) to have continued or recurrent bleeding. In such patients, the site of bleeding may be treated by injection therapy with vasoconstrictors or saline, thermal therapy by electrocautery, or mechanical therapy by placement of endoscopic clips. These endoscopic therapies decrease rates of rebleeding, mortality, need for transfusion, need for surgery, and length of hospital stay. Thermal or mechanical therapy, applied alone or in combination with injection therapy, is more effective than injection therapy alone. Recently developed alternatives, such as hemostatic sprays and cyanoacrylate compounds, offer additional modalities that can be used in such cases.

An overall approach to the patient with acute GI bleeding is outlined in Figure 33-2. Historical points and objective findings often enable localization of the bleeding site to the upper GI tract (proximal to the ligament of Treitz) or to the lower GI tract (distal to that point). For the patient with melena or hematemesis, the upper GI tract should be examined first. Patients with hematochezia more commonly have lower GI bleeding, but when the pace of bleeding is brisk, an upper GI tract lesion may manifest with hematochezia. Placement of a nasogastric tube with aspiration of contents is a reasonable first step. The absence of blood does not by itself rule out the presence of an upper GI source because blood from a duodenal bulb ulcer may not flow back into the stomach to allow sampling by the nasogastric tube. In general, in patients with acute GI hemorrhage who have

significant blood loss, an upper endoscopy should be the initial step in the evaluation.

Once the lower GI tract has been identified as the source of bleeding, sigmoidoscopy or colonoscopy is the test of choice. In cases of lower GI bleeding in which the pace of bleeding is so brisk as to preclude endoscopic visualization of the colon and rectum, scintigraphic erythrocyte scans using technetium-99m (^{99m}Tc)-labeled sulfur colloid or pertechnetate can localize the bleeding site if the rate of blood loss exceeds 0.5 mL/minute. Although the bleeding site identified by scintigraphic examination may not be accurate, it will direct the visceral arteriographic search while minimizing the amount of dye used. The recent description of capsule endoscopy followed by directed push or balloon enteroscopy has provided a possible endoscopic means of delineating and controlling bleeding lesions in the small bowel. There is *no* role for barium studies in the evaluation of acute GI hemorrhage.

CHRONIC GASTROINTESTINAL HEMORRHAGE

Chronic GI bleeding is a diagnostic challenge. It can manifest as self-limited, recurrent episodes of melena or hematochezia, but usually without the degree of hemodynamic compromise discussed earlier. Some patients have no overt evidence of blood loss but rather have persistent anemia and persistent occult blood loss. The evaluation of this condition differs from that of acute GI hemorrhage; the pace of the evaluation is less urgent, and the likely causes of bleeding differ from those associated with acute GI bleeding.

Patients with this condition usually have undergone upper and lower endoscopy at least once without identification of a bleeding source. Therefore, the bleeding must be from a source that is difficult to identify or one that emanates from the small intestine. The small intestine is a difficult area to examine because of its length and configuration. In general, the small intestine is initially evaluated radiographically. The patient may ingest barium, which is followed through the length of the small intestine. To distend the small bowel and provide greater mucosal detail, an enteroclysis tube may be placed with its distal tip near the ligament of Treitz, allowing more forceful administration of barium and air. However, computed tomography and magnetic resonance enterography are rapidly replacing fluoroscopic imaging. All

these imaging techniques have limited diagnostic utility. Flat mucosal lesions such as vascular ectasias, a common cause of obscure bleeding, may easily be missed.

If radiographic studies are unrevealing, endoscopic evaluation of the small bowel may be attempted by capsule endoscopy or with push or balloon enteroscopy (see [Chapter 34](#)). For the patient with persistent blood loss, no endoscopically identified source of bleeding in the upper GI tract or colon, and negative findings on radiologic studies, the entire small intestine may be examined at laparotomy with endoscopy in the operative suite. In addition, angiographic evaluation of the whole GI tract may reveal the source of chronic blood loss.

C. Malabsorption
