THE TRANSPLANTATION AND REPLACEMENT OF THORACIC ORGANS

The present status of biological and mechanical replacement of the heart and lungs

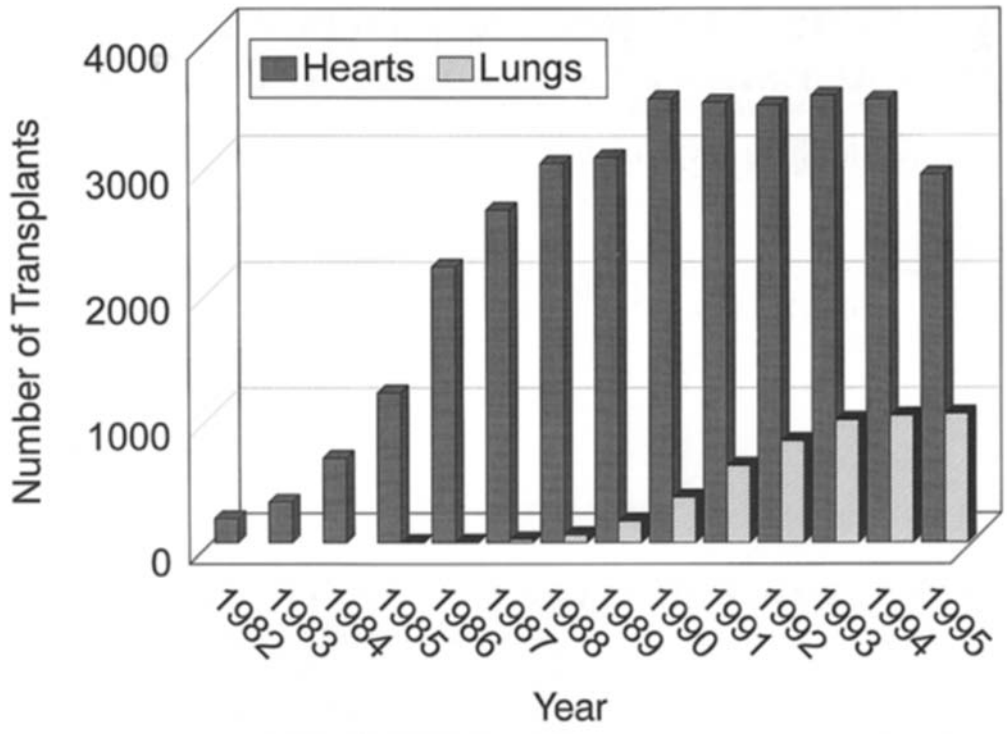
Second Edition

Edited by D.K.C. Cooper, L.W. Miller and E.A. Patterson

THE TRANSPLANTATION AND REPLACEMENT OF THORACIC ORGANS

The Present Status of Biological and Mechanical Replacement of the Heart and Lungs

SECOND EDITION



The number of heart and lung (single and double) transplants reported annually to the Registry of the International Society for Heart and Lung Transplantation from 1982 to 1995, inclusive (Courtesy J.D. Hosenpud, MD, Director, ISHLT Registry). The number of heart transplants performed worldwide reached a plateau in 1990 and, indeed, may have declined slightly in 1995 (although the figure for this year is not yet complete). The number of lung transplants performed worldwide has not increased significantly since 1993.

THE TRANSPLANTATION AND REPLACEMENT OF THORACIC ORGANS

The Present Status of Biological and Mechanical Replacement of the Heart and Lungs

Second Edition

Contents

Foreword: *Christiaan N. Barnard* *ix*

Preface *xi*

Contributing authors *xiii*

Acknowledgments – Personal *xix*

Acknowledgments – Journals *xx*

SECTION 1: GENERAL CONSIDERATIONS OF THORACIC ORGAN TRANSPLANTATION

1 The concept and diagnosis of brain death *1*
E.G. Warner

2 Medico-legal aspects *5*
S.S. Sanbar

3 Donor organ availability and transplant coordination *11*
J.S. Chaffin and *L. Mischke*

4 Selection and management of the donor *19*
D.K.C. Cooper and *I.L. Paradis*

5 Selection and evaluation of the potential thoracic organ transplant recipient – general considerations *35*
D.K.C. Cooper, N.K. Imes and *D.P. Nelson*

6 Pretransplant immunological considerations *43*
E.D. du Toit, M. Oudshoorn and *D.M. Smith*

7 Immunobiology of allograft destruction *57*
M.H. Sayegh and *D.R. Salomon*

8 Maintenance immunosuppressive drug therapy and potential major complications *69*
K.L. Tyndall and *D.K.C. Cooper*

9 Trends in immunosuppressive therapy with regard to cytolytic induction therapy and corticosteroid withdrawal *85*
J.A. Kobashigawa

10 Tacrolimus (FK506) in thoracic organ transplantation *89*
J.S. Gammie and *S.M. Pham*

11 Infection in patients undergoing thoracic organ transplantation: epidemiology, pathogenesis, and clinical management *97*
S.J. Thaler and *R.H. Rubin*

12 Malignant neoplasia in the immunocompromised patient *111*
I. Penn

13 Long-term management and late complications of the thoracic organ transplant recipient *119*
D.P. Nelson, N.K. Imes and *D.K.C. Cooper*

14 Psychiatric aspects *131*
E.S. Nash and *D.K.C. Cooper*

15 Medico-social aspects *137*
W.D. Paris, S.E. Thompson, N.J. Brawner, M.L. Penido, M.J. Bright, C.M. Robertson

16 Nutrition and diet *141*
M. Kanoski

17 A commentary on quality of life after thoracic organ transplantation *149*
M.M. Edgar

SECTION 2: HEART TRANSPLANTATION

18 Experimental development and early clinical experience *153*
D.K.C. Cooper

19 Selection and management of the potential candidate for cardiac transplantation *161*
L.W. Stevenson

20 The problem of pulmonary hypertension in the potential cardiac transplant recipient *177*
J.M. Chen and *R.E. Michler*

21 Mechanical circulatory support before heart transplantation *185*
J.S. Sapirstein and *W.E. Pae Jr.*

22 Anesthetic management, including cardiopulmonary bypass *195*
J.V. Booth, D.R. Wheeldon and *S. Ghosh*

23 Current techniques of myocardial protection for cardiac transplantation *199*
S. Aziz and *A.L. Panos*

24 Surgical technique of orthotopic heart transplantation. 1: Standard approach *207*
D.K.C. Cooper

25 Surgical technique of orthotopic heart transplantation. 2: Bicaval 'total' approach *215*
G. Dreyfus

26 Immediate postoperative care and potential complications *221*
D.K.C. Cooper and *N.M. Lidsky*

27 Physiology and pharmacology of the transplanted heart *229*
J.B. Young

28 Pathology of cardiac allograft rejection. 1: Vascular (microvascular) *239*
E.H. Hammond

29 Pathology of cardiac allograft rejection. 2: Acute cellular *253*
A.G. Rose

30 Clinical diagnosis of acute rejection *265*
M.R. Costanzo

31 Treatment of cardiac allograft rejection *275*
L.W. Miller

32 Infection in relation to thoracic transplantation *281*
K. Love

33 Pathology of cardiac allograft vasculopathy (chronic rejection) *313*
A.G. Rose

34 Pathogenesis of cardiac allograft vasculopathy (chronic rejection) *321*
B. Arkonac and *J.D. Hosenpud*

35 Diagnosis and management of cardiac allograft vasculopathy (chronic rejection) *333*
L.W. Miller, T. Donahue, T. Wolford and *J. Drury*

36 Cardiac retransplantation – indications and results *347*
S. Taniguchi and *D.K.C. Cooper*

37 Heterotopic heart transplantation – indications, surgical techniques and special considerations *353*
D.K.C. Cooper and *S. Taniguchi*

38 Heart transplantation in infants and children – indications, surgical techniques and special considerations *367*
C.B. Huddleston

39 Exercise rehabilitation of cardiac transplant recipients *379*
E.W. Derman, K.L. Derman and *T.D. Noakes*

40 Non-cardiac surgery in patients with heart transplants – anesthetic and operative considerations *391*
E. Becerra and *D.K.C. Cooper*

41 Recurrence of myocardial disease in the transplanted heart *395*
A.M. Keogh

42 Quality of life after heart transplantation *405*
C.E. Skotzko

43 Results of cardiac transplantation and factors influencing survival based on the Registry of the International Society for Heart and Lung Transplantation and the Cardiac Transplant Research Database *409*
M.P. Cinquegrani and *J.D. Hosenpud*

44 Results of cardiac transplantation and factors influencing survival based on the Collaborative Heart Transplant Study *417*
G. Opelz

SECTION 3: LUNG AND HEART–LUNG TRANSPLANTATION

45 Lung transplantation – experimental background and early clinical experience *429*
J.D. Hardy

46 Indications, selection and pretransplant management of the potential recipient *433*
J.R. Maurer

47 A comment on pretransplant management of the potential lung recipient *443*
N.K. Imes

48 Excision and storage of the donor lungs *445*
S. Keshavjee and *T.R. Todd*

49 Anesthesia for lung transplantation *451*
W.A. Demajo

50 Surgical techniques of single and bilateral lung transplantation *457*
H.A. Gaissert and *G.A. Patterson*

51 Lung size and impact on lung transplantation *465*
T.M. Egan

52 The split-lung technique for lobar transplantation *471*
J-P.A. Couetil

53 Postoperative management of the single lung transplant patient *479*
R.C. Daly and *C.G.A. McGregor*

54 Physiology and pharmacology of the transplanted lung *489*
R.E. Girgis, R. Fishman and *J. Theodore*

55 Histopathology of lung transplantation *505*
N.P. Ohori and *S.A. Yousem*

56 Diagnosis and management of acute rejection *517*
F.M. Wagner and *H. Shennib*

57 Infection after lung transplantation *527*
I.L. Paradis

58 Management of complications of the airway *543*
H. Date and *G.A. Patterson*

59 Diagnosis and management of bronchiolitis obliterans *547*
J.M. Kriett and *S.W. Jamieson*

60 Pulmonary retransplantation for obliterative bronchiolitis *557*
R.J. Novick, H-J. Schäfers, L. Stitt, B. Andréassian, W. Klepetko, R.L. Hardesty, A.E. Frost and *G.A. Patterson*

61 Lung transplantation for cystic fibrosis *565*
T.M. Egan

62 Lung transplantation in infants and children – indications, surgical techniques, and special considerations *573*
J.E. Davis and *V.A. Starnes*

63 Airway complications in children following lung transplantation *581*
C.B. Huddleston

64 Living donor lobar lung transplantation *589*
J.E. Davis and *V.A. Starnes*

65 Results of lung transplantation and factors influencing survival based on the St Louis Lung Transplant Registry *595*
M. Pohl and *J.D. Cooper*

66 Transplantation of the heart and both lungs – experimental background and early clinical experience *599*
E. Becerra, J. Kaplan and *D.K.C. Cooper*

67 Transplantation of the heart and both lungs – indications, selection and evaluation *605*
V.R. Kshettry and *R.M. Bolman III*

68 Transplantation of the heart and both lungs – organ procurement and recipient surgical techniques *609*
V.R. Kshettry and *R.M. Bolman III*

69 Lung and heart–lung transplantation: a review of progress and current status based on the Registry of the International Society for Heart and Lung Transplantation *621*
G.B. Haasler and *J.D. Hosenpud*

SECTION 4: CURRENT AND FUTURE ADVANCES IN THORACIC ORGAN REPLACEMENT

Advances in Control of the Immune Response

70 New pharmacologic immunosuppressive agents *635*
S. Trehan, D.O. Taylor and *D.G. Renlund*

71 New monoclonal antibodies *661*
M.R. Costanzo

72 Immunomodulation with photopheresis *665*
M.L. Barr

73 Gene transfer *669*
A. Ardehali, H. Laks and *A. Fyfe*

Advances in Thoracic Organ Storage

74 Advances in heart storage *675*
W.N. Wicomb, V.F. Portnoy and G.M. Collins

75 Advances in lung storage *689*
G. Speziali, R.C. Daly and *C.G.A. McGregor*

Advances in the Development of Temporary and Permanent Mechanical Devices

76 Permanent cardiac replacement by a total artificial heart: experimental background and current problems *693*
W.J. Kolff

77 Early clinical experience with permanent cardiac replacement by a mechanical device *703*
D.K.C. Cooper

78 Long-term cardiac support with the HeartMate vented electric left ventricular assist system *709*
T.J. Myers and *O.H. Frazier*

79 Temporary support of the lungs – the artificial lung *717*
W. Federspiel, P. Sawzik, H. Borovetz, G.D. Reeder, B.G. Hattler

Advances in Thoracic Organ Xenotransplantation

80 Xenotransplantation of the heart 729
D.K.C. Cooper

81 Pathology of cardiac xenograft rejection 737
A.G. Rose

82 Clinical experience with cardiac xenotransplantation 743
S. Taniguchi and *D.K.C. Cooper*

83 Xenotransplantation of the lung 749
R.N. Pierson III

Advances in Biological Augmentation of the Failing Myocardium

84 Cardiomyoplasty – skeletal muscle assist 753
J.A. Magovern and *R.C. Reddy*

85 Blood pumps constructed from skeletal muscle 759
K.A. Greer, D.R. Anderson and L.W. Stephenson

86 Dynamic cardiomyoplasty: multicenter clinical trials 767
B.D. Mott, L.L. Austin and R.C-J Chiu

87 Cultured cardiomyocytes 775
F.W. Smart, W. Claycomb, J. Delcarpio and C. Van Meter

88 Myocardial regeneration with skeletal muscle satellite cells 785
G.J. Magovern Sr.

Advances in Alternative Surgical Therapy to Lung Transplantation

89 Lung volume reduction surgery in patients with emphysema 789
W. Klepetko, E. Tschernko, W. Wisser and *T. Wanke*

90 Pulmonary endarterectomy – treatment of choice for patients with pulmonary hypertension due to emboli 797
S.W. Jamieson

Index 807

Foreword

It is a great pleasure for me to contribute a few words as an introduction to the second edition of this volume, first published in 1990 when it was edited by David Cooper and Dimitri Novitzky. The first edition was, in fact, a greatly expanded version of an even earlier volume *Heart Transplantation*, edited by David Cooper and Robert Lanza and published in 1984. This first work, authored by members of the medical staff of Groote Schuur Hospital and the University of Cape Town Medical School, was, I believe, the first volume reviewing this relatively new field of medicine.

The present volume, therefore, continues the documentation of the development of the transplantation and replacement of intrathoracic organs begun over a decade ago by the editors of the original volume. The pace of advance during the past 10 years has been considerable, as evidenced by the excellent results being achieved by many heart transplant centers and the ever improving results of lung transplantation and the functioning of mechanical cardiac assist devices.

The current editors bring a wealth of expertise and experience to their task, and have blended together absolutely superb contributions by many of the world's experts in their fields. This comprehensive and highly readable volume documents the present 'state of the art' in the field of transplantation and replacement of thoracic organs. It provides an invaluable and unparalleled source of information for those concerned with heart and lung medicine or surgery, and is essential reading for all who wish to keep abreast of developments in this field.

March, 1996

Christiaan N. Barnard
Cape Town, South Africa

Preface

The second edition of this volume reflects the major developments that have taken place in the field of thoracic organ transplantation and replacement since the first edition was published in 1990. With the exception of the 'historical' chapters, every chapter has been extensively rewritten and updated and many new chapters have been added.

In particular, with the rapid growth of single and bilateral lung transplantation, these topics have required considerably more attention and space. In contrast, relatively less space has been devoted to the field of transplantation of the heart and both lungs, where activity has declined significantly in recent years. Similarly, the increasing importance of left ventricular assist devices, and the decreasing clinical activity relating to the total artificial heart, are also reflected in the text.

In a comprehensive work of this nature, some topics are inevitably addressed by more than one author. We make no apology for any such duplication as it almost always relates to topics of great importance, where the opinions of more than one expert are valuable. For example, the subject of infection following thoracic organ transplantation is reviewed by recognized experts in three different chapters which, between them, provide an unparalleled review of this increasingly important field. Several other topics, such as aspects of cardiac allograft vasculopathy and the newer immunosuppressive agents, are also discussed by more than one author, who together provide the reader with comprehensive overviews of these subjects.

Considerable emphasis has been placed on the current experimental and clinical developments taking place in both the transplantation and the mechanical replacement of thoracic organs, thus providing a preview of the clinical advances that are anticipated within the next few years.

In summary, this volume provides by far the most comprehensive review of this subject that has been published to-date. For those entering this field of medicine, this work will provide a sound and extensive basis of information; for those already experienced, we hope it will prove an invaluable source of reference and update for many years to come.

List of Contributing Authors

Anderson, David R., M.A., M.B., B. Chir, F.R.C.S. (Ed).
Division of Cardiothoracic Surgery, Wayne State University School of Medicine, Detroit, Michigan, USA (Currently, Consultant Cardiothoracic Surgeon, Guy's Hospital, London, UK)

Andréassian, Bernard, M.D.
Chief, Thoracic and Vascular Surgery Service, Hôpital Beaujon, Clichy, France

Ardehali, Abbas, M.D.
Chief Resident, Division of Cardiothoracic Surgery, Department of Surgery, UCLA Medical Center, Los Angeles, California, USA

Arkonac, Burak M., M.D.
Postdoctoral Fellow, Department of Cardiology, Medical College of Wisconsin, Milwaukee, Wisconsin, USA (Currently, Postdoctoral Fellow, Cardiovascular Biology Laboratory, Harvard School of Public Health, Boston, Massachusetts, USA)

Austin, Lorinda L., R.N., B.S.N.
Worldwide Clinical Manager for Cardiac Assist Venture, Medtronic, Inc., Minneapolis, Minnesota, USA

Aziz, Salim, M.D.
Associate Professor, Division of Cardiothoracic Surgery, University of Washington Medical Center, Seattle, Washington, USA

Barr, Mark L., M.D.
Associate Professor of Surgery, Co-Director, Cardiothoracic Transplantation, and Director, Cardiothoracic Surgical Research, Division of Cardiothoracic Surgery, University of Southern California, Los Angeles, California, USA

Becerra, Eduardo, M.D.
Cardiothoracic Surgeon, Hospital Gustavo Fricke, Viña Del Mar, Chile. Formerly, Senior Registrar, Department of Cardiothoracic Surgery, Groote Schuur Hospital, Cape Town, South Africa

Bolman, R. Morton III, M.D.
C Walton and Richard C Lillehei Professor of Cardiovascular and Thoracic Surgery, Department of Surgery, and Chief, Division of Cardiovascular and Thoracic Surgery, University of Minnesota, Minneapolis, Minnesota, USA

Booth, John V., M.B., Ch.B., F.R.C.A.
Clinical Fellow in Cardiothoracic Anaesthesia, Cardiothoracic Surgical Unit, Papworth Hospital, Papworth Everard, Cambridge, UK

Borovetz, Harvey S., Ph.D.
Professor of Surgery, Biotechnology and Bioengineering Center, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania, USA

Brawner, Nancy J., ACSW.
Clinical Social Worker, Private Practice, Oklahoma City, Oklahoma, USA

Bright, M. Jane, MSW.
Clinical Transplant Social Worker, The Toronto Hospital, Toronto, Ontario, Canada

Chaffin, John S., M.D.
Cardiothoracic Surgeon, Oklahoma Transplantation Institute, Baptist Medical Center, Oklahoma City, Oklahoma, USA

Chen, Jonathan M., M.D.
Postdoctoral Research Scientist, Department of Surgery, Columbia University College of Physicians and Surgeons, New York, New York, USA

Chiu, Ray C-J., M.D., Ph.D., F.R.C.S. (C).
Professor and Chairman, Division of Cardiovascular and Thoracic Surgery, McGill University, The Montreal General Hospital, Montreal, Quebec, Canada

Cinquegrani, Michael P., M.D.
Associate Professor, Co-Director, Cardiac Intervention Program, and Director, Coronary Care Unit, Division of Cardiology, Medical College of Wisconsin, Milwaukee, Wisconsin, USA

Claycomb, William, Ph.D.
Professor of Biochemistry and Molecular Biology, Ochsner Medical Institutions, New Orleans, Louisiana, USA

Collins, Geoffrey M., M.B., M.S., F.R.C.S.
Director of Transplantation, California Pacific Medical Center, San Francisco, California, USA

Cooper, David K.C., M.A., Ph.D., M.D., M.S., F.R.C.S.
Immunologist (Surgery) and Lecturer on Surgery, Transplantation Biology Research Center, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts, USA, and Associate Member, Scientific Staff, Oklahoma Medical Research Foundation, Oklahoma City, Oklahoma, USA. Formerly, Cardiothoracic Transplant Surgeon, Director of Research and Education, and Scientist-in-Residence, Oklahoma Transplantation Institute, Baptist Medical Center, Oklahoma City, Oklahoma, USA

Cooper, Joel D., M.D.
Professor of Surgery and Head, Section of Thoracic Surgery, Division of Cardiothoracic Surgery, Washington University School of Medicine, St. Louis, Missouri, USA

Costanzo, Maria Rosa, M.D.
John H. and Margaret V. Krehbiel Professor of Cardiology, and Medical Director, Rush Heart Failure and Cardiac Transplantation Program, Rush-Presbyterian-St. Luke's Medical Center, Chicago, Illinois, USA

Couetil, Jean-Paul A., M.D.
Cardiothoracic Surgeon and Director of the Lung Transplantation Program, Department of Cardiovascular Surgery, Hôpital Broussais, Paris, France

Daly, Richard C., M.D.
Assistant Professor of Surgery, Mayo Medical School, and Consultant in Thoracic and Cardiovascular Surgery and Cardiothoracic Transplantation, Mayo Clinic, Rochester, Minnesota, USA

Date, Hiroshi, M.D.
Lung Transplant Fellow, Division of Cardiothoracic Surgery, Washington University School of Medicine, St. Louis, Missouri, USA

Davis, James E., M.D.
Pediatric Cardiothoracic Research Fellow, University of Southern California School of Medicine, Los Angeles, California, USA

Delcarpio, Joseph, Ph.D.
Associate Professor of Anatomy, Oschner Medical Institutions, New Orleans, Louisiana, USA

Demajo, Wilfred A., M.D., F.R.C.A., F.R.C.P. (C).
Assistant Professor of Anaesthesia, The University of Toronto, and Director, Medical/Surgical Intensive Care Unit, The Toronto Hospital, Toronto, Ontario, Canada

Derman, E. Wayne, M.B., Ch.B., B.Sc. (Med) (Hons), Ph.D., F.A.C.S.M.
Senior Lecturer, and Director, Chronic Disease Rehabilitation Program, Sports Science Institute of South Africa, Department of Physiology, University of Cape Town Medical School, Cape Town, South Africa

Derman, Kirsten L., B.Sc. (Med) (Hons), M.Sc. (Med).
Research Assistant, Medical Research Council/University of Cape Town Bioenergetics of Exercise Research Unit, Sports Science Institute of South Africa, Department of Physiology, University of Cape Town Medical School, Cape Town, South Africa

Donahue, Thomas J., M.D.
Associate Professor of Medicine, J.G. Mudd Cardiac Catheterization Laboratory, Division of Cardiology, Department of Internal Medicine, St. Louis University Health Sciences Center, St. Louis, Missouri, USA

Dreyfus, Gilles D., M.D.
Professor of Cardiovascular Surgery, Université Paris V–René Descartes, Hôpital Foch, Suresnes, Paris, France

Drury, John H., M.D.
Clinical Fellow, J.G. Mudd Cardiac Catheterization Laboratory, Division of Cardiology, Department of Internal Medicine, St. Louis University Health Sciences Center, St. Louis, Missouri, USA

du Toit, Ernette D., M.D.
Professor and Head, Provincial Laboratory for Tissue Immunology, University of Cape Town Medical School, Cape Town, South Africa

Edgar, Max M., Ph.D.
Health Science Psychologist, Oklahoma City, Oklahoma, USA

Egan, Thomas M., M.D., M.Sc.
Associate Professor of Surgery, and Director, Lung Transplant Program, Division of Cardiothoracic Surgery, School of Medicine, The University of North Carolina, Chapel Hill, North Carolina, USA

Federspiel, William J., Ph.D.
Assistant Professor of Surgery, Biotechnology and Bioengineering Center, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania, USA

Fishman, Robert, M.D.
Assistant Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Department of Medicine, Stanford University School of Medicine, Palo Alto, California, USA

Frazier, O. Howard, M.D.
Professor of Surgery and Chief, Division of Cardiovascular and Thoracic Surgery, University of Texas – Houston Medical School. Chief, Cardiopulmonary Transplantation, St. Luke's Episcopal Hospital, and Director, Surgical Research, Cullen Cardiovascular Research Laboratories, Texas Heart Institute, Houston, Texas, USA

Frost, Adaani E., M.D.
Associate Professor, Pulmonary Section, Department of Medicine, Baylor College of Medicine, and Medical Director, Pulmonary Transplant Program, Methodist Hospital, Houston, Texas, USA

Fyfe, Alistair I., M.D., Ph.D.
Assistant Professor of Medicine/Cardiology, and Director, Center for Cholesterol and Lipid Management, Division of Cardiology, Department of Medicine, UCLA School of Medicine, Los Angeles, California, USA

Gaissert, Henning A., M.D.
Assistant Professor of Surgery, Brown University, Providence, Rhode Island, USA

Gammie, James S., M.D.
Research Fellow, Division of Cardiothoracic Surgery, Department of Surgery, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA

Ghosh, Sunit, M.B., B.S., F.F.A.R.C.S.
Consultant in Cardiothoracic Anaesthesia and Intensive Care, Cardiothoracic Surgical Unit, Papworth Hospital, Papworth Everard, Cambridge, UK

Girgis, Reda E., M.B., B.Ch.
Clinical Assistant Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Department of Medicine, Stanford University School of Medicine, Palo Alto, California, USA

Greer, Kevin A., M.D.
Cardiovascular Research Associate, Division of Cardiothoracic Surgery, Wayne State University School of Medicine, Detroit, Michigan, USA

Haasler, George B., M.D.
Associate Professor, Department of Cardiothoracic Surgery, Medical College of Wisconsin, Milwaukee, Wisconsin, USA

Hammond, Elizabeth H., M.D.
Professor of Pathology, University of Utah School of Medicine, and Chairman of Pathology, LDS Hospital, Salt Lake City, Utah, USA

Hardesty, Robert L., M.D.
Professor of Surgery, Division of Thoracic and Cardiovascular Surgery, University of Pittsburgh Medical Center. Presbyterian University Hospital, Pittsburgh, Pennsylvania, USA

Hardy, James D., M.D.
Veterans Administration Distinguished Physician, Professor Emeritus of Surgery, and Formerly, Chairman, Department of Surgery, University of Mississippi Medical Center, Jackson, Mississippi, USA

Hattler, Brach G., M.D., Ph.D.
Professor of Surgery, Division of Thoracic and Cardiovascular Surgery, University of Pittsburgh Medical Center. Presbyterian University Hospital, Pittsburgh, Pennsylvania, USA

Hosenpud, Jeffrey D., M.D.
Professor and Chairman, Division of Cardiology, Department of Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin, USA

Huddleston, Charles B., M.D.
Assistant Professor of Surgery, and Chief, Pediatric Cardiothoracic Surgery, St. Louis Children's Hospital, Division of Cardiothoracic Surgery, Washington University School of Medicine, St. Louis, Missouri, USA

Imes, Norman K., M.D.
Pulmonologist, Baptist Medical Center, and Co-Director, Lung Transplantation Program, Oklahoma Transplantation Institute, Baptist Medical Center, Oklahoma City, Oklahoma, USA

Jamieson, Stuart W., M.B., B.S., F.R.C.S.
Professor of Surgery, and Head, Division of Cardiothoracic Surgery, University of California San Diego, San Diego, California, USA

Kanoski, Marilyn M., M.S., R.D., L.D.
Clinical Dietitian, Transplant and Critical Care, Baptist Medical Center, Oklahoma City, Oklahoma, USA

Kaplan, Jorge, M.D.
Cardiothoracic Surgeon, Hospital Gustavo Fricke, Viña del Mar, Chile

Keogh, Anne M., M.D., F.R.A.C.P.
Cardiologist in Cardiac Transplantation, St. Vincent's Hospital, and Senior Lecturer, University of New South Wales, Sydney, New South Wales, Australia

Keshavjee, Shaf H., M.D., M.Sc., F.R.C.S. (C).
Assistant Professor of Surgery, Division of Thoracic Surgery, and Director, Thoracic Surgery Research Laboratory, University of Toronto, The Toronto Hospital, Toronto, Ontario, Canada

Klepetko, Walter, M.D.
Professor of Surgery, Department of Cardiothoracic Surgery, University of Vienna, Vienna, Austria

Kobashigawa, Jon A. M.D.
Medical Director, University of California Los Angeles Heart Transplant Program, and Associate Clinical Professor of Medicine (Cardiology), Department of Medicine, UCLA School of Medicine, Los Angeles, California, USA

Kolff, Willem J., M.D., Ph.D.
Distinguished Professor of Medicine and Surgery, Department of Surgery, Division of Artificial Organs, University of Utah, Salt Lake City, Utah, USA

Kriett, Jolene M, M.D.
Associate Professor of Surgery, Division of Cardiothoracic Surgery, University of California San Diego, San Diego, California, USA

Kshettry, Vibhu R., M.D., F.R.C.S.
Assistant Professor, and Co-Director, Thoracic Organ Transplant Program, Division of Cardiovascular and Thoracic Surgery, University of Minnesota, Minneapolis, Minnesota, USA

Laks, Hillel, M.D.
Professor and Chief, Division of Cardiothoracic Surgery, and Director, Heart and Lung Transplantation Program, Department of Surgery, UCLA School of Medicine, Los Angeles, California, USA

Lidsky, Nathan M., M.D.
Chief, Transplant Intensive Care Unit, Oklahoma Transplantation Institute, Baptist Medical Center, Oklahoma City, Oklahoma, USA

Love, Kathryn, M.D., B.M.S., F.R.C.P. (C).
Clinical Associate Professor, Department of Medicine, University of Minnesota, and Section Head of Infectious Diseases, Abbott-Northwestern Unit for Teaching and Research, Abbott-Northwestern Hospital, Minneapolis, Minnesota, USA

Magovern, George J., Sr., M.D.
Professor of Surgery, Division of Thoracic Surgery, Allegheny-Singer Research Institute, Department of Surgery, Allegheny General Hospital, The Medical College of Pennsylvania and Hahnemann University, Pittsburgh, Pennsylvania, USA

Magovern, James A., M.D.
Associate Professor of Surgery, Division of Thoracic Surgery, Allegheny General Hospital, The Medical College of Pennsylvania and Hahnemann University, Pittsburgh, Pennsylvania, USA

Maurer, Janet R., M.D., F.R.C.P. (C).
Head, Section of Lung Transplantation, Department of Pulmonary and Critical Care Medicine, The Cleveland Clinic Foundation, Cleveland, Ohio, USA

McGregor, Christopher G.A., M.B., B.S., F.R.C.S. (Ed and Glas).
Director of Cardiothoracic Transplantation, Section of Thoracic and Cardiovascular Surgery, Mayo Clinic, and Professor of Surgery, Mayo Medical School, Rochester, Minnesota, USA

Michler, Robert E., M.D.
Director, Cardiac Transplant Program and Director, Cardiac Research Laboratory, Division of Cardiothoracic Surgery, Columbia University College of Physicians and Surgeons, New York, New York, USA

Miller, Leslie W., M.D.
Professor of Medicine and Surgery, and Director, Heart Failure/Heart Transplantation Program, Department of Internal Medicine/Division of Cardiology, St. Louis University Health Sciences Center, St. Louis, Missouri, USA

Mischke, Larry, R.N.
Cardiothoracic Transplant Coordinator, Oklahoma Transplantation Institute, Baptist Medical Center, Oklahoma City, Oklahoma, USA

Mott, Brian D., M.D.
Research Fellow, Department of Surgery, McGill University, The Montreal General Hospital, Montreal, Quebec, Canada

Myers, Timothy J., B.S., C.R.A., R.C.P.T.
Coordinator, Clinical Research, Cullen Cardiovascular Research Laboratories, Texas Heart Institute, Houston, Texas, USA

Nash, Eleanor S., M.B., Ch.B., F.R.C.P. (Ed), D.P.M., F.F. Psych. (SA).
Formerly, Associate Professor, Department of Psychiatry, University of Cape Town Medical School, Groote Schuur Hospital, Cape Town, South Africa

Nelson, David P., M.D.
Transplant Physician, Oklahoma Transplantation Institute, Baptist Medical Center, Oklahoma City, Oklahoma, USA

Noakes, Timothy D., M.D., F.A.C.S.M.
Professor and Director, Medical Research Council/University of Cape Town Bioenergetics of Exercise Research Unit, Sports Science Institute of South Africa, Department of Physiology, University of Cape Town Medical School, Cape Town, South Africa

Novick, Richard J., M.D., M.Sc., F.R.C.S. (C).
Associate Professor of Surgery, Division of Cardiovascular and Thoracic Surgery, University of Western Ontario, and Consultant Cardiothoracic Transplant Surgeon, London Health Sciences Centre, University Campus, London, Ontario, Canada

Ohori, N. Paul, M.D.
Assistant Professor of Pathology, Department of Pathology, Montefiore University Hospital, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania, USA

Opelz, Gerhard, M.D.
Director, Department of Transplantation Immunology, Institute of Immunology, University of Heidelberg, Heidelberg, Germany

Oudshoorn, Machteld, Ph.D.
Head, Clinical Cellular Immunology Laboratory, Department of Immunohematology and Blood Bank, and Director of the Europdonor Foundation, Leiden University Hospital, Leiden, The Netherlands

Pae, Walter E., Jr., M.D.
Associate Professor of Surgery, Division of Cardiothoracic Surgery, Milton S. Hershey Medical Center, The Pennsylvania State University College of Medicine, Hershey, Pennsylvania, USA

Panos, Anthony L., M.D., M.Sc., F.R.C.S. (C).
Assistant Professor, Division of Cardiothoracic Surgery, University of Washington Medical Center, Seattle, Washington, USA

Paradis, Irvin L., M.D.
Physician-in-Charge, Lung Transplantation, Oklahoma Transplantation Institute, Baptist Medical Center, Oklahoma City, Oklahoma, USA. Formerly, Medical Director, Lung Transplantation, University of Pittsburgh Medical School, Pittsburgh, Pennsylvania, USA

Paris, Wayne D., M.S.W.
Clinical Transplant Social Worker, Oklahoma Transplantation Institute, Baptist Medical Center, Oklahoma City, Oklahoma, USA

Patterson, G. Alexander, M.D., F.R.C.S. (C).
Professor of Surgery, Section of Thoracic Surgery, Barnes Hospital, Washington University Medical Center, St. Louis, Missouri, USA

Penido, Marcia L., L.C.S.W.
Clinical Transplant Social Worker, Cedars-Sinai Medical Center, Los Angeles, California, USA

Penn, Israel, M.D.
Professor of Surgery, Department of Surgery, University of Cincinnati Medical Center and Cincinnati Veterans Administration Medical Center, Cincinnati, Ohio, USA

Pham, Si M., M.D.
Assistant Professor of Surgery, and Director of the Adult Heart Transplant Service, Division of Cardiothoracic Surgery, Department of Surgery, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA

Pierson, Richard N., III, M.D.
Assistant Professor of Cardiothoracic Surgery, and Director, Heart and Lung Transplantation, Vanderbilt University Medical Center, Nashville, Tennessee, USA

Pohl, Mary, R.N., B.S.N.
Clinical Trials Nurse Coordinator, Division of Cardiothoracic Surgery, Washington University School of Medicine, St. Louis, Missouri, USA

Portnoy, Vladimir F., M.D., Ph.D., Sc.D.
Scientist, Transplantation Research, California Pacific Medical Center, San Francisco, California, USA. Formerly, Professor of Surgery and Head, Department of Experimental Surgery, Academy of Medical Science Vishnevsky Institute of Surgery, Moscow, USSR

Resident, Division of Thoracic Surgery, Allegheny General Hospital, Pittsburgh, Pennsylvania, USA

Reeder, Gary D., B.S.
Adjunct Assistant Research Professor, Biotechnology and Bioengineering Center, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania, USA

Renlund, Dale G., M.D.
Professor of Medicine, Division of Cardiology, University of Utah Health Sciences Center, and Director, the Utah Transplantation Affiliated Hospitals Cardiac Transplant Program, Salt Lake City, Utah, USA

Robertson, Cina M., A.C.S.W.
Clinical Transplant Social Worker, Barnes Hospital, St. Louis, Missouri, USA

Rose, Alan G., M.D., M. Med. (Path)., F.R.C. Path.
Director, Jesse E. Edwards Registry of Cardiovascular Diseases, St. Paul, Minnesota, USA. Formerly, Wernher and Beit Professor and Head, Department of Pathology, University of Cape Town Medical School and Groote Schuur Hospital, Cape Town, South Africa

Rubin, Robert H., M.D.
Chief of Transplant Infectious Disease, Department of Medicine, Massachusetts General Hospital, Director, Center of Experimental Pharmacology and Therapeutics, Harvard-Massachusetts Institute of Technology Division of Health Sciences and Technology, and Osborne Chair in Health Sciences and Technology, Boston, Massachusetts, USA

Salomon, Daniel R., M.D.
Director of Transplantation Research, Division of Organ Transplantation, The Scripps Clinic and Research Foundation, and Assistant Member, Department of Molecular and Experimental Medicine, Department of Immunology, The Scripps Research Institute, La Jolla, California, USA

Sanbar, S. Sandy, M.D., Ph.D., J.D., F.C.L.M.
Cardiologist, Baptist Medical Center, Oklahoma City, Oklahoma, USA and Past President, American College of Legal Medicine

Sapirstein, John S., M.D.
Research Fellow, Division of Cardiothoracic Surgery, Milton S. Hershey Medical Center, The Pennsylvania State University College of Medicine, Hershey, Pennsylvania, USA (Currently, Resident, Department of Surgery, University of Chicago, Chicago, Illinois, USA)

Sawzik, Patricia, Ph.D.
Adjunct Research Professor, Biotechnology and Bioengineering Center, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania, USA

Sayegh, Mohamed H., M.D.
Assistant Professor of Medicine, Harvard Medical School, Department of Immunogenetics and Transplantation, Renal Division, Brigham and Women's Hospital, Boston, Massachusetts, USA

Schäfers, Hans-Joachim, M.D.
Professor of Surgery, Division of Thoracic and Cardiovascular Surgery, Surgical University Clinic of the Saarland, Homburg, Saar, Germany

Shennib, Hani, M.D., F.R.C.S. (C).
Director, Montreal Lung Transplantation Program, and Associate Professor of Surgery, Centre of Immunobiology and Transplantation, McGill University, Montreal, Quebec, Canada

Skotzko, Christine E., M.D.
Assistant Professor, Department of Psychiatry, University of Maryland at Baltimore, Baltimore, Maryland, USA

Smart, Frank W., M.D.
Director of Medical Transplant Services, and Co-Director of Heart Failure and Cardiac Transplantation, Ochsner Multi-Organ Transplant Center, Ochsner Medical Institutions, New Orleans, Louisiana, USA

Smith, Douglas M., M.D., Ph.D.
Director, HLA Laboratory, Department of Pathology, Oklahoma University Health Sciences Center, Oklahoma City, Oklahoma, USA

Speziali, Giovanni, M.D.
Fellow, Thoracic and Cardiovascular Surgery, Mayo Clinic, Rochester, Minnesota, USA

Starnes, Vaughn A., M.D.
Professor and Chief, Division of Cardiothoracic Surgery, and Director, Lung Transplant Program, Children's Hospital, University of Southern California, Los Angeles, California, USA

Stephenson, Larry W., M.D.
Ford-Webber Professor of Surgery, and Chief, Division of Cardiothoracic Surgery, Wayne State University School of Medicine, and Chief, Cardiothoracic Surgery, Harper Hospital and Detroit Medical Center, Detroit, Michigan, USA

Stevenson, Lynne Warner, M.D.
Associate Professor of Medicine, Harvard Medical School, Cardiovascular Division, Brigham and Women's Hospital, Boston, Massachusetts, USA

Stitt, Larry, M.Sc.
Assistant Director, Biostatistical Support Unit, Department of Epidemiology and Biostatistics, University of Western Ontario, London, Ontario, Canada

Taniguchi, Shigeki, M.D.
Cardiothoracic Transplant Clinical and Research Fellow, Oklahoma Transplantation Institute, Baptist Medical Center, Oklahoma City, Oklahoma, USA

Taylor, David O., M.D.
Assistant Professor of Medicine, Division of Cardiology, University of Utah Health Sciences Center, Salt Lake City, Utah, USA

Thaler, Scott J., M.D.
Associate Physician, Infectious Disease Division, Brigham and Women's Hospital, and Instructor in Medicine, Harvard Medical School, Boston, Massachusetts, USA

Theodore, James, M.D.
Pulmonologist and Associate Professor of Medicine, and Medical Director, Heart–Lung and Lung Transplant Program, Division of Pulmonary and Critical Care Medicine, Department of Medicine, Stanford University Medical Center, Palo Alto, California, USA

Thompson, Sharon E., L.S.W.
Clinical Transplant Social Worker, Shands Hospital, Gainesville, Florida, USA

Todd, Thomas R., M.D., F.R.C.S. (C).
Professor and Chairman, Division of Thoracic Surgery, University of Toronto, The Toronto General Hospital, Toronto, Ontario, Canada

Trehan, Sanjeev, M.D.
Fellow, Division of Cardiology, University of Utah Health Sciences Center, Salt Lake City, Utah, USA

Tschernko, Edda, M.D.
Department of Cardiothoracic Anesthesiology, University of Vienna, Vienna, Austria

Tyndall, Kirsten L., Pharm. D.
Clinical Specialist Pharmacist, Baptist Medical Center, Oklahoma City, Oklahoma, USA

Van Meter, Clifford, M.D.
Cardiothoracic Surgeon, and Co-Director of Cardiac Transplantation, Oschner Medical Institutions, New Orleans, Louisiana, USA

Wanke, Theodor, M.D.
Assistant Professor of Pulmonology, Lainz Hospital, Vienna, Austria

Wagner, Florian M., M.D.
Clinical Fellow, Montreal Lung Transplantation Program, McGill University, Montreal, Quebec, Canada

Warner, Ernest G., M.D.
Neurologist, Baptist Medical Center, Oklahoma City, Oklahoma, USA

Wheeldon, Derek R., M.I.Biol.
Senior Research Technician, The Transplant Unit, Papworth Hospital, Papworth Everard, Cambridge, UK

Wicomb, Winston N., Ph.D.
Director, Organ Preservation, Transplantation Research Institute, California Pacific Medical Center, San Francisco, California, USA

Wisser, Wilfried, M.D.
Surgeon, Department of Cardiothoracic Surgery, University of Vienna, Vienna, Austria

Wolford, Thomas L., M.D.
Assistant Professor, J.G. Mudd Cardiac Catheterization Laboratory, Division of Cardiology, Department of Internal Medicine, St. Louis University Health Sciences Center, St. Louis, Missouri, USA

Young, James B., M.D.
Chief, Section of Heart Failure and Cardiac Transplant Medicine, The Cleveland Clinic Foundation, Cleveland, Ohio, USA

Yousem, Samuel A., M.D.
Chief Pathologist and Director of Anatomic Pathology, Montefiore University Hospital, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania, USA

Acknowledgments – Personal

We thank Professor Christiaan Barnard for once again contributing the Foreword to this volume, and greatly appreciate the support he has given us in the preparation of this comprehensive review. We remain exceedingly grateful to all of our collaborators on this major project.

We thank, in particular, Crystal Taylor of CompOne Services, Oklahoma City, who has typed or retyped almost the entire volume. She has done this with a speed and accuracy to be admired, and this has greatly facilitated the preparation of the text.

Many of the excellent surgical drawings were reproduced from the first edition and are the work of Jenny Kukielski of Earls Colne in the United Kingdom, and much of the photographic work was carried out by John Philbin of Oklahoma City in the USA, and to both we are indebted.

1
The Concept and Diagnosis of Brain Death

E.G. WARNER

INTRODUCTION

The concept of brain death as opposed to clinical death was first formulated by Mollaret and Goulon in 1959[1]. At the onset this new concept of death produced a considerable amount of discussion, some of it acrimonious, in medical circles. The public was also interested in this new concept of death as distinguished from what it had previously understood.

Up until this time the recognized criteria for diagnosis of clinical death were cessation of respiration and cessation of heartbeat, both usually occurring in close proximity to each other. Thus a new concept, the concept of brain death, when it was first promulgated, was rather revolutionary.

The reason the new concept was essential is because of the effectiveness of resuscitation which is now available after an acute injury or acute organ failure. This has produced a large number of patients who are mechanically ventilated with circulatory parameters stabilized artificially, but without the possibility of recovery of cerebral function. This then is the diagnosis of brain death as opposed to clinical death by the older cardiovascular standards.

This new concept of brain death now signifies the death of the individual, and is accepted throughout most of the world, although there are a few countries which do not recognize this new concept.

From the transplantation standpoint most of the organ donations are from patients who are brain dead. The care of this type of patient has not only ethical importance, but also legal importance. It is the accurate diagnosis and timing of the occurrence of brain death that is essential, not only in procuring organs but in order to continue appropriate perfusion and other techniques necessary to maintain the organs in the best state possible for transplantation. It is not the task of the neurosurgeon or any medical practitioner to provide organs for donation. However, neither should any doctor, on the basis of insufficient evidence or personal prejudice, deny patients in need of transplant surgery their chance for a cure[2,3].

TOTAL BRAIN DEATH VERSUS BRAINSTEM DEATH

At the onset it should be noted that there is a difference in distinguishing between total brain death, which implies irreversible cessation of function of the entire brain, including the brainstem, and failure of the brainstem itself. The importance of this difference varies by geography. In the United States the concept of total brain death is defined as irreversible loss of function of the entire brain including the brainstem. In some other countries the concept of brainstem death is rendered equivalent to brain death.

The etiological factors which produce irreversible brain death are several; these include: (a) supratentorial lesions such as subdural or intracerebral hematomas, subarachnoid hemorrhage, cerebral infarctions, tumors or abscesses; (b) infratentorial masses which directly damage the brainstem, such as brainstem or cerebellar hemorrhage, brainstem infarction, or tumor; (3) hypoxic encephalopathy of a high degree, usually occurring after prolonged asphyxia. Other metabolic factors, such as severe toxic insults or in the setting of severe hepatic necrosis, are not uncommon.

The parameters necessary to diagnose brain death will now be described. These are the descriptions that would be appropriate to clinical evaluation in the United States. In other some countries the use of only brainstem criteria may be adequate.

The end-result of major trauma, whether physical or chemical, which leads to progressive brain swelling, is herniation of the hippocampal gyri with lateral pressure on the brainstem. This eventuates in the loss of brainstem function. Any expanding lesion will increase intracranial pressure to equal systemic arterial pressure, at which point there will be complete arrest of cerebral circulation. Cerebral circulatory arrest can therefore be confidently used as a criterion of irreversible cerebral injury. Functional disintegration, following the conditions described above, leads to cessation of spontaneous respiration. This results in turn in hypoxic cardiac arrest. If gaseous exchange and circulation are maintained artificially, the heart, kidneys and liver may continue to function for some hours or days. However, after brainstem death has occurred, cardiac arrest will usually follow reliably within 1–2 weeks[4].

CONFOUNDING FACTORS IN THE DIAGNOSIS OF BRAIN DEATH

There are a number of factors which may confuse a diagnosis of brain death; these are the following, and must be excluded to

make a proper diagnosis of brain death: (a) hypothermia – this becomes operative, however, only when rectal temperatures are below 32°C; (b) drug intoxication; (c) factors producing severe electrolyte or endocrine disturbances; (d) identification of a structural lesion that might be amenable to surgical treatment, by appropriate imaging techniques; (e) the effect of neuromuscular blocking agents – if these agents have been used, enough time must be given so that they will have dissipated from the blood. To emphasize again, the exact diagnosis (or as close to being exact as possible) must be made as to the etiology of the comatose state.

ESTABLISHING THE DIAGNOSIS OF BRAIN DEATH

There are therefore two major areas of testing which are required to establish the status of brain death. The first is that of coma – total unresponsiveness to any stimuli. The second is the absence of brainstem reflexes, including apnea.

(1) *Coma* – the patient must be totally unresponsive to painful stimuli. This can be tested by supraorbital pressure, sternal pressure, nailbed pressure, or other appropriate means.
(2) *Brainstem death* – measured by absence of brainstem reflexes:
   (a) Absence of pupillary response to light – there must be an adequate level of illumination to make it a valid test. One must exclude previous pupillary abnormalities and/or topical drugs that may be applied to the eyes.
   (b) Absence of corneal reflex – tested by taking a moist piece of cotton or paper tissue and touching the cornea. This should produce a direct response in the eye being tested. It should also produce a consensual response in the opposite eye.
   (c) No oculovestibular reflexes. Irrigation of each ear individually with cold water, using an adequate amount (which is usually defined as 50–60 ml). The patient is allowed to rest for several minutes after the injection. This is then repeated on the opposite side. The head should be elevated 30° during the irrigation on each side. A positive response is deviation of the tonic variety toward the cold stimulation, signifying an intact brainstem. With brainstem death there is no deviation of the eyes with stimulation.
   (d) Absence of oculocephalic reflex: this is absent 'doll's eyes', performed by rapid turning of the head from the neutral or forward position to 81–90° rotation on each side. A similar test may be made with vertical movements of the head. The eye movement is to the opposite side from the deviation of the head. Then, as the movement of the eyes lags behind the head movement, they rapidly adjust to their new position.
   (e) Gag reflex absent after stimulation of the pharynx.
   (f) No cough reflex – this can be determined with bronchial suction.
   (g) Absence of respiratory activity (demonstration of apnea – see below.)

Respiration is driven from a center in the brainstem. If the above brainstem tests are all negative (that is absent), the next procedure to be performed is a test for apnea. Loss of brainstem function produces apnea as well as hypotension.

A large number of factors influence respiratory drive, including P_{CO_2}, pH, etc. The recommendations that will follow are based on the concept of reaching a Pa_{CO_2} level >60 mmHg for maximum drive or stimulation of the respiratory center in the brainstem. Lower levels may be sufficient, but at 60 mmHg there is no question that the respiratory drive should be definitely present if the respiratory center can respond to the hypercarbia. Caution must be used in interpreting these values in patients who have severe COPD or other causes for chronic hypercarbia. In these instances, greater reliance should be placed on other confirmatory tests. Because hypotension may result during the procedure, it is essential that the patient have as normal a blood volume as possible.

One should preoxygenate the patient to a Pa_{O_2} of approximately 200 mmHg. The arterial P_{CO_2} should be within normal limits. Then disconnect the ventilator. Be sure that a diffuse type of oxygenation can take place by giving 6 l/min oxygen via the trachea or placing a fine cannula at the level of the carina. Disconnect the respirator. Generally, if one starts with a P_{CO_2} of 40 mmHg, the value will gradually increase after 6–8 min to a level of approximately 60 mmHg. It will rise probably 3–6 ml/min, but is variable depending on the individual patient. Observe the patient for any respiratory movements that would produce an adequate tidal volume.

At the 8-min interval, check for pH, P_{CO_2} and P_{O_2}. The object here is to be sure that the P_{CO_2} is above 60 mmHg. If no respiratory movements are seen at this level, that is a P_{CO_2} >60 mmHg, then assume that the respiratory drive is adequate and the response of the brainstem is negative. This fits with the diagnosis of brain death. If, however, respiratory movements are observed, then there is still present a response to this level of P_{CO_2}, and the brainstem is not dead. In the event that the patient becomes abruptly hypotensive or significant cardiac arrhythmia develops, the respirator should be restarted promptly and the volume adjusted until the O_2 saturation is >90% (or arterial P_{O_2} >90 mmHg).

To summarize, irreversible apnea is part of the diagnosis of clinical total brain death, particularly involving the responsiveness of the brainstem. Respiration must be absent with a P_{CO_2} of 60 mmHg.

There are other protocols which may be used to ensure adequate respiratory drive to the brainstem occurring in the presence of adequate peripheral oxygenation. At this point there is no agreement on the exact protocol that should be followed in regard to this issue.

COMMENT

Many problems are seen in these critically ill patients in the intensive-care unit (ICU). Particularly troublesome are those patients who have severe facial and head injuries, such that examination of cranial nerves is difficult, if not at times virtually impossible. The presence of confounding drugs, e.g. sedatives, etc., can be evaluated from a thorough history and toxicological analysis. Often these problems, as well as the etiology of the coma, will be clarified with continued observation and laboratory testing[5].

Not infrequently one may have the 'Lazarus reaction' – that is, spinal reflex activity – particularly during apnea testing. If this reaction occurs it may suggest to the observer purposeful movements. Hence, it is our policy to exclude the family from the agonal period so that these reflex actions are not considered as evidence of an error in the diagnosis of brain death. These patients may sit up in bed, swing their arms in front of them, move one limb in a jerking-type action, or even make pseudowalking movements with their legs. Some of these movements may involve chest muscles, but they do not produce adequate movement to enable a respiratory exchange with significant tidal volume.

Since deep tendon reflexes are of spinal origin they may remain present, although they are usually absent; the same applies to Babinski signs.

CONFIRMATORY TESTS

In this particular area there is considerable disagreement between physicians in the USA and those in other parts of the world, particularly in Britain. In the USA the criteria for total brain death include a total lack of function of the entire brain – not only the brainstem but the entire brain. In the UK, however, the argument is made that if one has no evidence of activity in the brainstem, for practical purposes the patient is truly 'brain dead'. Semantically there is, of course, considerable difference here, as the total brain is not necessarily dead when only the brainstem is non-functional. Nonetheless, it is quite true that if all brainstem reflexes are absent there is virtually no chance that the patient will recover. However, given the litigious atmosphere in the USA, we tend to use and advise confirmatory tests. One may use arteriography via a four-vessel (carotid and vertebral arteries) injection. This should show no intracerebral spread of the dye, although it may reach the external carotid circulation. No intracranial arterial dye should reach the external carotids[5].

Other techniques which are used in the USA are somatosensory evoked potentials, transcranial Doppler, isotope angiography, etc. However, none of these has been fully accepted for widespread use. Part of the reason is that they are technically difficult procedures to do in an intensive-care unit with consistent reliable results.

Electroencephalography (EEG), however, has been accepted very widely, and is used in most major hospitals to confirm brain death. The appropriate finding here is an isoelectric EEG. This does not mean that the record is totally isoelectric, but that there is no measurable activity over 2 μV. Standards have been set up for the type of recording necessary, and these must be meticulously and carefully followed. Reference should be made to their publication, which details the exact criteria published by the American EEG Society[7].

Unfortunately, recording EEG in an intensive-care unit can be very difficult. The ICU is electrically an electronic jungle with multiple sources of extraneous electrical potentials. Frequently one may find a given cubical in the ICU unit in which recording of the EEG is absolutely impossible despite every maneuver possible. This has become less common as EEG machines have been improved, but still does occur. In this case the only alternative is to move the patient to another area of the ICU which has less electronic 'noise' in the environment. Careful attention must be paid lest one creates grounds to the patient which could in fact cause an unknown electrical shock. Again, the details of the correct recording of the EEG, and the use of the equipment and instruments, are detailed in American EEG Society guidelines[7].

CHART DOCUMENTATION

The last documentation occurs when all the evidence is present and total brain death is diagnosed. This evidence should then be recorded in an appropriate note in the permanent record. All the major criteria should be listed, and the results of testing noted. In any case when there is a question involved, particularly if there is a question of hypoxic insult or an insult due to extraneous drugs, the testing should be repeated at an interval of no less than 6 hours.

APPENDIX

Minimum criteria for a diagnosis of brain death

The diagnosis of brain death can only be made if the answer to all the questions is No.

(1) *Cerebral state*
   (a) Is the patient responsive to stimuli (painful, auditory, etc.)?
   (b) Is the cause of coma unknown?
   (c) Does the coma appear to be reversible?
   (d) Have any drugs which may affect ventilation or the level of consciousness been administered during the past 12 hours?

(2) *Brainstem reflexes*
   (a) Do the pupils react to light?
   (b) Do the pupils react to painful stimulation?
   (c) Is the corneal reflex present?
   (d) Are doll's eye movements present?
   (e) Does nystagmus occur when each ear is in turn irrigated with ice-cold water for 1 min?

(f) Is there a gag or a reflex response following bronchial stimulation by a suction catheter passed down the trachea?

(g) Is there spontaneous ventilation?*

(3) *Body temperature*

Is the rectal temperature below 35°C?

**Methods of testing for spontaneous respiration*

(a) If arterial blood-gas analysis can be performed:
  (i) Ventilate the patient with 100% oxygen for 15 minutes.
  (ii) Check $Paco_2$ – must be within normal limits (5.3–6.1 kPa).
  (iii) Disconnect the patient from the ventilator.
  (iv) Administer oxygen (6 l/min) through a catheter in the trachea.
  (v) Check $Paco_2$ – must be greater than 6.7 kPa.

(b) If arterial blood-gas analysis cannot be performed:
  (i) Ventilate the patient with 100% oxygen for 10 min.
  (ii) Ventilate the patient with 5% carbon dioxide for a further 5 min.
  (iii) Disconnect the patient from the ventilator.
  (iv) Administer oxygen (6 l/min) through a catheter in the trachea.

2
Medico-legal Aspects

S.S. SANBAR

INTRODUCTION

The legal and ethical aspects of human organ transplantation vary from country to country, although in broad terms the legal and ethical requirements denote substantial similarities. This chapter provides an overview principally of the statutory requirements relating to heart transplantation.

The major legal issues that pertain to human organ donation include:

(1) consent by donor or by those authorized by law to speak for the donor;
(2) legal tests and doctrines applied to organ donors;
(3) determination of time of death of donor;
(4) professional liability or medical malpractice;
(5) ethical and economic considerations.

INFORMED CONSENT

Competent adults

When dealing with adults of legal age and sound mind, their rights of self-determination and privacy rank supreme and are fundamental. When the transplant donor or donee is a competent adult, his or her consent should be given freely, knowingly and intelligently after being fully and reliably informed regarding the transplant procedure, its material risks, prognosis, and all alternative procedures. The doctor may not induce consent by minimizing the dangers of the surgery, or by misrepresentation or duress.

Donation by a competent adult prior to death

Any person may make such a donation to be implemented after his death: (1) in his will, if he is competent to make such a will; (2) in any document attested to by two competent witnesses; (3) by an oral statement made by the deceased during life in the presence of two persons of at least 18 years of age; and (4) by wearing a prescribed identity tag issued by an approved institution (e.g. driving license). Any such donation may be revoked prior to death by the donor.

In the USA the Uniform Anatomical Gift Act of 1968[1], and amended in 1987[2], allows any individual of sound mind who is over 18 years of age to make a gift during his life by will (to be effective immediately upon death without waiting for probate), or by a card or other document. If the donor is incapable of signing for any reason, including sickness, then the document can be signed on his behalf, if validated by two witnesses. The amended Uniform Anatomical Gift Act of 1987 added provisions for routine inquiry, required requests, presumed consent for Medical Examiner cases, and prohibition of the sale of human organs.

The system of donor cards has the merit of simplicity and portability. A typical example is the Uniform Card developed in the USA following the Uniform Anatomical Gift Act. This card, which can be carried easily in a pocket or wallet, states in simple words the donor's desire to make an anatomical gift to take effect upon death. On the reverse side the card contains provisions for signature, witnessing and personal details. Similar cards are available in several other countries, including Australia, Canada and Britain. In Britain, under the Human Tissues Act, 1961, a patient may carry a signed donor card or record his wishes 'in writing at any time or orally in the presence of two or more witnesses during his last illness'.

Donation by a relative of the deceased

In the absence of specification by the individual while alive (as above), permission to donate organs at death may be obtained from certain specified next of kin of the deceased, i.e. the adult or legally competent spouse, child, parent, brother or sister, provided the deceased donor had not forbidden such a donation. Prior to actual organ removal, any donation by a relative may be revoked by the next of kin who made it. In this context legal competency refers to a person of sound mind who is over the age of 18 or 21 years, depending on the legally specified age of majority for the country.

In the USA, relatives of a deceased may also legally donate by document, telegraph, recorded telephone or other recorded message; in order of legal priority the next of kin are the spouse,

adult children, parents and adult siblings. In many countries 'relative' is not defined.

Donation by an authority empowered to donate after death

The acquisition of hearts in the absence of donation (as above) may be possible in some countries. If a relative authorized at law to consent to a donation cannot be traced, the law of some countries may allow for a designated official to authorize under certain prescriptions the removal of tissue from a deceased person for purposes of a donation, e.g. the District Surgeon in South Africa, and the Coroner in England and Wales. In the USA, however, the law makes no actual reference to the deposition in use of an unclaimed cadaver. A few states allow transplantation of certain organs (such as corneas) if a reasonable effort has been made to trace the relative; authorization must be given by the Medical Examiner.

An adult, mentally competent prisoner may be judicially compelled in the United States to submit to lifesaving treatment, including human organ transplantation, by a declaratory judgement and a temporary restraining order. The judge uses a balancing test weighing the patient's non-absolute constitutional right of privacy and self-determination against the state government's most significant interest – namely, the preservation of life.

Minors and other incompetents

When dealing with minors, mentally retarded patients, or psychiatric patients who are legally incompetent to give a valid consent, several legal problems can arise. As a general rule a court order will almost always be required before organ transplantation may occur. The consent of parents or guardians is also usually required. However, refusal by the parents or guardians of necessary treatment for the incompetent child or mental case may not always be conclusive. In those circumstances involving minors and incompetents the judge applies the doctrine of *parens patriae*, an equitable doctrine which, in essence, permits the juvenile court to act as a parent and attempts to protect the minor from the abuse or neglect by the real parent or guardians.

Cadaver organs

For cadaver donors, where an informed consent by the donor prior to death is unavailable, there are three considerations in obtaining the requisite consent. First, there must be a valid consent from one who is legally capable of granting such a consent (generally, next of kin). Second, the determination of the time of death should be in accordance with the law. Third, the removal of organs from one who has died from a violent cause involves the Medical Examiner, who has jurisdiction over the body. There are certain circumstances where the Medical Examiner may not approve organ donations, including homicide, poisoning, industrial accidents, car accidents involving other persons, and where there is a question of liability.

Unclaimed bodies

For unclaimed bodies, statutes generally require that one should wait 48 hours after the death of the patient, during which time the hospital that is in possession of the body must make a reasonable search for the next of kin. Until such a search is carried out, the body is technically not claimed. In addition, the physician who wishes to use the unclaimed body in a transplant procedure is required to obtain clearance from the Medical Examiner. The physician must document carefully all aspects of the transplant procedure in the medical records in an attempt to avoid future liability.

Anencephalic

Anencephalic infants represent an important potential source of organs. Organs from such infants could meet the bulk of the current demand for infant organs. Organs from stillborns and infants dying from other diseases are not generally suitable for procurement and transplantation.

The first transplant of the heart from an anencephalic infant in the USA occurred in October 1987 at the Loma Linda University Medical Center in California without legal incident. Subsequently, other parents requested that their anencephalic children be used as donors to help other children. It is noteworthy that the anencephalic does not fall under the category of brain-dead. Hence, the brain death statutes are inapplicable under those circumstances. However, in some states an anencephalic infant may fall under the category of either a patient in a 'vegetative state' or the 'terminally ill', or both, as defined by statutes. Without specific federal or state statutes that prohibit anencephalics from donating organs before actual death has occurred, it is conceivable that a State Court may order the organ donation of an anencephalic infant when death is 'imminent', in a matter of hours or days, if the parents, doctors, hospital, clergy, and a court-appointed guardian *ad litem* all approve of the donation.

LEGAL TESTS AND DOCTRINES IN THE UNITED STATES

Simple judicial approval of parental consent

In cases involving intra-familial transplants among minors and incompetents (e.g. mentally retarded and schizophrenics), where both parents agree, judicial approval has generally been granted.

In a 1972 Connecticut case, *Hart v. Brown*[3], the court approved a transplant between two identical 7-year-old twins, considered the medical ramifications, and stated that the parents' motivation and reasoning had met with approval of the guardians *ad litem*, physicians, clergymen, and the court itself.

Best interest test

By statute in Louisiana, medical intervention must be in the 'best interest' of minors and incompetents. A 1975 Louisiana case, *In re Richardson*[4], involved a husband who brought an action against his wife to compel her to consent to surgical removal and transplantation of one of her minor's kidneys for donation to the boy's older sister. Such surgical intervention would invade the minor's right to be free in his person from bodily intrusion, and was not shown to be in the best interest of the minor. In a concurring opinion, a judge stated that before the court might exercise

this awesome authority in this instance, and before it even considered the question of the best interest of the child, certain requirements must be met. He said: 'I am of the opinion that it must be clearly established that the surgical intrusion is urgent, that there are no reasonable alternatives, and that the contingencies are minimal. If those requisites are not met, then the court will not need to address the best-interest of the child issue'.

In 1975 the Supreme Court of Wisconsin reached a similar holding, *In re Guardianship of Pescinski*[5], where a permit was sought for removal of a kidney from a mentally incompetent 39-year-old catatonic schizophrenic to donate to his 38-year-old sister. The Wisconsin Court found that there was absolutely no evidence in this case that any interest of the mentally disturbed brother would be served by the transplant. The court held that where no benefit had been shown to the mentally incompetent, and no consent for the kidney transplant had been given by the incompetent or his guardian *ad litem*, the judge had no power to order such surgery.

Substituted judgement doctrine

Most courts have been using the doctrine of 'substituted judgement', which was first applied in 1816 in an English case. The decision was amplified in 1840 by a second English case, and in 1844 the doctrine of substituted judgement was first applied in the United States in a New York case. In 1945 the United States Supreme Court held that the doctrine of substituted judgement requires that the court substitute itself as nearly as possible for the incompetent, and act with the same motives and considerations as would have moved the incompetent.

In 1969 the doctrine of substituted judgement was first applied in a transplant case, *Strunk v. Strunk*[6]. The mother of a 27-year-old mentally retarded male, with an IQ of approximately 35 and a mental age of approximately 6 years, petitioned the court for authority to proceed with a kidney transplant for the 28-year-old brother who was suffering from chronic renal nephritis. In applying the doctrine of substituted judgement the court did not apply the best interest test. Instead, it applied the 'avoidance-of-detriment' test *vis-à-vis* the donor. The court based its opinion on psychiatric testimony to the effect that the death of the donor's brother would have an extremely traumatic effect on the donor. Stated differently, the benefit to the transplant donor is detriment avoidance, and what the court is trying to avoid is the grave emotional impact on the donor. The latter concept was used by a Massachusetts court in the 1950s when ruling on incompetent candidates for renal transplantation.

Parens patriae doctrine

As a general rule, when parents request permission from the judge to give consent on behalf of minors, e.g. incompetent twins for kidney transplantation, the court applies the equitable doctrine of *parens patriae*, thereby empowering it to permit parental consent on behalf of the minor. On the other hand, when the parents do not request permission of the judge, or even refuse to consent to necessary organ transplantation for minors, the court may resort to the doctrine of *parens patriae* to protect the incompetent.

In Kansas there is statutory authority that allows the judge to delegate powers to a committee of persons who will be appointed by the judge to act for the mentally incompetent under the supervision of the county court. Thus, in addition to its inherent common-law powers, the Kansas court by statute may rightfully act as the *parens patriae* and substitute its judgement to protect and benefit the incompetents who are incapable of protecting themselves.

Guardian *ad litem*

In most cases involving intra-family transplants from incompetent donors, judicial approval has been granted. The court may appoint a guardian *ad litem*, often an attorney, who will be required to argue whether the transplantation procedure is in the incompetent's best interest. The judge then determines as a question of fact whether the parents' exercise of substituted consent is in the incompetent's best interest.

Substantial psychological benefit test

This test was used in a 1979 case, *Little v. Little*[7], from the Court of Civil Appeals of Texas. There, the mother of a 14-year-old daughter with Down's syndrome applied for an order authorizing her to consent to the removal of a kidney from her incompetent, mentally retarded daughter for transplant into her son who was suffering from end-stage kidney disease. The judge appointed an attorney *ad litem* to represent the daughter. The attorney was opposed to transplantation. The mother argued, first, that the daughter with Down's syndrome was the only relative suitable for donating a kidney to her brother; second, that the transplant would provide great and tangible benefit to her; third, that there was no threat to her life; and fourth, that, to the best of the mother's knowledge, the transplant was what the daughter would have wanted for her ill brother. The judge authorized the transplant over the objection of the attorney *ad litem*, using as his yardstick the 'substantial psychological benefit' test. The judge noted that the donor's participation in a procedure that would save her brother's life would be substantially beneficial to the donor from a psychological standpoint.

DETERMINATION OF TIME OR FACT OF DEATH

The 1961 British Human Tissues Act allows removal of tissue once a registered medical practitioner has satisfied himself by personal examination of the body that life is extinct.

The 22nd World Medical Assembly, at the meeting in Sydney, Australia, in 1963, issued a statement that 'the determination of death should be based on clinical judgement supplemented, if necessary, by a number of diagnostic aids, of which electroencephalography is currently most helpful'. In the case of those persons kept alive by artificial means of resuscitation (in use or contemplated), or in which the transplantation of an organ is being considered, it emphasized that the moment of irreversibility of the processes leading to death must be determined, rather than the moment of death. This declaration further states that, while the electroencephalograph is the most useful diagnostic aid, 'no single technological criterion is entirely satisfactory in the present

state of medicine, nor can any one technological procedure be substituted by the overall judgement of the physician'[8].

In the United States the 1978 Uniform Brain Death Act specifies that 'For legal and medical purposes, an individual who has sustained irreversible cessation of all functioning of the brain, including the brain stem, is dead. A determination under this section must be in accordance with reasonable medical standards'. The law is, however, silent on the actual criteria to be used for determining death. The time of death is determined by the physician who attends the death, or, if none, by the physician who certifies the death. By this law, too, this physician may not participate in the procedures for removing or transplanting a part of the deceased's body[9].

In addition to cessation of heart beat and respiration, therefore, brain death is recognized by law. In 1975 a New York court addressed the legal definition of time of death as used in provision of the Anatomical Gift Act. The court held that the term 'death' implies a definition consistent with the generally accepted medical practices of doctors who are primarily concerned with effectuating the purposes of the Anatomical Gift Act. It was noted that the intent of the Act was to provide a systematic procedure of implementing the public policy of New York State, which is to encourage anatomical gifts on death.

Under the Uniform Anatomical Gift Act of 1968, adopted in all 50 USA states, the physician may incur possible liability for making an errant determination of the time of death in the transplant donor, resulting in premature harvesting of the organ(s). (The time of death of the patient must be determined by a 'treating' physician.) However, when the physician removes an organ from a donor patient in 'good faith', the physician is not liable in a civil action under the terms of the Act or an applicable state law. The physician is probably protected from criminal liability, particularly when it involves the question of the determination of the time of death. However, the surgeon who removes the desired organ prematurely may not be protected from a wrongful death action, even though the act may protect the surgeon from the charge of mutilation or mayhem.

Failure to comply with the Anatomical Gift Act is evidence of 'bad faith' *per se*. A physician who makes an honest effort to determine the time of death based on reasonable and well-recognized medical standards, and who acts in the best interest of the patient, would probably be considered to be exhibiting good faith.

In contrast with the United States, most other countries have no specific laws relating to brain death as evidence of the fact of death, and generally rely on acceptable medical criteria. A Working Party on behalf of the Health Departments of Great Britain and Northern Ireland has prepared a quasi-legal Code of Practice, intended for hospital staff and medical administrators relating to 'Cadaveric Organs for Transplantation'. In the section dealing with brain death it states: 'There is no legal definition of death. Death has traditionally been diagnosed by the irreversible cessation of respiration and heart beat. This Working Party accepts the view held by the Conference of Royal Colleges that death can also be diagnosed by the irreversible cessation of brain-stem function – "brain death". In diagnosing brain death, the criteria laid down by the Colleges should be followed.' (The clinical diagnosis of brain death is discussed in detail in Chapter 1).

PURPOSE OF DONATION

In most countries each donation or 'removal' must be for the purposes of medical and dental education, research, or therapy (including use in any other living person), or for any other scientific purpose; such purpose need not be specifically expressed and may include the production of a therapeutic, diagnostic, or prophylactic substance.

THE DONEE

In the USA, state statutes vary with regard to permissible recipients of donated tissue. In general, licensed hospitals, teaching institutions, colleges, medical schools, universities, storage banks, state public health and anatomy boards and institutes approved by the State Department of Health may be donees. Unless the donee has been previously indicated during life by the deceased, the attending physician becomes the donee. If he so desires he can transfer his ownership to another person. Although he is not permitted to participate personally in removing and transplanting organs or parts, he is allowed to communicate with other relevant donees or transplant teams.

AUTHORIZATION FOR THE REMOVAL OF ORGANS

Once a donation has been made in South Africa, a donee specified, and the fact of death certified, the transplant surgeon or a member of the team must request authority from the appropriate medical practitioner (for example, the medical superintendent of the hospital in which the donor is being cared for, or his authorized medical deputy) to remove the donated organ, which removal may only be undertaken by or on the authority of a medical practitioner or dentist. The person authorizing removal must satisfy himself that the body is not required for examination in terms of other legislation which has a higher ranking claim on the body, e.g. the Inquest Act.

Authority to remove a valid donation in the United Kingdom is not essentially different from the above provisions, with the noticeable exception that the person lawfully in possession of the body of a deceased may so authorize, after practicable inquiries, providing that the deceased had not expressed objection to his body being so dealt with, or the surviving spouse or any relative of the deceased expressed objection. Normally, the 'person' lawfully in possession of a dead body is a National Health Service hospital until such time as the body is claimed by the person with the right to possession, i.e. the coroner, the executor, or the next of kin[10].

CONFIDENTIALITY

Disclosure to any other person of any fact whereby the identity of the deceased donor or donee may be established is prohibited by statute in some countries. In the United Kingdom confidentiality is not prescribed, but the staff of hospitals and organ procurement organizations 'must respect the wishes of the donor, the recipient, and the families with respect to anonymity'[10]. There appear to be no specific statutory laws regarding transplantation confidentiality in the USA. However, the constitutionally protected right of

privacy and general statutes governing medical care in the USA preclude unpermitted disclosure.

At common law the privacy of the individual may not normally be intruded upon. The legal and ethical obligations of a medical practitioner to treat patient information as confidential appear to be based also on contract. Experience has shown that breaches in confidentiality in regard to heart transplantation have generally had their origin beyond the medical profession.

IMPORTATION/EXPORTATION OF TISSUE

In most countries the importation or exportation of tissues is subject to permission being obtained from a government authority.

SALE OF TISSUE

An authorized institution or the importer of tissue may receive payment for providing tissue to any person for therapeutic or scientific purposes. If any other person receives payment for such tissue, he shall refund such payment to the person who made it. The object of this and the aforementioned provision is to prohibit trading in tissue, which ethically and scientifically is unacceptable. This prohibition, however, does not prevent a medical practitioner from being paid for his services in the collecting or use of such tissue as a part of therapy.

In the USA the sale of organs is prohibited by the National Organ Transplant Act of 1984, as amended in 1986 by the fiscal 1987 Budget Reconciliation Legislation, setting a uniform policy in this area following a private attempt to establish an organ brokerage firm in Virginia during 1983[11,12]. A reasonable charge for removal costs is allowed. While questions have been raised concerning the constitutionality of the non-sales provision under the 'right of privacy' doctrine, the better position is that the provision is constitutional under the commerce power, and does not properly fall within the sphere of constitutional privacy.

TRANSPLANT MALPRACTICE

With regard to medical malpractice involving transplantation, the reasons for malpractice as a cause of action are the same in transplant cases as in any other medical situation: negligence, lack of informed consent, battery, invasion of privacy, fraud, abandonment, breach of fiduciary duty, etc. To date there have been relatively few cases of medical malpractice involving transplant patients, probably because transplantation is still relatively new and experimental. Also, expectations for success are low, and there has usually been a cultivated personal relationship and good communication between the transplant surgeon and the patient and relative. What suits have occurred have generally turned on the question of informed consent, rather than the applicable standard of care[13].

An area of developing concern, in light of current AIDS malpractice litigation, is that of liability on the part of the physician, the hospital, and the donor's estate for the transplantation of AIDS-infected organs. A cause of action could also arise on the part of the donor's family, if they became involved in an active concealment of the donor's health status prior to death.

This is, in reality, an extension of the general question of strict liability for body tissues in the areas of blood and blood products. While early cases allowed the plaintiff to hold the blood supplier strictly liable for contaminated blood products, the clear trend of later cases has been to reject strict liability, considering blood as a 'service'. This is in keeping with provisions of the Federal Act preventing the sale of organs. Thus, the major impact of the increase in AIDS cases will most likely be to limit the number of organs available for transplant, rather than produce a significant risk of malpractice to the practitioner (in the absence of negligence).

ETHICAL AND ECONOMIC CONSIDERATIONS

The United States' health-care system is subject to an ever-expanding technologic pace plus an insatiable consumer demand for the most advanced medical care; and yet our health care faces a future of limited organ resources and inescapable cost-containment measures[13].

Who shall live? Who shall pay? And who shall decide who will get the next transplant? Not only are there problems in securing organs for transplant, but there are also dilemmas for third-party payers in deciding whether to pay for the costly new transplant procedures. The soaring cost of health care has become a significant factor in determining the zealousness of the physician's search for innovative treatment, be it transplantation or other novel treatment. Although seemingly distasteful to some, cost considerations *vis-à-vis* the patient, the community, the state, the payer, and the physician do influence health-care delivery. Cost–benefit considerations are having an impact on the development of the standard of care.

Economic considerations are also important in determining the performance and acceptance of the innovative procedures and, secondarily, in influencing the standard of medical care. Concerns of the patient, the government, health-care insurers, and the public regarding the escalating cost of health care have resulted in increasing scrutiny of transplants. Affordable types of transplantation may also help determine the standard of care in some cases.

Physicians are becoming sensitized to cost-containment. They find themselves caught between demands to provide the best possible treatment for patients and to keep down the cost of medical care. Fortunately, in many cases the cost-effective use of organ transplantation and good medicine are one and the same. Transplant surgeons appreciate that, as consumers of health care, the patient, the government, and the third-party payer demand accountability.

COMMENT

One can expect that national standards for transplantation, including socioeconomic considerations, will be set by the medical profession and applied by the courts. In addition to (or in lieu of) the standard of care set traditionally by the medical community, the courts may take into consideration legal, ethical, moral and economic considerations. They may, as they have in other situations, develop standards that will be set as a matter of law, or judicially imposed. The problems of informed consent and time-of-death determinations should be completely resolved soon.

Regrettably, affordable medical care is, by definition, selective. When coupled with federal budget constraints and resistance by the third-party payer to cost-shifting by the health-care provider, the net result may be the rationing of health care. This is indeed the dilemma of contemporary and managed medical care, and transplantation is a part of the dilemma.

3
Donor Organ Availability and Transplant Coordination

J.S. CHAFFIN AND L. MISCHKE

INTRODUCTION

Organ donation is a process that begins with a need. The need is a patient suffering from failure of an essential organ. To satisfy that need, organ procurement organizations (OPO) have developed mechanisms for identification, referral, and equitable distribution of organs that are made available[1]. The primary function of most OPO is education, not only of the general public but, more importantly, of the professional community, regarding the need for organs and tissue for transplantation. Unfortunately, most OPO are still burdened by the lack of suitable donor referrals.

'Harvesting organs' is not a phrase transplant surgeons commonly use, or enjoy hearing used, in public; but, with rare exceptions, we use it routinely in work, journals, and at medical meetings unattended by the press. In today's climate of ever-expanding demand for organs, the mounting pressure to find viable organs is felt by all transplant units. Nowhere is the pressure felt more greatly than by the retrieval team, whose job it is to evaluate, prepare, and 'harvest' the organ(s).

REASONS FOR INADEQUACY OF DONOR ORGAN SUPPLY

Gallup polls have determined that more than 80% of Americans state that they are willing to donate their organs and tissue for transplantation after death. Only about 17%, however, carry organ donor cards[2]. Currently, in the USA, a significant percentage of patients approved for heart or lung transplantation die awaiting a donor organ[3]. If 80% of Americans actually donated post-mortem organs for transplantation we would be closer to supplying our current needs.

Personal experience demonstrates that grieving families frequently welcome an opportunity to consider organ and tissue donation. The knowledge that other lives have been enhanced through the gift of organs is generally a strong solace for a family struggling to accept what they feel is a 'meaningless' death. The reason given by a significant number of those who do not donate, is that either they were not approached, or that the personnel involved in the care of the patient were not aware of the suitability of the patient as a donor of organs. Well-coordinated public and professional education programs must continue to be developed[4].

In 1968 the National Conference of Commissioners on Uniform Law and the American Bar Association drafted the 'Uniform Anatomical Gift Act', an attempt to provide the states within the USA with a model for recognizing and formalizing methods through which individuals or families could make a gift of their organs or those of a relative. The Act authorizes an individual 18 years of age or older, in the presence of two witnesses, to record his wishes regarding organ donation by will, donor card, or other written document, or orally in the presence of two witnesses, and authorizes the next of kin to consent to organ donation in the absence of the deceased's known objection. Space has been made available on the back of all drivers' licenses for recording the wishes of potential organ donors. Less than 10% of those eligible, however, actually mark their license[5].

While it may not seem to be healthy or 'natural' to anticipate one's own death, or the death of a family member, such anticipation is not infrequent – we buy life insurance to provide benefits upon death, we prepare wills and trusts, and even buy cemetery plots in anticipation of death. In a similar manner we must convince the members of the public to accept consent for organ donation as a logical preparatory step for their own demise.

Trust in the system is imperative, and lack of knowledge or understanding of organ donation procedures may instill fear or lack of trust (Table 1). Common sources of concern or mistrust include: (a) lack of awareness of religious or moral propriety of invasion of the body or removal of parts for transplantation; (b) concern over the care of, or proper respect for, a body after donation; (c) concern that organs may be sold for profit of others; (d) fear that signing a donor card might accelerate their own death, and finally (e) fear that organs might be removed from a person before death has occurred[6]. It is the responsibility of the transplant community to alleviate such fears and concerns through proper education. Historically, mankind responds with altruism when called upon to meet needs it understands and trusts.

Table 1 Questions frequently asked by the family of a potential organ donor

Is there anything more that can be done?
Is he really dead?
Why does his heart still beat?
What organs or tissue will be used?
Who will remove the organs?
Who will receive the organs?
What will surgery be like?
How long will surgery take?
Will an autopsy be necessary?
Will the body be picked up by the funeral home?
Will the Medical Examiner be involved?
When can a funeral be held?
How will he look, after donation?
Who will pay the cost of organ donation?
Will anyone know we donated?
Will the media be involved?
Will we be able to make contact with the recipient?
When will we know if the organs were used?

ORGAN PROCUREMENT NETWORKS

Our own personal experience has been largely in the USA, where organization of organ retrieval is now well advanced at a national level. Most of our comments will therefore relate to the system of organ retrieval as it is in the USA, though the underlying principles are relevant in all countries where organ transplantation is performed.

USA

Currently there are 69 separate OPO in the USA, and another eight in Canada, either hospital-based agencies serving the parent hospital or, more commonly, independent organ procurement agencies serving several transplant centers in a given area.

In 1982 the demand became so great for organizations that could expedite procurement, preservation, and distribution of vital organs that the North American Transplant Coordinators Organization (NATCO) established a computer registry called '24-Alert' to facilitate the distribution of organs other than kidneys. This system coordinated more than 80% of the hearts transplanted in the USA from September 1982 through June 1986.

The National Organ Transplant Act, signed into law in 1984, called for the design and implementation of a national computerized network that would include transplant centers, procurement agencies, voluntary health organizations, and the public. The United Network for Organ Sharing (UNOS) now coordinates organ donation nationally, and lists all vital organs required and available, and produces a printout of the listing. This system cannot be activated without a computer terminal[7]. The computer database includes information on all potential recipients, including name, age, sex, weight, blood type, lymphocytotoxic antibody status, medical status, and identification of unacceptable HLA antigens.

Western Europe

Western Europe now has a number of regional organ-matching services, the first of which was set up in the Netherlands, which is now the base of the European Transplantation Service (Eurotransplant)[8]. Most of these units were set up originally for kidney placement. Although most fulfill their functions primarily in their own areas, should there be no suitable local recipient the organ will then be offered to another transplant service. In this way there has been progress towards an international organization. Since 1984 there has been a marked increase in multiple organ donation throughout Europe. Each region retains the right to service its own population first; only if there is no suitable recipient will that organ be offered to another region.

With multiple organ retrieval the potential for chaos in the operating room seems great when perhaps four separate surgical teams, possibly unknown to each other and speaking different languages, may gather for organ removal. One possible solution, pioneered in Cambridge, England, is to provide one surgical team trained to remove and preserve all organs and tissues for transplantation[8]. It is possible that, in the future, such teams will become available throughout the world to expedite multiple organ retrieval.

Elsewhere

In most other countries, such as South Africa, organ retrieval networks are not as yet so well organized. Major transplant centers tend to rely on organs in their immediate vicinity, and on direct referral from physicians at other hospitals who are aware of their requirements. In South Africa, for example, there is no central unified organ retrieval network, though organs are exchanged from center to center depending on need.

ORGANIZATION OF ORGAN RETRIEVAL

The transplant coordinator

With the evolution of transplantation has come a number of new health-care professionals, none more important than the transplant coordinator. In the USA, coordinators are organized under the North American Transplant Coordinators Organization (NATCO) for credentialling and certification. The OPO usually provides the donor coordinators, and the recipient center provides recipient coordinators. The donor coordinator provides expertise in the management of the brain-dead potential donor, and in the procurement, preservation, and distribution of transplantable organs. The recipient coordinator is responsible for coordination of the pretransplant assessment and preparation of the recipient, together with post-transplant care and follow-up.

Transplant coordination

Recipients are listed on computer by their individual criteria through the United Network for Organ Sharing (UNOS). Once an organ has been identified for transplantation, the chain of events may be lengthy but, in practice, the system works efficiently (Figure 1).

A member of the medical or nursing team caring for the potential donor will contact the local organ procurement agency, either directly or through the hospital transplant coordinator. A member of the local procurement agency will generally go to the hospital to

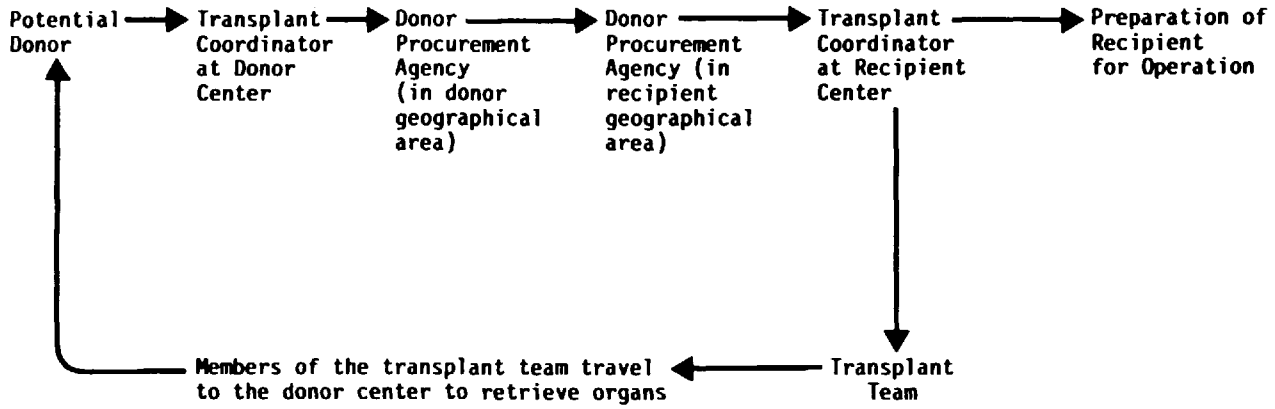

Figure 1 Chain of communication when a thoracic organ donor becomes available

assess the donor personally, and initiate therapy to maintain the donor in as stable a hemodynamic state as possible (Figure 2). A number of essential blood tests will also be requested (Chapter 4).

When basic data, such as blood group, height, weight, and age, are known, the procurement agency will enter this information into the computer, and search for a compatible recipient. With regard to thoracic organs, a potential recipient is generally located within the geographical region in which the donor hospital is situated, but a recipient in a distant region may on occasion be identified as the most suitable.

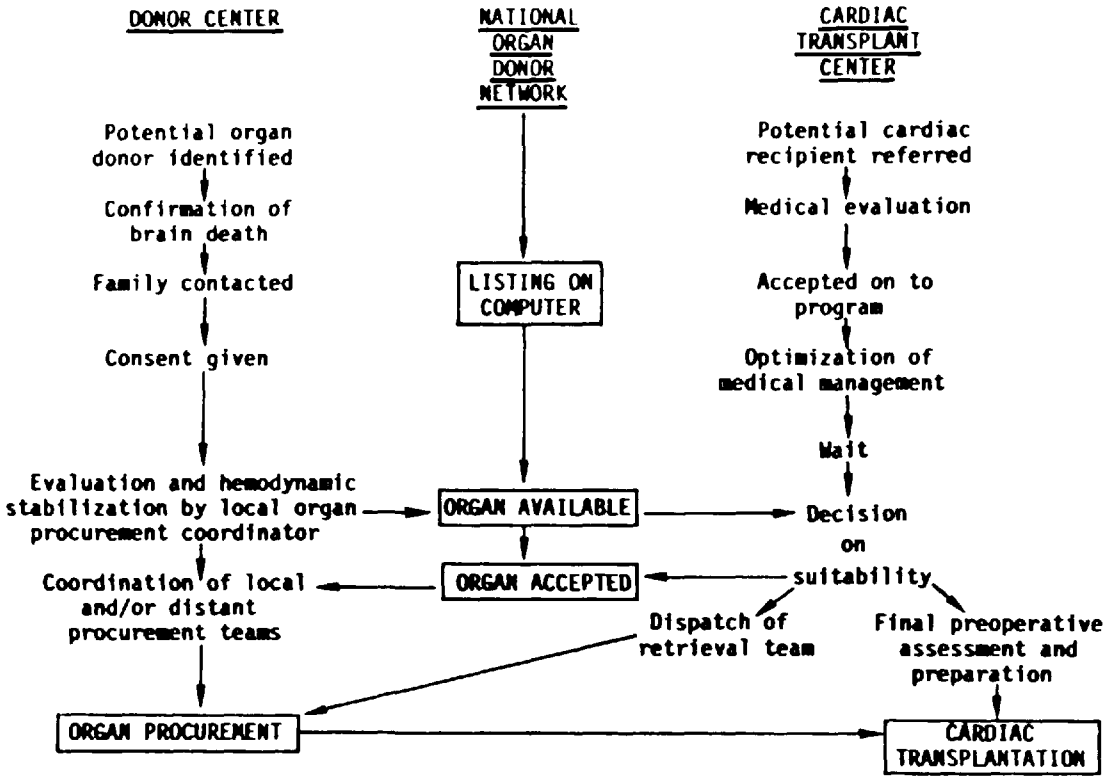

Figure 2 Pretransplant steps involved in the performance of a successful thoracic organ (e.g. heart) transplant

If the recipient is at a distant center, communications will be via the procurement agency serving that area. This agency will, in turn, contact the transplant coordinator or a member of the transplant team in the hospital on whose waiting list the potential recipient is listed. If the donor appears a suitable match for the potential recipient, a number of activities are set in motion.

Transplant coordination at the recipient center

The transplant coordinator at the recipient center organizes the retrieval team (who will travel to the donor center usually with a member of the local donor procurement agency), and the necessary equipment (Table 2). The most expedient transportation (road transport for short range, helicopter for medium range, and private jet for longer distances) is organized. If the potential recipient is not an inpatient he (or she) is notified, arrangements are made to transport him to the hospital, and he is prepared for surgery, which will include any necessary preoperative laboratory tests. All potential recipients waiting as outpatients carry pagers so that they may be easily contacted.

Contact must be made with all appropriate staff (surgeons, anesthesiologist, pump technician, and the operating room personnel) who are advised of the planned transplant procedure. They are advised of the timing, and may require updating at intervals. Contact must be kept with the donor retrieval team to ensure that there will not be an unnecessarily prolonged organ ischemic time. The recipient family is updated frequently by the coordinator during both the pretransplant waiting period and the surgical process. Confidentially as to the donor must be respected and honored.

Transplant coordination at the donor center

Simultaneously, the coordinator at the donor center confirms information on both donor and recipient to ensure acceptable matching of size and blood type. It is not unusual in the USA to have retrieval teams arriving from at least three or four different locations to harvest heart, kidneys, liver, and possibly lungs and/or pancreas. The local coordinator arranges ground transportation from the airport for the teams. It is the donor coordinator's responsibility to ensure that the donor is properly cared for prior to arrival of the retrieval teams, and that on-site arrangements are made for operating-room personnel to assist in the retrieval. This would include anesthesia personnel, as they do not usually travel with the harvest teams. An added burden in the European community might be to ensure a translator is present to overcome any language barrier that might exist between the retrieval teams.

Since we believe that, whenever possible, the heart or lungs should not be ischemic for more than approximately 4 hours, and as 30–60 minutes of this time must be allowed to sew in the transplanted organ, the time of donor aortic cross-clamp should be arranged so that the organ can be delivered to the transplant center within 3 hours. It is essential that close communication be maintained between the retrieval team and the team preparing the recipient, to ensure that the ischemic period is not unnecessarily prolonged. The liver and kidney retrieval teams are usually cooperative, as they appreciate that the heart and lungs have the shortest ischemic survival times of any of the solid organs.

It is vitally important that coordination between the thoracic organ retrieval team(s) and colleagues at the recipient center(s) be well organized at this point, because unnecessary delays of the other retrieval teams do not go unnoticed; a poorly coordinated team may find that it is not invited a second time! Multi-organ procurement etiquette requires being able to work professionally with multiple surgical teams from other programs without creating turbulence. Factors causing friction include arriving late, being unnecessarily demanding with regard to investigations and/or operating room personnel support, and discourteous behavior.

When the procurement team arrives, the surgeon reviews the relevant charts, chest radiographs, and electrocardiogram. The surgeons and/or coordinator call the recipient center to confirm the donor's suitability and coordinate the final stages of preoperative care for the recipient.

Table 2 Equipment required by the heart/lung retrieval team

Supplied generally by donor hospital	*Supplied and transported by retrieval team*
Esophageal temperature probe	Necessary drugs
Blood warmers	Sternal saw
Sterile drape	Sternal retractors – several sizes
Cautery	Special clamps, retractors, or instruments
Suction	Cannulas and administration sets (for cardioplegic/pulmoplegic infusion)
Vascular instruments	Cardioplegic/pulmoplegic solution(s)
Vascular clamps (e.g. Cooley)	PGE1
Pedicle clamps	Cold (4°C) normal saline or ice slush
Satinski clamps	Sterile intestinal bags (for transport of donor organs)
DeBakey forceps	Stapler devices (for trachea, bronchi, SVC)
Umbilical tapes, vessel loops	Portable cool box
Hemoclips	Specimen bottles for lymph nodes
Ties: silk (0000,000,00,0, #1, #2)	
Sutures: silk retention sutures (0)	
Cold (4°C) normal saline or ice slush for irrigation	
Large basin(s)	
Extra poles for supporting intravenous infusion fluids and cardioplegic bags	
Table covers – towels	
Ice and ice bucket	
Heparin	
Inotropic agents	

Before the surgical recovery begins, the surgeons from each of the procurement teams should agree on an order of organ excision which is acceptable to all concerned.

COMMENT

As heart and lung transplantation mature medically, a number of ethical and policy issues remain. A central fact about organ transplantation is the scarcity of organs for transplantation.

The essential need to continue a program of making both the public and the medical profession aware of the requirements of the patient awaiting transplantation has already been discussed. There are, however, several other ways in which the number of organs made available for transplantation could be significantly increased. Several involve possible changes in the laws concerning donation, and some of these will be discussed below. Furthermore, attention must be paid to the efficient use of such organs; unnecessary wasting must be eliminated whenever possible.

'Consent' to donation requirements

The laws governing donation of organs differ from country to country and from state to state. They can basically be divided into three groups: (a) where there are no such laws, (b) required request, and (c) presumed consent.

'*Required request*' implies that the hospital in which a potential organ donor is identified is required by law to ensure that the next-of-kin of the donor is informed of the option of organ donation. The decision as to whether to donate, however, is that of the next-of-kin. Hopefully, this system at least ensures that all potential donors are identified, and that the possibility of organ donation is discussed with their families. Various personnel may be involved in the request for donation. At some centers it is a member of the nursing staff, at others a physician, a hospital chaplain, or an organ donor coordinator. The success of this policy of required request varies greatly from center to center.

The system of family consent for donation from brain-dead, heart-beating cadavers does not result in donation of all of the organs that are medically acceptable for transplantation. It is likely that more hearts and lungs could be retrieved if the need for family consent were modified or even eliminated. The argument in favor of doing this rests on the assumption that the harm that might be inflicted on a (potential donor's) non-consenting family is of less concern than that suffered by a transplant candidate (and his family) who dies from lack of a suitable donor organ.

An alternative is '*presumed consent*', in which the consent of the deceased to donate is assumed unless he/she had previously indicated a formal objection, e.g. in the form of a '*non*-donor' card or by registration on a central computer. Some countries (e.g. Austria, Belgium, Denmark, Finland, France, Norway, and Singapore) currently have such laws, and have seen a significant increase in the supply of organs. Although the law makes it unnecessary, the policy at most centers in such countries is to request family consent, and not to retrieve organs against their wishes. To override strong family objections would almost certainly lead to damaging publicity and impair public relations.

In the USA no state has such a law, although 21 states have some form of presumed consent laws applying to removal of corneas for transplantation, and in Pennysylvania citizens may legally register their objection to donation by attaching a 'non-donor' card to their driver's license. In many states the Medical Examiner can give consent for donation if next-of-kin cannot be located (after reasonable efforts have been made to reach them). In Texas a symbol can be attached to a driver's license that indicates the wish to donate organs without the approval or consent of any family member.

A more radical option would be the elimination of consent altogether, allowing the routine salvage of organs in every suitable brain-dead patient. Routine salvage would treat the deceased's organs or body as a community resource, and permit organs and tissue to be excised as needed. This may not be as radical a solution as it seems. The military 'draft', or the conscription of young people into the armed forces, which is or has been legal in many countries, demonstrates the community's willingness to accept jurisdiction of the live body when an important public purpose – the safety of the community – is at stake.

Relaxation of brain death requirements

Some persons have proposed relaxing the requirement for brain death, which at present includes death of the brainstem, to permit organ retrieval from persons who lack cortical function only[9]. Such a re-definition of death would allow organ retrieval from irreversibly comatose and anencephalic patients. While such a change is not likely to increase significantly the supply of adult thoracic organs, it may prove to be an important factor in the expansion of pediatric heart and lung transplantation.

'Rewarded gifting' – financial incentives to donation

Some form of financial or material incentive to the donor family has been proposed as a way to increase the supply. One plan would enable the donor's family to be rewarded by the State for their humanitarianism in making this valuable gift. Such acknowledgement, by the material rewarding and honoring of families, already occurs in some countries of the Middle East. Offering a small State grant to help pay for funeral expenses, or some form of tax rebate, would be a possible means of financial reward.

Others have suggested more aggressive financial incentives, which would risk making a competitive market of these valuable resources. In the USA, however, it is a federal crime, punishable by 5 years in prison, to 'acquire, receive, or otherwise transfer any human organ for valuable consideration'[10]. Opponents of the 'sale' of organs point out the adverse effect it would have on voluntary organ donation and on donors' families, and its dehumanizing symbolic connotation. Concern has been expressed that a financial inducement would increase the pressure on poor families to donate, but not on wealthier ones, and would therefore lead to discrimination.

Proponents feel that these concerns can be minimized, and are outweighed by the benefits to recipients of a probable increase in the supply of organs. If organ transplant operations are 'sold' by surgeons, inasmuch as the recipient pays the surgeon, the proponents see no harm in 'selling' the organs that make the operations

possible[9]. There are persuasive arguments on both sides, but at present no Western country has passed a law making it legal to offer a financial material incentive to donation.

Modifications in recipient selection

The scarcity of thoracic organs for transplantation inevitably requires a rationing of the organs that do become available. The basis for selecting recipients involves a balance between efficiency and equity in the use of organs. Efficiency is clearly favored at the candidacy evaluation stage, while equity plays a larger role in deciding which candidate on the waiting list receives the organ.

The cardiologist's/pulmonologist's attitude in referring patients for evaluation for candidacy plays an important role in the selection of patients for transplant, and will draw greater scrutiny in the future. The frequency of referral for evaluation varies with the knowledge and attitudes of each individual cardiologist/pulmonologist treating patients with end-stage cardiac or pulmonary disease. Physicians who are unaware of transplant options, or who neglect to refer patients for evaluation, may be denying their patients a viable therapy. Although, to our knowledge, malpractice suits challenging referral decisions have not yet been brought, negligence may soon be claimed in cases of non-referral of patients to transplant centers for evaluation.

The current selection system regarding heart transplantation gives priority to those candidates on the list whose poor physical condition makes them most urgent. These include those who are rejecting a transplant and frequently those who have received a temporary mechanical assist device or artificial heart as a bridge to transplantation. A strict concern for the efficacious use of donated hearts might argue against such an allocation, for the most urgent cases may be less likely to do as well as healthier candidates[11].

While efficiency is important, a strong equity consideration is to avoid abandonment of critically ill patients. Once on the candidate list, one could argue that there is a special commitment not to abandon those in greatest need. Retransplantation after acute rejection of an organ, however, appears to conflict with efficiency by allocating a second organ to a patient who may not have as good a chance of survival as a healthier candidate. Aggressive efforts on behalf of a recipient in acute rejection, however, are viewed by some physicians as essential to demonstrate commitment. Transplantation of a third organ, particularly after acute rejection, would appear to be even more controversial, and policy in this situation is divided between the major centers. Not infrequently these situations are self-limiting, because a donor organ does not become available at the time it is required, particularly during a severe irreversible acute rejection episode.

A similar situation arises with the use of the total artificial heart or ventricular assist device as a bridge to transplantation. Since a significant number of candidates die awaiting transplantation, mechanical hearts and assist devices are used in some programs to act as a bridge until a donor heart becomes available[12]. This actually exacerbates rather than relieves the supply problem for the entire group of potential recipients, although it benefits the individual involved. It increases the number of patients awaiting a transplant, thus increasing the pool of patients from which selection for the next available heart must be made[13]. Moreover, some of these patients will be urgent cases. Although the results of subsequent transplantation in this group are steadily improving, they remain slightly inferior, but the urgent patient will gain priority in the allocation of the scarce resource of the donor heart. This may be considered by some to be a source of inefficiency in the use of donor hearts.

Official designation of transplant centers

Now that heart and lung transplantation have achieved accepted status, a major issue is whether there should be limits on the number of centers doing such transplants. There were 12 centers performing heart transplants in the USA in 1983, but there are well over 100 today, many of which perform relatively few transplants. The situation is developing similarly with lung transplantations.

The Federal Task Force on Organ Transplantation recommended that heart transplants be carried out only at those centers meeting certain criteria, including a minimum volume of 12 transplants a year[11]. Reimbursement through Medicare for both heart and lung transplants limits reimbursement to centers meeting certain requirements for volume and survival. The purposes of permitting only those centers that meet volume and survival criteria to perform thoracic organ transplants include the protection of recipients and the efficient use of scarce organs. Since physicians, patients, and institutions do not have an inherent right to the use of scarce organs, the community is free to limit transplants to designated centers if it deems this limitation essential to the efficient use of this resource.

Physicians in centers unable to meet criteria will argue that access to transplantation in one's own community is a distinct advantage, or that the local community should receive first priority for the organ donations it generates. They should be aware, however, that poor outcomes in centers that do not meet designated standards may be vulnerable to malpractice claims. It is arguably negligent to conduct a transplant program when components that are reasonably deemed essential to good outcome are missing. In any event, it is essential that transplant candidates be informed of a local center's compliance with, or deviation from, accepted standards. In addition, the referring physician should be aware of the standards of a specific center and realize that referral to a center not meeting public criteria for center designation could lead to malpractice claims, and poor patient outcome.

Finally, organ procurement agencies must consider whether it is wise to provide organs to programs that do not meet minimum criteria for safe and efficacious use of donated organs. Presumably, a national network that controlled the distribution of organs would not permit supply to unqualified centers.

The medical and legal constraints on organ donation result in a chronic shortage of hearts and lungs for transplantation. It seems that the demand for organs will always outweigh the supply. How donated organs are distributed, how recipients are selected, etc., are issues of public concern, with demands voiced for public accountability in rationing organs. Medical efficacy plays a major role in selecting recipients, but a variety of equitable and other concerns also enter into the picture. More public scrutiny and

debate about conflicts between efficiency and equity are likely, as is a reduction in the freedom now held by medical professionals to resolve these questions themselves[14].

Selection and Management of the Donor

D.K.C. COOPER AND I.L. PARADIS

INTRODUCTION

The importance of well-functioning donor organs cannot be overemphasized; it is crucial to the success of a heart or lung transplant procedure. Donor organ failure contributes towards a significant number of early deaths in thoracic organ transplant patients today, and is therefore an area where improvements can still be made. Careful selection and management of the potential donor therefore remain essential.

SELECTION OF DONOR HEART OR LUNG

Donor age

Heart

As the incidence of coronary atheroma in Caucasian men increases markedly after the age of 40–45, many groups will exclude men above this age from donation of hearts (and women over the age of 45–50 years) unless fully investigated by cardiac catheterization and coronary angiography. The shortage of donor hearts has become so acute, however, that many centers now consider hearts of both men and women up to the age of 65 years, as long as echocardiography, left ventriculography, coronary angiography, and basic pressure measurements (such as left ventricular end-diastolic pressure or pulmonary capillary wedge pressure) reveal no significant disease. As most donors will be donating multiple organs, including the kidneys, coronary angiography and left ventriculography should be performed using the smallest amount of contrast medium possible, in order not to impair renal function.

Should coronary angiography not be available at the donor center, but it is essential to find a heart for a desperate recipient, some transplant groups believe that the heart could be used if: (a) echocardiography shows normal left ventricular wall movement; (b) direct coronary palpation and inspection reveal no significant signs of atheromatous disease; and (c) no significant ECG changes suggestive of ischemia (preferably with the heart rate increased to >140 beats/min by the infusion of isoproterenol) are present. Though these studies provide only a crude assessment, it is probably justified to use such hearts under urgent circumstances.

Potential donors of certain ethnic groups in some countries may be considered to an older age without the need for coronary angiography. For example, black patients in rural South Africa have an extremely low incidence of coronary atheroma, and may be acceptable as donors up to the age of approximately 60 years without coronary angiography.

A policy of using older hearts for older recipients is now followed by several centers. As early as 1989, Schuler *et al.*[1] provided evidence that donor hearts up to the sixth decade yield satisfactory graft function, even when taken from donors who had not undergone coronary arteriography. Graft function was as good in the recipients of these older hearts as in patients with younger donor hearts. Late complications from reduced ejection fraction and accelerated graft atherosclerosis did not occur more frequently in older donor hearts. Also in 1989, the Houston group similarly showed that there was no increased risk using donors in their 40s compared with younger donors[2]. Both groups urged that consideration should be given to the use of hearts from donors of previously unacceptable age groups, and this has certainly been the trend in recent years, stimulated primarily by the shortage of donor organs.

Recent experience at our own and other centers has shown successful use of hearts from donors in their 60s. However, our own opinion is that coronary arteriography should always be performed in patients of this advanced age group. Despite a good outcome reported at several centers, some caution must be shown as data from the International Society for Heart and Lung Transplantation Registry indicate that increasing age of the donor is associated with a higher recipient mortality (Chapter 43).

Lung

Some centers do not like to utilize lungs from donors who are 50 years or older, and a majority become cautious when donors of 55 years or older are presented. Even if the patient has not been a smoker, there is some loss of lung function in many patients >50 years of age, and this may increase the risk of poor lung function

after transplantation. Multivariate logistic regression analysis of risk factors for 1-year mortality after heart–lung transplantation reveals that a donor older than 40 years is a statistically significant risk factor for survival of the recipient. Similarly, a donor >45 years old is a significant risk factor for death in the first year after double lung transplantation[3]. Some centers would therefore not utilize a donor aged >40 years for transplantation of the combined heart and both lungs (Chapters 67 and 69). The age of the donor (<55 years of age) has not been shown to affect survival after single lung transplantation.

Donor size

Heart

The donor heart must clearly be large enough to support the recipient's circulation immediately after transplantation, but not so large that it is compressed when the chest is closed. The latter circumstance is relatively rare in adults, as most patients undergoing heart transplantation have large native hearts and large pericardial cavities. It is a much more important consideration in children. There are no absolute rules, and successful transplantation has been performed using donors weighing <50% to >150% of the recipient. However, a good working guideline is that the body mass of the donor should not vary from that of the recipient (either larger or smaller) by more than approximately 25–33%. A donor whose body mass is within these limits will usually support the circulation after orthotopic transplantation without difficulty, and will not prove too large or too small.

Chan *et al.*[4] used echocardiographic measurements of left and right ventricular internal dimensions, left ventricular mass, and percentage fractional shortening, and showed there were no significant differences in left ventricular internal dimension when women weighing 40–109 kg were compared with men weighing up to 80 kg. Left ventricular size was not statistically different among men weighing 50–99 kg. No difference was noted in right ventricular size among men and women. Body weight, therefore, does not correlate well with adult cardiac size, and should possibly not be used as an exclusion criterion for a donor heart.

Other factors, therefore, may have to be taken into consideration. The relative heights, muscle masses, and ages of the two subjects are also important factors. The heart from a tall, muscular, yet slim athletic teenager may be functionally satisfactory for a short but much heavier, though relatively inactive, older patient. In contrast, the heart may prove inadequate if the recipient is much taller and has little fat when compared with the donor. If the need of the recipient for transplantation is urgent, and yet the body mass of the donor is >33% less than that of the recipient (i.e. the donor weighs <67% of the potential recipient), then heterotopic heart transplantation should be considered as a possible option (Chapter 37).

Several groups have reported the results of using undersized donor hearts. For example, Blackbourne *et al.*[5] used 28 hearts where the donor-to-recipient body weight ratio was only 0.6–0.8. Hospital survival for non-urgent (UNOS status II) recipients was no different when undersized donors were used than when normal or oversized donors were used. However, in more critically ill patients (UNOS status I) there was a significantly higher mortality when undersized donors were used. This would suggest that, in patients where the risk is already high, the additional risk of utilizing a small heart may reduce survival. However, not all groups have confirmed this increased mortality. The Tucson group showed comparable survival in recipients receiving hearts from donors with a weight difference of >30% (range 30–46%)[6].

In a study from Loyola in 1991[7], the clinical and hemodynamic characteristics of recipients weighing more than their donor (undersized) were compared with those of recipients weighing less than their donor (oversized). Oversizing of donor hearts did not improve the outcome of orthotopic heart transplant recipients who had reversible preoperative pulmonary hypertension. Acceptance of undersized donor hearts was not detrimental to allograft function and recipient survival. This group therefore recommended the use of undersized donor hearts to maximize the use of this critically scarce donor organ.

The Vanderbilt group went one step further and concluded that, in the presence of moderate preoperative pulmonary hypertension, long-term cardiopulmonary function was compromised in recipients of oversized allografts and mildly impaired in recipients of size-matched allografts[8]. In the absence of pulmonary hypertension, cardiopulmonary function was impaired to similar degrees with undersized, size-matched, and oversized allografts. These findings supported the liberal use of undersized hearts for transplantation in patients without moderate pulmonary hypertension and, furthermore, suggested that oversized allografts are not beneficial to long-term cardiopulmonary function in patients with moderate pulmonary hypertension.

By carrying out right-sided cardiac catheterization 3 months after transplantation, Hosenpud *et al.*[9], however, demonstrated that although cardiac output was maintained at levels appropriate for recipient size, patients who had received small hearts relied on an increased heart rate and elevated filling pressures to achieve this end. This suggested that the small cardiac allograft had not adapted to recipient body size by 3 months.

Reviewing all of these studies, it would appear that close matching of donor and recipient sizes is not essential, but probably preferable.

In contrast to orthotopic heart transplantation, a close size match between donor and recipient thoracic cavities is required for transplantation of the heart and both lungs (Chapter 67). Undue compression of the donor lungs within the recipient's thoracic cage results in significant atelectasis and cardiac compression. Although fewer problems result from the use of smaller donor organs, the donor thoracic cavity dimensions should not deviate from those of the recipient by more than approximately 20%[10].

Lung

Selection of a suitable lung is based more on the respective heights of the potential donor and recipient than on the weight. The etiology of the lung disease, however, is of great importance. Patients with chronic obstructive pulmonary disease with emphysema have overexpanded lungs, and therefore can accept a donor lung that is rather larger than would be expected. Therefore, a shorter patient with emphysema could accept a lung from a rather taller donor. However, care has to be taken to ensure that the lung is not too large, or chest movement will be impaired.

A patient with pulmonary fibrosis will have a small thoracic cage and therefore may require a donor lung that is smaller than would be anticipated for the patient's height. Patients with primary pulmonary hypertension often have lungs that are of normal size in relation to height.

A comparison of the measurements taken on chest radiographs usually provides fairly reliable information regarding the relative sizes of the donor and recipient thoracic cavities. Sometimes external measurements of the donor chest (e.g. the submammary thoracic perimeter[11]) are also made, to compare with those of the recipient chest. Given the great variability in muscle and fat mass around the thoracic cage (and the variable size of breasts in women) a comparison of chest radiographs probably provides a more accurate assessment. The chest radiographs to be compared should be taken at a standard distance from the subject (e.g. 1 meter), preferably with both subjects in a supine position. If possible, both anteroposterior and lateral films should be available for comparison.

Measurements on the chest radiograph that have been found useful are illustrated in Figure 1. Alternative measurements that have been used at some centers are: (a) sternal notch to xiphoid, (b) sternal notch to lower rib margin, (c) sternal notch to acromion, (d) chest diameter halfway from sternal notch to lower rib margin, and (e) chest diameter at the level of the lower rib margin. All of these measurements can be readily obtained from the potential recipient during his or her initial evaluation, and from the donor at the time when brain death is established.

When the internal thoracic diameters of the donor are larger than those of the recipient, the donor may need to be excluded from donation for that recipient, although experience is developing in reducing the size of the donor lung when necessary (Chapters 51 and 52). When the internal thoracic diameters of the donor are up to 25% less than those of the recipient, the donor will generally be acceptable.

Some centers no longer rely on comparison of chest and/or chest radiograph measurements, but prefer comparisons of height, weight, and total lung capacity (measured or predicted)[12,13]. The total lung volume of the donor (and the recipient) can be calculated approximately from a knowledge of his/her height and sex (Figure 2)[14]. This is probably the most accurate guideline for the size of lung that could be accepted by any individual recipient.

The *actual* measured total lung volume of the recipient is likely to be increased in the emphysematous patient and restricted in the patient with pulmonary fibrosis. In the case of the emphysematous patient, the optimum size of the donor lung is difficult to determine; as a general guide the *estimated* size of the donor lungs should be approximately 80% of the recipient's *measured* total lung capacity[12,13]. This may necessitate selecting lungs which have a greater volume than that *estimated* for the recipient by the height/sex-based formula.

The experienced Barnes Hospital group from St Louis[15] attempt to provide a prospective recipient with donor lungs that would be an appropriate size for the patient if the thoracic configuration were not altered by his or her lung disease. For single lung recipients they attempt to oversize the donor lung. In contrast, for double lung recipients they make an effort not to oversize, so as to facilitate recipient chest closure. In general, patients with pulmonary fibrosis receive a lung larger than the

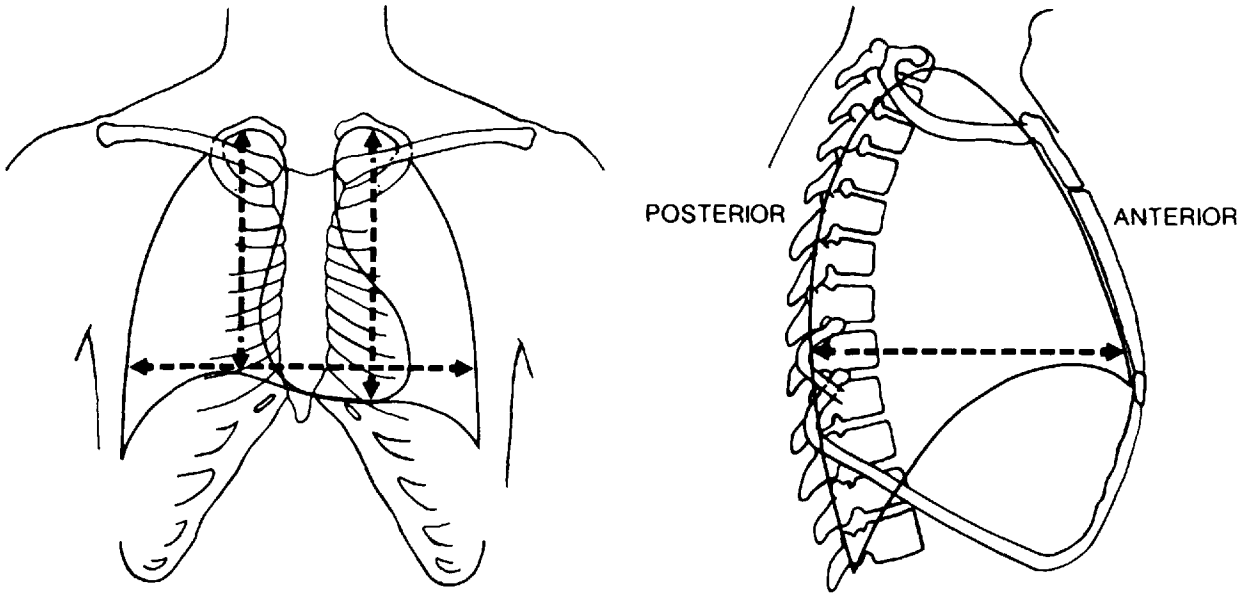

Figure 1 Measurements of anteroposterior and lateral chest radiographs found helpful in assessing relative sizes of donor lungs and recipient thoracic cavity. All measurements are made on chest radiographs ideally taken in the supine position with the camera at a set distance from the radiographic plate. Measurements include: (a) vertical distance from the apex of the pleural cavity to the diaphragm on both right and left sides; (b) the transverse diameter of the widest point of the chest (this is usually near or at the costophrenic angle). If lateral chest radiographs are available (which is rarely the case with the donor) then (c) the anteroposterior diameters from the anterior surface of the vertebral column to the posterior surface of the sternum, and from the posterior curvature of the ribs to the back of the sternum (both of these measurements being made at the midsternal and diaphragmatic levels), can provide additional information.

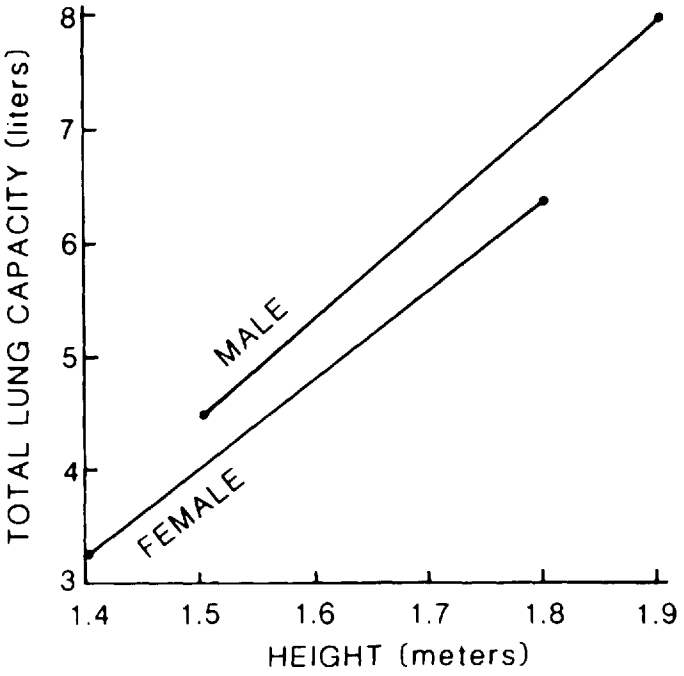

Figure 2 The total lung capacity of the donor can be calculated approximately from the knowledge of his/her height and sex (modified from ref. 13)

native one, and patients with emphysema receive a lung smaller than the native one(s). This rationale is based on observations of mediastinal shift, diaphragm realignment, and chest cavity changes subsequent to lung transplantation. To date this group has observed no difference in outcome or in function related to whether a right- or left-sided single lung implant is placed. For patients with pulmonary hypertension, a single lung that is larger (by 30%) than the size of the native lung is preferred, in order to accommodate the pulmonary blood flow, which is almost all preferentially directed into the allograft due to the elevated vascular resistance in the remaining native lung.

For transplantation of the heart and both lungs a discrepancy of 2–4 liters in pulmonary capacity between donor and recipient can generally be tolerated without the risk of complications. Atelectasis and intrapulmonary shunting have been reported when donor lungs that were too large for that particular recipient were transplanted[13].

Blood group compatibility

It is essential to have ABO blood group compatibility between donor and recipient (Chapter 6). There is an estimated approximate 60% risk of early hyperacute or accelerated acute rejection if ABO incompatibility is present[16]. There are data that suggest that a recipient who receives a heart from an ABO-identical donor (e.g. O to O, or A to A) may survive longer than one who receives a heart from an ABO non-identical, yet compatible, donor (e.g. O to A)[17] (Chapter 6). The shortage of donors is such, however, that most groups will transplant if there is ABO compatibility. Rhesus blood group compatibility is not considered to be of importance.

Presence of lymphocytotoxic antibodies in the recipient

Whenever lymphocytotoxic (LCT) antibodies have been demonstrated to be present in the recipient serum (by prior screening against a panel of lymphocytes), the results of a donor lymphocyte–recipient serum crossmatch should be obtained if at all feasible (see also Chapter 6). Some groups would consider this may not be essential if the level of panel reactive antibodies (PRA) was <10–15%. In the presence of a positive crossmatch (demonstrating antibodies to be present in the recipient serum against the donor cells), there may be a significant risk of hyperacute rejection of the transplanted organ and, unless expert opinion is otherwise (Chapter 6), that donor should not be used for that specific recipient (except possibly if the recipient is likely to die before another donor becomes available, when the risk may be justified).

Exclusion of cardiac or pulmonary disease in the donor

Heart

Patients with pre-existing cardiac disease are obviously unsuitable for heart donation, as are those who have undergone thoracic trauma resulting in contusion of the heart. Previous surgery within the pericardial cavity usually also precludes donation. A history of: (a) severe or long-standing diabetes mellitus, particularly if known to have been poorly controlled or when there is evidence of microvascular disease; (b) long-standing systemic hypertension, particularly if it was known to be resistant to antihypertensive drug therapy or if poorly controlled through the patient's non-compliance; and (c) smoking for many years, may all preclude donation of the heart, or at least indicate the need for very careful assessment of cardiac function, particularly in older donors. For example, features suggestive of ischemia or significant left ventricular hypertrophy on ECG or echocardiography may be sufficient to abandon the heart, or to proceed to coronary angiography and left ventriculography.

The presence of a gross cardiac disorder can generally be excluded by: (a) taking, whenever possible, a clinical history from the patient's relatives or his/her own medical practitioner; (b) careful clinical examination; (c) chest radiography; (d) 12-lead electrocardiography; and (e) echocardiography[18]. However, invasive studies may be required when there is a high suspicion of the presence of cardiac disease from the donor's history. If murmurs or added sounds are not to be missed, it is essential that the clinical examination be performed when a normal arterial pressure is present. Intracranial damage itself may cause ST and T wave changes on the ECG[19,20], which may not be important if all other investigations suggest a normal heart. Hypothermia leads to bradycardia and/or presence of J waves, which are of no pathologic significance, but can be confused with ECG changes suggestive of ischemia.

Echocardiography to determine ventricular wall shortening fraction should also be carried out to give some indication of the quality of myocardial contractility. Septal motion is often paradoxical in brain-dead subjects, though the cause of this is unclear; in our experience its presence does not appear to be associated

with impaired ventricular function in the post-transplant period. It may be unwise, however, to accept a heart where the left ventricular ejection fraction (LVEF) is significantly <50%, particularly if the donor is receiving moderately high doses of an inotropic agent (e.g. dopamine at 12–15 μg/kg per minute). Imaging is not easy in some donors, and transesophageal echocardiography should be considered if transthoracic visualization is not adequate[21].

Individual judgement is required in each case, and the experienced transplant surgeon may accept a heart that has a LVEF <50%. In a study from the University of Virginia at Charlottesville[22], cardiac dysfunction was defined by an ejection fraction <45% and/or a significant segmental wall motion abnormality using standard two-dimensional echocardiographic criteria. These 'marginal' donors were considered acceptable at the time of inspection if: (a) there was no obvious reason for poor function, such as the presence of coronary artery disease or cardiac trauma; (b) the inotropic support requirement was only modest (<10 μg/kg per minute dopamine); (c) hemodynamic parameters were otherwise normal; and (d) the donor heart appeared viable without evidence of cardiac contusion.

More sophisticated tests that assess left ventricular function (such as monitoring of the left ventricular pressure–volume relationship[23]) can be employed, but are more invasive and are frequently unavailable. Measurement of total serum creatinine phosphokinase (CPK) and the CPK-MB isoenzyme should be carried out in cases in which myocardial injury is suspected, and caution should be used in decisions regarding hearts from donors in whom the CPK-MB isoenzyme is extremely elevated. Cardiac troponin I, a sensitive and highly specific marker of myocardial injury[24], is also being explored at some centers in an attempt to detect unsuspected myocardial injury.

Ideally, there should be no history of severe hypotension or cardiac arrest at any time. Recovery from such episodes, however, with return of an adequate blood pressure and diuresis, suggests that myocardial function remains satisfactory. Cardiac arrest requiring a prolonged period (e.g. more than a few minutes) of external cardiac massage, or repeated cardiac arrests, or frequent or intractable episodes of ventricular dysrhythmias, are generally contraindications for use of the heart, unless a long period of stable myocardial function has subsequently been clearly documented.

Many cardiac surgeons believe that the most reliable means of assessing donor heart function is by direct inspection of the organ at the time of procurement, and this is clearly a most important part of donor selection. It is therefore essential that an experienced surgeon should assess each donor heart on an individual basis. Donor heart assessment and retrieval is not a procedure that can safely be left to an unsupervised junior member of the surgical team.

The UCLA group[25] has performed coronary artery bypass surgery on donor hearts with localized atherosclerosis. The surgery has been performed *ex vivo* while the donor heart is still stored in cold saline. Although this has enlarged the donor pool, and has been relatively successful, this procedure is not without its risks and should not be undertaken without very careful consideration.

Lung

Patients with known lung disease are clearly unsuitable for donation. This would include patients with obvious chronic obstructive airway disease or pulmonary fibrosis, as well as lung trauma. Previous surgery within the pleural or pericardial cavities usually precludes donation. The presence of a chest tube (frequently placed to treat a pneumothorax following insertion of a central venous pressure line) is not a contraindication to use of the lung if there is no significant air leak. Patients with infections of the lung, whether chronic or acute (pre- or post-brain death), are also usually excluded. The presence of neurogenic pulmonary edema, a not-uncommon sequel to the hemodynamic changes that take place during brain death, is generally exclusionary. An acutely failing donor heart generally results in poor lung function and therefore may preclude lung donation, but the presence of an acute or chronic cardiac disease (e.g. coronary artery disease) in itself is not a contraindication to lung donation if pulmonary function remains good.

A history of asthma is a borderline contraindication. If severe and prolonged for many years, then this may be an absolute contraindication. Evidence suggests that asthma in the donor leads to asthma in the recipient[26].

Although smoking is not exactly a 'disease', patients who have smoked a total of more than 20 pack-years (i.e. one pack a day for 20 years or equivalent) are generally excluded on the grounds that their lungs may have lost some elastance.

Pulmonary function, as assessed by compliance and gas exchange, may require repeated assessment to ensure that no significant deterioration is occurring before the lungs are excised. With positive end-expiratory pressure (PEEP) of 5 cmH_2O and an F_iO_2 of 0.4 (40% O_2), the Pao_2 should be >100 mmHg. On an F_iO_2 of 1 (100% O_2), the Pao_2 should be >300 mmHg. Lung compliance should exceed 0.1 l/cm H_2O at a tidal volume of 10 ml/kg. In a patient with a non-obstructive endotracheal tube *in situ*, an inspiratory volume of 15 ml/kg should not result in a *static* pressure of more than 20 cmH_2O being measured. This will indicate a relatively normal lung compliance. The measurement should be repeated three times and an average taken. Possibly the simplest way of testing lung compliance is by increasing the ventilatory tidal volume from a minimum 500 ml in an adult by 100 ml increments to 1000 ml; *peak* inspiratory pressure should not rise above 30 mmHg. Airway resistance, though not a routine measurement (on mechanical ventilation), should be <1.6 cm H_2O/l per second[27,28].

In order to achieve or maintain good lung function, fluid restriction is necessary, especially with respect to crystalloid solutions. Close monitoring of central venous pressure (which should be maintained as low as possible compatible with the maintenance of other vital organs), and cautious application of catecholamines are mandatory. Prolonged artificial ventilation, an F_iO_2 exceeding 0.5 (50%), and positive end-expiratory pressures >10 mmHg should all be avoided, if possible.

Due to nosocomial infections, mechanical ventilation in brain-dead subjects for more than 4–7 days will generally preclude use of the lungs for transplantation. The chest radiograph should be clear of major pulmonary infiltrates, including post-traumatic opacifications, suggesting contusion or infection, though some would not decline use of the lungs on these grounds alone if there were no confirmatory evidence of pulmonary damage or infection. Minor areas of infiltrate may not preclude donation[15]. Before the donor operation, frequent aseptic and thorough endotracheal suction and toilet is mandatory, and a broad-spectrum antibiotic should be administered (see below).

The majority of donors have bacterial colonization of the tracheobronchial tree despite normal radiographic appearances. Therefore, specimens should be taken before (optimally, via a bronchoscope) harvesting, to allow immediate Gram stain and cultures[29-31]. The presence of purulent sputum with a large number of organisms on Gram stain, especially if of only one type and if intracellular, indicates the presence of an active infection and may be a contraindication to donation. Some centers, however, might accept such a donor if the offending organism(s) had been identified and specific antibiotic therapy initiated in both donor and recipient. The presence of some neutrophils but no organisms on Gram stain will generally not preclude donation. Postoperative antibiotic treatment can be based on the results of culture. The presence of heavy fungal colonization of the tracheobronchial tree is generally considered a contraindication to donation.

Many believe bronchoscopy to be essential before a final decision is made to accept a lung for transplantation[32]. In 26 otherwise acceptable donors, bronchoscopy was abnormal in 10 (38%) and was sufficiently abnormal in six (23%) to preclude lung donation. The allografts of two recipients whose donor had evidence of aspiration of gastric contents, but normal chest radiograph and gas exchange, failed at 15 and 12 days post-transplantation. The allografts of two recipients whose donors had evidence of aspiration of blood only had uncomplicated post-transplant courses. Certainly, if: (a) the chest radiograph shows any abnormality in the lungs; (b) the endotracheal aspirate is purulent, or significant microorganisms are seen on Gram stain; or (c) there is a possibility of aspiration of gastric contents into the tracheobronchial tree during the course of the donor's care, then fiberoptic bronchoscopy should be performed. Inflammation of the walls of the bronchi with or without the presence of purulent secretions/gastric contents strongly suggests aspiration, and contraindicates use of the lung(s).

Based on bronchoscopy, the absolute contraindications to accepting a donor lung are grossly purulent secretions (especially if voluminous) and the finding of aspirated foreign material or evidence thereof (e.g. severe erythema and tracheobronchitis)[14]. Blood entering the airways is obviously common after head trauma. With the passage of time the blood imparts a distinctly brown coloration to the bronchial secretions, which can be distinguished from pus. If this can be cleared by suctioning, and the bronchial mucosa appears normal, the lung is generally considered suitable for use[15].

The University of Virginia group consider a lung donor to be marginal with a Pa_{O_2} of <350 mmHg on 100% F_iO_2, the presence of infiltrates on chest radiograph, or purulent secretions on bronchoscopy[22]. However, they found these marginal lungs frequently acceptable if the patient had been on a ventilator <24 h and the secretions could easily be cleared by suctioning, even if purulent material was present. A Gram stain revealing bacteria did not exclude a donor unless there was evidence of gross fungal contamination.

The Barnes Hospital group in St Louis considered a lung donor to be marginal with a Pa_{O_2} <300 mmHg on F_iO_2 100%, or when radiographic infiltrates or evidence of trauma were present in either lung. There was, however, no difference in outcome as defined by: (a) $A\text{-}a_{O_2}$ gradients, (b) time on ventilator, and (c) 30-day survival, between marginal and ideal donors[33].

Transferable disease

Neither heart nor lung should be transplanted from donors with transferable disease, such as a malignant lesion (other than a primary tumor of the central nervous system, which generally does not metastasize elsewhere) (Chapter 12) or certain serious infections.

The presence of pyrexia in the hours or days before death may be related to the brain injury itself, and may not necessarily indicate serious infection, although every effort must be made to exclude this possibility. Once brain death has occurred, body temperature usually falls to subnormal levels over the course of a few hours. The length of time that the patient has been ventilated mechanically is equated with an unavoidable degree of pulmonary infection, overt or otherwise, and possibly also with some lung injury; not more than 3 days is desirable, particularly in the case of the lung, and longer than 7 is usually unacceptable even for the heart.

The presence of overt acute pulmonary infection almost certainly precludes donation of the lungs, but does not rule out heart donation. In one study from St Louis, in 43% of cases in which bronchial washings from donor lungs grew at least one organism, similar organisms were isolated from the tracheobronchial tree of the recipient[34]. Six of these recipients (21%) subsequently had invasive pulmonary infection as a result of the organism originally isolated in the donor. The St Louis group recommended that antibiotic coverage in transplant recipients should be initiated on the basis of Gram stain results, and modified on the basis of cultures obtained from the donor lungs. Others also follow this policy[29,31,35].

Infection in the renal tract of the donor is not a contraindication to use of the heart or lungs. Many hearts and some lungs have been transplanted successfully from donors with positive blood cultures; the decision to use an organ from such a donor is a difficult one, and not without risk, but, if the infected organism is known, the recipient can be administered the appropriate antibiotic(s). The policy of many groups in regard to the chance finding of a positive blood culture is liberal; if the patient has clinical features of sepsis, however, the organs should not be excised for transplantation.

Positive human immunodeficiency virus (HIV) antibody serology should preclude transplantation, and this test should clearly be performed before donor organ excision[36]. When positive, if time allows, the test should ideally be repeated, as false-positive results can occur. If the donor is believed to be 'high risk' for HIV positivity (e.g. homosexuals, intravenous drug abusers, hemophiliacs), and yet the HIV antibody serology remains negative, the decision whether to use the organ must be based on the urgency of the potential recipient's condition, after full discussion with the patient and/or his or her family. When making such a decision, the possible risks to operating room, intensive-care unit, and laboratory staffs must also be taken into consideration. Current opinion is that organs from 'high-risk' donors should probably not be used[37]. Transfer of HIV has been reported with kidney, liver and heart transplants with poor survival[38-42]. In five such heart transplants, only two patients had survived with a mean follow-up of 2.75 years.

Blood specimens from the donor are taken for bacterial culture and serologic tests for syphilis, cytomegalovirus, hepatitis B

surface antigen (HBsAg), and hepatitis C serology[36] (which are essential), and Epstein–Barr virus, herpes simplex virus, *Toxoplasma*, and hepatitis A (which may also prove to be valuable). The results, especially for hepatitis B and C, should be available before the organ is excised. If, under unusual circumstances, the transplantation has already taken place when the results become available, the result, if positive, may be of considerable importance in the subsequent care of the recipient.

A thoracic organ from a donor known to be HBsAg-positive should probably not be utilized unless the recipient has previously been vaccinated against hepatitis B. When the need of the recipient is extremely urgent, however, this should possibly not prevent donation, as long as the recipient is covered by a course of gamma-globulin.

Hepatitis C may take several years to cause clinical symptoms, although its progress may be much more rapid in an immunosuppressed subject. The decision to use a thoracic organ from an anti-hepatitis C antibody-positive donor is, therefore, a difficult one, and depends to a great extent on the status of the potential recipient. The recipient almost always seroconverts after transplantation[43]. Even if he or she does, clinical or biochemical features of hepatitis may not develop for several years. We have therefore chosen to transplant such hearts into patients whose life expectancy is short (i.e. days), who are deteriorating in an intensive-care unit despite inotropic, intra-aortic balloon pump with or without ventilator support. Availability of therapy with interferon in the post-transplant period (if the recipient seroconverts) has made us slightly more liberal in the use of hepatitis C-positive donors in such cases. However, the development of clinical hepatitis in the recipient can be fatal, and the decision to risk this eventuality should not be taken without due consideration, which includes full discussion with the patient and his/her family.

With regard to organ transplantation in hepatitis C-positive recipients and the use of hepatitis C-positive organs, Milfred *et al.* carried out a survey of 45 cardiothoracic transplant centers[44]. Seventy-five percent stated that they would list an HCV-seropositive candidate (either directly or by lack of routine screening to exclude such a patient). Only 16% would not accept HCV-seropositive candidates. Nine percent had no policy. Overall, 69% accepted organs from HCV-seropositive donors, at least for selected recipients. Twenty-two percent of the centers said they would accept an HCV-positive donor for any recipient (although a knowledge of the practice at other centers does not support this surprisingly high figure), 45% would select for only HCV-seropositive and/or urgent (UNOS status I) recipients, and 2% would not screen donors and would therefore be unaware of the HCV status of the donor. A total of 27% of the centers would never accept organs from an HCV-seropositive donor, and 4% had no policy towards this issue.

The presence of a positive test for syphilis in the donor need not preclude donation, but it would seem wise to give the recipient a course of antibiotic therapy to prevent transfer of disease. An IgM level suggestive of recent cytomegalovirus infection would generally not preclude use of the heart for transplantation, though an occasional group would not use a CMV IgM- or IgG-positive donor for lung or heart–lung transplantation in a cytomegalovirus-negative recipient.

Toxoplasma has been transplanted with the donor heart[36,45], and unless clinically suspected in the donor is likely not to be diagnosed until after transplantation, sometimes purely on endomyocardial biopsy[45].

Effects of drugs of addiction/substance abuse on the donor organs

Cigarette smoking is probably the most common form of substance abuse and a high percentage of donors will have such a history. This may clearly have a direct effect on the heart or lungs to be used for transplantation, by contributing towards ischemic heart disease and/or emphysema. These matters have been discussed above.

Marijuana/heroin

The smoking of marijuana is also fairly common. If only occasional, it probably is of little significance, either as a contributing factor toward injury to the organ or as an indicator that the donor may be in the high-risk category with regard to HIV or hepatitis. If marijuana use has been heavy, particularly if it has extended over many years, the suspicions of the surgical team must be aroused to the possibility of the intravenous use of other drugs (e.g. heroin) that would increase the possibility of the donor having been exposed to HIV or hepatitis. The history of drug use is frequently inadequate and vague, making decisions of this nature difficult. Physical evidence for intravenous drug abuse (e.g. needle marks in the cubital fossa) should be sought. In the absence of positive serology, and when the clinical history of intravenous drug abuse is certain or strongly suspected, the risks of transfer of an infectious agent to the recipient have to be weighed against the current status of the recipient for whom the organ is intended.

Cocaine

The increasing use of cocaine worldwide – in the USA an estimated 6 million individuals use the drug on a regular basis – leads to the supposition that some donor organs are from unknown cocaine users. Toxicology screening of all donors may more accurately define the incidence of cocaine usage in the donor population. Cocaine produces vasoconstriction, which results in a reduction in coronary artery diameter and coronary blood flow. Cocaine use appears to be associated with a variety of cardiovascular diseases, including ischemic events, myocarditis, and myocardial dysfunction[46–48]. Electrocardiographic and echocardiographic abnormalities are common in long-term cocaine abusers. Several autopsy and endomyocardial biopsy studies in cocaine users have shown contraction band necrosis, myocyte necrosis, and diffuse inflammatory cell infiltration.

Minor *et al.*[46] reported cocaine-induced myocardial infarction in patients with normal coronary arteries. Experimental evidence suggests that cocaine has direct and indirect sympathomimetic effects on vascular smooth muscle, attenuates endothelium vasodilator capacity, exerts a potent depressant effect on cardiac myocytes, and promotes atherogenesis. Cocaine-induced myocardial infarction in patients with normal coronary arteries therefore probably involves adrenergically-mediated increases in myocardial oxygen consumption, vasoconstriction of large epicardial

arteries or small coronary resistance vessels, and coronary thrombosis. Accelerated atherosclerosis and impairment of endothelium vasodilator function may occur after chronic cocaine use.

Warner has reviewed cocaine abuse in some detail[48]. In the USA 7% of adults between 18 and 34 years old had used cocaine during the previous year. In the 1970s and 1980s the development of 'free base' and 'crack' cocaine revolutionized the use of the drug by providing a form that could be smoked. Cocaine can be absorbed through any mucous membrane or injected intravenously. Ninety percent of cocaine users have snorted cocaine, making intranasal insufflation the most common route of use. About one-third of users have smoked the drug, and fewer than 10% have injected it. Free base and crack are the same chemical form of cocaine, but are made using different techniques.

Complications associated with cocaine use include chest pain, myocardial infarction, arrhythmias, cardiomyopathy, myocarditis, pneumothorax, pneumomediastinum, pneumopericardium, pulmonary edema, exacerbation of asthma, pulmonary hemorrhage, bronchiolitis obliterans, and 'crack lung'.

The use of hearts and lungs from donors with a history of cocaine abuse remains controversial. Information regarding the route of administration, purity, quantity, and duration of cocaine exposure is frequently incomplete. Traditionally, hearts from cocaine-using donors have been excluded from procurement. Certainly, if a history of intravenous drug abuse is elicited, such hearts are declined. Routine two-dimensional echocardiography and the inspection of the donor heart by the surgeon at the time of procurement may help to identify and exclude any hearts with significantly depressed global myocardial function.

In a study from Los Angeles, however, 16% of donors had a positive history for non-intravenous cocaine use[49]. No detrimental effects of cocaine usage on donor heart function, recipient survival, hospital stay, or rejection frequency could be detected. Survival rates between this group and those who did not have such a history were similar at 30 days and at 1 year. Freedom-from-rejection rates were also similar at 30 days and 6 months. The investigators concluded that the outcome of patients who received transplanted hearts obtained from non-intravenous cocaine users was favorable, suggesting that the use of such hearts is safe.

Among the Los Angeles patients, none of the initial endomyocardial biopsies carried out within the first 2 weeks after transplantation showed significant inflammatory infiltrates or myocyte necrosis. This finding could possibly be explained by: (a) preselection of hearts without global dysfunction, (b) exclusion of intravenous drug users as donors, and (c) the time elapsed from the last exposure of cocaine until the first biopsy.

Since chronic and irreversible lung dysfunction secondary to cocaine use has not been demonstrated, most groups would not decline a lung from a donor solely on the grounds that he or she was a cocaine user.

Alcohol

A report from Paris investigated the relatively high proportion (approximately 20%) of donors in France who had a history of chronic alcoholism, which was found to be a very detrimental factor to survival of the recipient after heart transplantation[50]. Fifty-four percent of patients who had early cardiac graft dysfunction versus only 12% of patients who had immediate normal graft function had received a graft from an alcoholic donor. Among the early deaths from cardiac dysfunction, 40% of patients had an alcoholic donor. Excluding such alcoholic donors or reserving them for critically ill recipients would seem preferable.

Preclinical alcoholic cardiomyopathy seems to be independent of the duration of chronic alcoholism and of the quantity of cumulative alcohol intake. This latent cardiomyopathy may be unmasked in the recipient because of the particular hemodynamic conditions to which the myocardium is exposed, e.g. myocardial ischemia, elevation of right and left heart filling pressures. The condition can be diagnosed with echocardiography by demonstration of increased ventricular wall thickness and by left ventricular filling impairment without, at this stage, any alteration in the parameters of contractility.

Chronic alcoholism in the donor would not appear to be a contraindication to use of the lungs for transplantation.

Effects of poisoning on the donor organs

There are few reports on the use of thoracic organs from donors who have died of poisoning. In Belgium, 12 poisoned 'brain-dead' patients were considered as organ donors[51]. The toxic substances were various, but included barbiturates, insulin, carbon monoxide, and cyanide. Two heart transplant patients died within 24 h from stroke and acute heart failure, respectively. The Brussels group, although not absolutely excluding organ procurement from a few select donors with acute poisoning, drew attention to the risk of graft damage resulting from some poisons.

Cyanide

Most cyanide poisoning victims do not survive, due to rapid lethal massive cellular anoxia within minutes, particularly if large amounts have been ingested[52]. Reported mortality is as high as 95%. Due to its rapid absorption and paralysis of cellular respiration, the time from ingestion to treatment is critical. Cyanide causes cytotoxic intracellular anoxia. Cellular oxygen utilization is blocked, and anaerobic metabolism with glucose ensues, leading to lactic acidosis. There is consequent respiratory failure due to the high susceptibility of the central nervous system (CNS) to anoxia. The cyanide–cytochrome oxidase complex that is formed, however, is dissociable, with rapid recovery of respiration upon cyanide removal.

Cardiac studies have shown a direct myocardial toxic effect manifested by left ventricular dysfunction and conduction abnormalities. Cyanide causes vascular smooth muscle contraction, arterial vasoconstriction, and accelerated myocardial ischemia. While the myocardium is very susceptible to cyanide anoxia, almost complete dissociation of the cytochrome oxidase enzyme–cyanide complex has been demonstrated.

Intentional cyanide poison victims are not usually considered for organ donation. With rapid antidote administration and close follow-up, however, the cyanide victim with irreversible CNS damage may have organs with reversible cyanide effects that may be suitable for transplantation. A heart has been transplanted from a patient who committed suicide by cyanide ingestion[52]. After transplantation, the recipient was initially on multiple low-dose hemodynamic agents to augment cardiac output, but was successfully weaned off of these on the seventh postoperative day.

Presumably, in such cases of reversal of cyanide effects, the lungs could also be considered for donation.

Carbon monoxide

The potential reversibility of hypoxic organ damage induced by carbon monoxide inhalation depends on the amount of hemoglobin bound to carbon monoxide and on the tolerance of the organ to hypoxemia[53]. It has been suggested that death from carbon monoxide poisoning with a blood carboxyhemoglobin level >20% is an absolute contraindication to use of the heart, and a level <20% is a relative contraindication[21].

Hearts from brain-dead victims of carbon monoxide poisoning have, therefore, generally been reported to be unsuitable for heart transplantation. However, heart transplants have been performed successfully using such donors[54,55]. Carbon monoxide poisoning is therefore not an absolute contraindication to cardiac allograft procurement in the setting of clinical and objective evidence of satisfactory cardiac function.

Iberer *et al.*[55] reported that, despite early post-transplant ECG abnormalities and elevated serum transaminase levels suggesting myocardial damage, after 16 days the ECG reverted to normal. No evidence of ischemic areas or myocardial cell necrosis could be found in any heart biopsies. At the time of reporting, the patient was doing well 4 months post-transplant.

A report from Australia documented two patients who underwent successful transplantation with cardiac allografts from donors who had suffered acute carbon monoxide poisoning[54]. The authors suggest that an ECG, assay of cardiac enzymes, and echocardiography are required to assess the degree of myocardial injury in potential heart donors. Cardiac enzyme elevation suggests severe myocardial injury, but transient elevations may be due to hypoxic injury to other organs. The myocardial effects of acute carbon monoxide poisoning, however, may be delayed. These authors therefore recommend that a short period of observation be incorporated in the overall assessment of the potential heart donor, and suggested that careful consideration of the following variables may minimize any potential risk in using carbon-monoxide-exposed hearts for transplantation: (a) normal ECG and satisfactory echocardiographic findings, (b) minimal elevation of cardiac enzymes, (c) requirement for minimal inotropic support, (d) a short ischemic time, (e) favorable donor-to-recipient weight ratio, and (f) the avoidance of recipients with high pulmonary vascular resistance.

There is one report of successful transplantation of a lung from a donor with carbon monoxide poisoning[56], but presumably the same cautious guidelines apply.

Anticipated donor organ cold ischemic period

Most surgeons would prefer to have the donor organ (heart or lung) reperfused by recipient blood within a maximum of 4 hours after aortic crossclamping in the donor (Chapter 23). If the anticipated cold ischemic period is likely to be much longer than 4 h (e.g. because of the long distance between donor and recipient centers) the surgical team may decide to decline acceptance of the donor on these grounds alone, particularly if: (a) the donor has other 'borderline' characteristics or (b) the recipient has other factors that may complicate the procedure. There is a natural tendency on humanitarian grounds to accept a long ischemic time (with or without a borderline donor) for critically ill potential recipients (e.g. those on ventilators with or without intra-aortic balloon pump with or without high doses of inotropic therapy) for whom there is doubt that a subsequent donor will become available before the patient dies. Such as decision, though understandable, may substantially increase the risk of failure or major complication of the operative procedure, and it may be prudent to decline such a donor.

Although the surgeon's primary concern is to the patient most in need of the transplant, he or she must never fail to remember the many other patients awaiting organ transplantation throughout the world. Failure of a transplant from an accumulation of risk factors may have prevented successful transplantation in another, more suitable, recipient. A poor decision in such circumstances may be associated with three deaths: (a) borderline donor, (b) high-risk recipient, and (c) the low-risk recipient who may subsequently die through lack of a suitable donor organ.

Cold ischemic times of >4 h have frequently been reported, but are associated with an increased risk of early donor organ failure (Chapters 43 and 44). The pediatric heart appears to be less susceptible to cold ischemia, and cold ischemic intervals of >9 h have been documented.

Perhaps surprisingly, in view of its delicate structure, the adult lung may be more tolerant of cold ischemia than the heart, as cold ischemic times <8 h have been reported[57]. As a general guideline, however, the risk of early organ failure is likely to increase if ischemic times of >4–5 h are incurred.

Comment

In an important review of 1719 consecutive primary cardiac transplants performed at 27 institutions, Young *et al.*[58] documented that risk factors for death of the recipient included: (a) old donor age ($p = 0.001$); (b) smaller donor body surface area (female donor heart placed into larger male patient) ($p = 0.003$); (c) greater donor inotropic support ($p = 0.01$); (d) donor diabetes mellitus ($p = 0.01$); (e) longer ischemic time ($p = 0.0003$); (f) diffuse donor heart wall motion abnormalities by echocardiography ($p = 0.06$); and (g), for pediatric donors, death from causes other than closed-head trauma ($p = 0.02$). The 30-day mortality rate was 7%, but increased to 11% when donor age exceeded 50 years, and was 12% when inotropic support exceeded 20 μg/kg per minute dopamine plus dobutamine, and 22% with diffuse echocardiographic wall motion abnormalities. The interaction of donor risk factors was such that the heart of the smaller female donor given high-dose inotropes placed into a larger male recipient produced a predicted 30-day mortality rate of 26%, and the heart of a 25-year-old male donor given high-dose inotropes with diffuse echocardiographic wall motion abnormalities transplanted into a 50-year old male recipient led to a predicted 30-day mortality rate of 17%. The authors concluded that their analysis supported cautious extension of criteria for donor acceptance but with an anticipated greater risk in the presence of diffuse echocardiographic wall motion abnormalities and long ischemic time, particularly in older donors given inotropic support.

Such data based on a large number of lung transplant patients are not yet available.

THE EFFECTS OF THE AGONAL PERIOD AND BRAIN DEATH ON MYOCARDIAL AND PULMONARY FUNCTION AND STRUCTURE IN THE DONOR

The major source of donor hearts has been, and would appear to continue to be, persons dying of head injury or spontaneous intracranial hemorrhage. The adverse effect of brain dysfunction on the heart was demonstrated as early as 1954[59–63]. Electrocardiographic changes have been reported clinically in association with subarachnoid hemorrhage, intracranial infections, and cerebral tumors. Subendocardial hemorrhage and even myocardial necrosis have been reported in association with intracranial lesions. Electrocardiographic changes can be produced in animals by midbrain stimulation, and chronic stimulation produces myocardial necrosis; excessive sympathetic discharge may be etiologically responsible.

The pathological sequence of events that leads to brain death (i.e. the mode of death) varies to some extent depending on the cause of death (e.g. exsanguination, asphyxia, etc.). There is experimental evidence that the mode of death influences the extent of myocardial injury. For example, experimental studies have indicated that hearts arrested by exsanguination of the animal are easier to resuscitate than those arrested by asphyxia[64–66], and have therefore presumably suffered less injury and/or depletion of energy stores.

Studies in both experimental animals and potential clinical donors, which have been reviewed elsewhere[67,68], have suggested that brain death has major histopathological and functional effects[69–77].

Two major effects of brain death have been observed in experimental studies. The first is a series of electrocardiographic, hemodynamic, and histopathological changes which take place during and immediately following the agonal period[69,70,72,74,76]. The second consists of significant changes in circulating levels of certain hormones, which in turn result in major changes in body metabolism[69–71,75]. The time-course and nature of these events may be greatly modified under clinical circumstances.

'Autonomic (sympathetic, catecholamine) storm'

A sudden increase in intracranial pressure or the sudden onset of ischemia of the brain leads to a series of major pathophysiological changes which may collectively be referred to as the 'autonomic storm'[69,71,72,74]. Though there is a brief initial period of excessive parasympathetic activity, evidenced by a marked bradycardia, most of the effects are brought about by the sympathetic nervous system[71,72,74]; the terms 'sympathetic storm' or 'catecholamine storm' have therefore also been used to describe these events.

There is a large increase in circulating and endogenous catecholamines in the early few minutes after induction of brain death, which is associated with an increase in myocardial activity, together with the appearance on the EKG of ventricular arrhythmias[69]. Within 5 min of a sudden rise in intracranial pressure, circulating epinephrine, norepinephrine, and dopamine concentrations rise markedly, though they return to control levels within 10–15 min[69].

Electrocardiographic effects

When intracranial pressure is increased acutely (or the brain made acutely ischemic), an immediate bradycardia, progressing to sinus standstill with occasional junctional escape beats and a short period of atrioventricular dissociation, is rapidly followed by a sinus tachycardia and, subsequently, ventricular ectopic activity of multifocal origin[69] (Figure 3). A further period of sinus tachycardia follows but, on this occasion, with marked ischemic changes.

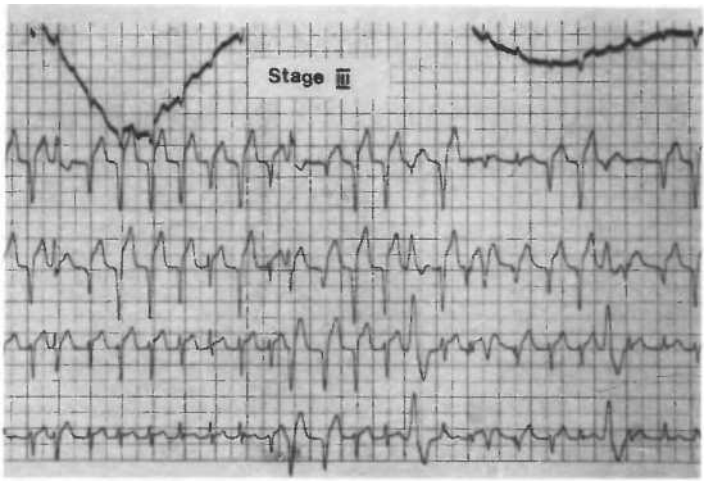

Figure 3 Electrocardiogram taken during development of brain death in an experimental animal showing multifocal ventricular extrasystoles

Factors which contribute to cardiac ischemia possibly include endogenous catecholamine release, spasm of coronary arteries (indicated by contraction band necrosis in the major coronary arterial walls), and a high systemic vascular resistance (SVR) from increased sympathetic activity which increases afterload and results in acute temporary myocardial oxygen supply–demand imbalance. This ischemia not infrequently results in myocardial histopathological damage, especially in the subendocardium, though this is rarely significant enough to exclude use of the heart for transplantation.

Finally, there is a reduction in rate to the pre-agonal level or below, with a regular rhythm. Fifty percent of experimental animals, however, continue to show abnormalities of the QRS complex and/or ST segment, including pseudo-infarct patterns. These ECG changes rarely indicate severe ischemic injury, and are believed to be due to loss of energy within the cell.

Hemodynamic effects

The hemodynamic changes observed in such experimental animals reflect the body's attempts to compensate for the intracranial changes taking place during 'coning' (Cushing's reflex)[71]. The classic picture is outlined below, but this may be greatly modified in the clinical situation.

Significant and often massive increases in SVR and mean arterial pressure (MAP) occur (Figures 4 and 5), and are almost cer-

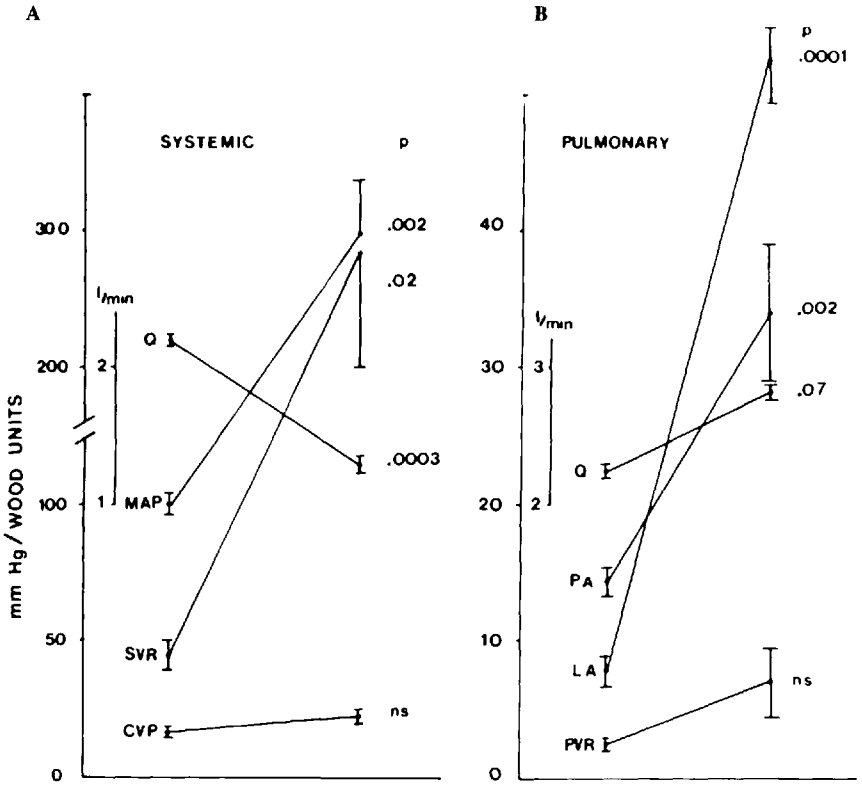

Figure 4 Mean changes in systemic and pulmonary hemodynamic data during the induction of brain death in eight baboons. The left hand graph shows changes in systemic hemodynamics between control levels (**A**) and those recorded at the peak of systemic vascular resistance (**B**). (MAP = mean arterial pressure (mmHg); SVR = systemic vascular resistance (Wood units); CVP = central venous pressure (mmHg); Q = aortic blood flow (l/min).) The changes in MAP, SVR and Q reached statistical significance. The right-hand graph shows changes in pulmonary hemodynamics between control levels (**A**) and those recorded at peak of systemic vascular resistance (**B**). (PA = pulmonary artery pressure (mmHg); LA = left atrial pressure (mmHg); PVR = pulmonary vascular resistance (Wood units); Q = pulmonary artery blood flow (l/min).) The changes in PA and LA reached statistical significance

tainly the direct result of a great increase in sympathetic nervous activity, which produces an extreme degree of peripheral vasoconstriction. Blood is therefore redistributed into the capacitance vessels, leading to a rapid accumulation within the great veins and right atrium. Due to a combination of low pulmonary vascular resistance (PVR), high pulmonary vessel compliance, and pulmonary capillary reserve recruitment, associated with a higher degree of right ventricular compliance compared to the left ventricle, the right ventricle is able to adjust to this increased venous return, and increase its output, demonstrated by an increase in pulmonary artery flow compared with aortic flow at this time[72].

The left atrial pressure may actually exceed the pulmonary artery pressure for a matter of seconds during the period of peak peripheral vasoconstriction[72]. This remarkable and surprising observation implies that the pulmonary capillary blood flow temporarily ceases entirely. The extreme rise in SVR which occurs during the agonal period almost certainly results in transient mitral regurgitation following temporary failure of the left ventricle. It would seem likely that it is during this period that disruption of the normal pulmonary capillary anatomy can occur. As the peak left atrial pressure far exceeds the normal hydrostatic pulmonary capillary pressure, capillary integrity within the lungs may be disrupted, resulting in pulmonary edema with high protein content and interstitial hemorrhage.

Histopathological effects

In approximately 75% of experimental animals undergoing brain death, histopathological changes develop in the left ventricular wall[69,71]. These consist of contraction bands, focal coagulative necrosis, and myocytolysis, with edema formation and interstitial mononuclear cell infiltration (Figure 6). Contraction band necrosis may even develop in conduction tissue and in coronary arterial smooth muscle.

In addition, over a third of the animals show pulmonary edema with an exudate rich in proteins (Figure 7); there is also evidence of capillary endothelial damage and, on occasion, diffuse hemorrhage, both in the alveolar walls and into the alveolar spaces[72].

All of these changes are believed to be the result of the catecholamine excess which occurs during the development of brain death, and are thought to be related to cytosolic calcium overload. Similar myocardial structural damage has been clearly documented in human potential organ donors[73]. Various combinations of the three forms of acute myocardial necrosis have been described; namely contraction bands, coagulative myocytolysis, and coagulative necrosis (colliquative myocytolysis). Focal mononuclear cellular infiltration has also been described surrounding areas of myocyte necrosis.

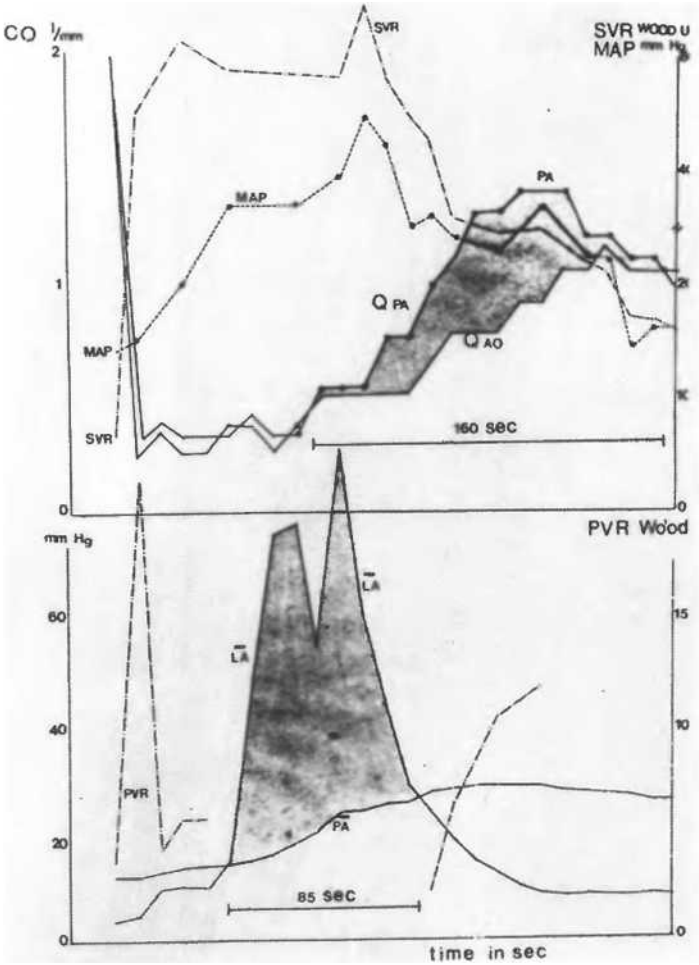

Figure 5 Systemic and pulmonary hemodynamic data during induction of brain death in a baboon. The upper graph shows changes in systemic vascular resistance (SVR) (Wood units), mean arterial pressure (MAP) (mmHg), pulmonary artery blood flow (PA) (l/min) and aortic blood flow (AO) (l/min). The discrepancy between pulmonary artery and aortic blood flows (shaded area) represents the period and extent of blood pooling within the lungs; in this case blood pooling extended for a period of 160 seconds. In the lower graph, changes in mean left atrial pressure (LA) (mmHg), mean pulmonary artery (PA) (mmHg) and pulmonary vascular resistance (PVR) (Wood units) are shown. The shaded area represents the period of 85 seconds during which the left atrial pressure exceeded the pulmonary artery pressure

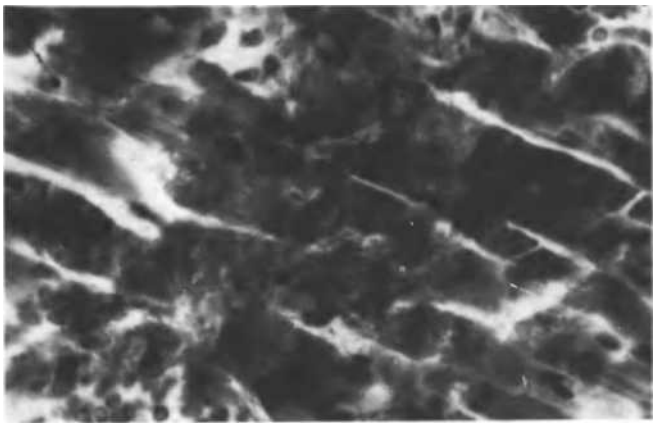

Figure 6 Light micrograph section of myocardium showing widespread contraction bands and edema (H&E × 310)

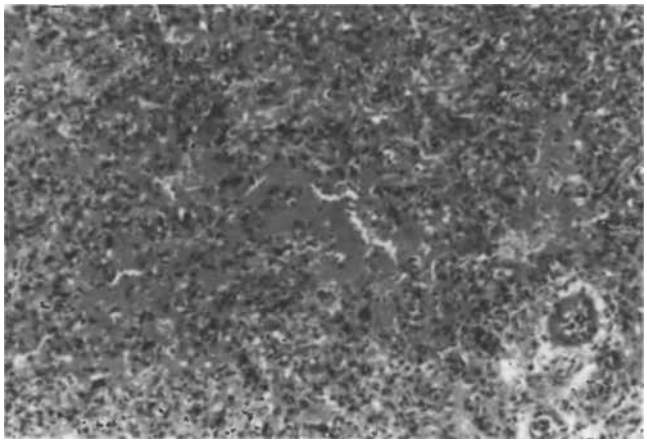

Figure 7 Light micrograph of lung following induction of brain death. Alveolar wall hemorrhage due to disruption of capillary integrity can be seen, as well as considerable pulmonary edema. The heavy eosinophilic staining of the edema fluid demonstrates it to be an exudate rich in protein (H&E × 100)

A majority of human donor hearts show mild (or occasionally more severe) degrees of myocardial injury (Figure 8), such as subendocardial hemorrhage, presumably once again due to the high catecholamine output during the period of brain injury and the development of brain death. Changes of ischemic injury incurred at the time of brain death can sometimes be seen in the myocardium at the time of the first post-transplant endomyocardial biopsy.

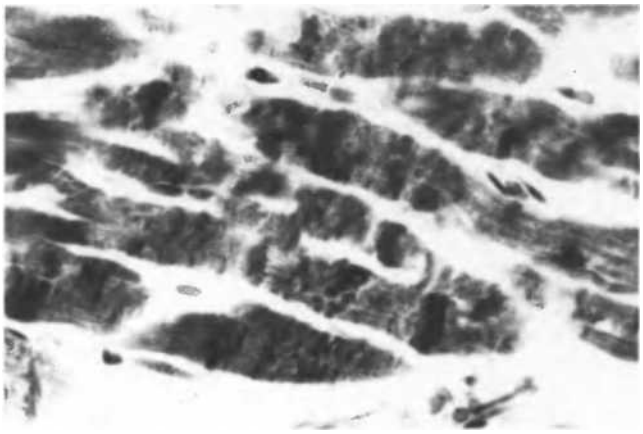

Figure 8 Light micrograph of a human donor heart which failed 2 hours after operation, showing extensive contraction bands (H&E × 320)

Endocrine changes and metabolic responses

This subject remains one of considerable controversy, and has recently been reviewed in some detail[78]. There is considerable

variation in the findings of different groups who have been interested in this potentially important field.

In the baboon, the thyroid hormones plasma free triiodothyronine (T3) and thyroxine (T4), together with plasma cortisol and insulin, fall significantly within a few hours of the onset of brain death[71]. Antidiuretic hormone also disappears from the plasma within a few hours. These changes are associated with a reduction in myocardial energy stores (adenosine triphosphate (ATP), creatine phosphate (CP) and glycogen), as well as a significant increase in myocardial lactate[69,70,79]. These myocardial tissue changes suggest that there is impairment of aerobic metabolism following brain death.

The functional testing of hearts taken from brain-dead animals demonstrates a deterioration in myocardial function, as evidenced by significant reductions in cardiac output, stroke volume, and left ventricular pressure[70,79]. There is also evidence that brain death leads to functional deterioration of the kidney[80].

Plasma free T3 levels have also been shown by most investigators (but not all) to be reduced in human potential donors, and there would appear to be some correlation between the level of T3 and the time interval that has elapsed since brain death took place[77]. Cortisol and insulin have also been shown to be in the low normal range.

Further experimental work in the baboon, studying the kinetics following single bolus injection of 14-carbon labeled metabolites (glucose, pyruvate, and palmitate) has indicated that there is a major change in metabolic oxidative processes following brain death, involving the entire animal[75]. The rates of glucose, pyruvate and palmitate utilization were found to be markedly reduced, and there was an accumulation of lactate and free fatty acids in the plasma. These findings indicated a change from aerobic to anaerobic metabolism affecting the body as a whole, and correlated well with the previous findings relating to metabolism in the heart and kidney alone. Evidence was provided that high-energy phosphates are rapidly depleted under this changed metabolic environment, almost certainly leading to deterioration in function of all organs. These observations, however, and their interpretation, remain controversial, although recent confirmatory evidence has been provided[81].

MANAGEMENT OF THE DONOR

Care of the donor can be a time-consuming activity. If the patient is to be maintained in an ideal state for organ donation, as much care has to be taken over his management as would be given to any patient in an intensive-care unit. When brain death has been confirmed, interest in the care of the 'patient' by the primary medical and nursing personnel may wane, and support by the staff of the organ procurement agency and/or retrieval teams is often called for.

Some donors are in a less-than-optimal hemodynamic/pulmonary state when first seen, and initially the organ(s) may not seem suitable for donation. In many cases, however, intensive monitoring and management of the donor leads to improvement in status, resulting in excision of organs of good quality[82,83]. In contrast, however, particularly in the case of the lungs, organs that initially appear acceptable may show signs of deterioration despite intensive care, excluding them from use. It is important, therefore, to repeat important tests (e.g. the Pa_{O_2} on an Fi_{O_2} of 40% or 100%) at intervals throughout the period of donor management[84]. If the donor no longer fulfills the necessary criteria, the organ(s) may need to be abandoned.

As the majority of brain-dead donors are donors of multiple organs, the aim of management has to be to achieve a balance so that no organ is functionally improved at the expense of another. For example, the heart may function better if the central venous pressure is increased by intravenous fluid infusion, but this may be detrimental to the lungs. Increased inotropic support may therefore be preferable in such a situation.

Mechanical ventilation will already be employed, and blood gases are maintained within the normal range. The donor will be maintained on a (physiological) PEEP of 5 cmH_2O with the lowest possible Fi_{O_2} sufficient to maintain an oxygen saturation of 90–95%. Maintaining an Fi_{O_2} of 100% for several hours, if necessary, is probably not deleterious to subsequent lung function. If the lungs are to be donated, frequent tracheobronchial suction is required to prevent secretions from collecting. At the earliest opportunity, tracheobronchial aspirate should be sent for Gram stain and aerobic and fungal culture.

A urinary catheter may already be *in situ*; if not, one is inserted. A central venous pressure (CVP) monitoring catheter is essential if the volemic state of the patient is to be well controlled. A Swan–Ganz catheter is not generally required, but it may prove helpful in donors who continue to show signs of hemodynamic instability. An arterial pressure line is an advantage, but is not essential if monitoring by sphygmomanometer cuff is satisfactory; its presence, however, facilitates the frequent estimation of arterial blood gases. (The femoral artery and vein, or jugular vein, can be utilized for easy access for arterial and CVP monitoring.) At least one, and preferably two, other peripheral venous infusions are set up for fluid and drug administration. Care is taken to introduce all vascular and urinary catheters under sterile conditions, especially if the groin is used for vascular access.

As a result of pituitary injury, brain-dead patients frequently pass large quantities of urine (diabetes insipidus), and rapidly become hypovolemic and hypotensive if fluid is not replaced. Fluid, preferably warmed to prevent hypothermia, is administered in the form of electrolyte solution or colloid. If the patient has bled significantly, e.g. from a head or other injury, whole blood (or packed cells) is given to maintain the hemoglobin >8 g/dl. The serum sodium may rise to high levels in patients with impairment of production of antidiuretic hormone, and the administration of sodium chloride as a replacement fluid is therefore avoided. Potassium is lost in the urine and may require frequent monitoring and replacement on a large scale; 30 mEq potassium chloride are added to each liter of intravenous fluid given. Further supplements of 15–40 mmol/l administered in 30–100 ml of intravenous fluid over periods of 15–60 min may be necessary to maintain the serum potassium level above 3.5 mmol/l.

A systemic MAP of between 60 and 80 mmHg (with a systolic pressure of ± 100 mmHg) would appear sufficient to provide adequate coronary flow. Such a pressure may be best obtained by a combination of fluids, to maintain a moderate preload, and an intravenous infusion of vasopressin (or small increments of intramuscular vasopressin) to increase the afterload. Excessive increases in either preload or afterload may be damaging to the myocardium, and particularly to the lungs. Heart function should

be satisfactory with a central venous pressure of 5–10 mmHg but, if the lungs are to be procured, every effort should be made to maintain good cardiac function and an acceptable systolic blood pressure with a CVP that does not exceed 5 mmHg. Fluid overload must be prevented. If the kidneys are also to be excised for the purpose of transplantation, as is usually the case, an MAP of much below 60 mmHg may prove inadequate to maintain renal perfusion, and the CVP may need to be slightly increased.

If fluid replacement (including blood, if necessary) sufficient to maintain a CVP of 5–10 mmHg (or less, if the lungs are to be utilized) does not maintain an adequate systolic blood pressure, inotropic support should be initiated. Dopamine is the usual inotrope of choice, and should be used at the lowest dose necessary to maintain the systolic blood pressure at approximately 100 mmHg. Doses of <10 μg/kg per minute are usually sufficient. If a rate of >15 μg/kg per minute is required, the acceptability of the heart for donation needs to be reviewed.

If urinary output is excessive, making adequate fluid replacement difficult, vasopressin given intravenously or intramuscularly is of value in reducing this loss. Since vasopressin at concentrations higher than those required for antidiuresis results in peripheral (including renal) vasoconstriction, great care is required in its administration if the kidneys are to remain suitable for donation. (Similarly, phenylephrine is contraindicated, although neither of these agents is harmful if the heart or lungs alone are to be donated.) The intramuscular administration of vasopressin can be particularly effective, only small doses being required (0.1–0.25 U/kg), repeated as necessary. For intravenous infusion, vasopressin (100 U/250 ml normal saline), administered initially at approximately 0.25 ml (0.1 U/min) usually results in a decrease in urine flow and/or increase in blood pressure.

Desmopressin (dDAVP), a synthetic analog of arginine vasopressin (AVP), has enhanced antidiuretic potency, diminished pressor activity, and a prolonged half-life and duration of action compared to the natural hormone AVP[85,86]. It also has a greatly reduced splanchnic vasoconstrictor effect. It is therefore preferred by some centers for the control of diabetes insipidus. Doses of 2 μg i.v. for up to two doses have been found satisfactory[86].

Brain-dead patients lose thermoregulation and rapidly cool to low temperatures if not actively warmed with an electric warming blanket. Although a mild degree of hypothermia may, in fact, be beneficial to the preservation of organs in a satisfactory condition, ventricular fibrillation can occur at temperatures below 30°C. Our policy has been to maintain the central temperature at approximately 35°C.

If the Pa_{O_2} and Pa_{CO_2} are maintained within normal limits by mechanical ventilation, and if the central venous and arterial pressures are also maintained within the desired range, acid–base balance may remain within normal limits. If acidosis occurs, as a result of a combination of increasing anaerobic metabolism and peripheral vasoconstriction associated with hypothermia, sodium bicarbonate should be administered to correct the base deficit (base deficit × body weight (kg) × 0.3/2 = ml 8.4% sodium bicarbonate).

A suitable wide-spectrum, non-nephrotoxic antibiotic (e.g. a cephalosporin) is administered at regular intervals until the donor is taken to the operating room for organ excision. Some pulmonologists prefer more aggressive antibiotic cover, depending on the results of Gram stain of the sputum. A combination of vancomycin (1–1.5 g as a single dose) and ampicillin/sulbactam (Unasyn) (3 g repeated q. 6 h) provides very wide cover. If the donor is known to be allergic to penicillin, a combination of aztreonam (2 g i.v.) and clindamycin (900 mg i.v.) given 8-hourly is effective.

By the measures outlined above, the heart and lungs of most brain-dead donors can be maintained in a viable state for several hours, occasionally up to 24 h. In our experience, however, increasing instability of the circulation is the rule, and every effort should be made to organize the transplant operation as soon as possible.

If there is undue delay in retrieval of organs it is wise, if not mandatory, to repeat the chest radiograph and oxygen challenge in potential lung donors. The appearance of a new infiltrate or edema on chest radiograph or a significant reduction in P_{O_2} (even if still >300 mmHg) should be reviewed with concern, and the decision to utilize the lungs may need to be reconsidered.

Hormonal therapy

Noting both the deterioration in cardiac function and depletion of myocardial energy stores that can occur after brain death, consideration has been given as to whether these effects resulted from the depletion in circulating hormones, such as T3, cortisol, and insulin, and, furthermore, could be reversed by replacement therapy.

Experimental observations

Brain-dead experimental animals treated with these hormones showed a return toward control level in respect to cardiac output, though left ventricular pressure remained slightly reduced[79]. Myocardial ATP, CP, glycogen (which had been depleted) and lactate (which had been increased) did, however, return to control values[79]. Similarly, there was a return to normal renal function following hormonal therapy to the brain-dead animal[80].

When T3 was administered to a brain-dead baboon (2 μg at hourly intervals), there was a dramatic increase in the rate of metabolite (glucose, pyruvate, and palmitate) utilization, and reductions in plasma lactate and free fatty acids[75]. These changes indicate stimulation of aerobic metabolism in the body as a whole, resulting in a reversal from anaerobic to aerobic metabolism in the brain-dead animal. These observations correlated well with the earlier studies which showed replacement of myocardial energy stores and improvement in myocardial function.

Clinical observations

In an initial study, a group of potential donors was treated with intravenous T3 (2 μg), cortisol (100 mg), and insulin (10–20 international units) when first seen, and the therapy repeated at hourly intervals, depending on the condition of the donor and his response to the treatment, until the heart was excised. Observations in this group of potential donors were compared with those in potential donors who did not receive any form of hormonal therapy[77]. The hormonally-treated group showed a marked improvement in cardiac performance, as measured by significant

increases in MAP and heart rate and a fall in CVP, despite a significant reduction in inotropic requirements. This was in contradistinction to the donors who did not receive hormonal therapy, in whom there was no improvement in cardiac function, despite a significant increase in the level of inotropic support. In the hormonally treated donors there was a reduction in the bicarbonate requirement, and falls in serum lactate and pyruvate; in those who did not receive hormonal therapy the need for bicarbonate administration increased by 100% over the same period of time.

Nineteen percent of the donor hearts in the untreated group were eventually considered unsuitable for subsequent transplantation on the basis of poor or deteriorating hemodynamic performance, whereas all of the hormonally treated donors were considered suitable for transplantation, and all showed immediate good function following transplantation, and good long-term performance except where affected by acute or chronic rejection.

A further larger study showed a similar good response. The optimum dosage of T3, which is considered the most important of the replacement hormones, remains uncertain, but may be more than the 2 μg/h given in the above studies. Unpublished data from the Papworth group in the UK suggest that, to achieve and maintain normal blood levels of T3, an initial bolus of 4 μg is required, followed by an infusion of 4 μg/h (Wheeldon, D., personal communication).

It should be stressed that hormonal therapy remains controversial, and is not yet fully accepted by the transplant community[21,78]. There are increasing data, however, to suggest that it may prove a physiological way of maintaining donor organs in a viable state before excision and transplantation.

Selection and Evaluation of the Potential Thoracic Organ Transplant Recipient – General Considerations

D.K.C. COOPER, N.K. IMES AND D.P. NELSON

INTRODUCTION

Selection of appropriate recipients for heart or lung transplantation may be the most important factor determining long-term survival, yet selection remains difficult and guidelines vary to some extent from one institution to another[1–3]. With increasing experience and success, there has been a relaxation in selection criteria in heart transplant candidates, with both older and younger patients and insulin-requiring diabetics now being offered transplantation. Similarly, with increasing experience in lung transplantation, selection criteria are gradually being modified. Greater experience with the new immunosuppressive regimens that are steadily becoming available, including tacrolimus (FK506) and mycophenolate mofetil, is likely to further broaden the criteria for transplantation.

EVALUATION OF THE POTENTIAL RECIPIENT

Screening of the recipient begins with a full history and physical examination. At this stage any major contraindication may already be evident. Some patients will be rejected at this early, informal evaluation, as they are seen to be completely unsuitable. Usually this is on the grounds of extremely advanced age or prohibitive, coexistent disease in other organ systems.

Once having passed this informal assessment, candidates undergo systematic and extensive medical screening. If full data on the cardiac or pulmonary status have not already been obtained, a thorough assessment is completed. Once the patient is judged to be a candidate for transplantation on the basis of his/her cardiac or pulmonary clinical status, then further screening is performed to ensure that: (a) the patient is likely to withstand the rigors of surgery, (b) major contraindications to the use of immunosuppression are not present, and (c) there is no condition that will prevent satisfactory post-transplant rehabilitation or long-term survival.

This screening process is obviously guided by good clinical judgement, and the sequence of testing may be altered because of clinical suspicions generated by the history or physical examination. For example, if a lung transplant candidate is suspected of having ischemic heart disease, a coronary arteriogram should be done early in the evaluation. The early identification of disqualifying cardiac disease might result in a significant monetary saving, since other expensive tests will then not be necessary.

General screening tests (Table 1) include urinalysis, chest radiography, a complete blood count, biochemical blood screening of liver and kidney function, glucose metabolism (including glycosylated hemoglobin), calcium, thyroid, and coagulation status. Serum cholesterol, triglycerides and prealbumin levels are helpful as baseline values, since they may be altered by the transplant process and subsequent drug therapy. Serologic tests for HIV, HTLV1 and 2, and hepatitis B (surface antigen) and C (antibody and RNA) are performed during the early evaluation of patients and may reveal disqualifying disease to be present. A rapid plasma reagin (RPR) test for syphilis should also be performed. Serologic testing, such as for CMV and toxoplasmosis, may be delayed until late in the evaluation process, as this information will assist in post-transplant management but will not preclude candidate selection.

Other screening tests include a 24-hour urine collection for creatinine clearance and protein, skin tests (PPD for tuberculosis with suitable control, and *Candida*), and any bacteriological studies that might be indicated by the history and physical examination. All cardiac transplant patients should have pulmonary function studies unless this is precluded by the status of the patient (e.g. if on a ventilator). At our own center we assess the vertebral bone density in all patients >40 years of age as a baseline for following the development or treatment of osteoporosis post-transplant[4].

Doppler ultrasound studies of the carotid arteries and abdominal aorta–iliofemoral systems are performed in all patients over the age of 40 years, and in younger patients with a history of ischemic heart disease or considered to be at risk for peripheral vascular disease. If Doppler ultrasound demonstrates more than mild arterial disease we progress to arteriography and/or aortography, for reasons that will be discussed later.

Further investigation of major systems, such as gastrointestinal endoscopy and intravenous pyelography, are performed when indicated by the history, physical examination, or laboratory data.

Table 1 Suggested general evaluation of the potential thoracic organ recipient

General data
Comprehensive history and physical examination
Blood chemistry determinations, including renal and liver function panels, TSH
Complete blood count, differential white blood count, platelet count, prothrombin time, partial thromboplastin time, fibrinogen
Urinalysis
Stool for guaiac examination ×3*
24-hour collection of urine for creatinine clearance, total protein
Chest radiography
Pulmonary function testing
Psychological questionnaire (e.g. MMPI)
Mammography*
Papanicolaou smear*
Lung ventilation–perfusion scanning*
Vertebral bone densitometry*
Doppler ultrasound of peripheral arteries*
Sputum cytology*
Consultations*
Nutritional status and diet history
Psychiatry
Physical therapy
Social services
Dental (+ dental radiography)
Otorhinolaryngology
Essential cardiovascular data
Electrocardiography
Radionuclide ventriculography*
Echocardiography*
Right heart catheterization
Left heart catheterization*
Endomyocardial biopsy*
Essential immunologic data (see also chapter 6)
Blood type and antibody screening
Human leukocyte antigen (HLA) typing (may be performed at the time of transplant)
Screening of panel of reactive (lymphocytotoxic) antibodies
Essential infectious diseases data
Serology for:
Hepatitis HBsAg (HBsAb, HBcAb), HcAb, HcRNA
Human immunodeficiency virus (HIV)
HTLV1 and 2
Cytomegalovirus (CMV) IgM and IgG antibody
Toxoplasmosis
EB viral capsid IgG and IgM antibody*
RPR
Lyme titers*
Urine culture and sensitivity*
Stool for ova and parasites × 3*
Skin testing for tuberculosis (PPD) and *Candida*

* If indicated by history, age, or physical examination.

In older women (>40 years) mammography should probably be performed, if not done within the previous 12-month period.

Selected patient groups, such as those with cystic fibrosis, may require extensive organ system evaluation and testing for resistant bacteria (such as *Pseudomonas cepacia*) and fungi. The presence of chronic sinusitis may require consultation with an otorhinolaryngologist in an effort to control sinus infection.

Psychological evaluation is performed on all patients, with particular attention being paid to: (a) a history of noncompliance with medical advice or therapy, (b) substance abuse, or (c) overt psychiatric illness. Patients complete a psychological questionnaire (e.g. MMPI), and psychiatric evaluation is requested in patients where doubt exists regarding their compliance or psychiatric health. A dietary consultation is necessary in obese or cachectic patients, to assess and modify eating behavior.

Based on the results of these investigations, specific therapy may be indicated to improve the treatment of the patient's disease, or the patient may be deemed unsuitable for transplantation. If the patient cannot be improved by medical measures and no contraindication is detected, then the patient becomes a candidate for transplantation and awaits a suitable donor.

WHICH PATIENT WILL BENEFIT FROM HEART OR LUNG TRANSPLANTATION?

The substantial improvement in survival that has occurred following thoracic organ transplantation in the past decade is principally the result of improvement in survival during the first 3 postoperative months. This reflects improvement not only in management but also in patient selection. Retrospective analysis has aided recognition of recipient-related factors that influence survival after transplantation (see Chapters 43, 44, 65 and 69).

The major limiting factor in thoracic organ transplantation remains availability of donor organs and, therefore, careful consideration should be given to providing this scarce resource to the most likely candidates to survive long-term and enjoy a sufficient improvement in quality of life.

Contraindications

There are a number of 'absolute' and 'relative' contraindications to heart or lung transplantation (Table 2). However, what was an 'absolute' contraindication 10, or even 5, years ago may be only a 'relative' contraindication today[5–10]. The weight given to these 'relative' contraindications will differ between different transplant centers, depending on the availability of donor organs, the number of recipients waiting, and prior experience.

Active infection

Patients with active infection must generally be excluded because of the risk of exacerbation by postoperative immunosuppression unless the infection is confined solely (or predominantly) to the organ(s) being transplanted (for example, bilateral lung transplantation for cystic fibrosis). In some cases, however, when the infecting organism is known and specific therapy is effecting a satisfactory response, it may be acceptable to proceed with transplantation if the cardiac or pulmonary status of the patient is critical. The high risk of death from the underlying cardiac/pulmonary disorder may outweigh the risk of transplantation carried out in the presence of persisting infection.

The presence of antibiotic-resistant organisms, particularly in candidates for lung transplantation, may render the patient permanently unsuitable for transplantation, or unsuitable until the microorganism is replaced by susceptible organisms. For example, resistant *Pseudomonas cepacia* in patients with cystic fibrosis has resulted in a high percentage of transplant failures (Chapter 61). The policy of many groups is to attempt, by reduced and judicious use of antibiotics, to decrease the drug resistance of

Table 2 Contraindications to heart or lung transplantation

'Absolute'	*'Relative'*
Active infection	Advanced age
Untreated malignancy	Poorly controlled insulin-requiring diabetes mellitus with microvascular disease
Coexisting systemic illness that may severely limit life expectancy	*Active* peptic ulcer disease
Irreversible and severe dysfunction of any other major organ (kidney, liver)	Significant peripheral vascular or cerebrovascular disease
	Drug addiction, alcoholism, mental illness, or psychosocial instability
	Severe obesity or cachexia
	Non-compliance with medical care
	Unresolved pulmonary infarction (may not be an absolute contraindication to lung transplantation if this lung is to be removed and if there is no further risk of pulmonary embolism)
	Acute diverticulitis
	Severe osteoporosis

the organism before transplantation is carried out[11]. The objective is to have a candidate with an organism in his/her sputum that is sensitive to at least two antibiotics. Under such circumstances, many groups feel it is safe to proceed with the organ transplant. Fungal colonization of the airways with *Aspergillus* requires eradication prior to transplantation.

Serologic evidence of HIV or active hepatitis B are also generally accepted as contraindications to thoracic organ transplantation (Chapters 11, 32 and 57). The situation is less clear with regard to the hepatitis C-positive candidate, although, if active hepatitis C infection is present, transplantation is almost certainly excluded, unless the patient tolerates and responds to a course of interferon therapy.

Pre-existing malignancy

Pre-existing malignancy may progress rapidly in the immunocompromised patient (Chapter 12). A history of successfully treated malignancy may represent a relative contraindication as immunosuppression may impair the body's ability to control residual malignant cells. Many centers consider an absence of symptoms or signs of malignant disease for 5 years or longer to be an adequate period of time to permit transplantation, but more specific evaluation related to the malignancy (e.g. the exclusion of 'silent' distant metastases) may be warranted before making a final decision.

The disease for which transplantation is being considered may, in fact, be related to therapy given for the original malignant condition (e.g. chemotherapy-induced cardiomyopathy or radiation-induced pulmonary fibrosis). If there is no evidence of recurrence of the malignancy, transplantation is not contraindicated in these cases.

Coexisting systemic disease

The decision to reject a transplant candidate under the broad general category of coexisting systemic illness is clearly subjective. The availability of donor organs and prior experiences may determine the ultimate decision regarding the possibility of transplantation in patients afflicted with disease in other organ systems. For example, many transplant physicians may exclude patients with collagen vascular disease. As a general rule, pre-existing conditions that will significantly reduce early post-transplant survival, or that will adversely affect the long-term ability of the patient to withstand the side effects or infections secondary to immune suppression, should be considered contraindications to transplantation.

Dysfunction of other major organ systems

Dysfunction of a major organ system (e.g. renal or hepatic) may be secondary to the end-stage cardiopulmonary disease present in the thoracic transplant candidate. It is frequently difficult to determine whether this dysfunction will be partially or completely reversible once myocardial or pulmonary function has returned to normal after transplantation. Correction or improvement of the underlying circulatory state by heart transplantation will result in variable recovery of function of such organs as the kidneys or liver. Therefore, pretransplant evaluation must include every effort to determine the reversibility of the impaired organ's function. For example, pulmonary diseases such as emphysema and chronic bronchitis may be extremely difficult to evaluate in the presence of left ventricular failure, but if significant lung disease is present, heart transplantation may be contraindicated. Furthermore, cyclosporin and azathioprine may adversely affect kidney and liver function, respectively, so great care must be taken to ensure that significant irreversible renal and/or hepatic function are not already present. Accurate assessment of reversibility is not always possible, but diligent evaluation may discover disease which precludes transplantation.

In patients being considered as candidates for lung transplantation, a full cardiac evaluation is usually indicated in those patients over 40 years of age, or in those felt to be at risk for coronary artery disease at a younger age. Most emphysema patients will have a long smoking history, which will increase the risk of cardiovascular disease. Left and right heart catheterization with visualization of the coronaries and left ventricle, as well as pressure measurements, is warranted. Significant coronary artery disease

or left ventricular dysfunction will almost certainly exclude the patient from further consideration. A considerable degree of *right* ventricular failure, however, has clearly been demonstrated to be reversible after lung transplantation, particularly when the primary pulmonary disease was associated with pulmonary hypertension.

However, if right ventricular failure or pulmonary hypertension has been severe and long-standing, permanent injury to the liver may have occurred (leading to cirrhosis), which is a contraindication to thoracic organ transplantation because of the risk of developing coagulopathy, encephalopathy and/or liver failure in the post-transplant period[11,12].

Advanced age

The first heart transplants performed were in older patients. Using conventional immunosuppressive therapy with azathioprine and methylprednisolone, the early experience revealed that mortality rose in patients over the age of 40 years. More recently, even before cyclosporin became available, improved survival was achieved in carefully selected patients over the age of 50 years[13]. There are now many reports of successful transplants in older patients, even into the late 60s[14–17]. Indeed, there is decreased frequency of rejection episodes in this group[18], which is attributed to an age-associated decline in immune function. Obviously this might well represent a survival advantage to this group. Most physicians now believe that absolute age limits are no longer applicable. Attention must be paid to the general condition of the patient, and physiologic age considered in preference to chronologic age of the patient. One early study suggested that the likelihood that a patient over age 55 is a suitable recipient decreases as age increases, and reaches zero at age 67[10]. With improved selection and post-transplant management this is probably no longer true, but it does draw attention to the fact that older patients have to be assessed particularly carefully.

In the selection of lung transplant candidates (where overall survival is currently less than after heart transplantation) most groups are still relatively conservative with regard to age criteria. Patients with emphysema and interstitial pulmonary fibrosis are generally considered up to the age of 60–65 years, but rarely later. Patients with cystic fibrosis are in any case generally much younger when they present with the need for lung transplantation. Transplant candidates with primary pulmonary hypertension are also usually younger, and a higher risk of early post-transplant complications may make patients >50 years of age less suitable for lung transplantation. The operation that is to be undertaken may also influence the decision. Many groups will offer single lung transplantation to suitable patients with a physiologic age <65 years, double lung transplantation to those <60 years, and heart–lung transplantation to those <50 years of age[11].

Once again, however, the medical team must keep in mind the shortage of donor organs, and carefully consider the allocation of an organ to an 'elderly' patient when there are many young patients on the waiting list who, hopefully, may gain many more years of benefit from the transplanted organ.

Unresolved pulmonary infarction

A heart transplant candidate with recent unresolved pulmonary infarction should probably be excluded because of the risks of: (a) cavitation and secondary infection, (b) increased pulmonary vascular resistance, and (c) further embolic disease. This is a temporary condition and, when resolution and scarring have occurred, the patient once again becomes eligible. If the patient is to be given the best chance of survival, most centers would wish to delay transplantation for 2–6 weeks whenever possible. Anticoagulation should be provided during this period, to minimize the risk of further emboli from venous thrombosis.

A major pulmonary embolus may dramatically raise pulmonary artery pressure and pulmonary vascular resistance from incomplete clot lysis, and it is wise to re-evaluate the pulmonary circulation again when the infarction has resolved before proceeding to heart transplantation.

Recent pulmonary infarction is a less significant contraindication in potential lung transplant candidates if it has occurred in the lung to be replaced. However, transplantation should again be delayed until it is certain that no deep vein thrombosis remains that could prove a post-transplant source of further emboli.

Insulin-requiring diabetes mellitus

A generally accepted contraindication to heart transplantation in the pre-cyclosporin era was insulin-requiring diabetes mellitus, because of the post-transplant exacerbation of diabetes by high-dose corticosteroids. Therapy with cyclosporin and azathioprine alone (or with added low-dose corticosteroids) has been successful, thus allowing heart or lung transplants in patients with diabetes mellitus. Although insulin-requiring diabetics without evidence of end-organ disease have shown heart transplant survival comparable to non-diabetics, transplant outcome has not been carefully studied in patients with limited diabetic complications. Some programs exclude diabetics with any significant diabetic complications, including microvascular disease (e.g. retinopathy, nephropathy, neuropathy) in view of the likelihood of post-transplant impaired renal function complicating cyclosporin or tacrolimus therapy. Other centers, including our own, assess such patients on a case-by-case basis. Unstable brittle diabetes should probably exclude transplantation. Those with type II diabetes and impaired glucose tolerance are warned that they may require insulin therapy when taking corticosteroids, especially during the early post-transplant period.

Active peptic ulcer disease

Active peptic ulcer disease is a contraindication because of the risk of bleeding, perforation, and infection in the immunosuppressed patient. This, too, is temporary, and healed ulceration is not a contraindication. With the plethora of currently available agents to suppress gastric acid secretion, and to treat *H. pylori* infection, active peptic ulcer disease rarely precludes heart or lung transplantation today. Healing of ulceration should ideally be confirmed by endoscopy before proceeding to transplantation.

Peripheral or cerebrovascular disease

The presence of significant peripheral or cerebrovascular disease will prevent the transplant patient from obtaining maximum benefit from the procedure, and increase the short-term risk of complications.

We believe that carotid ultrasound, followed by arteriography in selected cases, is important to assess the risk of cerebrovascular events at the time of transplantation. We have had a policy of performing carotid endarterectomy as an elective procedure pretransplantation in a number of patients. Similarly, particularly in patients with previous cardiac surgery, in whom the need to cannulate the femoral artery and vein to initiate cardiopulmonary bypass is a possibility, we believe it is essential to have eliminated the presence of significant atheromatous disease in the aorta–iliofemoral systems.

Apart from these above considerations, it has been our experience that patients with widespread peripheral atheromatous disease, even if only moderate, do not do well long-term after heart transplantation. Complications such as gastrointestinal ischemia and renal dysfunction have not been common. It is perhaps too early to come to a conclusion with regard to the influence of peripheral vascular disease on long-term survival after lung transplantation, but it is likely that its presence will lead to increased morbidity and decreased quality of life.

Obesity/cachexia

The overweight heart or lung transplant candidate creates a difficult selection problem for which there is no clear-cut solution. When obesity is gross (e.g. >25% above ideal weight), we believe transplantation should not be offered until a considerable amount of weight has been lost. The patient's name may be placed on the waiting list, but with the clear understanding that transplantation will not proceed unless significant weight reduction (to within 10–15% of ideal body weight) is achieved.

This policy can be justified by the considerations that: (a) the patient in cardiac or respiratory failure may improve symptomatically with weight loss, possibly even to the point of being able to postpone (or, in rare cases, avoid) transplantation; (b) post-transplant mobilization and rehabilitation will likely be much more rapid in the non-obese patient; (c) obesity may make the technical aspects of the transplant surgery more difficult; (d) obese patients have greater problems with postoperative pneumonia, atelectasis, hypoventilation, thrombophlebitis, and physical rehabilitation[19,20]; (e) the corticosteroids, that form part of the immunosuppressive regimen at most centers, tend to increase the patient's appetite and thus are likely to increase weight further post-transplantation; and (f) in the large, obese patient, e.g. patients >6 ft (1.83 m) in height and >250 lb (113 kg), it may be exceedingly difficult to obtain a donor heart large enough to support the patient adequately in the immediate post-transplant period. Varying results have been reported of the influence of obesity on transplant and post-transplant mortality and morbidity, but extreme obesity clearly complicates many aspects of patient care, and is generally considered to increase morbidity and possibly mortality.

This nutritional policy can be followed and is generally well understood by the transplant candidate, unless the patient's clinical condition rapidly deteriorates to the point that intensive care unit support is required and organ transplantation becomes an emergency. It is extremely difficult to deny a patient (particularly a young patient) heart or lung transplantation purely on the basis of obesity but, if gross (e.g. >50% in excess of ideal body weight), refusal to transplant may be necessary. Furthermore, when such an urgent situation arises, a suitably large donor may not become available.

When obesity is less extreme, we still believe that every effort should be made towards a voluntary reduction in weight. This will require excellent nutritional advice, frequent outpatient follow-up, and a modest program of exercise if the cardiac or respiratory status allows this. The most important factor in the success of such a weight-reducing program, however, is patients' self-discipline and compliance.

Cachexia (e.g. <80% of ideal body weight) related to the poor cardiac status of the patient is today relatively rare, and therefore an unusual reason for not progressing with heart transplantation. If present to any degree, however, every effort should be made to improve the patient's nutritional status before transplantation (Chapter 16). Malnourished patients are at a greater risk for such postoperative complications as poor wound healing, infections, and greater difficulty in physical rehabilitation.

Obesity is a less common finding in patients presenting for lung transplantation due to emphysema, whereas cachexia may be a major problem. Extreme weight loss and malnutrition may occasionally prove a contraindication to lung transplantation, but usually can be reversed to some extent by food supplements, nasogastric tube feeding, or intravenous hyperalimentation (Chapter 16).

Prolonged mechanical ventilation of a lung transplant candidate is a contraindication to proceed to transplantation because of its effect on the state of the patient's (a) general nutrition, (b) muscle strength, and (c) propensity to infection. After transplantation these patients have great difficulty in developing the strength to breathe spontaneously and cough effectively[8]. The recovery of lung recipients who were ventilator-dependent for <2 weeks, however, has been reported to be similar to that of non-ventilator-dependent recipients[21].

Psychological instability/substance abuse/non-compliance

The psychosocial criteria regarding patient selection, including substance abuse and non-compliance, are, by their very nature, difficult to define, and are to some extent subjective. Inevitably they arouse more controversy than the relatively straightforward medical criteria[22–24].

Patients currently addicted to drugs (including narcotics, tranquilizers, and stimulants), who consume excessive amounts of alcohol, or continue to smoke, are not suitable candidates for heart or lung transplantation. Patients with psychiatric illnesses that are predicted to preclude a reasonable expectation of desirable outcome after transplantation are also considered to be poor candidates, and require very careful assessment and consideration. The drug-addicted or alcoholic patient is unlikely to comply during the postoperative period with a complex drug regimen and regular attendance for follow-up visits. This noncompliance increases the risk of transplant rejection, side-effects of drugs, and likelihood of infections.

The policies of thoracic transplant centers towards these problems vary considerably. Most centers insist on a period of abstinence from addictive substances, including alcohol, before transplantation can be performed. However, the length of abstinence required, and the degree to which it is confirmed by the

performance of blood or urine testing, vary considerably between transplant centers.

Our own policy has been not to offer transplantation to patients with a long history of addiction, who are unlikely to remain abstinent and compliant post-transplantation. With selected patients, in whom the history of addiction has been less clear or prolonged, we will accept them if compliance with a 6-month period of abstinence can be documented. In nearly all cases we have insisted on careful monitoring and screening of the patient's compliance by the transplant social worker or psychiatrist. Frequently, patients with problems relating to alcohol have been referred to organizations such as Alcoholics Anonymous for help at this stage (and in the post-transplant period).

Compliance with a non-smoking policy may be difficult to assess and monitor. Random testing for cotinine, a breakdown product of nicotine, can be carried out[11,25] to assist in monitoring compliance. Although we always impress upon all patients the need to refrain from smoking, it may prove difficult to absolutely deny an otherwise acceptable cardiac patient a lifesaving procedure such as transplantation solely on the grounds that he or she continues to smoke an occasional cigarette, or even two or three cigarettes, each day. Ideally, the medical team should probably be as strict with regard to smoking as with regard to alcohol or substance abuse, particularly in patients in whom smoking has contributed to the disease process. In reality, however, we have found it difficult to be quite so rigid, and undoubtedly have allowed some patients to undergo heart transplantation when we were aware, or suspected, that they continued to smoke intermittently. Other centers may well feel differently, and would be justified in denying this scarce resource of a donor organ to a patient who persisted with this destructive behaviour.

Lung transplant candidates, however, are absolutely excluded from consideration if they continue to smoke, primarily because it makes assessment of the allograft post-transplant infinitely more difficult[11]. In the non-smoker long-term allograft dysfunction can be caused only by infection, rejection, or complications at the airway anastomosis. In the smoker, allograft dysfunction can also be caused by bronchospasm, airway irritation, infectious bronchitis, and/or respiratory bronchiolitis. In single lung recipients these effects can occur in the allograft and in the native lung.

Perhaps more than most major surgical procedures, the success of heart or lung transplantation depends on the patient's ability to understand fully the lifelong treatment and follow-up program that is an essential part of his or her management. A strong supportive family may be of great value in seeing the patient through the perioperative and early post-transplant periods, but the patient must ultimately take responsibility for his or her own well-being.

In particular, the patient's will and ability to comply with medical therapy, and to undergo possibly repeated admissions and unpleasant procedures (biopsies and bronchoscopies) after transplantation, are difficult to assess. These are best evaluated by a team consisting of the physician responsible for the care of the patient, a psychiatrist, and a social worker experienced in the problems associated with heart or lung transplantation. Not infrequently, an initial evaluation that a patient is unsuitable for transplantation because of inadequate family support or emotional instability is shown to be incorrect (and vice-versa). Observation and evaluation over a period of time may show that some such patients, initially judged to be unsuitable, are indeed capable of adhering to complex medical regimens involving multiple diagnostic tests, clinical visits, and medications.

This is, in fact, one of the few advantages of the current delay in obtaining a suitable donor organ for an individual patient. This period of time (frequently several months) allows a continuing assessment of the patient's compliance with medical advice and family support. A patient who proves noncompliant during this period (e.g. by not taking medication regularly, by failing to attend outpatient appointments, or by failing to make any effort to lose weight, etc.) is likely to prove noncompliant post-transplantation.

Noncompliance of this nature in the post-transplant period has proved to be a major factor in morbidity and mortality in patients at some centers[26–28]. Our impression is that it is perhaps particularly seen in younger patients (those <30–40 years of age) who may be less mature or have less experience in managing a chronic medical condition than do older patients. In addition, our selection of younger patients is possibly not so rigorous, and for compassionate reasons we are more inclined to offer transplantation despite the presence of modest noncompliance concerns.

Financial considerations

In countries where there is no universal health-care insurance, such as the USA, an important practical matter is to ensure that the patient has sufficient financial resources to pay for the costs of organ transplantation. In *all* countries, however, it is important to ascertain that the patient will be able to find resources for expenses not covered by the state, private health insurance, or some other medical aid agency. While the state or health insurance organization, or the success of fundraising, may bear the cost of the operation and postoperative care, there may be many additional and 'hidden' costs, such as chronic drug therapy and the cost of travel to and from the transplant center.

In the USA, for example, the Federal medical healthcare system (Medicare), which is available to only a relatively small section of the population, does not currently cover the cost of medications after the first 2–3 years post-transplantation. This may well leave the patient in a difficult or nearly impossible financial situation. Some relief can be obtained by arranging for drugs to be provided free of charge (if a case can be made) through relevant pharmaceutical companies' indigent patient programs (e.g. NORD – the National Organization for Rare Diseases).

COMMENT

Organ transplantation has provided physicians with a successful form of therapy for end-stage heart or lung failure. At the same time, however, it has posed difficult questions related to allocation of scarce resources (both organs and economic resources), selection of patients for such therapy, and maintenance of the dying patient. In view of the inadequacy of the availability of donor thoracic organs, great care has to be taken to ensure that patients selected for these procedures are those most likely to benefit long-term. Patients with significant medical or psychosocial contraindications, or who have proven themselves to be noncompliant, should, in general, be excluded.

In summary, the ideal thoracic organ transplant recipient should have severe cardiac or pulmonary failure untreatable by conventional surgery or medical therapy. He (or she) should be free of any condition likely to predispose to the complications of immunosuppression, be psychologically stable and compliant, and have sufficient resources to support self and family through the perioperative period prior to full rehabilitation.

Pretransplant Immunological Considerations

E.D. DU TOIT, M. OUDSHOORN AND D.M. SMITH

INTRODUCTION

Consideration of a patient's state of prior sensitization and the effects of histocompatibility antigen matching are critical to avoid antibody-mediated rejection and improve the long-term outcome of transplantation. Since there are many reviews of transplantation immunology in the literature and the mechanism of allograft destruction is outlined in Chapter 7, this chapter will concentrate only on those immunological considerations that affect pretransplant histocompatibility testing and recipient selection for thoracic organ transplantation. When applicable, prospects for developing new procedures to circumvent antibodies in the recipient will be discussed, as will new technologies in histocompatibility testing. The discussion will be divided into four topics: (a) the importance of donor–recipient ABO and Rh blood group compatibility, (b) human leukocyte antigen (HLA) typing and the role of HLA matching, (c) evaluation of recipients for prior sensitization and the importance of the lymphocytotoxic crossmatch, and (d) the effect of pretransplant blood transfusion in recipients of cardiac allografts.

As there is considerably more information in all of these fields relating to kidney and, to a lesser extent, heart transplantation, rather than lung transplantation, emphasis will inevitably be placed on renal and cardiac, rather than pulmonary, transplantation. Increasingly, what has been demonstrated to influence renal allograft survival has subsequently been found to be of importance with regard to cardiac allograft survival. There is no reason to believe that, when sufficient data have been accumulated, the same will not be the case for lung allografts.

RED BLOOD CELL GROUPS

ABO groups

ABO blood group antigens are carbohydrate structures that are components of glycoproteins and glycolipids found on cell surfaces throughout the blood and tissues of the body. Antibodies to these antigens are consistently found in the serum of individuals that lack one or more of these antigens. These antibodies appear before the age of 6 months and persist throughout life. Sensitization occurs due to the presence of these antigens on bacterial flora. (Indeed, animals that are maintained germ-free from birth do not develop similar antibodies.) Each person's antibody titer is highly variable and may diminish with age or chronic illness.

ABO blood group compatibility between donor and recipient has traditionally been regarded as a prerequisite in patients undergoing organ transplantation. ABO incompatibility frequently leads to rapid destruction of the allograft[1,2]. A or B antigens present on the vascular endothelium of the allograft are targets for antibodies and complement in the recipient's serum[3] and rejection may be immediate[4]. A number of factors contribute towards renewed attempts to break the ABO barrier, such as (a) the shortage of cadaver organs, (b) the over-representation of patients with O blood group on transplant waiting lists, (c) difficulties in finding ABO-compatible grafts for presensitized patients, and (d) the importance of maximal utilization of potential living-related donors in kidney, liver, and, to a small extent, lung transplantation.

Doubt about the importance of ABO compatibility arose following the observation that a proportion of ABO-incompatible liver transplants continue to function[5] (and raise the hope that the ABO barrier may be overcome). In a recent retrospective study of 30 patients receiving emergency liver transplants it was concluded that the use of ABO-incompatible grafts is justified in emergency cases when no other donor is available, but should only be used in patients with O blood group[6]. Farges and coworkers showed that the 5-year patient and graft survival rates were 50% and 20%, respectively, in 43 ABO-incompatible liver transplants[7]. Various immunomodulatory management techniques have been used in ABO-incompatible liver transplantation and have included the use of prophylactic antilymphocyte globulin or OKT3 therapy, pretransplant splenectomy, pre- and posttransplant plasmapheresis, and immunosuppressive therapy with FK506[8,9]. Using these techniques for the management of liver transplants from ABO-incompatible living-related maternal and paternal donors resulted in a 1-year patient survival rate of 77%[8].

Opelz, in 59 cases, verified that ABO-incompatible cadaver kidney transplants showed poor results[10] and a similar poor graft survival was observed in a subset of these patients treated with cyclosporin. However, there have been occasional reports of successful renal transplants involving major ABO incompatibility[4]. Most of these have been achieved by immunological modification of recipients, including immunoadsorption, plasmapheresis and splenectomy[11,12]. In a recent study, 10 ABO-incompatible live-related renal transplants were performed after immunoadsorption to reduce anti-A and anti-B IgM titers in the recipients. The graft survival rate at 6 months to 2 years was 83%[13,14]. The few successful renal transplants performed across the ABO barrier without modification of the recipients have been explained by low initial titers of isoagglutinins in the recipient[15], or the weak expression of A antigens, as seen particularly in the case of blood group A_2 donors into O recipients[16]. Although ABO-incompatible kidney transplantation must still be considered experimental, its relative success to date, combined with the desperate need for more organs, warrants its continuation, especially if done under the close scrutiny of the transplant community[17].

In a survey by Cooper, the incidence of irreversible hyperacute or accelerated acute rejection in patients receiving incompatible ABO hearts was approximately 60%[18]. The results of a study on the expression of blood group antigens on the mesothelial cells on the surface of the epicardium and the cardiovascular endothelium indicated that there is some variation in the antigen expression between individuals. This may explain why approximately one-third of organ transplants are successful even when breaching the ABO blood group barrier[19].

Experimental techniques continue to be explored. In hyperimmunized baboons, Cooper and co-workers[20] showed that the continuous intravenous infusion of specific A or B trisaccharides (pre- and post-transplant for several days) inhibited rejection of ABO-incompatible cardiac allografts, and that this protection continued in some cases even after the infusions were discontinued. This form of therapy may permit cadaveric organ allotransplantation across the ABO blood group barrier in the human.

Data collected from the Collaborative Heart Transplant Study by Opelz show no influence of recipient–donor ABO blood type on graft survival[21]. However, several individual transplant centers have shown that group O recipients survive longer after renal[22,23] and cardiac[24] transplantation than non-O recipients, particularly in the presence of HLA-DR mismatching. Early in the series of cardiac transplants at Groote Schuur Hospital in Cape Town (with patients immunosuppressed with azathioprine, corticosteroids, and antithymocyte globulin), poor survival of recipients with the B antigen (blood groups B and AB) was observed[25]. It was presumed that those with blood group B might elicit a greater immune response. This presumption, however, remains controversial[26,27]. There is some evidence that patients receiving ABO-identical hearts (e.g. A to A) have significantly improved survival and less fatal rejection episodes than those receiving ABO-nonidentical hearts (e.g. O to A)[27–29]. Similar results have been clearly documented in large studies of renal transplants[30]. Opelz's multicenter data, however, showed no evidence that ABO-compatible (as opposed to ABO-identical) cardiac transplants have an inferior success rate[21].

Rh group

Rh antigens in transfused blood are strong immunogens but they are not significant tissue antigens and are therefore not generally considered important for heart allograft rejection[31], although a few studies have found improved renal allograft survival in Rh-positive recipients when compared with Rh-negative recipients[32]. Furthermore, there appears to be a low rate of Rh immunization in patients receiving cyclosporin immunosuppression[33], but caution is still advised in young Rh-negative women who may still wish to bear children, and in patients who may have been previously sensitized to Rh antigens by transfusion or by pregnancy[34].

THE HUMAN LEUKOCYTE ANTIGEN (HLA) SYSTEM

The most important antigens involved in tissue rejection are named the major histocompatibility antigens. The genes encoding these antigens constitute the major histocompatibility complex (MHC), known in humans as the human leukocyte antigen (HLA) system. The MHC has been identified in all vertebrates and consists of a number of closely linked genetic loci that are usually inherited as a unit (haplotypes).

The HLA system is the human homologue of an evolutionarily ancient system of major histocompatibility complex (MHC) proteins[35]. They serve to hold and display peptides on the surface of cells so that receptors on T lymphocytes may recognize them as being derived from self or foreign antigens[36,37]. They are essential to the immune system's ability to recognize intracellular infections such as viruses and in providing T-lymphocyte 'help' for the primary antibody response to foreign proteins. The central role of these MHC proteins in the immune response and their widespread tissue expression make their effect on graft survival as important as all other polymorphic protein antigens (minor histocompatibility antigens) combined.

The major histocompatibility antigens can be divided into two groups: (a) the MHC class I antigens composed of an MHC encoded α-chain associated with β_2-microglobulin and (b) the MHC class II antigens composed of two molecules, the α-chain and the β-chain, both of which are encoded in the MHC region[35].

Genes of the major histocompatibility complex

The MHC genes are located on the short arm of chromosome 6 (Figure 1) with the HLA class I genes located telomeric to the HLA class II genes[38]. The distance between the HLA-A locus and the HLA-B locus, and the distance between the HLA-B locus and the first HLA class II locus (HLA-DR), is about 1 centimorgan. This means that there is only a 1% chance that any child will inherit a haplotype having a crossover between the A and B loci, or between the B and DR loci of their maternal or paternal chromosomes. It is therefore sometimes helpful to type other family members in difficult cases.

To date, 37 closely linked HLA genes have been described and are designated HLA-A, B, C, E, F, G, H, J, K, L, DRA, DRB1, DRB2, DRB3, DRB4, DRB5, DRB6, DRB7, DRB8, DRB9, DQA1, DQB1, DQA2, DQB2, DQB3, DOB, DMA, DMB, DNA,

HLA-A–H = class I heavy chain genes, DRA–DPA = class II α-chain genes, DRB–DPB = class II β-chains, TNF = tumor necrosis factor α and β genes, Hsp 70 = heat shock proteins, Cyp 21 = 21 hydroxylase genes, C2–C4 = complement components. (Adapted from ref. 38)

DPA1, DPB1, DPA2, DPB2, TAP1, TAP2, LMP2 and LMP7[39]. Some of these genes are pseudogenes and some of them are not known to be expressed, thus not all of these genes are involved in immune functions or transplant rejection[40].

The A, B, and C antigens are composed of an α-chain and β_2-microglobulin. Only the α-chain gene is located within the MHC. The HLA-A, B and C α-chains are highly polymorphic and expressed on most nucleated cells of the body. They are therefore known as the classical HLA class I antigens. There are three other expressed non-classical class I genes: the E, F, and G loci. These genes show limited polymorphism and tissue distribution and have not been shown to have any role in transplantation[41]. The HLA-G antigen has only been found on trophoblast cells of the placenta and may have a role in maternal–fetal tolerance[42,43]. There are also many HLA class I pseudogenes. These are partial copies of HLA class I genes that have arisen during evolution by gene duplication but which have defects (deletions, frame-shift mutations, premature stop codons, etc.) which prevent the transcription of messenger RNA, or translation into functional protein.

The HLA-DR antigens are coded for by a family of very tightly linked genes. The first gene codes for the HLA-DR α-chain. The HLA-DR α-chain forms a dimer with a HLA-DR β-chain. The highly polymorphic HLA-DRB1 gene codes for the β-chain of HLA-DR1–18 antigens. The HLA-DRB5, DRB3, and DRB4 genes code for the HLA-DR51, DR52, and DR53 antigens, respectively. The HLA-DR genes are so tightly linked that one can rely on certain associations, such as the association of HLA-DR3 with HLA-DR52. These associations can be helpful clues in determining an individual's HLA type.

The HLA-DQ antigens are coded for by two genes for the HLA-DQ α-chain and two genes for the HLA-DQ β-chain. The HLA-DQ and HLA-DR loci are also tightly linked to one another. This linkage can make it difficult to distinguish the effects of HLA-DR matching from those of HLA-DQ matching on graft survival. At least one study has suggested that HLA-DQ mismatches may have an adverse impact on cardiac graft survival.

Within the MHC are also many other genes that have important functions in the immune system, including antigen processing. These include the TAP genes which encode a transport protein that moves peptides from the cytoplasm to the endocytoplasmic reticulum, where they can form complexes with HLA proteins[36]. The LMP genes code for a protease which cuts cytoplasmic proteins into peptides of the right size to complex with HLA proteins[36]. Additional genes, of which the function is uncertain, are also included in the class II region (DMA, DNA, DMB, and DOB), as well as several pseudogenes.

HLA-A, B and C antigens (MHC class I)

HLA-A, B and C antigens are expressed on the surface of virtually all nucleated cells. To determine an individual's HLA-A, B and C phenotype, the lymphocytes (T lymphocytes or whole blood lymphocytes) are incubated with a large panel of antisera with known HLA specificities, and then with rabbit complement. These antisera are derived mostly from the serum of multiparous

women, and interpretation may be complicated by cross-reactivity or unrecognized specificities in these antisera. The lymphocytes are lysed if they bear the antigen recognized by the antisera. For example, if the antiserum known to contain antibodies against HLA-A1 lyses the lymphocytes, then those lymphocytes are coded as HLA-A1. Some monoclonal antibodies are now available and, when enough specificities are developed, these may replace antisera.

It has recently become possible to type the HLA-A, B and C genes using molecular techniques[44–48], but to date HLA-A, B and C antigens are not routinely typed by molecular methods. In the research setting these methods have already shown that existing HLA serologic types may be broken down into many additional subtypes. DNA typing methods are currently being used in the clinical laboratory, primarily for HLA class II antigen typing (and therefore DNA typing methods will be discussed further under the section on MHC class II antigens). As DNA testing methodology improves, HLA class I antigens will probably also be determined by DNA typing methods.

At the HLA-A locus there are 57 known alleles (different genes that may occupy the same position or locus on a specific chromosome), at the HLA-B 118 alleles, and at the HLA-C 35. Each allele produces a gene product which is expressed on the cell surface as an antigen. Table 1 shows only those specificities which can be detected using serological methods[39]. Each individual has two chromosomes 6, one inherited from each parent, and therefore has two of the 57 HLA-A antigens (for example, A1 and A2), two of the 118 HLA-B antigens, and two of the 35 HLA-C antigens. If the recipient and donor are not HLA-identical, the immune response of the recipient following organ transplantation

is directed primarily against those antigens on the surface of the donor organ that are not shared by the two individuals.

The exact role of HLA-A, B and C matching between recipient and donor in allograft survival remains controversial, but analyzes from large regional and national centers in Europe and North America have found a consistent correlation between HLA-A and/or B matching and improved renal graft survival[49–51] (Chapter 44). The survival rate of recipients of well-matched renal allografts is approximately 10–20% higher than that of recipients of poorly matched allografts. According to some, matching for 'splits' (subgroups) of HLA-A, B antigens resulted in better long-term graft survival than when transplants were matched for a 'broad' antigen[52,53]. It should be noted that matching for HLA-B, DR or DR alone (see MHC class II) seems to be most beneficial in improving graft survival. Several reports have demonstrated no evidence for an improved outcome of cardiac allograft survival with HLA-A and B matching[28,54–58]. However, in a study of 164 consecutive cyclosporin-treated cardiac transplant patients, the Stanford group found that the degree of matching for HLA antigens at the A and B loci correlated with long-term survival in their patients[59]. The group at Houston also found that a better donor/recipient HLA matching was associated with improved graft and patient survival[60]. In addition they, like several others, showed that the incidence and severity of graft rejection episodes were diminished in the well-matched patient group[58,60–62]. Preliminary studies have shown that death from allograft vasculopathy after a heart transplant is associated with a higher degree of HLA mismatches[63]. The clinical relevance of HLA matching in heart transplantation is (as is the case in kidney transplantation) most noticeable when matched for HLA-B and DR or DR alone (see MHC class II)[52,56,62,64–66].

Analysis of the effect of HLA-C matching on renal allograft did not show any significant difference in transplant outcome between well-matched and poorly matched donor–recipient groups[54,67]. This may be due to the fact that there is a high frequency of undefined HLA-C 'blank' phenotype when using serological methods, presumably due to the lower expression of HLA-C antigens on the cell surface compared to that of HLA-A and B antigens. Recently, HLA-C typing by molecular techniques has become a reality[48], and may throw a different light on the role of HLA-C antigens as transplantation determinants. In a renal transplant recipient, mismatched for a subtype of HLA-B22 as well as the HLA-C locus, Baan *et al.* demonstrated that the *in vitro* response by the kidney-derived lymphocytes was stronger against the HLA-C locus than the HLA-B locus product[68]. This confirmed the immunological competence of the HLA-C antigens in a clinical setting.

HLA-DR, DQ and DP antigens (MHC class II)

The MHC class II region contains all the genes encoding the known HLA class II molecules: HLA-DR, DQ and DP. The HLA class II antigens have a more limited tissue distribution than do the class I antigens. HLA class II antigens are expressed on the surface of B lymphocytes and on antigen-presenting cells (e.g. macrophages, dendritic cells, etc.) and thymic epithelium, all of which are involved in interaction with helper T lymphocytes during normal immune responses. They are also expressed on other cell types, including vascular endothelial cells, thymic epithelium, and Langerhans cells. Many other cells which do not express class II antigens under normal conditions may be induced to express them. One example would be T lymphocytes which express class II antigens when activated[69]. Also, cytokines, such as γ-interferon, are known to induce HLA class II antigen expression on epithelial or endothelial cells. Thus, increased expression of class II antigens has been seen on renal epithelial cells which are involved in a rejection episode[70].

The expression of HLA class II antigens on antigen-presenting cells reflects their importance in the process of presenting antigens to CD4+ helper T cells. Class II antigens are thought to preferentially present peptides that are derived from proteins that are phagocytosed by antigen-presenting cells[37]. In contrast, class I antigens preferentially present peptides derived from cytoplasmic proteins (e.g. self and viral peptides) to CD8+ cytotoxic T cells.

Serologic typing of HLA-DR and DQ antigens is performed in the same manner as HLA class I typing, except that purified B cells are used instead of whole blood lymphocytes, which are about 80% T cells (which do not bear class II antigens). HLA-DP typing is rarely used for patient selection in clinical laboratories because there is little evidence that DP matching affects graft outcome, and because until recently typing had to be determined by complicated cell culture assays. More recently, monoclonal antibodies for HLA-DP typing have become available, as have DNA techniques.

Many laboratories are using DNA testing to determine the class II antigen types for some or all of their patients. Some of the advantages of DNA-based typing are:

(1) It does not depend on antigen expression, purified B cells, or cell viability, which makes it more reliable with fewer blank alleles and less repeat testing.
(2) It is more precise. Many of the amino acid differences between alleles occur in areas of the protein that are not accessible to antibodies, and are therefore not recognized by antisera. Although subtle, these differences can be recognized by the T cells responsible for cell-mediated rejection. Many such subtypes of serologic types have been identified.
(3) Unlike antisera, which are in short supply and expensive, DNA typing reagents can be synthesized in unlimited quantities. However, not all information gained from DNA typing may be clinically useful.

The most common DNA-based typing methods used in clinical laboratories are polymerase chain reaction-sequence specific oligonucleotide probe (PCR-SSOP), PCR restriction fragment length polymorphisms (PCR-RFLP)[71], and PCR-sequence specific primers (PCR-SSP)[72–75]. The main disadvantage of DNA-based typing is that polymerase chain reaction-based tests are very sensitive to contamination by DNA from previous specimens. Thus, great care must be taken in designing the facilities and procedures to prevent such contamination. Fewer laboratories are performing class I typing by DNA-based methods because it is more complicated. There are more HLA class I alleles that must be distinguished and the polymorphic areas of the HLA class I alleles are spread across multiple exons. However, DNA testing technologies are evolving rapidly and many more laboratories will be using DNA-based typing even for HLA-A, B, C typing within a few years.

Matching for HLA-DR was first shown to influence the outcome of cadaveric renal transplantation by Ting and Morris[76] and Persijn *et al.*[77] in 1978. It has been said by Ting that HLA-DR incompatibility between donor and recipient may well be the major stimulus for the generation of the immune response against a transplanted kidney[78]. The positive effect of matching for HLA-DR has been confirmed by numerous single and multicenter studies[79–81].

Data from the Collaborative Transplant Study showed that many of the serological HLA-DR typings were incorrect when compared to the DNA-RFLP method, and graft survival was significantly improved ($p < 0.02$) in the HLA-A, B, DR DNA-matched grafts (87%) compared to the mismatched grafts (69%)[82,83]. Even centers which had previously found no association, or only a weak association (presumably due to incorrect HLA-DR typing), now find an association between the results of matching and kidney graft survival when using molecular methods to type for HLA-DR[84,85].

The question whether matching by genomic DRB1 typing (i.e. typing for alleles which cannot be determined by serology) may lead to further improvement of graft survival in HLA-DR matched combinations were studied by Leivestad *et al.* and Ichikawa *et al.*[86,87]. They found that genomic DRB1 matching did indeed further improve the clinical course of serologically (DR1–10) matched renal grafts. This is in contrast to the findings of Opelz *et al.*, who found no such effect[83]. The importance of HLA-DRB1 amino acid residue matching between recipient and donor cadaveric renal transplantation was investigated by the group of Tsuji from Japan[88]. They found that rejection correlated with the incompatibility of the DRB1 amino acid residue on the β-pleated sheet rather than on the α-helix. Especially the frequency of mismatches in the second variable region on the β-pleated sheet was significantly higher in the rejection-positive group as compared with the rejection-negative group.

There are many studies indicating that matching for HLA-DR improves cardiac allograft survival[28,64,66,89,90]. HLA-DR matching also appears to reduce the incidence and severity of rejection episodes in cardiac transplant recipients[58,64,90–94]. The role of matching for HLA-DRB1 in heart transplantation has hardly been evaluated. Poli *et al.*[95] found no HLA-DRB1 matching effect on heart transplantation outcome. However, HLA class II matching also appeared to influence survival after combined heart–lung transplantation[96].

Few data are available on the relevance of matching for HLA-DQ antigens in organ transplantation, due partly to the fact that not all centers type for HLA-DQ and partly to the strong linkage disequilibrium of HLA-DQ with DR. There are studies which have shown a beneficial effect of HLA-DQ compatibility on the survival of cadaveric renal allografts[97–100]. However, the study of Bushell *et al.* showed no significant effect on renal graft function or outcome in a small group of patients with HLA-DQ mismatches in the presence of compatibility for HLA-DR[101]. That the effect of HLA-DQ compatibility in organ transplantation still has to be elucidated is most markedly demonstrated by the fact that one group even found a negative effect of HLA-DQ compatibility on the survival of haplo-identical living-related kidney grafts[102]. A study conducted by the Pittsburg group on 349 cardiac transplant patients demonstrated an increase in the risk of earlier-onset cellular rejection and lower rejection-free survival when recipient/donor pairs were incompatible for HLA-DQ[61].

The role of HLA-DP in the outcome of heart and kidney transplantation has hardly been investigated. In a single-center report on renal graft survival no effect of HLA-DP matching was found[103]. This group also investigated the effect of HLA-DPB1 mismatches in a group of zero-mismatched HLA-A, B and DR renal transplants, and again found no effect of HLA-DP matching on graft survival[104]. However, in a study on HLA-DP matching in HLA-haplo-identical living-related kidney transplants it was demonstrated that DPB compatibility increased the long-term graft survival rate[105].

Is it time to allocate hearts on the basis of HLA matching?

A report from the Collaborative Transplant Study analyzing 8331 patients who underwent primary cardiac transplantation in 104 centers shows an impressive correlation between matching for HLA-A, B and DR and graft survival after 3 years[106] (Chapter 44). Matching for HLA-DR alone was also associated with a beneficial effect, but not as marked as that of matching for HLA-A, B and DR. The time constraints surrounding donor heart preservation have made prospective HLA matching impossible. Opelz and Wujciak[106], however, suggested that the time has come to begin transplanting hearts on the basis of prospective HLA matching. This could be done by typing all potential recipients in advance and typing the potential donor (before the heart is removed) with the newly developed rapid DNA typing techniques. They estimated that the creation of a pool of 1000 recipients would allow approximately one-third of patients to receive a heart with no or only one HLA-A, B or DR mismatch. In a comment on this study, Morris supported the view of Opelz and Wujciak in saying that evidence is slowly accumulating to support prospective HLA matching, including crossmatching in sensitized recipients, in order to select well-matched recipients for cardiac transplantation[107].

Do we have to look at matching for HLA antigens differently?

An interesting new view on HLA matching in renal transplantation has been proposed by Terasaki's group[108]. They were able to identify permissible mismatches based on an extensive analysis of the UCLA renal transplantation data. Permissible antigens were defined as those mismatches that led to immunologic failure in less than 15% of cases. They found that cadaver donor kidney transplants, judged to have received a permissible mismatch of the A, B or DR loci, had graft survival rates equivalent to grafts where there were no A, B, DR mismatches. These data were supported by the Eurotransplant data[109]. The data are preliminary but, if confirmed, could greatly increase the number of well-matched grafts.

SEROLOGIC HISTOCOMPATIBILITY TESTING

Patients who require a transplant may have preformed (allogeneic) antibodies due to their previous exposure to sensitization sources: (a) blood transfusion, (b) organ transplantation and/or (c) pregnancy. Since the original discovery of hyperacute rejection

of kidney allografts in patients with preformed HLA antibodies, lymphocytotoxic crossmatches have been performed before all kidney transplantations[110]. Currently, hyperacute rejections are exceedingly rare. Thus, conventional crossmatching techniques are adequate to nearly eliminate the risk for such complications[111].

It has long been established in kidney transplantation that antibody-mediated graft rejection is most often caused by preformed antibodies to HLA antigens[110]. These antibodies, identified by testing for reactivity with a panel of T and/or B lymphocytes which have been previously HLA typed, are known as panel-reactive antibodies (PRA). A lymphocytotoxic crossmatch identifies antibodies reactive with the donor's lymphocytes.

However, it is not generally accepted that crossmatches have to be performed before allogeneic liver, heart or lung transplants, since it has not been unequivocally shown that these organs can succumb to hyperacute rejection[61,112]. The debate arises, in part, due to a lack of standardization in assay techniques and an incomplete description of the antibodies responsible for the positive crossmatch[113]. More recent data indicate that the presence of donor-specific HLA antibodies is associated with an increased risk of immunological complications following both liver[114] and heart transplantation[115]. The absence of HLA-specific antibodies does not guarantee that hyperacute rejection will not occur. Hyperacute rejection has been reported in patients without evidence of a positive PRA and in patients with a positive PRA but who had a negative donor lymphocyte crossmatch[112]. Also, not all patients who have had a positive crossmatch will have hyperacute rejection[116]. However, the presence of donor HLA class I-specific IgG antibodies should be considered a high risk factor for early graft failure. In a study by Smith *et al.*[117] the actuarial 1-year survival of 258 recipients with negative T lymphocyte crossmatches was 73% compared to 28% for seven recipients with a positive crossmatch. Ratkovec *et al.* also analyzed 328 cardiac allografts and showed that rejection occurred earlier, and survival was poorer, in recipients with a positive crossmatch[113].

Data from the International Society for Heart and Lung Transplantation Registry showed that in retransplantation the incidence of a positive PRA rises to 20% from 2% in primary transplants, and the incidence of a positive T lymphocyte crossmatch rises to 17%[118]. Patients retransplanted with a positive crossmatch had an actuarial 1-year survival of 33% compared to 72% for recipients with negative crossmatches[118]. Reports of uneventful transplantation of patients who were found retrospectively to have positive crossmatches have generally stated that the crossmatches were weak or doubtfully positive, were IgM, or had no specificity for the donor's HLA antigens. The interpretation of crossmatch results at the time of transplant is made much easier and more reliable if pre-existing antibodies have been well characterized prior to transplant.

Panel-reactive antibodies

The panel-reactive antibody (PRA) screen is used to determine the degree of humoral sensitization of a patient awaiting transplantation. When a patient becomes a candidate for thoracic organ transplantation, a fresh serum sample should be screened against a panel of at least 30 HLA typed T lymphocytes. If the screen is positive, the serum should be tested against a larger panel in order to identify the HLA specificity of the antibodies (i.e. to detect preformed HLA antibodies in the recipient). These antibodies are often multispecific, but often these specificities fall into one of several well-characterized crossreactive groups[119]. A history of the patient's prior transfusions, pregnancies, miscarriages, or transplants should be obtained, and this information given to the laboratory. A positive PRA in a patient with no history of a sensitizing event should be carefully scrutinized.

Patients who show reactivity with a high percentage of the panel, without a well-defined specificity, should also be tested for the presence of an autoantibody. The characteristics of an autoantibody are that it: (a) reacts with the patient's own cells, (b) reacts with many of the panel cells without a clear specificity, and (c) is entirely of the IgM class. A crossmatch with the patient's own cells will determine if the antibody is autoreactive, and treatment of the serum with a reducing agent such as dithiothreotol (DTT) will remove any IgM antibodies[120]. If the serum is autoreactive and DTT treatment removes that reactivity, then the PRA should be repeated with DTT-treated serum to determine if there is also a true alloantibody previously hidden by the autoantibody. If an autoantibody is present, then at the time of transplant the crossmatch should be performed using DTT-treated serum.

Patients who have high PRA results and who are transplanted with a crossmatch-negative donor may still have an increased risk of rejection. The influence of preformed non-donor-specific T cell lymphocytotoxic antibodies (that is, antibodies that have been demonstrated against a panel of T lymphocytes only, but not specifically against donor T cells) on the subsequent survival of an allograft remains uncertain. There is some evidence that patients with broadly reactive antibodies (antibodies with a high frequency of lymphocytotoxicity against a random panel) have impaired renal[121–123], heart–lung[96], and cardiac[116] graft survival rates. In a histological analysis of 2564 endomyocardial biopsies in 349 cardiac transplant patients, Zerbe and co-workers showed that sensitized patients with panel-reactive lymphocytotoxic antibodies >10% experienced more histological rejection than non-sensitized patients[61].

Should the recipient be shown to have preformed lymphocytotoxic antibodies against T cells, difficulty may be met in finding a compatible donor for that patient. If there are no preformed antibodies, selection of a suitable donor should in all likelihood be easy. Most cardiac transplant centers require a negative prospective donor-specific lymphocyte crossmatch in 'sensitized' recipients with elevated PRA values[112,113,116,124]. We believe that a donor-specific lymphocytotoxic crossmatch should be performed whenever preformed lymphocytotoxic antibodies (HLA class I IgG) have been identified, and that it is preferable in cases where no antibodies have been detected.

The difficulty in obtaining donor blood or lymph nodes prior to organ harvesting from distant donors, and the very limited acceptable cold ischemia times, may make this impractical. In that case the patient may be limited to the use of organs from local donors, which may make it very difficult to find a suitable donor organ. Many centers for this reason set thresholds of PRA of >10% or 15% for requiring a prospective crossmatch.

If the patient receives a blood transfusion after his/her initial antibody screen, it is extremely important that the patient be tested again approximately 1 month after the transfusion. If this

screen is positive, the patient should be followed monthly for 3–6 months because the specificity often becomes narrower, or sometimes disappears. Retesting patients after transfusion is probably the most often overlooked procedure, but if not done may have catastrophic consequences, since those patients with a negative PRA are usually transplanted before the results of lymphocytotoxic crossmatching become known.

Lymphocyte crossmatching

Lymphocyte crossmatching is performed to detect donor-specific anti-HLA antibodies in the serum of the transplant recipient. Most cardiac transplant centers require a negative prospective donor-specific lymphocyte crossmatch in 'sensitized' recipients with elevated PRA values[112,113,116,124]. HLA class I antigens are found on most nucleated cells in the body, including the graft endothelial cells, which are the principal target of hyperacute rejection. HLA class II antigens are not normally expressed on endothelial cells so the presence of antibodies to these antigens is probably rarely associated with hyperacute rejection.

The crossmatch method that has been widely used is the cytotoxicity method, using either donor splenic or whole blood lymphocytes (>80% T cells which do not express HLA class II antigens), or purified populations of T and B lymphocytes. This method only detects complement-fixing antibodies, i.e. of the IgM class and of some IgG subclasses (IgG1, IgG3). New and more sensitive methods have recently been introduced for crossmatching (see below) which, in addition to being more sensitive, are not dependent on complement binding and therefore can be used to detect non-complement-fixing IgG2, IgG4 and IgA antibodies. The augmented antiglobulin test or the flow cytometric assays are much more sensitive than the conventional cytotoxicity tests. Antibodies demonstrable only by these more sensitive crossmatch methods have been found in patients with early non-functioning kidney allografts, as well as patients with early acute rejection. Recent reports have also shown that certain non-HLA antibodies may be harmful to the transplanted allogenic kidney graft[111]. Endothelial cell-specific antibodies have been identified in patients with early immunological complications. These antibodies can be identified using fluorescent activated cell sorter analysis. The importance of a low-level allosensitization only demonstrated using the more sensitive crossmatch methods is still uncertain[111].

Several modifications of the standard complement-mediated lymphocytotoxicity assay have been developed, and different laboratories may use one or more of these techniques. The final crossmatch should be done using a technique that has increased sensitivity over the standard NIH method[125].

Standard NIH method

Donor lymphocytes are isolated from the donor's blood, lymph nodes or spleen and incubated for 30 minutes with the donor's serum, undiluted and diluted. Baby rabbit complement is then added and incubated for 60 minutes. The reaction is stopped by the addition of EDTA and a vital dye (eosin or trypan blue), and the reactions are scored from 1 to 8+ based on the percentage of cells killed.

Extended incubation method

The standard method is used except that the incubation times are extended up to 60 min with the patient's serum and 2 hours with complement. This increases the sensitivity of the crossmatch but may also increase the incidence of non-specific cytotoxicity.

Amos modified method

The standard method is used except that the cells are washed once after incubation with the patient's serum, before adding complement. This removes any 'anti-complementary activity' that may be present in the serum, prior to incubation with complement, and thus increases the sensitivity of the assay.

Anti-human globulin method

The standard method is used except that an antiglobulin reagent (usually a polyclonal anti-human kappa light chain antiserum) is added after incubation with the patient's serum. This modification increases the sensitivity of the crossmatch for antibodies that bind complement poorly.

Flow cytometric crossmatch

This method uses fluorescently tagged secondary antibodies (anti-IgG or anti-IgM) and a flow cytometer to analyze reactivity with individual cell types. This can be useful in determining the specificity of recipient antibodies and in enhancing the sensitivity of the crossmatch.

The patient's initial serum and a current specimen collected within 48 hours prior to transplant should be tested, along with any sera collected following a sensitizing event or showing a peak in PRA activity. If a positive crossmatch is seen, then the immunoglobulin class should be determined by incubating the serum with a reducing agent such as DTT. An IgG antibody in a current serum should be considered a contraindication to transplantation. However, in cases of extreme urgency some patients have been transplanted using plasmapheresis and immunosuppression to remove most of the serum antibody[126].

The significance of an IgM antibody in a current serum is more controversial. In some studies of primary transplants a positive crossmatch has not been predictive of hyperacute rejection[58,61,112]. In most cases these have been described as weak or doubtfully positive due to IgM. In those patients who also had a positive PRA, the specificity of the antibodies was not to the donor's HLA type. This is consistent with the experience in renal transplantation where the presence of IgM antibodies only was not predictive of hyperacute rejection[120]. If the patient has recently been transfused, then the presence of IgM antibody alone may be indicative of a primary antibody response, and thus may be of more significance. Patients receiving secondary grafts are at increased risk of graft rejection. Although there are no data on the significance of IgM antibodies in this group, one might be more reluctant to discount such an antibody in a patient about to undergo a second transplant.

A positive crossmatch with a past serum, when the current serum is negative, may not be predictive of graft survival in primary transplants. Cardella and co-workers claimed, and re-

cently affirmed, that kidney transplantation in recipients who had a positive historic-serum donor-specific reaction, but negative current-serum crossmatch, could safely be transplanted[127]. However, others reported a reduced survival in patients transplanted where the same conditions pertained[111]. Similar data are not available for recipients of cardiac or pulmonary transplants.

Although the importance of T cell lymphocytotoxic antibodies in the subsequent destruction of an allograft is accepted, that of B cell lymphocytotoxic antibodies remains uncertain[128]. As a result of the uncertain clinical significance, the B cell crossmatch is not universally performed before renal transplantation. It should be noted that reactivity with B lymphocytes can be caused by autoreactive antibodies, by other non-HLA specific antibodies, or by low concentration of class-I-specific antibodies, rather than the commonly assumed presence of HLA class-II-specific antibodies[111].

The role of B cell antibodies in clinical transplantation has received much attention following the first reports of a successful graft outcome in the presence of a positive B cell lymphocytotoxic crossmatch[129,130]. Donor-specific B lymphocytotoxic antibodies, when present in a potential recipient before transplantation, have been variously reported to: (a) lead to early graft rejection[131–133], (b) bear no relationship to subsequent outcome[134,135], and (c) correlate with improved graft survival[136]. It has been established, however, that preformed donor-specific B cell antibodies do not lead to immediate or early allograft failure from hyperacute or accelerated graft rejection, which may occur when preformed donor-specific T cell lymphocytotoxic antibodies are present in the serum[137,138]. Isolated cases have been reported[139], and recently Bunke *et al.*[140] investigated the effect of a positive B cell crossmatch in 69 patients receiving orthotopic cardiac transplants. Six patients in this group who had a positive B cell crossmatch and a negative T cell crossmatch demonstrated an increased incidence and increased severity of rejection episodes in the first 6 months post-transplant.

The evidence that antibody formation following rejection of a renal allograft confers a less favorable prognosis on subsequent graft survival is supported by our own observations in one patient following cardiac retransplantation[141]. This patient developed strong multispecific antibodies against T lymphocytes after rejection at 5 weeks of an HLA non-identical heterotopic cardiac transplant. The heterotopic allograft was excised, and the patient remained alive supported by his own heart. After some months the antibodies could not be detected, although they recurred following a test transfusion of 500 ml of HLA non-identical blood. When another donor heart became available, the donor-specific T cell lymphocytotoxic crossmatch test using both stored and fresh recipient sera was negative. A second heterotopic heart transplant was performed, but the donor heart failed within 5 days, following the onset of a severe irreversible acute rejection episode. At that time, a 32-fold increase in lymphocytotoxic antibodies against donor T cells was demonstrated in the patient's blood.

The following suggestions were made at the recent workshop[111] on the clinical relevance of new crossmatching techniques:

(1) As no consensus could be reached at the workshop, many speakers advocated future controlled trials to clearly establish the clinical importance of the new crossmatch techniques.
(2) It was suggested that panel-reactive antibodies should be characterized in all patients who are to undergo kidney transplantation in terms of the presence of autoreactive antibodies, non-HLA antibodies, and Ig complexes, and that the HLA specificity of the PRA should be defined.
(3) It was proposed that, if sera from alloimmunized patients contain panel-reactive cytotoxic HLA class I-specific antibodies, crossmatches should be performed using a sensitive assay for reactivity against donor cells.
(4) Crossmatches should be performed with donor T lymphocytes using current serum as well as historic serum with the highest reactivity.

The workshop report also stated that crossmatches are not performed before liver and heart transplantations, in most centers. However, inferior survival of grafts performed against a positive crossmatch caused by HLA antibodies was reported in both categories of patients. The importance of HLA-specific alloantibodies in recipients of liver and heart allografts has to be further studied.

PRETRANSPLANT BLOOD TRANSFUSIONS

Prior to 1973, blood transfusions were avoided whenever possible in potential transplant recipients in order to minimize the risk of presensitization to HLA antigens. It was thought that the development of cytotoxic antibodies to HLA alloantigens would reduce the number of potential donors compatible with the particular patient[142,143]. In 1973, however, it was demonstrated in a large renal transplant series that transplant recipients who had never received blood transfusions before transplantation had a significantly lower allograft survival rate than their counterparts who had been transfused[144]. These results have been confirmed by most renal transplant centers[145–148], though the magnitude of the effect varies markedly from center to center. Clinical data on pretransplant transfusions in cardiac allograft recipients also indicate a beneficial effect[149,150].

The beneficial effect of pretransplantation blood transfusion in cyclosporin-treated patients is controversial. Several studies have reported that, in patients transplanted without prior transfusion, graft survival is no longer substantially lower than that in transfused patients[55,151–153], while others still report a beneficial effect[154]. As mentioned by Cecka *et al.*[154], these controversial reports (coupled with the public awareness that recipients of blood transfusions may be at higher risk for acquired immunodeficiency syndrome (AIDS) and other viral infections) present a serious impediment to the physician who must justify recommending blood transfusions to a potential transplant recipient.

The impact of HLA sensitization on a patient needing a cardiac transplant is also much greater than the impact on a patient needing a renal transplant. The renal transplant candidate may have to remain on dialysis for a longer period of time, but in a cardiac transplant patient this may greatly limit the pool of potential donors, and therefore greatly decrease the chance of finding a suitable donor.

Although one major center has reported that favourable renal allograft outcome is directly related to the number of pretransplant transfusions received[155], other groups have not confirmed this. On the contrary, they reported that a single transfusion is as

effective as several transfusions, and lessens the risk of the potential recipient developing antibodies against HLA antigens[156,157]. The number of transfusions needed for optimal effect might also depend on the specificity of the recipient's HLA antigens[158]. Virtually every study indicated that the transfusion effect must contain leukocytes to induce the graft-protecting effect.

The influence of HLA compatibility on the blood transfusion effect has also been studied to determine whether the sharing of one genotypically identical HLA haplotype between the recipient and the donor-specific transfusion might have something to do with these excellent results. Little is known about the effect of HLA class I matching between unrelated blood transfusion donor and recipient. Nube *et al.*[159] observed a beneficial effect of such a matched pretransplant blood transfusion on graft survival, whereas Albert *et al.*[160] were unable to confirm these findings. A study by Lagaaij *et al.* has shown a significant positive effect of one HLA-DR antigen-matched blood transfusion compared to completely HLA-DR mismatched blood transfusions on the survival of heart and kidney allografts[161]. The beneficial effect was said to be due to the absence of increased CTLp reactivity in the one HLA-DR antigen-matched group[162]. Middleton and colleagues demonstrated that the incidence of rejection episodes was significantly reduced in patients who received blood matched for one HLA-DR antigen compared with patients who received random blood[163]. Similar results were seen by Bayle *et al.* in a group of naive patients (no previous pregnancies or blood transfusions) who received haplo- or semi-identical transfusions[164]. This group of patients did not develop anti-HLA antibodies, and had significantly less acute rejection episodes when compared to a group of naive patients who received three random transfusions. Data of Van Twuyver and colleagues suggest that the beneficial effect of donor-specific blood transfusions before transplantation may be explained by the induction of specific transplantation tolerance which may be due to the presence of mixed chimerism[165].

In general, there are three mechanisms that might explain the induction of specific transplantation tolerance[166]: (a) clonal deletion, which implies the elimination of all T cells bearing receptors that are reactive with the specific transplantation antigens of the donor; (b) clonal anergy, which is defined as the inactivation but not elimination of alloreactive cells; and (c) active immunologic suppression, which implies the existence of a specific suppressor cell population capable of inhibiting alloreactive cells.

COMMENT

In summary, although ABO-incompatible transplantation is still considered experimental, the shortage of donors possibly warrants cautious continuation of such trials, despite the limited success rate. This should be combined with immunological modification of the recipient and should be continued only under the close scrutiny of the transplant community. There is evidence to show that HLA compatibility and, in particular, matching for HLA-B, DR or DR alone, seem to be beneficial in improving graft survival. With the advent of HLA class I typing by molecular techniques, new light may be thrown on the role of the HLA-C antigens as transplantation antigens. Investigations into permissible mismatches should be pursued, since this is likely to provide a greater number of successful transplants. Patients with high levels of circulating T-lymphocytotoxic antibodies are at higher risk of losing graft function from acute rejection, despite a negative donor-specific crossmatch at the time of transplantation. However, the importance of B cell lymphocytotoxic antibodies remains uncertain.

The policies and procedures of each thoracic organ transplant center may vary according to the program director's assessment of the available studies. The following recommendations are based upon the authors' assessment of the studies reviewed above.

(1) ABO compatibility between recipient and donor should be confirmed (unless a formal clinical trial has been approved).
(2) All patients to be listed for thoracic organ transplantation should be screened for anti-HLA class I antibodies against a panel of at least 30 HLA-typed T lymphocytes (PRA).
   (a) If the PRA is negative, it is extremely important to have policies and procedures that will assure notification of the transplant team and laboratory if the patient is transfused, or has another potentially sensitizing event (e.g. pregnancy or transplant). If a patient is transfused, he/she should be followed for at least 1 month post-transfusion, to determine whether new antibodies have developed. If new antibodies develop, the patient should be followed monthly until the specificities have been stable for several months (if the patient's clinical status makes this possible).
   (b) If the PRA is positive: (i) the patient's history of transfusions, pregnancies or prior transplantation should be obtained or reviewed; (ii) the serum should be tested against a larger panel of cells (e.g. 60) in order to identify the HLA specificity of the antibody; (iii) the immunoglobulin class of the antibody should be identified by treating the serum with DTT (IgM vs IgG); (iv) if the PRA is high (>50%), has no identifiable HLA specificity, or is entirely IgM, then a crossmatch against autologous lymphocytes should be performed to identify any autoantibody.
(3) All patients who have evidence of prior sensitization to HLA class I antigens should have a T lymphocyte crossmatch performed prior to transplantation, whenever possible. It is acceptable to have a policy that sets a threshold PRA value (usually <10–15%) below which a transplant will be performed before a crossmatch is completed, if prior crossmatching is not feasible (e.g. distant donor).
   (a) A positive crossmatch on a current specimen should be considered a relatively strong contraindication to transplantation. If medical necessity requires immediate transplantation, then some form of antibody reduction treatment should be performed.
   (b) Autoantibodies alone are not a contraindication to transplant.
   (c) There is insufficient evidence in cardiac or pulmonary transplantation to recommend whether a patient with a currently negative but historically positive crossmatch should be transplanted. Evidence from renal transplantation may support transplantation in patients who have not previously been transplanted.

(4) If logistics allow, one should strive to match HLA antigens of the donor and recipient, with preference given to good DR or B/DR matches. There is increasing evidence of improved long-term survival of well-matched grafts, but often medical necessity outweighs HLA matching considerations.
(5) Avoid transfusion of potential transplant candidates whenever possible, and use leukocyte-depleted blood products when transfusion is necessary. The risk of HLA sensitization outweighs any effect of transfusions on graft survival when using modern immunosuppression.

Immunobiology of Allograft Destruction

M.H. SAYEGH AND D.R. SALOMON

INTRODUCTION

The past decade has been marked by a veritable explosion in our understanding of the immune response to alloantigens and the mechanisms of graft rejection. We can now consider both cellular and molecular events that directly impact on the function and survival of transplanted organs. The immune response that once may have seemed a relatively simple set of cell–cell interactions has now been expanded into such marvelous detail that the resulting complexity is a major and daunting challenge for both clinicians and scientists.

For example, we can start with one cell and describe transcription of multiple specific cytokine genes whose secreted products connect with cytokine receptors, resulting in transmembrane signalling connecting these events to a complex cytoplasmic network of enzymes. These in turn signal across the nuclear membrane via DNA binding proteins to regulate the transcription of another set of genes determining cellular behavior. As a result the universe in which we view the immune response now extends from our original vantage point at the cell–cell level to encompass events taking place in the cell cytoplasm and nucleus.

A major theme of this chapter is that we cannot escape the implications of biological complexity of the immune response for the practice of clinical transplantation. On the contrary, we must create an organization for this new material that is relevant to the decisions we make affecting patient care, including the choice of new therapies, and that will survive as a framework for our understanding of new information in this rapidly expanding field. We will consider three questions in this chapter:

1. What is the molecular basis of the immune response?
   (a) the major histocompatibility complex (MHC)
   (b) mechanisms of allorecognition
   (c) mechanisms of T cell activation
2. What are the mechanisms of graft rejection?
   (a) acute and chronic rejection
   (b) cell-mediated and humoral-mediated injury mechanisms
   (c) the adhesion paradigm in rejection
3. Will tolerance ever be a clinical reality?
   (a) definition and mechanisms of tolerance
   (b) strategies to induce tolerance

WHAT IS THE MOLECULAR BASIS OF THE IMMUNE RESPONSE?

The major histocompatibility complex

The MHC molecules are the principal targets of the immune response to allografts[1], although minor or tissue-specific antigens may be other targets. In humans the MHC is located on the short arm of chromosome number 6; it encodes for class I and class II MHC molecules which are expressed on the surface of cells. Class I molecules are on all nucleated T cells and consist of two non-covalently bound polypeptide chains. The heavy (44 kDa) chain is inserted into the plasma membrane, and consists of three domains: α_3 is the closest to the cell membrane and has homology to immunoglobulins, while α_1 and α_2 contain the antigenic portions. The light (12 kDa) chain is called β_2-microglobulin, encoded by a gene on chromosome 15.

There are three class I heavy chain loci: HLA-A, B, and C. The first MHC molecule to be crystallized was HLA-A2[2]. X-ray diffraction studies show that the two membrane distal domains, α_1 and α_2, form a groove along the top surface of the molecule facing away from the cell membrane. The margins of the groove are formed by α-helices, and the base is floored by a series of eight parallel β-strands. The groove, approximately 25 Å long and 10 Å wide, contains a peptide fragment, which is eight or nine amino acids long[3]. The origin of the peptides is the intracellular pool of polypeptides derived from metabolic turnover of housekeeping proteins or intracellular infections, such as viruses. Interestingly, the genes controlling this process are located in the same region as the class II MHC[4].

Class II molecules are expressed on B lymphocytes, monocytes/macrophages, dendritic cells, and some activated T lymphocytes. Endothelial and epithelial cells can express class II MHC upon activation. Class II molecules consist of two non-covalently associated glycosylated polypeptides, both of which are inserted into the cell membrane: α (34 kDa) and β (28 kDa). Each of these chains has two domains with the polymorphic (antigenic) regions on the outer, N-terminal, domains. There are three class II loci: HLA-DP, DQ, and DR. The crystal structure of class II HLA-DR1[5] shows a remarkable similarity to class I, the main

difference being the longer size of the peptides (13–26 residues)[6,7]. Peptides bound to class II molecules are derived from proteolysis in acidic endosomal compartments and represent endocytosed exogenous proteins or micro-organisms.

Mechanisms of allorecognition

T cell recognition of allo-MHC is the primary and central event which initiates allograft rejection[1,8,9]. The two fundamental questions in allorecognition are: first, why is the frequency of alloreactive T cells so high? second, how can positively selected self MHC-restricted T cells recognize foreign antigens as well as allo-MHC?

Lechler and Batchelor, in the early 1980s[10,11], proposed that there are two 'routes' of alloimmunization: one stimulated by MHC antigens on graft passenger cells, and the other by donor MHC antigens after processing and presentation by host antigen-presenting cells (APC). Recent work confirms at least two distinct pathways of allorecognition[8,9]. In the 'direct' pathway T cells recognize intact allo-MHC molecules on the surface of donor or stimulator cells. This recognition is probably by 'molecular mimicry' where T cells recognize *allo-MHC* because it resembles *self-MHC* at the molecular level of three-dimensional structure[12]. Peptides, derived from endogenous proteins, including MHC molecules, bound into the groove of the MHC appear to play an important role in direct allorecognition. In the 'indirect' pathway T cells recognize alloantigen which has been processed and presented as allopeptides in the groove of host MHC by self-APC. Mounting evidence indicates that this indirect pathway may also play an important role in mediating the rejection process.

Direct and indirect allorecognition are not mutually exclusive pathways. Each is mediated by different sets of T cell clones and may both be involved simultaneously (Figure 1). Direct allorecognition clearly accounts for the cytotoxic T cell function targeted against graft cells, while both direct and indirect allorecognition synergize to initiate and amplify T helper cell function. Activated $CD4^+$ T helper cells secrete cytokines and provide the necessary signals for the growth and maturation of effector mechanisms of allograft rejection including $CD4^+$ lymphocytes mediating delayed-type hypersensitivity (DTH), cytotoxic $CD8^+$ T lymphocytes, and antibody-producing B lymphocytes (see below).

It has been suggested that early acute allograft rejection is predominantly mediated by the direct pathway, since the graft contains a significant number of donor-derived passenger APC which are capable of providing the necessary co-stimulatory signals for full T cell activation (see below). The indirect pathway of allorecognition, on the other hand, may play the dominant role in chronic allograft rejection. However, the relative contributions of direct versus indirect allorecognition to acute and chronic rejection remain unclear, and studies to elucidate these mechanisms are necessary for the development of better strategies to prevent chronic rejection. Finally, in xenotransplantation there is evidence for both direct as well as indirect presentation of xeno-MHC, although the contribution of these pathways to xenograft rejection is currently unknown.

T cell activation, co-stimulation and adhesion

The first step in T cell activation is the binding of the TCR to the MHC molecule. The TCR is a two-chain protein complex (a

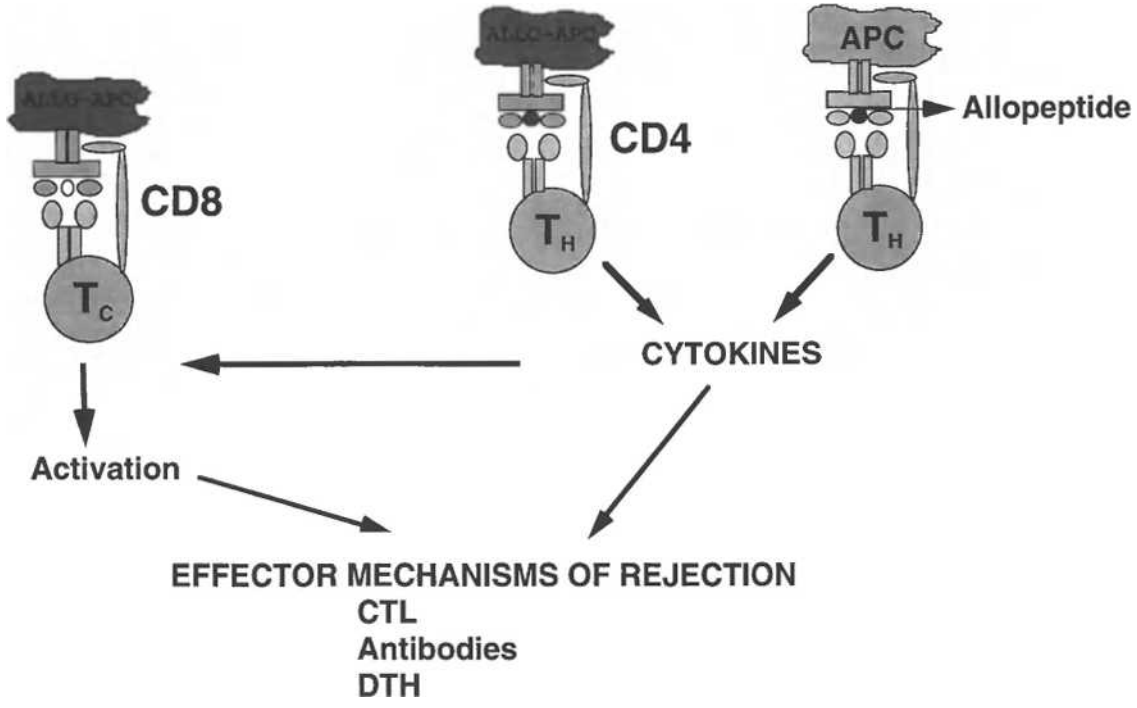

Figure 1 Direct and indirect allorecognition pathways are related

heterodimer) which is anchored in the T cell's membrane at one end (C-terminal) while forming a complex antigen-binding site with its outermost portion. The amino acid sequences of the two TCR chains, α and β, determine the antigen specificity of the two-chain complex. In turn the TCR is connected to the CD3 complex, which consists of at least five molecules all of which are required for signal transduction after the TCR successfully engages its specific antigen. Because the TCR cannot be expressed on the T cell surface without the CD3 complex, we refer to the whole group as the *TCR/CD3 complex*.

Concept 1: The repertoire of antigens capable of triggering T cell activation is determined during T cell development in the thymus

The earliest steps in T cell development occur in the thymus and involve the random rearrangement of specific variable regions on the TCR α and β chain genes to produce millions of different TCR, each of which is expressed on a given T cell clone. In the next stage the thymus selects those TCR rearrangements that are capable of recognizing self-MHC molecules with good affinity and eliminates the remaining inefficient T cell clones. This is called *positive selection*. In the third step the thymus destroys all the T cell clones that recognize self peptide antigens presented by self-MHC. Otherwise, if these autoreactive T cell clones escaped the thymus they could attack the patient's own tissue and cause autoimmune disease. This is called *negative selection*. The end-result of both positive and negative selection is that less than 5% of the T cell progenitors originally produced in the thymus complete the full cycle of development and leave the thymus to function in the peripheral immune system. The rest die through a process of programmed cell death called *apoptosis*.

As discussed above, the implication of this active thymic selection process for transplantation is that circulating mature T cells are very capable of efficiently binding and responding to antigenic peptides presented by self-MHC molecules (indirect allorecognition) and allo-MHC molecules (direct allorecognition)[8,9]. Whether direct and indirect T cell recognition of allo-antigen differ in activation signals is not presently known.

Concept 2: Adhesion and co-stimulation are necessary and regulate T cell activation

A fundamental feature of the immune response is that the actual affinity of TCR binding to the antigenic peptide/MHC complex of APC is too low to create stable adhesion and T cell activation. Thus, by design, successful TCR engagement requires the simultaneous engagement of one or more secondary adhesion or co-stimulatory molecules to stabilize the cell–cell interaction and provide the necessary signal for full T cell activation.

We have known for quite some time that the CD4 and CD8 molecules define the T helper and cytotoxic T cell subsets, respectively. Two relatively recent advances help explain the significance of this differential expression.

First, it was discovered that the CD4 molecule binds selectively to the MHC class II molecule while CD8 binds to the MHC class I molecule. Thus, these CD4 and CD8 accessory molecules are *adhesion molecules*. In fact, they are members of the *immunoglobulin gene superfamily* which includes adhesion molecules such as ICAM-1 and VCAM-1. This CD4/CD8-mediated adhesion to either MHC class II or I molecules means that $CD4^+$ helper cells must be restricted by antigens presented in the context of class II molecules, and $CD8^+$ cytotoxic T cells must be restricted to antigens presented by MHC class I.

Second, it turns out that endogenous antigens, including self peptides and viral proteins produced within the cell by ongoing replication of virus, are preferentially presented in the context of MHC class I. In contrast, exogenous antigens engulfed and processed by macrophages, such as viral proteins obtained from dying or injured cells or transplant antigens from the organ donor, are preferentially presented by MHC class II molecules. Therefore, the differential expression of CD4 and CD8 has an enormous regulatory significance for the generation of immune responses. This molecular view of helper and cytotoxic T cell activation is also being used to design some novel immunosuppressive strategies based on creating peptide analogs that selectively inhibit either CD4 or CD8 binding to the MHC molecules[45,46].

A perfect example of how complex our understanding of the immune system has become is the evolution of the initially simple concept of accessory molecules described above for CD4 and CD8 molecules. The *first* level of increased complexity is that the T cell expresses multiple molecules besides CD4 and CD8 which can act a receptors for ligands which are capable of stabilizing its interaction with antigen-presenting or target cells. A partial list of T cell surface molecules and their ligands is given in Table 1. Each molecule is capable of mediating a physical adhesion of two cells by binding the respective ligand on the opposite cell surface. This adhesion is the first step in stabilizing the recognition of antigen by the TCR/CD3 complex. The *second* level of complexity is that most of these molecules are constitutively expressed on all T cell surfaces and can bind their ligands without any further cell activation. Thus, T cell activation mediated by TCR/CD3 complex engagement of antigen can simultaneously involve multiple molecules, not just CD4 or CD8. The *third* level of complexity is that there may be a difference between molecules primarily responsible for *adhesion* and those mediating *co-stimulation*. In its strictest definition, co-stimulation may be viewed as signals which prevent *anergy*. Anergy is a state in which the T cell can recognize the antigen via the TCR/CD3 complex yet not initiate its activation cascade. For example, the CD28/CD80 (or B7) pathway is a co-stimulatory pathway. In fact, strategies targeted at blocking CD28-B7 co-stimulation have been effective in suppressing T-cell-mediated immune responses in autoimmune as

Table 1 Adhesion molecules and ligands

Receptor	*Ligand*
LFA-1 (CD11a)	ICAM-1 (CD54)
LFA-1 (CD11a)	ICAM-2 (CD102)
CD2	LFA-3 (CD58)
CD28	B7-1 (CD80)
CD28	B7-2 (CD86)
VLA4 ($\alpha4\beta1$)	VCAM-1 (CD106)
L-selectin (CD62)	MadCam-1
$\alpha4\beta7$	MadCam-1
PECAM (CD31)	CD31
CD31	$\alpha v\beta3$ (VNR)
CD45	Glycolipids

well as transplantation models (see below). In addition, inhibiting LFA1/ICAM1 or CD2/CD58 interactions can also result in potent suppression of the immune response.

These complexities give rise to several questions. If all these molecules are involved in adhesion/co-stimulation, how can we block the immune response by inhibiting one pair? Are there primary and secondary interactions? Do these molecules share signals so that some form of synergy is created? Are there differences in signals for different T cell subsets? Do different immune mechanisms engage different molecules so that blockade of these signal might have one effect on transplant rejection and another on antiviral cytotoxicity or autoimmunity? Are the signals delivered in some specific order so that we could design a strategy to block only the last step in the cascade? Clearly, these questions are directly relevant to the potential future use of these blocking reagents in transplantation therapy.

Concept 3: Cell–cell adhesion/co-stimulation and TCR/CD3 complex engagement triggers a cascade of cytoplasmic enzymes leading to T cell activation

Once the T cell has successfully recognized the target antigen presented by the appropriate MHC molecule the next steps in T cell activation occur in the cytoplasm. In fact, our current view of cytoplasmic signalling is now as complex as the network of T cell subsets, cytokines, and surface receptors determining the course of the immune response on the cell's exterior. Table 2 is a list of currently known cytoplasmic signalling intermediates adapted from a recent review[47].

Table 2 Intracytoplasmic signalling molecules associated with cell membrane receptors and cell activation pathways

Kinases	*SH2–SH3 signalling*	*GTPases*	*Phospholipid mediators*
FAK	Crk	Ras	PIP-5K
Src	Grb2	Rho	cPLA2
Fgr	PI-3K	mSOS1	Arachidonic acid
Csk	PLC	C3G	5-lipoxygenase
PKC		RasGAP	
MAP kinase			

From ref. 47

As shown in Figure 2, the cytoplasmic tails of the different co-stimulatory adhesion molecules, including CD4 and CD8, serve as connecting points for a very complex array of intracytoplasmic enzymes. Our current thinking is that the engagement of the adhesion molecule with its ligand on another cell surface results in a conformational change that is transmitted through the protein to the cytoplasmic tail of the molecule. This conformational change reveals a binding site for the first of several cytoplasmic signalling molecules which triggers a signal cascade much the way we think of cytokines or clotting factor cascades in the extracellular space. This process of molecular activation can also connect the adhesion molecule to the cell's cytoskeletal frame-

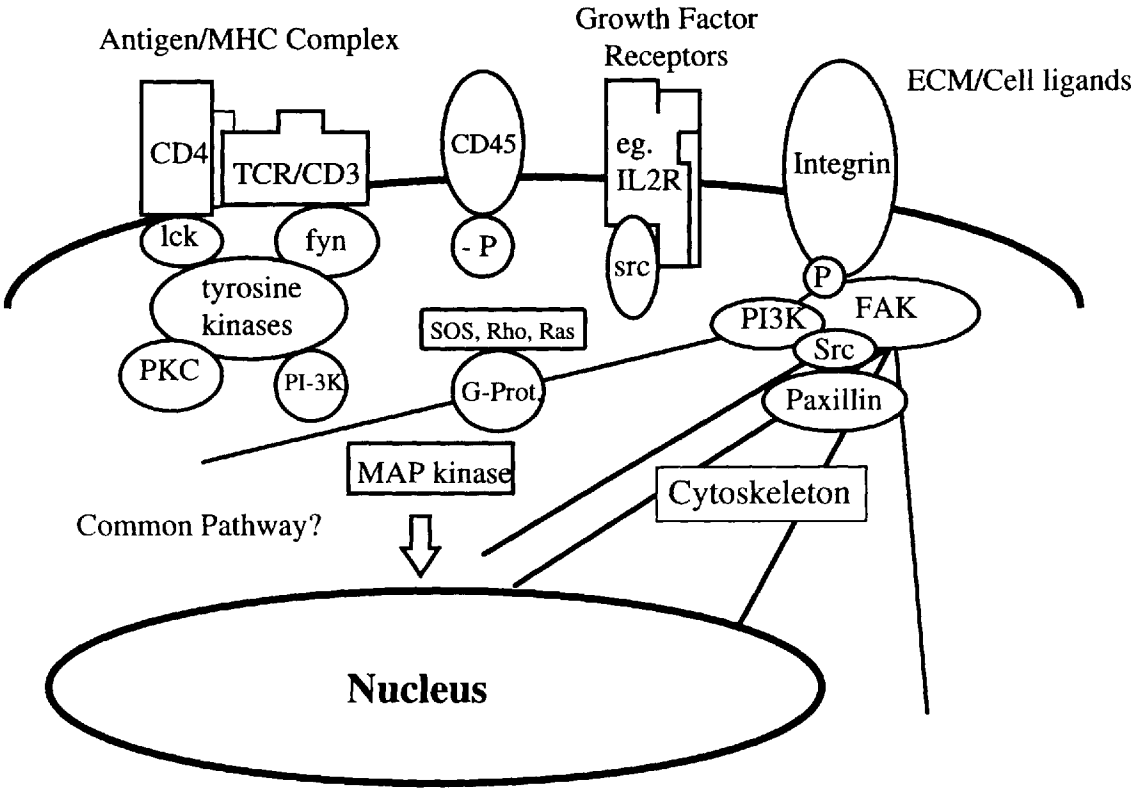

Figure 2 Intracellular cytoplasmic signals

work, a process that is necessary for cell migration and that also determines cell shape.

The TCR/CD3 complex is also directly involved in the generation of cytoplasmic signals; in fact it is the CD3 molecule complex that is responsible for this signalling. A number of cytoplasmic tyrosine kinases such as src, lck and fyn can bind to the CD3 complex, and are activated when the TCR engages its antigen on the cell's exterior surface. Moreover, the close physical location of the co-stimulatory CD4 or CD8 molecule, which is binding to the same MHC molecule as the TCR binding its antigen, may serve to create a bridge between kinases bound to the cytoplasmic tails of the CD3 complex and kinases such as lck bound to the CD4 or CD8 molecules.

Concept 4: Cytoplasmic signalling leads to activation of nuclear transcription factors

The final stage in the molecular events of T cell activation is gene transcription. For example, we know that when a $CD4^+$ helper T cell recognizes an alloantigen during transplant rejection it releases a number of inflammatory cytokines, such as IL-2 and INF-γ. Similarly, when a $CD8^+$ cytotoxic T cell is activated it increases the cell content of an enzyme called granzyme and the molecular complex called perforin, both of which are necessary for killing a target cell. These events in both CD4 and CD8 T cell activation require gene transcription.

Gene transcription is regulated by the cell through the cytoplasmic activation of a number of DNA-binding proteins called *transcription factors*. When a transcription factor is activated in the cytoplasm it can cross the nuclear membrane where it binds to specific regions of the genes usually located upstream of the coding regions and called *promoter sites*. These promoter sites are the control boxes for gene transcription.

While at first glance the idea of transcription factors and promoter regions may seem very esoteric for transplant clinicians, they actually directly determine the function of our most effective immunosuppressive drugs, cyclosporin and FK506 (tacrolimus). When either of these drugs binds to the two cytoplasmic carrier proteins, cyclophilin or FK-binding protein, the resulting complex inhibits another set of cytoplasmic enzymes which prevent the activation of transcription factors, including NFkB and NF-AT. In turn, the lack of the activated transcription factors in the nucleus blocks transcription of the IL-2 and INF-γ genes. The immunosuppressive efficacy of both cyclosporin and FK506 depends on the effective suppression of cytokine gene transcription.

Concept 5: New immunosuppressive strategies will evolve from our knowledge of the molecular basis of T cell activation

We stated in the introduction that a major purpose of this chapter was to create an organization for understanding the immune response at the molecular level that would be useful for following the new developments in immunology.

First, as noted in Concept 4, the mechanisms of action of our two key immunosuppressive drugs are directly explained by alterations in cytoplasmic signalling altering transcription factor function at the gene level.

Second, our discussion of co-stimulation and adhesion molecules explains the immunosuppressive mechanism of a number of new reagents under development for clinical transplantation. For example, a number of monoclonal antibodies to block adhesion molecules are currently in clinical trials, such as anti-ICAM-1, anti-FA-1, and anti-CD45 antibodies. Another generation of new reagents is just being developed, including soluble, molecular-engineered recombinant fusion proteins such as CTLA4-Ig and CD2-Ig which block the CD28/CD80 and CD2/CD58 pathways of activation, respectively (Table 1). We have mentioned that peptide analogs designed to selectively block CD4 or CD8 adhesion are being developed, and anti-CD4 and anti-CD3 monoclonal antibodies are already well tested.

Third, the high complexity of the intracytoplasmic signal cascade has also created numerous possibilities for new drug design. For example, the new immunosuppressive, rapamycin (sirolimus), appears to work by interfering with cytoplasmic signals generated by cytokine receptors and required for cell activation and proliferation. One possible mechanism of immunosuppression with mycophenolate mofetil may be alterations in the synthesis of GTP, a high-energy phosphate intermediate implicated in a number of cytoplasmic and cell membrane kinase activities.

Finally, whole new possibilities for direct immunosuppression will be created as we extend our understanding of the molecular structure and regulated function of nuclear transcription factors and their ability to bind the specific promoter regions of the cytokine genes in the nucleus.

WHAT ARE THE MECHANISMS OF GRAFT REJECTION?

Acute and chronic rejection defined

It is important to understand that acute and chronic rejection can be defined in clinical terms, pathological terms, or immunological terms. However, once defined by one set of terms it is critical to keep all subsequent observations and conclusions in the correct context. The danger is when discussions move back and forth across this field without recognizing the fundamental differences in these definitions.

Clinical rejection is defined by the post-transplant timing of diagnosis, the rate of progression, and by specific disturbances in graft function. Typically, an *acute* cardiac rejection episode occurs in the first 6 months after transplantation and may be associated with increased pulmonary artery pressure, increased ventricular wall thickness or decreased compliance measured by ultrasound. Fortunately, cardiac dysfunction, such as a significantly decreased ejection fraction, or clinical evidence of congestive cardiac failure is rarely seen. In fact, the majority of acute rejection episodes after heart transplantation are based on pathological terms and are just correlated with the clinical situation. In contrast, acute rejection after lung transplantation may present with clinical dysfunction and signs, including dyspnea, and radiographic changes of interstitial inflammation. The clinical aspects of acute rejection in both heart and lung transplantation will be described in great detail in subsequent chapters. A defining feature of clinical *acute* rejection is the sense of urgency that a failure to treat aggressively and successfully can result in the rapid progression to a fulminant rejection and acute deterioration in heart or lung function.

Chronic rejection after heart transplantation typically occurs after 1 year, is often associated with discrete coronary artery lesions identified by angiography, and may also present with significant cardiac dysfunction or electrocardiographic signs of ischemia. The rate of progression is typically slow, measured in months or even years. However, if organ function is diminished at the time of presentation clinically, or if significant myocardial ischemia is present, the patient's clinical situation can deteriorate very rapidly. The progression of chronic lung transplant rejection is often marked by more clinical symptoms and a more rapid downhill course.

Pathological rejection is defined with biopsy material typically viewed by standard light histology, though the use of immunofluorescent staining has also been described. Clearly, the use and interpretation of the routine endomyocardial biopsy in heart transplantation have been one of the major advances in the field. Subsequent chapters will describe the pathological criteria for acute and chronic rejection. The key point to make in the present discussion is that finding pathological changes consistent with organ injury does not predict clinical presentation, and is only roughly correlated with subsequent clinical course.

A second point is that the endomyocardial biopsy provides material from the muscular portion of the right ventricular wall, but provides very little in the way of larger vascular structures for analysis. Thus, the biopsy is a good window into the interstitial cellular infiltrates and injury typically associated with acute rejection. However, it provides little or no information on the larger arterial structures, such as the coronary arteries, which are the focus of the vascular injury defining chronic rejection. These differences are also true for the transbronchial biopsy done in lung transplantation, where there is little sampling of larger vascular structures. Ironically, as a result of these biopsy limitations, our understanding of the progression of chronic rejection at the tissue level is very limited despite the fact that chronic rejection is probably the single greatest challenge to long-term successful transplantation that we face today.

Immunological rejection is the most likely rejection definition to cause confusion. The complexity described above for T cell activation creates multiple immunological mechanisms to test in rejection. For example, the expression of cell proliferative activity in culture with donor-specific APC, the presence of killer cell activity, elevations of cell activation markers such as the IL-2 receptor and adhesion molecules, the release of specific T cell cytokines such as IL-2 or IFN-γ or inflammatory cytokines such as IL-6 and TNF-α, and/or the transcription of the genes for these cytokines or their receptors can all be measured in the laboratory and interpreted as evidence of acute or chronic rejection. Unfortunately, a large number of these immunological parameters will be positive in every patient post-transplantation, and those that are negative may simply reflect the effect of the immunosuppressive drug therapy being routinely administered.

Little is known to correlate the immunological mechanisms directly with the clinical and pathological definitions of rejection. This has resulted in a controversy over whether there is a unique immunological mechanism responsible for chronic rejection, or whether it is merely the progression of low-grade or episodic acute rejection. Thus, despite little or no evidence for a unique immunological mechanism in chronic rejection, the distinct clinical and pathological features have led many to conclude that there must be a separate process. We are skeptical that this is the case, and rather believe that chronic rejection is merely the expression of a lower-grade and ongoing immune response to the transplanted organ. There is no problem if these arguments are used to generate scientific studies to test various theories. However, there is a problem when clinicians determine immunosuppressive therapies and test new drugs based on a conviction that acute and chronic rejection mechanisms are fundamentally separate events.

The summary point is that we must be careful to determine how rejection is defined in any given study or theory, whether it be a laboratory culture, an animal model or a clinical study. While all these approaches are exciting and valuable to our growing understanding of rejection mechanisms, we must remain critical and keep the differences in context. Our ultimate achievement will be when we understand the mechanisms of rejection well enough to successfully integrate the separate clinical, pathological and immunological manifestations into a single working definition directly relevant to patient care, prognosis, and the development and testing of new immunosuppressive strategies.

Cell-mediated and humoral-mediated injury mechanisms

Rejection, acute or chronic, involves tissue injury directed to the transplanted organ and caused by several mechanisms of immune-mediated cell damage. This injury can be cell mediated or humoral mediated.

Cell-mediated Injury

The classic acute cellular rejection seen in the cardiac or lung interstitium is cell mediated. This cell-mediated immune response is initiated by $CD4^+$ T cell recognition of donor antigens. The predominant effector cells are $CD4^+$ T cells and macrophages mediating DTH responses and $CD8^+$ cytotoxic T cells. Stabilization of target binding of T cells is accomplished by adhesion molecules, such as LFA-1 and CD2, on the T cell surface to ICAM-1 and CD58 on the target cell surface. In the case of $CD8^+$ T cells, successful adhesion to the donor target cell results in T cell activation and the insertion of the perforin molecular complex into the donor cell's membrane. Cytolytic enzymes such as granzyme are released by the activated killer cell. The end-result is cell injury leading to death, which is seen on the biopsy as T cells in proximity to injured or dying myocytes or bronchial epithelium. This distinction is important for pathologists, since the mere presence of T lymphocytes in the organ interstitium without evidence of cell injury or inflammation does not constitute evidence of rejection.

For the immunologist the presence of T cells without injury has always been an interesting challenge to explain. Some think that it represents the success of baseline immunosuppression to prevent tissue injury while not being able to prevent activated T cells from entering the transplanted organ. However, others interpret these local T cell infiltrates as specific modulator or suppressor cells which are capable of inhibiting the immune response and injury mediated by the killer T cells. This theory has been given a lot of attention recently, based on the discovery that $CD4^+$ T helper cells can be divided into two opposing subsets based on the pattern of cytokines that they produce. One subset, called Th1, produce primarily IL-2 and INF-γ, while the second subset, called Th2,

produce primarily IL-4, IL-10 and IL-13. There is evidence from animal studies that rejection is a Th1-mediated phenomenon, while Th2 cytokines are relatively suppressive and have been associated with a state of tolerance to allografts (see below). Thus, the balance of Th1 and Th2 cytokines in a transplanted organ may be one determinant of whether rejection occurs or not. Human studies to confirm these observations in animals are required, since they may impact on decisions regarding optimal therapy based on understanding immunological mechanisms of rejection.

The word 'humoral' is defined in the dictionary as pertaining to the body's 'humors'. Immunologists are referring to antibodies and inflammatory cytokines. Transplantation clinicians usually refer to humoral mechanisms in the context of chronic rejection and vascular injury. However, it must be remembered that antibody-mediated rejection can destroy a vascularized transplant in minutes, by causing such profound vascular injury that the vessel thromboses and the organ is acutely ischemic. This hyperacute rejection process is a critical issue in xenotransplantation where natural antibodies recognizing species-specific vascular surface antigens are present.

Antibodies are produced by B cells and plasma cells which receive help from activated $CD4^+$ T cells. The binding site of an antibody is determined by gene rearrangements similar to the rearrangements which produce the TCR specificities in the thymus. A naive B cell may become sensitized to a new antigen when it is presented by the same antigen-presenting cells involved in $CD4^+$ T cell activation. Alternatively, mature B cells can use the antibodies expressed on their cell surface to present antigen to naive B cells and even T cells. The B cells' ability to bind antigen via antibody is very high, so that adhesion molecules are not required to stabilize the binding complex the way they are required for T cell activation. On the other hand, it is important to emphasize that the regulation of B cell immunity does require co-stimulatory signals, and so a rapidly growing number of unique B cell molecules have been identified recently, such as CD23, CD21 and CD40. Therefore, the potential of developing new strategies to manipulate the B cell immune response in transplantation is as great as for the new T cell reagents described above.

Another fascinating problem is to understand the molecular basis of controlling B cell function in the cytoplasm and nucleus. While we have potent T cell immunosuppression with cyclosporin and FK506, we do not have similar agents for suppressing B cell activation. Nonetheless, our current understanding of B cell biology clearly includes the roles of various cytoplasmic kinases and nuclear transcription factors in complex networks very similar to the T cell. It will be a major advance in immunosuppression when the problem of B cell activation is solved by development of a new drug or reagent.

When antibodies engage their antigen target, typically on vascular surfaces but also on the surfaces of epithelial cells in the transplant, they bind and activate complement components. The complement cascade ends with the insertion of a molecular complex into the target cell membrane that is the equivalent of the killer T cell's perforin complex. Complement activation also results in the recruitment of inflammatory cells like neutrophils and macrophages, which secrete various inflammatory cytokines such as IL-1, IL-6 and TNF-α. These cytokines can cause direct cell injury. For example, TNF (tumor necrosis factor) can cause epithelial cell death, and IL-1 can cause myocardial cell dysfunction as well as fever and peripheral vasodilatation. It is likely that such cytokine-mediated injury is a major determinant of fulminant heart transplant failure in some patients with severe acute rejection in which the degree of myocyte necrosis seen in the biopsy cannot explain the profound clinical state. The cytokines can also recruit other inflammatory cells, including T cells, into the site. Finally, the activation of complement, antibody-mediated endothelial injury, and inflammatory cytokine production can all result in local activation of the clotting cascade.

The adhesion paradigm in rejection

We have already described the role of cell–cell adhesion molecules in T cell binding to antigen-presenting and target cells. The adhesion molecules serve to stabilize the TCR/CD3 complex binding to MHC/peptide antigen complexes and may provide co-stimulatory signals involved in T cell activation. However, the role of adhesion molecules in transplantation is even more complex. While antigen recognition and T cell activation are the critical first step in the rejection cascade, the next major challenge is to regulate the traffic of activated T cells from the peripheral lymphoid organs (lymph nodes and spleen) via the peripheral blood to the transplanted organ where rejection must occur. We now understand that this process is also adhesion molecule dependent.

First, we must emphasize that the primary barrier between the transplanted organ and the host immune system is the vascular endothelium. In a vascularized transplant such as the heart or lung, the endothelium is basically from the donor. We have known for a long time that the donor endothelium expresses MHC class I molecules and will increase the expression level and express MHC class II antigens if activated by inflammatory cytokines. The significance of this cytokine-dependent up-regulation of donor alloantigens on the endothelial surfaces of the graft was recognized as generating a 'vicious cycle' where early rejection events were amplified.

The new information is that the donor endothelium will also express a number of ligands for the activated adhesion molecules on the T cells. As described in Table 1, there are multiple adhesion molecule and ligand pairs that could participate in T cell adhesion to the vascular surface of the graft. Moreover, the same inflammatory cytokines that up-regulate MHC molecule expression can also up-regulate adhesion ligand expression. Thus, the role of these inflammatory cytokines in amplifying the rejection process also involves the adhesion molecule paradigm. Three of the best-studied endothelial ligands are intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and a group of glyco-sialylated mucins (also called addressins) which bind the T cell adhesion molecules, LFA-1, VLA4, and L-selectin, respectively. These three endothelial ligands cooperate in a physical process that initially slows down and then stops the activated T cells and leukocytes as they flow through the vascular bed of the graft.

The *adhesion molecule paradigm* explains that a T cell activated by the recognition of alloantigen in a lymph node or the spleen will express the adhesion molecules on its surface in an activated state. T cells that do not recognize the transplant as foreign are left out of the process. The activated T cells circulate

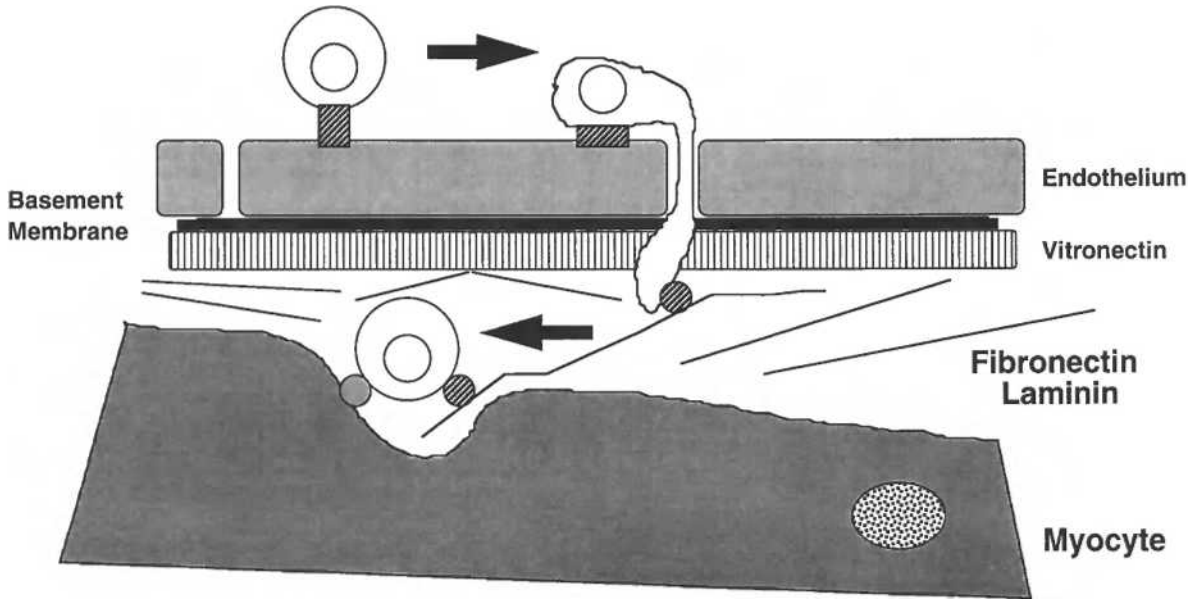

Figure 3 T lymphocyte crosses the vascular barrier and follows ECM fibrils to attack the myocyte: classic cell-mediated rejection

through the peripheral blood to the transplant where they come in contact with endothelial ligands, as described above, and this results in the adherence of these activated T cells to the graft endothelium. The activated T cells then use the combination of alloantigen recognition on the donor endothelium and adhesion molecule/ligand binding to further activate and migrate physically across the endothelial barrier and into the interstitium of the transplant, where rejection occurs. Figure 3 is a picture of such a process in which an activated lymphocyte is shown binding to the endothelial surface of the graft while a second lymphocyte, which has already bound and migrated into the interstitium, is shown attacking a myocyte (i.e. acute rejection).

The pharmaceutical and biotechnology companies have already discovered the potential significance of the adhesion molecule paradigm in the design of new agents to prevent and treat rejection. Clinical trials with a monoclonal anti-ICAM-1 antibody for induction therapy are now under way in kidney transplant patients. An anti-LFA1 antibody has been developed and some preliminary clinical trials started. Anti-VCAM-1 antibodies and anti-VLA4 antibodies have been shown to prolong cardiac allograft survival in animal transplant models. Finally, a whole new generation of novel peptide analog inhibitors of adhesion molecules are now being developed for clinical testing in the next few years.

WILL TOLERANCE EVER BE A CLINICAL REALITY?

Mechanisms of tolerance

The availability of TCR transgenic as well as specific knockout animals has made it possible to study the cellular and molecular mechanisms of self tolerance. The thymus plays the major role in development of self tolerance[13,14]. Precursor T lymphocytes reach the thymus early in fetal life, although there is a continuous input of prothymocytes throughout life. Immature T cells reside in the cortex, and lack the TCR, CD4, and CD8 molecules. These cells undergo population growth, rearrangement of TCR genes, and surface expression of CD4 and CD8 molecules ('double-positive' thymocytes). $TCR^+CD4^+CD8^+$ T cells interact with thymic APC (epithelial cells and bone-marrow-derived macrophages/dendritic cells) which express self-MHC molecules, and undergo selection processes which ultimately shape the T cell repertoire toward self-MHC restriction and self tolerance. Self tolerance is mediated by 'negative selection' by deletion of autoreactive T cell clones.

Surviving TCR^+ T cells move into the medulla, increase the density of TCR expression to that of peripheral T cells, and before leaving the thymus lose one of the co-stimulatory accessory molecules, thus becoming single-positive ($CD4^+CD8^-$ T cells or $CD4^-CD8^+$ T cells) T cells. At the same time 'positively selected' medullary thymocytes acquire MHC-class-II-restricted helper ($CD4^+$) or MHC-class-I-restricted cytotoxic ($CD8^+$) functions, and migrate to the periphery as immunocompetent T cells (see above). There are two types of thymic APC, bone-marrow-derived macrophages/dendritic cells and epithelial cells, and there is evidence that each type of thymic APC has a different function in the induction of self tolerance, and in T cell repertoire selection. Positive selection is thought to be mediated by thymic epithelial cells, and negative selection is mediated by the bone-marrow-derived cells.

Transplantation tolerance is defined as a state of immunologic unresponsiveness to the antigens of the graft without immunosuppression[15,16]. Operatively, tolerance is defined as a reduction in the immunocompetence of lymphocytes responding to the specific antigen. Transplantation tolerance involves several mechanisms (Table 3), and it is perhaps best to classify these mechanisms as 'central' or 'peripheral'. Central tolerance involves thymic deletional mechanisms analogous to self tolerance.

Central tolerance can be induced in experimental animals by creating mixed bone marrow chimeras[16]. This can be achieved by

Table 3 Mechanisms of tolerance

1.	Clonal deletion
2.	Clonal anergy
3.	Regulatory or suppressor cells (infectious tolerance)
4.	Immune deviation (Th1/Th2): ? Role of suppressive cytokines (IL-4, IL-10, TGF-β)
5.	Veto cells: phenotypically distinct cells which inactivate/delete alloreactive T cells
6.	Microchimerism: persistent donor cells in the recipient

infusing a mixture of donor plus syngeneic bone marrow coupled with some kind of a myeloablative regimen. The resultant animals become specifically tolerant to donor alloantigen, presumably by deletion of alloreactive T cells in the thymus. This can also be achieved by using bone marrow infusion with immunosuppressive drugs, although the mechanisms involved with such strategies may not be deletional. Other mechanisms which have been described with such strategies include 'microchimerism' or 'veto cells'. Microchimerism is the persistence of small numbers of donor-derived cells in the recipient[17]. Microchimerism has been reported to be associated with long-term acceptance of allografts in experimental animals as well as in humans, although it has not been established whether the persistence of donor cells is in fact responsible for induction or maintenance of tolerance. It is possible that the persistence of donor cells in the recipient is the result rather than the cause of the tolerant state. Finally, veto cells are cells with a unique phenotype which have been demonstrated to inactivate/delete alloreactive T cells[18,19]. Veto cells have been described in some transplantation models involving donor bone marrow infusion, although the mechanisms of how T cells recognize the veto cell leading to T cell inactivation/deletion remain unknown. Furthermore, whether veto cells mediate the observed association between graft acceptance and microchimerism has not been established.

Mechanisms of peripheral tolerance, on the other hand, involve 'anergy' and/or 'regulatory or suppressor cells'. Anergy is a state of functional inactivation in which antigen-specific T lymphocytes are present, but are unable to respond. Two types of anergy-related mechanisms have been described: T cell anergy which can be reversed by exogenous cytokines, such as IL-2, or 'dense' anergy which is not reversed by cytokines. Biochemical analysis indicates that increased intracellular calcium is associated with T cell anergy. Anergic T cells remain viable but are unresponsive for a minimum of several weeks both *in vitro* and *in vivo*. The fate and function of anergic T cells *in vivo* remain undetermined; however, evidence from experimental models suggests that anergic T cells can be reactivated by infections, presumably cytokine-mediated. Recent evidence also indicates that anergy can be accompanied by variable degrees of deletion, and that anergic T cells may become apoptotic. These observations suggest that anergy may be a reversible state, and that the therapeutic use of tolerance strategies involving mechanisms of T cell anergy alone, although potentially useful, may not lead to permanent tolerance. Strategies which promote peripheral deletion of anergic T cells may be more desirable.

The second major mechanism to explain peripheral tolerance is the identification of 'regulatory' cells which exert antigen-specific suppression of the immune response. The presence of 'regulatory' cells has been demonstrated *in vitro* by suppressor assays as well as *in vivo* by adoptive transfer experiments leading to a state of 'infectious' tolerance, whereby T cells from a tolerant animal can actively transfer tolerance to a naive animal[20]. Although suppressor phenomena have been clearly demonstrated, the suppressor cells themselves have proven difficult to grow and hence to characterize. In addition, the mechanism of action of suppressor cells is still poorly understood, although recent data suggest that, at least in some cases, the tolerogenic effects may be mediated by suppressive cytokines such as TGF-β, for example[21].

A related area which may explain the role of 'regulatory' cells in tolerance is the Th1/Th2 paradigm (see above)[22,23]. Studies of T cell clones show that CD4+ T helper cells are not homogeneous; for example CD4+ T helper cells can be subdivided by their pattern of cytokine production[24] into Th1 cells, which produce mainly IFN-γ and IL-2, and Th2 cells, which produce IL-4, IL-10, and IL-13. Allograft rejection is a predominantly Th1-mediated process, as suggested by up-regulation of mostly Th1 cytokines in rejecting allografts. Th1/Th2 helper T cell subsets have mutually antagonistic activities. IL-4 blocks up-regulation of IL-2 receptor expression and IL-2-dependent proliferation of T cells, suppresses production of IFN-γ by human mononuclear cells, and inhibits up-regulation of endothelial cell expression of ICAM-1 and other adhesion molecules in response to inflammatory stimuli. IL-10 inhibits the production of IFN-γ and IL-2 by Th1 clones. In some experimental transplantation models, intragraft analysis demonstrates that tolerant grafts have decreased expression of Th1 and up-regulation of Th2 cytokines[25].

Such a state of 'immune deviation' toward a predominantly Th2-cell function has also been described to be associated with tolerance in experimental models of autoimmunity[21]. The exact mechanisms responsible for steering the immune response toward Th2, and whether the tolerant state is actually mediated by Th2 cytokines, remain to be determined. The use of cytokine knockout animals, cytokine fusion proteins, and cells transfected to secrete a particular cytokine will help better understanding of these mechanisms, and may give rise to novel strategies for suppressing the immune response to allografts.

Clinically relevant tolerance strategies

Although the induction of transplantation tolerance has been readily achieved in experimental animal models, only few cases of tolerance have been described in humans[26,27]. The use of immunosuppressive drugs or monoclonal antibodies directed at specific T cell surface receptors to induce transplantation tolerance has been extensively studied in animal models of organ transplantation. It is obvious, however, that such strategies alone have not been successful in humans. The use of donor antigens with or without initial immunosuppression, on the other hand, may provide better strategies that can be clinically relevant. In addition, some recent advances in our understanding of mechanisms of lymphocyte activation and tolerance may lead to development of potentially clinically applicable strategies to induce specific tolerance in humans.

Donor antigens

Early experiments on the induction of neonatal tolerance proved that introduction of allogeneic cells or tissue at a 'critical period'

early in development would produce tolerance[28]. Studies have shown that neonatal tolerance is largely due to 'clonal deletion'. Thus, T cells reactive with alloantigen are deleted during their selection in the thymus, presumably by the same mechanisms that delete self-reactive T cells. In adults, administration of donor alloantigen with or without some form of transient immunosuppression has been shown to be effective in inducing tolerance to allografts in several experimental animal models.

Several factors have been found to play a role in the induction and maintenance of the tolerant state. These include the type of donor cells, the dose of alloantigen, the timing of administration of alloantigen, the route of administration, and the immunosuppressive protocol. In regard to the route of administration the intravenous, intraportal, oral, and intrathymic routes have been generally tolerogenic, while the subcutaneous route is typically immunogenic. Intrathymic injection of donor cells, soluble MHC, or MHC allopeptides has been recently shown to induce specific tolerance in several experimental transplantation models, although the mechanisms have not been fully elucidated[29,30]. The applicability of such a strategy in large animals is currently being tested.

Finally, recent data indicate that in certain models it is possible to induce tolerance by administering recipient cells transfected with donor MHC[31,32], thus obviating the need for administration of donor cells. Strategies utilizing donor alloantigen administration which have been investigated (or are currently under investigation in multicenter studies) in humans include donor-specific blood transfusions (from living or cadaver donors), one HLA-haplotype or DR-matched blood transfusion[33,34], and donor bone marrow infusion (Table 4). Initial studies in human renal transplant recipients using donor bone marrow infusion are encouraging[35], and a multicenter study is currently under way.

A related area is the use of MHC-derived peptides to immunomodulate the alloimmune response to allografts; synthetic class I and class II MHC peptides derived from highly conserved regions have potent immunomodulatory properties, although they appear to act by different mechanisms[36,37]. For class I MHC peptides, T cell unresponsiveness is precisely associated with induction of a calcium flux and binding of peptide to members of the hsp70 group of molecules. There are *in vivo* data in murine transplantation models that such peptides can prolong allograft survival or even induce tolerance[38], and initial clinical pilot trials in humans are under way. The mechanisms of action of class II MHC peptides remain unclear, although they may prove to be useful immunotherapeutic agents and warrant further investigation in experimental transplantation as well as in autoimmune models[39].

Table 4 Clinically relevant strategies for induction of transplantation tolerance

1. Donor-specific blood transfusion
2. One HLA-haplotype/DR-matched blood transfusion
3. Donor bone marrow infusion
4. Co-stimulatory blockade
5. MHC-derived peptides

Blocking co-stimulation

As discussed above, recent evidence also confirms that T cells require two distinct signals for activation. The first signal is provided by the engagement of the TCR with the MHC plus peptide complex on APC, and the second co-stimulatory signal is provided by engagement of one or more T cell surface receptors with their ligands on APC. Signalling through the TCR alone, without a co-stimulatory signal, leads to a prolonged state of T cell anergy. Increasing evidence suggests that interaction of CD28 on T cells with its ligands, B7-1 or B7-2, on APC appears to be the most important co-stimulatory pathway for the response to alloantigens[40–42]. Recently, strategies targeted at blocking CD28-B7 co-stimulatory T cell activation have been shown to be very effective in inducing tolerance in experimental transplantation models, and there are plans to try such strategies in humans[43].

CTLA4Ig, developed by Linsley *et al.*[44], is a recombinant fusion protein which contains the extracellular domain of human CTLA-4 (a gene highly homologous to CD28) fused to a human IgG_1 heavy chain. CTLA4Ig has a 20–100-fold higher affinity for B7 than does CD28, and acts as a competitive inhibitor of CD28 binding to B7-1 or B7-2. Human CTLA4Ig efficiently binds to human, mouse, and rat B7 molecules, and inhibits the immune response *in vitro* and *in vivo*, including induction of tolerance to allografts and suppression of autoimmune disease in experimental animal models. Plans are also under way to test the safety and efficacy of this molecule in humans.

Maintenance Immunosuppressive Drug Therapy and Potential Major Complications

K.L. TYNDALL AND D.K.C. COOPER

INTRODUCTION

The various pharmacological immunosuppressive agents available to those involved in organ transplantation have been discussed by a number of authors, and detailed accounts of their structure and mode of action can be found elsewhere. A comprehensive review of the newer agents presently in early clinical use, or in clinical or experimental development, is presented elsewhere in this volume (Chapter 70). The vast majority of centers today, however, utilize triple-drug maintenance therapy with cyclosporin (CsA), azathioprine (AZA), and corticosteroids. CsA-Neoral is beginning to take the place of CsA, and will eventually supersede it. Tacrolimus (FK506) has been introduced in place of CsA in a few centers (Chapters 10 and 70). (It is important to note that CsA and tacrolimus should not be given in combination, due to their severe nephrotoxic effect.) Cyclophosphamide is sometimes used to replace AZA, and mycophenolate mofetil is beginning to replace AZA in a small number of centers (Chapter 70). In addition, some centers include induction cytolytic therapy with an anti-T-cell polyclonal (an antithymocyte (ATG)/antilymphocyte (ALG) globulin) or monoclonal (OKT3) antibody.

Several areas of controversy currently persist and need to be addressed. These include: (a) Is induction therapy with cytolytic agents necessary or beneficial? If so, is ALG/ATG or OKT3 to be preferred? (b) Can corticosteroid therapy be withdrawn completely and, if so, at what stage of the post-transplant progress of the patient? (c) Are any of the newer agents, e.g. tacrolimus or mycophenolate mofetil, preferable to drugs such as CsA and AZA, respectively?

None of these areas will be discussed in any detail in this chapter. The first two of the above topics are discussed in Chapter 9 and the third topic in Chapters 10 and 70. There are increasing data with regard to subjects (a) and (b), but not yet sufficient evidence to know the conclusive answer to the question raised in topic (c). Few heart or lung transplant groups have as yet any significant experience with any of the newer agents.

As a preliminary to the discussion of these matters, however, some basic data on the use of the standard maintenance and induction immunosuppressive agents that are available today, and with which significant experience has been accumulated, will be provided in this chapter.

CYCLOSPORIN (CsA)

CsA was initially isolated from the fermentation broth of a soil fungus, *Trichoderma polysporum Rifai*[1]. The cyclosporins have a narrow spectrum of antibiotic activity[2], reducing the growth rate of a few yeasts and fungi. Full reviews of the immunosuppressive properties of this drug, which were first documented by Borel (Figure 12, Chapter 18), have been published previously[3–5]. The drug is lipid-soluble, metabolized in the liver and excreted mainly in the bile as metabolites. The immunosuppressive effect of CsA is much more specific than that of corticosteroids, AZA, or cyclophosphamide. The critical phase in the maturation of T-helper cells is the synthesis of lymphokines; CsA blocks this synthesis[5], primarily by inhibition of interleukin-2, a growth factor for T lymphocytes (Chapter 7). This action effectively prevents the development of mature cytotoxic T cells, and also prevents release of both gamma-interferon (macrophage-activating factor) and B cell activating factors.

CsA has little or no effect on antigen-presenting cells, and does not result in bone marrow suppression. Its prime value is in the prevention of rejection by shutting down the effector limb. CsA decreases T-helper cell activity, though T-suppressor cell activity remains at a normal level. The drug has no direct effect on macrophage function[6].

Administration and dosage

Ideally, CsA should be begun before operation (i.e. before exposure of the antigens to the T cells). The initial dose, administered orally, is modified depending on the physical state of the patient. A patient in good condition (no overt signs of cardiac failure, good renal and hepatic function) may receive 4–6 mg/kg body weight. A patient in extremely poor condition (severe cardiac failure with secondary renal and/or hepatic failure) should

receive no or very little CsA before operation. Rather, immunosuppression should be induced with the other available drugs until postoperative progress has been assessed. A perioperative period of hypotension or severe liver dysfunction in a patient receiving CsA may result in increased nephrotoxicity, which may greatly complicate management.

Whenever in doubt, it has been our experience that it is wiser to administer less rather than more CsA in the pre- or early post-transplant period. The drug level in the blood or serum should be monitored daily (or more frequently) and the dose gradually increased (by perhaps 1 or 2 mg/kg per day) until a safe therapeutic range has been reached. Immunosuppression can be obtained adequately for the first few post-transplant days without CsA, by administering a combination of AZA, corticosteroids, and a polyclonal or monoclonal anti-T-cell antibody while the CsA level is being slowly increased.

In regimens in which induction ATG or OKT3 is not used, the dose of CsA must be carefully modified in the light of the renal function of the patient. The University of Minnesota group, who have obtained excellent results using such a regimen[7], calculate the initial pretransplant dose of CsA on the basis of the serum creatinine (Table 1). No further CsA is administered for 24 hours, at which time a second dose equal to half of the initial dose is administered, again taking into consideration any change in serum creatinine. This dose is given twice daily until kidney function is normal (or near-normal), at which time the dosage is adjusted to obtain a whole blood trough level by high-pressure liquid chromatography (HPLC) of 200 ng/ml. Our own experience has indicated that a rather higher level (250–300 ng/ml) has to be maintained in lung transplant recipients if rejection is to be prevented.

Table 1 University of Minnesota triple-drug immunosuppressive protocol for heart transplant patients*

Cyclosporin (oral)
Pretransplant
6 mg/kg if serum creatinine <1.5 mg/dl (<133 μmol/l)
4 mg/kg if serum creatinine 1.5–2.0 mg/dl (133–177 μmol/l)
2 mg/kg if serum creatinine >2 mg/dl (>177 μmol/l)

Early post-transplant: 3 mg/kg, 2 mg/kg, or 1 mg/kg twice daily, depending on serum creatinine level

When renal function satisfactory: dosage adjusted to maintain whole blood CsA level (by HPLC) at 200 ng/ml*

6 months post-transplant: reduce blood level to 150 ng/ml*
12 months post-transplant: reduce blood level to 100–125 ng/ml*

Azathioprine (i.v. or oral)
Pretransplant: 2.5 mg/kg
Post-transplant: 2.5 mg/kg per day (maintain WBC >4000 cells/mm^3)

Corticosteroids
Methylprednisolone
500 mg i.v. during cardiopulmonary bypass
125 mg i.v. every 8 hours for 24 hours

Prednisone: 1 mg/kg per day (divided into four doses/day) for 3 days, reducing at 3-day intervals to approximately 0.4 mg/kg per day at 12 days. Thereafter monthly reductions (giving the drug in two divided doses/day) until a dosage of 0.125–0.15 mg/kg per day is reached after 6 months. This dose is maintained indefinitely.

*Levels approximately 25–50% higher are required in lung transplant recipients.
Based on refs 7 and 8.

For oral administration the drug comes in liquid or gelatin capsule form. If the patient is unable to take oral drugs, then CsA can be given by continuous intravenous (i.v.) infusion, but in much reduced dosage 1 mg hourly (*not* 1 mg/kg hourly). For this purpose the drug is diluted in normal saline or 5% dextrose (250 mg CsA in 250 ml) and administered continuously to reduce its renal toxic effect. Both the oral and i.v. forms can induce oliguria from toxicity on the proximal renal tubules. Though absorption of the drug when given orally is usual (though erratic) in patients recovering from cardiac transplantation, achievement of a stable therapeutic blood level may be difficult. Combined i.v. and oral administration of the drug for the first few days is preferable until the patient is eating and drinking normally, at which time oral therapy alone is continued. Using this regimen we have had excellent results with a low incidence of acute rejection, and yet little serious nephrotoxicity[8,9]. Intramuscular administration is not recommended, since the drug is poorly absorbed.

Monitoring of drug levels

Whether CsA is given orally or i.v., it is essential to measure the blood levels frequently (at least daily) until the dosage has been adjusted to achieve the correct therapeutic blood level. Blood levels are then estimated at intervals of a few days for one further month and on a less frequent basis thereafter. When CsA is being given orally, blood should be drawn immediately before administration of the drug to give a 'trough' level. If being given continuously only by the i.v. route, the blood level will clearly vary little throughout the 24-hour period.

CsA levels can be measured by radioimmunoassay (RIA)[10,11], fluorescent polarization immunoassay (TDx)[12], or by a HPLC technique[13]. As several metabolites of CsA are measured by RIA and TDx, but not by HPLC, the therapeutic range differs depending on the technique used, and is generally 50–75% lower when measured by HPLC. The therapeutic activity and significance of some of the metabolites are uncertain, and, therefore, the method of choice remains in doubt. The most commonly used method today is possibly TDx, which offers rapid sample turn-around times without putting great demands on the laboratory[12]. Some groups believe, however, that only the parent CsA should be measured, without the metabolites, and therefore the HPLC technique should be the method of choice.

Immunoassay methodology involves labeling an antibody with either a radioactive or a fluorescent molecule; the antibody, which can be monoclonal or polyclonal, is then bound to the CsA. The monoclonal form shows little or no cross-reactivity with metabolites of CsA[14], and the results correlate well with those obtained by HPLC. Monoclonal techniques therefore offer a simpler alternative to HPLC.

A number of other drugs affect the blood level of CsA (Table 2)[15], in particular ketoconazole and erythromycin, which increase its concentration, and phenytoin, phenobarbitone, and rifampicin, which decrease its concentration. Major changes in CsA dosage may be required if these other drugs are being administered simultaneously. Diltiazem, which increases CsA levels, is of particular interest as it may be useful in the treatment of CsA-induced systemic hypertension[16]. There is also some evidence that it may be associated with a reduced incidence of graft vasculopathy[17].

Table 2 Selected drugs which influence blood levels and toxicity of cyclosporin*

Increase blood levels Potentiate nephrotoxicity	*Decrease blood levels*
Diltiazem	Phenobarbitone
Aminoglycosides (gentamicin)	
Erythromycin	Phenytoin
Amphotericin B	
Ketoconazole	Rifampicin
Melphalan	
Corticosteroids	
Sulfonamides/cotrimoxazole	Sulphadimidine + trimethoprim (i.v. only)
Metoclopramide	
Trimethoprim	

*Only well-substantiated drugs have been included. Data provided by Sandoz Pharmaceuticals, USA. An extensive survey has been conducted by Lake[15].

The level of CsA that is considered therapeutic varies considerably from center to center, depending on the other therapy being given. For example, if large daily doses of ALG are being administered during the early post-transplant period, the patient may remain very adequately immunosuppressed whilst receiving only small doses of CsA. If no ALG or AZA are being administered, then the patient may require a high CsA level if acute rejection is to be prevented. Each center should ascertain for itself its own therapeutic and toxic ranges of CsA. The whole blood level is approximately 3–5 times that of the plasma. When HPLC is used to measure CsA level, whole blood trough levels of 200 ng/ml are generally considered adequate in the early post-transplant period, reducing to 150 ng/ml at 6 months and 100–125 ng/ml at 1 year[7–9].

Maintenance oral CsA therapy should consist of twice-daily doses (rarely it may be necessary to give three doses per day) sufficient to maintain the desired therapeutic level in the blood or plasma. When triple therapy (CsA, AZA and corticosteroids) is being administered, initial CsA dosage is generally between 4 and 10 mg/kg per day.

Major side-effects and complications

The major complication of immunosuppressive therapy, no matter what drugs are used, remains infection. However, other side-effects/complications are commonly seen with the use of these agents. The potential complications of the use of CsA are outlined briefly below and also discussed in Chapter 13. Some of these side-effects may not result solely from CsA therapy; for example, corticosteroids play a role in the systemic hypertension and hypercholesterolemia seen in the immunosuppressed patient.

Nephrotoxicity

Like many fungal antibiotics, CsA is nephrotoxic. The initial loading dose should be judged after considering the patient's general condition. In patients with already diminished renal function secondary to poor renal blood flow resulting from a low cardiac output, the initial dose of CsA should be withheld until the patient's renal function is clearly recovering after operation[7,8] (Table 1). A short period of hypotension during induction of anesthesia or during the operative procedure or early postoperative period, in the presence of a high blood level of CsA, can result in oliguria or anuria. Renal function usually recovers spontaneously as the CsA blood level falls, but even temporary dysfunction can be a major complicating factor in the early post-transplant period.

In view of the toxic effect of CsA on the proximal tubules, careful monitoring of the blood urea, serum creatinine, urine electrolytes, and creatinine clearance is essential. The most sensitive test would appear to be the creatinine clearance, which falls when toxicity occurs, though this does not differentiate CsA toxicity from acute tubular necrosis. For practical purposes, however, the serum creatinine provides an approximate but valuable guide to CsA nephrotoxicity. Certain other drugs, if given concomitantly, increase the risk of nephrotoxicity (Table 2).

Renal function usually improves following reduction of CsA dosage or, when impairment of function is severe, with complete discontinuation of the drug for a short period. Furosemide is also helpful in reversing the accompanying oliguria. Short-term hemodialysis may be required on rare occasions[8].

Systemic hypertension

Persistent hypertension has been noted as a major side-effect of CsA administration. Within the first year a majority of patients may be expected to have significant hypertension requiring treatment. Its onset may be gradual over days, weeks, or months, or at times precipitous. There appears to be no direct association between post-transplant hypertension and nephrotoxicity.

When rapid reduction in blood pressure is required, sublingual nifedipine (10 mg) is generally effective. Long-term therapy of hypertension in transplant patients is similar to standard antihypertensive treatment. Attention needs to be paid to such contributing factors as obesity and lack of exercise. Diuretics are used if needed for control of volume. We have found calcium channel antagonists (e.g. diltiazem, verapamil), central alpha-receptor stimulators (e.g. guanfacine, clonidine), and peripheral alpha-receptor-blocking drugs (e.g. prazocin, terazocin) to be useful, alone or in any combination. Angiotensin-converting-enzyme (ACE)-inhibiting medications (e.g. captopril, enalapril, lisinopril) may prove helpful additions to the antihypertensive regimen, though in some patients they have little effect. Beta-receptor blockers are less desirable, because of their depressive effect on myocardial function. In some cases hypertension is severe and requires the combination of two or more medications in full doses. As corticosteroids may play a role in the development of hypertension, gradual withdrawal of steroids should be considered if possible (Chapter 9).

Occasionally, supine hypertension and orthostatic hypotension are encountered, particularly in older patients. Treatment is empirical. In our hands diltiazem, starting with small (30 mg) doses, has been effective, perhaps because of the mild increase in circulating volume which accompanies this therapy. Treatment of the sitting/supine hypertension is not always possible without severe exacerbation of the orthostatic hypotension. Fortunately, the problem of orthostatic hypotension appears to diminish spontaneously with time.

Neuromuscular effects and neurotoxicity

Tremors, muscular weakness, and muscle cramps, particularly in the legs, are not uncommon[18–21], and appear to occur more frequently in association with a low serum magnesium[22,23]. Hypomagnesemia is common in transplant patients, possibly due to the renal effects of CsA, and may lead to increased cardiac irritability. We routinely monitor serum magnesium and prescribe oral replacement therapy at a rate of 500–1500 mg magnesium daily (in the form of magnesium oxide). The goal is to maintain the serum magnesium at 0.8 mmol/l (1.5 mEq/l, 1.8 mg/dl) or greater. Tremor also improves when corticosteroid dosage is reduced, and muscle cramps improve when diuretic doses are reduced.

A neurotoxic effect of CsA, which occurs in patients with abnormally low serum levels of cholesterol, was first described following liver transplantation[24]. Clinical features consist of seizures, confusion, cortical blindness, quadriplegia, and coma. Computerized tomographic scanning and magnetic resonance imaging studies disclose a severe diffuse disorder of the white matter. All central nervous system effects and radiographic findings may be reversed by discontinuation or reduction of the dose of CsA.

We have seen severe neurological damage occur following transplantation of the heart and both lungs in a patient who had a persistently low serum total cholesterol level[25]. It has since become our policy to reduce the dosage of CsA in patients with abnormally low serum levels of cholesterol, which is usually seen in debilitated patients during the early weeks after transplantation. A substantial portion of the whole blood or serum content of CsA is carried in the low-density lipoprotein (LDL) fraction of blood. It may be that when the LDL cholesterol is low, there is a higher proportion of CsA free in the serum.

Hyperlipidemia

In many patients, irrespective of their underlying pathologic condition for which transplantation was undertaken, there is a significant post-transplant increase in serum cholesterol and triglycerides[26,27]; this is believed to be related to CsA and/or corticosteroid therapy. The hyperlipidemia can develop at any time during the first year, or even later, after transplantation.

These patients should initially be encouraged to adhere strictly to a diet which is low in cholesterol. Weight loss and an exercise program are encouraged. Gradual withdrawal of corticosteroids should be considered. If these measures fail to reduce cholesterol and triglyceride levels to within normal limits within 3 months, we prescribe a single cholesterol-lowering drug. We were initially reluctant to use lovastatin because of the reported risk of rhabdomyolysis when this drug is administered to patients receiving CsA[28,29]. Further experience from many centers, however, suggests that this drug can be safely prescribed in low doses (20–40 mg/day) and is effective in reducing total and LDL cholesterol levels in transplant patients. An excellent response has also been documented to another HNG-CoA reductase inhibitor, pravastatin, which has also been demonstrated to have some correlation with a reduced incidence of severe rejection[30].

Other side-effects

A large number of other side-effects of CsA have been described (Table 3). In particular, the role of CsA in the development of osteoporosis post-transplantation is receiving increasing attention[31]. This topic is discussed under the late complications of immunosuppressive therapy (Chapter 13).

Table 3 Major potential complications from immunosuppressive drug therapy

1. *Cyclosporin (CsA)*
   - Nephrotoxicity
   - Hypertension
   - Neurotoxicity
   - ? Hyperlipidemia
   - Others (including hypertrichosis, gingival hyperplasia, tremor, hepatic dysfunction)
2. *Tacrolimus (FK506)*
   - Nephrotoxicity
   - Neurotoxicity
   - Hyperlipidemia
   - Endocrine disorders (including glucose intolerance/diabetes mellitus)
   - Gastrointestinal disorders
   - Hair loss
3. *Azathioprine (AZA)*
   - Hematopoietic disorders (including leukopenia, thrombocytopenia, and anemia)
   - Gastrointestinal disorders (including nausea and vomiting, hepatitis, and biliary stasis)
   - Others (including skin rashes, alopecia, fever, arthralgias, diarrhea, steatorrhea, and negative nitrogen balance)
4. *Cyclophosphamide (CPP)*
   - Hematopoietic disorders (including leukopenia, thrombocytopenia, and anemia)
   - Gastrointestinal disorders (including anorexia, nausea, and vomiting)
   - Genito-urinary disorders (including sterile hemorrhagic cystitis)
   - Gonadal suppression
   - Pulmonary disorders (including interstitial pulmonary fibrosis)
5. *Methotrexate (MTx)*
   - Hematopoietic disorders (including leukopenia, thrombocytopenia, and anemia)
   - Gastrointestinal disorders (including anorexia, nausea, and vomiting)
   - Hepatic dysfunction (fibrosis and cirrhosis, dose-related)
6. *Corticosteroids*
   - Gastrointestinal disorders (including peptic ulcer, pancreatitis, and ulcerative esophagitis)
   - Musculoskeletal disorders (including osteoporosis, vertebral compression fractures, pathological bone fractures, aseptic necrosis, muscle weakness, steroid myopathy, and loss of muscle mass)
   - Endocrine disorders (including development of Cushingoid state, suppression of growth in children, menstrual irregularities, decreased carbohydrate tolerance, and manifestations of latent diabetes mellitus, impotence)
   - Metabolic disorders (including fluid and electrolyte disturbance and negative nitrogen balance, hyperlipidemia)
   - Neurological disorders (including psychiatric complications and convulsions)
   - Ophthalmic disorders (including cataracts, increased intraocular pressure, glaucoma and exophthalmos)
   - Dermatological disorders (including acne, spontaneous hemorrhage, striae)
7. *Antithymocyte globulin (ATG/ALG)*
   - Anaphylactic shock
   - Others (including musculoskeletal pains, rash, fever, chills, and bronchospasm)
8. *OKT3*
   - Fevers, chills
   - Aseptic meningitis
   - Meningoencephalitis

CYCLOSPORIN–NEORAL (CsA-NEORAL)

CsA-Neoral is a microemulsion preconcentrate comprising the drug, CsA, together with a surfactant, a lipophilic solvent, a hydrophilic solvent, and a hydrophilic cosolvent. The active form of the drug has not been altered. CsA-Neoral has been developed in order to reduce or eliminate problems associated with the erratic absorption characteristics of CsA[32]. Due to the high lipophilicity of CsA, its absorption is influenced by the rate of bile flow, gastrointestinal motility, and concomitant food intake[33–35]. There is also a wide inter- and intra-individual variation in CsA absorption. With CsA-Neoral there is a more consistent absorption profile, with less influence by concomitant food intake and diurnal rhythm[36–38], and also less influence by bile flow and pancreatin[39]. Improved oral absorption of CsA in the microemulsion formulation has resulted in reduced inter- and intra-individual variation of CsA pharmacokinetics, with a more consistent and predictable concentration–time profile[38,40,41].

When CsA is administered in its original form (Sandimmune R), an oil-in-water emulsion forms in aqueous gastrointestinal fluids, with CsA mainly distributed in lipid droplets, which must be dispersed by pancreatin and bile to form micelles for drug absorption. Upon contact with aqueous fluids, CsA-Neoral forms a microemulsion, without the actions of bile, enzymes, or small intestinal secretions, and becomes rapidly available for absorption. It is this property which effectively increases the rate and extent of absorption[36,37] and also decreases the inter- and intra-individual variability of CsA absorption[38].

Clinical trials have been performed to study pharmacokinetics, absorption, bioavailability, safety, toxicity, and tolerability of Neoral in normal healthy volunteers[42]. Pharmacokinetic studies and clinical trials have also been conducted in stable renal transplant patients, and in *de novo* renal, liver and heart transplant recipients. Oral absorption of CsA is improved with the Neoral formulation in healthy volunteers and in established transplant patients[40,42–46]. In normal volunteers a one-to-one conversion from CsA to CsA-Neoral resulted in an increased bioavailability of 30%, an increase in maximum concentration (C_{max}) of an average of 60%, and a significant reduction in the time to reach C_{max} (T_{max})[42]. In patient studies, the extent of absorption was greater for CsA-Neoral when compared to CsA, and the increased bioavailability was achieved with less variability[43–45]. The correlation between trough concentration and area under the curve (AUC) was stronger with CsA-Neoral than with CsA, and there was less variability with this parameter[40]. Studies have shown Neoral to be well tolerated, with no significant difference in incidence or severity of adverse events[38,45,47].

Conversion from CsA to CsA-Neoral has been studied in healthy volunteers[42] and in stable renal transplant patients[41]. It appears that comparable CsA trough concentrations can be achieved by maintaining CsA-Neoral at the same CsA dose (a one-to-one conversion). Concomitant with this conversion, there was a significant increase in C_{max} and AUC, due to absorption-related differences between the formulations, but there were no associated problems with tolerability, or changes in blood pressure or clinical laboratory parameters.

Use of CsA-Neoral has been studied in cardiac transplant patients, with similar improvement in pharmacokinetic profiles. In this patient population, CsA-Neoral proved to be superior to that of CsA alone with less variability in AUC, T_{max} and C_{max}[43–45], as well as a noted improvement with respect to the correlation between AUC and corresponding trough levels in some patients. In patients with pre-existing malabsorption the absorption of CsA-Neoral appeared to be independent of bile flow and food intake, with an improved tolerance[44]. In all of these studies, overall tolerability was reported as good, with no significant adverse events attributed to CsA-Neoral, in spite of the increase in AUC and C_{max}, and no deterioration in renal function, or worsening of other pre-existing abnormalities.

Neoral is available as an oral solution and as a soft gelatin capsule. Although it appears that a one-to-one conversion for changing from CsA to CsA-Neoral will be a reasonable approach, ongoing trials should be referred to when making dose conversion determinations. Furthermore, it is recommended that frequent trough level monitoring and dose adjustment be done during the first few weeks of the conversion, due to the possibility of enhanced systemic exposure. Patients may benefit from the possibility for dose reduction with CsA-Neoral and improved drug safety due to fewer variations in drug exposure. The improved intra-individual reproducibility of CsA trough concentrations with CsA-Neoral should facilitate dosage optimization, with more reliable CsA dose prediction and safer CsA therapy.

TACROLIMUS (FK506)

Tacrolimus (FK506) was isolated in 1984, from the fermentation broth of a strain of *Streptomyces*, from a soil sample obtained from Tsukuba, Ibaraki Prefecture, Japan[48]. The strain is designated *Streptomyces tsukubaensis*, referring to the soil from which the organism was isolated. Tacrolimus is a novel 23-member macrolide with a chemical structure entirely different from that of CsA[49]. The immunosuppressive effects of this drug were discovered by Kino and colleagues in 1984, and full reviews have been published elsewhere[50–54].

Tacrolimus is absorbed from the gastrointestinal tract after oral administration with a mean bioavailability of about 20%, although variability in transplant patients is considerable. Tacrolimus is highly lipophilic and is distributed disproportionately between red blood cells and plasma. Its distribution in plasma is significantly different from that of CsA, as the drug binds mainly to serum albumin and α_1-acid glycoprotein. It undergoes hepatic metabolism with biliary excretion of most of the metabolites[55–58]. Like CsA, tacrolimus exhibits a narrow therapeutic index.

Tacrolimus affects the immune response through inhibition of interleukin (IL)-2 synthesis, thereby suppressing T cell-mediated immunity[58–61]. It exerts inhibitory effects on T cells similarly to CsA, as both agents inhibit the proliferation and generation of cytotoxic T lymphocytes in mixed lymphocyte culture (MLC)[62]. At the transcriptional level, tacrolimus inhibits the synthesis of interleukin (IL)-2 mRNA as well as mRNA of IL-3 and IL-4 and other factors up-regulated during T cell activation, including colony-stimulating factors, tumor necrosis factor-alpha, and interferons -gamma and -alpha[63–66]. It has also been shown to inhibit some B cell functions[67]. While tacrolimus inhibits T-cell-dependent antibody responses, its inhibition occurs in the early phase of T cell activation; it is therefore unable to inhibit the activity

of mature cytotoxic T cells[66]. The immunosuppressive activity of tacrolimus is up to 100 times more potent than that of CsA. A further discussion of the immunosuppressive properties of the drug is provided in Chapter 70.

Administration and dosage

Dosing principles and blood level monitoring have been studied in healthy volunteers, and in liver and kidney transplant patients[55,58,68,69]. Studies following cardiac transplantation, however, are still limited. The pharmacokinetics of tacrolimus can vary greatly between patients and within a patient over time[56]. Correlations between blood or plasma concentrations and toxicity or rejection episodes exist, but are not well defined; therefore, guidelines for target trough levels should be used in combination with clinical assessment and other laboratory parameters. Early clinical trials have targeted a plasma trough concentration in the range 0.5–2 ng/ml (5–20 μg/l) in clinically stable transplant patients.

Immunosuppressive therapy with tacrolimus is usually initiated within 6–12 hours after transplantation. Although experience in thoracic organ transplantation is limited, the University of Pittsburgh group has prospectively studied the use of the drug as primary immunosuppression in cardiac transplant recipients[70,71] (Chapter 10). In early trials, tacrolimus immunosuppression was initiated as a continuous i.v. infusion, at a dose of 0.05 mg/kg per day, for a period of 24–48 hours. As soon as gastrointestinal function returned, an oral dose was begun at 0.3 mg/kg per day, divided in twice-daily doses. Dosing adjustments were made according to whole blood trough levels, clinical status of the patient, renal and hepatic function, and rejection history.

Administration of i.v. steroids with the tacrolimus immunosuppressive regimen is begun in the operating room with a methylprednisolone dose of 7–10 mg/kg, with a further three doses (for a total of 5 mg/kg) in the first 24 hours post-transplantation[72]. Thereafter, when the patient is tolerating oral intake, oral prednisone is given at 0.15 mg/kg per day. Steroid-tapering, according to the University of Pittsburgh protocol, is begun at the twelfth post-transplant week and is based on freedom from rejection. Steroid-tapering protocols vary per institution and have been discussed in this chapter (with regard to CsA immunosuppressive regimen) and are further discussed in Chapter 9.

In the Pittsburgh immunosuppression protocol the use of AZA is reserved as adjuvant immunosuppressive therapy: (a) for cases of rejection or (b) to allow for lower tacrolimus dosage in patients with impaired renal function. OKT3 is used only in cases of severe rejection associated with hemodynamic compromise.

Experience with tacrolimus after pulmonary transplantation is very limited. A prospective randomized trial comparing tacrolimus to CsA has been conducted at the University of Pittsburgh[73]. In the study protocol, tacrolimus was administered as a continuous infusion (when the recipient was hemodynamically stable) at a dose of 0.025 mg/kg per day. Once tolerating oral intake, tacrolimus was given in two divided doses, each of 0.15 mg/kg per day, and adjusted according to target trough levels. There were fewer episodes of acute cellular rejection in the tacrolimus group during the early postoperative period; the prevalence of infection and survival were similar in the two groups.

Optimal dosing of tacrolimus has not yet been fully determined and clinical trials are still in progress. Management during the immediate postoperative period is tending away from the use of i.v. tacrolimus, and immunosuppression is being initiated with lower oral doses, in the range 0.1–0.15 mg/kg per day. If the i.v. route of administration is used, overlap of the i.v. and oral dose is generally not recommended, in order to avoid the possibility of reaching toxic blood levels. Adequate levels can usually be achieved with the oral route alone. In contrast to CsA, bile flow is not required for tacrolimus absorption, nor is absorption decreased in patients with liver dysfunction[56]. The drug plasma/blood level should be monitored daily and the dosage adjusted gradually until a safe therapeutic level has been reached. Dosage adjustments are also dependent on the clinical status of the patient, renal and hepatic function, and rejection history.

Similar to CsA regimens, patients in extremely poor condition (severe cardiac failure with secondary renal and/or hepatic failure) may be managed by delaying initial dosing of tacrolimus, or by induction with other available agents (e.g. ATG, OKT3), until postoperative progress has been assessed.

For oral administration, tacrolimus is available as a hard gelatin capsule, which can be swallowed whole or pulled apart for sublingual administration of the contents. The sublingual route of administration has resulted in therapeutic levels at dosages equivalent to or lower than the oral dose. It is preferable to administer the drug by the oral route, even in the absence of normal gastrointestinal function, as nephrotoxicity is more likely with the i.v. route of administration. If adequate levels are not achieved with oral or sublingual administration, the drug may be given i.v. at a dosage three to four times lower than the oral dosage. The i.v. dose must be diluted in normal saline or 5% dextrose and administered as a continuous infusion, to reduce renal toxicity.

Monitoring of drug levels

There are several factors which necessitate routine monitoring of plasma/blood tacrolimus levels, in order to provide an acceptable level of immunosuppression without toxicity. The drug, whether administered i.v. or orally, is a very potent compound with a significant nephrotoxic potential[56,74,75]. Pharmacokinetic studies have shown that there is a larger inter- and intra-individual variation of kinetic characteristics in transplant patients[75].

Dosage adjustments are made according to graft function, drug tolerance, adverse effects of immunosuppression, and plasma/blood levels of the drug. During the initial adjustment period, levels are checked daily in order to rapidly achieve a therapeutic level and avoid toxicity. There is a correlation between dose and the resulting trough plasma/blood level[55], which suggests that the trough is a good indicator of systemic exposure and may be used for therapeutic drug monitoring. When tacrolimus is administered orally, blood samples should be drawn immediately before administration of the drug to determine the 'trough' level. When administered as a continuous i.v. infusion, timing of the blood level is less relevant, as drug concentration will not vary appreciably.

Several assays are available for measurement of tacrolimus concentration in blood and plasma. Because the drug is primarily bound to red blood cells in whole blood, the whole-blood assay

may be more dependable than the plasma assay[76,77]. The enzyme-linked immunosorbent assay (ELISA) for measuring tacrolimus concentrations was first reported by Tamura *et al.*[78]. The drug can also be measured in whole blood by: (a) radioreceptor assay (RRA)[79], (b) high-pressure liquid chromatography with mass spectrometry (HPLC-MS)[80], (c) the Abbott IMx method[81], and (d) in biological fluids by a combined HPLC-ELISA method[82].

The ELISA is a manual enzyme immunoassay method based on CH_2Cl_2 extraction and has been used for therapeutic drug monitoring in clinical trials[78,83]. This method is highly sensitive, but is nonspecific, because the polyclonal antibody employed cross-reacts with the drug metabolites.

The IMx is a semiautomated technique based on the principle of microparticulate enzyme immunoassay (MEIA), and is used for monitoring tacrolimus in whole blood only[81]. It uses the same antibody as the ELISA method and is therefore nonspecific. The method is sensitive, but its limit of quantification is currently 5 ng/ml, which may not be sufficient for monitoring patients on low-dose maintenance therapy. IMx has a rapid turnaround time and is currently the most widely used method for quantifying levels in transplant patients.

The most accurate, sensitive, and specific assay for determining tacrolimus concentrations in blood is HPLC coupled with mass spectrometry (HPLC-MS)[80], which can separately quantify the parent compound and its metabolites. However, the usefulness of the HPLC-MS method is limited by lack of available instrumentation at most transplant centers, and difficulty in analyzing a large volume of samples on a routine basis.

There are wide variations in the pharmacokinetics of tacrolimus, which means that for a given dose there will be a wide variation in plasma concentration. In addition, like CsA, tacrolimus exhibits a narrow therapeutic index. Currently, the most commonly used assay is the Abbott IMx, due to its rapid turnaround time, semiautomation, and ease of use by laboratory personnel. In addition, the importance of tacrolimus metabolism is still poorly understood and the significance of the drug's metabolites and their corresponding cross-reactivities should be considered when interpreting drug levels.

There is potential for drug–drug interactions in transplant patients, as a number of drugs affect the blood level of tacrolimus[55]. Because tacrolimus is metabolized by the P450-3A4 enzyme system, concomitant use of drugs which inhibit or induce cytochrome P450-3A4 will influence its metabolism. The therapeutic significance of such drug interactions has not yet been demonstrated, and it is advisable to avoid concomitant use of drugs which have the potential to interact with tacrolimus metabolism. If administration of such agents is unavoidable, tacrolimus blood levels should be monitored more closely and dosage adjustments made as appropriate.

Major side-effects and complications

The most significant adverse events associated with tacrolimus therapy are nephrotoxicity, systemic hypertension, neurotoxicity, and new-onset diabetes mellitus. Nephrotoxicity is worsened in the presence of ischemia, use of other nephrotoxic agents (including CsA), and administration in the early post-transplantation period, particularly by the i.v. route. It can be controlled to some degree but, along with hypertension, it remains a serious problem in the transplantation setting. As both tacrolimus and CsA are nephrotoxic, they must not be used together.

Nephrotoxicity is well documented in all transplant settings[84–87], partly because the optimal dosage range for use of tacrolimus has not yet been well defined. The proposed mechanism for transient decline in renal function is efferent arteriole vasoconstriction leading to diminished glomerular filtration, with subsequent tubular dysfunction[85]. Hyperkalemia, secondary to renal tubular acidosis, is also common in patients receiving tacrolimus, and can be controlled with fludrocortisone. The use of i.v. tacrolimus as primary and rescue therapy after cardiac transplantation has been associated with significant nephrotoxicity requiring dosage reduction. However, an apparent advantage over CsA is the number of recipients who become free of antihypertensive agents[70,71].

Neurotoxicity with tacrolimus ranges from mild symptoms, such as tremors, insomnia, and headaches, to more severe symptoms, including incapacitating headaches, dysarthria, seizures, and coma[86]. It appears to be related to high levels of the drug, and symptoms often resolve with dosage reduction. Many of the neurological side-effects are observed in the immediate post-transplantation period, and resolve over time. However, in some cases patients are intolerant of the neurological symptoms and may need to be converted to CsA therapy.

Glucose intolerance has been associated with tacrolimus-based immunosuppression, and new-onset diabetes mellitus has occurred in liver transplant recipients[87]. Although a number of patients have required long-term insulin therapy, it has been suggested that the diabetogenic effects may subside with time.

Gastrointestinal disturbances, ranging from mild cramps to severe diarrhoea, occur frequently with tacrolimus therapy, but appear to respond to dose reduction and abate over time. Other less significant toxicities include hypercalcemia, hyperphosphatemia, and hair loss. Hyperlipidemia/hypercholesterolemia is similar to that reported with CsA.

Very recently there have been reports of myocardial hypertrophy in patients receiving tacrolimus (Lawrence, I.D., personal communication). In the majority of cases the observation is a thickening of the ventricular walls and/or interventricular septum on echocardiography, the pathophysiology of which is unclear. In the few instances in which histology is available, no evidence has been seen of disorganization of myocyte structure. The condition appears to be reversible following dose reduction or discontinuation of tacrolimus therapy. Of a total of 42 cases seen in the USA, only one occurred in a patient with a heart transplant, and none has yet been reported in patients with lung transplants. The majority of cases have occurred in patients who have undergone liver transplantation. Myocardial hypertrophy has been observed as early as 3 days and as late as 25 months from the initiation of tacrolimus therapy. Maximum trough concentrations in whole blood have ranged from 7.8 to 103 ng/ml. From clinical trials of tacrolimus, the incidence of clinically manifested myocardial hypertrophy is estimated to be 0.2%.

AZATHIOPRINE (AZA)

AZA is one of the large group of antimetabolite compounds that compete for and block specific receptors, thus affecting DNA and

RNA synthesis, and interfering with protein synthesis[88]. It reduces or prevents the rapid cell division that is an important part of the immune system response, thus blunting the ability of the host to generate cytotoxic T cells. Though it is active on B cells, this activity is much less than on T cells, which accounts for its suppression of cell-mediated rejection with less effect on antibody production. AZA was introduced into experimental and clinical practice with regard to renal transplantation by Calne (Figure 8, Chapter 18) in 1961[89]. Specifically, it is a purine antagonist that is similar in structure to 6-mercaptopurine. AZA is useful in the prevention of acute rejection rather than the reversal of established rejection. It is rather ineffective when used as a sole immunosuppressant following human renal transplantation[90,91], but has not been used alone after cardiac transplantation.

Administration and dosage

It is usual policy to begin AZA before operation with a loading dose of 2.0–2.5 mg/kg orally or i.v. After transplantation it is given initially i.v. and subsequently orally at the same dose (or the maximal tolerable levels judged by the absence of bone marrow and hepatic toxicity). In our experience the average maintenance dose for adults ranges between 0.5 and 2.5 mg/kg per day; the total white blood count should be monitored at intervals and maintained in the range 5000–7000 cells/mm^3.

Major side-effects and complications

AZA is an easy and generally safe drug to use, and is relatively free from serious complication. AZA's main toxic effect is on the bone marrow, which results in leukopenia, thrombocytopenia and, occasionally, anemia, though leukopenia is rarely severe enough to prove a problem. Following withdrawal or reduction of the drug, recovery of the bone marrow is usually rapid. Employment of agents such as granulocyte colony-stimulating factor (GCSF) is rarely necessary. AZA not infrequently results in minor abnormalities of liver function, but rarely leads to clinical hepatic dysfunction[92]. Withdrawal of AZA or substitution with cyclophosphamide is recommended in such cases. Its role in the occurrence of pancreatitis (see below) remains uncertain.

Spontaneous hemorrhages into the skin (ecchymoses) are commonly seen when AZA is used either alone or, particularly, in combination with a corticosteroid; similar spontaneous bleeding can occur with corticosteroids alone.

CYCLOPHOSPHAMIDE (CPP)

In patients who show refractory or repeated acute rejection despite triple or quadruple drug therapy, or in those in whom AZA is associated with hepatic dysfunction, we have found cyclophosphamide (CPP) to be a useful agent[93]. In view of its potential to cause severe bone marrow depression, however, it must be used cautiously.

CPP, an alkylating agent, has a more marked effect on B cells than does AZA[88]. The alkyl groups attach to DNA, interfere with its integrity, and thereby produce significant cytotoxic effects.

A low dose (0.5–1.5 mg/kg per day) of this drug is generally sufficient to maintain a total white blood count within the desired range, 5000–7000 cells/mm^3. Unlike AZA, CPP use may result in a precipitous fall in white blood count, resulting in a severe, life-threatening neutropenia (WBC <1000/mm^3), which may persist for several days before spontaneous recovery occurs. Neutropenia is, however, a less serious problem today than it was even a few years ago, in view of the availability of GCSF and GMCSF therapy.

Hemorrhagic aseptic cystitis may be a complication of CPP therapy, necessitating its withdrawal.

METHOTREXATE (MTx)

Methotrexate (MTx) is the 4-amino, N^{10}-methyl analog of folic acid which competitively inhibits dihydrofolate reductase, and is a potent cytostatic agent, which exerts inhibitory effects on cellular and humoral immunity[88,94–98]. It has also been shown to affect B cells by decreasing their ability to proliferate and secrete antibodies[99]. MTx functions as an antimetabolite and was initially used in the treatment of a variety of malignancies, as well as psoriasis and rheumatoid arthritis. More recently it has been used as adjunctive treatment of acute refractory cardiac allograft rejection[100,101], and for the treatment of persistent mild rejection[102,103]. Its role in maintenance immunosuppressive therapy in patients with thoracic organ transplants is therefore small. Future prospects for MTx include the possibility of prolonging allograft survival with combination low-dose CsA/MTx therapy[104], or the use of MTx for donor pretreatment, again in an attempt to prolong allograft survival[105].

Administration, dosage and monitoring

Clinical trials have utilized dosing regimens based on a once-weekly schedule (for 1–9 weeks), with the weekly dose, given orally, determined by total white blood cell count[100,101,103,106,107], but usually in the range of 5–25 mg/week. In these trials corticosteroid doses were also decreased as tolerated. The white blood count needs to be monitored regularly. Transient leukopenia occurs in almost all patients, but MTx is otherwise well tolerated.

In a limited number of cases, MTx successfully resolved mild-to-moderate rejection where corticosteroid treatment had failed (Chapter 30). The drug can also be used successfully as an adjunctive agent in conventional immunosuppressive regimens: (a) for patients in whom AZA has been discontinued or (b) to allow reduction in the dose of steroids[101].

It takes some time for its effect to develop, and therefore it is *not* valuable in *severe* acute rejection, where a response is required rapidly. In the future its ability to suppress B cell function may prove valuable in xenotransplantation (Chapter 80).

Major side-effects and complications

Adverse events associated with MTx therapy include leukopenia, hepatic fibrosis and cirrhosis (dose-related[108,109], and an increased risk of infection[110]. Leukopenia is by far the most common and potentially serious adverse event, and a clearer understanding of

MTx's ability to suppress the bone marrow is needed before it gains wider use. Although MTx-induced bone marrow suppression is uniformly reversible, it has resulted in deaths from infection.

CORTICOSTEROIDS

Steroids were introduced into clinical renal transplant practice in 1963[111]. It is the glucocorticoids, rather than the mineralocorticoids, which possess immunosuppressive activity.

Prednisone or prednisolone have been most commonly used in transplantation. They inhibit a variety of intracellular enzymes that depress protein, RNA, and DNA synthesis. There is extensive death of small lymphocytes in the blood, thymus, lymph nodes and spleen, though the mechanism for this effect is not well understood, but is possibly mediated by an increase in cytoplasmic calcium. Cell-mediated immunity is depressed in most species.

Much of the efficiency of corticosteroid therapy is related to nonspecific immunosuppressive and anti-inflammatory effects, and to the inhibition of migration of immune cells to the graft. There is also evidence they: (a) impair antigen recognition, (b) interfere with macrophage function, and (c), at very high doses, interfere with some membrane functions of lymphocytes.

Administration and dosage

There are many different regimens for administering maintenance steroids to transplant patients. Our own regimen consists of 500 mg methylprednisolone sodium succinate given i.v. during operation before reperfusion of the donor heart, and further i.v. boluses of 125 mg 8-hourly for the first postoperative 24 hours. Thereafter, if the patient is absorbing oral fluids, an oral prednisone dose of 1 mg/kg per day is given, divided into two doses. The dosage is slowly reduced according to the University of Minnesota protocol (Table 1)[7]. If the patient is not absorbing oral fluids, i.v. methylprednisolone is continued (at the equivalent dosage) until such time that prednisone can be started.

For an 80 kg patient, for example, the total daily dosage would be 80 mg initially, reducing by 10 mg every 3 days until a dosage of 30 mg/day was achieved. This would be maintained for 1 month. By 6 months the daily dosage would have been reduced to 10 mg/day, where it would remain for a further 6 months. In stable patients we would then reduce dosage to 8 mg/day.

Most centers use prednisone or prednisolone in similar dosage (1 mg prednisone being the equivalent of 0.8 mg methylprednisolone). Prednisone is converted to methylprednisolone in the liver, and is a much less expensive drug. Unless there are features of liver dysfunction, the patient should be switched to prednisone in the early post-transplant period. Policies regarding reduction in dosage or withdrawal vary from center to center and are discussed in Chapter 9. When ATG or OKT3 is part of the initial immunosuppressive regimen, low doses of corticosteroids can be administered in the initial post-transplant period, and some groups will give only 0.2–0.3 mg/kg per day.

There is increasing evidence that steroids can be withdrawn entirely in patients with heart transplants, particularly in the patient who has shown no signs of rejection within the previous 6 months (Chapter 9). Some groups have been more aggressive and have demonstrated that in approximately 50% of patients it is possible to discontinue the drug completely within the first few weeks or months after transplantation. In patients who have been receiving more than approximately 5 mg/day for some long period of time, it is essential to reduce the drug cautiously (by approximately 1 mg/month) to ensure that the patient's own corticosteroid production can provide the body's basic needs.

Our own policy until recently was to maintain prednisone indefinitely at 0.1 mg/kg per day. However, we have recently entered the majority of our patients in a multicenter trial, where they are being randomized into: (a) a slow-withdrawal group or (b) a no-withdrawal group. The results of this trial are not yet available for discussion (Opelz, G., personal communication).

More caution in withdrawing steroids is required in patients with lung transplants, as experience in this field is very much less.

Major side-effects and complications

As stated above, it is sometimes difficult to attribute a post-transplant complication to any specific drug, but corticosteroid therapy is believed to contribute to several post-transplant problems (Table 3). These include systemic hypertension, diabetes mellitus, osteoporosis and aseptic necrosis of bone, impotence and sexual dysfunction, growth retardation and delayed onset of puberty in children, gastrointestinal tract complications, and lenticular cataracts. Psychiatric complications are also considered to be associated with corticosteroid therapy in some patients. These complications are discussed in Chapter 13, but brief mention will be made of some that can be of concern in the early post-transplant period.

Diabetes mellitus

We have not considered uncomplicated diabetes to be a contraindication to heart or lung transplantation, though we have not accepted the patient with significant diabetic complications, such as microvascular disease or neurotrophic foot ulcers. Some degree of impairment of glucose tolerance is seen in virtually all patients at some point in the transplantation process.

In its simplest form, hyperglycemia is seen in the first few days following transplantation during high-dose methylprednisolone therapy. It is seen again during the treatment of an acute rejection episode with methylprednisolone pulse therapy. In these circumstances the hyperglycemia usually lasts only a few days. Without treatment, plasma glucose levels greater than 16.7 mmol/l (300 mg/dl) are commonly encountered. In the unproven belief that it is beneficial to maintain a near-normal metabolic milieu, we routinely monitor and treat this hyperglycemia with the goal of maintaining glucose levels closer to 5.6 mmol/l (100 mg/dl), and certainly below 8.3 mmol/l (150 mg/dl). Granulocyte chemotaxis may be impaired at higher plasma glucose levels.

Some patients presenting for thoracic organ transplantation will have a pre-existing degree of impaired glucose tolerance or even frank diabetes. In particular, those with long-standing congestive heart failure and its associated cachexia will have impaired tolerance. Typically, the pretransplant glycosylated hemoglobin

ranges from 6.5% to 10% in this group. (Non-diabetics typically have a glycosylated hemoglobin of from 4.5% to 5.5%). Following transplantation, the improved nutritional status of the patient, with restored vigor and muscular activity, is associated with resolution of the impaired glucose tolerance. Usually these patients require tapering doses of oral hypoglycemics in the first few post-transplant weeks only. Thereafter, they may display no sign of impaired tolerance or diabetes.

Many patients will present for transplantation with familial type II diabetes. The degree to which they display this diabetes will depend on several factors, which include: (a) relative body masses of muscle and adipose, (b) diet, and (c) activity. Their diabetes can often be controlled with proper diet and activity. These persons are profoundly affected by pharmacological doses of corticosteroids. Until the corticosteroid dose is reduced to physiological levels, or eliminated entirely, treatment for diabetes will be required. In the long-term follow-up of such patients after reduction of corticosteroid dosage, those who follow the prescribed diet and activity instructions rarely require pharmacological treatment of their diabetes. Many patients, however, are unable or unwilling to follow such instructions, and require prolonged treatment, usually with oral agents.

At our own center we have transplanted very few patients with uncomplicated type I diabetes. They have done well, but have required large doses of insulin (<300 units daily) during the periods when they were taking corticosteroids in high or moderately high doses.

Gastrointestinal tract complications

Several gastrointestinal diseases are not uncommon in the transplant patient. The severity and risks of these diseases are generally increased by corticosteroid therapy and, after heterotopic heart transplantation, by the addition of anticoagulation and antiplatelet therapy.

The first and most formidable of potential gastrointestinal tract complications is bleeding from the stomach or duodenum, which may result from the stress of surgery and/or prolonged high-dose steroid therapy. In general, endoscopic examination reveals the bleeding to be due to hemorrhagic gastritis or peptic ulceration.

Therapy for acute upper gastrointestinal tract bleeding is more complicated and hazardous in immunosuppressed patients, whether the treatment be by surgery or endoscopic thermal coagulation. We believe, therefore, that it is imperative to investigate and, where possible, treat all digestive diseases before transplantation. Upper or lower gastrointestinal endoscopy is today a benign procedure that can be tolerated by all except the most severely ill patients, and should not be postponed if indicated. When acid peptic disease is found, it is treated aggressively pretransplant by a suitable H_2 blocker.

After transplantation all patients receive H_2 blockers, the rationale for this being that the stress of the post-transplant period and steroid therapy may increase the patient's susceptibility to develop ulcer disease. Therapy is continued at least until corticosteroids have been discontinued. The wisdom of treating peptic ulcer disease prophylactically is well supported by a review of the literature, since the complications of active severe ulceration, perforation, and gastrointestinal hemorrhage have been reported by a large number of transplant centers[112-115].

Pancreatitis

The cause of post-transplant pancreatitis remains uncertain. Several etiologies have been implicated; these include drugs (corticosteroids, AZA, furosemide, epinephrine, and alcohol)[116-120], infections (cytomegalovirus, viral hepatitis, mumps, Coxsackie and enteroviruses)[121-124], autoimmune disorders[125,126], ischemia[127] and biliary tract or peptic ulcer disease[128]. The University of Arizona reported a 6% incidence in cardiac transplant patients within the first 3 months[112]. Incidences of up to 7% with a mortality rate of more than 50% have been reported from several renal transplant centers. Though clinically severe acute pancreatitis is relatively uncommon after organ transplantation, a low-grade, asymptomatic pancreatitis has been noted in 49% of heart transplant patients coming to necropsy[129]. Similarly, at Stanford, evidence of pancreatitis was found at necropsy in 70% of cardiac transplant patients[128].

Psychiatric complications

The incidence of psychiatric complications in patients receiving steroid therapy has been reported to be between 4% and 36%[130,131]. Suicide has been successfully attempted by transplant patients. In the early experience of the University of Arizona, 12% of the cardiac transplant patients developed major psychiatric complications[112] (Chapter 14). It is, however, difficult to determine whether such disorders are drug related or occur as a result of the stress of the post-transplant period or other factors. It seems likely that a combination of factors exists in many cases.

Symptoms vary in severity from insomnia, nervousness and mood changes, to manic or depressive symptoms, or agitation with paranoid ideation. Depression may on occasion be related to the changes in physical appearance that may follow prolonged steroid therapy, e.g. Cushingoid features, hirsutism; fortunately, with the low dosages used today, extreme changes in physical appearance are rare.

Other side-effects

The list of other complications of corticosteroid therapy is long (Table 3). Fluid and salt retention can lead to hypertension and edema formation. Diuretic therapy can usually control these clinical features. Increased appetite and weight gain are common and may lead to obesity if not controlled by a strict diet; increased deposits of fat are seen particularly over the trunk. Changes in menstrual cycle, sexual activity, acne, night sweats, myopathy, joint pains, and spontaneous petechial hemorrhages in the skin are also common.

POLYCLONAL OR MONOCLONAL ANTI-T-CELL ANTIBODIES

Antilymphocyte (or antithymocyte) polyclonal globulin

The immunosuppressive effect of antilymphocyte globulin (ALG) was first demonstrated in the rat skin graft model[132]. The properties of ALG depend to a large extent on its method of preparation. It can be prepared against a wide variety of anti-

gens, including those on thoracic duct or blood lymphocytes and thymocytes. ALG is prepared by immunizing, most commonly, horses, rabbits, or goats with human lymphocytes or thymocytes. A clear description of the steps involved in its preparation is given by Touraine *et al.*[133]. The dosage varies widely, depending on the preparation used. Several commercial preparations are currently available; there are variations in potency between them.

Administration, dosage and monitoring

ALG was probably first used in cardiac transplantation by several groups in 1968. Until 1989 we used ALG routinely as induction therapy. ALG was administered initially during operation, once the patient was on cardiopulmonary bypass; we adopted this policy following rapid circulatory deterioration from an anaphylactic-like reaction in two patients who were receiving ALG immediately before induction of anesthesia, even though skin testing showed no sensitivity to the drug. The dose is estimated as that necessary to reduce the circulating T lymphocytes to the therapeutic range of 50–150 cells/mm^3. The drug is usually given intravenously, with a usual loading dose of approximately 5–15 mg IgG/kg, depending on the initial T cell count. The drug can be given intramuscularly, but repeated injections are painful and can cause local inflammation and pain[134].

The T-11 lymphocytes are counted daily by flow cytometry using monoclonal antibodies (or by the sheep red cell rosetting test), and the dosage of ALG estimated accordingly. (The percentage lymphocyte count gives an approximate value for the T-11 lymphocytes as these form approximately 50% of the total lymphocytes. If the absolute lymphocyte numbers are kept in the region of 200–400 cells/mm^3, this probably represents an adequate reduction in T cell activity). ALG is given in doses as necessary (usually 5–10 mg IgG/kg per day) to maintain the T lymphocytes at the desired level; the daily dosage may vary widely from patient to patient and from day to day. The drug is diluted in 100–200 ml normal saline or 5% dextrose, and is usually given as a single daily infusion over a period of 4 hours. When severe acute rejection is occurring, and the T lymphocytes multiplying rapidly, it is on occasion necessary to count the T lymphocytes every 8 or 12 hours and administer ALG 8- or 12-hourly.

In several centers ALG is administered prophylactically daily until such time that the trough CsA level is considered adequate and consistent. This usually takes only a few days, rarely requiring more than 1 week of ALG therapy; at this time ALG is discontinued. It is introduced again only when required in the management of an acute rejection episode.

Major side-effects and complications

There is a small risk of anaphylactic shock following its administration, whether this be intravenous or intramuscular. At Stanford, approximately 2% of patients exhibited frank anaphylaxis with the intramuscular use of ATG[135]. The risk of anaphylaxis may be reduced by administering a test dose subcutaneously and observing for a severe histamine skin reaction, and by administering steroids and an antihistamine to the patient before the ATG dose is given.

Patients who experience anaphylactic shock may require urgent steroid and epinephrine therapy, vasopressor support, and mechanically assisted respiration. They may, however, cautiously receive further ATG on subsequent occasions; in our experience this reaction may be related to the batch of ATG used, rather than to the ATG *per se*. Should the complication occur again, ATG produced in a second species of animal (e.g. rabbit or goat rather than horse) may be found not to provoke the reaction, and may be used safely.

A small proportion of patients receiving ATG develop a combination of symptoms, which include rash, fever, chills, back and joint paint, and, less frequently, bronchospasm. During acute rejection episodes the chills and fever can be minimized by giving intravenous steroid therapy prior to the intravenous administration of ATG. Bronchospasm is treated as for anaphylaxis. Aspirin and antihistamines are useful in the treatment of joint pain and fever, and rash, respectively.

We have seen the clinical syndrome of serum sickness (fever, hepatomegaly, splenomegaly and lymphadenopathy, associated with upper abdominal discomfort and pain) during intravenous ATG administration in two patients; it resolved after discontinuation of therapy.

In our experience allergic reactions to ALG have been uncommon, but it is general policy to give a prophylactic antihistamine such as promethazine hydrochloride (12.5–25 mg) intravenously immediately before drug infusion.

In 1989, concerned by the increasing incidence of cytomegalovirus (CMV) infection in our patients during the first few post-transplant months, we discontinued the initial course of ATG, immunosuppressing the patient with the University of Minnesota regimen of CsA, AZA, and corticosteroids only (Table 1). The incidence and severity of CMV disease have been significantly reduced[136]. We therefore now reserve ALG only for those patients in whom it may be hazardous to administer CsA (e.g. in those with greatly impaired renal function) and for those undergoing a severe rejection episode unresponsive to intravenous corticosteroid therapy alone. This topic is discussed further in Chapter 9.

Similar effects are observed after therapy with antithymocyte globulin (ATG) or with antilymphocyte globulin (ALG), though the response is theoretically more specific. Only T cells are supposedly affected when ATG is administered, but both T and B cells are involved when ALG is administered. This is not always so in practice, as ATG often depletes all lymphocytes, not just T cells.

Monoclonal antibody (OKT3)

Monoclonal anti-T-cell antibodies are directed to, and block, the recognition of antigen by the recipient circulating T cells. Receptors are found on all circulating human T cells[137], and monoclonal antibodies can be raised against any T cell subset. The modes of action of monoclonal antibodies include removal of T cells from the circulation by complement-mediated lysis or by the reticuloendothelial system, and coating of cell surface antigens[138,139].

Immunosuppression with monoclonal antibodies is clearly more specific than with ATG or ALG. Monoclonal antibodies

have the advantages (over ATG and ALG) of better consistency in preparation, greater ease in monitoring serum levels, and administration of less foreign protein. As the immune response is so complex, however, there may be advantages of ATG or ALG in destroying or inhibiting a wider spectrum of lymphocytes.

OKT3, a murine monoclonal antibody of the IgG-2a series, is a pan-T cell suppressor. It can only be given intravenously. OKT3 causes an immediate but temporary decline in circulating T cells which persists while the antibody is being administered. OKT3 blocks all known T cell functions. A rapid and concomitant decrease in the number of T3 (CD3), T4 (CD4), and T8 (CD8) cells occurs within minutes of administration of OKT3. There is some recovery in the numbers of T4 and T8 cells within the first week of administration, though the T3 cells remain undetectable in the peripheral blood. Recovery of T3 cells to pretreatment levels occurs within a week once administration is discontinued.

OKT3 monoclonal antibody directly binds to the cell surface antigen, leading to loss of the cell's recognition apparatus[140]; these T cells can therefore play no further part in the acute rejection process. The initial decline in the number of T cells following institution of OKT3 therapy is probably brought about by opsonization of the cell surface, and removal of the cells by the reticuloendothelial system of the host[141]. Many monoclonal antibodies (other than OKT3) have been, or are currently being developed (Chapter 71).

Experience with OKT3 has rapidly accumulated, and several programs now use it to treat rejection unresponsive to conventional therapy (Chapter 30). A smaller number of centers use it in the early postoperative period as a prophylaxis to prevent rejection. The various indications for its use are, therefore: (a) treatment of refractory rejection; (b) treatment of life-threatening rejection when it is elected not to wait to assess the full response of conventional corticosteroid therapy; (c) rejection prophylaxis.

Administration, dosage and monitoring

It is recommended that 5 mg of OKT3 be administered daily for 10–14 days, each dose being given i.v. over 1 minute. This dose may require adjustment to maintain the T3 lymphocyte subset at about 20 cells/mm^3. To prevent excessive immunosuppression (and thus increase the risks of infection and lymphoproliferative disease) most groups suggest that, during therapy, concomitant immunosuppressive therapy should be decreased to approximately half the maintenance level. Others advocate discontinuing concomitant immunosuppressive therapy entirely. Normal maintenance immunosuppressive doses (of CsA, etc.) should be resumed 3 days prior to completion of OKT3 therapy.

Serum levels of OKT3 can be measured by an ELISA (enzyme-linked immunosorbent serum assay). A mean trough level of 0.9 μg/ml (achieved with the recommended dose) has been shown to block T cell effector functions *in vitro*.

Premedication with acetaminophen 650 mg orally, methylprednisolone 1 mg/kg i.v., and diphenhydramine 100 mg i.v. 30 min prior to administration of OKT3 is given to minimize allergic reactions. It is recommended that 100 mg of i.v. hydrocortisone be given intravenously 30 min after the injection of OKT3; further acetaminophen and antihistamines are optional.

One of the transplant groups to have considerable experience with OKT3 is the Utah group[141–143]. Their initial studies of its use prophylactically suggested improved patient and graft survival when compared with patients receiving ATG as prophylaxis during the same period of time. However, the sample size was not sufficient to demonstrate a reduction in mortality or graft loss in the OKT3-treated patients. More recent studies from this and other groups have suggested that OKT3 does not impart any increased benefit, and that its use is associated with an increased rate of infection, and a significant incidence of early vascular (humoral) graft rejection[144] (Chapter 28). These complications are particularly common if the prophylactic course is continued for 21 days.

IgM anti-OKT3 appears in approximately 21% of patients receiving this agent, while IgG anti-OKT3 is seen in 86%, and IgE anti-OKT3 in 29%, occurring approximately 20 days after treatment is begun. The numbers of T3 cells should be carefully monitored and, if they increase despite OKT3 therapy, the dosage of the monoclonal antibody should be increased at least 2–3 times. Patients who develop large quantities of IgG anti-OKT3 antibodies, and therefore fail to respond to OKT3 therapy, may not be candidates for another course of OKT3 treatment.

Anti-idiotypic antibody development, which is a prominent feature of the immune response to OKT3, and probably other monoclonal antibodies, can lead to a block in their therapeutic effectiveness and can arise despite intense immunosuppression[145]. This response may require the use of different idiotypes for prolonged or repeated courses of therapy, and may prove a major obstacle.

Major side-effects and complications

The side-effects of OKT3 include fever (which occurs in 73% of patients), chills, dyspnea, chest pain, vomiting, wheezing, nausea, tremor, and diarrhea. Aseptic meningitis, exhibited by fever, headache, neck stiffness and photophobia, has been reported.

Because of the risk (less than 2%) of fatal pulmonary edema, OKT3 is contraindicated in patients with fluid overload, as determined by pulmonary congestion on a chest radiograph and by a weight gain of more than 3% within the week prior to the planned OKT3 therapy. It is recommended that a Swan–Ganz catheter should be inserted before treatment is begun, and that if the pulmonary capillary wedge pressure is seen to be unduly high, OKT3 therapy should be avoided. The Utah group has shown, however, that OKT3 is generally well tolerated in the setting of cardiac transplantation[141].

COMMENT

With maintenance triple-drug therapy (CsA (or CsA-Neoral), AZA, and steroids), the development of severe acute rejection is today fairly unusual, and has been seen in only 2% of endomyocardial biopsies at our center during the past 5 years. This combination of drugs is, therefore, potent and efficient, and care has to be taken to avoid over-immunosuppression. Changes suggestive of mild or moderate acute rejection remain relatively common, but frequently do not warrant extra immunosuppressive therapy.

The efficacy of CsA has allowed steroid dosage to be significantly reduced, and in an increasing number of patients it

can be discontinued entirely. This is a major advance that reduces the debilitating effects and complications associated with long-term steroid therapy. The use of triple-drug therapy has not yet been shown definitively to reduce the incidence of graft vasculopathy (chronic rejection), which still occurs in a significant percentage of patients (Chapter 35), although our impression is that its onset is delayed when compared with 10 years ago.

Optimal combinations of immunosuppressive agents can be arrived at rationally and effectively only by a full understanding of the site and mode of action of each agent. As our knowledge of the various mechanisms that play a role in allograft destruction increases, so it should become possible to devise more sophisticated methods of blocking the sequence of events outlined in Chapter 7. The clinical employment of such agents may eventually enable graft destruction to be prevented, and yet allow the body to maintain all or most of its other host defense mechanisms.

Long-term immunosuppressive therapy is clearly associated with a large number of side-effects and complications. Some of these can be avoided or minimized by careful selection of the patient, or by pretransplant prophylactic treatment (e.g. for peptic ulcer), and others by post-transplant prophylactic medication. Avoidance of all such complications, however, cannot be ensured, and the potential risks must be considered when the potential recipient is initially assessed for organ transplantation.

Trends in Immunosuppressive Therapy With Regard to Cytolytic Induction Therapy and Corticosteroid Withdrawal

J. KOBASHIGAWA

IS CYTOLYTIC INDUCTION THERAPY BENEFICIAL?

A cytolytic agent (e.g. antilymphocyte serum) administered immediately after heart transplantation (HTx) is known as 'induction' therapy and is given in the hope of inducing graft tolerance[1–4]. The benefit of this form of therapy remains controversial, as no randomized studies have been performed. Forms of antilymphocyte sera include murine monoclonal antibody (OKT3), rabbit and equine antithymocyte globulin (ATG), and antilymphocyte globulin (ALG).

In general, all cytolytic induction therapies appear to have similar effects. Single-center studies have reported that cytolytic therapy appears to prolong the time to the first acute cellular rejection episode; however, the total number of rejection episodes within the first year after HTx is not reduced when compared with the number in patients receiving triple-drug immunosuppression alone (cyclosporin, prednisone and azathioprine, without cytolytic therapy)[5–7]. Barr and colleagues[6] reviewed 52 HTx patients, one-half treated with OKT3 for 14 days immediately postoperatively and one-half treated with triple-drug immunosuppression alone. Although time to first rejection was longer in the OKT3 group, there was similar rejection frequency, freedom from rejection, and survival in the two groups. Prieto *et al.*[18] showed similar results in a review of 82 HTx patients (35 treated with OKT3 versus 47 treated with triple-drug immunosuppression). A large multi-institutional study[9], involving 911 HTx patients, revealed that there was no benefit in the use of cytolytic therapy over triple-drug immunosuppression with regard to time of onset of first rejection or cumulative frequency of rejection episodes. However, this study involved many different antilymphocyte preparations, which might have masked the efficacy of any one agent.

The effectiveness of one form of cytolytic therapy over another has been compared in numerous studies[10–13]. These comparison studies are difficult to interpret, as many different doses and lengths of cytolytic therapy have been used. A non-randomized, retrospective study by Ladowski *et al.*[14] reported on 79 patients treated with equine ATG for 4 days (34 patients), Minnesota ALG for 10 days (15 patients), or OKT3 for 14 days (30 patients). Although there appeared to be an advantage of equine ATG in leading to a lower rejection incidence, there was no survival advantage. Furthermore, this was the only group to receive preoperative cyclosporin, which complicates interpretation of the results. Copeland *et al.*[15] demonstrated superior results in regard to survival, rejection, and infection with the use of rabbit ATG in 155 HTx patients; however, the 'controls' were the contemporary results of other programs.

A large multicenter database suggested that there may be an increase in infectious complications (cytomegalovirus) with the use of cytolytic induction therapy[16,17]. Review of 1553 HTx patients from 26 programs revealed, through multivariate analysis, that there was earlier development of cytomegalovirus infection in patients who receive cytolytic induction therapy. However, mortality due to cytomegalovirus was not increased[17]. OKT3 murine monoclonal antibody is the most common form of cytolytic induction therapy used, and has been associated with a higher incidence of cytomegalovirus infection[18] and, more recently, with the development of lymphoproliferative disease[19]. The use of OKT3 may also result in the development of human anti-mouse antibodies, which has been associated with adverse outcomes after HTx[20,21]. Specifically, vascular damage can be produced by immune complexes that contain host antibodies against highly immunogenic proteins, such as antithymocyte globulin or murine monoclonal antibodies[22,23]. Overall, however, due to the lack of randomized trials, controversy still exists as to the increased risks in HTx patients treated with OKT3 induction therapy[24].

Many centers use cytolytic induction therapy in short courses to allow delay of initiation of cyclosporin therapy, thus avoiding acute cyclosporin nephrotoxicity in patients at high risk for immediate or early-postoperative kidney failure. Kormos and colleagues[25] initially reported success in using rabbit ATG for 3 days and starting cyclosporin 24 h after surgery, to avoid postoperative renal dysfunction. Similarly, Barr *et al.*[6] successfully used a short course of OKT3 (5 days) to avoid renal dysfunction in high-risk HTx patients.

More recently, some HTx centers have employed short courses of cytolytic therapy in the hope of achieving graft tolerance and avoiding the complications associated with longer courses of

therapy. Menkis *et al.*[26] randomized 39 HTx patients to a short course of OKT3 (7 days) or to Minnesota ALG (7 days). There was no difference between the two groups in either cumulative rejection episodes or time to first rejection. A study by Alonso-Pulpon *et al.*[27] evaluated varying doses of OKT3 in 39 HTx patients; 23 were treated with 5 mg OKT3 and 16 with 2.5 mg OKT3, both for 7 days duration; there was no difference in the incidences of rejection or infection, or in the total methylprednisolone dose given.

Our HTx program at the University of California at Los Angeles (UCLA) Medical Center performed a randomized trial of short-course OKT3 therapy in 30 HTx patients[28]. Fifteen received a 5-day course of OKT3 while 15 received routine triple-drug immunosuppression alone. No patient had a baseline serum creatinine level of >1.5 mg/dl. At 6 months follow-up there was no difference between the two groups in: (a) the number of rejection episodes per patient; (b) the number of patients who were free of rejection; (c) the time to first rejection (25±29 days in the triple drug immunosuppression group compared to 57±68 days in the OKT3 group (p=0.1)); (d) renal function, determined by serum creatinine levels (no patient in either group required hemodialysis); and (e) infectious complications, including cytomegalovirus infection. Overall, there did not appear to be a benefit in the use of short-course OKT3 induction over triple-drug immunosuppression. However, the benefit of OKT3 induction, in which longer courses are used (e.g. a 14-day course), is yet to be determined.

COMMENT

The benefit of antilymphocyte sera administered immediately after HTx, known as 'induction therapy', remains controversial as no randomized studies have been performed. However, there are an increasing number of reports that suggest the use of OKT3 monoclonal antibody in induction therapy may have deleterious long-term effects in causing a higher incidence of cytomegalovirus infection and post-transplant lymphoproliferative disease. There may be a role for the use of early cytolytic therapy in patients at high risk for early postoperative kidney failure by allowing initiation of cyclosporin therapy to be delayed. It is unlikely that large multicenter studies will be performed comparing cytolytic induction therapy to triple-drug immunosuppression as the risks of cytolytic therapy have recently become more apparent and several new immunosuppressive medications are becoming available.

CORTICOSTEROID-FREE IMMUNOSUPPRESSION

The discontinuation of corticosteroid therapy (to allow steroid-free immunosuppression) has been attempted immediately and late (>6 months) after HTx, to avoid the complications related with such therapy[29–36]. Potential complications of steroid therapy are numerous, and include osteoporosis, avascular bone necrosis, myopathy, increased incidence of infection, salt and water retention, hypertension, gastrointestinal complications, hyperlipidemia, exacerbation of diabetes, weight gain, cosmetic alterations (such as hirsutism and Cushingoid habitus), and growth retardation in children (Chapter 8). In addition, corticosteroids may be atherogenic and potentially contribute to the development of transplant coronary artery disease (graft vasculopathy).

The objective of corticosteroid withdrawal is to improve the overall health and quality of life of HTx recipients by eliminating its long-term complications. One can decrease a patient's exposure to steroid complications by maintaining low prednisone doses or by complete withdrawal. There has been concern regarding the risks of steroid withdrawal, which may lead to inadequate immunosuppression and an increased risk of rejection. Therefore, there may be a need for long-term surveillance by endomyocardial biopsies. There is also the question of whether increased doses of other immunosuppressive agents (cyclosporin and azathioprine) are necessary to avoid rejection. Corticosteroid withdrawal symptoms may be quite significant, and include arthralgia, myalgia, fatigue, and headaches, and in some cases may require reinstitution of steroids. Finally, the role of corticosteroids in the development of transplant coronary artery disease (graft vasculopathy) remains unclear. As this is probably an immune-mediated process, steroids could play a role in its prevention. On the other hand, steroid therapy is known to be associated with elevated lipid levels and, therefore, may be atherogenic.

Approach to corticosteroid withdrawal

There are currently two approaches to corticosteroid withdrawal in HTx recipients: (a) it has been attempted immediately (1–30 days) after HTx, usually in programs that use cytolytic induction therapy[29–31]; (b) the other approach has been to wean steroids late (>3 months) after HTx; cytolytic induction therapy has usually not been used[32–35]. The apparent advantage of late steroid withdrawal relates to the opportunity of selecting for weaning those patients who have experienced either no or few rejection episodes. This may indicate that these patients show less immunologic response to their graft, and thus may be more likely to undergo successful steroid weaning without late rejection. However, no established superiority of either withdrawal approach has been documented, as there have been no prospective randomized trials comparing these two approaches. Even the benefits of steroid withdrawal have not been conclusively established.

Corticosteroid withdrawal protocols

Protocols

The early corticosteroid withdrawal protocols weaned steroids in a tapering dose schedule over 1–2 weeks after HTx. At the University of Utah Heart Transplant Program patients could experience up to three episodes of rejection before they were considered protocol failures and placed back on maintenance steroids[31].

Late corticosteroid weaning is routinely attempted at UCLA beginning 6 months after HTx[32]. Criteria for corticosteroid weaning include patients who: (a) have survived at least 6 months since HTx, (b) have not experienced even moderate rejection during the prior 3 months, (c) have not experienced more than two episodes of treated rejection, and/or (d) have experienced no hemodynamic compromise through rejection.

By 6 months, patients are usually at a baseline corticosteroid dose of 5 mg prednisone/day. They are weaned slowly by decreasing the daily prednisone dose by 1 mg each month.

Endomyocardial biopsies are performed monthly during the weaning period and 2 months after discontinuation of prednisone. Those patients who cannot be successfully weaned are placed back on 5 mg prednisone daily. The attempt to wean is repeated at least twice before considering a patient a protocol failure.

Results

Corticosteroid withdrawal attempted within the first 30 days post-HTx has a success rate of 40–61%[29,31,34]. Withdrawal attempted later than 3 months has a success rate of 73–92%[32,33,35]. Early (<30 days) withdrawal is attempted in *all* patients (not just those with a low incidence of rejection), which probably accounts for the lower success rate. Overall, similar numbers of patients are being weaned off corticosteroids by each approach (early versus late) since weaning is attempted in a smaller (but select) percentage of patients >3 months after HTx. In the UCLA Heart Transplant Program approximately 60% of patients are eventually weaned from steroids.

Factors that appear to affect the success of corticosteroid weaning include: (a) donor–recipient HLA-DR matching, (b) recipient gender, and (c) number of previous rejection episodes. At UCLA, donor and recipient HLA-DR antigens were compared in 75 patients[37]. Thirty of 31 patients (97%) with at least one HLA-DR match were successfully weaned from prednisone, compared with 33 of 44 (75%) with no HLA-DR matches ($p<0.05$). However, similar observations were not found in 62 patients evaluated at the St Louis University Heart Transplant Program.

Women are at higher risk of osteoporosis and, therefore, it is particularly desirable to reduce cumulative doses of steroids in female HTx patients. However, steroid withdrawal success rates in women have been reported to be only 13–18% in the HTx programs at St Louis, Utah, and UCLA (unpublished data). These findings are consistent with the fact that female HTx recipients have higher incidences of acute graft rejection and early mortality compared to male patients[38]. It is unclear whether the newer immunosuppressive agents will allow a higher success rate of steroid withdrawal in female patients.

The history relating to previous rejection episodes has been a good predictor of the success of steroid withdrawal in patients weaned late after HTx. At St Louis University the risk of developing a rejection episode after steroid withdrawal was almost 2-fold greater in patients who had experienced a previous rejection episode (while taking corticosteroids) when compared to patients who had experienced no prior rejection episode[33].

Benefits of corticosteroid withdrawal

Hyperlipidemia occurs in 60–80% of HTx patients[39]. Some investigators have shown a correlation between hyperlipidemia and transplant coronary artery disease (graft vasculopathy); others have been unable to confirm this finding. The development of hyperlipidemia after HTx is multifactorial, with corticosteroids being one of the contributing factors. At the University of Utah, corticosteroid withdrawal had a significant impact on serum cholesterol levels[40]. Beginning 3 months after HTx, the cholesterol levels for 51 patients maintained on a mean prednisone dose of 12.4±1.2 mg/day ranged from 262±8 to 272±8 mg/dl. This contrasted with the corticosteroid-free group, in which the cholesterol level ranged from 199±8 to 211±9 mg/dl. At UCLA the cholesterol levels (a) at the time of corticosteroid weaning and (b) 1 year later, showed an average decrease of 14±31 mg/dl in those successfully weaned, while the steroid-dependent group showed a rise in cholesterol of 20±41 mg/dl[37].

Corticosteroid withdrawal has been shown to decrease the need for antihypertensive medications. At UCLA, at the time of attempted steroid withdrawal, 80% of the patients (subsequently successfully withdrawn from corticosteroids) were taking antihypertensive medications[37]. One year later this number decreased to 73%. Of the patients who could not be weaned off corticosteroids (and were maintained with prednisone 5 mg/day) 54% were taking antihypertensives at baseline, and this number increased to 67% one year later. Similarly, at St Vincent's Hospital in Australia, after 4 years of follow-up, patients still receiving steroids required significantly more antihypertensive medications than those no longer receiving steroids[34].

Weight gain is common after HTx and is associated with steroid therapy. Corticosteroid-free immunosuppression has been reported to ameliorate weight gain[37,41]. At UCLA, after 1 year of follow-up, patients on steroid-free immunosuppression had an average 1±4 kg weight *reduction* compared to a 4±9 kg weight *increase* in those dependent on steroid therapy[37].

The University of Utah program evaluated 178 HTx patients to determine whether those on corticosteroid-free immunosuppression had a lower incidence of gastrointestinal complications[42]. Twenty-six patients on maintenance steroids developed 30 major abdominal complications whereas no steroid-free patient developed such a complication.

Corticosteroid withdrawal in children

The chronic use of corticosteroids in children may retard growth[43,44]. The effect of steroid-sparing regimens was retrospectively reviewed in 42 infants who underwent HTx at <6 months of age at Loma Linda University[43]. Ten of 15 infants who had abnormal growth were receiving steroids; maintenance steroids were subsequently discontinued in six, four of whom experienced rebound growth. Within 6 months of steroid withdrawal, three of the four patients moved from below the 5th percentile for growth to the 95th percentile or higher.

Safety of corticosteroid withdrawal

There is concern that corticosteroid withdrawal may lead to an increased development of transplant coronary artery disease. Steroid-free therapy may provide an adequate level of immunosuppression to prevent acute allograft rejection, but may not be sufficient to prevent immune-mediated endothelial injury in the coronary arteries. Available data from single-center studies suggest that steroid withdrawal does not cause an increase in the development of graft vasculopathy[33,45]. Unpublished data from the UCLA program reveal a *lower* incidence of angiography-defined transplant coronary artery disease in those patients successfully weaned from steroids. As patients who are able to be weaned from steroids may be immunologically privileged, then it is logical that they may be less prone to develop graft vasculopathy.

Data from several institutions reveal comparable or improved patient survival in those weaned from steroids[33–37]. Furthermore, data from Utah indicate that cardiac allograft function appears to be normal in those patients weaned from steroids[46].

Cyclosporin and azathioprine dosages are not routinely increased in patients who have undergone steroid withdrawal. It is important, however, that medication compliance be maintained, as the risk of rejection may be greater if the cyclosporin level becomes subtherapeutic.

COMMENT

Corticosteroid withdrawal, whether performed early or late after HTx, appears successful in the majority. Significant advantages in regard to weight, hyperlipidemia, and hypertension may be achieved. Steroid withdrawal does not appear to impact adversely on survival, development of transplant coronary artery disease, or on hemodynamics. Finally, through the avoidance of the complications of long-term steroid therapy, it is likely that corticosteroid-free immunosuppressive protocols will have a positive impact on the quality of life of HTx patients[47].

Tacrolimus (FK506) in Thoracic Organ Transplantation

J.S. GAMMIE AND S.M. PHAM

INTRODUCTION

Tacrolimus (FK506) was discovered as the result of a systematic screening program to look for an improved immunosuppressant. In the mid-1980s Goto and associates from the Exploratory Research Laboratories of Fujisawa Pharmaceutical Co. Ltd, Japan, discovered a macrolide compound that had potent immunosuppressive properties[1–3]. This compound, then named FK506, was extracted from the fermentation broth of the soil fungus *Streptomyces tsukubaensis*. Further preclinical studies on the immunosuppressive properties of this compound on organ transplantation were carried out intensively at Chiba University, Japan[4–9], Cambridge University, UK[10–12], and the University of Pittsburgh, USA[13–18]. The initial results of FK506 as an effective immunosuppressant in organ transplantation were presented at the first International Symposium on FK506 in June 1987, in Göteborg, Sweden, and were subsequently published in *Transplantation Proceedings* (Vol. 19, Suppl. 6, 1987).

The first clinical trial using FK506 in organ transplantation began at the University of Pittsburgh in February 1989[19]. In this trial, FK506 was used as a 'rescue' agent for liver transplant recipients experiencing refractory rejection on cyclosporin-based regimens. Encouraged by the initial results, clinical trials of FK506 as a primary immunosuppressant in liver, kidney, heart and lung transplantation were initiated later that year at the same institution[20–23]. Recent national and international trials have helped to define the role for this important immunosuppressant[24–27]. In 1994, FK506 was approved by the FDA in the USA for use in liver transplant recipients. Medicare and major third-party payors have approved the use of tacrolimus for approved transplant procedures. The generic name of FK506 is now *tacrolimus*, and it is marketed under the trade name Prograf® (Fujisawa USA, Deerfield, IL).

In this chapter we will review the pharmacology and clinical use of tacrolimus in heart and lung transplantation.

Chemistry

Tacrolimus, a macrolide lactone, is a member of the macrolide antibiotics whose chemical structure consists of a hemiketal-masked α,β-diketoamide incorporated in a 23-member ring (Figure 1). Other drugs belonging to the family of macrolides include erythromycin, oleandomycin, and rapamycin. Tacrolimus is a large molecule with a molecular weight of 822.05 daltons, and is highly lipophilic. Because it is practically insoluble in water, tacrolimus is dissolved in cremaphor for intravenous administration.

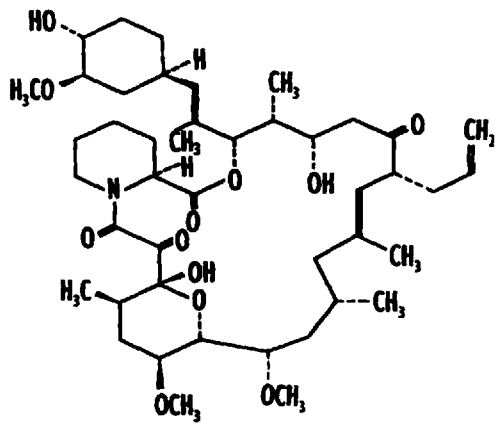

Figure 1 Chemical structure of tacrolimus

Mechanisms of action

Despite having different chemical structures, tacrolimus and cyclosporin (CsA) have similar mechanisms of action. In a broad sense these immunosuppressants work by inhibiting the T-cell activation that normally occurs in response to the presentation of antigens to the T-cell receptor (TcR)–CD3 complex on the surface of the T cell. They block the transcription of early-phase T-cell activation genes, including those genes encoding interleukin (IL)-2, IL-3, IL-4, IL-5, granulocytes–macrophage colony-stimulating factor (GM-CSF), tumor necrotis factor-α (TNF-α), and interferon (IFN)[28–31].

Tacrolimus and CsA initially bind to their respective cytosolic target proteins (known as immunophilins), cyclophilin and FK506-binding proteins (FKBP)[30]. The cyclophilin–CsA and the FKBP–FK506 complexes, in turn, bind to the calcium- and calmodulin-dependent cellular signaling protein calcineurin[31]. Calcineurin is a serine/threonine phosphatase that plays a key role in the transfer of information from the cell surface to the nucleus, ultimately resulting in the transcription of various cytokines (predominantly IL-2), which in turn leads to T-cell activation. The transfer of signals from the cytoplasm to the nucleus, to activate the transcription of the IL-2 gene, requires the nuclear factor of activated T-cell protein (NF-AT). NF-AT consists of two subunits, one located in the cytoplasm and one in the nucleus. Following stimulation of the T-cell receptor, the cytoplasmic subunit of the NF-AT is modulated by calcineurin and transported into the nucleus, where it combines with its nuclear counterpart to function as a transcription factor for the IL-2 gene[32]. The tacrolimus–FKBP complex binds to calcineurin and blocks the modulation of the cytoplasmic subunit of the NF-AT, resulting in the inhibition of IL-2 gene transcription and activation of T cells[33].

Bioavailability

Following oral administration tacrolimus is erratically and incompletely absorbed. Mean bioavailability is 27%, although there is significant inter- and intra-patient variability[34]. Time to peak plasma concentration ranges from 1 to 3 hours. In contrast to cyclosporin, and of some advantage in the liver transplant population, tacrolimus does not require an intact enterohepatic circulation for absorption. Fasting enhances the rate and extent of the absorption of tacrolimus. The mean maximal blood concentration in fasted patients is twice that observed in fed patients, and the time to maximal concentration is 1 as opposed to 3 hours[35]. However, the total drug bioavailability (area under the curve, AUC) is not significantly affected by fasting. Hence, it is suggested that tacrolimus be administered at least 1 hour before, or 2 hours after, a meal. Conversion between intravenous and oral dosages of tacrolimus is based on a 1:5 ratio.

Distribution

Volume of distribution of tacrolimus is 1300 liters, suggesting extensive extravascular uptake. Tacrolimus is rapidly partitioned into red blood cells, with a whole blood to plasma ratio of 15:1, and is more than 99% bound to plasma proteins (albumin and α_1-acid glycoprotein).

Metabolism

Tacrolimus is metabolized by the microsomal P-450 IIIA enzyme system in the liver and intestine, with less than 5% excreted unmetabolized in the stool[35]. Less than 1% of the drug is eliminated renally. Tacrolimus is not dialyzable. The main metabolic pathway includes 13- and 15-*O*-demethylation and 12-hydroxylation, with at least nine resultant metabolites, some of which retain immunosuppressant properties. Elimination is biphasic, with an overall half-life ranging from 5.5 to 16.6 hours (mean 8.7 hours).

Table 1 Drugs potentially interacting with the metabolism of tacrolimus*

Decrease ← Metabolism → Increase Increase ← Blood level → Decrease	
Erythromycin	Rifampicin
Troleandomycin	Phenobarbital
Clotrimazole	Phenytoin
Ketoconazole	Carbamazepine
Fluconazole	
Cyclosporin	
Diltiazem	
Verapamil	
Nifedipine	
Ethinylestradiol	
Methylprednisolone	
Midazolam	

* Adapted from ref. 35.

Because tacrolimus is metabolized by the cytochrome P-450 IIIA system, its metabolism is subject to influence by agents which induce or inhibit the P-450 system (Table 1)[34]. Drugs commonly used in transplant recipients that reduce the metabolism of tacrolimus (and thus increase its blood level) include erythromycin, clotrimazole, ketokonazole, fluconazole, and calcium channel blockers. Phenobarbital, phenytoin, and rifampicin, on the other hand, will reduce the blood level of tacrolimus.

Of clinical interest, and compatible with the observed augmented toxicities when cyclosporin and tacrolimus are combined, has been the recognition that tacrolimus inhibits the cytochrome P-450 IIIA enzyme oxidase, resulting in sustained CsA levels.

Blood level monitoring

It has been demonstrated that pharmacokinetic parameters for tacrolimus vary substantially between individual patients, and at different times in the same patient. There is also significant inter- and intra-patient variability of bioavailability and clearance, with the net result being a poor correlation between tacrolimus dose and blood levels[36]. Since dose alone cannot be used to predict overall drug exposure (area under the curve, AUC), a parameter that correlates strongly with the efficacy and adverse effects of the drug, frequent monitoring of drug levels is essential.

All tacrolimus assays are based on the same monoclonal antibody. Initial clinical studies in Pittsburgh and elsewhere were performed based on plasma trough level, using an enzyme-linked immunosorbent assay (ELISA)[37]. Plasma target levels were between 0.5 and 2.0 ng/ml. More recently a microparticle enzyme immunoassay (IMx) has been used[38] to measure whole blood level, with target levels between 5 and 30 ng/ml. Advantages of this assay include more rapid turn-around time (1–3 vs 10–20 hours), greater sensitivity, and lack of temperature dependence (tacrolimus partitions into red cells as temperature drops).

Side-effects

Given that tacrolimus and CsA share a similar mechanism of action, it is not surprising that their clinical toxicities largely

overlap. The most prominent side-effects of both drugs include nephrotoxicity, neurotoxicity, impaired glucose metabolism, hypertension, and gastrointestinal disturbances. The incidence and degree of nephrotoxicity was similar among patients taking CsA and tacrolimus both in the US multicenter liver transplant trial and in the European trial[26,27]. Transient renal dysfunction immediately following transplantation is frequently observed with intravenous administration of tacrolimus or CsA. However, the degree of renal dysfunction has been minimized with a continuous 24-hour infusion, instead of bolus infusion, of tacrolimus, and concomitant administration[39,40] of low-dose prostaglandin E_1. Hyperkalemia is more common with tacrolimus than with CsA, and is reported to be independent of renal function[41,42]. However, it is easily managed with fludrocortisone (Florinef®),

Neurologic toxicity, which manifests as tremor, insomnia, headache, dizziness and photophobia, is somewhat more prominent in patients taking tacrolimus than in those on CsA[41–43]. In most cases these symptoms are dose-dependent and reversible. Severe neurologic toxicity, including aphasia, coma, and seizures, has been reported but is uncommon[43,44]. The incidence of new-onset diabetes mellitus and hypertension is similar with tacrolimus and CsA[41,42]. Hirsutism, coarsening of the facial features, and gingival hyperplasia, known side-effects of CsA, are notably absent with tacrolimus.

INITIAL CLINICAL TRIALS

Tacrolimus as a 'rescue' agent

In its first clinical trial, tacrolimus was used as a 'rescue' agent in liver transplant patients experiencing rejection refractory to conventional immunosuppression. This initial pilot study at the University of Pittsburgh included 11 liver transplant recipients[19]. In this trial CsA was gradually tapered off while tacrolimus was administered at full dose. Rejection was reversed in seven patients, while three had persistent rejection requiring retransplantation. Serious nephrotoxicity was frequently observed. As a result, in subsequent rescue patients, CsA was discontinued a minimum of 24 hours before tacrolimus was administered.

Later reports of patients rescued from refractory rejection under conventional CsA-based immunosuppression (125 patients with refractory rejection in the US multicenter FK506 liver transplant study group) showed a success rate of 70% at 3 months after treatment, with graft and patient survival at 1 year of 50% and 72%, respectively[45].

Tacrolimus as a primary immunosuppressant

Encouraged by the initial 'rescue' trial, a prospective single-center study of tacrolimus as a primary immunosuppressive agent for commonly transplanted organs (kidney, liver, pancreas, and heart) was launched at the University of Pittsburgh[19–23]. Tacrolimus was found to be an effective primary immunosuppressive agent. Early reports of hepatic transplantation showed 1-year patient and graft survival to be significantly higher than in historical controls. Steroid requirements and the incidence of clinical rejection were also substantially lower in the tacrolimus-treated group.

These initial results were confirmed by subsequent prospective, randomized, multicenter trials both in the USA and in Europe[26,27]. In the US trial, which consisted of 529 liver transplant recipients from 12 centers, primary endpoints were patient and graft survival at 1 year, while secondary endpoints included the incidence of acute rejection, corticosteroid-resistant rejection, and refractory rejection. There was no difference in patient or graft survival between the two groups. However, the incidence of acute rejection (68% tacrolimus vs 76% CsA, $p<0.002$), corticosteroid-resistant rejection (19% tacrolimus vs 36% CsA, $p<0.001$), and refractory rejection (3% tacrolimus vs 15% CsA, $p<0.001$) were all significantly less common in the tacrolimus group.

Similarly, the European trial, which enrolled 545 liver recipients from 19 centers, found no difference in patient or graft survival at 1 year, but did observe a significant reduction in acute, refractory acute, and chronic rejection episodes in the tacrolimus-treated group. In both trials the cumulative dose of corticosteroids administered for both prophylaxis and treatment of rejection was significantly lower in the tacrolimus-treated patients than in the CsA-treated group.

TACROLIMUS IN CARDIAC TRANSPLANTATION

Tacrolimus as a primary immunosuppressant

Tacrolimus has undergone clinical testing at the University of Pittsburgh on the thoracic transplantation service since October 1989. The initial and intermediate-term results have been reported elsewhere[22,23,46–48]. Between 1 January 1989 and 31 December 1994, 243 heart transplant recipients were enrolled in a non-randomized fashion to receive either tacrolimus- or CsA-based immunosuppression. Excluded from this analysis were patients undergoing retransplantation, those receiving multiple-organ transplants, and those dying within 7 days of transplantation from primary graft failure.

There were a total of 121 patients in the tacrolimus group and 122 in the CsA group. The CsA group included two subsets: (a) 72 patients who received CsA plus lympholytic induction (CsA + LI), with either OKT3 (11 patients) or rabbit anti-thymocyte globulin (ATG, 61 patients); and (b) 50 patients who received CsA alone, based on a modified triple-drug regimen described by Bolman and associates[49].

The tacrolimus regimen included 15 mg/kg of methylprednisolone given intraoperatively, with 5 mg/kg of methylprednisolone given in three divided doses on postoperative day 1, followed by 0.3 mg/kg per day in a single dose on subsequent days. Conversion to prednisone was accomplished upon resumption of oral intake. Gradual weaning from steroids was initiated 3 months after transplantation. Early in the trial, tacrolimus was given at a dose of 0.15 mg/kg per day, in two divided intravenous doses within 6–12 hours of transplantation. Due to a high incidence of renal dysfunction, dosing was decreased to 0.01–0.05 mg/kg per day as a continuous infusion, with conversion to oral tacrolimus, at 0.2–0.3 mg/kg per day in two divided doses, upon return of gastrointestinal function. Whole blood (IMx) target levels were maintained at 5–30 ng/ml in the first 2 months after transplantation. The level was subsequently reduced to 5–15 ng/ml, depending upon the patient's renal function and rejection pattern. Azathioprine (2 mg/kg per day) was added if

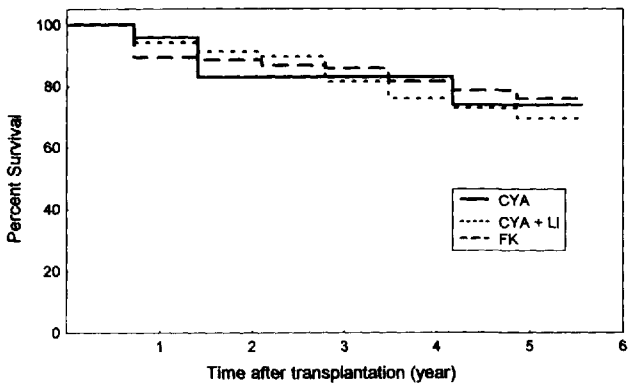

Figure 2 Actuarial survival following heart transplantation according to different immunosuppressive protocols. CYA = cyclosporin alone; CYA + LI = cyclosporin plus lympholytic induction; FK = tacrolimus

serum creatinine exceeded 2.0 mg/dl (to allow a reduction in the tacrolimus dosage), or if there was persistent rejection.

Acute rejection in both groups was treated initially with pulse steroids, while OKT3 was reserved for steroid-resistant rejection.

The tacrolimus and CsA groups were similar with the exception that the mean age in the tacrolimus group was lower than in the CsA group (34.2 ± 22.3 vs 47.8 ± 14.5 years; $p<0.05$). The mean duration of follow-up was longer in the tacrolimus group (3.2 ± 1.3 vs 2.3 ± 1.8 years; $p<0.01$).

One-year and 5-year actuarial patient survival rates were not significantly different (CsA alone: 91% and 74%; CsA + lympholytic induction {CsA + LI}: 93% and 69%; and tacrolimus: 90% and 76%) (Figure 2).

Actuarial freedom from rejection at 3 months for the CsA-alone group was 22%, significantly lower ($p<0.01$) than that of the CsA + LI (53%) and tacrolimus groups (47%) (Figure 3). The rate of rejection (episodes per 100 patient-days) in the tacrolimus group was significantly lower ($p<0.05$) than that of the CsA-alone or CsA + LI groups. Steroid boluses per 100 patient-days were lower in the tacrolimus group than in the CsA-alone ($p<0.01$) and the CsA + LI ($p<0.05$) groups (Table 2).

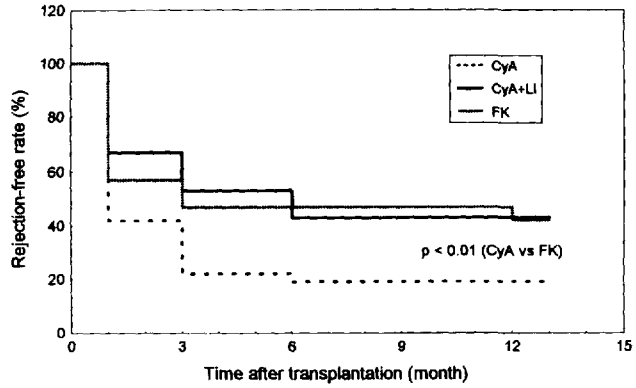

Figure 3 Actuarial freedom from rejection following heart transplantation according to different immunosuppressive regimens. CyA = cyclosporin alone; CyA + LI = cyclosporin plus lympholytic induction; FK = tacrolimus

Table 2 Rejection, and requirement for steroid boluses and lympholytic treatments, under different immunosuppressive protocols

	Immunosuppression		
	Tacrolimus	*CsA*	*CsA + LI*
Rejection-free rate at 30 days	47%	22%*	53%
Episodes of rejection†	0.09	0.26*	0.13**
Steroid bolus†	0.09	0.20*	0.11**
Lympholytic treatment†	0.009	0.06*	0.02

LI: lympholytic induction.
† per 100 patient-days.
* $p<0.01$ compared to tacrolimus group; ** $p<0.05$ compared to tacrolimus group

Thirteen patients in the CsA-alone and five patients in the CsA + LI groups experienced intractable rejection (refractory to at least one course of pulse steroids and one course of lympholytic treatment); all were successfully treated by conversion to tacrolimus. Only two patients in the tacrolimus group developed intractable rejection: one was rescued with methotrexate, while the other required total lymphoid irradiation.

Allograft coronary arteriopathy, defined as luminal irregularity or stenosis seen on coronary angiogram or the presence of diffuse coronary artery disease at autopsy, was evaluated in 183 patients. Actuarial freedom from allograft coronary disease at 4 years was 82% for the tacrolimus group (103 patients) and 73% for the CsA group (80 patients) (p = n.s.).

At last follow-up or at the time of death, 40 of 83 adult tacrolimus patients (48%) were free of steroids as compared to 16 of 95 adult CsA patients (17%) ($p<0.01$). Of those still on steroids, the average daily dose of prednisone was 5.8 ± 2.6 mg/day in the tacrolimus group and 8.0 ± 4.5 mg/day in the CsA group ($p<0.01$). The impact of tacrolimus was most dramatic in the pediatric group; 76% of the 42 pediatric recipients treated with tacrolimus were free of steroids. Of the 10 pediatric patients initially on CsA, eight required conversion to tacrolimus because they could not be weaned off steroids; all were eventually free of steroids.

Mean serum creatinine 1 year post-transplant was significantly higher in the tacrolimus (2.1 ± 0.5) group than in the CsA group (1.8 ± 0.5) ($p<0.001$). This difference disappeared by the second year. We believe that this early difference reflects a learning curve for the use of tacrolimus. New-onset hypertension was more prevalent in the adult CsA patients (84%) than in the tacrolimus patients (47%) ($p<0.01$).

Twenty-five adults and one pediatric patient (21%) who were on tacrolimus had persistent hyperkalemia ($K^+>5.0$ mEq/l) that required treatment. This was easily controlled with a low dose of fludrocortisone (0.2 mg/day). No patient died of hyperkalemia in this trial.

The prevalence of new-onset insulin-dependent diabetes mellitus was the same in both tacrolimus (26%) and CsA (22%) adult patients. One of 50 pediatric patients on tacrolimus (both as a primary agent, and after conversion from CsA) developed new-onset insulin-dependent diabetes mellitus.

Two pediatric patients in the tacrolimus group developed post-transplant lymphoproliferative disease (PTLD) at 4 and 5 months after transplantation; one resolved with reduction in immunosuppression and the other died of disseminated PTLD. Another pedi-

atric patient, who was initially on CsA, died of disseminated PTLD after conversion to tacrolimus. Of the adult patients, one in the tacrolimus group died of brain lymphoma; four in the CsA group died of other malignancies, comprising osteosarcoma (one), recurrent cardiac rhabdomyosarcoma (one), lung carcinoma (one), and testicular embryonal cell carcinoma (one).

Other side-effects of tacrolimus, which have been reported elsewhere[47] and include extremity paresthesias, akinetic mutism, myalgia, and tremor, were infrequent and transient. Notably absent in the tacrolimus group were gingival hyperplasia, hirsutism, and coarsening of facial features. No patients in the tacrolimus group had severe and persistent adverse events that required discontinuation of the drug.

In summary, although survival after cardiac transplantation with tacrolimus immunosuppression is similar to that with CsA immunosuppression, tacrolimus is associated with a lower rate of rejection. In addition, use of tacrolimus permits both lower doses of steroids, and more success in weaning from steroids. The incidence of new-onset hypertension is less in tacrolimus-treated patients. Finally, intractable rejection is more common in CsA-treated patients and shows an excellent response to conversion to tacrolimus.

Tacrolimus as a 'rescue' agent

We have evaluated tacrolimus as a 'rescue' agent for refractory rejection in 26 patients after an average of 435 days under cyclosporin-based immunosuppression. Refractory rejection was defined as persistent rejection of grade 3A or higher after at least one course of pulse steroids and one course of lympholytic therapy. In all patients, CsA was discontinued 1–2 days prior to initiation of tacrolimus. In 24 patients, tacrolimus successfully reversed the rejection within 2 weeks. One patient required an additional course of pulse steroids, while another needed both pulse steroids and OKT3 (after conversion to tacrolimus to reverse the rejection).

In view of the heavy immunosuppression received by this subset of patients prior to tacrolimus therapy (many had received multiple courses of pulse steroids and lympholytic treatment), it is not surprising that four had major infections, while another four developed PTLD. We believe that tacrolimus has an important role as a rescue agent for cardiac transplant recipients experiencing intractable rejection under CsA-based regimens. However, conversion to tacrolimus should be accomplished prior to heavy doses of adjunct immunosuppressive therapy to minimize the risk of PTLD and major infection.

TACROLIMUS IN LUNG TRANSPLANTATION

Encouraged by the results in heart transplantation we initiated a randomized trial comparing tacrolimus- and CsA-based immunosuppression for lung transplantation[40,50]. Between October 1991 and May 1994, 133 single and bilateral lung transplant recipients were randomized to receive either tacrolimus (66 patients) or CsA (67 patients). At the time of graft revascularization all patients were given an intravenous loading dose of azathioprine (4 mg/kg) and a 500 mg bolus of methylprednisolone. Postoperatively, azathioprine was continued at 2 mg/kg per day, with adjustment made to keep the white blood cell count greater than 5000 cells/mm^3.

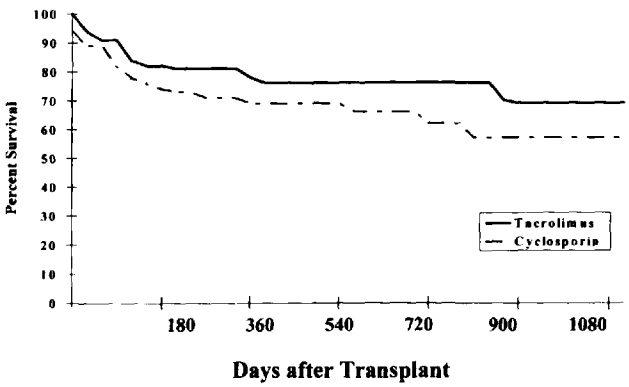

Figure 4 Actuarial survival following lung transplantation under tacrolimus and cyclosporin

Tacrolimus and CsA were administered intravenously at 6–8 hours after transplantation. Tacrolimus was administered at a dose of 0.025 mg/kg per day as a continuous infusion, and the dose was titrated to achieve whole blood levels of 10–20 ng/ml (serum levels of 0.5–2.0 ng/ml). Conversion to oral tacrolimus at a dose of 0.30 mg/kg per day in two divided doses was accomplished upon return of gastrointestinal function. Similarly, CsA was given initially at 2.5 mg/kg per day as a continuous intravenous infusion, and then by oral administration to maintain serum levels of 750–1000 ng/ml.

Overall survival in the groups was similar with respect to 1- and 2-year survival rates (83% and 76% for tacrolimus, and 71% and 66% for CsA) (Figure 4). The predominant causes of mortality in the perioperative period were ischemic lung injury followed by sepsis. Infection (primarily pneumonia) was the leading cause of death in the first year, while respiratory failure from obliterative bronchiolitis, with or without pneumonia, was responsible for six of nine late deaths.

The incidence of acute rejection (number of episodes per 100 patient-days) was lower in the tacrolimus group (0.85 $\pm$ 0.72) than in the CsA group (1.09 $\pm$ 0.72), although the difference did not reach statistical significance ($p = 0.07$).

Patients who survived 60 days or longer after transplantation, and therefore were considered at risk for developing obliterative bronchiolitis (OB), were analyzed separately. Of the 60 patients who received tacrolimus and were at risk, 13 developed OB (21.7%). In contrast, 19 patients (35.8%) treated with CsA developed OB ($p = 0.03$) (Figure 5). These intermediate-term results suggest that tacrolimus might reduce the incidence of OB.

Thirteen patients initially treated with CsA were switched to tacrolimus in the postoperative period. Indications for the conversion included persistent acute rejection in nine patients, with one case each of persistent chronic rejection (OB), acute nephrotoxicity, severe headaches with anorexia, and inability to obtain an adequate CsA level. In contrast, only two recipients initially treated with tacrolimus were converted to CsA – one for anorexia, and one for inability to maintain an adequate tacrolimus level. Six of the nine patients with persistent rejection resolved their rejection after conversion to tacrolimus.

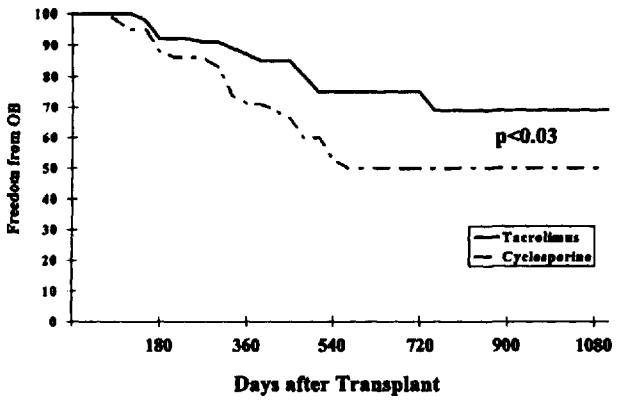

Figure 5 Freedom from obliterative bronchiolitis (OB) in lung transplant recipients treated with tacrolimus versus cyclosporin

At 1 year following transplantation the extent of renal impairment was similar in the two groups with serum creatinine levels averaging 1.95 ± 0.72 mg/ml for patients receiving tacrolimus and 1.68 ± 0.6 mg/ml for CsA recipients. The frequency of new-onset hypertension was similar in the two groups.

Tacrolimus was associated with a reduction in the incidence of obliterative bronchiolitis, a histologic manifestation of chronic rejection. We hope that with further follow-up this reduction in acute and chronic rejection will translate into improved survival.

COMMENT

Tacrolimus is proving an important immunosuppressant for heart and lung transplantation. While tacrolimus and CsA share a similar mechanism of action, clinical experience has demonstrated several distinct advantages of a tacrolimus-based immunosuppression protocol. These include a lower incidence of acute rejection in cardiac transplantation, and a trend toward less acute rejection and a lower incidence of obliterative bronchiolitis in lung recipients. Tacrolimus is highly successful in rescuing recipients of heart and lung transplants who have refractory rejection under CsA-based immunosuppresion. Notably absent in the tacrolimus group are the side-effects of hirsutism, gingival hyperplasia, and facial 'brutalization'. The lack of these cosmetic effects, as well as the reduced requirement for steroids, in the tacrolimus group have made tacrolimus a preferred drug for heart and lung transplant recipients at the University of Pittsburgh, particularly in the pediatric group.

Infection in Patients Undergoing Thoracic Organ Transplantation: Epidemiology, Pathogenesis, and Clinical Management

S.J. THALER AND R.H. RUBIN

INTRODUCTION

Over the past several decades, remarkable progress has been made in the management of patients with advanced cardiac and lung disease – medications such as angiotensin-converting enzyme inhibitors for the management of heart failure, implantable defibrillators for the prevention of cardiac sudden death, such new antibiotics as the fluoroquinolones and imipenem in the treatment of pulmonary infection, and exercise rehabilitation programs have all increased in the quality of life for these patients. However, all of these measures represent disease palliation rather than curative therapy and, in recent years, it has become apparent that the best chance for rehabilitation for patients with advanced cardiac and pulmonary disease (as it is for patients with advanced liver and renal disease) occurs with transplantation[1].

In the United States at the present time the 1-year allograft and patient survival rates following cardiac transplantation are 81% and 82%, respectively; following single lung allografts, 67% patient and graft survival; and following heart–lung allografts 53%. Even more remarkable is that the 5-year survival rate for cardiac allografts now approaches 70%[2]. Reflecting these successes, there are now approximately 1500 cardiac transplants, 500 lung transplants, and 200 heart–lung transplants performed in the United States each year, with approximately 80% of the world's cardiac transplants performed since 1985 and 90% of the lung transplants since 1988[1,2]. Transplantation of the thoracic organs as the treatment for end-stage disease of the heart and lungs has evolved over the past decade from an interesting experiment in human immunobiology to the most practical means of rehabilitating a growing patient population.

Despite this progress, three major hurdles must be overcome in every patient if transplantation is to be successful: the availability of a suitable donor organ in a timely fashion; host immunologic attack of the allograft in acute and chronic rejection processes; and the occurrence of life-threatening infection.

The first two of these are covered in other sections of this monograph; it is the purpose of this chapter to delineate the epidemiology, pathogenesis, and clinical management of infection in patients undergoing thoracic organ transplantation. The importance of these issues is illustrated by the following statistics: more than two-thirds of cardiac allograft recipients have at least one infectious episode in the first year post-transplant, with an even greater number of infectious events occurring in lung allograft recipients[3]. It is also important to emphasize that infection and rejection are intimately linked by the requirement for immunosuppressive therapy. An important axiom of organ transplantation is that any intervention that decreases the risk of infection will permit the more aggressive treatment of rejection, thus salvaging more allografts; conversely, any intervention that decreases the risk of rejection will allow the use of lesser amounts of immunosuppressive therapy, thus decreasing the risk of infection, and resulting in the salvage of more lives. *The therapeutic prescription, then, for the transplant recipient has two components: an antirejection program and an antimicrobial program to make it safe*[1].

RISK OF INFECTION IN THE ORGAN TRANSPLANT RECIPIENT

The risk of infection in the organ transplant recipient is largely determined by the interaction between the nature of the *epidemiologic exposures* the patient encounters and the patient's *net state of immunosuppression*. Table 1 delineates the epidemiologic

Table 1 Epidemiologic exposures of particular importance in the thoracic organ transplant recipient

A.	*Within the community*
	1. The geographically restricted systemic mycoses (histoplasmosis, coccidioidomycosis, and blastomycosis)
	2. Mycobacterial infection
	3. *Strongyloides stercoralis*
	4. Respiratory viruses (influenza, parainfluenza, respiratory syncytial virus, etc.)
B.	*Within the hospital*
	1. *Aspergillus* species
	2. *Legionella* species
	3. *Pseudomonas aeruginosa* and other Gram-negative bacilli

exposures of importance. These can be divided into two general categories: those occurring in the community and those that occur within the hospital environment. Within the community the issues are reactivation of such long-dormant processes as tuberculosis, one of the geographically restricted systemic mycoses (blastomycosis, coccidioidomycosis, and histoplasmosis), and strongyloidiasis; and acute, rapidly progressive infection with one of these or, more commonly, such acute respiratory viruses as influenza, respiratory syncytial virus, and others that may be circulating in the community. The general pattern for all these infections is systemic dissemination and/or a high rate of bacterial superinfection. For the clinician it is clear that a careful epidemiologic history of both recent and remote exposures is important in evaluating in infectious disease episode[1].

Within the hospital environment, such infections as invasive aspergillosis, legionellosis, and Gram-negative infection can be even more important problems, with an opportunity for nosocomial epidemics being constantly present. Two general epidemiologic patterns are observed with these nosocomial outbreaks: *domiciliary* spread, in which exposure occurs on the ward where the patient is housed, due to contaminated air or potable water, with identification of the outbreak being relatively easy because of clustering of cases in time and space; and *non-domiciliary* spread, in which exposure occurs as the patient travels to the radiology suite, the catheterization laboratory, or operating room for an essential procedure. This latter form of epidemic is far more difficult to identify because of the lack of clustering, but is far more common than the domiciliary outbreak. The leading clue to the presence of such a problem is the occurrence of an opportunistic infection at a point in time when the net state of immunosuppression would not normally allow it to occur (see below)[1].

The net state of immunosuppression is a complex and evolving state which is composed of a number of factors (Table 2). Of particular importance are the direct and indirect effects of the immunosuppressive regimen. It is clear that the prime determinant of infection risk is the dose, duration, and temporal sequence in which immunosuppressive drugs are deployed. These not only inhibit multiple limbs of the host defense system (particularly the microbial-specific, MHC-specific T-cell response which is so important in the control of herpes group viruses, fungi, mycobacteria, and other organisms), but also cause the reactivation and amplification of a group of immunomodulating viruses. It is now apparent that such viruses as the herpes group viruses, hepatitis B and C viruses, and the human immunodeficiency virus contribute significantly to the net state of immunosuppression. It is also apparent that a key determinant of the effects of these viruses is the nature of the immunosuppressive program being administered. The most critical of these interactions is the effect of immunosuppressive therapy on cytomegalovirus (CMV), the single most important infection in transplantation. The antilymphocyte antibodies, both the polyclonal antithymocyte globulins and the monoclonal OKT3, have potent effects in reactivating latent virus (in contrast to such drugs as cyclosporin, FK506, rapamycin, and corticosteroids). Once active, replicating virus is present, then these latter drugs have a marked amplifying effect on the virus due to their potent suppressive effects on the key cytotoxic T-cell response[1,4,5].

Table 2 Factors contributing to the net state of immunosuppression in the thoracic organ transplant recipient

1. Dose, duration, and temporal sequence of immunosuppressive therapy
2. Presence of another immunosuppressing condition
3. Neutropenia
4. Presence of indwelling foreign bodies or other factors that compromise the first line of defense against infection: the mucocutaneous surfaces of the body
5. Protein–calorie malnutrition
6. Such metabolic factors as uremia and hyperglycemia
7. Infection with one or more of the immunomodulating viruses (CMV, EBV, HBV, HCV, and HIV)

In addition to these complex interactions it is important for the clinician to recognize that other, more controllable factors contribute to the risk of infections. The vascular access devices, drainage tubes, catheters and other equipment such as pacing wires and stents that are essential for management in the early post-transplant period are important risk factors for infection. Extended intubation greatly increases the risk of pneumonia and sinusitis, and any extended period in the intensive-care unit markedly increases the risk of antimicrobial-resistant infection. Patients with difficulty in the first 2 weeks post-transplant also receive more than their share of antibiotics, which significantly increases their subsequent risk of antimicrobial-resistant infection, antibiotic-associated diarrhea, and loss of appetite. Malnutrition is extremely common in these individuals, with one measure of this, a low serum albumin, being linked to increased in-hospital mortality – usually due to infection[1].

TIMETABLE OF INFECTION IN THE ORGAN TRANSPLANT RECIPIENT

As immunosuppressive programs have become standardized, it has become apparent that there is a temporal pattern of the times at which different infections occur in the post-transplant period; that is, although such infectious disease syndromes as pneumonia can occur at any time point post-transplant, the microbial etiologies are very different at different time points. In the organ transplant patient the 'timetable for infection' can be divided into three periods: the first month post-transplant, the period 1–6 months post-transplant, and the late period, more than 6 months post-transplant (Figure 1)[1].

In the first month post-transplant there are three categories of infection that become clinically manifest[1]: infection that was present in the allograft recipient prior to transplant; infection conveyed with the allograft; and infection related to technical issues involved with the operative and perioperative management. For heart, lung, and heart–lung transplant recipients, many of whom are critically ill prior to the transplant, the most common pretransplant infections that will have a post-transplant impact are pneumonia and vascular access bacteremia, both of which will be exacerbated in the peritransplant period. Indeed, all active infection of the lungs and blood stream should be eradicated prior to transplant. As far as a contaminated allograft is concerned, infection, particularly with *Staphylococcus aureus*, Gram-negative bacilli, and *Candida* species, carries a high probability of seeding of the vascular anastomotic site, with the subsequent development of a mycotic aneurysm and catastrophic disruption of the anastomosis[6–11]. Contamination of the allograft, resulting in this disas-

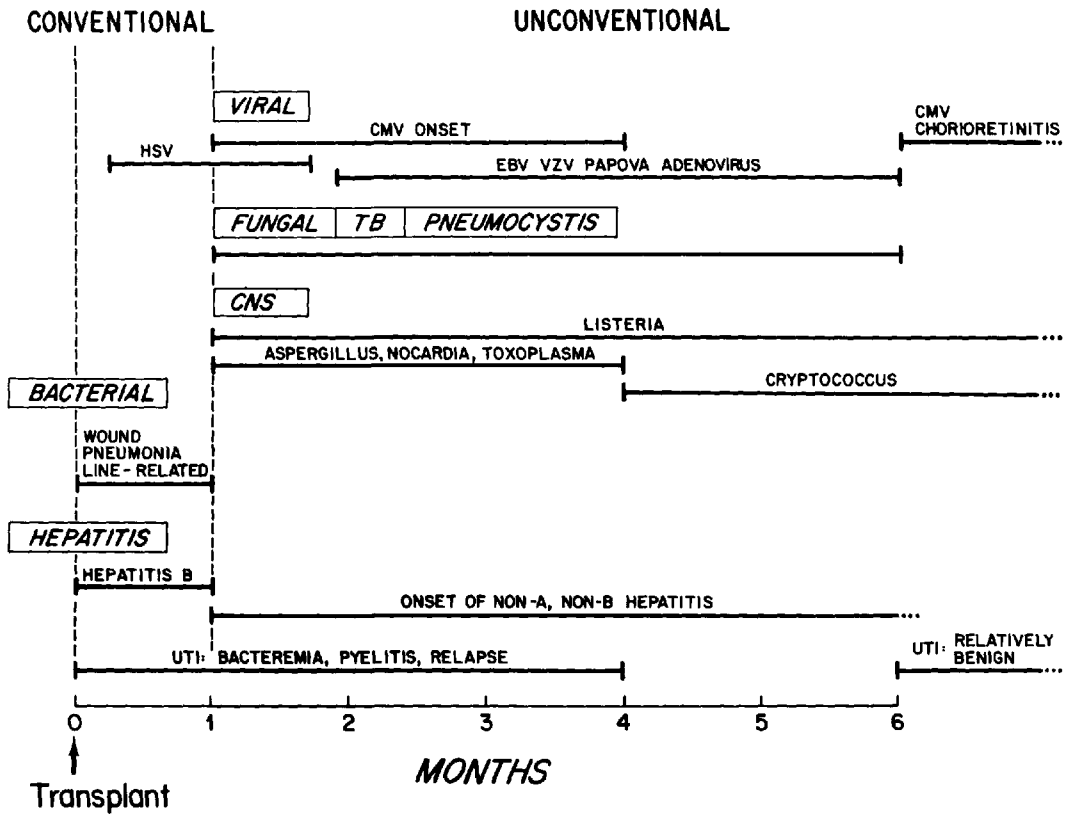

Figure 1 Timetable for the expected occurrence of different infections following thoracic organ transplantation (Modified from ref. 1)

trous sequence of events, may occur as a result of bacteremia or candidemia in the donor, contamination from respiratory flora during the harvesting procedure, or the handling of the organ prior to implantation.

More than 95% of the infections occurring in the first month post-transplant are the same bacterial and candidal infections of the surgical wound, lungs, urinary tract, and vascular access sites that occur in non-transplant patients undergoing comparable surgery, although the impact is greater in the transplant patient[12–15]. The key determinant in the development of these infections is the technical skill with which the operation is performed, the endotracheal tube managed, and the various vascular and drainage catheters assessed. A technical error in these patients is a virtual guarantee of potentially life-threatening infection. Prophylactic antibiotics at the time of the surgery can decrease the incidence of wound infection, but are of less importance than the technical outcome of the surgical operation.

Notable by their absence during this first month 'golden period' are opportunistic infections due to such organisms as *Pneumocystis carinii*, *Aspergillus* species, *Listeria monocytogenes*, etc. The net state of immunosuppression during this first month is normally not great enough for these to occur, *unless an unusually intense epidemiologic exposure has occurred.* There are two important implications of this observation. First, since the daily doses of immunosuppressive drugs are at their highest in this first month post-transplant, it is apparent that the duration of immunosuppression (the 'area under the curve'), the intensity over time, is a more important determinant of the net state of immunosuppression than is the daily dose administered. Second, the occurrence of a single case of opportunistic infection during this time period should be regarded as evidence of an excessive nosocomial hazard, and is usually an early indicator of a potential nosocomial epidemic[1].

During the period 1–6 months post-transplant the infections that occur may be divided into two categories, the second being in part dependent upon the first. By far the most important infections during this time period are those caused by the immunomodulating viruses: cytomegalovirus (CMV), Epstein–Barr virus (EBV), the two hepatitis viruses, B and C (HBV and HCV), and the human immunodeficiency virus (HIV). These not only cause infectious disease syndromes directly during this time period (e.g. CMV is the most common cause of fever in this time period), but contribute significantly to the net state of immunosuppression[16–18]. The combination of sustained immunosuppressive therapy and immunomodulating viral infection now makes it possible for opportunistic infection, particularly due to *Pneumocystis carinii*, *Listeria monocytogenes*, and *Aspergillus* species, to occur in this time period[1].

In the late period, more than 6 months post-transplant, transplant recipients can be divided into three groups in terms of their infectious disease risks: the majority (>75% overall) will have intact graft function without the continuing need for high-dose immunosuppressive therapy. These patients are at minimal risk for opportunistic infection; rather their problems resemble those

of the general community – influenza and other community-acquired respiratory virus infections, pneumococcal pneumonia, and urinary tract infection. In a small fraction of patients (approximately 10%), chronic, active viral infection persists, resulting in the inexorable development of end-organ failure (e.g. the liver from the hepatitis viruses or the retina from CMV), malignancy (e.g. hepatocellular carcinoma as a result of chronic hepatitis or squamous-cell carcinoma as a result of chronic papillomavirus infection, or the acquired immunodeficiency syndrome (AIDS) from HIV. Finally, approximately 15% of patients will have suffered recurrent bouts of acute and chronic rejection, requiring significantly greater amounts of acute and chronic antirejection therapy. Many of these patients will also have chronic immunomodulating virus infection. The end-result is the group of patients with the greatest net state of immunosuppression and the highest risk of opportunistic infection with such organisms as *Pneumocystis carinii*, *Cryptococcus neoformans*, and *Listeria monocytogenes*. Because of this risk, these 'chronic n'er-do-wells' are candidates for preventive therapy with low-dose trimethoprim-sulfamethoxazole and fluconazole on an ongoing basis[1].

Early bacterial or fungal infections following thoracic transplantation

The most common form of early infection following heart transplantation is bacterial pneumonia. Thus, in a recent review of 814 patients from 24 centers, bacterial invasion accounted for 47% of all infections, with pneumonia being the most common form of bacterial infection encountered[14]. Vascular access-related bacteremia, urinary tract infection, and gastrointestinal tract infection (particularly diverticulitis) are also not uncommon. The microbial species responsible for such infections are typical of those causing infection in seriously ill surgical patients: *Pseudomonas aeruginosa*, *Klebsiella* species, *Staphylococcus aureus*, and *Candida* species. Interestingly, wound infections following heart transplantation are relatively uncommon, a testimony to good surgical technique and the efficacy of perioperative antibiotic prophylaxis.

Lung and heart–lung recipients may be considered together, as the infectious disease problems of the latter more closely resemble those of the lung than the cardiac recipient. Once again, bacterial pneumonia is the most common serious early infection, occurring in 35–45% of patients, with Gram-negative bacilli and *S. aureus* being the most important pathogens[19–22]. A number of physiologic reasons explain this high rate of pneumonia: diminished cough reflex, prolonged intubation, abnormal mucociliary clearance, the abnormalities inherent in the bronchial anastomosis (which is particularly susceptible to ischemic injury), abnormal lymphatic drainage, prior colonization with organisms of either donor or recipient origin, as well as the most obvious reason – the lung is the only transplanted organ *in direct communication with the outside world*. Of interest, in a canine animal system, contamination of the donor trachea predicted pneumonia in the recipient[8,23]. The infecting organism did not always correlate with the donor flora; rather, the presence of bacteria was probably an indicator of impaired microbial clearance, setting the stage for overgrowth and pneumonia in the recipient.

A particular problem in the lung transplant patient is pretransplant colonization of the tracheobronchial tree with either *Aspergillus* species or *Pseudomonas cepacia* (both particular issues in patients with cystic fibrosis). In the case of *Aspergillus* colonization, unless eliminated, there is a >50% risk of either invasive pulmonary aspergillosis or a localized necrotizing infection at the bronchial suture line post-transplant[24,25]. Pretransplant and/or post-transplant colonization of the tracheobronchial tree with *P. cepacia* has been associated with a significantly worse prognosis for the successful rehabilitation and/or survival of the lung or heart–lung transplant recipient[26,27].

Mediastinitis and/or deep infection of the chest wound occurs more commonly in lung transplant recipients than in cardiac transplant recipients (13.5% vs 8.0%), reflecting the increased technical challenges associated with lung transplantation[19,28,29]. Although such unusual organisms as *Mycoplasma hominis* and *Legionella* species have been reported in these patients, the great majority of such infections are due to Gram-negative bacilli, *S. aureus*, and *Candida* species[30,31].

Infection due to herpesviruses following thoracic transplantation

All herpesviruses (which include CMV, EBV, herpes simplex virus types 1 and 2 (HSV-1 and HSV-2), varicella-zoster virus (VZV) and human herpesvirus-6 (HHV-6) exhibit three characteristics that make them particularly effective pathogens in the transplant recipient: *latency*, *cell association*, and *oncogenicity*[32]. The term 'latency' connotes dormant infection of cells capable of being reactivated; that is, herpesviruses incorporate their genomic DNA into the host chromosomes, with no active viral RNA transcripts produced during the latent state. Once activation occurs, viral RNA is again produced, with viral replication now proceeding. The laboratory marker for the presence of latent herpesvirus infection is the presence of circulating antibody to the particular virus (seropositivity).

In the case of CMV, VZV, and HHV-6, latency is quite stable, requiring particular stimuli (antilymphocyte antibody therapy, an allogeneic reaction, and pregnancy being common stimuli causing reactivation, especially in the case of CMV); in the case of EBV and HSV, although the same stimuli will reactivate virus, spontaneous reactivation or other relatively minor stimuli (e.g. stress, menses, ultraviolet light, etc. – especially in the case of HSV) can result in active viral replication[33,34]. Thus, approximately 25% of transplant patients at any one time have active replicating EBV, with this figure rising to >80% in the face of antilymphocyte antibody therapy of rejection[35]. Whatever the cause of herpesvirus reactivation, cyclosporin, FK506, and high-dose steroid therapy will amplify the level of virus replication due primarily to the interference with the key host defense – a virus-specific, MHC-specific, cytotoxic T-cell response. This is the key host defense against these viruses (although non-specific NK cell activity may also offer some protection), as the highly cell-associated nature of these viruses renders humoral immunity inefficient, and this limb of host defense of prime importance. Finally, all herpesviruses should be considered potentially oncogenic, although clear-cut evidence of this effect has been shown only in the case of EBV and its role in the pathogenesis of B cell lymphoma[36,37].

The impact of CMV on thoracic transplantation

CMV is by far the most important of the herpesviruses in terms of its impact on the outcome of transplantation[38–44]. Not only does it directly cause a variety of infectious disease syndromes (e.g. mononucleosis, pneumonitis, hepatitis, gastrointestinal tract inflammation and ulceration, myocarditis, chorioretinitis, etc.) in the transplant patient, it also has significant indirect effects on the transplant patient. These indirect effects, probably caused by cytokines elaborated in the course of CMV infection, include the following: an increase in the global state of immunosuppression, thus predisposing to opportunistic superinfection; a possible role in the pathogenesis of EBV-associated lymphoproliferative disease; and a probable role in the pathogenesis of both acute allograft injury and such manifestations of chronic allograft injury as accelerated coronary artery atherosclerosis and bronchiolitis obliterans[1].

CMV infection occurs predominantly 1–4 months post-transplant. Although evidence of viral replication (isolation of virus from urine or respiratory secretions, or rise in antibody titer) can be found in >50% of heart, lung, and heart–lung transplant recipients, the best laboratory marker for the presence of *clinically significant disease* is the demonstration of viremia[45–47]. Viremia, as defined by cultural techniques, by an antigenemia assay, or by polymerase chain reaction (PCR), is usually demonstrable 3–8 days prior to the onset of clinical disease, with >60% of these individuals developing symptomatic infection.

There are three general patterns of CMV infection, each having a different potential for causing symptomatic CMV disease[1]:

(1) *Primary* CMV infection, which occurs when a seronegative recipient becomes infected with CMV following the transfer of latently infected cells from a seropositive donor (a D+ R– transplant). More than 90% of the time the source of these latently infected cells is the allograft; however, viable leukocyte-containing blood products from a seropositive donor can also be a source of primary infection. More than 60% of individuals at risk for primary infection will develop symptomatic disease, with lung transplant patients apparently having an even higher attack rate.

(2) *Reactivation* CMV infection, which occurs when a seropositive recipient reactivates his or her endogenous virus from latency (an R+ transplant, with the donor status being irrelevant). Interestingly, although >50% of these patients will reactivate virus, only a minority (an estimated 20%) become ill, unless antilymphocyte antibody therapy is used to treat rejection, in which case the incidence of symptomatic disease rises to >60%.

(3) CMV *superinfection* occurs when an allograft from a seropositive donor is transplanted into a seropositive recipient (a D+ R+ transplant), and the virus that is reactivated is of donor origin (this occurs in approximately 50% of such transplants). It has been suggested that the attack rate for clinical disease is significantly greater for those patients with superinfection with the donor virus as opposed to reactivation with their endogenous viral strain. The known genetic and antigenic heterogeneity of CMV strains in nature makes this a plausible hypothesis, although definitive proof remains to be gathered.

The direct clinical effects of CMV infection are similar in all forms of organ transplantation: fever, often with accompanying leukopenia and thrombocytopenia, pneumonia (the most common of the life-threatening manifestations of CMV infection), hepatitis, and gastrointestinal inflammation and ulceration[48–52]. The major difference among the different forms of organ transplantation is that the organ transplanted is more severely affected than a native organ. Thus, pneumonia is a far more common and severe problem in recipients of lung and heart–lung transplants than in the other forms of transplantation, and myocarditis due to CMV is recognized almost exclusively in heart transplant patients[53,54]. Thus, Ettinger *et al.* found that among 52 lung recipients, the attack rate for pneumonia was 80% for those at risk for primary infection (D+ R–), and 75% among all recipients[43].

The incidence and severity of CMV disease are strongly influenced by two factors: the nature of the immunosuppressive therapy administered, and the past experience of donor and recipient with the virus (as denoted by the presence or absence of seropositivity). Two population groups have been shown to have >60% incidence of symptomatic disease due to CMV infection: D+ R– transplant recipients (primary infection); seropositive (R+) patients treated with antilymphocyte antibody therapy (either the polyclonal antithymocyte globulin or the monoclonal OKT3). Seropositive patients treated with induction antilymphocyte antibody therapy have an increase in CMV disease from approximately 10% to 24%; those treated with an antilymphocyte antibody for rejection have an increase from approximately 20% to >60%[5,55]. Recent evidence suggests that the release of tumor necrosis factor (TNF) is the key factor in these events: TNF acts as a promoter for the immediate early antigen of CMV, activating the virus from latency[56–58]. The increased amount of TNF elaboration in association with antirejection therapy, as opposed to induction therapy with antilymphocyte antibodies, is presumably responsible for the observed difference in CMV disease.

This proposed mechanism also explains two other observations: the occurrence of CMV disease following allograft rejection regardless of the immunosuppressive therapy employed; and the occurrence of CMV following bouts of urosepsis or bacterial pneumonia. In all of these instances TNF elaboration occurs, and CMV is reactivated; whether or not symptomatic CMV occurs, then, depends on the host's ability to control the replicating virus. This, in turn, is determined by the host's responsiveness to the virus, which is a function of the intensity of the immunosuppression being administered (particularly the amount of cyclosporin and FK506 being administered) and the past experience with the virus.

The potency of cyclosporin and FK506 in inhibiting the critical host defense against CMV, the virus-specific cytotoxic T-cell response, is further underlined by another clinical phenomenon: in the pre-cyclosporin era, relapsing CMV disease was essentially unheard of; at present, clinical relapse (defined as the occurrence of symptomatic disease within 6 weeks of completion of a 2–3-week course of intravenous ganciclovir for symptomatic disease which eradicated clinical evidence of CMV infection) occurs in approximately 20% of patients with symptomatic disease[38]. This figure, however, is somewhat deceiving in that the incidence of relapse is only about 10% in the R+ patients, whereas it is >60% for the D+ R– patients, again emphasizing the importance of the host's past experience with the virus.

The most important indirect effects of CMV infection are its contribution to the net state of immunosuppression and its possible role in the pathogenesis of allograft injury. As far as the first of these is concerned, both in the murine model and in humans there is abundant evidence that CMV adds significantly to the net state of immunosuppression, predisposing particularly to those opportunistic infections that are susceptible to cell-mediated immunity: aspergillosis, pneumocystosis, listeriosis, and disseminated candidiasis being notable examples[59–62]. CMV-induced leukopenia is an important marker for profound virus-induced immunosuppression.

Perhaps the most fascinating potential role of CMV is as a causal factor in the chronic vasculopathy of cardiac allograft atherosclerosis and bronchiolitis obliterans in the lung allograft[63,68]. In 1989 the Stanford group published compelling data on 301 cardiac transplant patients, 210 of whom were free of CMV infection[63]. The incidence of acute rejection, graft atherosclerosis, and patient death from atherosclerosis (as well as opportunistic fungal infection) were all greater in the CMV group. Since then a number of investigators have published series suggesting that acute and chronic rejection are more likely during chronic stimulation by CMV infection. The same has been suggested of bronchiolitis obliterans following lung transplantation[69]. Other groups have not found such associations[70]. If CMV is playing a role here, it is unlikely that the damage to the allografts is solely due to either direct viral injury or immunologic cross-reactivity (due to homologies between CMV antigens and certain MHC antigens). Rather, it is our belief that there is a link between allograft injury and CMV, that being the elaboration of cytokines in the course of the infection. These cytokines then modulate the display of MHC antigens on the allograft, as well as the host's response to these antigens[71–73]. Thus, CMV's effects are not the only way to cause those events that lead to serious graft injury; but rather, given the ubiquity of this virus in this patient population, CMV is an important way to enter this final common pathway.

Given the importance of CMV infection, a great deal of effort has been invested in the treatment and prevention of CMV disease[74–82]. Intravenous ganciclovir, at a dose of 5 mg/kg twice daily (with dosage corrections for renal dysfunction) for 2–3 weeks, is the standard of care for treating CMV, with many groups adding anti-CMV immunoglobulin to the regimen in patients seriously ill (as with pneumonia), those with primary infection, and those with relapsing disease. Foscarnet has not been an important therapy in transplant patients, for two reasons: ganciclovir-resistant infection in transplant patients, as opposed to AIDS patients, is essentially unknown; and foscarnet's toxicities for the transplant patient population appear to be significantly greater.

Table 3 delineates the various prophylactic programs that have been tried in patients to prevent CMV disease following thoracic transplantation and their efficacy. At present, although it is clear that the optimal program remains to be defined, the following conclusions appear to be warranted.

(1) One month of intravenous ganciclovir is effective prophylaxis against CMV disease for R+ patients.
(2) The addition of ganciclovir at a dose of 5 mg/kg per day intravenously to regimens that include antilymphocyte antibody therapy provides important added protection to any preventative program (so-called pre-emptive therapy).
(3) The relative values of combined immunoglobulin + antiviral regimens, sequential programs (intravenous ganciclovir followed by oral therapy with either oral ganciclovir or high-dose acyclovir) remain to be established.
(4) New laboratory approaches to diagnosing preclinical viremia (antigenemia assay or PCR) may permit the use of pre-emptive therapy on the basis of presymptomatic diagnosis of systemic infection.

The impact of Epstein–Barr virus on thoracic transplantation

Essentially all adults have experienced infection with the Epstein–Barr virus, with this occurring in developed countries predominantly in adolescence and young adulthood. EBV infects two cell types: primary infection of the epithelial cells of the upper respiratory tract, particularly the oropharynx and parotid duct, followed by secondary B lymphocytes traveling through the oropharyngeal lymphoid tissue[33]. Infection of epithelial cells is lytic, whereas in B cells infection results in transformation and immortalization. Control of this infection, including the immortalized B cells, is primarily via the host's cytotoxic T-cell response. The clinical consequence of these events in the immunocompetent individual is infectious mononucleosis, an illness characterized by fever, cervical adenopathy, pharyngitis, hepatosplenomegaly, and both an absolute and atypical lymphocytosis.

In the transplant patient there is little impediment to ongoing B cell transformation and the proliferation of transformed clones, because of the marked inhibition of the virus-specific cytotoxic T cell response[35]. In EBV seropositive individuals, reactivation of viral replication in the pharynx is quite common, occurring in 20–30% of those being treated with baseline immunosuppression, with this percentage rising to >80% with antilymphocyte antibody therapy. Although usually asymptomatic, EBV may cause a mononucleosis-like syndrome in the seropositive patient that is

Table 3 Current prophylactic programs against herpesviruses for thoracic organ transplant recipients*

Donor serologic status	*Recipient serologic status*	*Current recommendations*
Positive	Negative	4–6 weeks of intravenous ganciclovir, followed by 3 months of oral ganciclovir, ± hyperimmune anti-CMV globulin
Positive or negative	Positive	Intravenous ganciclovir for 2–4 weeks followed by high-dose oral acyclovir for 3–4 months
Negative	Negative	Intravenous acyclovir during anti-lymphocyte antibody therapy (against Epstein–Barr virus)

* Based on currently available information these are the programs we currently utilize. As new data appear, revisions will be made. In addition, intravenous ganciclovir is administered during antilymphocyte antibody therapy (unless donor and recipient are both seronegative for cytomegalovirus, in which case intravenous acyclovir is utilized)

indistinguishable from that caused by CMV. Far more important is the occurrence of EBV-associated post-transplantation lymphoproliferative disease (PTLD), which has been particularly common in lung and heart–lung transplant recipients (an incidence of 5–10%, as compared with an incidence of 1–2% in kidney transplant recipients)[83]. Factors particularly associated with the occurrence of PTLD include primary EBV infection (which primarily occurs in children), intensive immunosuppressive regimens that combine antilymphocyte antibody therapy with cyclosporin or FK506, and preceding symptomatic CMV disease[84–87]. This last may be due to the effects of cytokines elaborated in the course of the CMV infection, or merely due to similar effects of immunosuppressive therapy on these closely related herpesviruses.

Pathologically and clinically, PTLD should be regarded as encompassing a continuum from polyclonal lymphoid hyperplasia to a monoclonal, frankly malignant picture[88]. Symptomatically there is likewise a broad spectrum of disease, with fever, gastrointestinal bleeding, hepatitis, infiltration of the allograft, tonsillitis, bone marrow invasion, and invasion of the central nervous system singly or in combination all being possible. Unlike the situation with lymphoma in non-immunosuppressed patients, PTLD is not infrequently extranodal in presentation.

With evidence that the level of replicating virus present in the pharynx is predictive of the risk of PTLD, and the fact that acyclovir and ganciclovir can turn off EBV replication, it is hoped that the same kind of antiviral programs being developed for CMV prevention may be useful in the prevention of PTLD. Once PTLD develops, it is not yet clear what is optimal management. The role of the antivirals is biologically limited to controlling lytic infection in the pharynx, and has no effect on the episomal form of the virus present in the infected B cells. Thus, antiviral therapy is of only limited efficacy[89–91]. All patients require a significant decrease in immunosuppression, particularly in the use of cyclosporin, FK506, and antilymphocyte antibodies, with an estimated 20% responding to this course of action alone[92]. In patients with localized gastrointestinal tract disease, resection and radiation have been effective. For more widespread disease, survival is poor, although conventional antilymphoma chemotherapy is advocated. Because of the limited success of such programs, experimental therapies with T-cell infusions, anti-B cell antibodies, and α-interferon are currently also being evaluated[93].

The impact of herpes simplex virus on thoracic transplantation

Infections with both HSV-1 and HSV-2 are common in the general population, and approximately 75% of transplant recipients will excrete the virus post-transplant as a result of immunosuppression-induced reactivation[94,95]. About two-thirds of these will have symptomatic mucocutaneous lesions if no antiviral therapy is administered. In addition, a rare patient has acquired primary infection at the time of transplant, resulting in rapid systemic dissemination, multiorgan failure, and death unless early diagnosis and therapy are effected[96–98].

The most common clinical manifestation of HSV infection in transplant recipients is an aggressive form of herpes labialis, with large, ulcerating, hemorrhagic lesions around the mouth, anus, and/or genitalia. This disease process can extend into the tracheobronchial tree or esophagus, most commonly in the presence of an endotracheal tube or a nasogastric tube.

Patients undergoing heart–lung or lung transplantation appear to be at particular risk for pneumonitis due to HSV. In one recent series of 51 heart–lung recipients, nine HSV-seropositive recipients developed severe mucocutaneous disease and another six developed pneumonitis, five of whom died[95]. The high rate of viral excretion, local disease and the risk of pneumonitis all mandate the use of antiviral prophylaxis in lung and heart–lung patients. Fortunately, either acyclovir or ganciclovir is equally effective in this regard, and HSV prevention should be regarded as part of the general antiviral program aimed also at CMV and EBV. In cardiac allograft recipients, because the incidence of severe disease is more unusual, early intervention with acyclovir is an alternative to prophylaxis.

The impact of varicella-zoster virus on thoracic transplantation

Infection with VZV in the setting of transplantation is quite different in the pediatric and adult transplant populations. By the age of 15, >90% of United States residents are seropositive to VZV and no longer at risk for primary disease[99]. Approximately 10% of these individuals will develop dermatomal zoster, with essentially no risk for visceral spread. In contrast, seronegative children and adults with primary infection are at significant risk for disseminated visceral disease, which can include pneumonia, hepatitis, encephalitis, disseminated intravascular coagulation, and other complications[100,101]. Early therapy with high-dose intravenous acyclovir (e.g. 10 mg/kg every 8 h, with dosage adjustment for renal dysfunction) can be life-saving, but prevention is far to be preferred[102]. Zoster immune globulin prophylaxis offers only partial protection to seronegative transplant patients exposed to the virus. For this reason it is recommended that all transplant candidates be serologically screened for VZV, with seronegative individuals being administered the newly licensed varicella vaccine[103].

The impact of human herpesvirus-6 on thoracic transplantation

Both HHV-6 and HHV-7 can be considered 'orphan viruses' in transplantation. Whereas evidence of HHV-6 primary and reactivation infection has been well demonstrated in organ transplant recipients, its clinical impact is unclear[104–107]. HHV-7 has been isolated from the CD4-positive lymphocytes of asymptomatic immunocompetent individuals but, as yet, not from transplant patients[108]. If one were to postulate a role for these agents in the transplant patient, by analogy one would look for the direct production of a mononucleosis-like syndrome and indirect effects similar to those produced by CMV. Clearly, this is an emerging area of transplant infectious disease.

The impact of hepatitis viruses on thoracic transplantation

The prevalence of chronic liver disease in organ transplant recipients is approximately 10%[109]. Although a variety of drugs com-

monly employed in transplant patients (from azathioprine and cyclosporin to antihypertensive and antimicrobial agents) are potentially hepatotoxic, and the herpesviruses CMV and EBV can cause *acute* hepatocellular disease, hepatitis B and C viruses account for >95% of the chronic liver disease in the transplant population. Each of these viruses presents three major management issues: the appropriate approach to a seropositive donor; the suitability of a seropositive patient with end-stage cardiac and/or lung disease for transplantation; and the management of patients with active infection post-transplant.

The efficiency of transmission of HBV with organ transplantation from an infected donor approaches 100%, with a relatively high rate of acute hepatic failure associated with the acquisition of HBV in the peritransplant period[110–113]. Fortunately, with modern screening of blood products, the risk of transmitting HBV with blood transfusion is estimated to be 0.002% per unit tested; since the same techniques are used to screen organ donors, the risk of a seronegative donor transmitting HBV to the recipient should be comparable. Although it is clear that HBsAg-positive donors are to be avoided, it is also important to recognize that HBsAg-negative but HBcAb-positive donors can, on occasion, transmit the virus[113]. Because of this risk, we would only consider using such donors for patients awaiting an organ who are at immediate risk of death without a transplant.

Management of the HBsAg-positive transplant candidate remains controversial[114]. Post-transplant immunosuppression upregulates the level of viral replication and accelerates the rate of progression of the resulting liver disease. Beginning approximately 2 years post-transplant there is an increasing incidence of clinically important chronic liver disease and/or hepatocellular carcinoma. Thus, as reported by Rao *et al.*, in a population of HBsAg-positive renal transplant patients the prevalence of cirrhosis was 42% and the rate of death from liver disease was 54% over a time period of approximately 8 years[115]. Thus, many groups regard HBsAg-positivity as strong relative contraindication to transplantation[115–119].

Hepatitis C is responsible for >80% of the chronic liver disease that occurs in transplant recipients[109]. It is now recognized that there are six genotypes of the virus, with specific geographic clustering: subtype 1a is most prevalent in North America, whereas 1b occurs in North America and western Europe, type 5 in South Africa and type 6 in Hong Kong[120]. Recent studies suggest that these different genotypes have differing levels of viremia, clinical courses, and responses to interferon therapy[121]. The host response to HCV infection is at present incompletely understood: antibody to HCV does not appear for many weeks after the initiation of infection in normal hosts; this delayed response is probably even greater in the immunosuppressed transplant patient. Not only is this important in terms of diagnosis, anti-HCV testing being the most accessible means of assessing infection with the virus, previous infection does not protect against rechallenge against either the same strain or a different strain of the virus. The consequences of HCV infection are starting to become apparent: by 10 years post-transplant approximately 20% of transplant recipients with chronic HCV infection (and virtually all transplant patients with HCV infection will have chronic infection) will have serious consequences of HCV infection[122–124]. Therapy with α-interferon is far less effective in this patient population than in the general population, an approximately 25% initial response rate and a very high rate of relapse[125,126].

HCV infection by itself is not considered a strong contraindication to transplantation at most transplant centers, although careful assessment of the liver is required before proceeding, as post-transplant immunosuppression will clearly amplify the level of replicating virus[127]. Far more controversial is the appropriate approach to donors who might be harboring the virus. It is estimated that 1–5% of potential donors are anti-HCV-positive, with approximately half of these transmitting the virus to the allograft recipient. If PCR assay is performed for HCV RNA in the serum of the potential donor, it is apparent that essentially all viremic individuals transmit the virus with organ donation[128,129]. Thus, the anti-HCV assay has a high false-positive rate in terms of predicting transmission of HCV, as well as a high false-negative rate. Since the PCR assay cannot be performed routinely in the timely fashion needed to assist in evaluating a potential thoracic organ donor, it is unclear how best to optimize the number of organs available, while at the same time decreasing the transmission of HCV. Our own approach is to reserve organs from anti-HCV-positive donors for critically ill patients or for older recipients, feeling that the several years necessary for HCV to become clinically apparent post-transplant offers a trade-off that is acceptable for these two population groups.

The impact of toxoplasmosis on thoracic transplantation

Toxoplasma gondii causes a widespread zoonosis in which infection occurs following ingestion of undercooked lamb or pork contaminated with tissue cyst, vegetables contaminated with infected animal feces (particularly cats), or inhalation of infected cat feces[130]. Following inhalation or ingestion, the tachyzoites or invasive form of the parasite may infect a variety of cell types, with lymphadenopathy, a mononucleosis syndrome, and ocular disease being the most common manifestations in the immunologically normal individual. Although occasional cases of toxoplasmosis, including disseminated disease with a major effect on the central nervous system (both focal lesions and diffuse encephalitis akin to that seen in the AIDS patient), have been reported in organ transplant patients, these are rare in all but cardiac allograft recipients. Particularly important is the instance when the allograft donor is seropositive and the recipient seronegative for *T. gondii*. In these instances there is a >50% incidence of symptomatic toxoplasmosis, with myocarditis and myocardial dysfunction being the most common manifestations of toxoplasmosis in this patient population[131,132]. In addition, dissemination and central nervous system disease may also occur[133,134]. A not-uncommon error in these patients who are at risk for primary toxoplasmosis is to diagnose rejection and treat with increased immunosuppression, as opposed to anti-toxoplasmosis therapy, with this error having disastrous consequences.

All cardiac transplant patients who are seronegative for toxoplasmosis and are receiving an allograft from a seropositive donor should receive anti-toxoplasmosis prophylaxis. Whether or not trimethoprim-sulfamethoxazole is adequate for this purpose is at present unclear, and it is our policy to utilize either pyrimethamine plus a sulfonamide or atovaquone for 4 months in these patients[135,136].

The impact of *Pneumocystis carinii* infection in thoracic transplantation

Pneumocystis carinii infection is a major pathogen in organ transplant recipients. Whereas approximately 10% of renal transplant patients will develop symptomatic *Pneumocystis* pneumonia in the first 6 months post-transplant, the rate is significantly higher in cardiac (38% in one series) and lung (88% in one series) transplant recipients not receiving prophylaxis, although not all of these were symptomatic[137]. Patients with coexistent CMV infection, those receiving higher doses of corticosteroids, and those with chronic rejection are at particularly high risk.

The clinical presentation of *Pneumocystis* pneumonia among thoracic allograft recipients is similar to that of other populations: the subacute onset of fever, chills, dyspnea, non-productive cough, and a peribronchovascular ('interstitial') infiltrate on chest examination, with hypoxemia demonstrable on blood gas measurement. Differential diagnostic considerations include CMV infection, other viruses and, in the lung transplant patient, rejection. Therefore, in patients who have not been on effective *Pneumocystis* prophylaxis, rapid diagnosis, usually via bronchoscopy and bronchoalveolar lavage, is essential.

In addition to the morbidity and mortality associated with *Pneumocystis* pneumonia there is another compelling reason for attempting to prevent this otherwise common infection: treatment of transplant patients receiving antirejection therapy with cyclosporin or FK506 with the necessary dosages of either trimethoprim-sulfamethoxazole or pentamidine (the two first-line drugs for the treatment of *Pneumocystis*) is associated with a high rate of either nephrotoxicity or bone marrow toxicity. This is clearly an infection to be prevented, not treated. Low-dose trimethoprim-sulfamethoxazole (we use one single-strength tablet, containing 80 mg of trimethoprim and 400 mg of sulfamethoxazole, at bedtime for a minimum of 6–12 months post-transplant) provides virtually complete protection against this infection, while providing similar protection against nocardiosis, listeriosis and, perhaps, toxoplasmosis in the patient who is already seropositive for this organism[138–140]. In those patients who cannot tolerate trimethoprim-sulfamethoxazole, prophylaxis with a second-line regimen (e.g. atovaquone, dapsone, or monthly aerosol pentamidine) is obligatory.

The impact of mycobacterial infection on thoracic transplantation

Because of the critical role of T cell immunity and activated macrophages in controlling tuberculosis, it would be expected that, among transplant recipients, active tuberculosis would be an important threat. In fact, although tuberculosis is more common in transplant recipients, with an attack rate of 480 per 100 000 vs 13.1 per 100 000 in the general population, most centers in North America and Europe report that mycobacterial infection accounts for <2% of transplant-associated infections[141]. The rate is, however, significantly higher in populations such as those in developing countries, where the endemic level of tuberculosis in the general population is high. Thus, in India tuberculosis accounts for 10% of transplant-associated infections, with a mortality rate of approximately 25% (11% for pulmonary disease and 37% for disseminated disease)[142].

Most reports of tuberculosis in transplant recipients have concerned kidney transplant recipients. In these reports it appears that both disseminated and joint infection are more common than in the general population[143–145]. Less is known about recipients of thoracic organ transplants. A recent report of three cases of tuberculosis among heart transplant recipients brings the total reported cases to 12 among the approximately 12 000 heart transplants that have been carried out in the world[146]. About half of these reported cases are extrapulmonary or disseminated, with several occurring in conjunction with such other infections as CMV, nocardiosis, and aspergillosis. A small number of cases of tuberculosis have likewise been reported among lung transplant recipients, with the clinical presentation varying from that of a subacute pneumonia or focal pulmonary lesion to an isolated, unexplained pleural effusion[147,148].

Although the majority of patients developing tuberculosis represent instances of reactivation disease, several reports document the transmission of the infection with the allograft. In one report a donor was subsequently found to have tuberculous meningitis; both recipients of kidneys from this donor developed evidence of active tuberculous infection[149]. In another case, fatal miliary tuberculosis developed 11 weeks following heart–lung transplantation[148]. In retrospect a computerized tomographic scan demonstrated calcified lymph nodes, and pathologic examination of the donor lungs revealed an old Ghon complex. Clearly, then, tuberculosis can be conveyed with the allograft, and careful evaluation of prospective donors for this possibility is essential.

A more common issue is the management of individuals known to be tuberculin-positive. Because the bulwarks of antituberculous therapy, isoniazid and rifampin, may cause hepatic toxicity, as well as affect the metabolism of cyclosporin and prednisone, concern has been raised regarding the routine use of antituberculous prophylaxis in transplant patients with positive tuberculin tests. Our approach has been to utilize isoniazid in certain patients when at least one other risk factor for tuberculosis is present. Risk factors of importance include the following: noncaucasian racial background; history of past active disease, particularly if not treated optimally; significant abnormalities on chest X-ray; the presence of protein–calorie malnutrition; or the presence of some other immunosuppressing process[1].

In addition to infection with *M. tuberculosis*, transplant patients have an increased risk for localized and disseminated infection with a variety of atypical mycobacteria. Cutaneous infections, pulmonary disease, septic arthritis, and disseminated disease have all been reported in transplant patients due to these organisms[144,145,150–154]. In 1994 Patel *et al.* presented an extensive review of this topic, noting that 67% of patients presented with soft tissue, bone, or joint infection, and >50% had multiple sites of infection[151]. The clinical presentation was subacute, with active infection being present up to a year before diagnosis. Of the 28% of patients with pulmonary disease the majority were infected with *M. kansasii*; in contrast, those with soft tissue infection were commonly infected with organisms belonging to the *M. chelonae/fortuitum* complex. In addition, other atypical mycobacteria such as *M. avium-intracellulare*, *M. haemophilum*, *M. thermoresistibile*, and *M. scrofulaceum* have been reported. Risks factors for disease with these organisms include, in addition to immunosuppression: tissue injury (particularly to the skin), and exposure to contaminated water (as in aquariums, swimming

pools, freshwater ponds, etc.). Treatment of these infections remains non-standardized, but decrease in immunosuppression and surgical debridement are often necessary. Effective chemotherapy relies heavily on *in vitro* susceptibility testing, although the newer fluoroquinolones and macrolide antibiotics have greatly increased our ability to treat these uncommon infections.

The impact of fungal infection in thoracic transplantation

Fungal infection remains an important problem in thoracic organ transplantation. In the early days of heart transplantation >30% of cardiac allograft recipients developed significant fungal infection; fortunately, this has decreased to 5–21% in recent years[155,156]. In lung recipients, however, it is estimated that 35–45% of patients develop evidence of fungal infection[12,19,155]. The infections that occur can be divided into two major categories: infection with the geographically restricted systemic mycoses (blastomycosis, coccidioidomycosis, and histoplasmosis); and those due to the opportunistic pathogens, particularly *Candida* species, *Aspergillus* species, and *Cryptococcus neoformans*.

With respect to the geographically restricted systemic infections, three general patterns are observed[1]: (a) progressive primary infection following inhalation of the organism, resulting in both significant pulmonary disease and a high incidence of systemic dissemination; (b) reactivation of an old, dormant focus, with a significant risk of secondary dissemination; and (c) reinfection, again with a risk for systemic dissemination, in a previously immune individual, due to the combined effects of immunosuppression and a significant epidemiologic exposure. Thus, for the clinician, knowledge of both recent and remote epidemiologic history is of importance. Common clinical presentations of these infections in the transplant patient include the following: fever of unknown origin, unexplained cough or shortness of breath, or manifestations of metastatic infection (e.g. headaches due to meningeal coccidioidomycosis; mucocutaneous disease due to histoplasmosis; or cutaneous disease due to blastomycosis)[157–160].

Candidal infection accounts for more than three-quarters of the fungal infections in transplant patients. The most common manifestations include mucocutaneous infections, the incidence of which is related to steroid and antibacterial use, as well as adequacy of blood sugar control. Although thrush and vaginitis are bothersome, symptomatic esophagitis is the most important form of mucocutaneous infection. Many of the less invasive infections (such as thrush) respond well to topical therapy with clotrimazole or nystatin, although fluconazole may be used for more rapid control. Esophagitis, however, should be treated with fluconazole or amphotericin B. Candiduria is also common, and is usually treated aggressively, because of fear of dissemination. Again, fluconazole is the cornerstone of therapy, with low-dose intravenous amphotericin plus flucytosine a useful alternative, particularly when infection is due to candidal species resistant to fluconazole (e.g. *C. krusei* and *C. glabrata*). The time-honored method of amphotericin bladder irrigation via an indwelling catheter is less effective than systemic therapy, and carries the additional risk of bacterial superinfection. A particular form of mucosal disease that bears mention is the effects of candidal infection/colonization on the bronchial anastomosis in lung transplant patients[161]. Since this can affect wound healing we advocate aggressive prophylaxis and surveillance for the presence of candidal species in the first weeks following transplantation.

The most important serious infection with *Candida* is blood stream infection, which usually occurs as a consequence of vascular access infection. Candidemia in the transplant recipient carries a >50% risk of visceral dissemination, and even a single positive blood culture necessitates a course of systemic chemotherapy in addition to removal of the vascular access line[156]. The optimal treatment regimen is currently unknown. Pending the development of more data, our approach is the following: in the acutely ill patient, therapy is initiated with amphotericin until control of the process is achieved, at which time the patient is switched to fluconazole. In less acutely ill patients, therapy is initiated with fluconazole as long as the candidal species isolated is not thought to be resistant. The overall duration of therapy is determined by the patient's clinical presentation and response to therapy. In general, particularly when treatment can be accomplished with oral fluconazole, our preference is to treat for 1–2 weeks beyond the point at which the patient has been rendered free of all clinical evidence of the infection.

Aspergillosis, particularly that acquired within the hospital, remains a significant concern in all organ transplant recipients. Approximately 90% of the cases of aspergillosis observed involve the lungs, with the nasal sinuses accounting for most of the remainder (an occasional patient will have inoculation of *Aspergillus* spores directly into a surgical wound or vascular access site, resulting in invasive cutaneous aspergillosis)[162–168]. Wherever the primary site of infection, the cardinal signs and symptoms of aspergillosis in this patient population are due to the vasculotropic nature of this infection: tissue infarction, hemorrhage, and metastasis. Thus, clinical presentation can represent the primary site of involvement (i.e. the lungs or sinuses) or a site of metastasis. As far as the latter is concerned, the most common example of this is the patient with a focal neurologic deficit or seizures due to invasive aspergillosis metastatic from a relatively asymptomatic pulmonary focus[169,170]. In lung transplant patients a necrotizing lesion at the site of the bronchial anastomosis has been a particular problem unique to this population[24].

Aspergillus fumigatus and *A. flavus* account for >90% of these infections, with the other *Aspergillus* species accounting for the remainder. Once the respiratory tract is colonized with *Aspergillus*, more than two-thirds of patients will develop invasive disease, thus justifying an aggressive approach to this infection in this patient population[171–173]. *Aspergillus* species, in the non-immunosuppressed host, have a particular propensity for colonizing structurally and functionally abnormal respiratory tracts (e.g. in cystic fibrosis patients, those with bronchiectasis, and those with chronic sinusitis). Since many of these individuals are awaiting lung transplantation, it is important to demonstrate whether or not such colonization is present, and to attempt to eradicate this infection prior to transplantation. Unfortunately, the options for therapy against *Aspergillus* are limited. Itraconazole, presumably because of its erratic bioavailability, has not proven reliable as primary therapy in transplant patients, and can safely be used only to eradicate carriage in the pretransplant situation where therapeutic failure can still be corrected, or as 'wrap-up' therapy following an extended course of amphotericin. Otherwise,

at present, extended courses of amphotericin remain the standard of care. Because of the toxicities associated with such therapy, the emphasis should be on prevention, particularly on eliminating potential nosocomial hazards.

Cryptococcus neoformans occurs predominantly >6 months post-transplant, with a particularly high attack rate in the patient who has had multiple bouts of acute and chronic rejection, requiring higher than normal amounts of immunosuppressive therapy (the 'chronic n'er-do-wells'). *C. neoformans* also has a pulmonary portal of entry, often asymptomatic, occasionally presenting as a subacute pneumonia or isolated pulmonary nodule discovered on chest X-ray. Far more common, however, is the patient who presents with evidence of metastatic infection, with the skin or the central nervous system being the sites most commonly involved[155,156,174–176]. In >20% of transplant patients with cryptococcosis there is evidence of a skin lesion as the first sign of systemic infection for many weeks before other disease manifestations appear (this is also true for such other infections as nocardiosis and the other fungal infections). Thus, unexplained skin lesions merit biopsy for pathologic assessment and culture.

Other than biopsy, the cornerstone of diagnosis is testing for cryptococcal antigen in blood and cerebrospinal fluid. In addition, blood cultures performed by the lysis centrifugation technique ('Dupont isolators') also have a high yield. The cryptococcal antigen test gives a good measurement of organism load, and serial determinations provide an excellent guide to therapy[177,178]. Therapy of cryptococcosis is similar to that of candidal infection: fluconazole therapy for those subacutely ill and initial amphotericin therapy, followed by fluconazole, for those more seriously ill. Duration of therapy is prolonged and variable, determined by the patient's response, both clinically and in terms of antigen clearance.

PRINCIPLES OF ANTIMICROBIAL USE IN THORACIC TRANSPLANTATION

There are three underlying themes in the prescription of antimicrobial agents for the transplant patient: (a) antimicrobial therapies must be considered in the context of the immunosuppressive therapy being administered, both in terms of the manifold opportunities for drug interaction and in terms of the linkage of antimicrobial programs to the intensity of immunosuppression being prescribed; (b) prevention of infection rather than therapy is the overriding aim; and (c) when therapy of established infection is required, early diagnosis and initiation of therapy, as well as an adequately sustained duration of therapy, form the basis for success[1].

The advent of cyclosporin-based immunosuppression, and now the availability of FK506, have been a major advance in transplantation, responsible for much of the success observed with modern thoracic organ transplantation. At the same time, because of drug interactions, they have greatly complicated the use of antimicrobial drugs. Although clearly established in the case of cyclosporin, much of the following information is likely to be also true of FK506. In the case of cyclosporin there are three ways in which antimicrobial agents can interact in a clinically important way, with two of these being related to the key step in cyclosporin metabolism, which occurs via hepatic cytochrome P450 enzymatic metabolism[1]:

(1) Certain antimicrobial agents, most notably rifampin and, perhaps, isoniazid, up-regulate cyclosporin metabolism, thus decreasing cyclosporin blood levels, potentially leading to underimmunosuppression and allograft rejection.
(2) Certain antimicrobial agents, most notably the azole antifungal agents (ketoconazole > itraconazole ≫ fluconazole) and the macrolide antibiotics (erythromycin, azithromycin, and clarithromycin) down-regulate cyclosporin metabolism, resulting in elevated cyclosporin levels, potentially leading to toxicity or overimmunosuppression.
(3) Many antimicrobial agents, most notably amphotericin, the aminoglycosides, high-dose trimethoprim-sulfamethoxazole, high-dose fluoroquinolones and, perhaps, vancomycin, have a synergistic effect with cyclosporin in terms of producing nephrotoxicity.

Whereas the first two of these can be managed by adjustment in the cyclosporin dose, based on blood level measurements, the last is idiosyncratic. The implication of these observations is that, when antimicrobial therapy is needed, there is a particular emphasis on the use of β-lactams, fluconazole, and low-dose fluoroquinolones (e.g. no more than 500 mg of ciprofloxacin per day), and there is even further emphasis on the prevention of infection. Finally, a good rule of thumb is that if unexplained renal dysfunction occurs in a cyclosporin (and, presumably, an FK506) recipient, a drug interaction should be suspected, with antimicrobial agents being prime suspects.

There are three modes in which antimicrobial agents can be utilized in transplant recipients[1]:

(1) *Therapeutic*, in which curative antibiotics are administered to patients with clinically manifest infection.
(2) *Prophylactic*, in which antibiotics are administered to an entire population to prevent infection prior to an event. For prophylaxis to be appropriate, the infection needs to be important enough and common enough in the population to justify that step, and the antimicrobial therapy in question has to be non-toxic enough to make it worthwhile. Successful prophylactic strategies in the transplant patient include both low-dose trimethoprim-sulfamethoxazole (which is well tolerated, as opposed to treatment doses for *Pneumocystis*, which are poorly tolerated), which effectively eliminates pneumocystosis, nocardiosis, and listeriosis, and peritransplant surgical wound prophylaxis.
(3) *Pre-emptive*, in which antimicrobial agents are administered prior to the onset of clinical disease to a subpopulation identified on the basis of a clinical epidemiologic characteristic or a laboratory marker. For such a strategy to be justified, such a marker has to be highly discriminating, and effective 'emergency intervention' strategies must be available. Examples of successful pre-emptive strategies include the prescription of intravenous ganciclovir during antilymphocyte antibody therapy to prevent symptomatic CMV disease in CMV-seropositive individuals, or the prescription of anti-*Aspergillus* therapy to patients colonized with *Aspergillus* species. In both these instances, without such pre-emptive therapy the incidence of life-threatening infection is >60% for these subgroups and the antimicrobial intervention provides significant protection which is superior to more generally prescribed prophylactic programs.

COMMENT

Considerable strides have been made in the technical, immunosuppressive, and infectious disease management of patients undergoing thoracic organ transplantation. The next decade should see further improvement as new immunosuppressive therapies, as well as new antimicrobial strategies, become available. However, the principles that have become established over the past decades will remain the cornerstones of patient management. The most important of these are the following:

(1) Technically impeccable surgery and management of both the donor and the recipient are now, and will remain, the cornerstones of successful transplantation. A technical mishap is invariably associated with life-threatening infection.
(2) The occurrence of infection is determined by the interaction of the patient's net state of immunosuppression and the epidemiologic exposures encountered. These are translated into a timetable according to which different infections occur at different time points post-transplant.
(3) The therapeutic prescription for the transplant patient consists of an immunosuppressive strategy to prevent and treat rejection, and an antimicrobial strategy to make it safe. Thus, antimicrobial strategies (both drug and environmental protection) are closely linked to the intensity and duration of the immunosuppressive program that is prescribed.
(4) Prevention of infection is the goal.

With further advances in each of these areas it is expected that the opportunities for successful rehabilitation of patients with end-stage heart and/or lung disease via transplantation will only increase over the next decade.

Malignant Neoplasia in the Immunocompromised Patient

I. PENN

INTRODUCTION

The burgeoning numbers of patients who undergo cardiac or pulmonary transplantation make it increasingly important that cardiologists, pulmonologists and cardiothoracic surgeons be familiar with the complications of these treatments. One of these is an increased risk for the development of certain types of cancer. Much of this chapter is based on experience obtained from renal transplantation, but whenever possible observations made in cardiac, cardiopulmonary or pulmonary graft recipients (henceforth referred to as cardiothoracic [CT] recipients) will be stressed. The report is based on data collected by the Cincinnati Transplant Tumor Registry (CTTR) up till May 1995.

The chapter will consider three categories of malignancies: (a) transplanted cancers; (b) pre-existing tumors that were present before transplantation; and (c) *de novo* malignancies that developed in the recipient after transplantation.

TRANSPLANTED MALIGNANCIES

When assessing a potential cadaver donor for harvesting the heart or lungs, it is obligatory to determine whether or not he or she has cancer, or has been treated for it recently, as there is a danger of transmitting tumor cells with the transplanted organ(s)[1-3]. In normal individuals such foreign cells would be rejected promptly by the recipient. However, the immunosuppressive therapy, used to prevent graft rejection, impairs the host's immune defenses and prevents destruction of cancer cells which may grow, invade adjacent structures, and even metastasize.

The CTTR has data on 248 recipients of organs from donors who had malignancies at the time of donation, or had been treated for them within 10 years of transplantation or, in the case of the several living donors, who presented with neoplasms up to 18 months after donation. Allograft recipients included 227 renal, 10 hepatic, seven cardiac, two pancreatic, one cardiopulmonary and one pulmonary. In eight instances small tumors were removed from renal allografts immediately prior to transplantation. If we include these cases 103 recipients (42%) received organs that contained cancers. In 39 instances the tumor involved the allograft only, while in another six there was invasion of adjacent structures, and 58 recipients had distant metastases.

The most common tumors that caused metastases were malignant melanoma (28%), carcinoma of the kidney (19%), carcinoma of the bronchus (17%), choriocarcinoma (16%) and primary brain tumors (9%). Overall, 40 recipients died of cancer. However, 16 renal allograft patients had complete remissions of all transmitted neoplasms, usually following allograft nephrectomy, and cessation of immunosuppressive therapy, which presumably permitted host immunity to recover and reject residual tumor. These measures were supplemented in five patients by chemotherapy, immunotherapy (interferon; interleukin-2) or radiotherapy. Two other patients are currently alive with tumor after undergoing allograft nephrectomy and discontinuation of immunosuppressive therapy.

Seven heart, one heart–lung and one lung patients received organs from donors with cancer. Four recipients (three heart, one lung) died of metastases of carcinoma of the bronchus, medulloblastoma, malignant melanoma, and nephroblastoma respectively. The heart–lung recipient died of rejection 1 month after transplantation. At autopsy a metastasis of choriocarcinoma was found in one lung. Four cardiac recipients are alive from 0.5 to 57 (average 29) months after transplantation without evidence of malignancy, having received organs from donors with choriocarcinoma, adenocarcinoma of the uterine cervix, adenocarcinoma of the kidney, and carcinoma of the prostate, respectively.

While it is possible to remove part or all of a lung allograft that contains a metastasis, excision of a cardiac allograft and cessation of immunosuppressive therapy are not feasible unless an implantable artificial heart can be used, either as a permanent replacement or for a period of several months until all evidence of malignancy has disappeared and a new cardiac allograft can be inserted. None of these procedures has yet been attempted to treat transmitted malignancies in CT recipients.

It is therefore imperative to avoid using donors with tumors, except those with low-grade carcinomas of the skin, or with primary brain malignancies, which rarely spread outside the central nervous system[1-3]. However, it is important to have histologic proof that the cancers actually arose in the brain, as, in

several instances, the cause of the donor's death was misdiagnosed as intracranial hemorrhage, primary brain tumor, or multiple brain abscesses, when, in fact, the donors died of metastases mostly from choriocarcinoma, bronchial carcinoma, malignant melanoma, or renal carcinoma. We should also avoid using donors with primary brain tumors who have been treated with ventriculoperitoneal or ventriculovenous shunts, or who have had extensive craniotomies, radiotherapy or chemotherapy, as these open pathways for tumor dissemination[1-3].

PRE-EXISTING CANCERS

If a neoplasm in the potential recipient was treated before transplantation, it is possible that the immunosuppressive therapy may impair the ability of the host's immune defenses to control any residual cancer cells[4,5].

In a study of 939 pre-existing malignancies that occurred in 913 renal transplant recipients there was a 22% recurrence rate after transplantation[4,5]. Thirteen percent of the recurrences occurred despite removal of the primary malignancies 5 or more years beforehand. It was recommended that with the exception of patients with: (a) incidentally discovered renal malignancies, (b) *in situ* carcinomas of various organs, (c) focal neoplasms (a small microscopic focus) in organs such as the prostate or uterus, (d) low-grade bladder cancers and (e) basal cell carcinomas of the skin, transplantation should be delayed for at least 24 months after treatment of the tumors.

During this time renal transplant patients can be kept alive by dialysis. As regards potential cardiac transplant recipients, current experience with the artificial heart makes it extremely unlikely that they can be kept alive during this long waiting period. Because of the hopeless prognosis of potential CT recipients who do not receive transplantation, it is probably advisable to expeditiously proceed with transplantation as soon as donor organs become available, except in individuals with active major cancers or who have short life expectancies because of their neoplasms.

Pre-existing tumors (total 160) were present in 146 heart, eight lung and two combined heart–lung recipients who were treated from 504 months before to 12 months after transplantation (average 86 months before transplantation). Persistence or recurrence of cancer occurred in 30 patients (19%), a similar percentage to that observed in renal transplant recipients.

A favorable feature in many heart transplant recipients is that they had been successfully treated for a lymphoma (including Hodgkin's disease) or a sarcoma more than 5 years previously, and were apparently cured of their malignancies. Adriamycin-induced cardiotoxicity was a common indication for cardiac transplantation in these patients.

Of the 30 patients with persistent or recurrent tumors, 12 had tumors treated at or after transplantation, five were treated 24 months or less before transplantation, nine were treated more than 24 months before transplantation, and the time of treatment was not stated in four cases. The most common tumors that persisted or recurred were carcinomas of the lung (seven), non-melanoma skin cancers (five), lymphomas (four), carcinomas of the bladder (three) and carcinomas of the pancreas (two). In addition, two patients had primary tumors of the heart (malignant synovioma and angiosarcoma, respectively) removed at the time of transplantation and both, not surprisingly, had recurrences.

DE NOVO TUMORS

The CTTR has data on 8191 patients who developed 8724 cancers *de novo* after transplantation[6-8]. Of these, 772 received heart, and 29 combined heart–lung, and 29 lung allografts. There were also 6821 kidney transplant recipients and 540 recipients of other extrarenal organs (liver, pancreas, bone marrow, upper abdominal cluster organs and small bowel).

Data from several large renal transplant centers show an overall incidence of cancer ranging from 1% to 16%, with an average of 6%[6-8]. In a series of 182 cardiac transplant recipients who underwent 199 transplantations, the incidence was 10%[9]. Lanza *et al.*[10] compared the incidence of malignancies in cardiac and renal allograft recipients. They found a 2-fold greater increase of all neoplasms in cardiac patients, with nearly a 6-fold increased incidence of visceral tumors ($p<0.02$). They attributed the increase to the more intense immunosuppressive therapy used in these patients.

The incidence of cancer increases with the length of follow-up after transplantation. The actuarial probability of developing malignancy among patients who received cardiac transplants during childhood was 7% at 1 and 2 years, 12% at 3 years, and 15% at 4 and 5 years[11]. An Australasian study of 6596 recipients of cadaver renal transplants showed that the percentage probability of developing cancer 24 years after transplantation was 66% for skin neoplasms, 27% for non-skin malignancies and 72% for any type of tumor[12]. These exceptional figures must be interpreted with caution as most malignancies were skin cancers (which are very common in Australia) and the number of 24-year survivors was small. Nevertheless, they stress the necessity to follow transplant patients indefinitely.

Age of recipients

The malignancies affected a relatively young group of persons whose average age at the time of transplantation was 42 years (range 3 months to 80 years). Forty-three percent were under 40 years of age at the time of transplantation.

Sex

Males made up two-thirds and females one-third of the patients with cancer, roughly the same proportions as those undergoing renal transplantation.

Time of appearance of the neoplasms

In the general population there is a latent period of 5–20 years or even more, between exposure to many carcinogens and the development of malignancies. However, in transplant patients tumors appeared after a much shorter interval, at an average of 61, median 46 (range 0.25–313) months[6-8].

Some cancers appeared at fairly distinct intervals after transplantation[6-8]. Kaposi's sarcoma (KS) presented the earliest at an average of 21, median 12 (range 1–225.5) months after transplantation. Lymphomas appeared at an average of 36, median 12.5 (range 0.25–305.5) months after transplantation. Skin cancers appeared an average of 75, median 60 (range 1–313) months post-

transplantation. Carcinomas of the vulva and perineum appeared at the longest interval after transplantation at an average of 112, median 109 (range 1.5–285.5) months.

Types of tumors

The neoplasms that are frequently observed in the general population (carcinomas of the lung, breast, prostate, colon and invasive uterine cervical carcinomas) showed no increase or even a decrease[6–8]. Only two varieties of cancer often seen in the general population were encountered in significant numbers in transplant patients. Excluding lip neoplasms the percentage of non-melanoma skin cancers (31%) was similar to that observed in the general population (37% of all tumors), but the incidence of squamous cell carcinomas (SCC) was markedly increased (see below). The only other relatively common tumor in the general population, seen also in transplant patients, was *in situ* carcinoma of the uterine cervix, which comprised 3% of malignancies in both groups.

If non-melanoma skin cancers and *in situ* carcinomas of the cervix were excluded, as they are from most cancer statistics, we then observed a variety of malignancies in transplant patients that were uncommon in the general population: lymphomas 24% vs 6%; lip cancers 7% vs 0.2%; KS 6% vs a negligible incidence; carcinomas of the kidney 5% vs 2%; carcinomas of the vulva and perineum 3.5% vs 0.5%, hepatobiliary tumors 2.4% vs 1.5%; and sarcomas (excluding KS) 1.7% vs 0.5%[6–8].

These findings are in keeping with several epidemiologic studies that showed that when transplant patients were compared with suitable age-matched controls there was a 4–7-fold increase in skin cancer in people living in areas of low sunshine exposure, but a 21-fold increase in persons exposed to abundant sunshine[6–8,13]; a 29-fold increase in lip cancers[14]; a 28–49-fold increase in non-Hodgkin's lymphoma (NHL)[15,16]; a 400–500-fold increase in KS[17]; a 14-fold increase in carcinoma *in situ* of the uterine cervix[18]; and a 100-fold increase in carcinomas of the vulva and anus[14].

Cancers of the skin and lips

Overall, these were the most common and comprised 3178 of the 8724 tumors (36%)[6–8]. The incidence of skin cancers increased with the length of follow-up after transplantation, as shown by an Australasian study of 6596 recipients of cadaveric renal transplants who experienced a linear increase in the incidence of skin cancer reaching 66% at 24 years post-transplantation[12]. Similarly, a Dutch study showed a 10% incidence of non-melanoma skin cancers in renal transplant recipients at 10 years post-transplantation, which rose to 40% after 20 years[19].

CT recipients differed from the renal recipients in this series in that skin cancers were relatively uncommon, making up only 239 of 859 (28%) of all tumors compared with 39% in renal recipients. In part this may be related to length of follow-up, which was relatively short in many CT recipients.

The skin cancers of transplant patients differed in several respects from those seen in the general population[6–8,13,19]. Whereas basal cell carcinomas (BCC) outnumber squamous cell carcinomas (SCC) in the general population in a ratio of 5:1, the reverse occurs in CTTR patients, in whom SCC outnumber BCC by 1.8 to 1. In the population at large, non-melanoma skin cancers occur mostly in individuals in their 60s and 70s, whereas the average age of transplant patients is 30 years younger[6–8,20]. Multiple skin cancers occur in 42% of patients in the CTTR. This incidence is remarkably high, and is comparable to that seen only in people in the general population who live in areas of abundant sunshine[6–8]. Several patients each had more than 100 skin cancers. Malignant melanomas comprise 5.2% of skin cancers in the CTTR, in contrast with an incidence of 2.7% in the general population of the United States. This finding is consistent with several epidemiologic studies showing a 3.8–5-fold higher incidence of malignant melanoma in transplant patients compared with age-matched controls[13,15,16].

Most skin cancers in the CTTR were of low-grade malignancy but a significant percentage of SCC behaved much more aggressively than their counterparts in the general population[6–8,13]. Lymph node metastases occurred in 5.8% of patients. Seventy-five percent were from SCC and only 17% from melanomas. Another 8% were from Merkel's cell tumors, and <1% were from BCC. In addition, 5.1% of patients died of skin cancer, with 60% of deaths being from SCC and only 33% from melanomas. Five percent were from Merkel's cell tumors and 2% from BCC. These findings are consistent with a more than 10-fold increase in mortality from SCC of the skin observed in Australian renal transplant recipients[15]. The behavior of skin cancer in transplant patients is markedly different from that seen in the general population, in whom they cause only 1–2% of all cancer deaths, the great majority of which are from malignant melanoma. Most patients with SCC who developed lymph node metastases, or who died of their cancers, had skin, rather than lip, lesions.

In the overall series of patients with complications of their skin cancers, nine were cardiac allograft recipients. Eight developed lymph nodes metastases, six from SCC (skin four, lip two) and two from melanomas. Six patients died of their skin cancers, five from SCC (skin three, lip two) and one from malignant melanoma. Of the deaths, five occurred in patients who had had nodal metastases (SCC four, melanoma one).

Lymphomas

In several respects lymphomas were strikingly different from those seen in the general population[6–8]. The majority (94%) were NHL, whereas Hodgkin's disease and plasmacytoma/myeloma comprised less than 3% and 4% of lymphomas, respectively, compared with 11% and 18% respectively in the general population. Morphologically, most NHL were large-cell lymphomas. Of tumors studied by modern immunological techniques, 87% arose from B lymphocytes, 13% were T-cell lymphomas, and less than 1% arose from null cells. Whereas extranodal involvement was reported in 24–48% of NHL patients in the community at large, it occurred in 69% of NHL in transplant patients.

Surprisingly, one of the most common extranodal sites was the central nervous system (CNS), which was involved in 22% of cases[6–8,21]. Ten percent involved the CNS and other organs, a figure similar to the 8–12% of CNS involvement by systemic NHL in the general population[21]. However, most lesions in transplant patients involved the brain parenchyma, whereas in the general population most occurred in the leptomeninges,

perivascular spaces and nerve roots[21]. The other 12% were limited to the CNS, in contrast with a 1–2% incidence of primary CNS involvement by NHL in the general population[21]. In both groups the brain parenchyma was usually involved, and meningeal involvement occurred infrequently[21]. In the CTTR patients, brain lesions were frequently multicentric in distribution. In the CTTR series, spinal cord lesions were very unusual. In this regard the lesions resembled CNS lymphomas in the general population, in whom the spinal cord was affected in only 0–5% in different series[6–8].

A possible explanation for the frequency of brain involvement is that this organ has poor immunologic reactions, so that lymphoma cells that arise in it, or are carried there from other sites, grow more readily in this relatively immunologically privileged site than in other viscera[6–8].

A CNS lymphoma should be suspected whenever a transplant patient presents with neurologic symptoms[6–8]. A thorough workup is necessary to exclude more common causes of these symptoms in such a patient, including hypertensive encephalopathy, meningitis, brain abscess, or intracranial bleeding. Studies may include electroencephalography, brain scan, computerized axial tomography, examination of the cerebrospinal fluid, cerebral angiography, and magnetic resonance imaging.

Epstein – Barr virus (EBV) DNA has been isolated from many B cell lesions in transplant recipients[22,23]. In immunosuppressed individuals it is believed to cause a spectrum of lesions ranging from benign polyclonal B cell hyperplasias on the one hand to frank monoclonal B cell lymphomas on the other[22,23]. We do not know the cause(s) of T-cell lymphomas in transplant patients.

Of 339 CT patients with lymphomas, four had Hodgkin's disease and 11 had plasmacytoma or multiple myeloma. The remaining 324 patients had NHL, of whom 54 had no treatment (the tumor was an autopsy finding in 38 recipients), and in 14 instances treatment data were not provided. Of the 256 treated patients, 102 (40%) had complete remissions (Table 1). These occurred in 70 patients (69%) with disease localized to a single organ or site and 32 patients (31%) with widespread disease. Subsequently, 26 patients who had complete remission died of other causes. At present, of the 324 patients, both treated and untreated, 76 are alive and well, 43 are undergoing treatment, 115 died of their lymphomas, and 90 died of other causes. The results obtained with CT recipients mirror those obtained with all patients with lymphomas in the CTTR.

Table 1 Treatments used in cardiothoracic transplant patients with complete remissions*

Treatment	*No. of patients*	
	Multimodality therapy†	*Single-modality therapy*‡
Decrease or cessation of immunosuppression	43	30
Acyclovir or ganciclovir	20	1
Excision	16	8
Chemotherapy	16	7
Radiotherapy	13	6
Interferon	3	3
Monoclonal anti-B-cell antibodies	1	–

* Treatment given to one patient is not recorded.
† Used in 46 patients.
‡ Used in 55 patients.

Kaposi's sarcoma (KS)

The fact that KS composed 6% of tumors in the CTTR study stands in stark comparison with its incidence in the general population of the United States of only 0.02–0.07% of all tumors (before the AIDS epidemic started)[6,8,24]. Among CT recipients in the CTTR, KS composed 2% of all malignancies.

In the CTTR, patients with KS (356) exceeded those with two common cancers, carcinomas of the colon and rectum (305) and carcinomas of the breast (273), a most remarkable finding[6,8,24]. Apart from individuals with AIDS, in which KS is enormously increased[11], there is probably no other series in which the numbers of KS patients exceed those with either of these two common cancers, except possibly in tropical Africa where KS is common and colon cancer is infrequent.

KS affected males to females in a 3:1 ratio, substantially less than the 9:1–15:1 ratio seen with KS in the general population[6–8,24]. KS was most common in organ transplant recipients who were Arab (25%), black (16%), Italian (15%), Jewish (9%) or Greek (7%). Sixty percent had non-visceral disease confined to skin, or oropharyngeal mucosa, and 40% had visceral disease with involvement of internal organs, most commonly the gastrointestinal tract, lungs and lymph nodes[6–8,24].

After treatment, complete remissions occurred in 113 of the 213 patients (53%) with non-visceral disease. Whereas 78 remissions followed various treatments including alteration of immunosuppression, surgery, radiotherapy, chemotherapy or administration of α-interferon, 35 (31%) occurred when the *only* treatment was a drastic reduction of immunosuppressive therapy. In patients with visceral disease only, 38 of the 143 patients (27%) had complete remissions after treatment. However, 23 of the remissions (60%) occurred after reduction of immunosuppressive therapy only.

Of the 19 CT recipients with KS, 10 had visceral disease and nine non-visceral involvement. In the former group, six patients died of KS, two from other causes, and only two are alive, with one in complete remission of KS. In contrast, in the nine patients with non-visceral disease, three died of unrelated causes and six are alive, with four patients in complete remission of KS.

Carcinomas of the uterine cervix

Carcinomas of the cervix occurred in 300 of the 2744 women in this series (11%). At least 72% were *in situ* lesions[6–8,18]. Thus far, seven have affected CT recipients. It is advisable that all postadolescent female patients have regular pelvic examinations and cervical smears to detect such lesions, and also carcinomas of the vulva and perineum[6–8,18].

Carcinomas of the vulva and perineum

Carcinomas of the vulva, perineum, scrotum, penis, perianal skin and anus occurred in 220 patients: 159 women and 61 men[6–8,25].

The patients were surprisingly young when compared with individuals with similar lesions in the general population, who are mostly in their 60s and 70s. The average age of the women at the time of transplantation was 30 (range 15–59) years, and of the men 35 (range 18–62) years. One-third of patients had *in situ* lesions. In women there was sometimes a 'field effect', with involvement by cancer of the vulva, vagina, uterine cervix, and anus in varying combinations[6–8,25]. In approximately one-third of patients a possible viral etiology of these malignancies is suggested by a preceding history of condyloma acuminatum caused by human papillomavirus[25,26].

Renal carcinomas

There were 301 patients with carcinomas of the kidney, of which 262 involved the patients' own kidney(s) and 28 involved the allograft; in 11 the location was not stated[6–8,27]. These figures excluded 259 patients who had lymphomatous involvement of the native or allograft kidneys and three patients who had renal sarcomas (two involving the allograft and one a native kidney).

In various studies in the general population, 5–10% of renal tumors are carcinomas of the pelvis[27], whereas in the CTTR series these accounted for 14% of tumors. The increase is almost certainly due to the high incidence of analgesic nephropathy among renal allograft recipients, which occurred in 8% of CTTR patients with carcinomas of their native kidneys[27]. This disorder is known to cause carcinomas in various parts of the urinary tract. This is borne out in the CTTR series, in which 68% of patients with analgesia-related renal carcinomas had similar cancers elsewhere in the urinary tract[27].

Another predisposing cause of tumors in renal transplant recipients is acquired cystic disease (ACD) of the native kidneys. This occurs in 30–95% of patients receiving long-term hemodialysis, and is complicated by renal adenocarcinoma, which is increased 30–40-fold over its incidence in the general population[27,28]. With a successfully functioning transplant the ACD tends to regress, and presumably the risk of developing renal cell carcinoma also recedes.

There is no ready explanation for the 16 renal carcinomas seen in CT recipients in the CTTR.

Hepatobiliary tumors

Most cases in the CTTR were hepatomas[6–8,29]. A substantial number of patients had a preceding history of hepatitis B[29] and, less frequently, of hepatitis C infection.

Sarcomas (excluding KS)

Most involved the soft tissues or visceral organs, whereas cartilage or bone involvement was uncommon[6–8]. The major types were fibrous histiocytoma (20 patients), leiomyosarcoma (15), fibrosarcoma (12), rhabdomyosarcoma (nine), hemangiosarcoma (eight), mesothelioma (six) and liposarcoma (five).

Other cancers

In some studies an increased incidence of other malignancies was noted. For example, the Australia and New Zealand Dialysis and Transplant Registry reported a 289-fold increased incidence of endocrine cancers, 5.6-fold increase of leukemia, 2.5-fold increase in digestive organ cancers, 2-fold increase in respiratory system tumors, and 4.6-fold increase of miscellaneous cancers[12].

Biological behavior of post-transplant neoplasms

Malignancies that occur in organ allograft recipients frequently demonstrate a more aggressive nature than do similar neoplasms in patients who have not undergone transplantation[30].

Cancers in renal versus CT recipients

Marked differences in incidence were observed when 7318 cancers that occurred in 6821 renal transplant recipients were compared with 859 neoplasms that occurred in 830 heart CT recipients (Table 2).

The most significant finding was a disproportionately high incidence of lymphomas in cardiac compared with renal patients. They composed 39% versus 12% of all malignancies[6–8]. The difference was even more marked in pediatric compared with adult cardiac allograft recipients. In 49 pediatric patients with post-

Table 2 Cancer in renal vs cardiothoracic recipients

Type of cancer	*No. of tumors in renal recipients**	*No. of tumors in CT recipients†*
Cancers of skin and lip	2850	239
Lymphomas	844	339
Carcinomas of the lung	406	68

* More than one type of tumor affecting different organs occurred in 464 patients, of whom 31 each had three separate types of cancers and one patient had four.
† One cardiac transplant recipient had three separate types of neoplasm, and 26 others had two each. One pulmonary recipient had two tumors.

transplant malignancies, lymphomas composed 41 (84%) of the tumors compared with 298 of 810 neoplasms (37%) in adults. A similar high incidence of lymphomas was also seen in recipients of other extrarenal organs, in whom they composed 302 of 547 neoplasms (55%). The high incidence of lymphomas in CT recipients is confirmed by a study of 131 lymphomas from the University of Pittsburgh, which showed a 1% incidence in renal transplant recipients, a 2.3% incidence in cardiac allograft recipients, and a 3.8% incidence in recipients of combined heart and lung transplants[31].

In contrast, the renal patients in the CTTR exceeded the cardiac and related recipients in the incidence of skin cancers (39% vs 28%), carcinomas of the cervix (4% vs 0.8%) and carcinomas of the vulva and perineum (2.9% vs 0.7%). Somewhat similar findings have been reported by other workers[10].

Several factors probably account for these differences. In CT and other extrarenal organ recipients intense immunosuppressive therapy is frequently necessary to save lives by reversing rejection, whereas with severe rejection of kidney allografts physicians are likely to discontinue immunosuppression and return patients to dialysis therapy[6–8]. A complication of intense immunosuppressive therapy is a disproportionate increase in the incidence of malignancies that occur in the early months after transplantation, namely NHL.

This viewpoint is supported by a study of 75 survivors of heart and heart–lung transplantation who were treated with cyclosporine, prednisone and, in some instances, antithymocyte globulin. Lymphomas occurred in six patients. Measured quantitative parameters of immunosuppression during the first 3 months after transplantation (mean cyclosporine level, total antithymocyte globulin dosage, number of days of T cell suppression and mean cyclosporine level during T cell suppression) were higher in patients with lymphomas than in those who did not develop tumors[32].

Many renal transplants were performed in the era when immunosuppressive therapy consisted of azathioprine and prednisone (supplemented in some patients by ALG or ATG). In contrast, most CT transplants have been performed in the era of polypharmacy, usually involving triple therapy (azathioprine, prednisone and cyclosporine) sometimes supplemented by ALG or ATG or monoclonal agents such as OKT3. We are still learning how to use these drugs in varying combinations and doses. A problem is that some patients are being very heavily immunosuppressed, either inadvertently or intentionally to treat rejection, and the price for this is, again, an increased incidence of NHL[6–8].

A third factor is the length of follow-up after transplantation[6–8]. Many renal transplant recipients have been followed for a decade or even two decades or more, whereas most CT recipients were treated in the past 8–10 years. As neoplasms such as skin cancers, carcinomas of the cervix, and carcinomas of the vulva and perineum occur late after transplantation this may explain the discrepancy in the incidence of these tumors in renal versus CT recipients. The relatively small number of CT patients compared with the large number of renal transplant recipients may also have contributed to differences in the incidence of the various cancers.

Treatment of post-transplant malignancies

In dealing with patients with premalignant skin lesions or early skin tumors a useful treatment is a 6-week course of topical 5-fluorouracil cream applied twice daily[6–8]. This will eliminate many premalignant lesions and even superficial carcinomas. This treatment is rapidly being superseded by topical use of 0.05% tretinoin cream (a retinoid). This is efficacious in treating warts and keratoses in organ allograft recipients and, perhaps, may inhibit cutaneous carcinogenesis[33]. Treatment of skin cancers includes surgical excision, cryosurgery, chemosurgery or radiotherapy[6–8].

In situ carcinomas of the uterine cervix respond well to simple hysterectomy, cervical conization, or cryotherapy[6 8]. *In situ* carcinomas or small neoplasms of the vulva and perineum are treated by local excision. Large lesions require extensive operations such as total vulvectomy and inguinal node dissection, or abdominoperineal resection[25]. Other cancers are treated by standard surgical, radiotherapeutic or chemotherapeutic modalities.

The antiviral agents acyclovir or ganciclovir may be used to treat EBV-related NHL[6 8,22,23,31]. Alpha-interferon has been used to treat some patients with KS or NHL[6 8]. However, it may stimulate the immune system and cause rejection, and this has occurred in occasional patients[34].

In addition, we must consider reduction or cessation of immunosuppressive therapy[6–8,22,31]. The value of reducing immunosuppressive therapy is borne out by experience with certain neoplasms[6–8,22,31]. As mentioned above, several malignancies that were inadvertently transplanted from organ donors underwent partial or complete regression following cessation of immunosuppressive therapy[1–3]. Similarly, a significant percentage of KS and NHL (see above) regressed partially or completely after reduction of immunosuppressive therapy[6–8]. Disappointingly, regression of epithelial tumors following such treatment has been a rare event[6–8]. Nevertheless we may decrease the level of immunosuppressive therapy in patients with highly malignant, or extensive, or advanced cancers, in the hope that the immune system may recover and aid in their destruction. However, such treatment carries the risk of allograft rejection with return of renal allograft recipients to dialysis therapy, but CT recipients may die of this complication.

In individuals needing cytotoxic therapy for widespread cancers we must remember that most agents depress the bone marrow[6–8]. It is therefore prudent to stop or reduce azathioprine dosage during such treatment, to avoid severe bone marrow toxicity. As most cytotoxic drugs have immunosuppressive side-effects, satisfactory allograft function may persist for prolonged periods. Treatment with prednisone may be continued, as it is an important component of many cancer chemotherapy protocols.

As lymphomas are the single most common group of tumors in CT recipients, special mention is made of their management. In suitable patients with localized disease, excision or radiotherapy may suffice. In other patients with localized lesions, or in those with widespread disease, immunosuppressive therapy should be reduced, or even stopped (except for a small maintenance dose of prednisone) in patients who are seriously ill. As most lesions are associated with EBV infection the patients should be given acyclovir. If no improvement occurs, α-interferon should be administered. Failure to cause complete regression is an indication for using chemotherapy. As the patients are already heavily immunosuppressed, these agents should be used with caution as some patients have died of overwhelming infections following their use. It may be wise to reduce dosage of the drugs to 67–75% of that used

in non-immunosuppressed patients, and to restrict the number of courses given if the patient responds satisfactorily. Monoclonal anti-B cell antibodies have been used successfully to treat some B cell lymphomas but, apparently, these are no longer being manufactured.

Etiology of *de novo* malignancies

The causes of cancers in organ transplant recipients are not known, but a complex interplay of multiple factors is probably responsible[6–8,14,22,23,26,31]. A major role can be assumed for impaired immunity. Oncogenic viruses are also important, and may account for the short 'latent period' between transplantation and the development of many tumors. Other factors that may play a role include possible carcinogenic effects of some immunosuppressive agents; possible synergism of these agents with environmental carcinogens such as smoking, sunlight, radiation, food additives, etc.; the administration of other potentially carcinogenic drugs to some renal transplant recipients (such as diphenylhydantoin or isoniazid); and genetic susceptibility or resistance to certain types of neoplasia.

COMMENT

Although cancer is a complication of transplantation, one must stress that the great majority of organ transplant recipients do not develop this problem. Transplantation of malignancies can nearly always be avoided by careful selection of donors. CT transplantation should be considered in patients who were previously treated for cancers, except for those who have a short life expectancy from their tumors. Many patients who develop *de novo* cancers after transplantation have readily treatable malignancies of the skin, uterine cervix, or vulva and perineum. However, with the limited experience gained thus far, CT recipients appear to be more prone to develop potentially life-threatening malignancies, particularly lymphomas, related to the more intense immunosuppressive therapy that they require compared with renal transplant recipients.

Acknowledgements

The author thanks numerous colleagues, working in transplant centers throughout the world, who have generously contributed data concerning their patients to the Cincinnati Transplant Tumor Registry. This study was supported in part by a grant from the Veterans Administration.

Long-term Management and Late Complications of the Thoracic Organ Transplant Recipient

D.P. NELSON, N.K. IMES AND D.K.C. COOPER

INTRODUCTION

The care of thoracic transplant patients centers on the use of immunosuppression to balance rejection (Chapters 8–10) against infection (Chapter 11), and on the management of these two major complications when the balance achieved is uneven. Primary care delivery to these patients is accomplished in the context of the unique toxicities and drug interactions of the immunosuppressive agents used (Chapters 8 and 10). Although some management issues directly relate to surgically altered anatomy, most are the consequence of the drugs that permit the coexistence of self with non-self.

ARRHYTHMIAS

Bradycardia

Bradycardia occurs within the first 2 weeks postoperatively in about 20–40% of heart transplant (HTx) patients, but only 5–15% of heart recipients will require a permanent pacemaker[1–6]. Approximately 60% of bradycardias are related to sinus node dysfunction and 40% to AV block[5]. Infrequently, bradycardia may be related to atrial fibrillation with a slow ventricular response[4].

Bradycardia may be caused by rejection, pretransplant amiodarone administration, ischemic-preservation injury, and surgical injury to the sinus node, conduction system or sinoatrial blood supply. Although not highly sensitive or specific for rejection, the correlation of bradycardia with rejection is great enough that cardiac biopsy should be considered when it occurs. Late bradycardias (beyond 5 months post-transplant) have been reported in about 1.5% of patients, and half of these were associated with cardiac rejection[4].

Oral administration of slow-release theophylline has been used to reduce the incidence of pacemaker placement[7], but not everyone has enjoyed success with this approach. Oral terbutaline has been used in at least one case to convert a hemodynamically significant junctional rhythm to sinus rhythm[8].

Atrial fibrillation or flutter

These occur in about 25–50% of cardiac recipients and, although relatively insensitive for rejection, are moderately specific and their identification should generally result in cardiac biopsy[9,10]. In one study almost 80% of atrial flutter episodes were associated with rejection, but only about half of these were moderate or severe[9]. Histologic resolution of rejection following immunosuppressive therapy sometimes fails to convert the patient to normal sinus rhythm, but atrial overdrive has been successfully used for conversion in this setting[9].

Although originally it was not contemplated that digoxin would have a significant beneficial effect on slowing or converting atrial fibrillation or flutter, it is generally found to be helpful. Calcium channel blocking agents and quinidine may also need to be employed.

Ventricular arrhythmias

These are common early after HTx, but are not generally predictive of rejection[10].

Atrial dysrhythmias

Atrial dysrhythmias can develop following lung transplantation (LTx), as after any major pulmonary operative procedure, but can usually be controlled adequately with digoxin or calcium channel blocking agents.

LATE SURGICAL COMPLICATIONS

Pericardial effusion

Although pericardial effusions are common and usually benign sequelae to cardiac surgery, little has been published regarding their occurrence following HTx. Effusions usually occur within the first 3 postoperative months. Large effusions are relatively uncommon, although tamponade should always be considered in the

differential diagnosis of early postoperative hypotension, independent of effusion size. Both acute and chronic rejection have been associated with the development of pericardial effusions, but small effusions that do not increase are usually insignificant[11,12].

Persistent inguinal lymphocele

If the femoral vessels have been used for access for cardiopulmonary bypass, then a persistent lymphatic leak may result in the inguinal–femoral region. Although such lymphatic leaks are uncommon following routine heart surgery, they appear to be significantly more frequent following HTx. This is almost certainly related to the effect of corticosteroid therapy on wound healing. Lymph collects beneath the groin incision, forming a fluctuant, non-inflamed mass.

Although it can be repeatedly drained by syringe and needle, a permanent solution almost always requires a further operative procedure. Goldstein *et al.*[13] have described a rectus femoris flap repair, which combines ligation of obvious lymphatic fistulae with a muscle transposition to increase vascularity and to fill the dead space created by the lymphocele. We have preferred a technique in which the sartorius muscle rather than the rectus femoris is immobilized and utilized (E. Dalton, unpublished). Rotating the sartorius muscle into the defect is efficacious, is technically easier, and leads to no apparent loss of muscular function or strength in the lower extremity. The technique has been elegantly described by Mathes and Nahia[14].

COMPLICATIONS OF ENDOMYOCARDIAL BIOPSY

Cardiac perforation occurs in less than 1% of endomyocardial biopsies performed on HTx recipients[15]. The biopsy complication rate of 3% reported by one group using the jugular vein approach was predominantly a result of venous puncture (e.g. carotid puncture and bleeding)[16]. The elimination of 'major' complications has been reported by using the femoral vein approach, utilizing a catheter designed specifically for this purpose[17]. Ultrasonographically guided biopsies (in place of fluoroscopy) slightly improved safety and sampling in one study[15], but few operators have experience using this approach, despite its additional advantages of mobility (bedside biopsy) and elimination or radiation exposure. The selection of biopsy approach should depend on the patient's anatomy and level of hydration, and the personal preference of the physician performing the procedure.

Coronary-artery-to-right-ventricle fistulae have been angiographically documented in about 5–15% of HTx recipients and are thought to result from cardiac biopsies[18–21]. They are, however, generally clinically insignificant due to the small shunt volume.

Although the tricuspid valve may be damaged by the bioptome during the biopsy procedure, the incidence of tricuspid regurgitation does not appear to correlate with the number of cardiac biopsies performed[22].

Atrioventricular valve regurgitation

Tricuspid regurgitation is commonly seen immediately post-HTx. At about 5 months post-transplant, mild or moderate tricuspid regurgitation is seen in about 25% and 12% of recipients, respectively[23]. Mild mitral regurgitation occurs in about 20% of patients by the fifth postoperative month[23]. The incidence of tricuspid regurgitation increases to about 40% by 1 year post-HTx and to about 60% at 2 years[22]. Post-HTx tricuspid regurgitation has shown an association with the presence of pre- and postoperative pulmonary hypertension[24]. These valvular regurgitant problems, however, are usually hemodynamically insignificant[22].

COMPLICATIONS OF TRANSBRONCHIAL LUNG BIOPSY

Patients who receive lung or heart–lung allografts will probably undergo multiple bronchoscopies and transbronchial lung biopsies. Serious complications are unusual, but abnormalities of gas exchange are common during the procedure[25–28]. Transient hypoxemia, hypercapnia and hypotension during bronchoscopy can generally be satisfactorily tolerated by the patient, and the use of agents such as flumazenil and naloxone to reverse the effects of conscious sedation further add to patient safety.

Performance of transbronchial biopsies is associated with a greater risk of serious complication than is routine bronchoscopy, including: (a) perforation of the lung with subsequent pneumothorax, (b) excessive bleeding, and (c) dissemination of infection.

In early series, pneumothorax was reported to occur in as many as 5.5% of transbronchial lung biopsies[26,28]. However, pneumothorax did not occur in a series of 200 consecutive procedures reported by Trulock *et al.* in the evaluation of lung transplant recipients[29]. Post-bronchoscopy chest radiography or fluoroscopy to check for the presence of a pneumothorax is mandatory, since these patients may tolerate even a relatively small pneumothorax poorly, and may require chest tube placement to allow lung expansion.

Excessive bleeding is uncommon during transbronchial lung biopsy, but may be life-threatening. Patients with severe pulmonary impairment clearly tolerate bleeding particularly poorly. Emergency intubation and possibly balloon tamponade of a bleeding lung segment may be necessary to control post-biopsy hemorrhage[28,30]. When large numbers of biopsies are taken during a single examination, the incidence of bleeding appears to increase. Scott *et al.*[31] reported that 27 of 219 patients had 100 ml of bleeding or more when an average of 17.3 transbronchial biopsies were obtained. Preoperative screening for coagulopathy should be carried out in all patients who are to undergo transbronchial lung biopsy, and should include protime, partial thromboplastin time, platelet count, and any other studies suggested by preoperative evaluation.

The incidence of dissemination of infection within a transplanted lung is difficult to assess. Trulock *et al.*[29] reported a 2% incidence of pneumonia in their series of transplant patients undergoing transbronchial biopsies. Our policy has been to give broad-spectrum antimicrobial therapy to patients who have suspected infection, or who demonstrate grossly purulent secretions in the airways. More specific therapy is prescribed once the culture and sensitivities of the bronchoscopy specimens are reported.

NEPHROTOXICITY

The most important factor in the post-transplant development of nephrotoxicity in thoracic transplant patients is cyclosporin (CsA)

therapy. The pathophysiology is characterized by intrarenal afferent arteriolar vasoconstriction mediated by altered vascular responsiveness to vasodilators and vasoconstrictors, and perturbations in the balance between these vasoactive mediators, favoring constriction. These vasoactive mediators may be of endothelial, platelet, or other origin, and include endothelin, thromboxane A_2, nitric oxide, serotonin and prostaglandin. Renal tubular injury may also contribute to renal insufficiency[32–39]. Acute nephrotoxicity is dose-related and reversible, but chronic nephrotoxicity appears to be neither.

Chronic maintenance CsA therapy results in a decline in renal function that has been characterized as biphasic, with the initial decline occurring more rapidly over the first 6–24 months post-transplant, and a subsequent decline occurring more slowly thereafter[40–42]. Although reduction of CsA target levels beyond 18 months post-transplant has been correlated with increased rejection without improvement in renal function in heart recipients[43], it seems possible that the reduction of CsA administration which conventionally occurs in most programs during the first postoperative year is contributory to the stabilization of renal function beyond 6 months post-transplant. The observation that late renal function stabilizes, and that further reductions in CsA administration may result in rejection, but not improved renal function, has also been reported in renal transplant patients[44,45].

In HTx recipients, however, impaired cardiac function from acute rejection should always be excluded as a cause of decreasing renal function.

In 1990 the Pittsburgh group reported a 1.5% incidence of end-stage renal disease by 18 months post-transplant in their heart transplant population[40], results which are comparable to our own experience. The 6% incidence of renal failure reported in LTx patients[41] correlates well with the early experience following HTx nearly a decade earlier[39]. It is reasonable to expect that the renal failure rate in LTx patients will decline with experience, as it did with HTx.

Early postoperative CsA nephrotoxicity can be ameliorated in the patient with (or at risk for) acute renal failure by reducing or eliminating CsA dosing and employing antithymocyte globulin or OKT3 therapy instead, particularly during the first 14 postoperative days. However, this approach has its potential complications. (Polyclonal or monoclonal antithymocyte globulin use beyond the first 7–14 days has been associated with an increased incidence of post-transplant lymphoproliferative disease and xenosensitization, often resulting in graft loss from vascular rejection.) In our experience, if renal function compatible with maintenance CsA administration has not been achieved with a CsA-sparing protocol by 7–10 days post-transplant, such improvement often does not subsequently occur.

Less impaired renal function has been seen in renal transplant patients receiving omega-3 fatty acid therapy[46], but this benefit may result from reduced rejection, rather than from the effects of suppressed eicosanoid synthesis on CsA-induced nephrotoxicity. Cilastatin, which currently is available only in combination with imipenem, has been reported to reduce CsA nephrotoxicity during the first postoperative week[47], but experience is limited. The mechanism of protection has yet to be defined, but may be related to impaired tubular cell uptake of CsA. The early reports of reduced CsA nephrotoxicity with the use of prostaglandin E-series agents[48] have unfortunately not been supported by subsequent studies[49,50].

Pentoxifylline has been shown to improve renal function in bone marrow transplant recipients receiving amphotericin and CsA[51], and in animal studies has been shown to reduce CsA nephrotoxicity[52]. Possible mechanisms may include impairment of TNF m-RNA transcription, and reduced release or action of interleukin-2. In our own experience we have not found pentoxifylline to be helpful. The continuous intravenous infusion of CsA, particularly during the early post-transplant period, may offer some protection from nephrotoxicity by the elimination of peak CsA levels. Although this approach is not well established in the literature, our experience with it has been modestly favorable.

Because CsA nephrotoxicity results in the hyperexcretion of creatinine, serum creatinine level and creatinine clearance may overestimate the true glomerular filtration rate[53]. Several other tests of renal function, which are more accurate than creatinine clearance in CsA-dependent patients, have been identified and include the inulin and ^{99}mTc-DTPA tests, and urographic contrast media clearance methods[54,55]. While these methodologies are important in studying the comparative effects of various interventions on renal function, we have not found them practical or cost-effective in the routine clinical management of thoracic transplant recipients.

SYSTEMIC HYPERTENSION

Essential hypertension commonly predates transplantation, particularly in HTx candidates. The fluid-retaining properties associated with steroid administration further contribute to this problem post-transplant, but the major potentiator of post-transplant hypertension is the use of CsA. The incidence of hypertension in extrarenal organ transplant recipients approaches 90%[56–58].

As described in the discussion of CsA-induced nephrotoxicity, preglomerular vasoconstriction occurs at the level of the afferent arteriole through a variety of proposed mechanisms, and results in increased salt and water reabsorption by the proximal tubule. These latter effects, combined with the enhanced peripheral and renal sympathetic activity elicited by CsA, are thought to play an important role in the pathogenesis of CsA-associated hypertension[59].

Weight control, sodium restriction, and exercise play an important role in the management of hypertension in thoracic transplant recipients, just as they do in the general population. Renal magnesium loss (a consequence of CsA administration) may further potentiate hypertension. Normalization of serum magnesium levels with magnesium supplementation should, theoretically, contribute to improved blood pressure control, although to our knowledge no correlation between serum magnesium level and blood pressure has been reported.

Protocols for the treatment of post-transplant hypertension vary considerably from center to center. Our first therapeutic agent of choice is a calcium channel blocker. These agents inhibit afferent arteriolar vasoconstriction. Dihydropteridine calcium antagonists, other than nicardipine (isradipine, nifedipine, nitrendipine, and fleodine) do not interfere with CsA metabolism, but diltiazem and verapamil both interfere with the cytochrome P450 enzyme system metabolism of CsA, resulting in higher CsA levels. This latter effect has been intentionally used to reduce CsA dosages and thus defray costs[60], but may also result in elevation of the

serum creatinine. Diltiazem and verapamil may also have negative inotropic and, in the case of verapamil, chronotropic effects which may be important in some patients. For these reasons (impaired CsA metabolism and negative inotropic effect), we prefer using the dihydropteridine calcium blockers.

Angiotensin-converting-enzyme (ACE) inhibitors vasodilate the efferent glomerular arteriole, and in conditions of preglomerular vasoconstriction may result in a decline in glomerular filtration rate. At least one study has shown a significant improvement in renal function when hypertensive heart transplant recipients were converted from ACE inhibitors to calcium channel blockers[61]. ACE inhibitors have the additional disadvantage of causing hyperkalemia (adding to the CsA-associated hyperkalemia that not infrequently occurs), and sometimes cause a troublesome cough.

Diuretic administration for the control of peripheral edema has the added advantage of being adjunct therapy for hypertension. In our experience, thiazides have generally been less effective than loop diuretics. Overzealous diuretic use, however, will lead to intravascular depletion with resulting impaired renal function. Caution is therefore recommended when using these agents. If there is no edema or other evidence of fluid overload, diuretics should probably not be added as the second therapeutic agent for hypertension that is refractory to calcium channel blocker therapy.

We have found that the use of beta-receptor antagonists in HTx recipients commonly results in fatigue and decreased exercise tolerance. Others have noted a marked reduction in renal blood flow associated with their use[62]. These effects reduce the suitability of beta-receptor antagonists for the management of hypertension in thoracic organ transplant patients. Furthermore, their negative inotropic effect is unwelcome, particularly in patients with heart transplants.

In patients whose hypertension is refractory to calcium channel blockers with or without diuretics, and when a second hypertensive agent is required (which is not uncommon), we usually add a central alpha-receptor stimulator, such as clonidine, or a peripheral alpha-receptor antagonist, such as prazosin. HTx recipients (whose heart is vagotomized) may experience significant orthostatic hypotension with sympatholytics, particularly peripheral alpha-antagonists. We have, nonetheless, enjoyed some success with long-acting transdermal clonidine patches in those patients who demonstrate poor compliance with oral medications.

A loss of the usual nocturnal decline in blood pressure has been demonstrated in HTx recipients[63], and early-morning hypertension is commonly observed in patients who may remain relatively normotensive throughout the remainder of the day (following their morning antihypertensive drug therapy). Without the employment of nocturnal continuous blood pressure monitoring it is difficult to assess the duration or severity of hypertension in such patients. Our approach has been to employ evening antihypertensive dosing when an individual's blood pressure is clearly trending up by bedtime, and/or the early-morning blood pressure consistently demonstrates marked elevation (e.g. diastolic >105 mmHg). The role of ambulatory blood pressure monitoring in solid organ recipients is poorly defined, but when normative data with such monitoring are better established, such monitoring may facilitate improved management of nocturnal, early-morning, or activity-associated hypertension.

Supine hypertension with orthostatic hypotension is sometimes encountered in HTx recipients. We have attempted to manage this state with small (30 mg) doses of diltiazem, which may be effective because of the increase in intravascular volume associated with this therapy. Effective treatment of the supine (or sitting) hypertension is sometimes complicated by an increase in the orthostatic hypotension, although this fortunately generally resolves with time.

GASTROINTESTINAL COMPLICATIONS

It has been reported that approximately one-third to one-half of HTx recipients experience gastrointestinal (GI) complications, and one-third to one-half of these (or about 10–20% of the total) require some form of abdominal surgery[64-67]. Upper GI disease, such as esophagitis, gastritis, duodenitis, and peptic ulceration, is more frequent than lower GI disease, which includes diverticulitis, various types of hernia, perirectal abscess, anal fissure, and thrombosed hemorrhoids[68,69]. Cholelithiasis is common in HTx recipients, but there exists significant variability in the reported incidence of cholecystitis in these patients. Pancreatitis also occurs with variable frequency, but today is generally reported in <5% of patients (see below).

Reports of the GI complications associated with LTx are too limited to-date for meaningful comparison with the HTx experience, but similarities between these populations are anticipated. Procedure-specific surgical complications (e.g. omentopexy-associated morbidity in LTx patients) may, of course, occur.

Most GI problems resulting in the need for hospitalization or surgery develop during the first 3 postoperative months[66,70], which suggests that high-dose immunosuppression may play a role in their pathogenesis.

Pathogenesis

Pharmacologic immunosuppression, which is almost always more intense during the first 90 days post-transplant, potentiates infectious GI complications, such as CMV-associated enteropathies and herpes simplex virus (HSV) or candidal upper GI disease (Chapters 32 and 57). Immunosuppressive agents also have direct GI toxicities.

CsA and azathioprine can both be hepatotoxic, CsA is known to be lithogenic, OKT3 commonly causes diarrhea, and steroids may promote upper GI ulceration and possibly diverticular perforation. Steroid-sparing immunosuppressive protocols have been reported to offer some protection from significant GI complication. Merrell *et al.*'s study in Utah[70], where aggressive steroid tapering took place, reported that all HTx patients experiencing major abdominal complications were on steroids; no steroid-free patient developed such morbidity. Furthermore, one-third of the major abdominal complications were directly associated with a course of steroid pulse therapy. Of the newer agents, tacrolimus (FK506) may cause motility disturbances, and mycophenolate mofetil may cause nausea and exacerbate acid-peptic conditions.

Hepatotoxicity

Hepatotoxicity is common before and after thoracic organ transplantation. Passive congestion of the liver often predates trans-

plant, and pre-existing injury from alcohol abuse may also be present. Postoperative liver disease may result from drugs (e.g. CsA, azathioprine, or antilipemic agents), infection (usually viral, particularly CMV or hepatitis viruses) or cholecystitis. Azathioprine is perhaps the most common agent to cause disturbances of liver function, but these are generally mild and respond to reduced dosage or discontinuation of the drug.

Upper GI disease

Upper GI disease is usually secondary to sterile acid-peptic disease or infection by CMV, *H. pylori*, *C. albicans*, or HSV. Surgical complications, such as injury to the vagus nerve (resulting in delayed gastric emptying) or diaphragmatic hernia (associated with the use of omental wrap in LTx[71]), may contribute to symptomatology.

CMV disease involving the esophagus, stomach or duodenum may present with fever, dysphagia and/or epigastric pain, or even hemorrhage and/or perforation. Oropharyngeal CMV involvement is uncommon[72–74]. Nausea and bloating may result from CMV-induced impairment of gastric emptying[75]. The diagnosis is facilitated by the endoscopic appearance of lesions and biopsy demonstration of inclusion bodies. CMV is frequently present in the absence of symptoms. In one study of renal transplant recipients[76], almost half of the gastric and duodenal biopsies showed CMV inclusions even though these patients were asymptomatic. Diagnosis by shell vial assay or culture of biopsies is strongly supportive, but contamination by ingestion of salivary-shed virus is possible.

Intravenous ganciclovir therapy for 2–3 weeks is usually effective, although relapse is not uncommon. Ganciclovir resistance may emerge in the future, particularly with the anticipated increased use of the drug with the recent introduction of oral ganciclovir.

In severe infection, or when heavy immunosuppression is being utilized or is anticipated (e.g. during a rejection episode), the addition of intravenous immunoglobulin therapy, particularly of hyperimmune CMV globulin, is probably beneficial.

Helicobacter pylori infection is considered by some to be the most common cause of peptic ulcer in the general population[77], but its role is still not yet well defined in transplant recipients. Endoscopic sampling of 33 randomly selected renal recipients found a 40% incidence of *H. pylori* in the gastric antrum[78]; all patients positive for *H. pylori* were symptomatic. Given the known propensity of immunosuppressed patients for lymphoma (post-transplant lymphoproliferative disease), the recent report of a possible association between *H. pylori* infection and gastric B-cell lymphoma[79] warrants attentive management of *H. pylori* infections. *H. pylori* is diagnosed by the CLO test (*Campylobacter*-like organism, Delta West Ltd) on biopsied gastric mucosa. Various treatment regimens for this infection have been successfully employed. A 2-week course of a combination of bismuth, tetracycline, ampicillin, metronidazole (Flagyl), and an H-2 blocker has proved successful at our own center. Ampicillin is omitted in patients allergic to penicillin.

Although *esophageal candidiasis* and *herpes simplex esophagitis* are common sequelae of immunosuppression, the incidence of these problems has markedly declined in heart and lung recipients with the widespread use of nystatin and acyclovir prophylaxis. Nonetheless, a recent report suggests that intense antacid treatment with omeprazole (Prilosec) may result in esophageal candidiasis[80]. Both fungal and herpetic infection can occasionally develop during aggressive treatment for rejection despite prophylactic regimens or when prophylaxis has been discontinued. The choice of treatment of these infections (generally a choice between fluconazole and amphotericin for *Candida* and intravenous and oral acyclovir for herpes) is based on a variety of factors such as the patient's overall condition, the elapsed time since transplant, renal function, site and severity of the disease, actual or anticipated immunosuppressive therapy, and venous access.

Cholelithiasis

Approximately one-third of cardiac recipients have been shown to have cholelithiasis[81]. Between 6% and 60% of those cardiac recipients known to have asymptomatic cholelithiasis pretransplant will become symptomatic some time post-transplant[81,82]. Seventeen percent of those without gallstones pretransplant will develop them post-transplant[82].

Our current therapeutic approach is to consider pretransplant candidates with *symptomatic* gallbladder disease for pretransplant elective laparoscopic cholecystectomy, weighing the risks of their cardiopulmonary condition against the significant risk of emergency abdominal surgery in the post-transplant setting. Patients with *asymptomatic* stones identified pre- or post-transplant do not undergo laparoscopic cholecystectomy until the development of symptoms.

Oral therapy with ursodeoxycholic acid may dissolve non-calcified stones, but the mobilization of such stones following size reduction may result in common bile duct obstruction. The use of this agent has also been reported on at least one occasion to markedly increase the CsA level in the blood secondary to enhanced absorption[83]. We have used ursodeoxycholic acid in several patients for drug-associated cholestasis with only occasional, modest success, but with no adverse effects.

Pancreatitis

Clinically evident pancreatitis is reported to occur in 2–18% of HTx recipients[65,67,70,84]. The incidence and severity of disease appear to vary between centers. Subclinical pancreatitis may be fairly common. Aziz *et al.*[68] reported a 6% incidence of pancreatitis identified at autopsy in heart and heart–lung recipients (without clinical evidence of pancreatitis) dying of other causes. Fernandez and Rosenberg[85], however, found autopsy evidence of clinically unsuspected pancreatitis in 35% of kidney transplant recipients. Possible etiologic factors include cholelithiasis, hyperlipidemia, CMV infection, drug toxicity (CsA, azathioprine, cyclophosphamide, steroids, sulfonamides, tetracycline, furosemide, ethacrynic acid, phenformin, and procainamide)[86], and recent cardiovascular surgery.

The relationship between cardiopulmonary bypass (CPB) and pancreatitis has been thought in part to be perfusion related, but Fernandez-Del Castillo *et al.*[87] demonstrated the perioperative administration of calcium chloride (in dosages exceeding

800 mg/m^2 of body surface area) to be an independent predictor of pancreatic cellular injury in patients undergoing CPB. The comparable incidence of pancreatitis in heart and kidney transplant recipients suggests that CPB may play a relatively small etiologic role[85,88–90].

The diagnosis, prognostic indicators and treatment of pancreatitis are well described in a recent review[91]. Contributing factors (including drugs) should be eliminated or ameliorated, if possible. The temporary conversion of oral CsA administration to a continuous intravenous infusion may improve the pancreatitis, presumably by the elimination of high peak CsA levels.

Colonic perforation

There is scant material in the literature focusing specifically on colon perforation in heart or LTx recipients. Colon perforation has been reported in <2.5% of HTx recipients[70]. Despite its overall low incidence, it did represent 12% of major 'abdominal complication' described in one study[70].

This subject has, however, received more attention in the renal transplant literature[91–94], which has reported a possible decline in the incidence of colonic perforation in the CsA era, thought to be related to a reduction in steroid use. The postulate is that steroids cause lymphoid atrophy, gut wall thinning, decreased mucosal epithelial replacement, and decreased fibroblast reparative activity. Furthermore, when a perforation occurs, an impaired inflammatory response prevents abscess formation.

Risk factors for colon perforation identified by Church *et al.*'s review of the literature[92] include renal failure, ischemia, fecal impaction, and steroid therapy. A small percentage of perforations reported in the renal transplant literature were secondary to Ogilvie's syndrome (non-obstructive colonic dilatation), but by far the majority were related to perforated diverticula. The etiology of Ogilvie's syndrome is unknown, although it tends to occur in critically ill and/or uremic patients; it commonly responds to colonoscopic decompression. Diverticular perforation usually occurs in the left hemicolon, whereas Ogilvie's syndrome is usually on the right.

The diagnosis of *diverticulitis* may be confounded by maintenance steroid administration. Vague complaints of generalized abdominal, deep pelvic or lower quadrant (especially left) or even flank pain should arouse suspicion of diverticulitis, pyelonephritis, nephrolithiasis, or adnexal disease. Radiation of discomfort to genitalia or inner thighs may also occur in any of these conditions. Coexisting diarrhea suggests a colonic etiology. Physical signs may be unimpressive, and fever and leukocytosis may be absent or, if present, unhelpful in narrowing the differential diagnosis. CMV colitis and other enteric pathogens (e.g. *Clostridium difficile*, *Bacillus cereus*, *Salmonella*, etc.) must be excluded in patients with diarrhea. Computerized tomography of the abdomen with infusion may be helpful in making the diagnosis.

Free perforation into the peritoneum from any etiology is a surgical emergency. Empiric perioperative antibiotic selection should be based on a variety of considerations, including the local incidence of *Bacillus fragilis* resistance, a history of penicillin allergy, which would also exclude imipenem–cilastatin (Primaxin) use, current renal function, and recent antimicrobial use. The results of intraperitoneal cultures should be aggressively sought, and special attention given to the identification of enterococcal or *Candida* growth. Serial postoperative abdominal computerized tomography scans are commonly obtained to exclude the development of a phlegmon, which would require surgical drainage.

Diverticulitis without perforation should be treated by hospitalization and intravenous antibiotics, but consideration should be given to elective hemicolectomy, particularly with recurrent disease.

Emergency surgery for GI complications

Emergent abdominal surgery has been associated with a 71% mortality rate in one study, while elective procedures in the same study resulted in no mortality[65]. Most emergent surgeries are carried out for upper and lower GI perforations, and are infrequently performed for GI bleeding. Surgery for acute cholecystitis was problematic in some programs several years ago, but has become less so in recent years, probably because of the advent of laparoscopic cholecystectomy, which has also enabled elective surgery to be performed with low morbidity before such complications develop.

The presence or absence of free perforation may be extremely difficult to confirm without surgery, especially in patients on maintenance steroids, yet it is important not to delay surgery unduly. The Pittsburgh group's experience[94] demonstrated the timing of surgery for colonic perforation to be critical. If surgery was performed within 24 hours of perforation, the patient survival rate was 86%. If surgery was delayed for more than 24 hours following perforation, survival was only 25%.

HYPERLIPIDEMIA

Hyperlipidemia is a common complication of thoracic organ transplantation, and both steroid and CsA use have been shown to contribute to this problem. Although one study failed to show an association between pre- and post-transplant hyperlipidemia[95], another found post-transplant hyperlipidemia to be associated with pretransplant coronary artery disease[96]. Hyperlipidemia usually peaks by 3–6 months post-transplant[95,97]. Although both CsA and steroids have been reported to elevate both total and LDL cholesterol, triglyceride elevation has been inconsistently ascribed to either agent[98,99]. Cumulative prednisone dose has been reported to be a stronger independent predictor of elevated total and LDL cholesterol in HTx recipients than cumulative CsA dose[98].

Although graft vasculopathy in HTx recipients is thought to be primarily immunologic in origin, elevations in cholesterol and triglycerides have each independently been associated with transplant vasculopathy in a few reports. The consequences of immunologic vascular injury may be potentiated in a hyperlipidemic milieu. Treatment of hyperlipidemia must therefore balance the undefined role of hyperlipidemia in graft vasculopathy (combined with the extracardiac vascular risks of hyperlipidemia) against the known toxicities of pharmacologic intervention.

Antilipemic agents other than the 3-hydroxy-3-methylglutaryl coenzyme A (HGM-CoA) reductase inhibitors have risk/benefit characteristics which may limit their utility in thoracic organ

transplant recipients. Bile-acid-binding resins, such as cholestyramine, may interfere with CsA absorption and elevate triglycerides[99]. Nicotinic acid is hepatotoxic (as are CsA and azathioprine) and may contribute to the glucose intolerance already associated with steroid use. Time-released nicotinic acid reduces the skin-flushing experienced with the drug's use, but increases the risk of hepatotoxicity[100]. Gemfibrozil, a fibric acid derivative, is more useful than HMG-CoA reductase inhibitors in the treatment of hypertriglyceridemia, but is less effective in the treatment of elevated total or LDL cholesterol[101]. Fibric acid derivatives have been associated with cholelithiasis[99], which is of concern because of the increased incidence of cholecystitis in HTx patients. Because fibric acid derivatives and their metabolites are eliminated in the urine, their use in patients with CsA nephrotoxicity is limited.

HMG-CoA reductase inhibitors, such as lovastatin, simvastatin, and pravastatin, are probably comparably effective antilipemic agents, and are our agents of choice for hypercholesterolemia[101-104]. When these drugs are used in combination with other antilipemic agents (nicotinic acid or gemfibrozil), or used in high doses (lovastatin >20 mg daily or equivalent), there is a marked increase in risk of myositis, which may result in rhabdomyolysis[105,106].

Myositis in this population may result from CsA-induced changes in antilipemic drug metabolism, which has been shown to result in increased lovastatin enzyme inhibitor levels[102]. A commercial manufacturer of simvastatin (Merck) has recommended not exceeding a daily dose of 10 mg in patients taking CsA.

Kobashigawa *et al.*[103] have shown that pravastatin is not only effective and safe in lowering cholesterol levels after HTx but would also appear to have some immunosuppressive effect. When begun early (within 2 weeks) after HTx, at an initial dose of 20 mg/day (being increased to 40 mg/day if tolerated), it has been shown to be associated with less frequent cardiac rejection accompanied by hemodynamic compromise, improved patient survival, and a lower incidence of graft vasculopathy as determined by angiography and at autopsy. The exact mechanism whereby these beneficial effects are produced remains uncertain, but the cytotoxicity of natural killer cells was demonstrated to be lower in patients receiving pravastatin than in control patients.

OSTEOPOROSIS

The reported incidence of vertebral compression fractures in HTx recipients ranges from 1% to 44%, with most studies reporting an incidence >25%[107-111]. The program reporting the lowest fracture incidence[107] treated 38% of its patients with calcitonin, and the primary HTx physician at the time was a practicing endocrinologist who was particularly attentive to hormonal therapy (52% of the men received testosterone and 92% of the women received estrogen). The vertebral fracture incidence after HTx is comparable to that reported after liver transplantation (29%)[112]. Comparison with renal transplant populations is complicated by the occurrence of renal osteodystrophy in renal transplant patients.

Although some have reported a lower mean bone (mineral) density in those with fractures than those without, bone density has proven to be an unreliable predictor of fracture in heart and kidney transplant patients[107-111,113]. Patients with low bone densities are commonly free of fractures, and vertebral compression fractures may occur in those with normal vertebral bone densities. Nonetheless, despite its limitations, we believe that bone densitometry may be useful in these patients. No mineral biochemical predictors of fracture have been identified[110].

The pathogenesis of osteoporosis in thoracic organ transplant patients is primarily related to: (a) pre-existing osteoporosis antedating transplant and (b) the use of immunosuppressive agents post-transplant. The occurrence of osteoporosis in HTx candidates has been reported variably to be both common[107] and uncommon[110]. It is reasonable to presume that some thoracic transplant candidates have osteoporosis of multifactorial origin (hypogonadism, loop diuretics, inactivity, cachexia, cigarette smoking, anticoagulants, or steroid administration).

Steroid administration has direct effects on bone resorption and formation, and causes changes in: (a) calcium absorption from the gut, (b) gonadal secretion, and (c) vitamin D metabolism[114]. Steroids affect trabecular bone more than cortical bone, and vertebral bodies and ribs are the bones that most commonly suffer atraumatic fracture in steroid-dependent patients[114,115]. Although CsA can also adversely affect trabecular bone, the co-administration of CsA and steroids may be mutually protective because of the high and low bone turnover rates that result from CsA and steroid administration, respectively[116]. A recent study of bone and mineral metabolism in renal transplant recipients concluded that CsA did not significantly contribute to osteoporosis[117]. Tacrolimus, rapamycin, mycophenolate mofetil, azathioprine, and methotrexate have all shown effects on bone metabolism, which have not yet been exhaustively studied[116].

Although the occurrence of osteopenia in HTx recipients has been shown to correlate with the cumulative dose of steroids[110], the incidence of fractures has been shown to correlate with the number of rejection episodes rather than the cumulative steroid dose[109]. High-dose steroid administration may cause rapid bone loss resulting in fractures within weeks to months[118] and, because very rapid bone loss may result in micro-architectural abnormalities[119], it seems possible that high-dose steroids may result in fracture-prone architectural changes unappreciated by bone densitometry. Osteopenia has been reported to develop most rapidly in the first 6–12 post-transplant months[108,120].

Dual-energy X-ray absorptiometry (DEXa) appears to be the bone densitometry method of choice, and is preferable to either single or dual photon absorptiometry (SPA or DPA). Quantitative computerized tomography (QCT) is more expensive, is less precise, has greater radiation exposure, and is more time-consuming. However, it offers a truer measurement of cancellous density through three-dimensional imaging, and may avoid the posterior spine and aortic calcifications[119].

The treatment and prophylaxis of transplant-associated osteoporosis includes treatment of hypogonadism[107], avoidance of excessive thyroid replacement[121], and minimizing steroid administration. Although steroid elimination may expose the patient to the unopposed bone effects of CsA, the net effect of steroid reduction is almost certainly favorable to bone metabolism. Hormonal replacement is indicated in the oophorectomized or postmenopausal woman, and testosterone is probably beneficial in older men. Treatment of osteoporosis identified pretransplant seems prudent.

Treatment/prophylaxis with calcium supplementation, vitamin D administration, cyclic etidronate therapy, and calcitonin are common approaches. Although milk-alkali syndrome may result from calcium carbonate administration to cardiac recipients (especially those with renal insufficiency), it is the least expensive method of calcium supplementation if used with discretion[122]. Calcitonin has been successfully used to reduce bone loss in HTx patients, but is expensive[107]. Cyclic etidronate therapy has proven successful in other steroid-dependent populations[123], and a new biphosphonate, alendronate, appears particularly promising with continuous (non-cyclic) administration[124]. Experience with etidronate in patient with creatinine clearances <60 ml/min is limited, and calcitonin should be considered in these patients (S. Epstein, personal communication). Calcitonin and etidronate therapies have not been compared in the solid organ transplant population. It is unclear from existing publications whether the inclusion of 25-hydroxylated vitamin D with other therapeutic modalities is essential. The use of 1,25-hydroxylated vitamin D may be necessary in patients with advanced renal insufficiency, but caution should be exercised in use of this agent because of the risks of hypercalcinemia. Deflazacort has been reported to have less adverse effect on bone than prednisone[125], but experience with this agent in thoracic transplant recipients is still limited.

ASEPTIC BONE NECROSIS

Aseptic bone necrosis is known to occur in association with steroid administration, although its correlation with cumulative steroid dose has been poor. It has been reported to occur in 2.7–10% of HTx patients[109–126,127], but long-term survivors may demonstrate an even higher prevalence. Eighteen percent of 5-year survivors had required bilateral total hip or knee arthroplasties in one program[126]. The incidence in kidney transplant patients has varied from 3% to 41%[128,129] and has been reported in 10% of allogeneic bone marrow transplant recipients[130]. The mean time to diagnosis following HTx is reported to be 44 months[127], but the onset of hip pain has been reported to occur at a mean of 29 months post-transplant[126]. It develops earlier post-transplant in renal (12–22 months) and bone marrow (median of 12 months) transplant patients[130–133].

The incidence in patients with LTx is not yet certain, but is likely to be relatively high in view of the fact that many LTx recipients have received steroid therapy for treatment of their pre-transplant pulmonary condition.

Although a review of steroid-associated osteonecrosis found a correlation with mean daily steroid dose[134], this has been inconsistently demonstrated in individual studies. An association between rejection and osteonecrosis has been reported following heart[109] and kidney transplantation[129,132].

In those afflicted, a mean of 3.3 joints per patient were reported to be involved in one study, which also reported that 64% of these patients had hip involvement, 61% knee, 29% ankle, 21% shoulder, and 7% elbow involvement[130]. Half of the afflicted patients had bilateral hip involvement and half had bilateral knee involvement[130]. Clinical presentation is usually with pain, which may initially be episodic. Although disease is commonly bilateral, clinical presentation is often asymmetric. MRI is more sensitive than conventional radiologic imaging for the diagnosis of aseptic necrosis.

Non-surgical treatment, consisting of analgesics and reduced weight-bearing, is palliative; surgical therapy is frequently required[126,130].

HYPERURICEMIA AND GOUT

Hyperuricemia occurs in about 70–80% of HTx recipients[135]. Six percent of these patients have experienced gout pretransplant and 4–8% experience gout attacks post-transplant[135]. A history of pre-transplant gout is an unreliable predictor of post-transplant gout severity. Acute gout attacks occur at a mean of 17 months post-transplant[135]. Almost half of the patients with definite post-transplant gout have been reported to progress to polyarticular arthritis and/or tophaceous gout within a mean of 31 months[135]. Serious life-threatening joint infection may occasionally complicate gout in transplant recipients[136]. Although hyperuricemia does not correlate with CsA levels or renal insufficiency in HTx recipients[135] (comparable to the experience in renal transplantation at the same institution[137]), hyperuricemia is thought to result from CsA-induced reduction in renal urate clearance[138]. Hyperuricemia resulting from tacrolimus (FK506) administration is also thought to result from a change in renal urate excretion[139]. Diurectics (both loop and thiazide) may exaggerate hyperuricemia, and gout attacks may be precipitated by alcohol ingestion, binge eating, infection, or surgical stress.

Treatment and prophylaxis of gout in solid organ recipients is complicated because of drug toxicities and interactions. Treatment of the acute attack can be accomplished with colchicine, although both hepatic and renal insufficiency increase the risk of myelosuppressive and neuromyopathic toxicity with colchicine. Indomethacin may be effective, but may be nephrotoxic, myelosuppressive, and ulcerogenic. We have experienced modest success with surprisingly low doses of indomethacin (e.g. 25 mg p.o. every 8 hours for three doses and then every 12 hours for two doses). The use of maintenance prednisone may facilitate the success of this lower-than-usual indomethacin dosing. Care should be taken not to manipulate uric acid levels until the acute attack is resolved.

Allopurinol can be used to treat hyperuricemia, but its interference with azathioprine metabolism will result in severe myelosuppression if the azathioprine dose is not empirically reduced in concert with allopurinol administration. It has been recommended that the dose of azathioprine be reduced by 50–75% before initiation of low-dose allopurinol[136]. The risks of allopurinol administration may outweigh the benefits, and it is our general policy not to use allopurinol in our thoracic transplant recipients. The myelosuppressive effects of cyclophosphamide may also be increased by co-administration of allopurinol. Mycophenolate mofetil is not reported to interact with allopurinol, and may be an appropriate alternative to azathioprine in the patient with poorly controlled gout.

Probenecid uricosuric therapy for hyperuricemia is limited by the drug's relative ineffectiveness at glomerular filtration rates <30–50 ml/min[138]. If hyperuricemia is treated with allopurinol or probenecid, maintenance colchicine at 0.5 mg p.o. twice daily should probably be administered until the uric acid level is within normal limits, to prevent precipitation of an acute attack. Uncontrolled acute attacks very infrequently require an intra-articular steroid injection. Maintenance prophylaxis with

colchicine (0.5 mg p.o. twice daily), with careful monitoring for toxicity, should be considered in the patient with frequent exacerbations. A purine-rich diet should be avoided.

CHANGES IN SEXUAL ACTIVITY AND FUNCTION

There are a few data available on the incidence of impotence following heart or lung transplantation. In renal transplant series, however, impotence has been reported in 22–43% of male recipients[140]. Male potency is a complicated process, and the etiology of any impotency may be multifactorial.

Hypogonadotrophic hypogonadism occurs commonly immediately following organ transplantation or other open-heart surgery. We have documented reductions in serum testosterone from normal levels to levels at the lowest measurable limits in as few as 4 days following HTx. The duration of this hypogonadism appears to vary with the clinical status of the patient. For those who suffer repeated illnesses the hypogonadism will likely persist. Others who regain their vigor quickly may have relatively few weeks of hypogonadism. Older patients have a more prolonged period of hypogonadism. Impotence may last for only a few days or become permanent.

We now frequently provide testosterone supplementation therapy following cardiac or pulmonary transplantation, mostly because low levels may be an important contributing factor in the rapid loss of trabecular bone which occurs in many patients. Unfortunately, impotence may still occur, particularly in those with prolonged or frequent illness (such as from CMV infection) or psychological factors.

Erectile impotence, without loss of libido, may be reported by patients with extensive (diabetic or non-diabetic) atherosclerotic vascular disease or peripheral neuropathy. Relative impotence may occur during the period of weaning from a prolonged course of testosterone replacement therapy. Antihypertensive agents may also be a cause of impotence, but this can frequently be avoided by careful selection of the agent.

In contrast, post-transplant improved cardiac output or respiratory function may occasionally restore lost potency, and an increased sexual appetite may follow the increased capability and improved feeling of well-being.

DIABETES MELLITUS

We have not considered uncomplicated diabetes to be a contraindication to transplantation, though we have not accepted the patient with significant diabetic complications, such as microvascular disease or neurotrophic foot ulcers. Some degree of impairment of glucose tolerance is seen in virtually all patients at some point in the transplantation process. It is easy to overlook the presence of hyperglycemia in transplant patients since it is usually asymptomatic. In the post-transplant period, therefore, each patient must be willing to monitor his/her glycemia at home, keep records, and adjust therapy as prescribed. Certain patients will establish themselves as having a greater tendency towards hyperglycemia, and these patients should be monitored closely. Periodic monitoring of the glycosylated hemoglobin will help in identifying prolonged unacceptable hyperglycemia.

In its simplest form, hyperglycemia is seen in the first few days following transplantation during high-dose methylprednisolone therapy. It is seen again during the treatment of an acute rejection episode with methylprednisolone pulse therapy. In these circumstances the hyperglycemia usually lasts only a few days. Without treatment, plasma glucose levels >16.7 mmol/l (300 mg/dl) are commonly encountered. In the unproven belief that it is beneficial to maintain a near-normal metabolic milieu, we routinely monitor and treat this hyperglycemia with the goal of maintaining glucose levels closer to 5.6 mmol/l (100 mg/dl), and certainly below 8.3 mmol/l (150 mg/dl). Granulocyte chemotaxis may be impaired at higher plasma glucose levels.

Some patients will present for transplantation with familial type II diabetes. The degree to which they display this diabetes will depend on several factors, which include: (a) relatively body masses of muscle and adipose, (b) diet, and (c) activity. Their diabetes can often be controlled with proper diet and activity. These persons are profoundly affected by pharmacological doses of corticosteroids. Until the corticosteroid dose is reduced to physiological levels, or eliminated entirely, treatment for diabetes will be required. After reduction of corticosteroid dosage, those who follow the prescribed diet and activity instructions rarely require pharmacological treatment of their diabetes. Many patients, however, are unable or unwilling to follow such instructions, and require prolonged treatment, usually with oral agents.

At our own center we have transplanted very few patients with uncomplicated type I diabetes. They have done well, but have required large doses of insulin (<300 units daily) during the periods when they were taking corticosteroids in high or moderately high doses.

Treatment of diabetes in the transplant patient is, as in other diabetics, largely empirical. Home blood glucose monitoring is essential, and patients are encouraged to follow a program of diet and exercise. Those patients with relatively normal fasting blood glucose levels, but with postprandial hyperglycemia, are given glipizide, which rarely produces fasting hypoglycemia. Those with fasting hyperglycemia are treated with glyburide. When these agents alone prove insufficient, regular (soluble) insulin is added before some or all meals. Some patients also require intermediate-acting insulin. As the patients' overall health improves, and corticosteroid dosages are lower or discontinued, the insulin may be phased out, and the diabetes controlled with oral agents alone.

Good diabetic control is strongly encouraged. Our goal is to achieve preprandial glucose levels of 3.9–5.6 mmol/l (70–100 mg/dl) and 2 or 3 hours postprandial glucose levels of <8.3 mmol/l (150 mg/dl). Not all patients are sufficiently disciplined to achieve these goals. In long-term follow-up we monitor the glycosylated hemoglobin, the goal being to achieve levels of 7% or less. Levels of >8% are considered unacceptable. A glycosylated hemoglobin level of 9% would correspond approximately to a glucose level of 8.3 mmol/l (150 mg/dl).

GROWTH RETARDATION AND DELAYED ONSET OF PUBERTY

Before the introduction of CsA, because of the complication of growth impairment, many renal, liver and cardiac transplantation units were reluctant to accept children as potential recipients.

Growth retardation in children under the age of 12 or 13 could lead to such gross dwarfism that severe psychological problems ensued. The proportion of children who demonstrated normal growth following organ transplantation varied considerably from 13% to over 60% from one series to another[141,142].

Fortunately, it is now possible to immunosuppress some children without the need for steroid therapy (Chapters 9 and 38). In those that require steroids there is some evidence that the growth retardation effect is minimized by administering a double dosage of steroids on alternate days with no therapy on intervening days[143,146]. The availability of growth hormone preparations may now help prevent this complication.

OCULAR COMPLICATIONS

The eyes can be involved in several post-transplant complications, including CMV retinitis, diabetes mellitus, and temporary changes in visual acuity, almost certainly steroid-induced.

Cataracts can be induced by prolonged high-dose steroid therapy, but have become less common since the introduction of CsA. The typical lens opacity following long-term use of corticosteroid either systemically or topically is a posterior subcapsular opacity[145]. The high doses administered during rejection episodes produce subcortical crystalline opacities which usually affect the posterior pole of the lens. Low-dose corticosteroids sometimes provoke the development of cataracts, especially with prolonged use over at least 12–18 months. There remains controversy as to whether cataract formation is dose dependent[145,146].

BENIGN SKIN LESIONS

In addition to a high incidence of skin cancers (Chapter 12), patients on long-term immunosuppressive therapy not infrequently develop multiple benign skin lesions, which may require no treatment. Warts and keratoacanthomas are not uncommon. Warts are thought to result from reactivation of latent viruses rather than from primary infection[147,148]. It is important, however, to differentiate benign lesions from malignant tumors, such as squamous and basal cell carcinomas, which are the most common malignancies in immunocompromised patients (Chapter 12). All suspicious lesions should be biopsied or excised.

OTHER COMPLICATIONS

The list of other complications of long-term immunosuppressive therapy, especially if corticosteroid therapy, is long (see Chapter 8, Table 3). Clinical features of fluid and salt retention can usually be controlled by diuretic therapy. Increased appetite and weight gain are common and may lead to obesity if not controlled by a strict diet (Chapter 16). Changes in menstrual cycle, acne, night sweats, myopathy, joint pains, and spontaneous petechial hemorrhages in the skin are also common side-effects of steroid therapy.

Patients with widespread atheroma are, of course, at risk from progression of this disease. Reconstructive surgery to peripheral vessels, especially in the legs, or even amputation for painful ischemic ulceration, has been necessary in some patients with progressive peripheral arteriopathy.

14
Psychiatric Aspects

E.S. NASH AND D.K.C. COOPER

INTRODUCTION

Cardiac transplantation emerged in 1967 as a dramatic new way of saving the life of a dying cardiac patient[1]. It was not so much the radical nature of the procedure that triggered the reactions, but the removal and replacement of an organ that is seen by some solely as a physiological pump, but by others as the symbolic seat of love and loyalty[2,3].

Psychiatric experience in the fields of both heart and lung transplantation is indebted to contributions from two allied areas: firstly, the care of patients undergoing closed and open heart surgery, and secondly, experience obtained from involvement in renal and liver transplantation programs. The psychiatric implications of closed and open heart surgery have been extensively documented[4–6]. Of particular relevance was Kimball's identification of nuclear patterns of emotional reaction in patients who were assessed preoperatively; these patterns were found to have predictive value. Of the four groups that he identified, namely (a) the adjusted, (b) the symbiotic, (c) the depressed, and (d) those denying anxiety, it was the members of the latter two who caused concern. Depressed patients had a high postoperative mortality rate, while those who denied anxiety had a high incidence of postoperative psychiatric complications.

The second area, psychiatric experience obtained from involvement in organ transplantation since the first kidney transplant was performed in 1950, has centered around the issues of (a) selection criteria, (b) organ incorporation versus rejection, (c) postoperative psychosis, (d) the complications of immunosuppressive medications, (e) compliance, and (f) rehabilitation.

Psychiatric experience in heart transplantation over the past 25 years (and in lung transplantation for the past decade) has been similar; recipients require psychosocial screening, develop early and late postoperative emotional or behavioral disturbances and have to incorporate a new life-giving organ[7–11]. Thoracic organ transplant recipients have to face not only the physical challenges of organ rejection and systemic infections, but also the psychological challenges of reorganizing family relationships and of reentering employment. It is in all these areas that psychiatric insights have helped transplant teams. Each of these aspects will be considered in greater detail.

The importance of the role of the psychiatrist is well illustrated by the early observation in Cape Town that no fewer than 26% of deaths or loss of cardiac allograft function were related, in some part, to non-compliance on the part of the patient[12], thereby drawing attention to the psychological problems such patients display.

PATIENT SELECTION

Patient selection is important because basic issues of social policy, the limits of medical responsibility, and major ethical and legal considerations are encapsulated in the decision to choose or reject patients[13].

In the early years of cardiac transplantation, mental deficiency and overt psychosis were the only psychiatric grounds used to justify exclusion from a program[14]. With improved survival, and the subsequent expansion of transplantation, resulting in an inadequate number of donor organs, the selection of suitable recipients has become an important issue[15]. The situation with candidates for lung transplantation is similar. Many centers now have a committee of medical personnel who take medical, psychological and social criteria into account (Chapters 5 and 15). A preliminary screening inevitably occurs prior to the actual referral, which reflects to some extent the responses of the referring physician to the patient's personality and to the character of his or her family. Self-referrals for organ transplantation must be viewed with some caution, since this may be indicative of exhibitionistic traits in patients seeking publicity. (The self-referral of donors, however, requires immediate psychiatric intervention, since this suggests suicide intent.)

Many groups today carry out an initial screen using a self-report questionnaire, e.g. the Millon Behavioral Health Inventory (MBHI), or symptom checklist[16] that is completed by the patient. Although this will give helpful information regarding the patient's present psychological status, it may not necessarily predict post-transplant medical problems[16]. Whenever the questionnaire, or clinical history, suggests significant past or current psychological concerns, the patient should be referred for

further psychiatric assessment. This will include an in-depth interview that reviews the patient's personal development, family background and history of psychiatric illness, as well as his or her attitudes to current illness, disability, death, and transplantation.

During this interview it is of particular value to assess the patient's ego strengths, such as his or her capacity to: (a) understand the information offered, to think about problems in a rational way, to communicate needs, and be motivated to regain health; (b) face reality, and not resort to excessive denial or fantasy; (c) maintain a stable mood, without wide emotional swings from elation to the depths of despair; (d) control basic impulses, such as anger, greed, sexuality and self-abuse; (e) use mature ego defenses in everyday life and under conditions of stress; (f) perform age-appropriate life tasks, e.g. education, employment and social responsibilities; (g) make mutually rewarding relationships and use social support; and finally (h) define his/her values, abide by these, and use social resources that reinforce these. These ego strengths are based on those described by Beard[17] and Bellak *et al.*[18].

Dreams are useful cues to reveal unspoken concerns. It is also important to examine current mental functioning using a standardized method[19], which should include inquiry about depression, suicidal ideas and memory impairment, as well as assessment of intelligence, insight, and capacity to make sound judgements, with special relevance to the giving of informed consent. Formal psychological testing may be of assistance[20,21], but critically ill patients are frequently not able to carry out such tests. Where there are language barriers, competent and empathic interpreters, who are familiar with the transplant program, are invaluable.

Evidence of organic impairment may be found in patients with poor cerebral perfusion or chronic hypoxia or hypercarbia, but if this is associated with neurological deficits the impairment is likely to be permanent, and due to brain damage. Evidence of a disturbed personality, indicated by alcohol and drug dependence, an erratic work record, unstable interpersonal relations, and antisocial behavior, have been added in most programs to the original exclusion criteria of mental deficiency and overt psychosis[13]. Affective disorders, anxiety, or problems with adjustment must also be investigated, but are not necessarily contraindications to acceptance for transplantation[15,22–25]. The quality of the patient's psychosocial support is of great importance, and must also be taken into account (Chapter 15). This is particularly so in the occasional patient who has been fortunate in never before having to make a major adjustment in his or her life; such patients may find the adjustments forced on them by the need for thoracic organ transplantation particularly difficult, complicating their preparation for operation and their convalescence.

However, Kuhn *et al.*[26] found that pretransplant psychiatric diagnosis frequently reflected the patient's emotional reaction to current illness and, with the exception of behavioral management problems, did not correlate with subsequent emotional responses. Indeed, most psychiatric distress after evaluation appeared to be related to the protocol (e.g. the waiting period, endomyocardial biopsy, etc.) rather than to any pre-existing psychopathology.

In patients being assessed for cardiac transplantation, the nature of the heart disease in itself may be a cue to the patient's personality and his/her customary ways of adapting to stress. Since some candidates have a history of myocardial infarction (complicating coronary artery disease), they may well show features of the type A behavior pattern described by Friedman and Rosenman[27]. Such individuals characteristically show ambitiousness, striving, overcommitment to work, time urgency and impatience[28]. They strive to be 'good' patients postoperatively and are highly motivated to survive. Another identifiable group comprises those with cardiomyopathy linked to significant alcohol abuse, which has been associated with shorter survival. Careful thought has to be given before a transplant is offered to patients with a history of unpredictability, which may include unstable work and relationship patterns.

While patients with long-standing heart or lung disease, particularly those who have tolerated previous operative intervention, are likely to handle the stress of the transplantation procedure satisfactorily, they may have difficulty in relinquishing a well-established sick role; rehabilitation then becomes a major exercise. Factors that are predictive of a favorable outcome include a patient's ability to discuss the possibility of his or her own death, as well as having a clear use for the time gained by longer survival, reinforced by sound social support[29].

Olbrisch and Levenson[30] carried out a survey of heart transplant programs with regard to the psychosocial evaluation process. There was considerable disagreement among programs as to when a patient was not suitable on psychosocial grounds. Wide discrepancies in the criteria used, and in the rate of patients refused on psychosocial grounds, were discovered. More than 70% of all programs excluded patients for transplantation on the grounds of dementia, active schizophrenia, current suicidal ideation, history of multiple suicide attempts, severe mental retardation, current heavy alcohol use, and current use of addictive drugs. Lack of consensus was found for some exclusion criteria (cigarette smoking, obesity, non-compliance, recent alcohol or drug abuse, criminality, personality disorder, mild mental retardation, controlled schizophrenia, and affective disorder). The proportion of patients rejected for transplantation on psychosocial grounds ranged from 0% to 37%, with an average of 5.6% in the USA and 2.5% in non-USA programs.

WAITING FOR A TRANSPLANT

Once a patient has been accepted for a program, he or she has to await a donor heart[31,32]. Patients referred from distant places may have to live temporarily near the hospital, and are often supported by only one family member. This alien environment can be stressful, especially if the patient has left a well-established support structure and has to wait many weeks or even months[33]. Initial optimism may give way to anxiety, despair, and depression. Individuals who use acting-out, impulsive behavior have difficulty tolerating this phase; exclusion from the program, even at this late stage, should be considered.

POST-TRANSPLANT COMPLICATIONS

There is now a considerable literature on the psychiatric complications of heart transplantation[9,10,34–39] and some early experience after lung transplantation[40].

Immediate postoperative period

In the early days of cardiac transplantation, many patients became psychologically disturbed during the initial postoperative period, just as they did in the early days of heart surgery[6]. These changes were attributed to the convergence of such factors as altered cerebral circulation, prolonged anesthesia, overstimulation by the monitoring systems, the sensory deprivation of immobility, and the unfamiliar bland environment peopled by masked strangers.

The acute psychosis that can occur in this phase bears the features of both 'organic' and 'functional' disturbance; symptoms include reduced level of consciousness, hallucinations, paranoid delusions, disorientation from time and place, and mood disturbance such as depression or undue euphoria. Unconscious anxiety and fantasies about the transplanted heart may be voiced in this context[41]. In addition, there is some evidence that emotional factors can influence the immunologic balance of the body, thereby affecting the organ acceptance or rejection[42].

More recent reports from heart transplant centers indicate that there is now little disturbance in the early postoperative period, which is possibly indicative of improved patient preparation prior to the procedure[21]. However, postoperative organic mental syndromes were reported in a high percentage of the early lung transplant patients[40]; episodes of dementia were found particularly in patients who had undergone cardiopulmonary bypass, had high levels of cyclosporin, or who had to relocate to await surgery. Although many patients are persistently euphoric at having survived the procedure, and are delighted with their increased vital capacity and physical strength, this state of well-being can be threatened by episodes of organ rejection or infection that may trigger depression and anxiety. If hospitalization is prolonged, boredom and social isolation may also take an emotional toll. The steroids required to combat organ rejection pose an additional hazard since they are known to produce depression and even psychosis[43].

Mild symptoms respond to a psychotherapeutic interview and program modification; more severe disturbances such as regressed behavior, irritability, paranoid fears, and suicidal feelings and ideas may emerge and require treatment with neuroleptic medication such as chlorpromazine or thioridazine. Such drugs, however, have a relatively long half-life, and should be used with caution in debilitated patients; a butyrophenone, such as haloperidol, or a thioxanthine, may be preferable in such cases. Risperidol, a new antipsychotic, has a different side-effect profile from the neuroleptics in that it does not carry significant risk of extrapyramidal side-effects. Antidepressants such as the tricyclic or tetracyclic agents should also be administered with caution[44,45], again as they are long-acting, may share a metabolic pathway for degradation with cyclosporin, and may have an arrhythmogenic effect. Shorter-acting non-tricyclics, such as trazadone and maprotiline, offer an alternative. In more recent years, several newer antidepressants have become available, with relatively fewer side-effects. These include fluoxetine, paroxetine and sertraline, which are selective serotonin reuptake inhibitors. Bupropinon, a unicyclic, is also available.

Regressed behavior, which is often triggered by medical complications, responds to empathic and firm handling by staff. As dependency on the staff lessens, it becomes necessary for the patient to practice autonomy in taking control of some aspects of treatment. Some patients are anxious about leaving the security of the hospital and require gradual weaning from the intensive-care unit and, later, the ward environment. The spouse and/or other close family members also need reassurance and instruction. The psychiatrist, clinical psychologist, or psychiatric social worker can help the surgical team understand the anxieties that inevitably occur during and after any hospitalization, particularly if the hospital stay has been for organ transplantation[46]. It is also very important to remember that disturbed behavior, confusion, and headaches may have a neurological cause, such as an intracranial bacterial, viral, or fungal infection, which occurs more frequently in the immunologically compromised host. Epileptic seizures, local pain, or paralysis are indications for immediate neurological investigation to rule out organic pathology, including infection. Neoplasia may account for late neurological/psychiatric disturbance[47].

REHABILITATION

The successful transplant recipient has survived a unique life experience. During the past 50 years, cardiac resuscitation and cardiac surgery have introduced a new dimension of human experience: the patients both 'die' and are 'reborn' or 'resurrected'[48]. Some survivors of cardiac arrest admit to thoughts of resurrection and fantasies of rebirth[38,49]. Organ transplantation brings a new lease of life with the promise of improved health and renewed physical vigor. To quote Paul Coffey, an early British heart transplant survivor: 'Following the transplant, and being given a second chance of life, one has time to think about what really matters'[50]. The early risk of rejecting the transplanted heart or of other post-transplant complications, however, may initially inhibit long-term planning.

Integration of the new organ into the body image is effected in various ways. The organ has to be 'taken in' and become part of a healthy body representation. The heart is seen as a pump to the mechanically-minded patient, devoid of emotional significance, which can be replaced if worn out. At the other extreme, however, a few recipients unmistakably identify with the sex and personality of the donor. Reactions to the organ influence compliance with medication. Complete integration of the organ into the body image involves dealing at some level with feelings of guilt and indebtedness for having received an organ at the cost of another life[41,51].

Mai[52] has observed that, in 18 of the 20 heart transplant subjects that he studied, significant denial with respect to the graft, the donor or both, was present in the 30–90-day period following surgery. Bunzel *et al.*[53] also investigated how heart transplant patients cope with the fact that their own heart has been replaced by a donor organ from an unknown dead donor who was the target of disease, accident or even suicide. Three groups of patients were identified: (a) the complete deniers, who denied thinking about the donor; (b) the partial deniers, who were aware of avoiding thinking about the donor; and (c) those who coped, who accepted the death of the donor as reality and also reported having more or less close connections with the donor. Eighty-two percent of the patients interviewed accepted the donor heart immediately as their own, whereas the remaining 18% avoided talking and thinking about the graft and donor.

Recipients of donor organs, particularly the heart, have to deal with fantasies about the donor. Louis Washkansky, the first heart transplant patient, received a heart from a female donor. He enquired, 'Do you think ... that I might develop busts (breasts) like a woman? ... or become chicken-hearted?'[54] Other male recipients receiving hearts from female donors have also had this type of reaction, though, with the increasing frequency of the operation, such fantasies are becoming rare.

At almost every center the initial heart or lung transplants gained considerable media attention. The early transplant patients' 'fame', even if only local, nourished the rehabilitation process and ensured a 'survivor mission' reaction which was useful in gaining their co-operation. For subsequent survivors the rehabilitation process has been a less dramatic affair, with mundane issues such as housing, employment, and restored marital relationships to be faced (Chapter 15). As thoracic organ transplantation has become more commonplace, however, the patient has had a greater exposure to the experiences of fellow-recipients, and such interchange and sharing can be of great emotional support. Many centers have initiated support groups to enable patients to share their experiences and concerns.

While euphoria and improved self-esteem are found in many patients following operation, the steroid facies, which still occurs in a few, may make the recipient feel self-conscious. In some patients there are difficulties in concentration, emotional lability, and irritability, while, in others, features of mild organic brain impairment can be found[55]. Occasionally, recipients may show a morbid interest in their surgical 'twins' who have received organs from the same donor (e.g. kidneys), and identify closely with them.

Follow-up has to be carefully planned. On the one hand, transfer to physicians or surgeons remote from the transplant center, who have had little experience with transplantation programs, engenders insecurity and negative transference reactions. This may jeopardize compliance with dietary instructions and medication – and hence survival. On the other hand, follow-up by the patient's own doctor lessens the overidentification with fellow transplant patients and grief at their death.

The return to the family means there has to be a reorganization of the family system[20,56]. Wives often feel insecure in adapting to a more active spouse, though marital relations may be jeopardized by inadequate sexual function, to which several causative factors may contribute[57,58]. Although libido remains strong in post-heart-transplant male patients, erectile rigidity and orgasmic ability, already often impaired by pretransplant debility, decline further after the transplant[58]. Marital and family counseling is sometimes required.

Tabler and Frierson[59] documented sexual dysfunction in a number of patients following heart transplantation, such dysfunction including impotence, ejaculation problems, altered libido, and avoidance of sexual opportunities. Contributing factors to these sexual difficulties were fear of death during coitus, effects of medication on interest and ability to function, body image concerns, depression, uncertainty about the sexuality of the donor, and altered roles and responsibilities within the family. They recommended that members of transplant teams should: (a) obtain a routine sexual history during the evaluation of candidates; (b) be more aware of such sexual concerns; (c) aggressively treat clinical depression; (d) establish peer support groups for spouses of transplant patients; (e) provide didactic material on sexual issues after transplant; (f) adjust medications when sexual problems arise; and (g) address their own level of comfort in discussing sex-related topics with transplant patients.

TEAMWORK

Human organ transplantation is notable for its intensive interdisciplinary team work. It is a collaborative enterprise that requires the skills of a large number of health-care professionals. A key individual is the liaison nurse or coordinator, who mediates between the team caring for the donor, who have to abandon all life-saving procedures, and the transplantation teams, eager to receive organs in good condition. He/she has an important role in sustaining the donor's family in their grief and obtaining consent for organ usage. Here, too, psychiatric skills play a major role. Newcomers to the service may find that the unique demands of the program tax their professional equilibrium, especially if they have unrealistic expectations of their roles. Psychiatric assistance may be necessary for such individuals if team support is not enough. Frequent team meetings are valuable to allow members to express their feelings and ensure good communication and support.

COMMENT

Thoracic organ transplantation raises the cosmic issues of death, resurrection and immortality that transcend the mundane daily concerns of lymphocyte counts and blood cultures. Programs of this kind demand the best that an academic or a research center has to offer, and stretch the imagination in seeking how to extend productive lives. Psychiatrists and social workers have played a useful role in transplantation programs by assisting with selection, and helping transplant teams handle the more complicated behavioral, emotional and family problems which regularly accompany major procedures that aim to prolong life. Donor families may also need support in coming to terms with their grief and even anger. These families occasionally seek to find out the identity of the organ recipients, since the survival of the recipients gives their loss some meaning.

In addition, organ transplantation has opened up important ethical issues of selection, the finality of life, the definition of death, informed consent, and priorities in the allocation of scarce lifesaving resources[60–62]. The giving and receiving of a body organ – a gift of enormous value – is the most significant aspect of human organ transplantation. It is not a private transaction between the donor and recipient, but rather takes place within a network of personal relationships that includes families, the medical teams, and society.

Mauss[63] has described the gift relationship as a series of implied obligations – to give, to receive, and to repay. In the context of organ transplantation it is life that is given up, received, and renewed. Thus, donor, recipient, and kin can become bound to one another emotionally and morally in ways that can be fettering as well as self-transcending. Organ transplantation has brought issues of gift exchange and social solidarity to the fore, and has shown how technical advances tend to outstrip contemporary psychological and social organization. Thoracic organ trans-

plantation highlights the value medical science places on individual human life, and the progress that is possible through the application of science with compassion.

INTRODUCTION

With the introduction of cyclosporin a new era in transplantation began. Improved immunosuppression was partly responsible for the exponential growth of heart transplant programs from 1984 to 1987[1]. The first successful lung transplant was performed by the Toronto Lung Transplant Group in 1983 and, though less dramatic, there has been a steady increase in the number of lung transplant programs since that time[2]. More importantly, the increased frequency of organ transplantation has been accompanied by improved long-term survival. At the five heart and lung transplant programs represented by the authors of this chapter we found combined 1- and 5-year survival rates for heart (n=654) transplantation to be 89% and 75%, and for lung (n=196) transplantation to be 67% and 38%, respectively.

Survival statistics alone, however, do not reflect the challenges patients undergoing transplantation must face. The enduring focus of attention for patients and families will be the 'process' they undergo, rather than the surgery itself[2].

Medical social work services have historically been available to patients and their families to help meet the challenges of transplantation. As a member of the transplant health-care team the social worker assists in the selection, monitoring and rehabilitation of transplant recipients. The patients and their families are assisted in their adjustment to the psychological, emotional, social, and financial impact of transplantation. For the social worker the challenge is to continue to be a liaison between the transplant team, the patient and the family, while developing greater skills in assessing and following prospective candidates.

Bright *et al.*[2], Christopherson[3], and others[4] have identified a fairly predictable sequence of adjustment stages for early heart and lung transplant patients which include: (a) assessment, (b) awaiting donor, (c) immediate post-surgical, (d) recovery (first infection/rejection), (e) hospital discharge, and (f) early convalescence. In this chapter some of these stages will be combined and reference will be made to the social work services provided for heart and lung transplant recipients during the selection, perioperative, and rehabilitation phases.

ASSESSMENT PHASE

Psychosocial

The psychosocial assessment is the most important contact that a social worker has with a prospective candidate and his/her family. It should include an overall picture of the patient's personality and attitudes, mental stability and level of functioning, and current social matrix. In particular, a detailed history should be obtained of current or previous substance abuse, medical noncompliance, and psychiatric problems. Support system strengths and weaknesses, patient and family attitudes about transplantation, and the motivation and potential for post-transplant rehabilitation (physical, psychological and vocational) need to be fully evaluated. For lung transplant candidates their participation in a required post-assessment pretransplant pulmonary rehabilitation program provides an excellent opportunity to observe and further evaluate their behavior. The willingness with which they accept this requirement may in itself provide insight into their character, and into their potential post-transplant behavior.

The importance of the psychosocial assessment in determining proper patient selection has been well documented. Historically, patients have been denied transplantation on the basis of a history of (a) poor medical compliance, (b) mental illness, or (c) current or recent evidence of alcoholism or drug abuse[5]. Recently, the validity of some of the assumptions that have been made in relation to psychosocial factors and transplantation outcomes has been questioned.

Renal transplant recipients with a prior history of heroin abuse did well when compared with other recipients[6]. Preoperative depression and psychiatric distress were found to have little predictive value in regard to mortality and morbidity after heart transplantation[7,8]. Heart transplant recipients selected with liberal psychosocial criteria, and exposed to aggressive psychosocial intervention, had medical results at 1 year similar to those of patients selected with less liberal criteria[9].

At many centers the policy with regard to alcohol or drug abuse is to defer patients with a current, continuing problem. However, patients are accepted once they have maintained 6 months sobriety or drug-free behavior. Following this policy at the Oklahoma

Transplantation Institute, no patient has resumed alcohol or drug consumption post-transplant, although this group has been found to be significantly more likely to develop compliance or psychological problems which were associated with increased morbidity (but nor mortality) after the first post-transplant year[10].

Patient non-compliance, while sometimes difficult to identify or quantify, especially pretransplant, is an important issue that must be explored. Non-compliance has been documented to be more common in younger patients (<40 years), those single or divorced (presumably lacking family support), those with a lower level of education (less than high-school diploma), and those with no career skills[11]. Some believe that non-compliance may indicate depression, intellectual deficit, cognitive impairment, or ambivalence about surgery and/or survival[12], while others report that non-compliance in regard to taking medication is mainly associated with financial restrictions[13].

Any history of failing to follow medical advice should be noted. If there are social reasons for this behavior, attention and effort must be focused on identifying the underlying issues and helping the patient to develop an effective plan of corrective action. When there is a psychological or intellectual basis for this non-compliant behavior, its potential for treatment must be assessed.

The pretransplant psychosocial evaluation must also include, when applicable, an exploration of the possibility of the patient's return to work post-transplantation, and any need for training or education. It is reasonable to expect that the majority of thoracic organ transplant recipients will be able to resume a fully functioning lifestyle. According to a 1987 UNOS (United Network for Organ Sharing) public opinion survey on heart transplantation, 72% of respondents agreed that a patient's ability to return to work or other regular activities was second in importance only to patient survival (with which 83% of respondents agreed)[14]. It is at this early stage that the expectations of the transplant team with regard to the patient's return of work post-transplant should be clearly stated. The center's policy regarding the support (or misuse) of post-transplant disability claims should be emphasized to the patient[15]. Studies have shown that a clearly stated policy which expects employment (coupled with social work intervention) results in 12–15% of patients securing new employment[16,17].

On occasion, patients and/or family members experience some degree of disbelief and even anger when informed of the diagnosis of end-stage heart or lung disease and the need for transplantation. At times this may result in a reluctance to be totally factual during the assessment, because of the underlying fear of being denied candidacy. Potential recipients who have limited expectations of potential benefit, or view the transplant as merely a delay in the dying process, must be screened particularly carefully. Some lung transplant candidates (e.g. those with cystic fibrosis) may have difficulty in anticipating or imagining any meaningful post-transplant improvement because, due to the early age of onset of the disease and prolonged length of illness, they have no prior experience and little expectation of good health.

Financial

Before admission or transfer to the transplant service the social worker coordinates an assessment of the patient's financial history. In countries such as the USA, with a health-care system based largely on the patient's ability to pay, finances are a major issue. Ideally, a prospective candidate will have insurance which will cover 80–100% of medical expenses. In the absence of private or state insurance the patient may well have to rely on his or her own personal resources or local fund-raising efforts. When problems or potential problems are identified, the social worker may provide counseling services or refer the family to appropriate community resources. It is important to remember that insurance that covers pharmacy costs is as important as hospital and physician benefits because of the expensive, and long-term, post-transplant immunosuppressive regimen.

PERIOPERATIVE PHASE

The perioperative phase refers to the time from selection through early convalescence, and is characterized by contradictory emotions for the patient and family. Although patients may express relief about being accepted as a candidate, guilt and anxiety often occur once they realize that their return to health is dependent on another's death and the bereaved family's willingness to donate the organs. Alternatively, the patient may secretly wish for another's death. In some cases the patient will make known his or her idea of a suitable donor. Time spent awaiting a donor produces a severe strain on even the best of relationships within the family, or among friends. The social worker should be available to provide reassurance and emotional support and, when needed, to facilitate the ventilation of feelings[2]. Communication with patients who have undergone transplantation is encouraged, and has proven especially helpful to candidates.

The immediate post-surgical period is, if all goes well, a time of euphoria and relatively little stress which requires only minimal social work involvement. At some point most recipients will experience a real or suspected infection and/or rejection episode. It is because of this and the other side-effects of immunosuppressive medication that a patient soon realizes that he or she may have traded one set of symptoms or problems for another. This is perhaps particularly true for the lung recipient, due to the increased risk of infection and the difficulty of diagnosing rejection after lung transplantation.

In general, recovery and the preparation for hospital discharge may be a time of incongruous feelings (i.e. frustration and depression about functional limitations and ongoing weakness, etc., accompanied by excitement about leaving the hospital). At discharge a patient is expected to once again assume responsibility for his/her own physical and emotional care, which may result in conflicts with family members who have been fulfilling a 'caretaker' role during the patient's period of ill-health. Early convalescence is a furthering of this process, where a variety of family conflicts are likely to develop[18]. The amount of social work involvement at this time is dependent entirely upon the needs and wishes of the patient and family.

Though successful discharge may mean resolution of many of the medical factors that precipitated admission to the hospital, what lies ahead may be uncertain. As a result, discharge is often an anxious (fearful) time for both patient and family, and they may react with confusion, shock, or denial[19]. Any early unrealistic expectations about transplantation and its influence on social relationships are likely to be evident at this time.

The social worker should be available to work with the patient and family for any post-hospital counseling and/or referral needs. With improved medical results, and better pretransplant screening and counseling, discharge planning is a less important role for the transplant social worker than it once was.

REHABILITATION PHASE

Depending upon improved physical capacity, a transplant recipient should be restored to a level of general health comparable with that of the general population[20]. For both heart and lung transplant recipients aggressive cardiopulmonary rehabilitation efforts begin once the patient is medically stabilized post-transplant[21,22]. Successful long-term rehabilitation can be realistically claimed if a patient returns to (a) competitive employment, (b) school, (c) homemaking duties, or (d) active retirement.

Psychosocial problems identified at pretransplant assessment are likely to continue in some form, and will serve as a hindrance to a patient's rehabilitation potential. Therefore, the social work role during the rehabilitation phase should be clinically focused and directed towards reducing psychosocial problems and increasing the likelihood of returning to an active lifestyle.

Only recently have psychosocial factors and their relationship to transplantation outcomes been subjected to critical evaluation[6–9]. Patients with a history of substance abuse within 6 months of acceptance for transplantation, even if currently abstinent, should be monitored closely because of the risk of recurrence. Patients abstaining for longer than 6 months pre-acceptance are at risk of exhibiting previously undiagnosed psychological or compliance problems[10]. Psychological and non-compliance problems that existed pretransplant, whatever their form, are almost certain to recur post-transplant. Medication non-compliance may occur even in the previously compliant patient as the result of financial restrictions[13].

Since it has not been conclusively shown that the presence of any post-transplant psychosocial problem will increase mortality, social work intervention should be based upon the assumption that attempting to resolve these issues will improve the quality of life for heart and lung transplant recipients, but not necessarily increase longevity.

The rate at which transplant patients are gainfully employed is not synonymous with the medical results of transplantation. A recent multicenter study found 81% of heart transplant recipients were physically able to work, but only 45% were doing so[16]. There are no comparable data available as yet for lung transplant patients.

Obviously there are many barriers to employment post-transplantation. The factors typically associated with continued unemployment are: (a) potential loss of health insurance or disability income if the patient becomes employed, (b) less than a high-school diploma, and (c) lengthy pre- and post-transplant disability. However, heart transplant centers that refuse to support unsubstantiated (or poorly substantiated) disability claims post-transplant have been successful both in encouraging patients to return to their former jobs (if available) and in stimulating an additional 12–15% of patients to secure new employment[16,17].

A difficult and often-ignored aspect of a patient's rehabilitation is the patient's perception of continued disability. The discrepancy between the physician's assessment and the patient's perception of work ability is problematic, and as yet unresolved. Whether this is a real or imagined incapacity on the part of the patient is uncertain. Neither vocational rehabilitation nor psychotherapy has shown much success in altering patient perceptions, although this does not imply that they should be ignored.

Vocational programs offer the support necessary to remove educational barriers, and counseling can help to reduce the stress and anxiety associated with change. However, for patients to achieve full rehabilitation potential consistent with their medical improvement will require meaningful social reform and, in the USA, full implementation of the Americans with Disabilities Act.

COMMENT

The complexity of the issues confronting transplant patients and their families requires both sensitivity and creative intervention strategies. The multifaceted nature of the social workers' knowledge and role allows them to function in a clinical capacity and provide supportive, educational and/or counseling services and, when needed, referral for community services. It is incumbent, however, on social workers that they document their clinical experience and research knowledge. This will require them to refine outcome measurement tools and report the effectiveness of their intervention through publication. Solely reporting transplant patient or family needs is inadequate in an environment driven by the outcome mandates of insurance carriers, restructured organizations, and/or government regulations. Certainly, transplant social workers have already contributed towards these goals, but there remains much to be accomplished.

Nutrition and Diet

M. KANOSKI

INTRODUCTION

Organ transplantation has become a therapeutic option for hundreds of victims of cardiac and pulmonary failure each year. Since the first human heart transplant was performed by Christiaan Barnard in Cape Town, in December 1967, medical centers have been performing transplant procedures worldwide. Heart and lung transplants have made survival and rehabilitation possible for individuals with end-stage cardiac and pulmonary failure who would otherwise have died or have remained severely disabled. However, the number of patients waiting for transplantation increases each year, and many wait weeks or months before they receive a transplant. During this waiting period the patients' nutritional status can be maintained, or possibly improved, though repletion of the nutritional stores of a patient with end-stage organ disease may not be possible until a functioning organ is received.

The nutritional care of transplant patients is unique to the preexisting cardiac and pulmonary disease and postoperative therapy. Frequent reviews of the dietary requirements of the patient are essential, as they may differ markedly with changing clinical status. The nutritional status of transplant candidates and recipients significantly affects wound healing, surgical complications, length of hospitalization, quality of life, and mortality[1].

Blackburn *et al.*[2] noted a 53% incidence of significant malnutrition in patients with cardiac disease who were usually in New York Heart Association (NYHA) class III or IV. Poindexter's report on the assessment of 54 patients who underwent heart transplantation demonstrated that 25 exhibited compromised nutritional status preoperatively[3]. Advanced cardiac failure may result in cardiac cachexia, evidenced by multiple organ insufficiency (from hypoxia), muscle and adipose tissue loss, hypoalbuminemia, malabsorption, nausea, vomiting, and anorexia. The risk of mortality and postoperative complications increases with each of these factors[4].

Patients with advanced pulmonary disease usually present with weight loss. Possible mechanisms for this weight loss include impaired gastrointestinal function, altered dietary intake as a result of early satiety, the presence of hypermetabolism, increased resting energy expenditure, and increased work of breathing[5,6].

The degree of malnutrition in patients with respiratory disease usually correlates with deterioration in lung function. Depletion of the somatic protein stores is common in patients with chronic obstructive emphysematous pulmonary disease (COPD). Weight loss in COPD patients (who begin with normal weight) causes deterioration in respiratory and skeletal muscle strength. Weight loss in COPD patients who are initially overweight, however, usually improves respiratory muscle function and decreases arterial $PaCO_2$[5,7,8].

Patients with cystic fibrosis (CF) have difficulty absorbing fat, and require pancreatic enzyme replacement. Undernutrition is caused by unfavorable energy balance and there appears to be a direct correlation between the degree of undernutrition and the severity of pulmonary disease. Three major factors have been shown to lead to undernutrition: (a) reduced dietary intake caused by various factors, (b) malabsorption, and (c) increased energy expenditure. Girardet's research stressed that the resting energy expenditure (REE) in CF patients is higher than normal, even when pulmonary function is normal, and that it increases approximately 150% with deteriorating lung disease[9].

The above observations, combined with the known deleterious complications of immunosuppressive drugs and the stress of major surgery, support the need for nutritional intervention prior to transplantation, to improve the probability of a successful outcome. This chapter will discuss the primary areas of concern, and recommendations for nutritional therapy.

NUTRITIONAL ASSESSMENT OF THE TRANSPLANT CANDIDATE

At a time when candidates for transplantation are more numerous than donors, long-term pretransplant nutritional care becomes increasingly difficult, especially for those who require support by mechanical ventilation, a mechanical assist device, or an artificial heart. In order to treat nutritional abnormalities and malnutrition, such patients must first be identified. Accurate initial and follow-up assessments by the dietitian will identify those patients at risk in each phase of transplant care.

With transplant candidates presenting in a wide variety of nutritional status generally deteriorating while awaiting transplantation, routine pretransplant follow-up is essential to allow early intervention. Patients with better nutritional status at the time of transplant have a shorter length of hospital stay, and lower hospital costs[10].

The patient with slowly progressive disease (>6 months) may seem to have adjusted metabolically. The severe malnutrition that may accompany chronic heart failure has been termed cardiac cachexia. The condition may exist for many months or years. Factors contributing to the pathogenesis of this syndrome are: (a) dietary, (b) metabolic abnormalities, and (c) excessive loss of nutrients[11].

In cardiac patients, weight loss often appears minimal, but is usually masked by the presence of fluid overload[12]. Anthropometric measurements commonly detect a reduced lean muscle mass with varying degrees of adipose (calorie) reserves. Poor appetite, nausea and vomiting may reduce food intake at a time when all physical activities, including breathing, are placing greater nutritional demands on the patient. Abel *et al.* established that early malnutrition adversely affects cardiac function[13,14]. In turn, impaired cardiac function from nutritional deficit further interferes with food intake, which creates a downward spiral of deterioration until parenteral nutritional support is initiated[15].

Signs of a hypermetabolic state may include weakness, muscle wasting (in particular in the temporal region), severe weight loss, increased temperature, and hypoalbuminemia. The cardiovascular system may exhibit decreased cardiac output, increased blood pressure, and increased heart rate. Altered respiratory function may include increased respiratory rate, presence of rales, and dyspnea. Gastrointestinal aberrations may include decreased gastric motility, early satiety, anorexia, steatorrhea, hepatomegaly, hepatic congestion, and ascites. Renal function may be impaired, and result in increased nitrogen loss and rises in blood urea nitrogen and creatinine levels.

Pretransplant nutritional assessment should include biochemical and anthropometric measurements, history of weight loss, and diet history. The appropriate biochemical and anthropometric measurements are well documented in the literature[3]. Nutritional assessment includes recording of age, sex, height, and weight, and estimations of serum albumin and/or prealbumin and 24-hour urinary urea nitrogen and creatinine, when appropriate[2] (Table 1).

A thorough diet history, with estimated caloric intake levels, should be taken, to detect potential deficiencies, and may suggest methods to improve oral intake. The history should include usual home diet, utilization of any special food supplements, chewing and swallowing ability, and smell and taste perception. In addition, limitations on the procurement of food products, meal preparation, and eating arrangements should be evaluated. An attempt should be made to estimate dry weight (e.g. the weight 6 months prior to the onset of illness) and used to determine the patient's percentage weight change over a period of time. Current weight should be compared with desirable weight standards. The estimated desirable weight is then used to determine basal energy expenditure (BEE)[16]. When available, indirect calorimetry can be measured by a metabolic chart, to determine resting energy expenditure (REE).

A standardized, easily performed, cost-effective assessment tool is important to the success or failure of nutritional intervention. The subjective global assessment (SGA) of nutritional status (Table 2) is a clinical technique that estimates nutritional status on the basis of medical history, which includes current weight and weight history, dietary intake compared with usual pattern, gas-

Table 1 Nutritional assessment of the transplant patient

Height (cm) ___ Age: ___ Sex: M/F ___

Weight (kg) Actual: ___ Usual weight: ___ Weight 6 weeks ago: ___ Weight 6 months ago: ___

___ % change in ___ weeks (based on Blackburn*)

Albumin ___ Prealbumin ___ Total protein ___ Lymphocytes % ___

Na ___ Potassium ___ Chloride ___ CO_2 ___

Glucose ___ A1C ___

Hgb ___ Hct ___ WBC ___ BUN ___ Creatinine ___

24-hour UUN ___ 24-hour creatinine ___

Nitrogen balance study ___

Metabolic chart study ___

Diet history ___

Blackburn's evaluation of weight change[16]

Time	*Significant weight loss (%)*	*Severe weight loss (%)*
1 week	1–2	>2
1 month	5	>5
3 months	7.5	>7.5
6 months	10	>10

* Values charted are for percentage weight change.
Percentage weight change = (usual weight − actual weight) × 100 (usual weight).

Table 2 Patient-generated subjective global assessment of nutritional status

A. *History*

1. *Weight change*
   I weigh about ___ pounds
   I am about ___ feet ___ inches tall
   A year ago I weighed about ___ pounds
   Six months ago I weighed about ___ pounds
   During the past 2 weeks my weight has ___ decreased ___ increased ___ not changed

2. *Food intake*
   I would rate my food intake during the past month (compared to my normal) as
   ___ no change ___ changed
   (a) ___ more than usual
   (b) ___ less than usual
   (c) ___ much less than usual
   ___ only solids
   ___ only liquids
   (d) ___ very little of anything

3. *Problems with eating*
   Over the past 2 weeks I have had the following problems that have kept me from eating (check all that apply)
   ___ no problems, just did not feel like eating
   ___ no appetite, just did not feel like eating
   ___ nausea
   ___ vomiting
   ___ diarrhea
   ___ constipation
   ___ mouth sores
   ___ dry mouth
   ___ pain
   ___ things taste funny or have no taste
   ___ smells bother me
   ___ other _____

4. *Functional capacity*
   Over the past 2–4 weeks I would rate my activity as generally
   ___ 0 = normal, no limitations
   ___ 1 = not my normal self, but able to be up and about with fairly normal activity
   ___ 2 = not feeling up to most things, but in bed less than half the day
   ___ 3 = able to do little activity, and spend most of the day in bed or chair
   ___ 4 = pretty much bedridden (rarely out of bed)

The remainder of the form will be filled in by your doctor, nurse or therapist. Thank you.

5. *Disease and its relation to nutritional requirements*
   Primary diagnosis _____
   Metabolic demand ___ no stress ___ low stress ___ moderate stress ___ high stress

B. *Physical examination*
(For each trait, specify: 0 = normal, 1 = mild, 2 = moderate, 3 = severe)
___ loss of subcutaneous fat (triceps, chest)
___ muscle wasting (quadriceps, deltoid)
___ ankle edema ___ sacral edema ___ ascites

C. *Subjective global assessment (SGA) rating*
(Select one)
___ A = well nourished
___ B = moderately malnourished
___ C = severely malnourished

trointestinal symptoms >2 weeks duration, functional status, and metabolic demands, as well as physical examination of muscle, fat and fluid status. Based on these features a patient is categorized as: (a) well nourished, (b) having moderate (or suspected) malnutrition, or (c) severely malnourished. The original SGA has been validated in surgical patients and transplant patients[17].

Caloric requirement

The total estimated non-protein calorie requirements are calculated for maintenance and stress (e.g. surgery, sepsis) (Table 3). In the patient taking oral nutrition, requirements vary from 20% to 50% above BEE values[1,7]. These additional requirements should be assessed on an individual basis. An extremely stressed patient receiving enteral or parenteral support may need up to 75% above BEE[7].

In severely cachetic patients, repletion of fat and muscle stores may not be achieved for several months. Normalization of serum albumin can require several weeks. Extended periods of therapy during the preoperative stage are impractical due to the uncertainty of organ availability and the severity of end-stage disease.

Table 3 Estimation of nutritional needs

Basal energy expenditure (BEE) at ___ weight = ___ calories
Male = 66 + (13.7 × dry weight in kg) + (5 × height in cm) − (6.8 × age) =
Female = 655 + (9.6 × dry weight in kg) + (1.7 × height in cm) − (4.7 × age) =

Cachetic patients have an impaired tolerance to oral intake, and enteral (nasogastric tube feeding) and parenteral (intravenous) hyperalimentation support may also be poorly tolerated. Such refeeding must be cautiously approached, to avoid the refeeding syndrome, in which malabsorption and distressing diarrhea can occur. Support should ideally be initiated before the patient is severely malnourished, to allow gradual increases in caloric and fluid intake[12]. Supplying the optimal nutritional support requires constant reassessment and monitoring. Overfeeding a patient can stress the heart, liver and kidney, thus eliminating the benefits of such support[18].

Although BEE provides an effective estimate of average energy needs, the actual metabolic requirements of the individual patient may be difficult to assess. Resting energy expenditure (REE), a form of indirect calorimetry, is useful for determination of energy requirements and appropriate substrate utilization[19]. Indirect calorimetry is used to measure actual oxygen consumption ($\dot{V}O_2$) and carbon dioxide production ($\dot{V}CO_2$). The ratio of CO_2 produced and O_2 consumed results in specific respiratory quotient (RQ) values. The specific RQ values are as follows: Carbohydrate 1.0 (maximum carbohydrate utilization is calculated[17] at 5 mg/kg per hour; protein 0.8; fat 0.7; mixed substrates 0.85.

The RQ reflects the oxidation of a mixed fuel of fat, carbohydrate, and protein. An RQ >1.0 is thought to represent fat synthesis. With higher RQ values, CO_2 production is increased and can result in increased respiratory demands, causing increased work of breathing for a compromised pulmonary patient. This would be appropriate if the exact energy requirement of a non-ambulatory patient were needed[16].

Protein requirement

The protein requirement of any individual patient is based on laboratory and anthropometric findings (Table 4). Needs range from 1.2 to 1.5 g of protein per kilogram of appropriate dry body weight[1]. Protein requirements may increase to levels of 1.5–2.0 g of protein per kilogram in the severely depleted patient – for example, the patient supported by an artificial heart. In the depleted patient, renal failure should be treated by dialysis rather than by protein restriction.

Table 4 Nutrient needs

	Calorie	*Protein*
Lung		
Maintenance	1.0–1.2 × BEE	1.0–1.5 g protein/kg dry weight
Repletion	25–35 kcal/kg dry weight	1.5–2.0 g protein/kg dry weight
	(Promote weight gain with CF patients)	
Heart		
Maintenance	1.2–1.5 × BEE	1.2–1.5 g protein/kg dry weight
Repletion	25–35 kcal/kg dry weight	1.5–1.75 g protein/kg dry weight

NUTRITIONAL SUPPORT PRETRANSPLANT

The obese patient

The obese transplant candidate (>20% above desirable body weight due to adipose tissue) is also at nutritional risk. Protein status, eating habits, and family eating patterns are often poor. Detailed histories of diet, of nutritional status of members of the family, and of change in weight are helpful. If time allows, the patient should work with a dietitian and be guided toward gradual weight loss (0.5–2 kg/week) while maintaining adequate protein status. The patient should not be instructed to decrease weight without professional guidance and monitoring, as this often leads to severe protein and nutritional deficits.

The patient in the early stage of cardiac failure

The goal of nutritional support is to provide adequate calories, protein and other nutrients without overfeeding the patient. The New York Heart Association class II or III patient may show no problems with anorexia or weight loss. Education regarding nutritional requirements, suggesting a high-protein, high-calorie, moderate sodium intake, may be sufficient treatment at this stage (Table 5).

The patient in advanced cardiac failure

As cardiac function decreases, more intense support is necessary. Intake may vary daily, depending on gastrointestinal function and overall well-being. Cellular hypoxia, secondary to increasing cardiac failure, gradually leads to multisystem failure. Malabsorption occurs as the viscera become engorged with fluid, and the body is unable to utilize nutrients provided enterally[17]. Gastrointestinal motility may decrease, resulting in constipation and/or diarrhea. Reduced renal blood supply results in conservation of nutrients and water by the kidneys[1]. Free water, supplied in the form of nutritional support and medications, is retained unless diuretics are used. Diuretics deplete mineral and vitamin levels, requiring careful monitoring and supplementation[20].

Sodium restriction is commonly advised, yet should not compromise adequate nutritional intake, particularly protein intake. A high-protein diet can contain as little as 87–176 mEq (2–4 g) of sodium. Small frequent meals, snacks, and high-protein shakes are recommended to increase total protein intake as much as possible.

Calorie and protein counts and nitrogen balance studies can accurately indicate actual daily intake. If oral intake is consistently at or below the calculated BEE, additional support will clearly be necessary. Alternate routes of nutritional support, such as enteral or parenteral hyperalimentation, are often required. While enteral support is preferred, tolerance is generally poor. Peripheral venous hyperalimentation can be beneficial in supplementing oral intake in hospitalized patients. Central venous hyperalimentation is occasionally necessary, and should not be postponed until serial laboratory studies indicate severe nutritional deficits.

Table 5 Constituents of recommended diet*

The calorie level is calculated on an individual basis to achieve and maintain desirable body weight and should consider an activity factor for exercise if feasible.

The total number of calories should be made up of:
- *Carbohydrate*: 45–55%
  - 33% from simple sugars in fruits
  - 67% from complex carbohydrate high fiber (3–4 g/day)
  - Limited concentrated sweets/sugar/alcohol
- *Protein*: 25–30%
- *Fat*: 18–25%
  - 33% or less of calories from saturated
  - 33% monounsaturated
  - 33% polyunsaturated

The daily diet should not contain more than approximately 200 mg cholesterol and 176–220 mEq sodium (4–5 g)

*Recommendations listed are modified American Dietetic Association and American Heart Association guidelines. The modifications listed were deemed necessary after experience with transplant patients[1].

The patient with cardiac cachexia

The patient with rapidly deteriorating cardiac function may develop cardiac cachexia while awaiting transplantation[2]. Nutritional treatment often includes a form of hyperalimentation. Although cachexia may be a compensatory mechanism to reduce oxygen consumption and decrease cardiac demands, at least minimal energy and nutrient needs should be supplied to maintain the patient's immune status and survival[7]. The absolute quantities and relative proportions of carbohydrate, protein and fat desirable to maintain minimal nutritional support and reduce cardiac stress remain highly debated, and require further detailed investigation.

The patient on a mechanical assist device or artificial heart

The artificial-heart patient has postoperative metabolic stress in addition to pre-existing malnutrition. Increased cardiac output and nutrient distribution to atrophied tissues stimulates the anabolic process. Energy and protein requirements will exceed those before implantation of the device. If the patient had been taking adequate nutrition prior to implantation, his or her nutritional needs may not increase so significantly. A high-protein, high-calorie diet, with vitamin and mineral supplementation (and frequent 'snacks') is appropriate.

Oral intake may require supplementation in the form of enteral or parenteral hyperalimentation. The gastroenterologist, dietitian, and nutrition support team should monitor tolerance and intake closely. Weekly calorie counts and nitrogen balance studies should be checked to assess adequacy of nutritional support.

The patient with respiratory disease

In patients with respiratory problems, respiratory muscles, as well as other somatic muscles, are catabolized to meet energy needs when nutrition is not adequate. With a reduction in weight and body mass, respiratory muscle mass decreases. When this occurs, a decrease is observed in the availability of substrates that are used for production of energy and cellular growth. Severe hypoalbuminemia may be a contributing factor to pulmonary edema[20], with a reduction in oncotic pressure and fluid shifts into the interstitial space. The primary goal is to minimize CO_2 production while providing adequate nutritional needs, and avoidance of excess kilocalories, which could prove detrimental to pulmonary function and contribute to hypercapnia in some patients[8].

NUTRITIONAL SUPPORT IMMEDIATELY POST-TRANSPLANT

Immediate postoperative care should be focused on establishing hemodynamic stability, hydration status, and respiratory function, and on monitoring complications related to the surgery. The goal of post-transplant nutritional support is to provide adequate nutrients to promote anabolism and prevent infection. Well-nourished patients able to begin a diet within 3–4 days after surgery usually do not need nutritional support. Others who are unable to begin a diet within this time-frame, or who were malnourished pretransplant, may benefit from nutritional support. Nasogastric tube feeding is the preferred method of nutritional support. Total parenteral nutritional support is indicated when a patient is unable to tolerate tube feedings.

Post-transplant patients require increased amounts of nutrient for wound healing at a time when renal and hepatic function are frequently impaired, appetite may be poor, and side-effects of medications may result in gastrointestinal distress[4]. Postoperatively, the patient's diet is advanced to solid foods as tolerated, the goal being to provide a high intake of calories[16] (BEE $\times$ 1.5 = 1.75) and protein (1.2–1.5 g/kg dry body weight). For cachetic patients an injury factor of 1.2 for calories and 1.0–1.2 g of protein/kg dry body weight would be more appropriate. Hyperalimentation may be continued to support a previously malnourished patient. Small frequent snacks between meals, including commercial liquid nutritional supplements, are continued, but may be modified to conform to new dietary restrictions.

Biochemical values to be monitored include serum electrolytes, glucose, BUN, creatinine, albumin, and/or prealbumin. If BUN and creatinine rise, protein may need to be restricted. Intake is monitored by frequent calorie nutrient counts and nutritional assessments.

The patient's nutritional status and intake ability dictate the extent to which dietary restrictions can be implemented during the first week post-transplant. The restriction on sodium intake is usually relaxed to 176–220 mEq (4–5 g) per day, and sugar intake, especially in the form of concentrated sweets, is limited, to

minimize the effects of corticosteroids on glucose metabolism. Cholesterol and saturated fat restrictions are also implemented.

The protective isolation precautions used by some institutions may eliminate fresh fruit and vegetables from the patient's diet. Although aerobic Gram-negative bacilli are commonly found on such foods, they are no longer considered dangerous unless the patient is neutropenic[1,21]. Allowing fresh fruit and vegetables in the diet often improves intake, and has not been associated with increased infection rates[22].

LONG-TERM NUTRITIONAL CARE

Long-term nutritional care is best provided by a dietitian in conjunction with follow-up appointments with the cardiologist/pulmonologist or surgeon. The patient should be encouraged to record all food intake over a 3-day period at designated intervals: (a) immediately after discharge from the hospital, (b) after 6 weeks, and (c) 6 months later. A careful review of such intake is helpful in determining compliance, and the necessity for further dietary education and guidance. Changes in the diet may cause confusion, and therefore should be explained. Patient education is critical for long-term compliance with any modification in daily dietary habits.

Readmission or extended hospitalization is not uncommon in patients with organ transplants, due to episodes of infection or rejection. Nutritional assessment, monitoring, and support are recommended with any readmission. In the case of sepsis and high metabolic needs, a high-protein, high-calorie diet with supplements may be necessary to maintain adequate intake. Antibiotic therapy and poor oral intake add to nutritional risks.

Drug-related nutritional problems

The long-term nutritional care of the transplant patient must take into consideration drug-induced metabolic changes and the side-effects of medications. Because of more effective immunosuppressive drug regimens, the success of transplantation is increasing and recipients are living longer. Long-term post-transplant complications are therefore emerging. Obesity, hypertension, hyperlipidemia, diabetes mellitus, and osteoporosis are common complications. Since these complications affect survival, a treatment program in the form of diet and exercise should be included.

Corticosteroids affect carbohydrate, protein and fat metabolism, as well as adipose distribution in the body. Changes in carbohydrate metabolism can result in steroid-induced diabetes mellitus. Appetite and craving for sweets are also stimulated, contributing to obesity and abnormal blood sugar levels. Protein catabolism results in muscle wasting, thinning of the skin, dissolution of vertical bone matrix, and poor wound healing[23]. The influence of steroids on fat tissue results in loss of subcutaneous fat from extremities and excessive deposition in the trunk areas[23]. Excessive fat in the trunk has been associated with an increased risk of atherosclerotic disease[24].

Prednisone's antagonistic effects on vitamin D lead to changes in the body's calcium balance, contributing to osteoporosis, and its mineralocorticoid effect is associated with hypertension[22]. Zinc depletion, contributing to delayed wound healing, is another possible long-term effect[23]. These side-effects are reduced when low-dose prednisone therapy is administered, in conjunction with cyclosporin, though the incidence of hypertension may increase. Nutritional support aimed at reducing these effects of corticosteroids is a primary goal of post-transplant dietary care.

Cyclosporine therapy may be associated with hypertension, renal and hepatic dysfunction, and an increased risk of viral infection[25]. The intake of foods with high protein quality (e.g. meat and milk) and restricted sodium is recommended to counter these side-effects.

Azathioprine therapy may be associated with hematologic changes, gastrointestinal problems, hepatitis, or pancreatitis. Dietary modifications play an important part in the care of patients with gastrointestinal problems, and should be based on individual symptoms.

Tacrolimus (known as FK506 during the research phase of its investigation) is one of the newest immunosuppressive agents available for patient use (Chapter 10). Its use may be associated with hyperkalemia, hyperglycemia and hypermagnesemia. In addition, loss of appetite, along with nausea and/or vomiting, has been observed in some patients. Dietary modification should be based on individual symptoms and tolerance, but when gastrointestinal symptoms are severe, patients may benefit from taking liquid supplements (2 ounces every 2 waking hours).

Recommended diet for the heart or lung transplant recipient

Total caloric intake, as well as the types of carbohydrate, protein and fat taken, are controlled to minimize the short- and long-term nutritional complications that may be associated with immunosuppressive therapy. Calorie intake should be adjusted to achieve and maintain ideal body weight, and may in turn prevent complications of hypertension and carbohydrate intolerance. A low-cholesterol, low-saturated-fat diet with limited sugar and no concentrated sweets, and a moderate restriction of sodium of approximately 2–4 g per day is recommended. Dietary sodium is primarily restricted to reduce the sodium and fluid retention induced by steroid therapy. Potassium restriction may be necessary due to cyclosporin therapy. Cholesterol restriction is recommended on the basis that it may reduce the high incidence of atherosclerotic disease seen in patients with transplants (Chapters 13 and 35). Intake of polyunsaturated fat is increased to achieve at least a balance with saturated fat.

The pretransplant nutritional status of the patient will be an important factor in the strictness with which this diet can be applied in the early post-transplant period, though the long-term goal includes all of the restrictions listed. Specific recommendations for this special diet are listed in Table 5.

Vitamin and mineral supplementation may be necessary if dietary compliance is strictly followed. For example, if the patient avoids all red meats in order to reduce cholesterol and saturated fat, the intake of iron should be monitored carefully and iron supplements given if necessary. Detailed adjustments for food preferences should be made for each patient. Adequate amounts of extra lean (>95% fat-free), high-quality protein sources are encouraged to offset muscle wasting. A high intake of skim or 1% fat milk is beneficial as a source of protein, calcium and vitamins A and D.

However milk intake should be limited if renal failure results in hyperkalemia.

If the patient is underweight, it is important to increase body weight so that there are adequate fat and protein reserves for periods of infection or rejection. Conversely, once desirable body weight is attained, it is equally critical to prevent excessive weight gain, since obesity can lead to increases in blood cholesterol, triglyceride and glucose levels and in blood pressure, all of which are risk factors for coronary disease.

Whenever possible, nutritional counseling should include both the patient and his/her family members. Emotional support can enhance compliance with drug and nutritional therapy. This is important, as non-compliance with the drug regimen and other instructions has been documented as a major contributory factor to mortality in some recipients[26].

A Commentary on Quality of Life after Thoracic Organ Transplantation

M.M. EDGAR

INTRODUCTION

Survival of a patient and graft after transplantation was once thought to be the measure of a successful transplant. Today quality of life (QOL) issues are regarded as just as important as, if not more important than, simply the survival of the patient. Mai[1] suggests that 'Quality of life, probably more than any other aspect of a transplant program, is the acid test of the success and efficacy of the operation.'

At the time of writing, one of my childhood idols, the former baseball star Mickey Mantle, has just had a liver transplant. Organ transplantation has become commonplace at most major medical centers across North America, Europe and Australasia. The facts appear incontrovertible that organ transplantation does increase the recipient's lifespan. Unfortunately, in today's climate of bureaucracy and health economics, most medical decisions are as much a product of the business administrators as they are of the physicians. In other words the cost–benefit of any therapy is becoming increasingly analyzed and questioned.

Examples of this growing awareness of the cost of health care are numerous throughout the Western world, particularly in the USA.

'U.S. health care is the biggest industry in world history. In 1995, the United States is expected to spend an estimated $1 trillion on health care. The United States represents about 5% of the world's population; however, according to estimates by the World Bank and the World Health Organization, more than 40% of world health care expenditures occur in the United States' (World Bank, 1993, quoted by Kaplan[2].

'The system costs too much, and the accelerating costs have the potential to ruin the entire economy (affordability problem). Despite these high costs, there are significant numbers of people who have too little or no health insurance (access problem), and the United States is unable to demonstrate that its high expenditures on health care result in better outcomes for patients (accountability problem)'[2].

In February 1994 the state of Oregon began a plan that excluded payment for medical treatments for certain conditions where there was considered little or no evidence that the therapy improved the patient's longevity or improved his or her QOL. End-stage cancer and AIDS were included as disease processes for which there is no treatment that is known to be effective. Therefore, it behooves each and every health-care provider to be able to document to the fullest extent possible that the treatments offered (including organ transplantation) will increase longevity and/or will improve the patient's QOL. Increasing attention is therefore being paid to assessing QOL.

WHAT IS MEANT BY 'QUALITY OF LIFE'

In 1902 it was suggested to the readers of Mark Twain that 'the value of life must be discerned from the individual's perspective'[3]. Is there, therefore, a satisfactory method of measuring such QOL when it is such a subjective observation? The answer remains uncertain, but many conscientious attempts have been made to do so. It may clearly be preferable if we know the patient before the transplant, and his or her own preconceived expectations and notions about transplantation, and what he or she is hoping to accomplish post-transplant. Only then will we be in a position to know if indeed those expectations have been achieved.

There is a growing body of evidence that pretransplant expectations have a profound bearing on estimates of QOL post-transplant. In an article by Leedham, *et al.*[4], preoperative positive expectations were demonstrated to affect physical health after transplantation. Many explanations for this finding are possible, but it suggests that helping the patient pretransplant to become more optimistic about the outcome of transplantation could be helpful, and could indeed affect the outcome positively. The old adage that 'you get what you expect' may be very true.

Molzahn[5], in her review of the literature pertaining to QOL after organ transplantation, commented: 'It is generally known that these procedures increase the length of life, but less is known about the quality of that life.' She drew attention to several issues that remained to be addressed, including 'definitions of quality of life, dimensions of quality of life, expectations of quality of life and clinical assessment of quality of life'. Four years later these same issues remain in the forefront of QOL discussions.

'The major problem with QOL research is that nearly every researcher has defined the term differently'[5]. 'The first issue pertains to defining QOL. Although thousands of publications have been written on the topic, the definition of QOL is not at all clear. Most researchers define QOL in terms of happiness or satisfaction with life. However, the terms "happiness" and "satisfaction" differ from each other, with happiness generally referring to a transient feeling of pleasure, and satisfaction referring to an assessment of a life situation.

'Quality of life is a complex concept: there is no agreed definition nor is there a universally used measuring instrument' (McDowell and Newell, 1987 quoted by Mai[1]. Quality of life may, therefore, be exactly what you think it is; nothing more and nothing less. It may be just like 'beauty' – in the 'eye of the beholder'. We all appreciate there are certain things that cannot be measured by any method except personal choice.

My bias for a philosophical definition of QOL is best expressed by Kaplan[2] in his presidential address to the Division of Health Psychology of the American Psychological Association. It is entitled *The Ziggy Theorem: toward an outcomes-focused health psychology*. In the cartoon, Ziggy confronts a wise man and asks him, 'Tell me, old wise one, what is the meaning of Life?' The wise man replies, 'Ah, yes ... the meaning of life. Life, my boy, is doin' stuff!' The shocked Ziggy responds, 'Life is doing stuff? That's it?' The wise man then reflects, 'As opposed to death, which is *not* doin' stuff.' Ziggy reacts, 'It's a more elementary theory than I expected, but one you can't argue with!'

Over the past 20 years Kaplan has developed a 'general health policy model'. 'The model separates aspects of health status into distinct components. These are life expectancy (mortality), functioning and symptoms (morbidity), preference for observed functional states (utility), and duration of stay in health states (prognosis).'

'A model of health outcomes necessarily includes a component for mortality. Death is an important outcome that must be included in any comprehensive conceptualization of health. In Ziggy's terms, death is the most extreme and most permanent state of "not doin' stuff". Thus, death serves as an anchor against which to evaluate levels of wellness'[2].

'Researchers generally agree upon three important properties of quality of life: it is a multifactorial, subjective, and temporal concept'[3].

Schipper *et al.*[6] suggested four areas that contribute to QOL: '(i) physical and occupational function, (ii) psychologic state, (iii) social interaction, and (iv) somatic sensation'[3]. Bunzel *et al.*[7], however, considered nine areas that contributed to life quality: 'physical, emotional, mental, vocational, and sexual status, financial situation, leisure activities, partnership, and overall life quality.'

In fact, 100 life areas have been identified to constitute quality of life[8]. However, it appears an insurmountable task to measure each area. That researchers often attempt to sum up the results of a QOL assessment as a single score on a single scale illustrates an effort to simplify a complex subject that probably defies such simplification. Nevertheless, if we are to assess the results of our therapeutic procedures, we must make an effort to come up with some relatively simple scale.

METHODS OF MEASURING QUALITY OF LIFE

Numerous questionnaires have been designed in an effort to glean information from which QOL can be evaluated in patients who have undergone various procedures, not confined to organ transplantation. Appendix A reproduces one such questionnaire developed by Lim *et al.*[9]. This provides a good and rapid assessment of QOL in post-myocardial-infarction patients and, with appropriate word changes, could be used for patients with other clinical conditions, including those after organ transplantation.

Many such 'good' methods have been designed to assess quality of life (Appendix B). By 'good' it is meant to indicate that the method gives us information we believe to be true, but which otherwise we would not be able to present in an objective format. Many of the questionnaires or 'instruments' suggest substantial *reliability, but we must be cautious in interpreting the results obtained.* Whether you choose to take showers or baths *might* be a reliable indicator of the presence of schizophrenia. Unfortunately, it might equally be related to whether or not you have a shower. Thus, most instruments report significant reliability, but may not be measuring what the investigators think they are. One needs to be reminded of the teaching that an IQ is what an IQ test measures – nothing more and nothing less! Perhaps the same can be said for QOL.

RESULTS OF QOL STUDIES IN THORACIC ORGAN TRANSPLANT PATIENTS

Numerous QOL studies have been carried out on: (a) patients awaiting transplantation of hearts and other organs[3,10–13], (b) patients with heart transplants (all of which studies reported improved QOL for virtually all patients whose surgical outcome was successful)[4,7,14–21], and (c) patients, both adults and children, who received heart–lung transplants[19,22,23]. Certain authors have concentrated attention on pediatric recipients[19,22]. There appear to be no such studies as yet on patients who have undergone lung transplantation.

Dracup and colleagues[12], in a study of QOL in patients with advanced heart failure, concluded: 'These findings support the inclusion of quality of life as an outcome measure in any evaluation of treatment efficacy and suggest the interventions to improve the quality of life of patients with advanced heart failure need to be targeted at reducing depression and hostility and increasing daily activity levels.'

Levenson and Olbrisch[24] compared psychosocial evaluations of organ transplant candidates in terms of process, criteria and outcomes. In summary, cardiac programs, when compared with renal and hepatic programs, were the most 'stringent' in criteria for acceptance and in rates of refusal. Muirhead *et al.*[13] observed that 'patients awaiting heart transplantation, although dissatisfied with quality of life, maintain positive psychological and social adjustment.'

Wray and colleagues[25] concluded that 'early postoperative findings indicate an improvement in quality of life after heart or heart–lung transplantation but longer-term follow-up is now necessary.'

Jones *et al.*[26] reported longitudinal results on QOL and psychological adjustment after heart transplantation, and concluded that there was 'no evidence of mood disorder and a high level of well-

being in this sample of cardiac transplant recipients up to four years after transplantation.'

In 1990 Rosenblum *et al.*[15] followed 200 heart transplant recipients for as long as 10 years after heart transplantation and monitored their QOL. 'The most commonly reported complaints were generalized weakness (54%), fatigue (42%), and low back pain (37%) ... analysis of the individual items of the Sickness Impact Profile (SIP) revealed highly prevalent dysfunctional behaviors such as decreased sexual activity, decreased housework, abnormal sleep patterns, and decreased endurance.' Rosenblum suggested a program of physical and occupational therapy 'such as endurance training, body care and movement, and home activities/housework'. Interventions in these symptom constellations might prove beneficial in circumventing these QOL issues at a later date.

Bunzel *et al.*[7], however, in a QOL study on heart transplant patients, 'found an absolute increase in quality of life'.

Riether's group[27] measured outcomes in liver and heart transplant patients, and concluded that 'both groups showed significant improvements after transplant in neurocognitive functioning, depressive symptoms, and quality of life'.

In contrast, however, Baumann *et al.*[19] demonstrated that although 'life improved for the majority post-transplantation, recipients continue to experience work problems, financial burdens, family role changes, life-style changes, and side effects associated with long-term drug treatment'.

COMMENT

Hypothesis, theory, reliability, and validity of instruments (questionnaires) all contribute to an assessment of QOL, and indeed confirm that it is to some extent a measurable entity. However, Lofton[28] advises the transplant patient to ask questions to help clarify what it might be like to have a surgically successful transplant yet still feel 'I think I am merely dying a bit slower now.' He emphasizes how an organ transplant changes the patient's whole perspective on life. 'I hate it when people say "At least you're alive". I find myself more understanding of people who take their own life when they suffer serious medical problems.' Lofton delivers an insightful message to anyone involved in organ transplantation, and his article is recommended reading for all involved in the care of transplant patients. From time to time we should put aside the science and research, and take the time to listen to a real patient. His is a sobering message.

An old principle of treatment and research might be applicable to QOL researchers. This is the KISS principle, i.e. Keep It Simple, Stupid! Not infrequently it appears to the writer that lawyers, physicians, researchers, and, indeed, most educated individuals complicate subjects unnecessarily. In 25 years of working with people it never ceases to amaze me what we try to find out without actually asking the direct question. How do you really know what a patient wants from life and expects from a transplant without asking? It may be sufficient simply to ask the patient whether he or she would undergo the procedure (i.e. the organ transplant) again. As Bunzel *et al.*[7] say: 'When one understands life quality as a subjective experience ... the only sensible source of information is the patient.'

APPENDIX A: EXAMPLE OF A QOL QUESTIONNAIRE

An adaptation of a questionnaire directed towards an assessment of QOL after acute myocardial infarction utilized by Oldridge *et al.* and adapted by Lim *et al.*[9] In the interest of brevity, and in order to give the reader a general outline of the salient points, aspects relating to time periods have been omitted. For example, in the original questionnaire item 1 in full reads 'In general, how much of the time *during the last two weeks* have you felt frustrated, impatient or angry?'

Responses to all questions were to be differentiated as: (1) None of the time, (2) A little of the time, (3) Some of the time, (4) A good bit of the time, (5) Most of the time, (6) Almost all of the time, (7) All of the time.

Questions

1. How much of the time have you felt frustrated, impatient or angry?
2. How often have you felt worthless or inadequate?
3. How much of the time did you feel very confident and sure that you could deal with your heart problem?
4. How much of the time did you feel discouraged or down in the dumps?
5. How much of the time did you feel relaxed and free of tension?
6. How often have you felt worn out or low in energy?
7. How happy, satisfied or pleased have you been with your personal life?
8. How often have you felt restless or as if you were having difficulty trying to calm down?
9. How much shortness of breath have you experienced while doing your day-to-day physical activities?
10. How often have you felt tearful or like crying?
11. How often have you felt as though you were more dependent than you were before your heart trouble?
12. How often have you felt unable to do your usual social activities or social activities with your family?
13. How often have you felt as if others no longer have the same confidence in you as they did before you had the heart problem?
14. How often have you experienced chest pain while doing your day-to-day activities?
15. How often have you felt your heart problem limited or interfered with sexual intercourse?
16. How often have you felt unsure of yourself or lacking in self-confidence?
17. How often have you been bothered by aching or tired legs?
18. How much have you been limited in doing sports or exercise as a result of your heart problem?
19. How often have you felt apprehensive or frightened?
20. How often have you felt dizzy or light-headed?
21. How much have you been restricted or limited as a result of your heart problem?
22. How often have you felt unsure as to how much exercise or physical activity you should be doing?
23. How often have you felt as if your family is being overprotective toward you?
24. How often have you felt as if you were a burden on others?
25. How much of the time have you felt that you could manage chest pain if and when you had any?

APPENDIX B: QOL INSTRUMENTS OR METHODS

This is not designed to be a comprehensive list of QOL instruments or methods. For a further listing of psychological testing instruments and reliability and validity information on each, the reader is referred to *Buros Mental Measurements Yearbooks* or *Tests In Print* (both published by the Buros Institute of Mental Measurements, University of Nebraska, Lincoln, Nebraska).

Health Concerns Questionnaire (Spoth & Dush)
General Health Questionnaire (Goldberg)
The Nottingham Health Profile
Sickness Impact Profile
Quality of Life After Acute Myocardial Infarction (Oldridge)
Perceived Quality of Life Scale (Patrick *et al.*)
Health Behavior Scale (Miller *et al.*)
Profile of Mood States (McNair *et al.*)
Cardiac Health Knowledge Scale (Hanvik)
Hospital Anxiety and Depression Scale (Zigmond)
Coronary Prognostic Index (Norris)
UCLA-Social Support Inventory (Dunkel)
Specific Activity Scale (Goldman)
The Heart Patient's Psychological Questionnaire (Jan Van Dixhoorn)
State–Trait Anxiety Inventory (Speilberger)
Social Readjustment Scale (Holmes and Rahe)
The Psychosocial Adjustment to Illness Scale (Derogatis)
Karnofsky Performance Status Scale (Karnofsky)
Life Stressors and Social Resources Inventory
Coping Responses Inventory (Moos)
Strait–Trait Anger Expression Inventory (Speilberger)
Psychosocial Pain Inventory (Heaton *et al.*)
Coopersmith Self-Esteem Inventory (Coopersmith)
Coping Resources Inventory (Hammer and Marting)
Problem Solving Inventory (Heppner)
Millon Behavioral Health Inventory (Millon)
Brief Symptoms Inventory (Derogatis)

Experimental Development and Early Clinical Experience

D.K.C. COOPER

INTRODUCTION

Clinical heart transplantation was made possible by the considerable experimental work carried out earlier this century, which embraced mainly the technical, physiological and immunological aspects of the procedure. This chapter endeavours to review briefly the evolution and results of experimental surgical techniques utilized by cardiac transplant research workers; a comprehensive review appears elsewhere[1].

Experimental work on cardiac transplantation evolved through several overlapping phases. In the earliest experiments animals were given a second, often parasitic, heart which enabled certain physiological, pharmacological and pathological studies to be made. Initially the neck was chosen as the locus, though the abdomen and inguinal regions were occasionally used. The subsequent evolution of surgical techniques permitted the insertion of the donor heart into the chest as an auxiliary pump in circuit with the recipient organ. With the advent of hypothermia and the pump–oxygenator, total excision and replacement of the recipient heart became more feasible. Finally, after technical and physiological problems had been studied and minimized, efforts were made to combat the immune response with immunosuppressive agents.

TRANSPLANTATION OF AN ACCESSORY HEART

The first reported attempts at experimental heart transplantation were by Carrel (Figure 1) and Guthrie in 1905[2,3]. The principal technique they used is inadequately described as 'anastomosing the cut ends of the jugular vein and the carotid artery to the aorta, the pulmonary artery, one of the vena cava and a pulmonary vein. Although contractions of the donor atria appeared immediately, effective contractions of the ventricles did not begin for approximately 1 hour. The experiment was interrupted after a further 2 hours when coagulation occurred in the cavities of the heart.

The crucial factor of donor coronary perfusion (viviperfusion) was simplified in 1933 when Mann and his colleagues developed a technique of cervical transplantation[4] (Figure 2). Numerous investigators have subsequently used modifications of the Mann technique to study problems of heart transplantation and the response of the denervated heart to pharmacological agents and physiological stresses[1]. One such modification remains a standard model in many laboratories, including our own, for experimental animal studies on acute rejection and immunosuppression (Figure 3).

Figure 1 Alexis Carrel was awarded the Nobel Prize for Physiology and Medicine in 1912, primarily for his work on the anastomosis of blood vessels

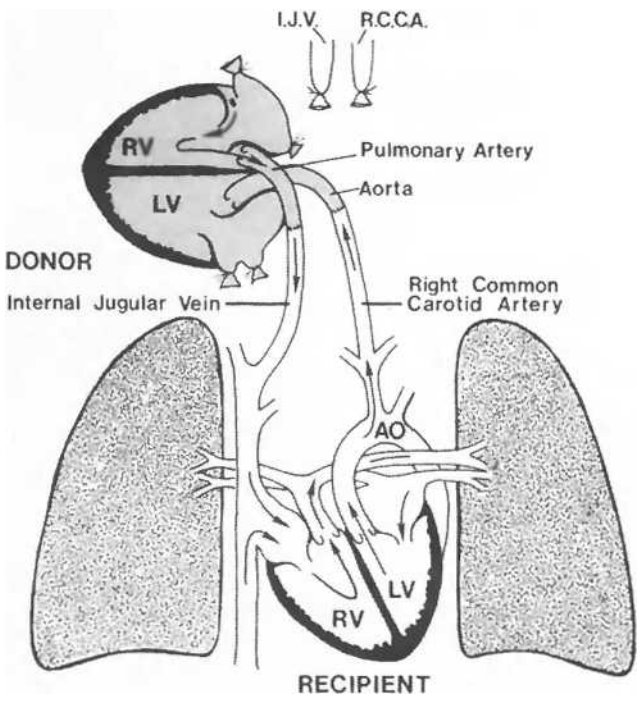

Figure 2 Technique of experimental heterotopic heart transplantation in the neck (Mann *et al.* 1933)[4], I.J.V. = internal jugular vein; R.C.C.A. = right common carotid artery

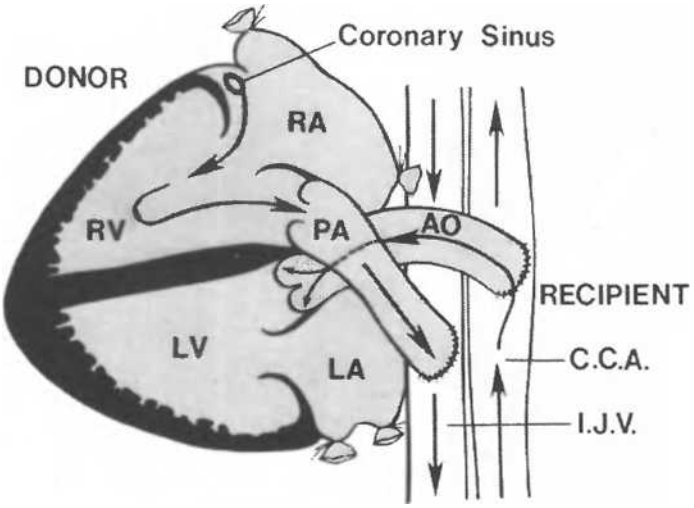

Figure 3 Modification of the Mann experimental cervical heterotopic heart transplantation technique[4] as used in our own laboratory

From their results, Mann and his co-investigators concluded that a functioning cardiac allograft was no less 'resistant' than a renal allograft, the graft failing to survive due to the same 'biologic factor' which also prevented survival of other homo (allo) transplanted tissues and organs. Such a transplanted heart, however, proved a valuable test object for the investigation of various physiological problems. For example, the effect of the intravenous administration of thyroxine to the host animal was investigated; the denervated donor heart was demonstrated to be more sensitive to the accelerating influence of the drug since central nervous system influence was inhibitory.

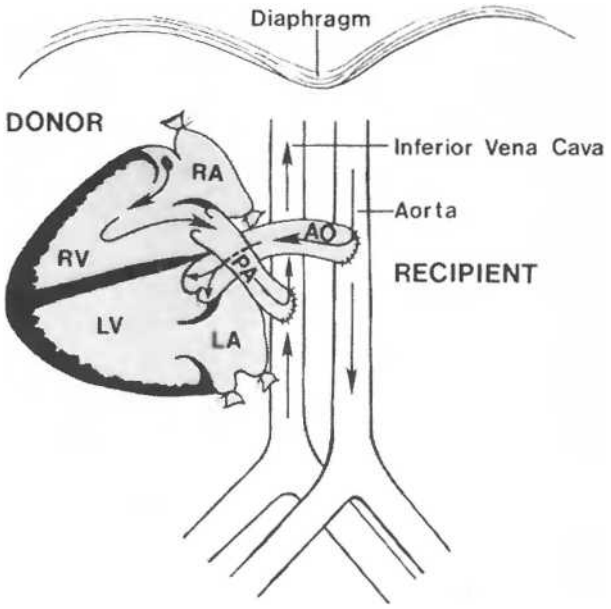

Figure 4 Technique of experimental heterotopic heart transplantation in the abdomen (Abbott *et al.* 1964)[5]

In more recent years, techniques for transplanting the auxiliary donor heart into the abdomen of the recipient have been described, principally for the study of the immune response and its modification by therapeutic agents (Figure 4); using microsurgical techniques it remains an important experimental model in rats[5,6].

THE TRANSPLANTED HEART AS AN AUXILIARY INTRATHORACIC PUMP

In 1946, Demikhov (Chapter 66, Figure 1) began extensive studies on transplantation of the heart into the thorax. These involved the addition of a second heart (occasionally with an attached lobe of a lung) as an auxiliary pump, as well as orthotopic transplantation of the heart with and without both lungs[7]. The ambitious nature of Demikhov's attempts can be appreciated best when it is remembered that supportive techniques, such as hypothermia and cardiopulmonary bypass, had not yet been developed.

In all, Demikhov described 24 variants of his technique to place an additional heart within the thorax, performing 250 operations on dogs utilizing most of the major vessels within the chest cavity. Few animals survived more than a few days, most of the early deaths being associated with technical problems. The best results with regard to functional activity of the transplanted heart and preservation of its structure were obtained after operations using the technique illustrated in Figure 5. Physiologically the transplanted heart was distinguished by the comparative constancy of its rhythm and by its greater resistance to the action of toxic doses of various cardiac glycosides. The physiological and pharmacological responses of the denervated, transplanted heart are discussed more fully in Chapter 27.

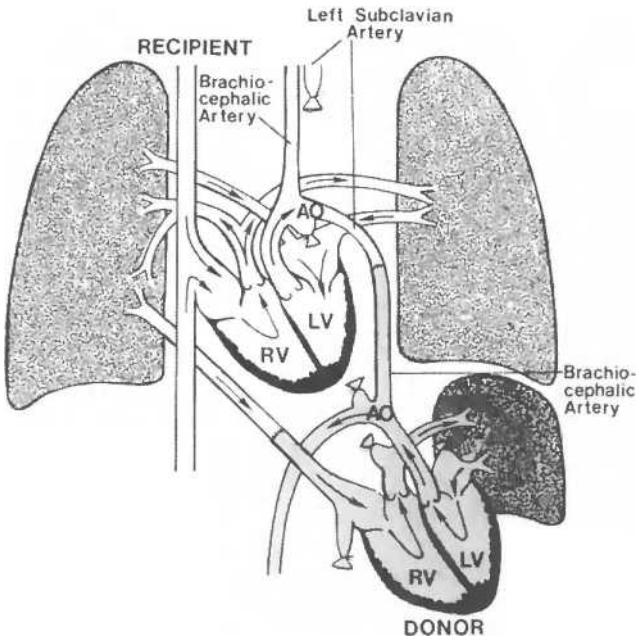

Figure 5 Technique of insertion of the heterotopic heart in the chest as an auxiliary pump (Demikhov 1962)[7]

In 1964, Reemtsma[8] described a method of inserting an additional intrathoracic heart as an auxiliary pump, which was similar in principle to that later developed and used clinically in the heterotopic heart transplant program in Cape Town[9,10]. The donor inferior vena cava was anastomosed to the recipient's right atrial appendage, followed by anastomosis of the two left atrial appendages, and end-to-side anastomoses of the two pulmonary arteries and aortae. Function as an auxiliary pump was maintained for a maximum period of 72 hours.

One year later, Sen and his colleagues described a further technique in which the transplanted heart supported only the systemic circulation of the recipient[11]. This auxiliary heart functioned in one animal for 48 hours, when it was surgically excised and the animal supported solely by its own heart once again, thus demonstrating the heterotopic heart transplant as a temporary left ventricular assist device.

ORTHOTOPIC TRANSPLANTATION OF THE HEART

On 25 December 1951 – a date which surely tells us a great deal about this surgeon – Demikhov made the first recorded attempt to replace the heart alone[7]. Without the availability of hypothermia or pump–oxygenator support, the technique was necessarily complicated. The procedure consisted of end-to-side anastomoses between the corresponding thoracic aortae, superior and inferior venae cavae, and pulmonary arteries. The two inferior pulmonary veins of the donor were joined together and connected to the recipient's left atrial appendage. After these anastomoses the ascending part of the recipient's thoracic aorta and pulmonary artery were ligated, and the recipient's left atrium was indrawn at its border with the ventricle by means of a purse-string suture. The entire segment of the recipient's heart thus excluded from the circulation was then excised.

Demikhov performed this procedure on 22 occasions, and in 1955 was successful in obtaining good cardiac function in two cases for periods of just over 11 and 15 hours respectively. In all but one case, death resulted from technical problems. These were amongst the first reported experiments, however, where animals survived for a few hours solely on the activity of a transplanted heart.

ADVENT OF SUPPORTIVE TECHNIQUES

With the advent of methods of supporting the recipient during the operative procedure, workers in this field became more ambitious. Significant early attempts were made by Neptune and his colleagues, using hypothermia[12], by Webb and Howard[13,14] and by Goldberg and co-workers[15,16], both using mechanical pump–oxygenator support.

In 1959, Cass and Brock reported six attempts at autotransplantation and homotransplantation using a modification of Goldberg's technique, where both atria were left intact in the recipient, thus simplifying the procedure[17]. Anastomoses of the

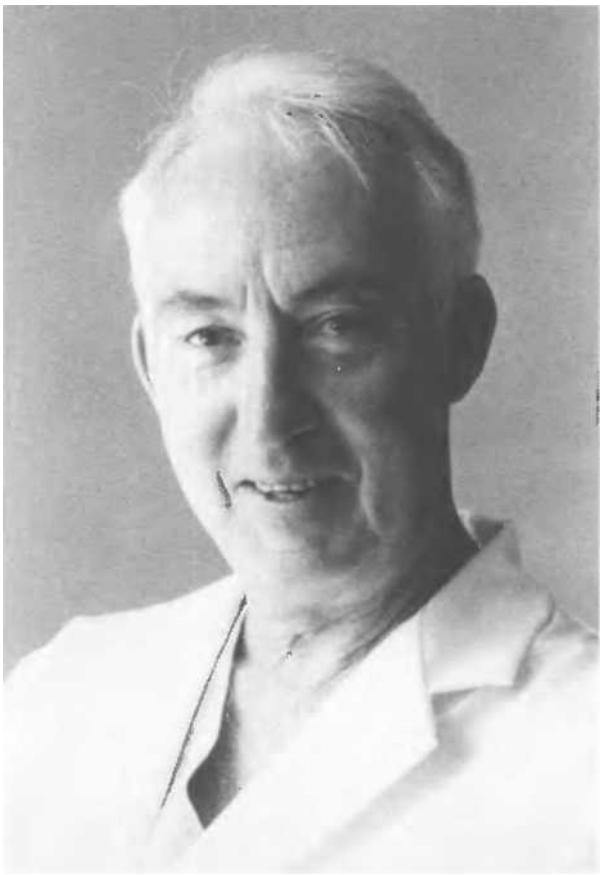

Figure 7 Norman Shumway, one of the major pioneers of heart transplantation. Much of the experimental work that led to the initiation of clinical heart transplantation was carried out in Shumway's laboratory at Stanford Medical School

atria, aorta and pulmonary artery were now all that were required. This procedure was described independently 1 year later at Stanford Medical School by Lower (Figure 6) and Shumway (Figure 7), who obtained the first consistently successful results[18]. With further modifications made by Barnard[19], the technique is now used in the clinical operation of orthotopic heart transplantation, and is described in detail in Chapter 24.

It was, therefore, not until 1960 that the major experimental advance was made, when Lower and Shumway reported that five out of eight consecutive dogs undergoing transplantation had lived for 6–21 days[18,20]. During convalescence the dogs ate and exercised normally, the pulse rate was variable and increased moderately with exercise, and only a few hours before death the ECG remained virtually normal, showing no evidence of arrhythmia or conduction defects. After death, microscopic examination of sections of myocardium demonstrated severe myocarditis, with massive round-cell infiltration, patchy necrosis, interstitial hemorrhage, and edema. The authors concluded that in all likelihood the graft would have continued to function for the normal life span of the animal if the immunologic mechanisms of the host had been suppressed.

These investigators and their colleagues subsequently studied autotransplantation[21,22] and allotransplantation[23–25] of the heart, achieving long-term survival, and contributing extensively to our knowledge of this subject[26–28]. In the experimental animal the transplanted heart was found to have the capacity to increase cardiac output under a variety of physiological stresses; a normal cardiac output was demonstrated 1 year after allotransplantation and $5\frac{1}{2}$ years after autotransplantation; evidence of autonomic reinnervation of the heart after autotransplantation was obtained.

Beginning in 1962, Willman and his colleagues produced the first of several papers on the subject of myocardial structure and function following autotransplantation of the heart[29], including autotransplantation in the primate[30].

USE OF PROFOUND HYPOTHERMIA

Orthotopic transplantation performed in puppies under profound hypothermia, rather than with a pump–oxygenator, was described by Kondo and his colleagues in 1965[31]. Total body cooling by iced water immersion of both recipient (to 16–17°C rectally) and donor (to 27–29°C) was carried out, allowing complete circulatory arrest of the recipient for the 45-minute operation. Heart massage was begun immediately after the anastomoses were completed. After being warmed to 26–28°C by body immersion and flushing of the chest cavity with warm saline, the heart was electrically defibrillated, and rewarming continued until the temperature returned to normal. One animal remained alive and well 112 days after operation.

PROLONGATION OF GRAFT SURVIVAL BY IMMUNOSUPPRESSION

When many of the technical and physiological problems had been overcome, investigators turned their attention to the problem of combating the immune response by chemotherapy. Reemtsma and his colleagues used Mann's cervical transplantation technique to study the effect of methotrexate, a folic acid antagonist[32]. In a control series of untreated dogs, cardiac activity continued for a maximum of only 10 days, whereas in the methotrexate-treated group maximal survival extended to 27 days. When the recipient was given azathioprine, a drug introduced as an immunosuppressive agent by Calne (Figure 8), the maximal survival was 32 days[8]. Blumenstock and his colleagues, using methotrexate in dogs with orthotopic transplants, obtained five dogs that survived from 12 to 42 days[33].

The Stanford group reported its experience with a combination of steroids (hydrocortisone or methylprednisolone) and azathioprine or mercaptopurine, achieving a mean survival of 17 days, in comparison to 7 days in control dogs[25]. Six further dogs were given immunosuppressant drugs only during threatened rejection, as demonstrated by diminution of the R-wave voltage in all leads of the ECG, which had previously been found to accompany immune rejection of the cardiac allograft; five of the six dogs survived for over a month, and three for over 3 months.

CARDIAC TRANSPLANTATION IN MAN – FIRST ATTEMPT USING A XENOGRAFT

By the mid-1960s a considerable fund of knowledge had been acquired. The increasing success of experimental cardiac transplan-

Figure 8 Sir Roy Calne, of Cambridge University, who was responsible for the introduction of azathioprine as an immunosuppressive agent in transplantation. Later, with David White, he carried out much of the experimental work on cyclosporine, and was the first to use this drug in a clinical transplant program

Figure 9 James Hardy, who, in 1963, led the team that performed the world's first single lung transplant and, in the following year, the first heart transplant. In this latter operation he used a chimpanzee as donor

tation led Hardy (Figure 9) and his colleagues at the University of Mississippi to consider heart transplantation in man. This group had considerable experience of cardiac and lung transplantation in animals, and had carried out the first lung transplant in man[34] (Chapter 43).

In 1964 they reported their attempt to transplant the heart of a large chimpanzee into the chest of a 68-year-old man with hypertensive cardiovascular disease, widespread atheroma, and evidence of previous myocardial infarction[35]. Before operation the patient deteriorated suddenly and passed into terminal shock. He was taken to the operating room, and supported by a pump–oxygenator just as effective heart action ceased. As no human donor was available, and as some of the members of the group had been impressed by the early results of kidney xenografts from chimpanzees to man reported by Reemtsma *et al.*[36], the heart of a 96 lb (43.6 kg) chimpanzee was used for orthotopic transplantation. After defibrillation the donor heart beat regularly and forcefully, but it soon became apparent that the rather small heart would not be able to support the circulation unless its rate were increased. The heart was paced at 100 per minute to maintain a systolic blood pressure of 60–90 mmHg. About 1 hour after the removal of the bypass catheters, however, the heart was judged incapable of accepting a large venous return without intermittent decompression by manual massage. Further support was abandoned.

THE FIRST HUMAN-TO-HUMAN HEART TRANSPLANT

After nearly 4 years and much further experimental work another attempt was reported. Barnard (Figure 10) and his colleagues performed the first human-to-human heart transplantation on a 57-year-old man with ischemic heart disease at Groote Schuur Hospital in Cape Town on the night of the 2–3 December 1967[37]. The operative procedure was successful, and the patient's orthotopically transplanted heart functioned satisfactorily throughout the early postoperative course. Immunosuppression was with azathioprine and corticosteroids. Like many patients who followed, however, he developed pneumonia, and died on the 18th postoperative day. At autopsy his transplanted heart showed features of mild to moderate acute rejection (Figure 11)[38].

The first patient who could realistically be acclaimed as a 'long-term' survivor was operated on in Cape Town 1 month later. This 60-year-old patient lived an active and full life for over $1\frac{1}{2}$ years, until he died from the hitherto undescribed complication of chronic rejection[39].

EARLY CLINICAL PROGRESS

The initial enthusiasm for heart transplantation waned as the problems of acute rejection and infection became apparent to those who had embarked upon a transplant program without a full understanding of the complications which might be involved. Four centers, those of Stanford University[40] and the Medical College of Virginia[41] in the USA, Hôpital La Pitié in Paris[42], and Groote Schuur Hospital in Cape Town[43], continued with planned programs of heart transplantation.

With improved patient selection based on experience, and improved postoperative care, in particular with regard to the administration of immunosuppressive drugs and the prevention, diagnosis and treatment of infectious complications, the results in these centers slowly improved. The introduction of the technique of percutaneous transvenous endomyocardial biopsy to diagnose acute rejection, by Caves and his colleagues in 1973[44,45], contributed much to the successful management of patients with cardiac allografts, allowing timely increases in immunosuppression or, of equal importance, the avoidance of over-immunosuppression.

The introduction of the operation of heterotopic heart transplantation by Barnard and Losman in 1975[9] added a further surgical technique, with some advantages and some disadvantages over orthotopic transplantation, which could be used by those treating patients with terminal myocardial disease.

During the late 1970s cardiac transplantation came to be accepted as a definitive form of therapy rather than as a clinical research program. As a result, in the late 1970s and early 1980s several other groups in North America and Europe initiated clinical heart transplant programs.

INTRODUCTION OF CYCLOSPORINE

Following the discovery of the immunosuppressive effects of cyclosporin A by Borel (Figure 12) in 1976[46], and extensive experimental studies at several centers, notably Cambridge in the United Kingdom[47] and Stanford in the USA[48], cyclosporin was introduced into a clinical cardiac transplantation program in 1980[49]. Until this time, immunosuppression had been achieved with a combination of azathioprine[50], corticosteroids[51], and anti-lymphocyte globulin[40], which was probably first used in cardiac transplantation in 1968 (Barnard, C.N., personal communication).

Prolonged survival of heart and heart–lung transplants in non-human primates was achieved using immunosuppressive regimens in which cyclosporin played a major role[48]. Based on these studies, the initial clinical programs suffered from incorporating

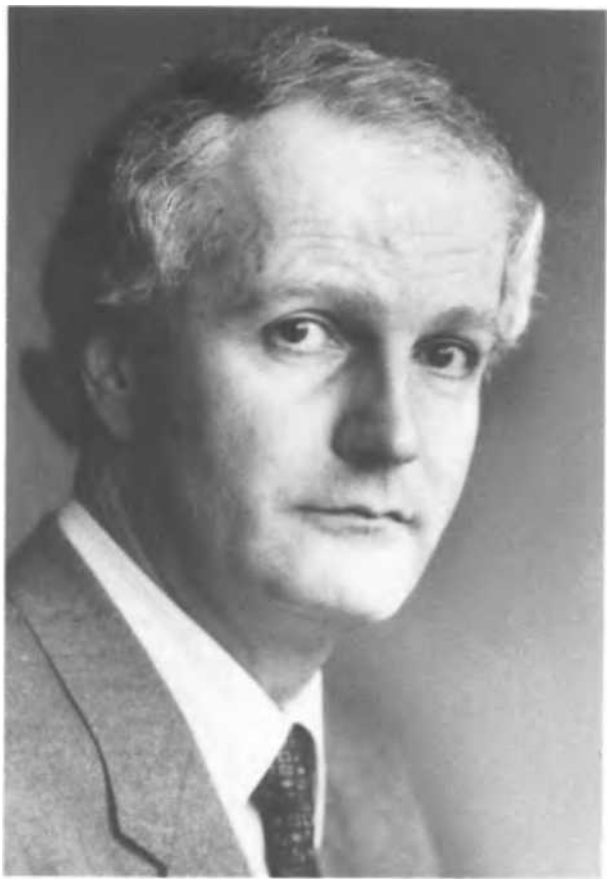

Figure 12 Jean Borel, of Sandoz Ltd, Basel, Switzerland, who discovered the immunosuppressive properties of the drug, cyclosporine A

an excessively high dose of cyclosporin in the pre- and early post-transplant period, and many patients suffered morbidity or even death from complications of cyclosporin therapy, in particular renal failure.

With experience, however, the dose of cyclosporin was gradually reduced, and the potential complications minimized.

The subsequent good results obtained with a combination of a lower dose of cyclosporin with azathioprine and low-dose corticosteroids, reserving antilymphocyte globulin and, more recently, the monoclonal antibody OKT3[52] primarily as treatment for rejection episodes, has encouraged many centers world-wide to embark on heart transplantation programs.

Selection and Management of the Potential Candidate for Cardiac Transplantation

L.W. STEVENSON

INTRODUCTION

The potential benefits of transplantation were already recognized in 1968, as reflected in the statement from the Bethesda conference chaired by Francis Moore[1]: 'Cardiac transplantation, still in an early stage of development, shows promise for the future treatment of many people with severe heart disease.' At that time there were 20 survivors of 50 heart transplant procedures. Since then, cardiac transplantation has evolved from an experimental to an accepted clinical procedure, endorsed by Medicare in 1986 as 'best therapy' for end-stage heart failure. The current survival rate is 80–85% at 1 year and 60–70% at 5 years[2]. There have been over 30 000 heart transplants performed in the world, involving over 250 heart transplant centers.

When transplantation was an experiment, patients were selected from those facing imminent death. The indications were obvious, and the contraindications could be liberally defined by the investigators. Improving results led to consideration of candidates for whom the immediate need for transplant was less urgent, but the longer waiting times required earlier anticipation of that need. At the same time, continuing refinement of immunosuppression diminished the immediate negative impact of many conditions such as diabetes and older age, which were initially criteria for exclusion due to associated higher risks of post-transplant complications. These changes have widened the channels into an ever-expanding pool of potential candidates (Figure 1). It is currently estimated that up to 40 000 people each year in the United States would potentially benefit from cardiac transplantation, an estimate surprisingly consonant with the 10 000–40 000 estimated in 1968. The original estimate of potential donor heart availability at that time, however, was 45 000 yearly in the United States, compared to the 2000–2500 actually achieved yearly for the past 5 years. Interestingly, their original estimate of cost was $50 000 in 1968 dollars[1], which is only

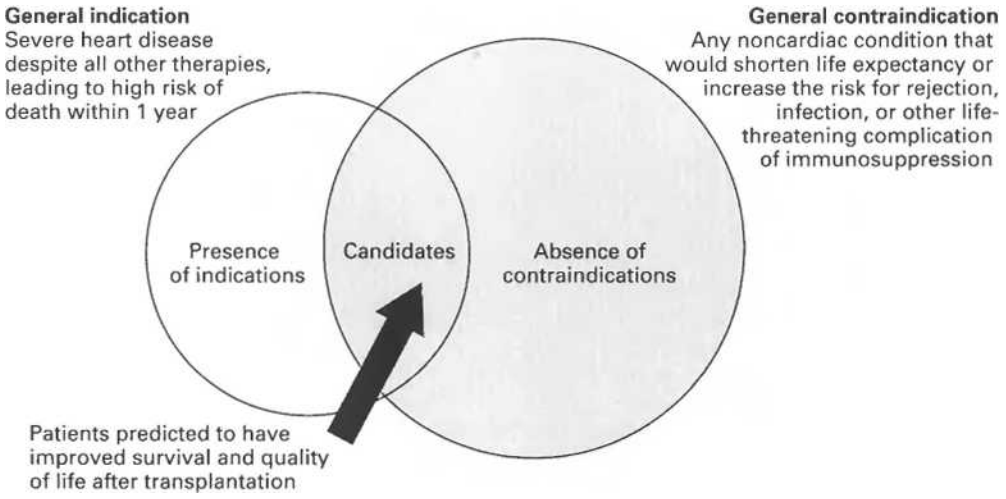

Figure 1 Intersecting circles demonstrate the principle of selection for cardiac transplantation of candidates who demonstrate indications without serious contraindications. As results of transplantation have improved, the indications broaden and the contraindications become less strict

slightly lower than the absolute figure currently negotiated for some contracts in 1995 dollars.

As cardiac transplantation has evolved, other medical and surgical alternatives to transplantation have also developed. Heart transplantation now represents only one facet of the therapies which should be offered by centers dedicated to the heart failure population. A left ventricular ejection fraction ≤25% no longer means that a new heart must be substituted in order for a patient to survive with a good quality of life. Surgery for reversible ischemia, distorted ventricular geometry, and valvular disease is successful in some patients despite poor left ventricular function and symptoms of heart failure[3-5]. Medical therapy has had dramatic impact on the symptoms of heart failure, with less but still significant impact on survival, challenging previous assumptions of when left ventricular dysfunction becomes 'end-stage'[6-8].

APPROACH TO THE PATIENT REFERRED FOR CARDIAC TRANSPLANTATION

The most common diagnosis in adults referred for transplantation is dilated heart failure, due in almost equal proportion to coronary artery disease and non-ischemic dilated cardiomyopathy. Primary restrictive cardiomoyopathy, primary valvular disease, and congenital heart disease account for slightly fewer than 10% of all candidates[2], with rare cases of cardiac trauma or tumor. The general approach to the identification of indications and contraindications is applicable regardless of etiology (Table 1), but most of the specific considerations below focus on advanced heart failure with low left ventricular ejection fraction.

Table 1 Approach to the potential candidate for heart transplantation

Address potentially reversible components of heart failure
Tailor medical therapy to relieve congestion
Evaluate functional capacity
Assess risks of deterioration or sudden death
Identify indications for transplant
Exclude contraindications to transplantation
Determine candidacy for transplantation: now, when needed, or conditional
Maintain and re-evaluate

Factors which are potentially reversible

All patients should undergo extensive investigation to identify the primary cause and any potentially reversible factors contributing to decompensation (Table 2). Occasionally a systemic cause of disease is identified which will preclude cardiac transplantation due to expected effects on other organs after transplantation. A low left ventricular ejection fraction may in some cases reflect major areas of hibernating or stunned myocardium, which may demonstrate improved function after revascularization with coronary artery bypass grafting or catheter-based interventional procedures[4,5]. Angina is frequently absent, and thallium redistribution after reinjection or prolonged delay is not always present. Areas of glucose uptake in regions with decreased flow may identify viability otherwise not evident. A history of multiple reoperations or chronic diabetes mellitus may predict worse outcome. The quality of distal vessels appears critical for success, particularly in this population.

Table 2 Potentially reversible factors in heart transplantation

Intrinsic factors
Recent-onset cardiomyopathy
Extensive myocardial ischemia with potential for revascularization
Secondary viral infection superimposed on primary disease
Major alcohol consumption
Tachycardias
Metabolic factors: thyroid disease, electrolyte disturbances, obesity
Anemia or other high-output state
Factors of therapy
Ineffective drug regimen:
ineffective doses or combinations of vasodilators
inadequate diuresis
Non-compliance:
with drug regimen
with salt and fluid restriction
Concomitant drug therapy causing:
increased fluid retention
depressed contractility

Recent practice surveys from metropolitan transplant centers suggest that no more than 3–10% of potential transplant candidates with coronary artery disease may be appropriate revascularization candidates[9]. There is even less information available regarding valve replacement in patients with severely reduced ejection fractions, although it is generally considered indicated in any patient with significant aortic stenosis, and recent experience suggests that mitral valve reconstruction may be feasible and helpful in some patients[3]. Vigorous searching for surgically reversible conditions is warranted, however, due to the implications both for the patient whose own heart may improve without transplantation and for another patient who may receive the donor heart which is spared.

Considering the limitation of donor hearts, an operative risk for an alternative procedure which is higher than for the same procedure in a patient with good ventricular function is not itself an indication for cardiac transplantation. Those who survive often demonstrate gradual improvement after 'salvage surgery', or at least stabilize sufficiently to undergo elective transplantation after discharge. Reliance upon 'transplant back-up' for post-cardiotomy shock, however, may be dangerous, as outcomes are uncertain for such patients. Patients requiring mechanical assistance to bridge from post-cardiotomy shock have been reported to have poorer outcome than patients receiving a primary bridge[10,11], although those surviving to transplantation have subsequent survival comparable to elective transplantation.

Recent cardiomyopathy, defined as less than 6 months of symptoms in the absence of major coronary artery or primary valvular disease, may improve spontaneously in up to 50% of patients, whether or not associated with a recent viral infection or with myocarditis on endomyocardial biopsy. When the clinical severity of symptoms leads to referral for transplantation, major improvement defined as ≥0.15% increase in left ventricular ejection fraction occurred in 27% of patients in one series[12], most often in those with the least elevation in filling pressures and least mitral regurgitation at the time of referral. For patients with this defined improvement, subsequent prognosis is excellent, although exercise capacity may remain somewhat impaired by diastolic dysfunction[13]. Recent-onset cardiomyopathy which does not improve, however, confers worse short-term prognosis than for

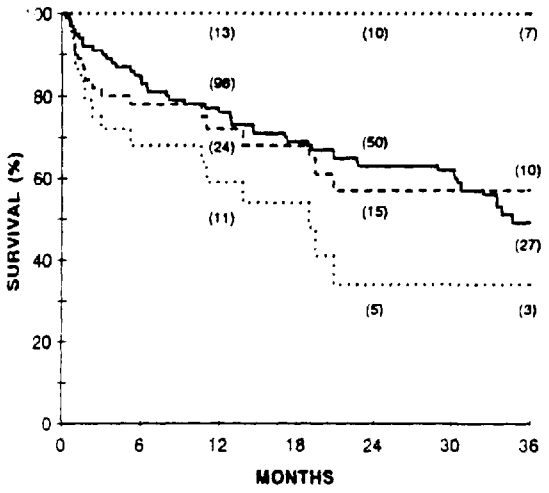

Figure 2 Survival for 297 patients with primary dilated cardiomyopathy referred for cardiac transplantation. The survival with chronic cardiomyopathy was not different from the total survival of all patients with recent-onset cardiomyopathy, but this recent-onset group could be divided into: (a) those with ≥15% ejection fraction improvement to ≥30% and (b) those with no improvement, for whom survival was significantly worse ($p = 0.0009$)[12]

patients with more chronic disease (Figure 2), particularly in patients under 33 years[12]. Occasionally, young patients present with a fulminant picture of acute cardiac and other organ failure, usually in association with a viral syndrome, from which the chance of complete recovery may exceed 50%, although high-dose catecholamine support, and occasionally mechanical ventricular support, may be necessary for 5–10 days. The incidence of this syndrome varies from year to year and is usually highest in the winter months.

Cardiomyopathy presenting within the last trimester of pregnancy or initial post-partum months may have a slightly higher chance of improvement than cardiomyopathy of other etiologies[14]. Symptoms often improve remarkably after assisted diuresis post-partum of the excess volume of water accumulated during pregnancy. Heart failure presenting earlier in pregnancy often reflects exacerbation of previous conditions.

Patients with known heart failure due to cardiomyopathy or coronary artery disease often demonstrate prolonged deterioration after respiratory and viral syndromes, perhaps as a result of the negative inotropic effects of cytokines, the accompanying tachycardia, or increased metabolic demands. Many patients are first referred for transplantation within weeks after such an episode. Restoration of fluid balance and adjustment of vasodilator therapy frequently allows recovery to previous levels of compensation within the next few months.

Approximately 10% of cardiomyopathy in the United States has been attributed to heavy alcohol consumption, although the incidence may be underestimated[15]. Consumption of two drinks daily, which is common in the general population, may be sufficient to worsen heart failure of other primary causes. Occasional dramatic improvement in the left ventricular ejection fractions of patients with old myocardial infarctions is sometimes explained later by the patient's retrospective admission of heavy alcohol consumption prior to referral. Complete abstinence from alcohol should be mandated for at least 3–6 months prior to transplantation candidacy, both to demonstrate the irreversibility of decompensation and to ensure the patient's ability to avoid excessive alcohol consumption after transplantation, although modest consumption is then acceptable.

Tachycardia is increasingly recognized as a primary cause of cardiomyopathy in both adults and children[16]. Supraventricular tachycardias and relatively slow ventricular tachycardias may not be initially recognized. Atrial fibrillation, present in approximately 20% of patients referred for cardiac transplantation, is frequently associated with excessive ventricular rates during exertion. Conversion to sinus rhythm usually leads to clinical improvement, but has also frequently been associated with major improvements in left ventricular ejection fraction[17]. Amiodarone is the safest and most effective antiarrhythmic agent in this population, of whom more than half may still be in sinus rhythm a year after cardioversion on amiodarone[18]. Atrioventricular node ablation and pacemaker implantation may be considered when atrial fibrillation is refractory and the rate cannot be well controlled.

Obesity has been implicated as a primary cause of cardiomyopathy. Weight loss is achievable and frequently easier during heart failure, even though activity is curtailed. Weight loss itself allows more effective distribution of limited cardiac output but, in addition, is frequently associated with significant improvement in left ventricular function[19], such that cardiac transplantation need not be considered. This should be emphasized to all potential transplant candidates. A pattern of weight maintenance is also critical to avoid morbid weight gain after transplantation, which limits rehabilitation, contributes to osteoporotic complications, and has been associated with transplant vasculopathy.

Tailored therapy prior to transplantation

At the time of serious consideration for transplantation, most patients have a left ventricular ejection fraction <25% (Table 3) (although this is not necessary for acceptance, see below), and symptoms of heart failure which limit daily life. These symptoms are dominated by elevated intracardiac filling pressures which on the left side cause orthopnea, paroxysmal nocturnal dyspnea

Table 3 Profile of 265 patients discharged after referral with class IV symptoms and ejection fraction ≤25%

Ejection fraction (%)	18 ± 5
CHF duration (months)	33 ± 34
Left ventricular end-diastolic dimension (mm)	75 ± 10
Mitral regurgitation (0–3)	2.0 ± 0.8
Tricuspid regurgitation (0–3)	1.7 ± 0.9
Serum sodium (mEq/l)	134 ± 5

Hemodynamics	*Initial*	*On revised therapy*
Right atrial pressure	13 ± 7	7 ± 4
Systolic blood pressure	106 ± 14	96 ± 13
Pulmonary wedge pressure	27 ± 9	17 ± 16
Systemic arterial pressure	85 ± 11	76 ± 10
Cardiac index ($l\ min^{-1}\ m^{-2}$)	1.9 ± 0.6	2.5 ± 0.5
Heart rate (beats/min)	94 ± 17	91 ± 15

(PND), and immediate dyspnea on light exertion (IDLE). (In contrast, dyspnea occurring only after several minutes of moderate exertion is more often due to the failure to increase cardiac output to levels adequate for aerobic metabolism during increased demand.) Elevated right-sided cardiac filling pressures cause the symptoms of systemic venous congestion, which can be manifest as gastrointestinal discomfort, anorexia, early satiety, ascites, and peripheral edema. Most patients have a history of recent hospitalizations during which intravenous diuretics, often in conjunction with a brief course of an intravenous inotropic agent, such as dobutamine or milrinone, have caused only a temporary clinical improvement, following which the congestion rapidly recurs.

The majority of patients at the time of referral are already receiving standard 'triple therapy', which includes digoxin, diuretics, and angiotensin-converting-enzyme inhibitors, which have in some cases been reduced or stopped due to hypotension. Although effective doses of vasodilators have been established in trials of mild–moderate heart failure[6,7], the use of different doses or different combinations frequently improves clinical status in patients with more severe heart failure[8,20]. For all potential candidates, transplant evaluation provides a vital opportunity to redesign the medical regimen, which is of central concern regardless of whether or not the patient is ultimately found to be a candidate for transplantation.

Therapy for severely symptomatic patients is dominated by the need to reduce congestive symptoms, and thus the filling pressures which cause those symptoms. The first challenge is to recognize the excess volume present in most of these patients[21]. Although many patients have 3–5 liters of excess fluid at the time of evaluation, the lungs are usually clear of rales in chronic heart failure, and peripheral edema and/or ascites occur in fewer than 30% of these patients. Orthopnea and jugular venous distension are the most reliable clinical indicators of volume overload, and almost always indicate the need for further therapy.

Previous therapy to relieve congestion has often been hampered by concern that therapy to decrease volume status will further depress cardiac output. This misconception is often strengthened by small rises in creatinine and blood urea nitrogen during diuresis, which is more often a direct result of reflex responses to decreased atrial distension than an indication of falling cardiac output. The majority of patients with chronically dilated heart failure[22] will achieve their highest cardiac outputs with pulmonary capillary wedge pressures in the range of 12–15 mmHg. Forward stroke volume often increases by 30–50%, due largely to forward redistribution of mitral regurgitant flow[23].

Resting hemodynamic compensation is maintained on standard doses of diuretics and vasodilators despite low left ventricular ejection fractions in most patients with left ventricular dysfunction, who have not been shown to benefit from hemodynamic monitoring to achieve more precise goals when already clinically compensated. Cardiac transplantation is rarely indicated in such patients except for other indications such as refractory angina or arrhythmias. Adjustment of vasodilators or diuretics can be guided by clinical assessment in some patients with mild hemodynamic abnormalities. When severe symptoms persist after empiric therapy, however, further intervention can frequently still restore compensation (Table 4)[20].

In the Bethesda conference on cardiac transplantation, the summary of general recommendations specifies that functional status should not be assessed until patients have undergone aggressive therapy with combinations of vasodilator and diuretic therapies[24]. 'Therapy should be adjusted until clinical congestion has been resolved or until further therapy has been repeatedly limited by severe hypotension (generally systolic blood pressure <80 mmHg) or marked azotemia. Patients should not be considered to have *refractory* hemodynamic decompensation until therapy with intravenous followed by oral vasodilators and diuretic agents has been pursued using continuous hemodynamic monitoring to approach hemodynamic goals.'

Hemodynamic monitoring allows the coupled optimization of both volume status and vascular resistances using simultaneous diuretic and vasodilator therapy, which can rarely otherwise be achieved safely and completely once decompensation is severe (Table 5). Hemodynamic status is often easiest to optimize initially during titration of intravenous vasodilators, such as nitroprusside. Intravenous inotropic agents, such as dobutamine, have also been used, but are less predictive of ultimately successful maintenance on oral regimens because the inotropic component cannot currently be duplicated with available oral drugs. Use of

Table 4 Suggested indications for invasive monitoring of hemodynamics during therapy of congestion

Congestion with concomitant hypoperfusion suggested by:
Mental obtundation
Pulse pressure < 25%
Cool extremities
Declining renal function
Hemodynamic intolerance to ACEI
(likely when systolic blood pressure < 90 mmHg or serum sodium < 133 mEq/l)
Congestion in the presence of:
Active ischemia
Symptomatic ventricular arrhythmias
Suspected active pulmonary disease
Impaired baseline renal function
Congestion persisting or recurring despite all of:
ACEI as tolerated
Combination high-dose diuretics
Sodium and water restriction
Serious consideration of heart transplantation for symptoms of heart failure

ACEI = angiotensin-converting-enzyme inhibitors

Table 5 Tailored therapy for advanced heart failure

1.	Measurement of baseline hemodynamics
2.	Intravenous nitroprusside and diuretics tailored to hemodynamic goals
	PCW ≤ 15 mmHg
	SVR ≤ 1200 dyne s cm $^{-5}$
	RA ≤ 8 mmHg
	SBP ≥ 80 mmHg
3.	Definition of optimal hemodynamics by 24–48 h
4.	Titration of high-dose oral vasodilators as nitroprusside weaned
	Combinations of: captopril, isosorbide dinitrate, hydralazine as needed as alternative or addition
5.	Monitored ambulation and diuretic adjustment for 24–48 h
6.	Maintain digoxin levels 1.0–2.0 ng/dl, if no contraindication
7.	Detailed patient education
8.	Flexible outpatient diuretic regimen including PRN metolazone
9.	Progressive walking program
10.	Vigilant follow-up

longer-acting inotropic agents is occasionally necessary for prolonged intravenous support, but the long half-life complicates monitored weaning onto oral agents. In addition to restoring clinical stability, reduction of left ventricular filling pressures over several days often demonstrates reversibility of pulmonary hypertension which during acute therapy appeared fixed.

The oral regimens established by tailored therapy often consist of relatively high doses of angiotensin-converting-enzyme inhibitors. Some data suggest that the best survival may be obtained in this population when angiotensin-converting-enzyme inhibitors are combined with oral nitrates[8]. Patients with the most severe decompensation, as indicated by very low serum sodiums and/or inability to tolerate sufficient doses of angiotensin-converting-enzyme inhibitors to optimize loading conditions, often derive sustained benefit from the combination of hydralazine and oral nitrate therapy[8].

Tailoring of therapy for hemodynamic goals in class IV heart failure often leads to dramatic improvement in hemodynamics and clinical status (Table 3). Prolonged maintenance of hemodynamic goals has been associated also with measured reductions in atrial sizes and mitral and tricuspid regurgitation, and with improvement in peak oxygen consumption (Table 6)[25–27]. In combination with patient education, progressive exercise, and meticulous ongoing care by an experienced heart failure team, this approach has been shown to reduce the rehospitalization rate by over 75%[27]. The impact of this care extends not only to the patient who can postpone transplantation, but also to the patient who can await transplantation in greater comfort and a more favorable condition for surgery, and perhaps most importantly, to the larger majority of patients for whom transplantation is not an option.

Table 6 Outcome of tailored therapy in patients referred for cardiac transplantation

	Pre-referral	*Post-referral*

Adjunctive outpatient therapies for heart failure

On the foundation of tailored therapy, other therapies may offer additional benefit in selected patients (Table 7). The use of adrenergic blocking agents has been shown to improve ejection fraction and clinical status in some patients with heart failure, but their benefit in decompensated heart failure has not been demonstrated[28,29]. The limited experience in advanced heart failure involves patients who were free of apparent volume overload or congestive symptoms when the drug was cautiously initiated in very low doses[30]. While patients frequently experience some fatigue during initiation of these drugs, administration should usually be stopped if accompanied by fluid retention unresponsive to diuretics. Withdrawal should be considered, although it is controversial, in patients presenting with severe decompensation while receiving these agents. Amiodarone has been associated with similar increases in ejection fraction, possibly related to similar decreases in heart rate[31]. Unlike other antiarrhythmic agents studied in heart failure, amiodarone does not appear to increase mortality[32,33]; in fact, several lines of evidence suggest that amiodarone may actually improve survival in advanced heart failure. This effect appears to be independent of the degree of baseline arrhythmia and to result in decreased heart failure endpoints, as well as sudden death[32].

Multiple non-glycosidic oral inotropic agents have been investigated in heart failure populations, often with deleterious effects at the doses used. There is not yet any consistent evidence that any such agents decrease mortality in the population for whom cardiac transplantation would otherwise be considered. Intermittent or continuous ambulatory infusions of dobutamine have appeared beneficial in some patients, but sustained benefit has not been proven.

Table 7 Outpatient therapies for potential heart transplant candidates

Routine use	*Selected use*	*Detrimental*	*Under clinical investigation*
Angiotensin-converting-enzyme inhibitors	Anticoagulation	Amrinone, milrinone	Carvedilol
Digoxin	Hydralazine	Flosequinan	Vesnarinone
Diuretics	Amiodarone	Prostacyclin infusion	Home dobutamine
Nitrates	β-blockers	Diltiazem, nifedipine	Pimobendan
Potassium	Magnesium	Type I anti-arrhythmic agents	Amlodipine
Exercise	AICD	Non-steroidal anti-inflammatory agents	Ibopamine
	Nocturnal oxygen		AII rec antagonist Coenzyme Q10 L-Carnitine Ultrafiltration Nocturnal CPAP (continuous positive airway pressure)

INDICATIONS FOR CARDIAC TRANSPLANTATION

The goal of cardiac transplantation is to maximize the benefit derived from each donor heart transplanted (Figure 3). Benefit is a function of both quality and length of life, with different relative values assigned by different patients. If the goal were instead to maximize overall survival after transplantation, the optimal recipient would be a healthy young athlete, who would himself derive negative benefit from the procedure. For the patient who remains critical in an intensive-care unit despite consideration of all other medical and surgical options, the expected benefit of transplanta-

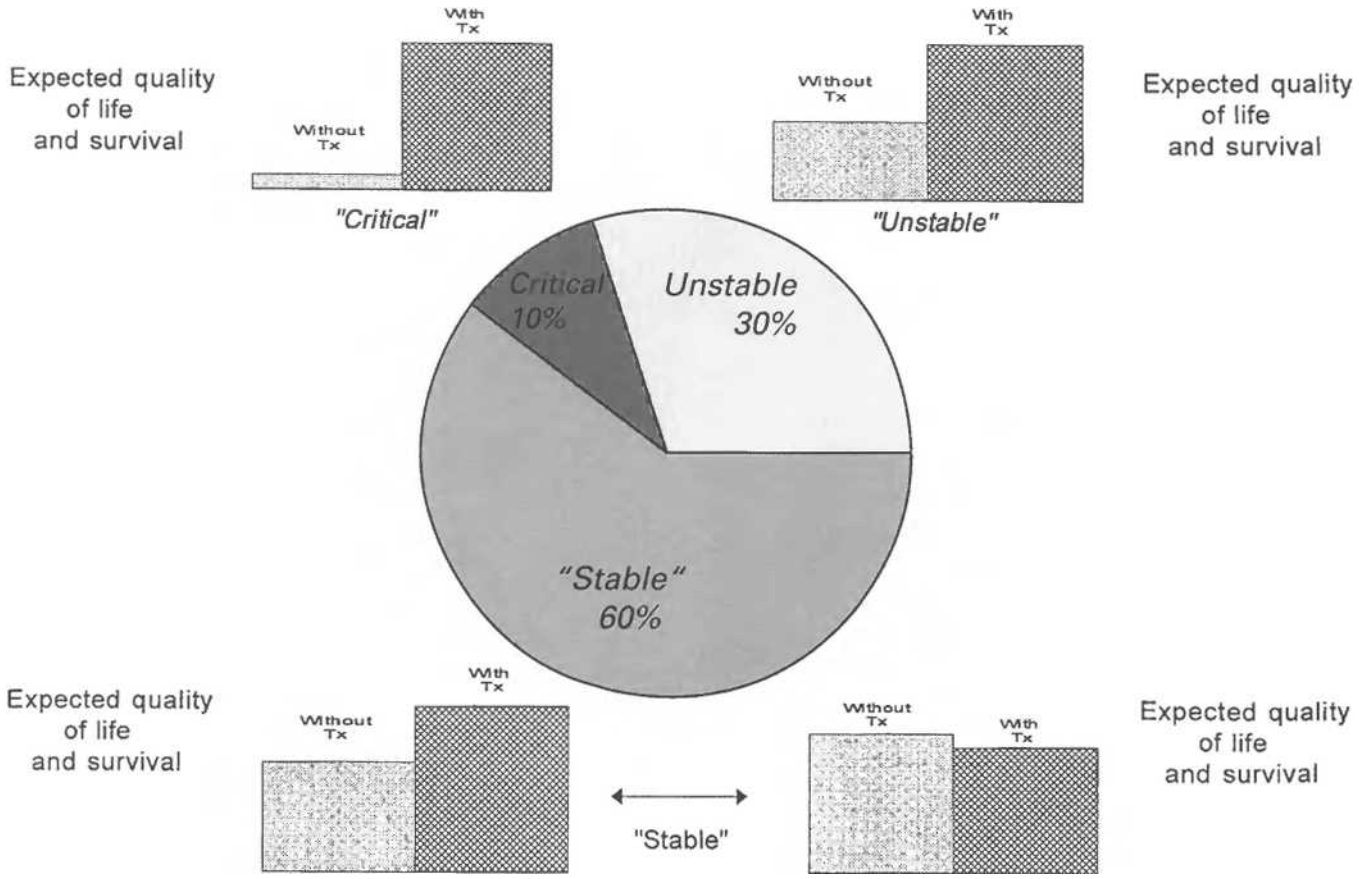

Figure 3 Expected benefit from transplantation according to clinical status achieved after therapy tailored for advanced heart failure. The relative proportions of the pie reflect the population referred to a major metropolitan transplant center, and would be expected to vary at other programs. Eligible patients remaining hospitalized in critical condition can expect major benefit in both quality and length of life. Patients remaining unstable, whether in or out of the hospital (see definition of stability, Table 13) can expect significant benefit. More refined analyses of functional and survival benefits are required to identify appropriate candidates from the population of patients who appear 'stable'

tion for both function and survival is obvious. For the patient who remains unstable, in or out of the hospital, with recurrent symptoms of congestion, the benefit is also obvious.

A major challenge of selection is the identification of the ambulatory patient at home who has sufficient clinical limitation or sufficient risk of deterioration and death to warrant the risks and limitations of cardiac transplantation. Many of the adverse prognostic factors validated in large heart failure trials are consistently present in the patients considered for cardiac transplantation. Factors proposed more specifically in severe heart failure relate to cardiac and hemodynamic parameters, the substrate for arrhythmias, and the systemic cardiovascular and neuroendocrine integration[34–40].

Table 8 Peak exercise oxygen consumption and expected benefit from transplantation

Peak Vo_2 with heart failure	*Expected after transplant*	*Estimated 1-year survival with heart failure*	*Estimated 1-year survival after transplant*	*Decision regarding transplant*
< 10	< 14–18	< 50–60%	≤ 80–90%	Transplant (if eligible)
10–14	14–18	60–75%	80–90%	Toward transplant
14–18	14–18	70–85%	80–90%	Away from transplant
> 18	> 14–18	80–95%	≥ 80–90%	No transplant (unless other indications)

Symptoms of heart failure

The presence of class IV symptoms of heart failure was originally considered to indicate 'end-stage' heart failure, and thus represented the major indication for transplantation. Since the early days of transplantation, however, medical therapy has evolved such that even patients with class IV symptoms can often improve to regain good quality of life. Although survival remains limited, it has also improved (Figure 4). While the extended prognosis of advanced heart failure remains worse than that of transplantation, the limitations both of donor supply and of lifespan after transplantation require that indications for transplantation be based on the expected increment in 1–2-year prognosis, with frequent

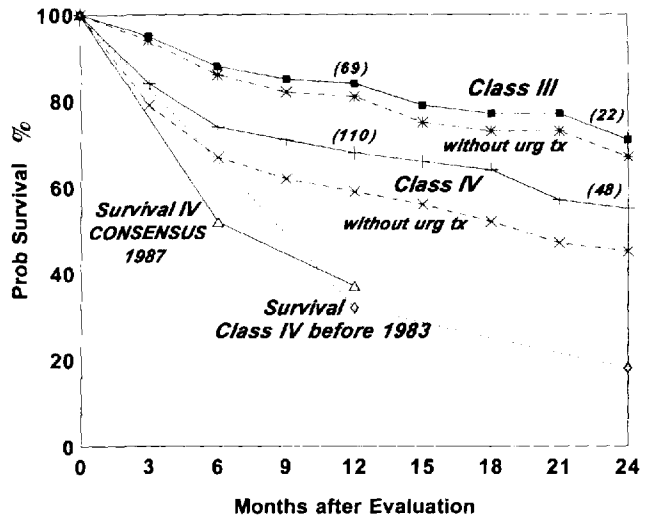

Figure 4 Overall survival and survival without urgent transplantation for 404 patients presenting with left ventricular ejection fraction ≤25% and New York Heart Association class III (n = 139) or class IV symptoms (n = 265). Recent survival of class IV patients is compared to those described by Wilson *et al.* in 1983[34] and the CONSENSUS trial in 1987[86]

reassessment. Considering the 70–80% 2-year survival after transplantation at major centers, it has been suggested that cardiac transplant candidates should have a predicted 2-year survival of ≤50% without transplant[41].

Left ventricular ejection fraction

Left ventricular ejection fraction below 20–25% has also been suggested to confer an unacceptable risk of mortality[42]. While this is certainly true when a population covering the spectrum from mild to severe disease is included, the prognostic value of left ventricular ejection fraction once it is below 25–30% is less clear.

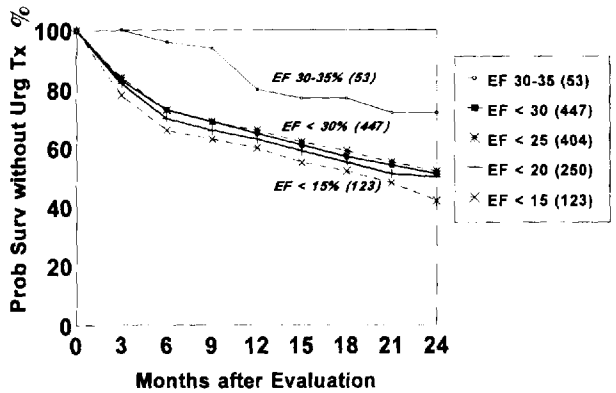

Figure 5 Relationship of left ventricular ejection fraction to actuarial survival without urgent transplantation (urg tx) in 500 patients presenting with New York Heart Association class III or IV symptoms 1988–1993 in one center. Left ventricular ejection fraction over 30% was associated with better survival but, once below 30%, progressively lower ejection fraction did not portend worse survival

If only those patients with class III or IV symptoms are considered, the left ventricular ejection fraction is not very helpful once it is lower (Figure 5)[43]. Interestingly, potential transplant candidates with massive left ventricular dilatation have a significantly worse prognosis than those with moderate dilatation, even when etiology of disease and degree of hemodynamic compromise are comparable[44]. Even for presentation with class IV symptoms and left ventricular ejection fraction ≤20%, prognosis after discharge on tailored medical therapy is not uniformly dismal, 45% surviving without death or urgent transplant[43]. (When comparing the outcome of other therapies to transplantation, it is important to consider the patients who are saved by 'urgent' transplantation as failures of alternative medical therapy, who would presumably have died had they not been hospitalized and supported until transplantation.)

Peak oxygen consumption

Measurement of peak oxygen consumption during exercise provides an index of overall cardiovascular reserve that is useful both to quantitate functional limitation and to estimate prognosis (Table 8). In mild–moderate heart failure of the Veterans Administration Heart Failure trials, a peak oxygen consumption <14.5 ml kg^{-1} min^{-1} predicted worse survival whether left ventricular ejection fraction was above or below 28%[45]. The experiences of Szlachic and Likoff in other populations confirmed the measurement of peak oxygen as an independent prognostic guide[46,47]. Mancini *et al.*[48] provided the initial validation of peak oxygen consumption as a criterion for transplant candidacy from her analysis of 114 potential transplant candidates, suggesting 14 ml kg^{-1} min^{-1}. Other experience has identified values between 10 and 14 ml kg^{-1} min^{-1} (Figure 6A)[49,50].

Some differences between programs may reflect varying practices of excluding patients with obvious resting symptoms. In addition, bicycle exercise yields peak oxygen consumption values slightly lower than treadmill exercise. Synthesis of the currently available information suggests that patients who are unable to perform exercise, or who can achieve peak oxygen consumption of <10–12 ml kg^{-1} min^{-1}, have the worst prognosis. The importance of indexing to predicted values remains controversial (Figure 6B). Patients with peak oxygen consumption over 16–18 ml kg^{-1} min^{-1} have 2-year survival similar to that of cardiac transplantation, in the absence of other confounding factors such as active ischemia or rapid deterioration (Table 8).

Many patients are unwilling to accept the burdens and risks of immunosuppression unless a major improvement in functional capacity is anticipated in addition to the survival benefit. For some patients with stable heart failure by clinical criteria[51,52], quality of life may not be significantly improved after transplantation[53]. Despite a left ventricular ejection fraction usually within normal limits, exercise capacity after transplantation is limited by multiple cardiac and systemic factors. Peak oxygen consumption, and other measures of exercise capacity such as the 6-minute walk distance, are often similar between patients with stable heart failure and cardiac transplant recipients, in the range of 50–70% of values predicted on the basis of age, size, and gender[52]. The perception of prolonged fatigue after exertion is less easy to quantify, but appears less common after transplantation.

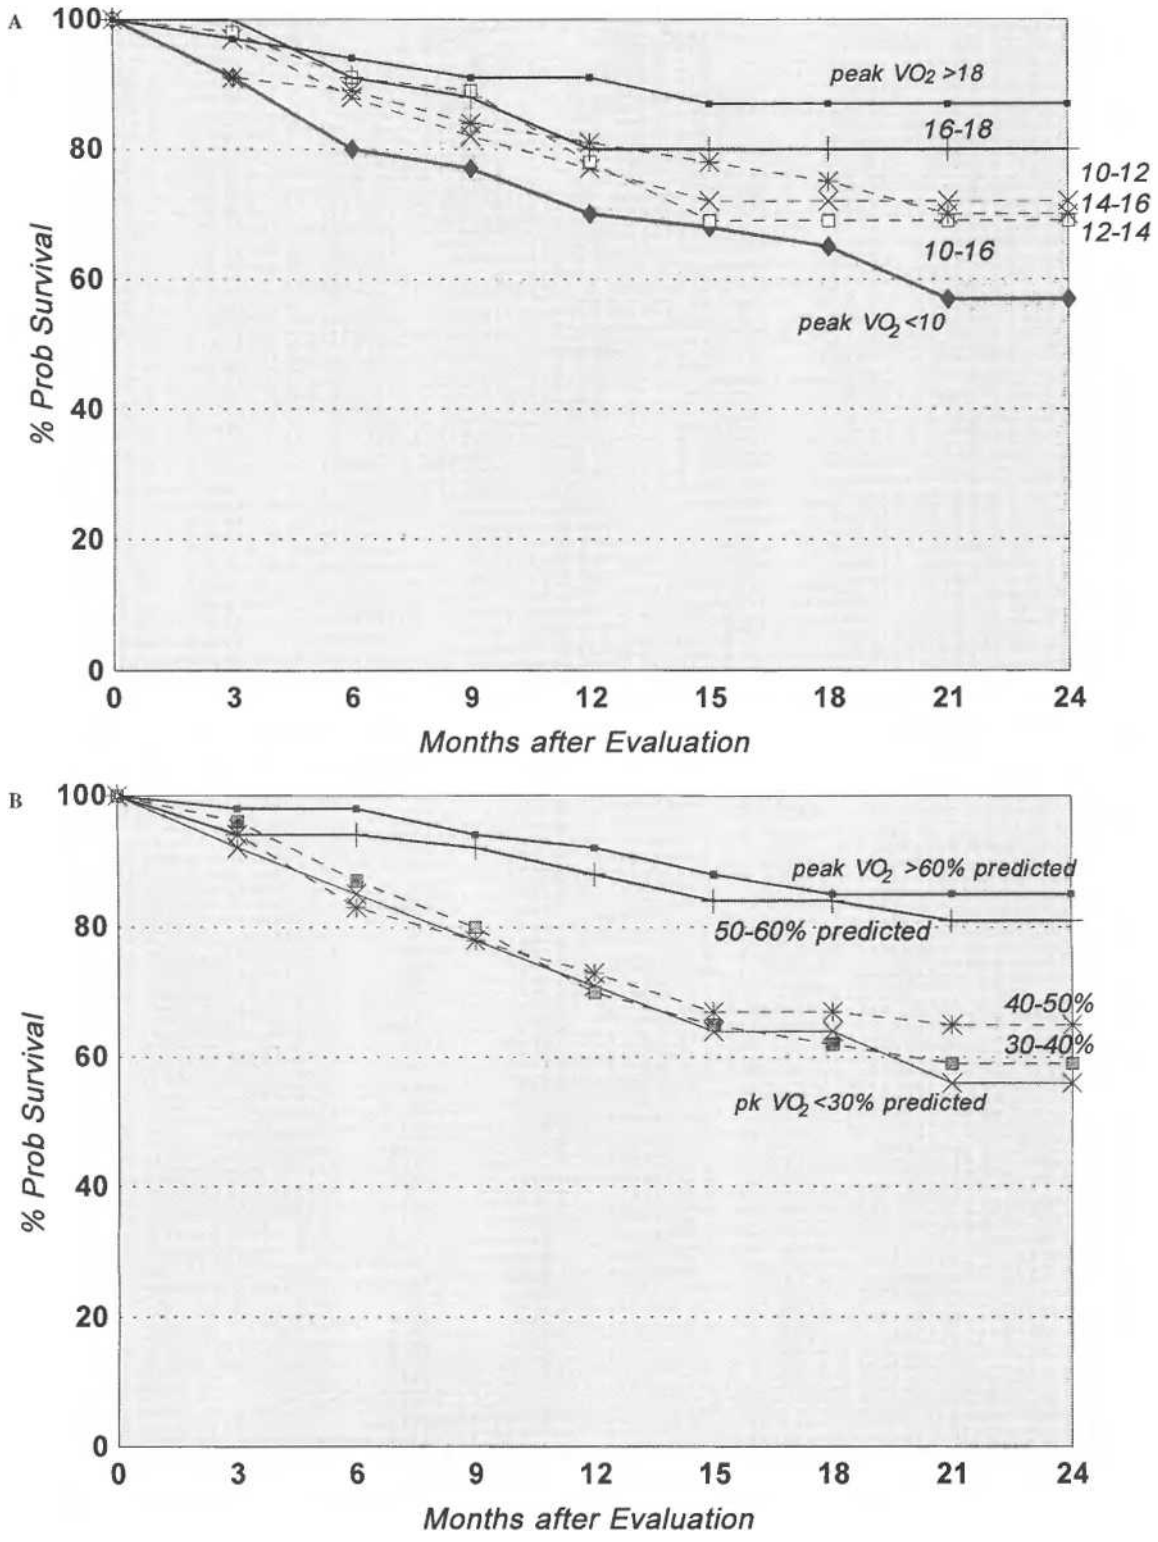

Figure 6 Actuarial curves of survival without hospitalization for urgent transplantation, analyzed for 320 patients undergoing cardiopulmonary exercise testing during the initial evaluation. **A**: Analysis according to peak oxygen consumption achieved <10 (n = 73), 10–12 (n = 67), 12–14 (n = 62), 14–16 (n = 46), 16–18 (n = 37) and over 18 ml kg^{-1} min^{-1} (n = 35). The test was performed with a bicycle ergometer, after a 6-min warm-up at 20 W, followed by a 5–10 min rest period and symptom-limited testing with a ramping interval of 15 W/min. **B**: Analysis according to percentage of predicted peak oxygen consumption which was actually achieved, demonstrating threshold value of 50% with little additional discrimination. (Adapted from ref. 87)

The current guidelines for cardiac transplantation focus on peak oxygen consumption as the basis for predicting improvements in survival and functional capacity after transplantation[24] (Table 9). While considerable debate surrounds the issue of whether to adjust for age- and gender-predicted maximal values, the threshold of peak oxygen consumption below which transplantation is indicated is generally adjusted upward for younger candidates and downward for older candidates. Functional capacity and prognosis should ideally be assessed after the impact of a revised medical regimen can be appreciated[51,52]. In practice, however, functional capacity and prognosis are usually assessed at the conclusion of a hospitalization for transplant evaluation, and interpreted in the light of improvement expected from changes in the medical regimen.

A patient referred, for example, after months of repeated hospitalizations for congestive symptoms might have a peak oxygen consumption of 11 ml kg^{-1} min^{-1} after evaluation, but the effective diuresis of 10 kg of fluid and enhanced vasodilator regimen might allow further symptomatic improvement and peripheral muscle reconditioning due to relief of exertional dyspnea. On the other hand, the same result would be an indication for listing of a patient referred on a stable regimen of angiotensin-converting-enzyme inhibitors, diuretics, and digoxin with an initial pulmonary capillary wedge pressure of 14 mmHg, who is unlikely to improve significantly with any changes in medical therapy.

Restrictive cardiomyopathy

A severely reduced left ventricular ejection fraction is neither necessary nor sufficient indication for transplantation (Table 9). Although the majority of patients referred have ejection fractions below 25%, patients may also have severe symptoms of congestion due to restrictive disease in which the ventricle is minimally dilated and the ejection fraction is 30–45%. Such patients may have severe difficulty maintaining fluid balance even with meticulous salt and fluid restriction. Amyloidosis needs to be excluded in such patients, even in the absence of a characteristic echocardiographic appearance. When restrictive disease has progressed slowly over many years, liver function should be carefully assessed, because these patients may be among the few to develop true irreversible 'cardiac cirrhosis'.

Hypertrophic cardiomyopathy

Cardiac transplantation is rarely indicated for hypertrophic cardiomyopathy when still in the hypercontractile stage. Diuretics and agents that decrease contractility can generally control congestive symptoms. Dual chamber pacing, myomectomy, and mitral valve replacement should be considered. In the minority of patients who progress to 'burned-out' cardiomyopathy, congestive symptoms and exercise intolerance may become severe, with only modest reduction of contractility to ejection fractions in the range of 30–40%, due to concomitant impairment in compliance. The natural history of these patients has not been well established, but their clinical limitation suggests that quality of life and outcome may be sufficiently compromised to warrant cardiac transplantation.

Other indications

Transplantation is occasionally indicated for reasons other than heart failure. Intractable angina may be an indication when multiple revascularization procedures have failed and no further attempts at surgical or catheter-based intervention are feasible. The left ventricular ejection fraction is usually below 30% in such patients, because those with better left ventricular function are generally candidates for some revascularization procedure. Transplantation is occasionally performed in patients disabled by recurrent discharges from automatic implantable defibrillators despite all attempts at catheter ablation and chemical control. Unusual trauma or isolated intracardiac tumors are rare indications for transplantation.

CONTRAINDICATIONS TO CARDIAC TRANSPLANTATION

Evaluation for transplantation includes a careful search for any non-cardiac condition that limits life expectancy or increases the risk of complications from the procedure, particularly from immunosuppression[24,54] (Table 10). Although this component of evaluation might logically take place after a patient has demonstrated indications for transplantation, in practice it is often more efficient to perform it simultaneously. Furthermore, in patients

Table 9 Selection criteria for benefits from transplantation

I. *Accepted indications for transplantation*
   1. Maximal Vo_2 < 10 ml kg^{-1} min^{-1} with achievement of anaerobic metabolism
   2. Severe ischemia consistently limiting routine activity not amenable to bypass surgery or angioplasty
   3. Recurrent symptomatic ventricular arrhythmias refractory to all accepted therapeutic modalities

II. *Probable indications for cardiac transplantation*
   1. Maximal Vo_2 < 14 ml kg^{-1} min^{-1} and major limitation of the patient's daily activities
   2. Recurrent unstable ischemia not amenable to bypass surgery or angioplasty
   3. Instability of fluid balance/renal function not due to patient non-compliance with regimen of weight monitoring, flexible use of diuretic drugs and salt restriction

III. *Inadequate indications for transplantation*
   1. Ejection fraction ≤ 20%
   2. History functional class III or IV symptoms of heart failure
   3. Previous ventricular arrhythmias
   4. Maximal Vo_2 > 15 ml kg^{-1} min^{-1} without other indications

Adapted from ref. 24

Table 10 Contraindications for cardiac transplantation

General eligibility
Absence of any non-cardiac condition that would itself shorten life expectancy or increase the risk of death from rejection or from complications of immunosuppression, particularly infection
Specific contraindications
Approximate age limit of 60–65 years (various programs)
Active infection
Active ulcer disease
Severe diabetes mellitus with end-organ damage
Severe peripheral vascular disease
Pulmonary function (FEV_1, FVC) < 60%* or history of chronic bronchitis
Creatinine clearance < 40–50 ml/min*
Bilirubin > 2.5 mg/dl, transaminases > 2 × normal*
Pulmonary artery systolic pressure > 60 mmHg*
Mean transpulmonary gradient >15 mmHg*
High risk of life-threatening non-compliance
Inability to make strong commitment to transplantation
Cognitive impairment severe enough to limit comprehension of medical regimen
Psychiatric instability severe enough to jeopardize incentive for adherence to medical regimen
History of recurring alcohol or drug abuse
Failure of establish stable address or telephone number
Previous demonstration of repeated non-compliance with medication or follow-up

* May need to provide optimal hemodynamics with nitroprusside and/or dobutamine for 72 h to determine reversibility of organ dysfunction caused by heart failure

who initially appear too well for transplantation, but may deteriorate, transplantation can be performed more expeditiously when eligibility has already been established.

The appropriate candidate for cardiac transplantation is sick enough to need a new heart, but sufficiently well in terms of overall condition and non-cardiac organ function to expect a good result. Age limits are controversial and usually expressed in relative rather than absolute terms. Highly selected older patients have good 1-year survival, but large series demonstrate decreased longer survival in older patients[55–57]. The older candidates are usually evaluated very carefully for evidence of diseases which commonly cause comorbidity in this age group.

Active systemic disease

Considerations regarding the etiology of disease are important to exclude patients with active systemic disease such as lupus erythematosus, rheumatoid arthritis, or scleroderma, which could cause disease after transplantation. In most programs, amyloidosis is a contraindication due to the tendency for systemic progression and recurrence in the allograft[58]. Chagas' disease may reactivate after cardiac transplantation, but is a common disease in South America, where suppressive therapy has been successfully used after transplantation[59].

Considerable emotional debate may develop regarding patients with chronic conditions with the potential to deteriorate after transplantation, as some patients at high risk will nonetheless do well after transplantation. The severe shortage of donor hearts curtails the systematic validation of each apparent contraindication. As described by Copeland, selection must therefore reflect 'a combination of empirically derived contraindications with limited natural history and considerable common sense'[60].

Diabetes mellitus is no longer an absolute contraindication for transplantation, although, in the early days, patients were excluded for abnormal glucose tolerance tests. Increasing severity of disease in terms of duration and insulin doses renders candidacy less likely. Initiation and augmentation of immunosuppression render glucose control very difficult, and hyperglycemia predisposes to infection. Patients with diabetes are evaluated carefully for evidence of other organ damage such as proteinuria and nephropathy, peripheral neuropathy, retinopathy, and small-vessel peripheral vascular disease, which are generally grounds for exclusion. Adult survivors of juvenile-onset diabetes are generally excluded for one or more of the above conditions.

Psychosocial factors

Failure to adhere to a rigorous regimen of medications, biopsies, and clinic visits remains a major factor in rejection and mortality for all organ transplant recipients[61,62]. Heavy psychological and financial burdens of chronic heart failure followed by transplantation, combined with labile mood changes during glucocorticoid augmentation, can precipitate lethal episodes of overt suicidal behavior or, more commonly, passive attempts to commit suicide through withdrawal of immunosuppression. Considerable debate surrounds the importance of various psychiatric and psychological conditions. Similarly, the importance of family support varies from patient to patient. Relative weaknesses in one area may be compensated by other strengths. The multiple factors relating to the patients and their support systems may best be combined into a profile from which the chances for long-term compliance can be assessed (Table 10). One of the many reasons that effective transplantation programs include integrated heart failure programs is the opportunity for reassessment of patients with a non-compliance history, who might later demonstrate sufficient compliance on complicated medical therapy to warrant acceptance[63].

Previous malignant disease

The incidence of malignancy is increased in organ transplant recipients and other patients on chronic immunosuppression[64], presumably due to impaired policing of potentially oncogenic

viruses and malignant clones, particularly of lymphomas, which may occur up to 40 times more frequently in transplant recipients. Transplantation is generally not performed within 3–5 years of neoplasms other than superficial skin lesions. A history of tumors with a predilection for recurrence, such as breast cancer and renal cell cancer, requires vigorous screening for recurrent disease. There is a growing population, however, of patients with successful transplantation late after successful chemotherapy with adriamycin-containing regimens for lymphoma, particularly Hodgkin's lymphoma.

Irreversible pulmonary hypertension

Multiple criteria for selection of recipients are profoundly affected by hemodynamic compromise, which may need to be addressed before candidacy can be confirmed (Table 10). Demonstration of sufficiently low pulmonary vascular resistance may require several days of vigorous reduction of left-sided filling pressures with vasodilators and diuretics, occasionally requiring support with inotrope-dilators also. Early pulmonary hypertension presents a heavy burden to the donor right ventricle, even if pulmonary pressures later decrease. Acute right heart failure continues to be a major factor in early postoperative morbidity.

Pulmonary hypertension is generally evaluated not by one number alone, but by a combination of calculations, including pulmonary vascular resistance, which should generally be reducible to below 240–300 dyne-s-cm^{-5}, pulmonary artery systolic pressure which should be reducible to levels below 50–60 mmHg, and transpulmonary gradient. The gradient, calculated as the mean pulmonary artery pressure minus the pulmonary capillary wedge pressure, usually shows least change during pharmacologic therapy[65] and should be below 12–15 mmHg. Although evaluation in some centers includes acute titration of intravenous nitroprusside to systemic blood pressure tolerance[66], reversibility of pulmonary hypertension in patients with pulmonary capillary wedge pressures chronically above 25 mmHg may be easier to demonstrate after sustained reductions in filling pressures over several days. The average patient with symptoms at rest, or with minimal exertion, has chronically elevated ventricular filling pressures and some reversible elevation in pulmonary pressures (Table 11). A brief trial of prostaglandin E1 may occasionally help to demonstrate reversibility after other modalities and assist in planning of postoperative hemodynamic management. Nitric oxide appears to be a potent pulmonary vasodilator, but its use should be tempered with caution, as it frequently leads to elevation in left-sided filling pressures, most likely due to increased right-sided cardiac output to the failing left ventricle. Heterotopic transplantation ('piggy-back' of the new heart on the old) has at times been employed for irreversible pulmonary hypertension, but this procedure has been associated with a 1-month mortality of 25% compared to 10%, and is now rare[67,68].

Impaired pulmonary function

Pulmonary function testing should be postponed until after hemodynamic optimization in patients with obvious resting congestion. Both obstructive and restrictive patterns may be observed with pulmonary congestion[69]. Maintained reduction of filling pressures and volume status, often for several days, allows optimal performance. General thresholds for acceptibility have been 50–70% of predicted forced vital capacity and forced expired volume. Cessation of smoking is generally required by most programs for at least 3 months, both to reduce perioperative pulmonary complications and to decrease the chance of postoperative smoking, which may increase the risk of early graft coronary artery disease[70]. Compliance with smoking cessation may be assessed with unscheduled urinary nicotine levels. Regardless of pulmonary function test results, a history of chronic sputum production and 'smoker's cough' is sometimes considered a contraindication due to risks of pulmonary infection during immunosuppression. No organized data have been collected on post-transplant outcome for patients with mild intrinsic asthma, which has generally not been considered a complication unless it has required intensive chronic therapy or multiple hospitalizations.

Hepatic dysfunction

Hepatic function is also optimized by vigorous diuresis and vasodilator therapy to reduce right-sided filling pressures and tricuspid regurgitation. This is important not only to establish transplant candidacy, but to minimize coagulopathy which may become profound after cardiopulmonary bypass during transplantation. All patterns of abnormal liver function have been observed with 'passive congestion'. Depressed cardiac output is much less important for hepatic function, except when circulatory collapse

Table 11 Preoperative reversibility of pulmonary hypertension during tailored therapy* prior to transplantation in 100 patients later receiving transplantation

	Initial PVR > 240 dyne-s-cm^{-5}	*Initial PAS > 50 mmHg*	*Initial TPG > 15 mmHg*
No	59% (9%) †	35% (6%) †	86% (7%) †
Yes	41% (5%)	65% (8%)	14% (7%)
If yes, reversible*	25% (11%)	41% (3%)	8% (17%)
Not reversible	16% (0%)	24% (10%)	6% (0%)

Numbers in parentheses indicate 30-day mortality after transplantation.‡

PAS = pulmonary artery systolic pressure; PVR = pulmonary vascular resistance; TPG = transpulmonary gradient (mean pulmonary artery pressure minus pulmonary capillary wedge pressure)

* Reversibility determined after 72 h of therapy tailored to reduce pulmonary capillary wedge to 15 mmHg, followed occasionally by a trial of prostaglandin E_1, if necessary.

† Reproducibility of this post-transplant survival may depend in part on the vigor with which pulmonary congestion is prevented preoperatively, the preservation and age of the donor heart, and early postoperative hemodynamic management.

leads to 'shock liver', when elevations of transaminases into the thousands may occur. This pattern should be allowed to recover during support with either devices or drugs prior to transplantation to avoid postoperative hepatic failure.

Renal dysfunction

Unlike pulmonary and hepatic function, renal function is more dependent on adequate cardiac output. In fact, even when cardiac output is adequate, renal function may decline temporarily after brisk diuresis of chronically congested patients, perhaps due to sudden decompression of distended atria and resultant reflex increase in renal vasoconstriction[71], and perhaps compounded by decreased atrial natriuretic peptide secretion[72]. Several days of inotropic infusions may be required to optimize function in some cases. Creatinine clearance of at least 50 ml/min is preferred, but lower rates may occasionally be accepted if clearly the result of acute decompensation, with normal renal size on ultrasound and absence of proteinuria. Disproportionate elevation of blood urea nitrogen is common. Patients with creatinine over 2 mg/ml, blood urea nitrogen over 50 mg/dl, or preoperative dependence on inotropic infusions, are at particularly high risk for early postoperative renal dysfunction, which may in some cases be decreased by the use of antithymocyte globulins rather than cyclosporin in the immediate postoperative period.

The critically ill patient

Evaluation presents a particular challenge when performed in a candidate seen first in critical condition. When the patient's major organ and cerebral function are acutely compromised, decisions regarding medical risk and patient commitment are based on experienced guesswork and emotional bias. Peripheral vascular disease is often under-appreciated, while renal and hepatic dysfunction believed (or hoped) to be reversible may become major impediments to postoperative recovery. A common ordeal is the decision regarding a young patient with a previous history of noncompliance or substance abuse for whom there is no time to confirm a commitment to reform. Some patients in critical condition must be refused transplantation, with the cost of immediate disappointment preventing the tragedy of protracted postoperative misery prior to death, and the tragedy of the premature end of a donor heart. Transplantation for otherwise doomed patients, however, is often the most rewarding, with the infinite relative increment in both quality and length of life (Figure 3). Increasing availability of mechanical support may allow many such patients to achieve stabilization and rehabilitation before transplant, following which the chance of favorable post-transplant outcome may be highest.

Documented risk factors

Collaboration between transplant programs is now yielding increasing information regarding the likelihood of good post-transplant outcomes. Of the two major multicenter experiences, the International Society for Heart and Lung Transplantation Registry has established older age, left ventricular ejection fraction <11%, mechanical support while waiting, and female gender as risk factors for death after transplantation[2]. It should be noted, however, that some risk factors for post-transplant death also identify high risk without transplantation. The Cardiac Transplant Research Database provided the first multivariate analysis of death, demonstrating older age, elevated serum creatinine, low cardiac output, and mechanical ventilation prior to transplantation to be associated with worse survival, while female gender was associated with more rejection but equivalent survival[73]. A separate study of program attributes found the most important program factor in patient survival to be the previous experience of the transplant cardiologist, with strong contribution from the transplant nurse coordinator[74].

CANDIDATES ON THE WAITING LIST: MANAGEMENT AND RE-EVALUATION

The average waiting period for candidates has increased from 6 weeks for all candidates in 1984 to over 6 months on average. Patients waiting at home frequently do not undergo cardiac transplantation for over a year after listing, particularly if they have blood group O. During the prolonged waiting time, outpatients require careful management and re-evaluation for both deterioration and improvement. As recommended by the Consensus conference on transplantation, waiting candidates should be seen at least monthly by the heart failure/transplant cardiologist at the center where the transplant will be performed[9]. Assessment of clinical stability by history, particularly evidence of congestion, examination of postural vital signs and jugular venous pressure, and laboratory monitoring of electrolytes, renal and hepatic function, and anticoagulation are critical to ensure that the candidates are in optimal condition for transplantation. More frequent visits with the primary physician are often necessary.

Medical management for transplant candidates is dominated by the same principles developed to decrease the need for transplantation and provide alternative hope to ineligible patients. Maintenance of low filling pressures not only serves to minimize congestive pulmonary and abdominal symptoms and improve nutrition, but also reduces the risk of postoperative pulmonary hypertension, prolonged intubation, coagulopathy, and hepatic dysfunction during the postoperative course. Patients should be compliant with a regimen which includes, in most cases, restriction to $\leq$2 g of sodium and $\leq$2 l of fluid daily, and always a daily weight diary which guides patient adjustment of diuretic dosage. The spectrum of medications in this population is shown in Table 7.

Anticoagulation

The issue of anticoagulation for patients with low left ventricular ejection fractions and dilated ventricles remains controversial. It is accepted that patients with an additional risk factor such as atrial fibrillation, history of previous embolic event, or pedunculated thrombus need anticoagulation, with the strongest risk factor being atrial fibrillation, associated with a yearly embolism risk as high as 18% in the presence of heart failure[75]. In 120 transplant candidates without any of these risk factors, the incidence of embolic events during a mean follow-up of 300 days without anticoagulation was 4%[76]. The official National Practice Guidelines

for Heart Failure do not at this time recommend routine anticoagulation for heart failure patients without other risk factors[77]. The decision reflects the estimated balance of risks of embolic events, which can lead to tragic strokes and death, and the risks of hemorrhage, which can rarely lead to intracranial hemorrage or other life-threatening events. The risks of bleeding are low when anticoagulation is monitored closely and doses decreased for amiodarone and impaired hepatic function. Perioperative bleeding is often greater after coumadin therapy despite administration of vitamin K prior to the transplant.

Ventricular dysrhythmia

Non-sustained ventricular tachycardia occurs in 50–80% of patients with heart failure severe enough to warrant evaluation for transplantation[40]. Although sudden death occurs in 15–30% of these patients, its relationship to previous non-sustained ventricular tachycardia remains controversial. The risk of sudden death is increased in heart failure patients with a history of syncope, which is an indication for admission and evaluation. Therapy for asymptomatic non-sustained ventricular tachycardia has generally not been undertaken unless the runs are long and rapid. Type I antiarrhythmic agents appear to increase the risk of sudden death in heart failure patients, and are rarely used except, occasionally, to decrease the frequency of discharges from an implantable cardioverter–defibrillator. Therapy with amiodarone does not worsen and may improve survival in severe heart failure[32], with benefits for ventricular function and heart failure endpoints as well as sudden death. The GESICA trial studied patients with an overall mortality of 55% at 2 years, similar to that of ambulatory transplant candidates with class IV history, and found a 28% decrease of mortality with amiodarone[32]. The differences between this trial and the Veterans Administration trial may reflect in part the different disease severity[33]. Perioperative pulmonary and hemodynamic problems attributed to prolonged amiodarone use have been described in other surgical populations, but have rarely occurred after transplantation[78].

Hospitalization

Candidacy is a dynamic state from which movement is possible, particularly during the lengthening waiting periods (Figure 7). Deterioration to require hospitalization has in the past occurred in up to 30% of candidates during the first 6 months, and may be more frequent with growing adherence to more defined criteria of disease severity before listing[79]. Hospitalization may be indicated to prevent imminent death, or to prevent serious organ system deterioration which could compromise the outcome of transplantation (Table 12). Progressive right heart failure, and worsening renal or hepatic dysfunction, could be indications for hospitalization even if the candidate finds them compatible with life at home. Escalating fluid retention can increase perioperative

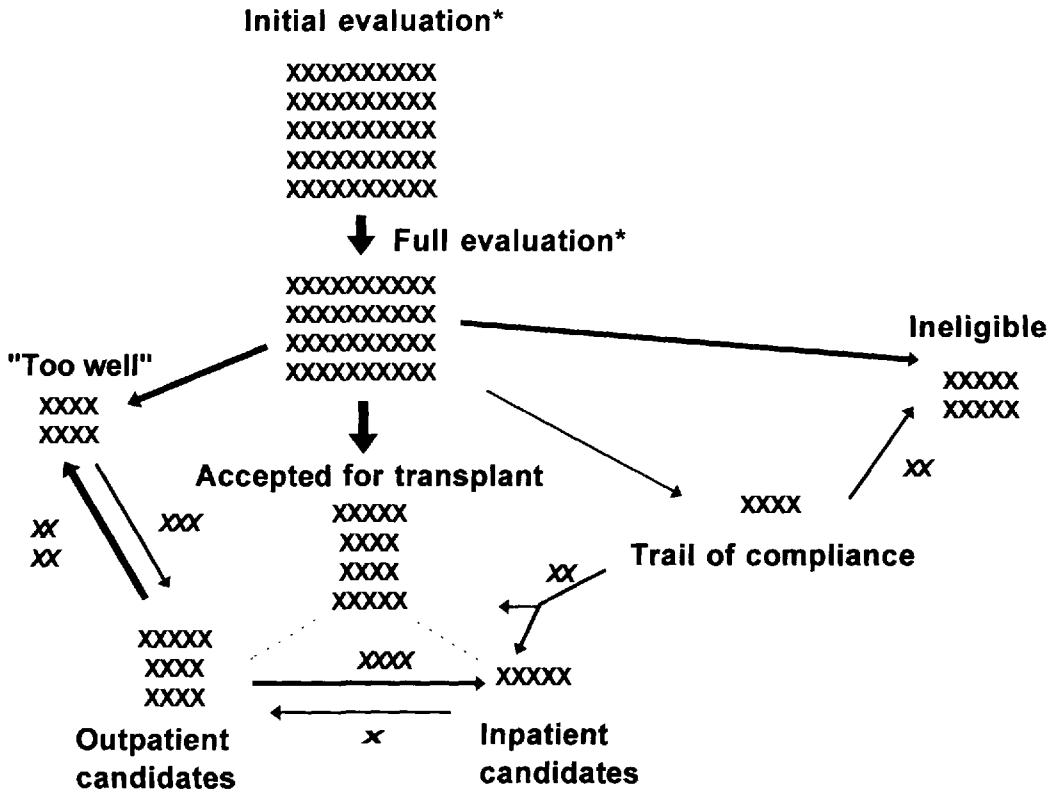

Figure 7 Progress through evaluation and continual re-evaluation for cardiac transplantation, demonstrating the dynamic nature of candidacy. The relative frequencies of outcomes will depend upon the local policies regarding complete and partial evaluation of candidates (*) who appear to be ineligible or 'too well' for transplantation

Table 12 Frequent indications for admission of waiting candidates

General considerations
To prevent death at home
To prevent conditions which jeopardize perioperative outcome
Specific considerations
Unstable angina
Syncope
Frequent Implantable cardioventer defibrillator discharges
Suspected embolic event
Congestion refractory despite good compliance to increased diuretics, which:
(a) renders patients bedridden
(b) causes marked hepatic congestion
(c) may worsen borderline pulmonary hypertension
Systolic blood pressure persistently < 70–75 mmHg
Pulse pressure < 12 mmHg, particularly with cool extremities
Creatinine > 2.0 and rising

pulmonary hypertension, prolong intubation requirements, and worsen coagulopathy, but also seems to be associated anecdotally with increased risk of unexpected death at home, which may in part be related to the difficulties of controlling potassium, both high and low, during fluctuating diuresis and electrolyte replacement. Although patients with the most severe compromise can expect the greatest improvement from transplantation, perioperative condition is a critical determinant of postoperative outcome, and should be optimized.

For the hospitalized patient the escalating approach includes hemodynamic monitoring for 24–48 hours when major changes are made in vasoactive therapy, although prolonged maintenance of indwelling lines should be avoided due to the risks of infection. Low–moderate doses of dobutamine, dopamine, and phosphodiesterase inhibitors, alone or in combination, are frequently adequate to stabilize patients to a level compatible with ambulation with an intravenous pump. The full agonists, epinephrine and norepinephrine, can be useful to increase cardiac output in an emergency setting, but the continued need for these agents should usually trigger consideration of a mechanical assist device.

Mechanical support

The indications for mechanical support continue to evolve. The hemodynamic criteria often suggested for heart failure were actually originally proposed for the very different setting of post-cardiotomy shock needing intra-aortic balloon counterpulsation[80]. These criteria include cardiac index <2.0 l min^{-1} m^{-2}, pulmonary capillary wedge pressure >20 mmHg, systolic blood pressure <90 mmHg and systemic vascular resistance >2100 dyne-s-cm^{-5}, which are typical of many heart failure patients who can be not only stabilized but also discharged after adjustment of medical therapy. The clinical impact of hemodynamic parameters varies greatly, particularly in relation to the duration of compromise, but at the most severe end of the spectrum, mechanical support would generally be indicated for continued inability to maintain a systolic blood pressure >75 mmHg, cardiac index ≥1.5 l min^{-1} m^{-2}, and pulmonary venous saturation >50% on maximal pharmacologic support. (Severely elevated filling pressures, on the other hand, generally indicate the potential for improvement from further adjustment of medical therapy). More subtle trends of declining cardiac index and renal function on maximal therapy are difficult to interpret, but are at least as important as the absolute measured numbers[81].

Patients who require mechanical support in the absence of coronary artery disease may be considered for direct placement of left ventricular assist devices without intervening therapy with an intra-aortic balloon, from which the benefit is controversial in this population. Patients with coronary disease who demonstrate continued dependence on intra-aortic balloon counterpulsation may eventually also be considered for placement of a left ventricular assist device, which allows ambulation and rehabilitation prior to transplantation. Over 300 left ventricular assist devices, both the HeartMate and Novacor models, have been implanted in the United States[82]. Complications include infection, usually through the drive line, bleeding, and thromboemboli from the heart and from the device itself, which may be less common with the HeartMate due to the endothelialization of the titanium surface.

Recent experience with left ventricular assistance as bridging to transplantation has shown approximately 70% survival to transplantation. In an uncontrolled trial of candidates with cardiac indices below 2 l min^{-1} m^{-2} on intravenous inotropic agents and balloon counterpulsation, survival after transplantation was 90% for recipients who had been bridged, compared to 70% for those compromised patients surviving without bridging (Eric Rose, personal communication). The good outcome for bridged patients after transplantation results from better preoperative status, but may also reflect the selection by death of the highest-risk transplant candidates during the period of mechanical support.

Re-evaluation

The long waiting periods also allow demonstration of improvement in some patients able to wait at home. The highest period of risk for outpatients may be the first few months, after which some of the factors which led to deterioration and referral may resolve spontaneously, and the benefits of optimal medical therapy may be realized. The Bethesda Conference and the Consensus Conference on Selection both emphasize the important of periodic re-evaluation of waiting candidates[9,24]. Suggested criteria for re-evaluation include an assessment of clinical stability and demonstration of improved exercise capacity measured by peak oxygen consumption (Table 13). Up to 30% of ambulatory pa-

Table 13 Assessment of clinical stability for re-evaluation of waiting candidates

Clinical criteria
1. Stable fluid balance without orthopnea, elevated jugular venous pressures, or other evidence of congestion on the flexible diuretic regimen
2. Stable blood pressure with systolic at least 80 mmHg
3. Stable serum sodium (usually >133 mEq/l)
4. Stable renal function (blood urea nitrogen usually <60 mg/dl)
5. Absence of symptomatic ventricular arrhythmias
6. Absence of frequent angina
7. Absence of severe drug side-effects
8. Stable or improving activity level without dyspnea during self-care or 1 block exertion.
Exercise criteria (if initial peak oxygen consumption <14 ml kg^{-1} min^{-1})
1. Improvement in peak oxygen consumption of ≥2 ml kg^{-1} min^{-1}
2. Peak oxygen consumption of ≥12 ml kg^{-1} min^{-1}

tients initially listed with initial average peak oxygen consumption <14 ml kg^{-1} min^{-1} (average 11) demonstrated sufficient improvement to leave the list, with a subsequent 2-year survival of 92%[51].

COMMENT

The personal dedication of the early teams for heart transplantation, combined with the advances in surgical techniques and immunosuppression, have established this as the best current therapy for patients with truly end-stage heart disease. Once referred for transplantation with New York Heart Association class IV symptoms and an ejection fraction less than 25%, even when patients can be maintained out of the hospital, survival without urgent transplant is less than 50% at 2 years[43], compared to a 60% chance of surviving 6 years and a 35% chance of surviving 10 years after transplantation with current protocols[2]. Most recipients achieve a good to excellent quality of life, although less than 50% return to full-time employment[83].

As originally projected at the time of the first Bethesda conference on transplantation over 25 years ago, however, the promise of transplantation has not been fulfilled[1]. Despite arduous efforts the donor heart supply is limited to 2000–2500 yearly in the United States, compared to the 40 000–45 000 originally projected in 1968. Over 70% of these hearts are being used for patients waiting in hospitals. It has been said that heart transplantation is currently to heart failure what the lottery is to poverty (attributed to Arnold Kats and others).

Left ventricular assist devices currently offer hope for those hospitalized patients who might otherwise not survive until transplantation. Although now employed only as 'bridges' to transplantation, increasing refinement and experience suggest that permanent ambulatory devices may extend a highway even to patients ineligible for transplantation. At the other end of the spectrum of heart failure, there is now increasing evidence that early intervention can reduce development of heart failure[84,85]. Even after symptoms of heart failure have appeared, new approaches to both medical and surgical therapy may prolong the period of cardiac and clinical compensation[3–5,20]. In particular, recognition of the contributions of mitral regurgitation and left ventricular distortion to the progression of heart failure has stimulated the development of new surgical approaches to cardiac remodelling.

A beneficial side-effect of cardiac transplantation has been the increased medical and public focus on the problem of heart failure, which affects over 3 million patients in the United States, almost 1 million of whom have class III–IV heart failure. The magnitude of the miseries and costs of this problem warrant increasing focus on innovation and collaboration at all levels of research and clinical care.

The Problem of Pulmonary Hypertension in the Potential Cardiac Transplant Recipient

J.M. CHEN AND R.E. MICHLER

INTRODUCTION

Despite advances in perioperative management, right-sided circulatory failure (RSCF) remains a significant source of morbidity and mortality early after cardiac transplantation. Perioperative RSCF, while clearly multifactorial in nature, has traditionally been associated with pretransplant pulmonary hypertension, as suggested by elevated pulmonary hemodynamic indices revealed on pretransplant cardiac catheterization. While severely elevated values of such indices represent a contraindication to cardiac transplantation at many centers worldwide, there currently exist no standard guidelines regarding the validity and importance of these preoperative abnormalities for postoperative outcome. The purpose of this chapter is to review the problem of pulmonary hypertension and the potential cardiac transplant recipient – its diagnosis, management and manipulation, and long-term clinical significance.

Severe preoperative pulmonary hypertension is thought to result in post-transplant RSCF due to a marked increase in afterload presented acutely to the donor right ventricle. Since Griepp and colleagues first reported a relationship in 1971 between elevated preoperative pulmonary vascular resistance and the risk of death from acute right ventricular failure post-transplant, numerous studies have confirmed this association[1]. Indeed, preoperative pulmonary hypertension has not only been associated with overall post-transplant morbidity from acute right heart failure and all-cause perioperative mortality, but also has been associated with other sources of postoperative morbidity, including post-transplant infections and arrhythmias[2-12].

Despite this, substantial controversy has persisted regarding the power of individual hemodynamic indices to predict perioperative mortality (and RSCF) accurately. Transplant physicians have traditionally placed an emphasis on calculated estimates of pulmonary hypertension (pulmonary vascular resistance (PVR), pulmonary vascular resistance index (PVRI) and transpulmonary gradient (TPG)) in the preoperative evaluation of cardiac transplant candidates in an effort to assess the right ventricular afterload that will be presented to the transplanted heart[2-10]. The equations from which these indices are derived are outlined in Figure 1.

As shown, a substantial degree of co-dependence exists among these variables; PVR and PVRI differ by a factor of body surface area, and PVR and TPG differ by a factor of cardiac output. Addonizio and co-workers have favored PVRI on the basis that it represents the PVR 'indexed' to body surface area, thus theoretically eliminating bias due to body size and weight (especially important in the pediatric population)[7]. Proponents of the transpulmonary gradient have suggested that PVR (and thus PVRI) may prove unreliable due to inherent inaccuracies in the method of thermodilution, particularly at low cardiac outputs[6].

Pulmonary vascular resistance (PVR, Wood Units (WU))

$$PVR = \frac{(PA\ mean - PCW)}{CO}$$

Pulmonary vascular resistance index (PVRI, Wood Units · m^2)

$$PVRI = \frac{(PA\ mean - PCW)}{CI} = PVR \cdot BSA$$

Transpulmonary gradient (TPG, mm Hg.)

$$TPG = PA\ mean - PCW$$

‡‡ Group I vs group III, $p < 0.05$; group I vs group IV, $p < 0.05$.
NS = not significant

The transpulmonary gradient, it is argued, is flow-independent and thus may better reflect resistance to flow across the pulmonary bed[6]. In contrast, others have argued that the gradient across the pulmonary bed is itself flow-dependent, and thus requires that total flow (or its estimate as represented by cardiac output) be included in its definition.

Table 1 summarizes reports in the literature that analyze the utility of calculated hemodynamic indices as predictors of both right heart failure and perioperative mortality[2–12]. As shown, the relative acuity of individual indices to predict either 30-day mortality or right heart failure remains unclear. In an effort to compare these indices quantitatively, we recently evaluated data from 476 patients transplanted at the Columbia-Presbyterian Medical Center from 1983 to 1994 using standard historical threshold values to divide patients into cohorts with elevated and non-elevated preoperative profiles[13]. These findings were then correlated with 30-day all-cause mortality.

Quantitative comparison among these cohorts was established with receiver operating characteristic (ROC) curves, traditionally plotted as graphic representations of the relationship between sensitivity and specificity (the true-positive and false-positive rates). The area under these ROC curves (AUC) not only represents the probability that normal and abnormal test results are associated accurately with the presence or absence of a given outcome, but also reflects a means by which the discriminating ability of individual indices may be compared[14–16]. Representative ROC curves and their AUC are depicted in Figure 2. We found no statistical difference in the AUC for PVR, PVRI or TPG in the prediction of 30-day mortality, suggesting that none of the tests was superior in its ability to predict perioperative mortality. The high degree of co-dependence of the variables may explain these findings, and further suggests that different combinations of such elevated indices would likely have similar results.

REVERSIBILITY

Once the diagnosis of preoperative pulmonary hypertension has been confirmed by cardiac catheterization, some have suggested that patients may be subdivided further into those with 'fixed' or 'reactive' components to their pulmonary hypertension, the relative proportions of which may be elucidated using pulmonary vasodilator therapy such as sodium nitroprusside[17,18]. Those patients, it is argued, with a high degree of 'reactivity' to their pulmonary hypertension (i.e. who have a substantial drop in their PVR, PVRI or TPG from an elevated value to a non-elevated value with vasodilator provocation) may have a large 'reversible' component and, as such, may have a perioperative mortality comparable to patients who have no preoperative pulmonary hypertension. Conversely, those patients whose pulmonary hyper-

tension responds less well may have a larger 'fixed' component that may, it is postulated, adversely affect their post-transplant outcome.

The largest study in the literature to date regarding the use of nitroprusside in the evaluation of patients for cardiac transplantation examined 293 patients and revealed four distinct cohorts of patients separated on the basis of risk stratification for 90-day

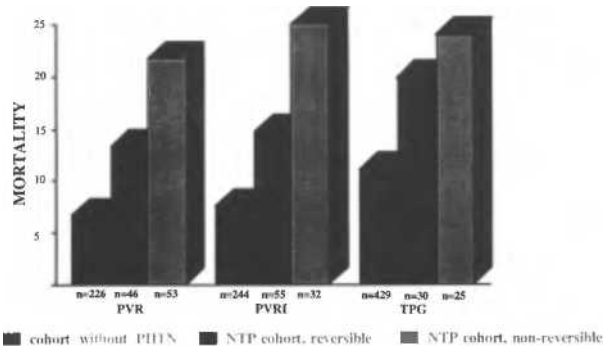

Figure 3 Bar graph representing the effect of preoperative 'reversibility' on 30-day mortality (PHTN = pulmonary hypertension; NTP = nitroprusside

mortality[17]. We examined a similar cohort of 181 patients with elevated preoperative pulmonary hemodynamic indices who under went vasodilator challenge with nitroprusside preoperatively, using 30-day perioperative mortality as the end-point of the study (Figure 3)[13]. The conclusions of these investigations were three-fold. First, those patients with irreversible pulmonary hypertension had a nearly four-fold increase in their incidence of mortality when compared with those without preoperative pulmonary hypertension. These differences were statistically significant. Second, those patients with reversible hypertension appeared to demonstrate a 25% reduction in their incidence of 30-day mortality when compared with those patients who were non-reversible. These differences, while clinically relevant, were not statistically significant. Finally, those patients with reversible hypertension still exhibited a marked increase in the incidence of mortality when compared with patients without preoperative pulmonary hypertension. These differences demonstrated statistical significance for the parameter TPG, and borderline significance for PVR and PVRI, with p-values between 0.05 and 0.1. In sum, these data suggested that while 'reversibility' with nitroprusside therapy was associated with improved overall 30-day mortality, it was not associated with improvement to a level comparable to those patients who did not have preoperative pulmonary hypertension.

VASODILATOR CONDITIONING

Some investigators have suggested that continuous low-dose nitroprusside therapy may help to 'optimize' those patients with a substantial reactive component to their pulmonary hypertension. However, this modality is limited by the adverse systemic effects of nitroprusside, the most pronounced being severe hypotension from peripheral vasodilatation[17–19]. Recent enthusiasm has arisen regarding other pulmonary vasodilators and cardiac inotropes that may have actions specific enough to the pulmonary vasculature to limit their systemic effects[20–29]. Table 2 summarizes the literature regarding these agents.

Adenosine, while potentially superior to nitroprusside (NTP) in its ability to lower TPG, and comparable in its ability to lower PVR, has been shown (a) to have little effect on cardiac output and (b) to increase pulmonary capillary wedge pressure, rendering it a poor modality for long-term use in patients with congestive

Table 2 Compilation of the literature regarding vasoactive agents used in the preoperative pulmonary hemodynamic evaluation of transplant candidates (DBA = dobutamine; NTG = nitroglycerin)

	Agent studied	*No. of patients*	*Response*	*Comment*
Nitroprusside (NTP)				
Kawaguchi *et al.* (1989)[30]	NTP	13	PVR < 4 ($n = 6$)	One RSCF, two biventricular failure in each group
			PVR 4.8 → 2.5	No side-effects noted
Simonsen (1990)[42]	NTP	23		NTP given introperative and post-transplantation also No side-effects noted
Costard-Jackle and Fowler (1992)[17]	NTP	78	PVR ≤ 2.5, SBP ≥ 85 → 3.8% 90-day mortality	
		40	PVR ≤ 2.5, SBP ≤ 85 → 27.5% 90-day mortality	
		32	PVR > 2.5, no effects on SBP → 41% 90-day mortality	
Nitric oxide (NO)				
Semigran *et al.* (1994)[27]	NO	16	PVR: 3.2 → 1.7 ($p < 0.05$) TPG: 11 → 7 ($p < 0.05$)	2 patients had postoperative RSCF 7 patients had significant hypotension
	NTP	16	PVR: 3.3 → 2.1 ($p < 0.05$) TPG: no change	
Adatia *et al.* (1995)[28] (pediatric)	NO–high LAP	6	PVRI: 14.9 → 7.6 ($p < 0.05$; TPG: 45 → 27 ($p < 0.05$)	No noted side-effects of NO, NO most effective in patients with LA hypertension
	NO–low LAP	5	PVRI: 36 → 31 ($p < 0.05$); TPG: 64 → 62	
	Ach-high LAP	3	PVRI: 12.9 → 12.2 (NS); TPG: 43 → 42 (NS)	
	Ach-low LAP	4	PVRI: 33.2 → 32.3 (NS); TPG: 64 → 63 (NS)	
Adenosine				
Haywood *et al.* (1992)[20]	Adenosine	21	↓ PVR 41%, ↓ TPG 35%	No effects on cardiac output, but increase in PCW with adenosine
	NTP	18	↓ PVR 42%, ↓ TPG 9%	MAP < 60 in 21% of NTP patients
Amrinone				
Bolling *et al.* (1988)[21]	Amrinone	27	PVRI: 6 → 2.4 ($p = 0.001$)	Two patients with thrombocytopenia requiring transfusion
			TPG: 19 → 10 ($p = 0.001$)	89% of total 27 were 'responders'
Deeb *et al.* (1989)[22]	Amrinone	22	PVR: 5.8 → 2.5 ($p = 0.0001$)	Two patients with thrombocytopenia requiring transfusion
			TPG: 19 → 11 ($p = 0.0001$)	
	'Conventional' therapy	16	PVR: 5.1 → 3.3 ($p = 0.003$)	
			TPG: 18 → 13 ($p = 0.03$)	
Prostaglandin E1				
Murali *et al.* (1991)[23]	NTG	8	TPG: 16 → 15(NS); PVR: 4.1 → 3.5 ($p < 0.005$)	Hypotension, headache
	NTP	7	TPG: 18 → 16(NS); PVR: 5.4 → 3.6 ($p < 0.01$)	Hypotension
	PGE1	29	TPG: 17 → 13($p < 0.001$); PVR: 4.9 → 3.0 ($p < 0.001$)	Hypotension, headache, flushing, nausea, vomiting
	DBA	11	TPG: 16 → 17; PVR: 3.5 → 1.2 ($p < 0.001$)	Increase in premature ventricular complexes (PVC)
	Enoximone	11	TPG: 18 → 21; PVR: 5.8 → 3.9 ($p < 0.01$)	Nausea, vomiting, increase in PVC
Murali *et al.* (1992)[24]	NTG	9	No change in TPG; PVR 4.3 → 3.7 ($p < 0.01$)	Nine transplanted, no RSCF, but nausea, vomiting, hypotension in eight patients who were non-responders to PGE1
	NTP	12	TPG: 20 → 17 ($p < 0.01$); PVR: 6.2 → 3.9 ($p < 0.01$)	
	PGE1	39	TPG: 18 → 12 ($p < 0.01$); PVR: 5.1 → 2.7 ($p < 0.01$)	
Iberer *et al.* (1993)[25]	PGE1	13	PVR: 5.3 → 2.7 ($p < 0.005$)	Given 6-day course of PGE1, restudied 7 days later; side-effects included edema, joint pain, headache, abdominal pain. Eight transplanted, no RSCF but also given PGE1 post-transplant
Combination therapy				
Zales *et al.* (1993)[29] (pediatric)	DBA	7	Combined drug study:	
	DBA and NTP	9	TPG: 18.5 → 12.0	
	DBA/NTP and/or Amrinone	8	PVRI: 10 → 4	

Ach = acetylcholine, LAP = left atrial pressure, NO = nitric oxide

heart failure[20]. Amrinone has been shown in long-term therapy studies to be more effective in reducing PVR and TPG than conventional triple-drug therapy with digoxin, diuretics and ACE-inhibition, despite a potential risk of thrombocytopenia[21,22].

In short-term therapy preoperatively, prostaglandin E1 (PGE1) has been demonstrated to be more effective than nitroglycerin (NTG) and NTP in reversing pulmonary hypertension, and to achieve postoperative mortality rates comparable to patients without preoperative pulmonary hypertension[23–26]. However, although PGE1 is hypothesized to have a 90% clearance in the lung on a single pass (thus theoretically limiting its systemic effects), it has also been shown to result in significant hypotension, and increased facial flushing and nausea when compared with NTG, NTP dobutamine (DBA) or enoximone[23].

Nitric oxide (NO) has been demonstrated to have substantially fewer systemic effects when compared with other vasoactive agents, and to induce a reduction in hemodynamic indices to a comparable degree to NTP[27,28]. Studies using NO in the pediatric population have described a greater degree of reversibility for those patients with elevated left atrial pressures prior to administration[27,28]. Adatia and colleagues have suggested that preoperative evaluation with NO challenge may further help to establish which pediatric patients would better benefit from heart–lung rather than heart transplantation[28]. Interestingly, evaluation of NO in the adult population, however, has demonstrated an increase in left ventricular filling pressures in patients with severe heart failure, a finding that may potentially limit its long-term preoperative use[27,28].

In addition, Zales and co-workers have also suggested that because of both the poor left ventricular systolic function and elevated diastolic pressures in patients with end-stage heart disease, a more substantial decrease in pulmonary hemodynamic indices may be revealed with additional inotropic support[29]. Their results in pediatric patients with combined DBA, NTP and amrinone therapy, while not compared specifically to vasodilator therapy alone, indicate potential new methods for preoperative evaluation with combination therapy[29].

OUTCOME

The question remains how to utilize these data regarding preoperative hemodynamic indices and reversibility with vasodilator challenge in the pretransplant evaluation. For example, does reversibility truly identify those with fixed elevated pulmonary indices, and should such patients be denied cardiac transplantation, or be referred for heart–lung transplantation? Or, as Kawaguchi has suggested, is perioperative mortality more reflective of graft viability and overall graft ischemic time than reversibility of hemodynamic indices in the potential recipient[30]? In attempting to answer these questions, the natural progression of preoperative pulmonary hypertension both prior to and following cardiac transplantation must be evaluated.

Grant and colleagues have documented that patients with marginally acceptable or slightly elevated pulmonary hemodynamic indices may improve on maximal medical therapy, and thus should be studied serially pretransplant to establish candidacy for transplantation[31]. These findings have also been confirmed by Boffa and co-workers, who similarly noted changes in pulmonary hemodynamic indices over time, the magnitude of which, however, was unpredictable preoperatively[32].

Postoperatively, patients with previously documented pretransplant pulmonary hypertension (PVR > 6) have been noted to resolve their pulmonary hypertension by the first week post-transplant, as evidenced on two-dimensional echocardiogram and right heart catheterization[33]. Bhatia *et al.* evaluated post-transplant hemodynamic changes over time for patients with preoperative pulmonary hypertension, and reported a continual decrease in hemodynamic indices throughout the first year[33]. Eighty percent of such patients demonstrated normalization of a previously elevated PVR when studied at 1 year post-transplant. Interestingly, they further reported right ventricular remodeling in the transplanted heart in response to the increased afterload, as evidenced by the gradual development of right ventricular dilatation and tricuspid regurgitation at 1 year postoperatively despite a resolution in pulmonary hypertension[33].

Similarly, Corcos *et al.* have described a resolution of elevated right-sided circulatory pressures documented at 1 week post-transplant by 6 months post-transplant in most recipients[34]. Von Scheidt and co-workers further evaluated long-term post-transplant hemodynamics in a cohort of 57 patients and found no substantial changes in PVR from 12 to 84 months (no preoperative hemodynamic data given), suggesting a stabilization of hemodynamic indices for those long-term survivors of cardiac transplantation[35]. In a cohort of pediatric recipients, Gajarski *et al.* described a resolution of elevated PVRI by the first post-transplantation biopsy, the absolute value at which time, interestingly enough, was not statistically different from PVRI values achieved during vasodilator challenge preoperatively[12].

SURGICAL ALTERNATIVES

Empirically, the most substantial morbidity associated with RSCF after cardiac transplantation occurs within the first 30 days. Numerous strategies have been attempted in an effort to decrease the perioperative morbidity for this select group of transplant recipients. Donor/recipient size mismatching, with a deliberate oversizing of the donor heart, has been employed based upon the premise that the oversized right ventricle would be more suited to tolerate the increased afterload of the pulmonary hypertensive recipient. In two separate investigations, Costanzo-Nordin *et al.*[36] and Yeoh *et al.*[37] evaluated the deleterious relationship of cardiac allograft size mismatching and post-transplant function. Costanzo-Nordin *et al.* demonstrated a significantly greater risk of death for recipients of oversized donor hearts, independent of preoperative TPG values[36]. Similarly, Yeoh *et al.* described a compromise in long-term cardiopulmonary function (as evidenced by peak exercise oxygen uptake) in those patients with preoperative pulmonary hypertension who were recipients of oversized donor hearts[37].

Another surgical option based on the same principle is heterotopic heart transplantation. In related investigations, Villanueva *et al.*[38] and Kawaguchi *et al.*[30] assessed the utility of heterotopic heart transplantation in patients with severe preoperative pulmonary hypertension. Villanueva and colleagues described a decrease in PVR and TPG for *both* heterotopic transplant study patients and orthotopic transplant control patients: these improvements were maintained for the first year postoperatively[38]. Kawaguchi *et al.* similarly reported a reduction in postoperative PVR for *both*

heterotopic and orthotopic heart transplant recipients[30]. However, heterotopic transplant recipients in this cohort had a significantly increased rate of pulmonary complications and infections, presumably due to the anatomic position of the transplanted heart. In addition, heterotopic recipients were noted to have a higher incidence of biventricular failure and graft ischemia.

These studies indicate that operative strategies to overcome the potential post-transplant RSCF may not provide benefits in perioperative mortality enough to outweigh the procedural morbidity. The natural long-term course of patients with an elevated preoperative pulmonary hemodynamic profile suggests that those patients who survive the perioperative period may undergo a normalization of elevated right-sided pressures due to right ventricular remodeling in response to the increased afterload.

COMMENT

What, then, is the value of an elevated preoperative pulmonary hemodynamic profile, and what is its utility in the overall pretransplant evaluation? Naeije *et al.* have suggested that PVR calculations are insufficient to describe the functional state of the pulmonary circulation in patients with advanced congestive heart failure[39]. This finding has further been confirmed by Martí and co-workers, who have documented that an elevated PVR *per se* may not directly influence the incidence of graft dysfunction[40]. Further, in a multivariable analysis by Morley and Brozena, only right atrial pressure and a calculated 'high risk score' (incorporating parameters of both left- *and* right-sided circulatory function) were significantly associated with 1-year post-transplant mortality, despite a strong univariate association of PVR with 1-year mortality[41].

These findings suggest that, while generally useful as part of the entire pretransplant evaluation, preoperative pulmonary hemodynamic profiles must be viewed with caution. There does not appear to be agreement regarding threshold values for pulmonary hemodynamic indices beyond which cardiac transplantation is absolutely contraindicated; rather, threshold values (based on theoretical estimates of the norm) have previously been arbitrary in definition. Pulmonary hemodynamic indices represent a spectrum of values traditionally thought to have a direct linear relationship with postoperative mortality; the higher the value, it was postulated, the more likely postoperative mortality. Data described herein, however, refute this notion, and instead suggest that the relationship between an elevated preoperative index and postoperative mortality is but an association – direct but not exact, and by no means linear.

For example, can a patient with a preoperative PVR of 15 Wood Units undergo successful transplantation? Can a patient with a preoperative PVR of 2 Wood Units develop RSCF? Anecdotal data would support both of these scenarios. The preoperative pulmonary hemodynamic profile must therefore be evaluated as but one part – albeit important – of the entire pretransplant evaluation. Clearly, those candidates with severely elevated pulmonary hemodynamic indices are at great risk for postoperative complications. However, these risks must be weighed in concert with all other potential physiologic and psychological risks of transplantation.

At our institution no absolute threshold values are employed as inclusion or exclusion criteria for transplantation; this represents a policy that has evolved over our nearly two decades of experience with cardiac transplantation. Those candidates with an elevated preoperative pulmonary hemodynamic profile currently undergo vasodilator challenge with nitroprusside and additionally may receive either repetitive nitroprusside conditioning or long-term dobutamine therapy. It is our hope that, as these and other substantial preoperative risk factors for post-transplant morbidity and mortality are more effectively elucidated, complex algorithms will be developed that help to assess the cumulative risk of transplantation for the individual patient. These, in addition to investigations evaluating both waiting time and postoperative mortality, may then potentially unveil the true problem of pulmonary hypertension for the potential recipient.

Mechanical Circulatory Support Before Heart Transplantation

J.S. SAPIRSTEIN AND W.E. PAE Jr

INTRODUCTION

Cardiac transplantation has become a standard therapy for carefully selected patients with incapacitating end-stage cardiomyopathy. Since the introduction of the procedure, refinements in organ procurement, surgical technique, and immunosuppression have prompted the loosening of recipient inclusion criteria, while at the same time generating better survival. The large numerical discrepancy between organs available for cardiac transplantation and potential recipients is well recognized[1]. Today the number of patients for whom transplantation is clinically indicated – between 10 000 and 40 000 in the USA alone[2] – far exceeds the supply of donor organs. Between 10% and 40% of waiting recipients die before a suitable heart becomes available[3], and donor supply will probably remain the major impediment to broader use of this procedure. Efforts to expand the donor pool in the future are being made[4]; currently many patients can lengthen their status as appropriate allograft candidates with mechanical circulatory assistance.

INDICATIONS AND PATIENT SELECTION

Mechanical circulatory support is indicated when the heart can no longer safely meet the perfusion requirements of the body. Devices such as the intra-aortic balloon pump (IABP) are currently used routinely for relatively short-term support of end-stage cardiomyopathic patients awaiting an allograft. Bridging to transplantation with ventricular assist devices (VAD) and total artificial hearts (TAH) has been successfully performed for over a decade[5–7], and mechanical circulatory support systems specifically designed for chronic bridging are now commercially available. There is a wide spectrum of devices available today to treat a patient with a failing heart. The best support system, though, will always be that device which can provide the best potential results in the simplest possible manner.

Table 1 presents criteria that make an individual an appropriate candidate for mechanical bridging. In general this patient, who otherwise is an acceptable candidate for transplantation, must have deteriorating cardiac function that cannot be supported by more conservative pharmacological techniques. Coexisting processes such as renal failure or sepsis would be contraindications to bridging, to the extent that they would preclude allografting. However, if renal dysfunction is believed to be readily correctable by an improvement in cardiac performance, then mechanical support would be an appropriate intervention. Likewise an infection such as pneumonia should not prevent bridging if the resultant improved perfusion could reasonably be expected to facilitate recovery before transplantation.

Mechanical support is most often required to support the failing left ventricle (LV). Isolated right heart failure in the adult population is rare. When present, right ventricular (RV) failure usually manifests after the initiation of LV mechanical support. Either improved left-sided hemodynamics 'unmask' concomitant right heart dysfunction, or successful decompression of the LV may

Table 1 Criteria for insertion of cardiac assist device

(1)	Cardiac index < 1.8–2.0 l/min per m^2
(2)	Systolic blood pressure < 90 mmHg (or mean arterial < 60 mmHg)
(3)	Left atrial (or pulmonary capillary wedge) and/or right atrial pressure > 20–25 mmHg)
(4)	Urine output < 20 ml/hour (in adults)
(5)	Systemic vascular resistance > 2100 dyne s cm^{-5}
(6)	Trial of volume infusion, maximal pharmacologic (vasopressor and vasodilator) support, and intra-aortic balloon counterpulsation (if vascular access permits) without adequate improvement of ventricular function
(7)	Other signs of poor perfusion (e.g. metabolic acidosis, decreased mentation) may be present
(8)	If the cardiac assist device is intended as a bridge to transplantation, then clearly the patient must be acceptable as a candidate for cardiac transplantation

actually precipitate RV failure[8] as a result of the static and dynamic interactions (cross-talk) that functionally link the ventricles. If RV failure does develop, pharmacological support with inotropic agents and pulmonary vasculature dilators (isoproterenol, prostaglandin E_1, and nitric oxide) can be tried. Persistent dysfunction may then require mechanical support of both ventricles, either with two independently functioning devices or with a TAH.

INTRA-AORTIC BALLOON PUMP

Sarnoff *et al.* proposed in the 1950s that myocardial oxygen consumption is a function of ventricular wall tension[9]. The 'tension–time index' (TTI), the integral of the arterial pressure trace, came to reflect the heart muscle's consumption of O_2. In 1958 Harken suggested that decreasing the TTI would aid the failing heart, and his group described a device that lowered the TTI by withdrawing blood from the arterial tree just prior to ventricular systole and returning it to the circulation during diastole[10]. In 1962 Moulopoulos *et al.* described a catheter-mounted balloon with hemodynamic effects similar to the Harken pump, but without an extracorporeal circuit[11]. The balloon was positioned in the aorta and inflated during ventricular diastole, thereby augmenting diastolic blood flow. Deflation just before cardiac ejection essentially decreased the LV afterload, and thus systolic 'work'.

Kantrowitz *et al.* reported the first clinical use of the intra-aortic balloon pump in 1968 for the treatment of cardiogenic shock secondary to acute myocardial infarction[12]. Reemtsma *et al.* presented the use of IABP counterpulsation before cardiac transplantation in 1978[13]. The development of percutaneous insertion techniques in 1980 enabled the institution of counterpulsation to be much more timely. The efficacy of using this device in a transplantation candidate is well established. Hardesty *et al.*[14] reported that IABP-supported patients' results compared favorably with those obtained in healthier patients who did not require aggressive hemodynamic support. The University of Utah employed the IABP in 9% of 401 heart transplantation procedures[15]. Rosenbaum *et al.*, in their review of 43 patients supported before transplantation with an IABP, concluded that counterpulsation was both safe and effective, even with durations of support exceeding 1 month[16].

Nonetheless, recent series continue to show complication rates for the IABP (all indications) between 12% and 30%[17–20]. Ischemia distal to the catheter's insertion site is the most common complication, occurring in 9–25% of recipients; experience suggests that between 40% and 80% of these patients will require surgical intervention to treat the ischemic event. Other, less common complications include: (a) infection and localized hematoma, (b) pseudoaneurysm formation at the vessel puncture site, (c) vessel perforation with extensive hemorrhage, (d) lymphatic disruption with fistula formation, (e) aortic dissection from catheter passage below the intima, and (f) peripheral nerve damage. The IABP severely restricts patient mobility, thereby limiting the physical rehabilitation of transplantation candidates awaiting a donor heart.

Because of the potential morbidity associated with chronic IABP support, many transplantation centers rely upon this strategy as a 'first-step' mechanical circulatory support. At our own institution 74% of recent ventricular assist device (VAD) recipients awaiting heart transplantation were initially supported by an IABP, while 24% of all transplantations involved IABP support followed by a VAD[21].

VENTRICULAR ASSIST DEVICES

Overview

Over the past 20 years many types of VAD have been designed, tested and, less frequently, marketed. Some devices can support only the left ventricle, whereas others are appropriate for left- and/or right-sided use. The delivered flow may be pulsatile or non-pulsatile in character. We are limiting this discussion to those devices currently available in the United States, and to newer systems in their final stages of development with the highest likelihood of routine clinical use in the near future. The fundamental indication for VAD use is severe, refractory cardiac dysfunction. During the 1960s and 1970s most of the recipients fulfilling this criterion were in cardiogenic shock secondary to acute myocardial infarction. In general, the results of such device applications were poor. More recently the predominant indications for a VAD have overwhelmingly consisted of postcardiotomy cardiogenic shock (PCCS) and bridging to cardiac transplantation[22]. Indeed, our own group's recent use of circulatory support beyond the IABP has been exclusively for bridging to transplantation.

Implantation of a VAD usually requires the use of cardiopulmonary bypass. Major complications of the devices include: (a) perioperative bleeding, (b) infection, (c) thromboembolism, and (d) hemolysis. The risk for bleeding depends in part upon the anticoagulation requirements of the specific device. Excessive bleeding may require transfusion of blood products, predisposing the patient to infection with blood-borne pathogens.

Of particular concern for the bridge-to-transplantation patient is transmission of cytomegalovirus, which can severely complicate post-transplantation management. Exposure to foreign antigens also makes subsequent location of an antigenically acceptable organ more difficult. Similarly, pre-existing infection in a transplantation recipient about to receive induction immunosuppression is very dangerous. Patients requiring mechanical circulatory support are at increased risk for infection for several reasons. At the time of device placement these patients are hemodynamically unstable, a condition that compromises the immune response. The implanted components of the systems serve as a large, potential nidus for infection. Additionally, all current systems employ percutaneous elements that amplify the risk of developing foreign-body infections.

Blood pumps can result in substantial blood trauma. Hemolysis results from the physical trauma to erythrocytes caused by the mechanical pumps; high rates of hemolysis can in turn lead to organ systems' injury and anemia. Stress on the blood and all of the elements suspended within it is directly proportional to the shear rate, the rate of change of the blood's velocity upon moving away from the pump walls. The stress imposed upon erythrocytes can lead to membrane instability and hemolysis with release of free hemoglobin into the bloodstream. If the body's ability to scavenge hemoglobin (predominantly through haptoglobin-binding sites) is overwhelmed, plasma free hemoglobin levels

will rise. Hemoglobin casts form in the renal tubules when plasma free hemoglobin levels approach 40 mg/dl, and acute renal failure can then develop. Hemolysis also contributes to hepatic insufficiency, coagulopathies, and anemia. A relatively high degree of hemolysis has been documented in non-pulsatile pumps[23].

Shear stresses have profound effects on platelets and the clotting cascades. Shearing can elicit changes in the expression and functionality of platelet membrane glycoproteins[24], inducing the binding of von Willebrand factor and fibrinogen. These events are critical to the activation and aggregation of platelets and the formation of platelet thrombi. Shearing also causes platelet fragmentation, exposing more cellular surface upon which catalytic amplification of the clotting cascade can occur[25]. Coupled with the obligatory exposure of blood to various biomaterials, the pumping action of a VAD always carries a risk of thrombus formation and subsequent embolization.

Non-pulsatile VAD

The efficacy of supporting the circulation with non-pulsatile blood flow is clearly demonstrated by the more than 300 000 cardiac procedures performed each year with CPB. There are three general types of non-pulsatile VAD: roller-head pumps, centrifugal pumps, and axial flow pumps. These devices operate in a continuous, 'one-direction' fashion; consequently the pumps are, from a design standpoint, mechanically simple. However, the high-speed nature of non-pulsatile pumps creates particularly high shear stresses. Thrombus formation and relatively high levels of hemolysis, as well as some unique operational constraints mentioned below, have limited non-pulsatile ventricular support to short-term use lasting several days to a week. Non-pulsatile pumps therefore appear not to be the optimal choice for bridging to transplantation.

Roller-head pumps

The majority of CPB machines in use today incorporate roller-head pumps to deliver flow. Roller-heads compress the circuit's flexible tubing, thereby generating flow in a peristaltic fashion. Given the general familiarity with the set-up, it is not surprising that roller-head pumps have been employed outside of the operating room as VAD[26]. The primary advantage of a roller-head VAD is the fact that every institution performing cardiac surgery can conceivably use this relatively inexpensive support strategy. Generally, the inflow cannulation is via the left atrial appendage, with the tubing exiting the left chest tunneled parasternally by way of the second or third intercostal space, or below the xiphoid process. The outflow cannula is brought out through the sternotomy incision or tunneled below the xiphoid[27,28]. Right heart bypass may be instituted alone or in combination with left heart bypass by inflow right atrial cannulation and outflow pulmonary artery cannulation.

These pumps were not designed for protracted use in a single patient, and limitations to extended VAD application arise. Compression of pump tubing creates a jet of blood involving high shear stresses. Prolonged exposure to repetitive compression also leads to fatigue deformation of the circuit's flexible tubing, and thus the physical integrity of the circuit must be carefully monitored. Constant oversight by trained staff is also mandatory, since outflow obstruction can produce pressure overload and catastrophic tubing disruption. Conversely, an inlet cannula obstruction may result in air aspiration from around the cannulation site, leading to air embolization.

Centrifugal pumps

A so-called centrifugal pump draws upon Bernoulli's theorem to generate dynamic pressure from kinetic energy imparted to blood by a spinning chamber. Two centrifugal pumps have been used extensively in the USA. The Bio-Medicus Bio-Pump (Medtronic Bio-Medicus, Inc., Eden Prairie, MN) contains rotating cones within the blood-spinning chamber (Figure 1). The Sarns centrifugal pump (Sarns/3M Health Care, Inc., Ann Arbor, MI), shown in Figure 2, relies upon an impeller mechanism to deliver energy to the blood.

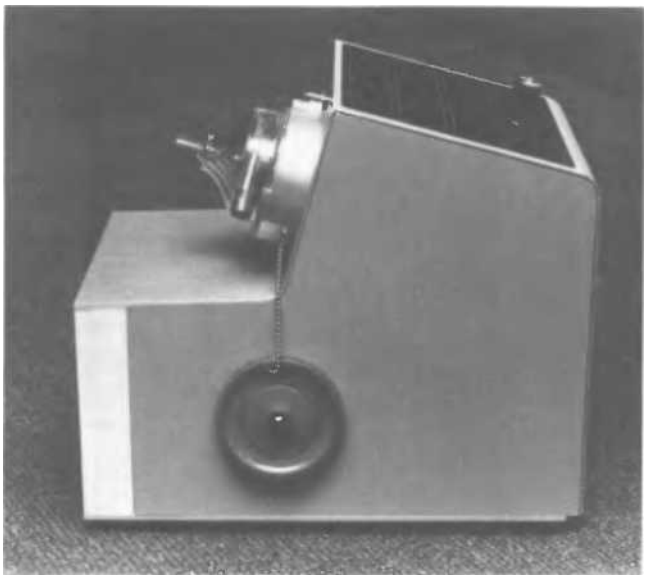

Figure 1 The BioPump console with centrifugal pump head in place

Figure 2 The Sarns centrifugal blood pump. The spinning pump head continuously drains and returns blood with non-pulsatile flow

An axle and bearing support these blood-contacting elements. Reusable consoles spin the pumping chambers through the technique of magnetic coupling. Seals are designed to prevent the leakage of blood onto the axle–bearings assembly. Implantation techniques are similar to those employed with roller-head pumps.

Data from the voluntary registry of mechanical circulatory support show that, between 1983 and 1993, centrifugal pumps were the most commonly applied support devices (other than IABP), making up approximately 50% of all devices used[22]. The vast majority of patients, though, were being treated for PCCS, not for bridging to transplantation. Nearly half of the patients were reported to have had excessive bleeding. This complication is not wholly unexpected given the anticoagulation regimens that are usually used, and reoperation is often necessary[29]. Seal disruption, sometimes precipitating abrupt device failure, does occur in centrifugal pumps, and the development of 'seal-free' pumps is underway[30]. Seal leakage and thrombus formation have restricted the typical duration of support with centrifugal pumps to between 2 and 8 days, and the physical size of a complete system prevents, or at best severely limits, patient mobility. For these reasons the centrifugal pump's role as a definitive bridging device is limited.

Axial flow pumps

Several groups are developing small, implantable axial flow blood pumps. These pumps deliver non-pulsatile blood flow in much the same way that a ship's propeller displaces water[31–33]. Most of the systems are being designed to provide circulatory support lasting up to several months. The projects are all in the *in-vitro* and early animal studies stages, meaning that clinical availability lies many years away. Considerable engineering challenges remain to be solved, most notably the long-term maintenance of pump bearings, and the potentially deleterious effects from long-term non-pulsatile blood flow will need to be thoroughly evaluated. Nonetheless, these compact systems may eventually prove to be the mainstays of long-term circulatory support.

Pulsatile VAD

Pulsatile VAD contain blood-pumping chambers that are completely isolated from their actuating mechanisms. As a result the need for biocompatible seals and bearings is greatly reduced, and the systems are therefore better suited for longer-term periods of pumping. Pulsatile VAD are therefore particularly advantageous when bridging a patient until heart transplantation. The issue of non-physiological blood flow is also less important with pulsatile pumps.

Pierce–Donachy VAD

The Pierce–Donachy VAD (Thoratec Laboratoires Corp., Berkeley, CA) has been used in extensive clinical trials for bridging to transplantation, PCCS, and support of acute myocardial infarction. The VAD (Figure 3) is based upon a seamless, 70 ml polyurethane blood sac which fits within a rigid polycarbonate case. An attached drive console withdraws and injects air into the case, thereby causing the sac to fill or empty. The device lies in a paracorporeal position over the patient's upper abdomen, with the atrial or ventricular apex inlet cannula and the aortic or pulmonary arterial outlet cannula exiting the body through subcutaneous tunnels. The cannulae are fabricated from wire-reinforced polyurethane, and arterial graft material permits a standard end-to-side arterial anastomosis. Tilting-disc prosthetic valves ensure unidirectional blood flow. A magnetic switch in the pump detects a completely filled sac, prompting the initiation of pump ejection with an air pulse. Alternatively, the pump can be run in synchrony with the native heart rhythm via the electrocardiogram signal. Fixed-rate pumping, independent of sac filling or heart beat, is also possible.

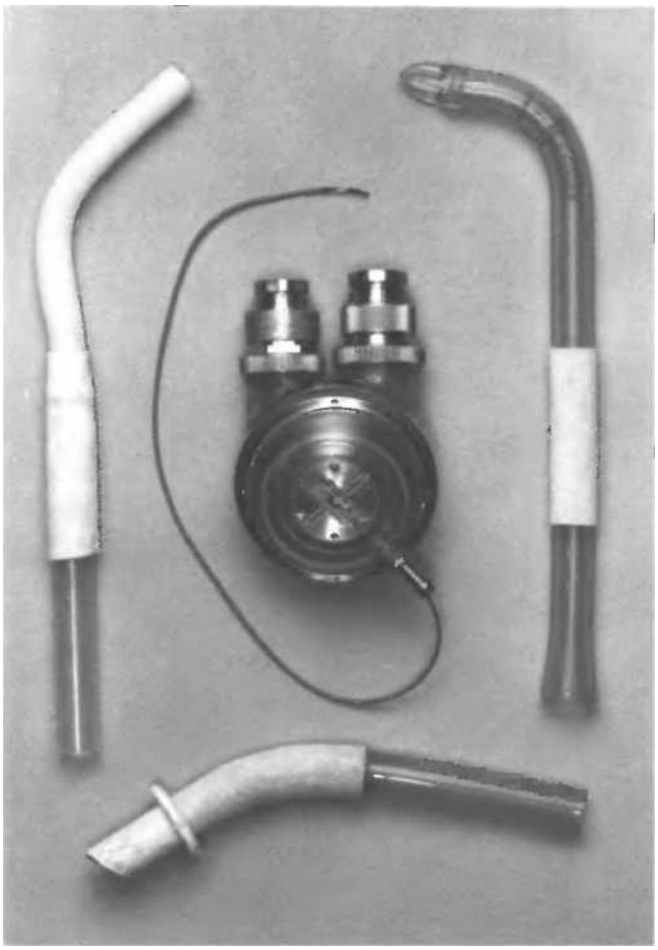

Figure 3 Prototype of the Pierce–Donachy (Thoratec) ventricular assist device

Left, right, or biventricular support is available with this type of device (Figure 4). The implantation generally is made during CPB. In instances where atrial pressures are high, the risk of air embolization is small, and atrial inlet cannulation can be performed without CPB. A median sternotomy provides the optimal exposure for assist pump placement. A patent foramen ovale must be searched out and closed if only a left ventricular assist device (LVAD) is being placed, since decompression of the left heart may lead to significant right-to-left shunting and hypoxemia. We prefer the LV apex as the site of cannulation for VAD inflow, since maximal LV drainage can be obtained, the risk of ventricular thrombus formation is decreased, and more atrial remnant tissue is available for subsequent allografting. In instances where

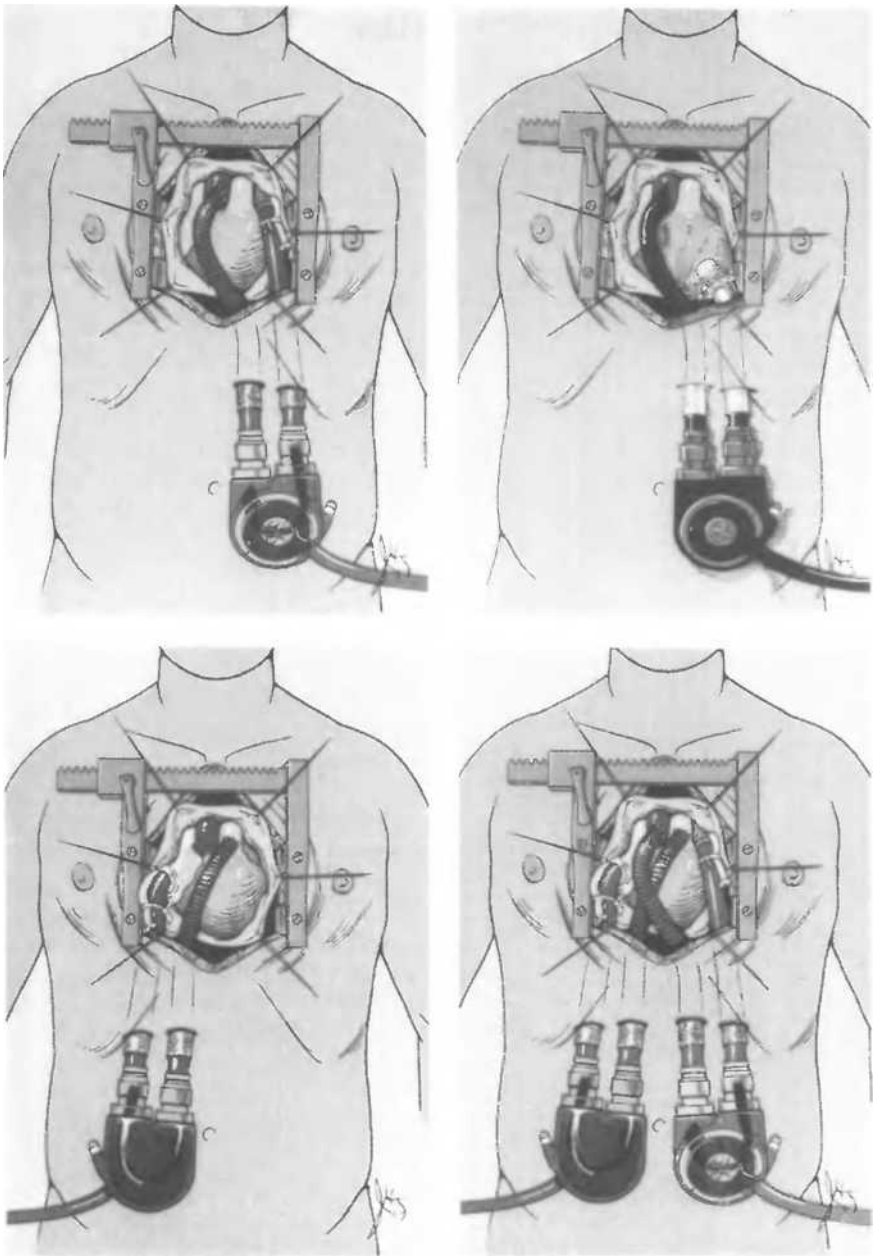

Figure 4 Illustrations of the Pierce–Donachy ventricular assist device in various applications. Clockwise from top left: **A:** left ventricular assistance with atrial inflow cannulation and blood return to the ascending aorta; **B**: left ventricular assistance with ventricular inflow cannulation; **C**: biventricular assistance with left and right atrial cannulation; **D**: right ventricular assistance with right atrial inflow cannulation and blood return to the pulmonary artery. This pump is positioned intraperitoneally, and a percutaneous wire (left) connects with a portable power supply and control unit

adequate exposure of the ventricular apex involves considerable operative risk (e.g. extensive mediastinal scarring from prior coronary artery bypass grafting), left atrial inlet cannulation can be employed with good results. The outlet graft is sutured as low as possible to the ascending aorta in order to allow for its excision during recipient cardiectomy. Pumping is gradually initiated after the pump has been de-aired. A drive-line vacuum pressure can be used to promote faster, more complete pump filling.

At our institution a standard approach is taken to the post-operative management of bridging-to-transplantation patients. Patients return to the intensive-care unit having resumed their perioperative inotropic medications. These agents are weaned as rapidly as RV function will permit. If present, the femorally placed intra-aortic balloon is removed within the first 12 post-operative hours. Patients are extubated according to standard respiratory parameters. The presence of prosthetic, mechanical

valves mandates systemic anticoagulation. Anticoagulation with intravenous heparin followed by oral sodium warfarin begins when mediastinal bleeding has slowed, with the goal of maintaining the prothrombin time 1.5–2 times the control value. Antiplatelet aggregation agents (aspirin and dipyridamole) are added only if signs of embolism develop. Antibiotic prophylaxis includes vancomycin and gentamicin. Appropriate therapy for infections is based upon culture results; if no specific organism can be identified, broad-spectrum, empirical treatment is instituted. Early postoperative mobility leads to a rehabilitation regimen that includes daily exercise with a treadmill and/or stationary bicycle. Duodenal tube feeding or total parenteral nutrition is administered if the dietary intake is inadequate.

TCI Heart-Mate

The Heart-Mate 1000 IP (Thermo Cardiosystems, Inc., Woburn, MA) is indicated solely for left ventricular support as a bridge to transplantation and a system appropriate for chronic, longer-term use is under development (Chapter 78). The blood-contacting surfaces of this pump consist of sintered titanium microspheres and a textured polyurethane diaphragm. These surfaces promote the formation of a biologically active pseudoneointima shortly after exposure to blood[34]. Additionally, porcine xenograft valves are used at the pump's inlet and outlet; therefore the requirement for systemic anticoagulation is greatly reduced or obviated. The diaphragm is bonded to a rigid pusher-plate that moves back and forth with air pulses delivered from an external drive unit; as the pusher-plate moves, blood alternately enters and leaves the pump via attached cannulae. The pump is placed intraperitoneally in the left upper quadrant, with the left ventricular apex inflow and aortic outflow cannulae traversing the patient's diaphragm. A percutaneous airline connects the pump with its drive console. This bridging device was the first to gain approval for commercial use from the United States Food and Drug Administration (FDA).

The Heart-Mate VE LVAD is an electromechanical device based upon the pneumatically driven unit (Figure 5)[35,36]. A diaphragm separates the pump's electric motor from its blood chamber. Compression of the diaphragm causes ejection of blood, and filling of the pump occurs passively. Again, the pump is placed intraperitoneally in the left upper quadrant. The LVAD is externally controlled; permanent, percutaneous wires connect the pump to a wearable controller-battery pack. A permanent percutaneous vent permits the displacement of air from the pump as the LVAD diaphragm moves. This system is already being tested clinically under an Investigational Device Exemption (IDE) for bridging to transplantation[37].

Novacor N100

The Novacor N100 Left Ventricular Assist System (Novacor Division, Baxter Healthcare Corp., Oakland, CA) is also designed specifically for bridging to transplantation. This device, implanted in the preperitoneal space or within the abdomen, consists of a polyurethane blood sac compressed by two opposing pusher-plates (Figure 6). The N100 does not use air pulses to compress the blood chamber. Instead, the pump is actuated by a pulsed solenoid energy converter. Bovine pericardial valves direct the flow of blood. An external controller and power console connects with

Figure 5 The TCI HeartMate VE LVAD. The left ventricular outflow attachment is on the left and the aortic inflow graft is on the right

the pump by means of a percutaneous wire, and a percutaneous vent allows the implanted pusher-plates to oscillate freely[38]. A wearable, electrical control console that allows for improved patient mobility during long-term use is now under clinical investigation[39]. Modifications that make the system appropriate for permanent implantation are also being investigated.

TOTAL ARTIFICIAL HEARTS

A total artificial heart (TAH) consists of orthotopically positioned blood pumps that physically and functionally replace the native left and right ventricles. Akutsu and Kolff achieved the first experimental success with a TAH when they temporarily supported a dog with two pneumatically activated polyvinyl chloride blood pumps[40]. Cooley (Chapter 77, Figure 1) *et al.* then first used a TAH clinically in 1969, as a bridge to transplantation[41]. Currently, the primary indication for placement of a TAH is biventricular failure that cannot be corrected through the use of a left VAD and pharmacological support of the right ventricle. This

Figure 6 Unencapsulated Novacor left ventricular assist device

situation might also be appropriately treated by the implantation of bilateral VAD. In instances where the heart is extremely dilated, though, there may be an advantage in excising the theoretically thrombogenic native ventricles. The TAH is also the device of choice for a small number of patients with left-sided failure whose myocardium is so compromised that LVAD placement would be unsafe or ineffective. This group includes transplantation candidates with ischemic cardiomyopathy who develop ventricular rupture or an irreparable ventricular septal defect with a large shunt.

The decision to use a TAH as opposed to VAD support is not trivial, for the implantation of the more complicated TAH puts the patient at increased risk of perioperative morbidity. The procedure, involving cardiectomy, carries a higher risk of bleeding. If the device were to fail, there is no residual native heart function that might minimally sustain the circulation while corrective measures are taken. Control of a TAH is also intrinsically more difficult than that of a VAD. Typically a VAD maximizes its output in direct proportion to the pump's 'preload', a function of the intravascular volume status. However, the equilibrium blood volumes pumped by the native left and right ventricles are not equal, the discrepancy due in part to a left-to-left shunt of bronchial blood and to different characteristics of the great vessels. A TAH control algorithm must be able to respond to differing left and right volume requirements if adequate perfusion is to be maintained. This response must also include consideration of passive pulmonic perfusion, or left-to-right 'pass-through' flow, that has been identified in TAH[42]. Two TAH, both pneumatically driven, are under clinical investigation in the United States.

CardioWest C-70 TAH

The CardioWest C-70 (CardioWest Technologies, Inc., Tucson, AZ) represents a smaller, modified version of the Jarvik heart (Fig. 7) made famous by DeVries (Chapter 77, Figure 2) *et al.*, who in 1982 electively implanted the device in an individual who was not a transplantation candidate (Chapter 77)[43]. The Jarvik heart, manufactured by Symbion, had been withdrawn from the US market due to manufacturing difficulties, but it continued to have fairly wide use in foreign countries. In the early 1990s CardioWest Technologies assumed responsibility for the TAH, and the result has been renewed clinical evaluation of the 70 ml stroke volume device. The C-70 consists of two pneumatically compressed, polyurethane ventricles placed in the orthotopic position (Figure 8). Percutaneous drive lines connect the pumps to an external drive unit; two mechanical valves in each ventricle assure the correct direction of blood flow[44].

The Penn State Heart

The 'Penn State Heart' (Figure 9), designed and built by our group at the Pennsylvania State University, consists of two valved, pneumatic ventricles; it shares many features with the Pierce–Donachy VAD also developed at Penn State. Our experi-

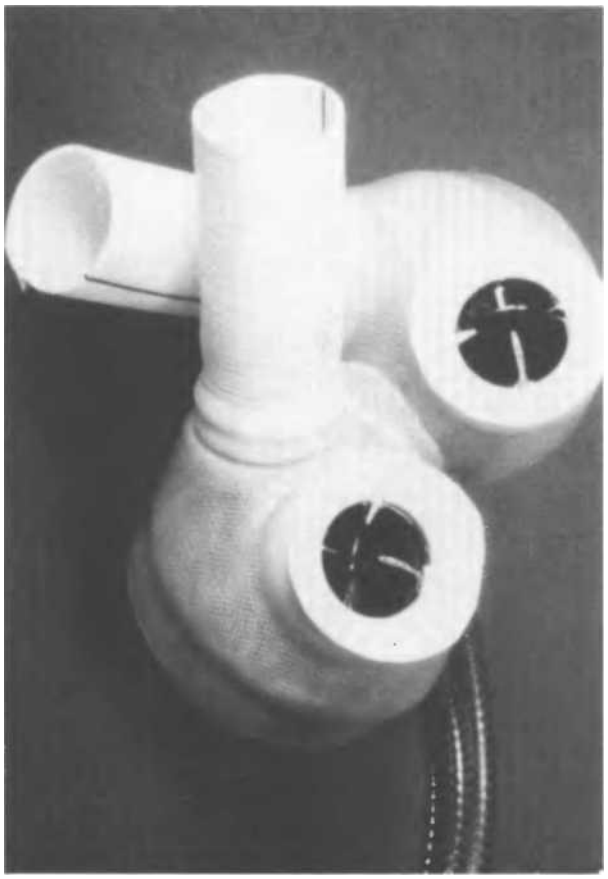

Figure 7 Jarvik-7-100 total artificial heart

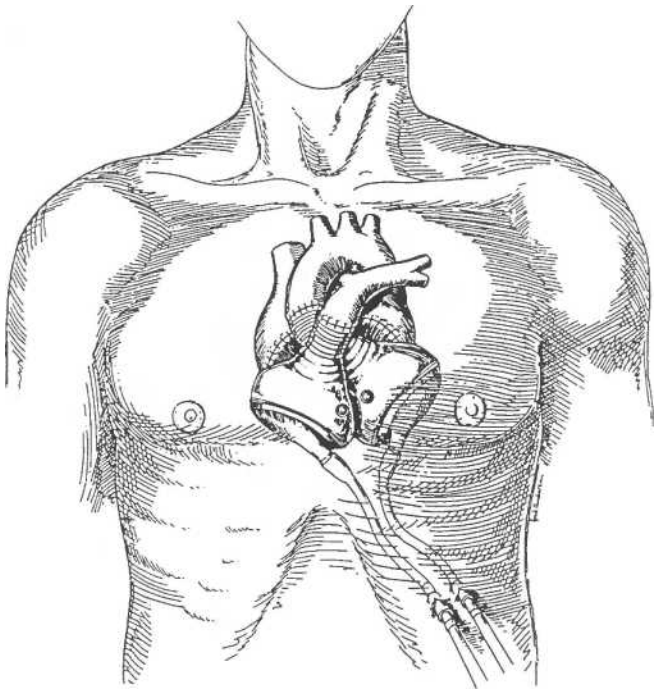

Figure 8 Implantation of the CardioWest C-70 Total Artificial Heart

Figure 9 Implanted blood pumps of the Penn State Heart

ence with clinical use of this system is limited; only five patients have presented to our institution thus far with the need for a temporary TAH. One of these patients was supported for 223 days with the device. The device remains approved by the FDA for clinical application.

RESULTS OF BRIDGING TO TRANSPLANTATION

As experience with bridging techniques has increased, results have improved. A voluntary device Registry shows that, from 1983 to 1993, 584 patients received mechanical circulatory support (excluding IABP) for the specific purpose of bridging to transplantation[22]. Four hundred (69%) of these patients successfully underwent transplantation, with 274 patients (69% of those transplanted) ultimately being discharged from the hospital. Reported results in patients who are bridged now suggest outcomes identical to transplantation alone[6,38,45].

Device-specific results are also very encouraging. Fifty-four percent of all patients implanted with the Thoratec Pierce–Donachy VAD as a bridge to transplantation have survived after receiving an organ[46]. A recent series from our institution had 74% of patients with a bridging Pierce–Donachy left VAD (Sarnes/3M Healthcare, Ann Arbor, MI) successfully supported until transplantation; each of these individuals was eventually discharged from the hospital[21]. Approximately 68% of patients supported with the TCI HeartMate IP during clinical trials subsequently underwent cardiac transplantation (K.A. Dasse, personal communication), and 80% of transplanted patients have ultimately been discharged from the hospital[47]. Since 1984 over 200 patients have received the Novacor Left Ventricular Assist System as part of a multicenter clinical trial (L. Strauss, personal communication), and approximately 60% of these patients went on to cardiac transplantation. Overall, about 50% of the recipients left the hospital after transplantation[48].

The data for the newly investigated CardioWest C-70 TAH are obviously less voluminous, but the results indicate a similar trend. Between January 1993 and May 1996 74 patients had received the device as part of an international clinical trial; 59% of these patients had successfully undergone transplantation and been discharged from the hospital (R.G. Smith, personal communication).

A review of the indications for 476 reported bridging procedures[49] showed that hemodynamic deterioration before transplantation is by far a more common indication (92%) than is acute rejection necessitating retransplantation (8%). Of 40 patients treated with circulatory support during rejection, only 23 (58%) underwent a second transplantation. Eight of the 23 patients (35%) ultimately were discharged from the hospital, with the overall salvage rate being 19%. When the indication was hemodynamic instability and organ unavailability, the best outcome was seen with univentricular support (62% of patients discharged); the rates of subsequent transplantation, as well as hospital discharge, were independent of the type of left ventricular assist device used (i.e. pneumatic, electrically activated, or nonpulsatile). Biventricular paracorporeal support yielded a 45% post-transplantation discharge rate. Only 35% of TAH recipients ultimately left the hospital.

Kaplan–Meier survival estimates for all patients undergoing staged cardiac transplantation at 1 and 2 years after the procedures, inclusive of the 30-day operative mortality, were nearly 65%. This is in contrast to the nearly 90% actuarial survival in isolated orthotopic cardiac transplantation. However, when survival estimates were prepared for each type of mechanical support employed in conjunction with transplantation, the 1- and 2-year estimates for univentricular support were equivalent to isolated orthotopic cardiac transplantation.

The complications precluding transplantation after establishing circulatory support were numerous. Most of the patients suffered more than one complication. Stepwise logistic regression analysis indicated, in decreasing order of importance, that bleeding, neurological events, and biventricular and renal failure had significant negative effects on future transplantation. Not surprisingly, bleeding, renal failure, persistent respiratory failure, infection, and rejection negatively affected hospital discharge. Multivariate analysis indicated that bleeding, infection, and renal failure were the most important predictors of hospital death after staged transplantation. The causes of death after 30 days paralleled those of the isolated cardiac transplantation population.

COMMENT

The collective experience with VAD and TAH undeniably underscores the efficacy of mechanical circulatory support as a bridge to cardiac transplantation. Some data are beginning to suggest

improved outcomes after transplantation in supported patients. Recent results from Penn State, for example, included a 30-day mortality after transplantation of 0% in mechanically bridged patients, compared to a 14% mortality in non-bridged Status I recipients[21]. Such results are all the more encouraging when one considers that these bridged patients would most likely have died before allografting had mechanical circulatory support not been available.

While the benefit to an individual patient may be substantial, the derived benefits in broader terms are less obvious. Heart transplantation remains the final objective of VAD and TAH use today. Bridging, though, does nothing to fix the biggest problem with heart transplantation – inadequate organ supply. Indeed, bridging devices can only worsen the disparity between available organs and potential recipients. If bridging continues to generate better post-transplantation outcomes than more traditional patient management approaches, then the use of the devices may be justifiable from a public-health standpoint. One must acknowledge that these devices involve considerable expense. Analyses have shown that overall pretransplantation costs incurred by mechanically bridged patients are significantly greater than those incurred by non-bridged patients[50,51]. Certainly this relationship will reverse itself as the need for intensive, in-hospital monitoring of patients with bridging devices gives way to relatively inexpensive, out-of-hospital management. There is also some evidence that a physically active, bridged patient may recover more rapidly from the transplantation procedure than will a bedridden, physiologically 'sicker' candidate supported by inotropic agents[50]. In this manner, bridging could help to decrease the cost of treating end-stage cardiomyopathy.

Perhaps the greatest benefits from bridging to transplantation will be realized in the eventual application of permanent circulatory support systems (Chapter 78). Permanently implanted VAD and TAH are under active development, with large-animal survivals of greater than 1 year having been attained for both types of devices. The successful rehabilitation of patients supported with temporary, bridging devices has validated the experimental results obtained with permanent systems, and information gleaned from the bridging experience will make more chronic devices a clinical reality in the next 5–10 years. At that time patients with relative or absolute contraindications to transplantation will be given the opportunity to resume productive lives through cost-effective, unobtrusive, mechanical support, while scarce donor hearts can be allocated to a smaller set of younger patients who stand to benefit more from heart transplantation.

Anesthetic Management, Including Cardiopulmonary Bypass

J.V. BOOTH, D.R. WHEELDON AND S. GHOSH

INTRODUCTION

Since the first successful transplantation of the human heart over 25 years ago many groups of anesthetists have described the anesthetic techniques they use for managing their patients during the recipient operation[1-11]. There has been an enormous variety of different anesthetic agents employed in transplantation, and it appears that each unit has based its regimen on experiences in patients with decompensated cardiac failure. As experience is gained in transplantation, previous boundaries are stretched, with older patients being accepted for transplantation and an increasing number of patients with relatively higher transpulmonary pressure gradients being operated on. The choice of individual anesthetic agents is in itself of relatively little consequence provided that the overall technique employed does not produce marked cardiovascular effects.

PRE-ANESTHETIC MANAGEMENT

In our practice it is rare for the recipient to be in our hospital when the donor call is received. The recipient is contacted either in his/her local hospital or at home, and then transferred to our center and prepared for operation. Most patients will therefore not have had any oral intake for 5–6 hours before induction of anesthesia. On admission a period of intense activity follows. The patient is bathed and shaved, bacteriological swabs are obtained, and a final surgical and anesthetic assessment undertaken. The circumstances surrounding heart transplantation in respect of distant organ procurement and the coordination of organ donor to recipient matching usually allows limited time for preoperative assessment and preparation of the recipient. The anesthetist can assume that the patient will have evidence of severe cardiac and respiratory dysfunction as well as secondary renal or hepatic impairment. The preoperative visit is not designed to alter therapies, which should already be optimal, but rather to assess the extent and clinical implications of the patient's organ dysfunction. The history is usually well described in the medical case notes, so patient evaluation can be limited to current cardiovascular and respiratory function and exercise limitation. A brief relevant history is taken, concentrating on drug history, drug sensitivities, previous anesthetics, the anatomy of the upper airway, and recent oral intake.

Our practice is to avoid prescribing any sedative agent in the preoperative period. Patients with low cardiac output can be very sensitive to central nervous system depressants, with resulting hypopnea or apnea. Sensitivity may be due to impaired redistribution of the drug from central to peripheral compartments because of low tissue perfusion consequent to a low cardiac output state. Alternatively, the increased depressant effects of these drugs may be due to decreased protein binding, particularly in chronic debilitating diseases. Low tissue binding allows higher concentrations of free drug at the receptor sites.

MONITORING

As for all major cardiothoracic procedures, monitoring of the patient comprises routinely: (a) continuous multi-lead electrocardiography, (b) pulse oximetry, (c) capnography, (d) inspired oxygen concentration, (e) central venous pressure, (f) systemic arterial pressure at the radial artery, (g) hourly urine volumes, and (h) core temperature. A careful aseptic technique should be employed when inserting vascular cannulae. This is especially important in these patients, whose risk of infection is heightened considerably by perioperative immunosuppresive therapy.

We routinely insert a 7.0F gauge triple-lumen central venous pressure catheter. Although we do not routinely insert a pulmonary artery flotation catheter (PAFC), we often insert the 8.5F gauge sheath through which the PAFC can be advanced if required following cardiopulmonary bypass. PAFC may increase the risk of infection in these patients[7], although some authors have questioned this[12]. A survey published in 1986 reported that 32% of hospitals in North America used PAFC routinely during heart transplantation prior to cardiopulmonary bypass, and that 44% used them after bypass[13].

Some centers now use intraoperative transesophageal echocardiography (TEE) to assess cardiac function, particularly right ventricular function[14], although the role of TEE in heart trans-

plantation has yet to be evaluated. Others have advocated the use of right ventricular ejection fraction catheters that allow assessment of beat-to-beat changes in right ventricular ejection[15].

ANESTHETIC MANAGEMENT

The risks of absolute or relative overdose of anesthetic agents, leading to further myocardial depression, during a rapid sequence induction must be balanced against the risks of pulmonary aspiration in patients with a full stomach. At Papworth Hospital we find that this is rarely a problem. Good planning almost always allows the potential recipient to have fasted before induction of anesthesia. A true rapid sequence induction is relatively contraindicated, as this may exacerbate the underlying high pulmonary vascular resistance, further depressing cardiac output and causing decompensation. If the risk of aspiration is considered high, a modified rapid sequence induction may be used that aims for cardiovascular stability. As consciousness is lost, cricoid pressure is applied, and the lungs ventilated cautiously during the transition from spontaneous to mechanical ventilation. The judicious use of H2 blockers preoperatively may also further decrease the risks of pneumonitis due to aspiration. Before cardiopulmonary bypass, cardiac function can be augmented by pharmacologic means to optimize perfusion of other organs without concern for detrimental effects on the heart in the early postoperative period.

Induction of anesthesia should be gradual and controlled to avoid any precipitous increase in the pulmonary vascular resistance or marked decrease in systemic arterial pressure. We use midazolam 0.1 mg kg^{-1}, or diazepam 0.15 mg kg^{-1}, followed by fentanyl at a total dose of 10–15 mg kg^{-1} given in increments slowly, and titrated against hemodynamic response. Muscle relaxation is achieved with pancuronium 0.15 mg kg^{-1} to 0.2 mg kg^{-1}. The endotracheal tube should have a high-volume, low-pressure cuff. The lungs are ventilated with oxygen, air and isoflurane 0.5–1% to maintain anesthesia. Alternatively, an infusion of propofol at 3 mg kg^{-1} h^{-1} is satisfactory.

Almost all the transplant recipients have been optimized on maximal medical therapy, involving potent diuretic agents, resulting in a contracted intravascular volume[16]. Hypotension is likely, with a loss of sympathetic tone and a decrease in catecholamine concentrations. This responds well to vasoconstrictors titrated carefully i.v. We use diluted phenylephrine or metaraminol with 0.1–0.25 mg increments.

Immunosuppression (with azathioprine and steroids) and antibiotics are commenced on induction. If RATG is to be given, then this is started as an infusion at the onset of cardiopulmonary bypass to control the profound fall in systemic pressure that may accompany its administration.

CARDIOPULMONARY BYPASS

We delay cardiopulmonary bypass until the donor organs are certain to arrive in the operating room, except when severe cardiovascular instability requires cardiopulmonary support. Heparin 300 units kg^{-1} i.v. is given for anticoagulation. The dose may have to be adjusted if the patient is on heparin or warfarin preoperatively. We aim to maintain an activated clotting time >400 seconds.

The aorta is cannulated higher than for routine cardiac surgery, to facilitate access to the pericardial sac. Bicaval cannulation is performed (cannulation of the inferior vena cava and superior vena cava separately), and the cavae snagged around the cannulae to prevent venous blood spillage into the atrium.

If the patient has had previous cardiac surgery the femoral artery and femoral vein may be cannulated for cardiopulmonary bypass before sternotomy. This allows rapid intravascular fluid resuscitation and the option of partial bypass in the event of massive bleeding following sternotomy. In all cases the groins should be prepared in case femoral cannulation is required. The routine at Papworth is to use a membrane oxygenator and to provide non-pulsatile perfusion with moderate hypothermia (30°C). The machine is primed with crystalloid solution to which 6000 IU of heparin are added. Pump flow is 2.41 l min^{-1} m^{-2} at normothermia, reducing to 2.0 l min^{-1} m^{-2} at 30°C.

Facilities are always available for hemofiltration and/or hemodialysis should either prove necessary[17]. Patients in congestive cardiac failure with enlarged hearts may present a large volume load for the cardiotomy reservoir at the onset of cardiopulmonary bypass.

Pressure on bypass is controlled to give a perfusion pressure between 40 and 60 mmHg. At the initiation of bypass, various factors combine to produce a fall in peripheral resistance. This is normally self-limiting, but can be progressive, particularly if the patient was receiving regular angiotensin-converting-enzyme inhibitor drugs. Vasoconstrictors such as metaraminol or phenylephrine are administered when the pressure is below 40 mmHg, and phentolamine is used as a vasodilator to control hypertension during cardiopulmonary bypass.

Rewarming is initiated during the aortic or pulmonary artery anastomosis, the aim being to achieve a blood temperature of 37°C by the time of release of the aortic clamp. Potassium is added, if required, to keep the serum potassium level above 4.5 mmol l^{-1}, as low potassium levels have been associated with an increased incidence of arrhythmias.

Discontinuation of cardiopulmonary bypass follows the same principles as during elective cardiac surgery. The lungs are ventilated with as low an inspired oxygen concentration as possible, commensurate with adequate tissue oxygenation. The heart is slowly filled to optimum pressures to avoid overdistending the ventricles while bypass flow is reduced. The transition from cardiopulmonary bypass is usually uneventful. Direct observation of the heart is often the best guide to filling of the right atrium and ventricles. This is particularly relevant, because right ventricular systolic and diastolic dysfunction is common in the early post-transplant period[18,19]. Such dysfunction is often associated with a raised pulmonary vascular resistance. Isoprenaline (isoproterenol) 0.005–0.01 μg kg^{-1} min^{-1} by infusion i.v. is used to decrease pulmonary vascular resistance whilst augmenting inotropic and chronotropic activity. Persistent right heart failure may require infusion of prostacyclin 0.1 mg kg^{-1} min^{-1} i.v.[20], intra-aortic balloon pump correction of septal wall dislocation[21,22], or inhaled nitric oxide[22,23].

POSTCARDIOPULMONARY BYPASS PERIOD

Once separated from cardiopulmonary bypass and hemodynamically stable, protamine is given to antagonize the anti-

coagulation induced by heparin. At this stage the ventricles are poorly compliant. The transplanted heart is also denervated, rendering it volume dependent and unable to respond to decreased preload by an increase in heart rate. Protamine should be administered cautiously to avoid hypotension from systemic arterial vasodilatation, raised pulmonary vascular resistance, and its negative inotropic effects[24].

The recipient may present with abnormal coagulation indices preoperatively due to hepatic congestion secondary to right ventricular failure, or anticoagulant or aspirin therapy. After surgery, if the activated clotting time returns to the recipient's baseline value, or within 10% of it, it is likely that heparin neutralization is complete. Results of a platelet count may be misleading, because although absolute numbers of platelets may be within the normal range, those platelets may be dysfunctional. Platelet dysfunction post-bypass is caused by factors that decrease the concentration of the GPIb and GPIIb receptors on the surface of the platelets. These receptors are essential for platelet-to-platelet interaction and aggregation[25]. Continued bleeding after surgery may require platelets, fresh-frozen plasma, or desmopressin (DDAVP) to be administered. Transfusion of stored blood is required when the hemoglobin concentration falls below 85 g l^{-1}.

Although we do not routinely use aprotinin for all heart recipients, it is useful when excessive bleeding is anticipated, such as in those who have had previous cardiac surgery or those who have been chronically anticoagulated. In these cases we use a loading dose of 2 million units of aprotinin given as a slow bolus injection after a test dose of 200 000 units given before cardiopulmonary bypass. A further 2 million units is added to the bypass prime, and following bypass an infusion of 500 000 units per hour is continued for 1 hour postoperatively.

Although most intraoperative anesthetic problems in the heart transplant recipient occur in the prebypass period, the incidence of ventricular arrhythmias has been reported as high as 79% after bypass[26]. A proportion of these (18%) may persist for more than 24 hours[27]. If the venous preload is adequate, there should be no decrease in systemic arterial pressure when the chest is closed.

We deliver analgesia to patients using an infusion of morphine 1–5 mg h^{-1}, initiated in the operating room just prior to transfer of the patient to the intensive-care unit. In our institution the majority of heart recipients are extubated within 6 hours postoperatively.

Current Techniques of Myocardial Protection for Cardiac Transplantation

S. AZIZ AND A.L. PANOS

INTRODUCTION

Improvements in immunosuppression and pre-, peri-, and post-operative management have resulted in increased survival being obtained after heart transplantation (HTx)[1] (Chapters 43 and 44). Currently used techniques of myocardial protection for preservation of the donor heart allow only limited time for transportation between donor and recipient hospitals. Mild to moderate cardiac allograft dysfunction is not uncommon after HTx. Ischemic times greater than 5 hours are associated with increased need for inotropic support, and increased morbidity and mortality[2] (Chapters 43 and 44). Early failure of the donor heart (primary graft dysfunction) is still responsible for up to 25% of the deaths following HTx and can result from poor donor selection or inadequate organ preservation, or both[3]. The ideal method of preservation is one that will give the longest preservation time while maintaining excellent graft function. Improved methods of organ preservation should therefore demonstrate improved graft function despite a prolongation in procurement time.

Improvements in cardiac allograft preservation could: (a) increase the current 4-hour limit of ischemia; (b) decrease the incidence of primary graft dysfunction; (c) allow time to determine viability of the allograft (Although currently there is no specific test able to predict viability of the graft, future developments using various indirect methods, such as magnetic resonance spectroscopy, may be able to evaluate myocardial metabolism *in vivo*.); (d) enhance donor organ metabolic status at the end of the period of transport and prior to implantation; (e) increase the pool of available donors (by allowing the utilization of less-than-ideal organs); and (f) allow for possible future immunologic manipulation of the donor (e.g. by monoclonal antibodies, gene therapy).

In this chapter we will review the current theories and methods of myocardial protection used during HTx, and touch upon some promising new avenues of research for future development. A further review of experimental work in cardiac storage appears in Chapter 74.

HISTORY OF MYOCARDIAL PRESERVATION

Much has been learned from the principles of myocardial preservation developed for general cardiac surgery, and these have been applied to transplantation (and vice-versa). The efficacy of hypothermia as a means of decreasing myocardial injury during cardiac surgery was first demonstrated in the 1950s by Bigelow, Lewis and Taufic, Swan and others[4-10]. Topical hypothermia was also used as a means of protecting the donor heart during HTx[11,12]. Shumway and Lower were able to demonstrate that topical hypothermia alone was able to provide adequate protection during experimental orthotopic HTx[11]. The Stanford group also demonstrated that excellent results could be obtained using topical cold for routine cardiac surgery[13]. Clinically, the first human-to-human HTx was performed by Barnard in 1967. At that time, because the concept of brain death had not been introduced, the donor heart was not removed until there was electrical and mechanical silence, at which time the donor was placed on cardiopulmonary bypass and cooled prior to explantation of the heart[14].

In the initial period of HTx, in an effort to keep ischemic times to a minimum, only local donors were used, with the procurement being performed in the same hospital in an adjacent operating room. Following extensive experimental work that demonstrated the safety of longer cold ischemic times, workers at the Medical College of Virginia and Stanford University demonstrated the clinical safety of long-distance procurement[15,16].

With the reintroduction of cardioplegia for myocardial protection in cardiac surgery in the 1970s[17-19], this was also used for donor procurement. Following extensive experimental work that demonstrated the safety of longer cold ischemic times, the practice was extended to the clinical arena. In 1978 Thomas *et al.* reported the first successful long-distance procurement of a preserved heart[15]. Watson *et al.* likewise demonstrated the safety of long-distance procurement using hypothermic cardioplegia and storage in cold saline for transport[16]. They reported no differences between locally procured hearts (mean ischemic time 52 ± 12 min) and long-distance-procured hearts (mean ischemic time 154 ± 30 min) with regard to: (a) the

need for postoperative inotropic support, (b) 90-day mortality, or (c) rejection frequency. In another study Billingham *et al.* found that, although there were no functional differences between local and long-distance-procured donor hearts, there were ultrastructural differences between the two groups[20].

In comparison to advances in developing solutions for clinical preservation of other solid organs, progress in the development of solutions for myocardial preservation for HTx has been slow. Experimentally, several investigators have demonstrated the safety of preserving hearts for <24 h. However, clinically, most centers restrict their preservation times to <5 h because of an increase in morbidity and mortality that is associated with more prolonged ischemic times[2]. The reason for this disparity between experimental and clinical findings remains the topic of much discussion and debate.

THEORETICAL CONSIDERATIONS

During periods of myocardial ischemia the myocardium is damaged in a time-dependent fashion because of the imbalance between metabolic demand and substrate supply. This results in depletion of high-energy phosphates, accumulation of waste products, intracellular acidosis, membrane injury, and contractile dysfunction. If the ischemic time is prolonged, these abnormalities will not be corrected even after perfusion is re-established. As Stinson has aptly stated: 'the term "myocardial protection" is really a euphemism for minimizing myocardial injury during cardiac operations that involve an interruption of coronary flow and arrest of ventricular contractions'[21] (see Table 1).

The principles of myocardial protection have been reviewed extensively by others[22–26], but we will recapitulate some of the important highlights. The approach to myocardial preservation can best be summarized by the concept of the 'supply/demand' ratio – i.e. the ability to maintain a balance between the supply and demand requirements of the heart. In HTx, however, once the heart is explanted (and in the absence of an *ex vivo* support system) the donor heart is deprived of any source of supply of energy. The attempt to optimize the supply/demand ratio could involve: (a) supplying nutrients to the heart, or (b) decreasing the metabolic demand.

Enhancing supply: machine preservation

The concept of using *ex-vivo* perfusion to protect organs for transplantation found most applicability in renal transplantation. Although a number of papers have reported the use of *ex-vivo* perfusion for experimental HTx, few centers have ventured into this arena clinically on a consistent basis[27,28]. The obvious theoretical advantages of a continuous perfusion system include supplying substrates and removing metabolic wastes continuously. Robicsek *et al.*[29] and others[30] developed *ex-vivo* autoperfusion circuits for prolonged storage periods. The equipment needed, however, was relatively cumbersome, and this approach was not routinely adopted. Flush perfusion techniques, on the other hand, are simple, cheap and convenient, and therefore have become widely used clinically.

Decreasing demand

Efforts have concentrated upon protecting the heart by decreasing its energy requirements until perfusion is re-established. Historically, hypothermia has been the main method of decreasing myocardial metabolic demand during periods of ischemia, and all clinical methods of cardiac preservation for HTx today use hypothermia. From the moment the heart is deprived of its blood supply its metabolic supply is removed, products of metabolism accumulate, and tissue damage occurs (which is initially reversible but eventually becomes irreversible). By slowing down the rate of metabolic activity, hypothermia reduces the rate of organ deterioration that accompanies ischemia. Although hypothermia slows down the rate of degradation of the tissue, the optimal temperature is not known. Experimental work by Karck *et al.*[31] suggested that hypothermia at 4°C (as compared to 15°C)

Table 1 The stages at which injury to the donor heart may be minimized

1. Prior to explant (following brain death):
   correct effects of endocrine failure (T3, cortisol, insulin)
   optimize donor hemodynamics (volume, electrolytes, hematocrit, temperature)
   decrease inotropic support to a minimum
   administer antioxidants to the donor
2. Donor procurement:
   gentle handling
   prevent cardiac distension
   ensure prompt and efficient delivery of cardioplegia
3. Storage for transport:
   choice of cardioplegic/storage solution
4. Implantation:
   continue myocardial protection (frequent doses of cardioplegia)
   prevent cardiac distension
5. Reperfusion
   'hot shot' prior to re-establishment of antegrade flow
   prevent cardiac distension
   use of monoclonal antibodies against adhesion molecules
   use of leukocyte depletion filters
6. Early postoperative period
   avoid excessive and inappropriate use of inotropes
   avoid hypoxia

prolonged myocardial protection with respect to: (a) ATP preservation, (b) prevention of the fall in intracellular pH, and (c) enhancement of postischemic hemodynamic recovery.

A number of experiments have suggested that surface cooling alone can lower myocardial temperature. However, the cooling may not be rapid or uniform, and surface cooling alone is an inefficient method for reducing the core temperature of the heart. Others have emphasized that cooling should be accomplished as quickly as possible, but too rapid cooling can result in tissue damage.

Although hypothermia retards the development of ischemic injury it has many other effects, many of which can be damaging. The unwanted side-effects include: (a) decreasing enzyme function[32], (b) changing membrane stability[33], (c) calcium sequestration[34], (d) interfering with glucose utilization[35] and ATP generation and utilization[36], as well as (e) changes in pH[37] and osmotic homeostasis, leading to cell swelling[38].

Cardioplegia

Cardioplegic solutions were developed to produce rapid and even cooling of the heart and to enable rapid cessation of cardiac contractility (to rapidly reduce utilization of large amounts of myocardial energy reserves). The administration of cardioplegic solution is akin to the use of flush solutions used in other solid-organ preservation techniques which enable rapid, even cooling, and eliminate blood from the vascular compartment. However, in recent years the concept of using blood cardioplegia has become widespread, and has resulted in improved myocardial preservation. The importance of the chemical composition of the cardioplegic solution is well recognized. Increasingly complex preservation solutions have been developed, with special additives being used to decrease the injury resulting from the numerous insults that occur during procurement, preservation and reperfusion.

Although advances in myocardial protection for HTx have been closely linked to developments in myocardial protection for routine cardiac surgery, there are features that are unique to protection of the cardiac allograft. Once explanted from the donor, during the period of transport there is no source of collateral blood supply and thus a lack of rewarming. This has also limited the applicability of the newer concepts of myocardial protection, such as the administration of continuous retrograde cardioplegia, from being applied during donor heart transportation.

Ischemia and reperfusion injury

HTx by its nature requires a period of obligatory ischemia followed by reperfusion. The previous discussion dealt with methods to decrease this ischemic insult. The important role that free radicals, calcium overloading, neutrophils, adhesion molecules, and platelets play in mediating injury, particularly during reperfusion, has been described. With current technology we are still unable to avoid ischemia/reperfusion injury completely, but with increasing understanding of the mechanisms involved, in there exists the potential to develop further therapeutic interventions.

CURRENT CLINICAL TECHNIQUES OF MYOCARDIAL PROTECTION FOR CARDIAC TRANSPLANTATION

Most centers now use cold flush solutions to stop and cool the donor heart at the time of procurement. The ideal cardioplegic solution should: (a) decrease energy demand, (b) prevent accumulation of toxic metabolites during the period of storage, (c) maintain normal ionic composition and pH, (d) prevent cell swelling and ultrastructural damage to the cell membrane. In addition, it should (e) prevent the development of excessive vascular resistance during storage and upon establishment of reperfusion, (f) minimize the extent of reperfusion injury, and (g) prevent long-term damage to myocyte, interstitium and vasculature.

Many different cardioplegic solutions are used in HTx programs, but a number of surveys attest to the widespread use of cardioplegic solutions of extracellular-type composition (Chapter 74). Because of initial experimental evidence that the University of Wisconsin (UW) solution (an intracellular-type solution) was effective in providing myocardial protection for long periods of time, a number of centers have resorted to use of this solution, with good results. UW solution is said to be effective because it contains a number of cell impermeant agents, such as lactobionic acid, raffinose, and hydroxyethyl starch, that prevent cell swelling during ischemic storage. It also contains glutathione and adenosine, compounds that stimulate recovery of normal metabolism on establishment of reperfusion by: (a) augmenting the antioxidant potential of the organ and (b) stimulating the generation of high-energy phosphates.

Others have reported that improved results are obtained if 2,3-butanedione monoxime (a reversal inhibitor of cardiac contracture) and calcium are added to standard UW solution[39]. Wicomb *et al.* have suggested that a fresh supply of glutathione be added to UW solution prior to its use[40]. During cold storage of human cardiac allografts in UW solution, the expression of major histocompatibility complex antigens and vascular adhesion molecules on endothelial cells and myocardial cells remains unchanged[41]. The possibility that the high potassium content of UW solution could result in endothelial injury has been reported[42–44], and a higher incidence of graft coronary artery disease in patients whose hearts were preserved with UW solution (in comparison to the Stanford cardioplegic solution) has been reported[45]. However, this finding has not been confirmed by other centers that also routinely use UW solution.

OTHER FACTORS AFFECTING GRAFT VIABILITY

It is now apparent that 'protection' of the donor heart begins before its removal from the donor. A number of reports describe the beneficial effects of manipulation of the hormonal environment of the donor. In addition, attention must be focused upon correcting electrolyte, hemodynamic, and temperature parameters prior to and during the procurement process.

The ability to safely wean the donor heart from cardiopulmonary bypass is often the best indicator of the efficiency of the myocardial protection used. However, it must not be forgotten that factors other than preservation can affect the initial function of the cardiac allograft. These may include: (a) the presence of underlying donor cardiac disease (e.g. coronary artery disease or myopathy); (b) injury sustained at the time of trauma (that

resulted in brain death); (c) the deleterious effects associated with brain death; (d) inadequate donor management (e.g. unsuitable volume replacement, inefficient use of inotropic agents, inadequate prevention of hypoxic insults); (e) poor technique of donor procurement; (f) inadequate experience of the anesthetic and surgical teams; (g) suboptimal management of cardiopulmonary bypass in the recipient; (h) suboptimal steps to minimize reperfusion injury; and (i) immune-mediated injury.

The sum total of preservation injury, the aforementioned non-preservation-related injuries and the additional effects of poor donor selection may become manifest in the early postoperative period as difficulty in weaning from cardiopulmonary bypass with the need for high-dose inotropic support, intra-aortic balloon pump counterpulsation or a mechanical assist device.

Effects of brain death

This topic is discussed in Chapter 4, but in view of its relevance to myocardial preservation and its importance with regard to immediate post-transplant cardiac function, brief mention will also be made of it here. It has long been established that cardiac death eventually follows brain death. The state of 'brain death' is an interesting and physiologically unusual state[46–49]. Major changes in cardiac metabolism, histology, and function occur in brain-dead patients, and these changes may be the cause of unexplained cardiac allograft dysfunction after HTx.

Histology

The histologic changes described in brain-dead patients include hemorrhage and myocardial necrosis. Subendocardial hemorrhage is found at autopsy in patients who die of head trauma[50]. Morphological changes were also seen in the hearts of mice that had undergone the intracranial injection of a small amount of blood[51]. Novitzky *et al.* found pathologic changes affecting the myocardium, coronary artery smooth muscle cells, and conduction tissue that appeared to be mediated by the autonomic nervous system in a baboon model of brain death[52,53].

Endocrine

The cessation of brainstem function affects the anterior pituitary gland, leading to decreased ADH production, causing diabetes insipidus in 50–70% of organ donors[54]. Novitzky *et al.* reported that changes in plasma levels of triiodothyronine, cortisol, and insulin occur with brain death[53,55]. Taniguchi *et al.* noted the average time between the diagnosis of brain death and cardiac arrest was 4.3 days[56], but in patients who received hormone supplementation this interval was prolonged to 11.5 days.

Metabolism

Hearts in brain-dead subjects have been found to be energy-depleted, but could be resuscitated with substrate enhancement[57]. There is also an important shift towards anaerobic metabolism resulting in ATP consumption[48].

Function

In an experimental study using rat hearts, Galinanes and Hearse showed that 60 min after brain death a number of indicators of cardiac contractile function decreased by approximately 50%[49,58]. However, once excised and perfused *ex vivo*, the hearts recovered function identically to hearts from animals that had not been subjected to brain death. When hearts from brain-dead animals were excised, stored (6 h at 4°C), and reperfused *ex vivo* with blood, they also recovered a functional capability identical to that of control hearts. These studies indicated that hemodynamic instability in brain-dead individuals may not necessarily be an irreversible phenomenon, and that such hearts could be considered for transplantation. Clinically, a number of echocardiographic reports suggest that septal motion abnormalities may be peculiar to the brain-death state as they improve upon implantation of the heart into the recipient[59].

Cytokines

There is also evidence from clinical studies that donors have an altered state of the cytokine system, with elevated plasma concentrations of interleukin-6, 8 and soluble p55 TNF type 1, and also of C reactive protein[60]. What effect such elevations in cytokine levels have on graft function is not clear. The ability to block the effects of these cytokines would seem worthy of study.

Treatment

The brain-dead state has important metabolic, structural, and functional effects on the donor heart. We may therefore be able to improve the donor heart's metabolic state, possibly by administering hormone therapy before excision[53].

FUTURE AREAS FOR RESEARCH

Future areas for research can be considered to encompass all phases of donor selection and management, and donor heart preparation, excision, transportation, implantation, and reperfusion.

Donor selection

The development of a viability assay which could predict the ability of the heart to assume full function upon reperfusion remains an important goal. Although currently there are no such tests readily available, there is encouraging research using biochemical markers, most notably troponin T[61]. Perhaps other non-invasive predictive tests will become available using non-biochemical techniques, such as NMR spectroscopy or imaging[31,62–65].

Donor preparation

It may be possible to prevent or reverse the myocardial changes that occur with brain death. This might be pursued by the use of better 'cocktails' to correct the hormonal and metabolic state of the donor heart. Blockers of inflammation or free radical

scavengers may prove useful in preventing injuries mediated by the inflammatory system and oxygen free radicals[66–73].

Preservation solutions

Better preservation solutions may be designed to prevent free radical injury, buffer pH changes, provide metabolic substrates, or contain additives that improve preservation.

Transportation

This entire area is fertile for research. Perfusion systems and solutions may be improved to provide 'nutrition' and maybe even 'resuscitation' during transportation. However, newer techniques of *ex-vivo* perfusion, based on microperfusion, hold great promise[74]. Wicomb *et al.* have shown experimentally that hearts can be satisfactorily preserved for <24 h using microperfusion[75].

Organ freezing

The cessation of *all* metabolism in a stored organ could be achieved by freezing. Organ banks could be developed where organs could be frozen for days, weeks, or months until the need arises to use them. Advancements in the field of cryobiology, however, have to date been limited by our inability to mitigate the deleterious effects on the cells of freezing and thawing.

Implantation

Changes in the implantation procedure would center around reduction of the reperfusion injury and, ideally, 'resuscitation' of the transplanted heart. There is evidence that neutrophils play a role in reperfusion injury, and that the depletion of leukocytes by the use of filters may be useful in limiting this injury[76–79]. Alternatively, interfering with neutrophil function by blocking the adhesion molecules that participate in neutrophil activation has proved beneficial in an experimental model[76].

The use of a 'hot shot' of blood cardioplegia, either with or without substrate enhancement, has been advocated by some surgeons. This can be achieved by inserting a cannula into the coronary sinus and starting retrograde perfusion of the heart during the implantation procedure using warm blood cardioplegia[80–83]. Furthermore, such solutions might be better tailored to 'resuscitate' the heart while it is being implanted.

Extending the donor pool

With an increase in experience the initial strict criteria established for harvesting of donor hearts have been liberalized. 'Marginal' donor hearts can now often be used safely. The question has been raised (especially in countries where brain death is not accepted as a definition of death) as to whether hearts that have already arrested can be successfully transplanted. If so, what is the maximum safe period of arrest?

About 20 years ago, experiments under certain conditions demonstrated that canine hearts arrested after exsanguination could be resuscitated if the warm ischemic period did not extend >60 min[84]. If the cause of cardiac arrest was anoxia, resuscitation was less likely to be successful but could still be obtained if the ischemic period was <30 min. More recently, Gundry *et al.* have shown the feasibility of transplanting lamb hearts harvested 30 min after death from exsanguination[85]. Shirakura *et al.* have reported good function of donor hearts harvested from non-heart-beating donors that had been pretreated and cooled by cardiopulmonary bypass prior to heart procurement[86,87].

COMMENT

The ideal preservation method is one that will provide the longest preservation time while maintaining excellent graft function. Improved methods of organ preservation should demonstrate improved graft function despite a prolongation in ischemic time. Myocardial protection of the donor heart plays an important role in determining morbidity and mortality after HTx. Our understanding of the factors that are involved in minimizing cardiac injury during the periods of procurement, storage for transport, implantation, and reperfusion has increased, but remains incomplete. Indeed, progress in heart preservation has been slow when compared with other organs. Unlike other organs the heart must provide *immediate* support upon separation of the patient from cardiopulmonary bypass. Currently, all methods of cardiac preservation continue to use hypothermia to decrease metabolic activity. Better preservation would allow hearts to be procured from further afield. It must not be forgotten, however, that many factors other than preservation can affect the immediate function of the cardiac allograft.

In the future, emphasis should be placed on enhancing our understanding of hypothermia-mediated cell injury and reperfusion injury, and on the development of techniques to decrease both of these insults.

Surgical Technique of Orthotopic Heart Transplantation. I: Standard Approach

D.K.C. COOPER

INTRODUCTION

There are two very different basic operations for performing heart transplantation – *orthotopic*, in which the recipient heart is excised and replaced in the correct anatomical position by the donor heart, and *heterotopic* (the so-called 'piggy-back' heart transplant), in which the donor heart is placed in the right chest alongside the recipient organ, and anastomosed in such a way as to allow blood to pass through either or both hearts. Both procedures, however, have various modifications.

In recent years, orthotopic heart transplantation has been modified to include excision of the right atrium with bicaval anastomosis (rather than anastomosis of the two right atria) and reduction in the remnant of the recipient left atrium – the so-called bicaval or 'total' technique. These 'modifications' (which in the experimental laboratory actually predate[1] the standard technique[2,3], which aimed to simplify the operation), are described in Chapter 25. Heterotopic heart transplantation can be performed to provide support for both recipient ventricles or for only the left ventricle. These techniques are outlined in Chapter 37.

In this chapter the *standard technique* of orthotopic heart transplantation that has been used successfully in clinical heart transplantation for almost 30 years will be illustrated.

With any heart transplant, ideally the recipient operation should not be begun until the donor has been carefully assessed by the transplant surgeon, and found to be suitable for transplantation. Whenever there is doubt, e.g. when there is the possibility of cardiac injury from chest trauma, the recipient operation should certainly be delayed until the donor chest has been opened and the heart inspected.

The basic technique of orthotopic heart transplantation was developed in the research laboratory in the late 1950s and early 1960s[1] (Chapter 18). It was the work of Lower and Shumway in 1960[2] which established the operation as a successful procedure in the experimental animal. The operation was first attempted clinically by Hardy and his colleagues in 1964[3] and by Barnard in 1967[4]. In 1968, Barnard[5] contributed a small but significant modification to the operative technique whereby the incision in the right atrium of the donor heart was extended from the opening of the inferior vena cava (IVC) into the base of the right atrial appendage, and not into the superior vena cava (SVC), thus avoiding the region of the sinoatrial node. The operation has remained essentially unchanged since then, and is the operation of choice in the majority of centers performing heart transplantation today.

DONOR HEART EXCISION

Heart excision is almost always part of multiorgan retrieval (and will be described as such below). The needs of the surgeons retrieving other organs must be considered at all times. Acute or unexpected failure of cardiac action may result in loss of all donated organs. Good communication between the various surgical teams is essential if retrieval of the various organs is to be satisfactorily coordinated.

With the subject supine, a median sternotomy is performed and the pericardium opened longitudinally. The heart is inspected in at-risk donors for external signs of injury caused by trauma or external cardiac massage. The coronary arteries should be palpated to exclude obvious coronary disease. The contractions of the ventricle should be observed closely and, if weak or irregular, consideration should be given to the cause and to means of improving ventricular performance.

The ascending aorta is dissected from the pulmonary artery to allow subsequent application of a cross-clamp. The SVC is mobilized up to the azygos vein to allow SVC ligation cephalad to the sinus node. Two heavy ties are placed around the SVC, but not ligated at this stage. The IVC is mobilized. (Preparations by the liver surgeons usually take longer than preparation of the heart, and are completed at this stage.) The donor is fully heparinized (25 000–30 000 units intravenously). A cannula for infusion of cold cardioplegic agent is inserted into the ascending aorta, and is maintained in place by a purse-string suture and 'snugger' or 'snare' so that it does not have to be held by one of the surgical team, thus releasing all available hands for more important activities. If the liver is to be procured, and if IVC blood is not to be drained retrogradely, the right pleural cavity is opened from sternum to IVC to allow drainage of inferior vena caval blood when the thoracic IVC is subsequently divided.

When all the other surgical teams are fully prepared, excision of the heart can proceed. The SVC is doubly ligated (or suture ligated or stapled) and divided between the ligatures. (Any indwelling central venous pressure cannula must be withdrawn high into the SVC by the 'anesthesiologist' before this vessel is ligated and divided.) The IVC is divided at the diaphragm, completing inflow occlusion, and decompressing the right side of the heart. Inferior vena caval blood from the liver (together with the liver perfusion solution) drains largely into the right pleural cavity, but it is essential to have good suction available to ensure that neither the liver perfusion solution nor warm blood contaminate the heart or interfere with the surgical field in which the cardiac surgeon is working. It is convenient to introduce a suction catheter into the IVC to avoid blood obscuring the operative field in the pericardial cavity. (If the liver is not being procured, the IVC can be clamped at the diaphragm before it is divided.) One or more pulmonary veins are incised or divided to decompress the left side of the heart. (If the lung is being procured, the left atrial appendage is opened to allow this decompression.) Adequate decompression of the heart is essential before the aorta is cross-clamped. (If the aorta is cross-clamped first, the heart may become distended and considerable injury may occur to the myocardium.) If an arterial line is in place, the pulse wave should be lost, indicating that the left ventricle has emptied. The ascending aorta is then cross-clamped at the level of the brachiocephalic (innominate) artery, and cardioplegic solution (approximately 10 ml/kg at 4°C, or 1 liter) infused into the root of the aorta. At least 1–2 liters of cold saline (at 4°C) are poured over the heart to cool it rapidly. (Perfusion of the lungs, liver and kidneys is also initiated.)

The pressure in the aorta during cardioplegia infusion should not exceed approximately 100 mmHg. This can be achieved by placing the bag containing the cardioplegic agent in a pressure bag, pressurized to 300 mmHg; experience has shown that this results in an aortic pressure in the desired range. Frequent palpation of the ascending aorta by the surgeon allows approximate estimation of the aortic pressure, and the infusion pressure should be adjusted if the pressure in the aorta becomes too high or too low. During infusion, the heart should be gently massaged at intervals to ensure adequate decompression is maintained. Cardioplegic infusion is usually complete within 3–5 minutes (although infusion of the lung preservation solution into the pulmonary artery may take longer).

During the ischemic period in which the heart is transferred to the recipient there will be no cardioplegic washout from collateral blood flow (as occurs to a cardioplegically arrested heart during open-heart surgery). It is theoretically, therefore, only necessary to give sufficient cardioplegic agent to bring about arrest of the heart. The cardioplegic infusion, however, also contributes towards rapid cooling of the myocardium, and it is therefore our policy to infuse approximately 10 ml/kg (500–1000 ml) even if the anticipated ischemic period is expected to be short.

Once the cardioplegic (and pulmoplegic) agent has been administered, the topical cold saline is sucked out of the pericardial cavity, and section of the four pulmonary veins is completed. (If one or both lungs are being retrieved then the lines of incision into the donor heart should be around the left or right pulmonary vein orifices, allowing a cuff of left atrium to be retained with the pulmonary veins (Chapter 48). Division of the aorta as high as possible, immediately proximal to the cross-clamp, and of the pulmonary artery at its bifurcation (or at the origins of its main right and left branches) completes division of the major vessels.

The apex of the heart is then lifted anteriorly, and the mediastinal tissue posterior to the atria and major vessels is divided, allowing the heart to be removed from the pericardial cavity. The approximate time taken from ligation of the SVC to completion of excision of the heart is usually 5–10 minutes.

PREPARATION OF DONOR HEART

The heart is placed in a bowl of cold (4°C) saline while it is prepared for insertion into the recipient.

The tissue between the orifices of the four pulmonary veins on the posterior aspect of the left atrium is excised, leaving one large opening (Figure 1). The edges of the left atrium usually require trimming at the time of insertion into the recipient. It is wise to inspect all four cardiac valves to exclude the presence of traumatic injury or unexpected conditions such as bacterial endocarditis[6]. (The aorta and pulmonary artery should not be shortened at this stage, as it is preferable to wait to trim them to the ideal lengths when these vessels are to be anastomosed in the recipient.) The right atrial cavity is opened, beginning posterolaterally at the IVC orifice and continuing the incision into the base of the right atrial appendage, thus avoiding the areas of the coronary sinus and the sinoatrial node[5] (Figure 2). The atrial septum is inspected for the presence of a patent foramen ovale (PFO) or atrial septal defect. Unless large, it is not necessary to close a PFO.

The heart is stored in normal saline in ice for the period of transportation. It is usual to place the heart in a bag containing 1 liter of normal saline, to place this in turn in another bag containing a further liter of normal saline, and this into a

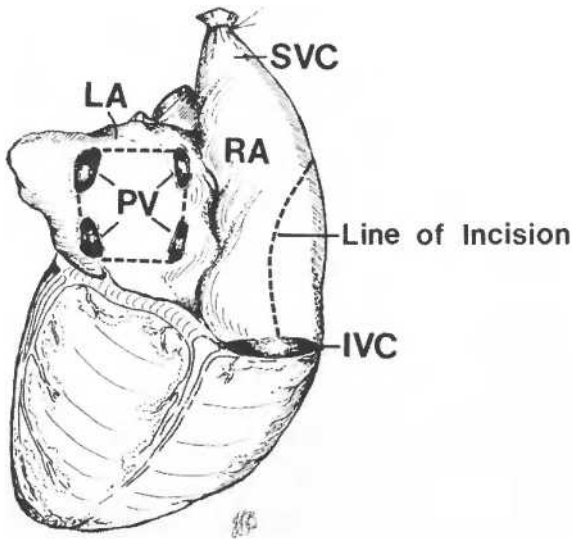

Figure 1 Excised donor heart (posterior view), showing lines of incision. (Abbreviations used in figures in this chapter are: LA = left atrium; RA = right atrium; SVC = superior vena cava; IVC = inferior vena cava; PV = pulmonary vein; RV = right ventricle; PA = pulmonary artery; AO = aorta; LV = left ventricle)

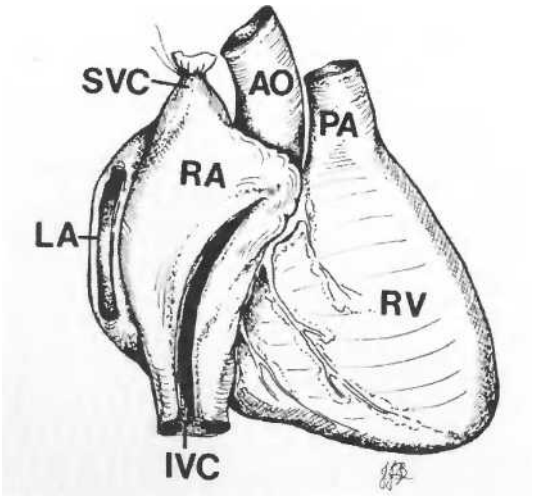

Figure 2 Donor heart (right anterolateral view) prepared for implantation

third bag containing one liter of normal saline. When these bags are placed in ice, the heart is protected from freeze injury during transportation.

The heart can then be transferred to the surgical team preparing the recipient.

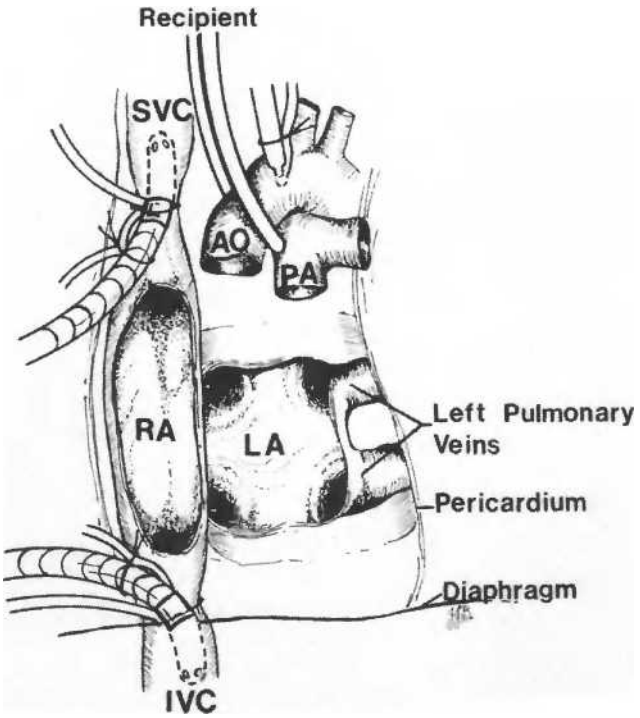

Figure 3 View of recipient pericardial cavity after excision of the recipient heart

THE RECIPIENT OPERATION

When no previous cardiac surgery has been undertaken, preparation of the groin is unnecessary. With the patient lying supine, a median sternotomy is performed, the pericardium opened longitudinally, and its edges retracted. If the patient has undergone previous cardiac surgery there are likely to be adhesions between the heart and pericardium or posterior surface of the sternum. Dissection of a poorly functioning heart under such circumstances may require considerable handling, and acute cardiac failure may intervene, placing the life of the patient at risk. It is therefore wise to prepare the groin in case access to the femoral vessels is required for urgent initiation of cardiopulmonary bypass. In hemodynamically unstable patients it is preferable to actually prepare the femoral vessels for urgent cannulation if necessary. If the femoral artery and vein have been prepared, heparin can be given and the vessels cannulated rapidly, allowing pump-oxygenator support to be begun. The dissection of the heart can then be completed without undue urgency. When this has been achieved it is usual to cannulate the SVC and IVC (in addition to the femoral vein).

Initiation of cardiopulmonary bypass

After heparinization, cardiopulmonary bypass (CPB) is initiated via cannulae inserted into the ascending aorta at or near to the level of the brachiocephalic artery, and into the SVC and IVC via the lateral wall of the right atrium (Figure 3). Snares (snuggers) or clamps are placed around the SVC and IVC to bring about total CPB. Body cooling to at least 28°C, and possibly lower (26°C), helps prevent early rewarming of the donor heart as it lies in the pericardial cavity during insertion. The aorta is then cross-clamped immediately proximal to the aortic cannula.

Excision of recipient heart

The heart is excised by dividing the right and left atrial walls (close to the atrioventricular groove) and atrial septum, leaving a cuff of atrial wall to allow easy suture of the donor heart. Both atrial appendages should be excised to prevent thrombus formation occurring in these cavities after transplantation. The aorta and main pulmonary artery are divided as close to their respective valves as possible (Figure 3). Subsequently these vessels may be trimmed before being anastomosed to their counterparts of the donor heart.

In essence, therefore, only the ventricles have been excised, with a short cuff of the two atria.

The chronological order of division of these structures is unimportant, but a simple sequence is: (a) free wall of right atrium; (b) free wall of left atrium, excluding the superior wall posterior to the origins of the aorta and pulmonary artery; (c) pulmonary artery, (d) aorta, (e) (after retracting the proximal aorta and pulmonary artery anteriorly) the remaining superior wall of the left atrium, and (f) the atrial septum.

Insertion of donor heart – order of anastomoses

The order of anastomoses of the various chambers and vessels followed by most groups for many years was: (a) left atrium (LA), (b) right atrium (RA), (c) pulmonary artery (PA), (d) aorta (AO). However, this delayed reperfusion of the donor heart until

the operation was completed by the performance of the aortic anastomosis. In recent years the desire to reperfuse at an earlier stage, and thus reduce the ischemic time, has led to variations of this sequence. The aortic anastomosis can, therefore, be carried out immediately after completion of the left atrial anastomosis. Air needles can be inserted in the apex of the left ventricle and aorta, the aortic cross-clamp can be removed, and the myocardium can be perfused while the pulmonary artery and right atrial suture line are performed.

Anastomosis of the pulmonary artery can be slightly difficult under such circumstances because: (a) access to the pulmonary arteries is partially obscured by the aorta, and (b) blood return from the coronary sinus to the donor pulmonary artery (via the right ventricle) may obscure the operative field. To avoid these additional problems the pulmonary artery anastomosis (which takes only a few minutes) can be performed before the aortic, leaving only the right atrial anastomosis to be carried out while reperfusion is continuing. Coronary sinus return may obscure the right atrial anastomosis in the region of the IVC, but this can be avoided by adequate suction.

The latter sequences (LA, AO, PA, and RA, or LA, PA, AO, and RA) have been the ones of choice (depending on the individual anatomy and need to reduce the ischemic time) at our center for the past several years. However, in this chapter the sequence used in the original technique (LA, RA, PA, AO) will be illustrated.

Anastomosis of left atria

The donor heart is placed (or held by an assistant) over the left side of the divided sternum, parallel to the remnants of the excised recipient heart. The donor heart is rotated 90–180° to the left so that its posterior surface faces anteromedially (towards the surgeon if he or she is standing to the right side of the table); the free walls of both recipient and donor left atria will then lie adjacent to each other (Figure 4). Using a double-ended 4/0 polypropylene suture, the left atrial walls are anastomosed by a continuous suture, beginning at the base of the donor left atrial appendage and at a point close to the caudal end of the recipient left superior pulmonary vein (Figure 4). The suture can be tied immediately after drawing the heart into the pericardial cavity or, alternatively (if it is chosen not to ligate the suture), at a convenient stage the donor heart is drawn down into the pericardium and the suture tightened. The suture is continued around the superior and inferior borders of the left atrium on to the atrial septum, and tied in the middle of the septum (Figure 5).

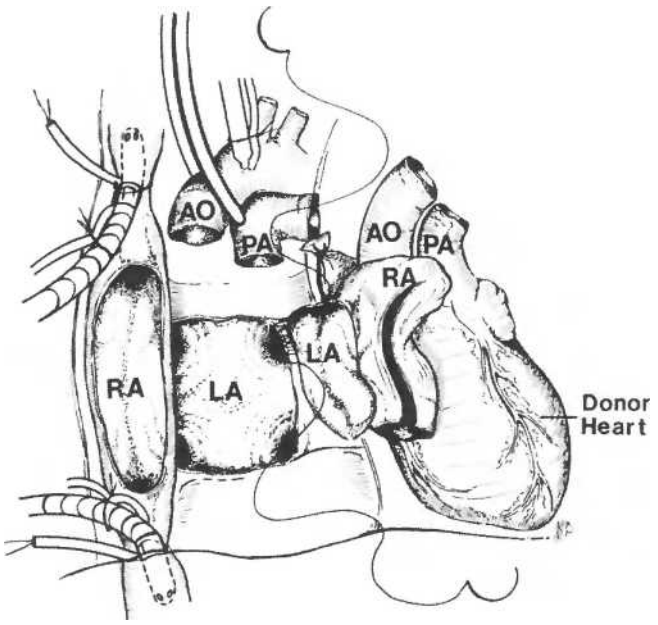

Figure 4 Donor and recipient hearts, showing the beginning of the anastomosis between the two left atria

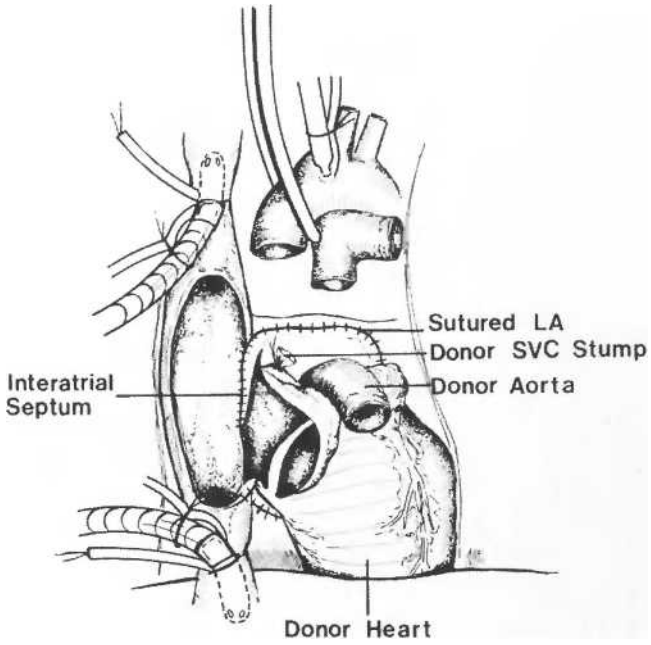

Figure 5 Completed left atrial free wall suture line; the anastomosis between the two septa is being performed

It is essential to maintain myocardial temperature as low as possible, preferably below 15°C, throughout the ischemic period, though tissue damage from freezing must be avoided. Between the performance of each suture line, therefore, the pericardium should be temporarily irrigated with cold saline to maintain a low myocardial temperature, or, ideally, a system of continuous myocardial cooling should be utilized. (Signs of ventricular myocardial activity rarely occur, but if such activity is seen or detected on the electrocardiogram, then further cardioplegic agent should be administered.)

At this stage, as discussed above, if it is decided to minimize the donor heart ischemic time, the surgeon can immediately progress to the aortic anastomosis (Figure 6).

Anastomosis of right atria

The two right atria are anastomosed using a double-ended suture of 4/0 polypropylene (or of 5/0 polypropylene if the right atrial walls are particularly thin). The suture is initially placed at the mid-point of the donor septum and at a convenient point in the

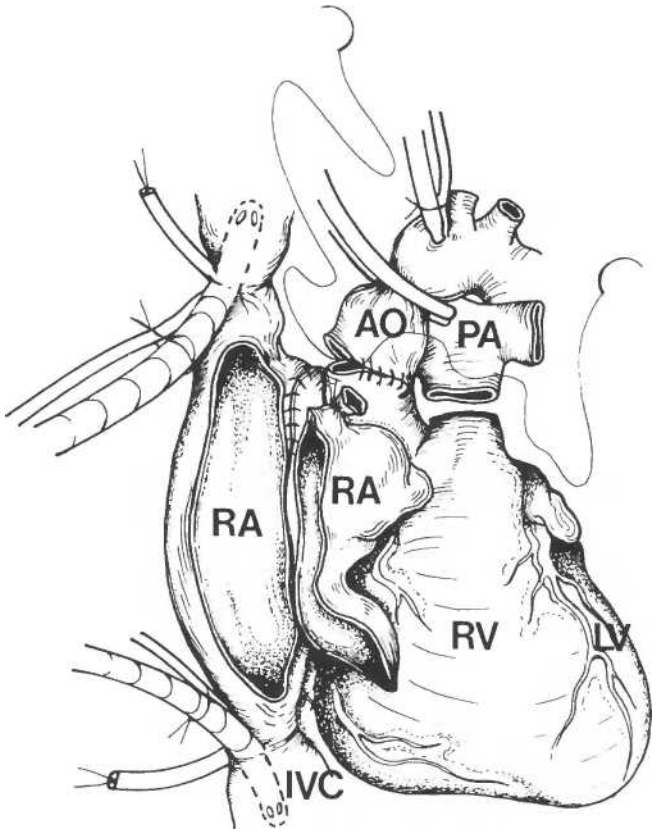

Figure 6 Alternative approach that can be utilized to minimize the donor heart ischemic time. The left atrial anastomosis has been completed. The aortae are being anastomosed, after which the aortic cross-clamp can be removed and the myocardium reperfused. The pulmonary artery and right atrial anastomoses can be performed while reperfusion is continuing

posterior lip of the incision in the recipient right atrium (usually slightly caudal to the mid-point). The anastomosis is continued first inferiorly, as this is the more difficult area in view of the small cuff of recipient right atrium which remains in the region of the IVC. Subsequently, the superior anastomosis is completed, and the two ends of the suture (inferior and superior) tied at the mid-point of the right atrial free wall (Figure 7). The atrial septum has therefore been sutured twice, once on the left atrial side and once on the right.

Anastomosis of pulmonary arteries

The two pulmonary arteries are then trimmed to their required lengths and anastomosed using a continuous suture of 4/0 polypropylene (Figure 8). It is important to trim the pulmonary arteries to the correct length. If they are left too long, kinking of the pulmonary artery can occur after anastomosis, and can be partially obstructive to blood flow.

Anastomosis of aortae

The aortae are similarly trimmed and anastomosed by continuous suture using 4/0 polypropylene (Figure 8).

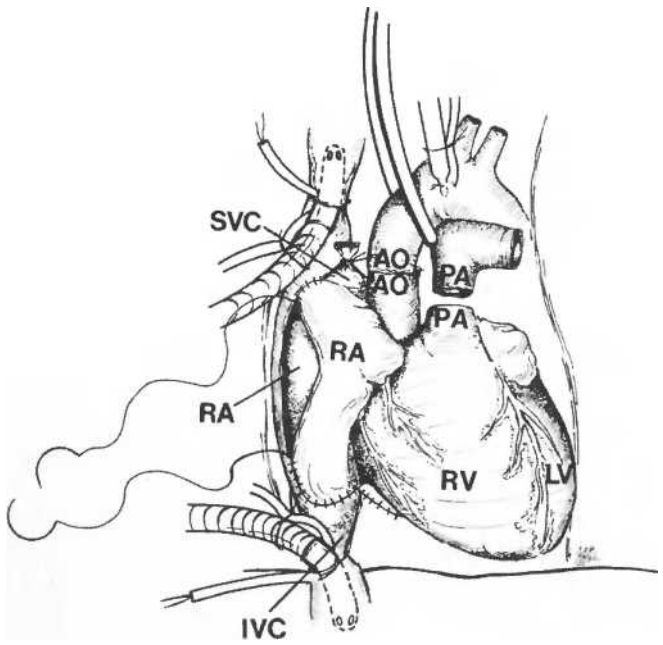

Figure 7 The septal anastomosis has been completed; the free walls of the two right atria are being anastomosed

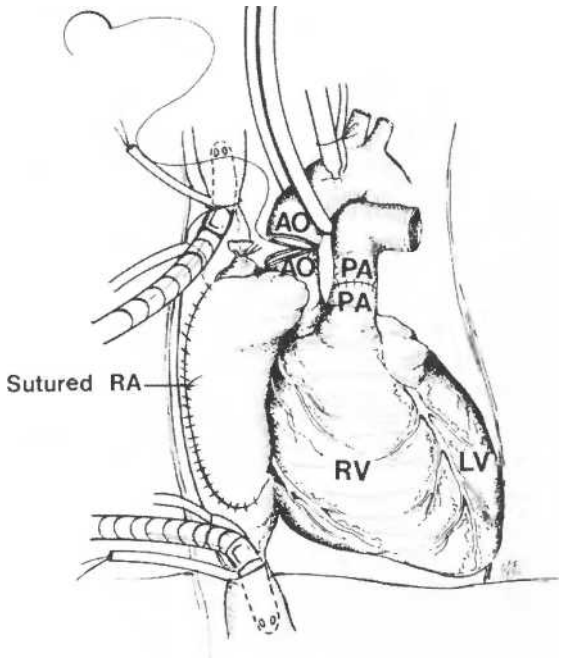

Figure 8 The right atrial and pulmonary artery suture lines have been completed; beginning of aortic anastomosis

Air needles are then placed in the apex of the left ventricle, anterior wall of the right ventricle, ascending aorta and main pulmonary artery. (Additionally, the left atrial appendage can be incised.) The SVC and IVC snares or clamps are released and the heart is gently massaged to expel air from the ventricles and major vessels. The lungs should be gently ventilated to increase the venous return to the left side of the heart, thus expressing

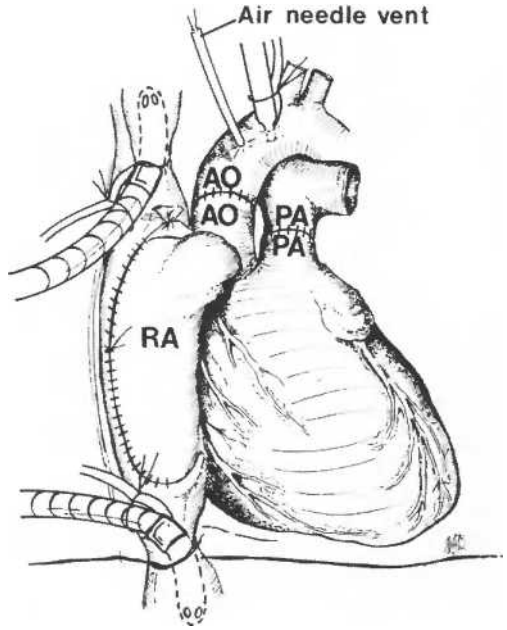

Figure 9 The aortic anastomosis has been completed and the aortic cross-clamp removed. An aortic air needle vent has been inserted. Similar needle vents should be placed in both ventricles and main pulmonary artery

further air, though care must be taken to ensure that the heart is not over-distended. The aortic cross-clamp is then released, allowing the coronary arteries of the donor heart to be perfused once again with oxygenated blood (Figure 9). Further efforts are made to expel air from both ventricles and major arteries.

Total body rewarming can now begin. Ventricular pacing wires are routinely applied in case temporary heart block or bradycardia ensues; in such cases the ventricles are paced to stimulate ejection of blood and ventricular decompression. A period of asystole is, in fact, not uncommon, particularly if the ischemic time has been prolonged. Temporary pacing may therefore be required. In many cases, however, vigorous ventricular fibrillation or spontaneous coordinated myocardial contractions occur. If ventricular fibrillation is present, electrical defibrillation will be necessary. Further vigorous efforts to expel air from the cavities of the heart should then be repeated. Until coordinated contractions are sufficient to eject blood and thus decompress the ventricles, the heart should be manually decompressed gently at intervals if distension occurs.

In our experience it is advisable to begin an inotropic infusion before discontinuation of cardiopulmonary bypass (CPB). Our own choice is isoproterenol, as this is the most efficient at increasing cardiac rate. A rate of 110 beats/minute is probably the most efficient in the early postoperative period as the donor heart that has been ischemically stored is more dependent on rate than stroke volume for its cardiac output. The infusion rate can be modified as necessary when cardiac function is assessed post-CPB. Many of these patients, particularly those who have been in hemodynamic distress pretransplantation, remain significantly vasodilated in the early post-transplant period, leading to difficulty in obtaining an acceptable systemic blood pressure. A low-dose phenylephrine (neosynephrine) infusion can be beneficial at such a time, and if doses of less than approximately 1.5–2.0 $\mu g\ kg^{-1}\ min^{-1}$ are infused, it has not been found to be detrimental to renal blood flow. By providing a little vasomotor tone, such doses of phenylephrine may significantly increase blood pressure.

It has been our policy to provide at least 30–60 minutes of pump-oxygenator support after release of the aortic clamp, to allow full recovery of the donor heart from its ischemic episode, before challenging it with responsibility for support of the circulation. During this period a careful check for bleeding is made on all suture lines, and further sutures inserted if necessary.

Discontinuation of pump-oxygenator support

When myocardial function is clearly satisfactory, and adequate rewarming has taken place, the ventricular and pulmonary artery air needles are removed, and their insertion sites oversewn with 4/0 or 5/0 polypropylene. The SVC cannula is withdrawn into the right atrium, and the IVC cannula removed. CPB is discontinued, and, after a few minutes observation, the aortic air vent is removed and its site oversewn. If cardiac performance is satisfactory, then the aortic and SVC cannulae are removed and protamine sulphate administered (Figure 10).

Two drains are inserted, one into the pericardial cavity posterior to the heart and the other into the anterior mediastinum; the pericardium may be left entirely open, though it has been our policy to close it partially, particularly over the aorta, as this provides a barrier to sternal infection tracking posteriorly to the region of the aortic suture line. Complete closure, even when the pericardial cavity is very large, should probably be avoided as a safeguard to help ensure that early or late tamponade does not occur. The sternum is reunited with at least six stainless-steel wire or other strong sutures, and the tissues anterior to the sternum are repaired.

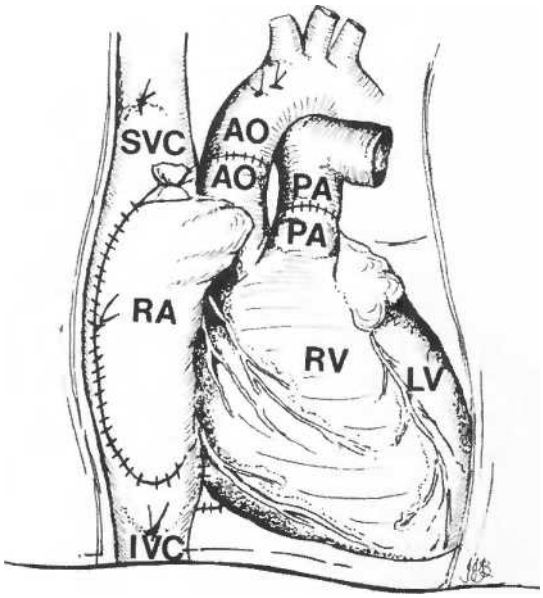

Figure 10 Completed operation. Arterial and venous cannulae have been removed

COMMENT

The two potential major complications of this operation are bleeding, in view of the extensive areas of anastomosis, and systemic air emboli. Great care must be taken to dispel all air from the left atrial and ventricular cavities before the donor heart resumes coordinated contractions after reperfusion.

Every effort must be made to maintain donor myocardial temperature as low as possible (yet avoid freezing injury) during transfer of the heart from donor to recipient, and this should be continued until blood reperfusion is commenced. The limitations of simple hypothermia and other storage methods in maintaining myocardial viability are discussed elsewhere (Chapters 23 and 74).

Unfortunately, inadequate donor heart function, or even nonfunction, is still reported, and may be a consequence of the effects of the agonal period or brain death on the myocardium, or result from inadequate preservation during transportation. If neither inotropic or intra-aortic balloon support retrieve the situation, then the only options open are to continue pump-oxygenator support or provide some other form of mechanical assistance until a second donor heart becomes available. Although rarely necessary, on occasion we have found the intravenous administration of triiodothyronine (T_3) to the recipient to be beneficial when all other measures had failed[6]. This form of therapy, the background to which is discussed in Chapter 4, remains controversial however.

Surgical Technique of Orthotopic Heart Transplantation. 2: Bicaval 'Total' Approach

G. DREYFUS

INTRODUCTION

Since 1960, orthotopic heart transplantation (OHT) has been performed according to the technique of Lower and Shumway[1] (Chapter 24). Barnard introduced a small but useful modification whereby the sinoatrial node could be more readily avoided by opening the right atrium from the inferior vena cava to the right atrial appendage (Chapter 24). In 1990, Reitz[2] introduced the domino procedure by using the native heart of a patient undergoing heart–lung transplantation. This was the first approach to bicaval anastomosis with end-to-end anastomoses of both superior (SVC) and inferior (IVC) venae cavae. In 1989 Yacoub and Banner[3] had reported modifications to the standard technique by removing both native atria. Finally, in 1991 the 'total' orthotopic heart transplant technique was first reported[4].

There are therefore two different methods of performing OHT: (a) the standard technique, which can be considered as a biventricular transplant (Chapter 24) and (b) the alternative technique of total OHT, which is an anatomical transplant of both atria and ventricles. In this chapter the major differences in the technique of total OHT (when compared with the standard procedure) will be outlined. (For other details, the reader is referred to Chapter 24)

DONOR ASPECTS

Donor heart excision

Harvesting of the donor heart is very slightly modified from the standard technique, as both venae cavae should be maintained as long as possible. Both SVC and IVC should be completely transected, the SVC intrapericardially just below the azygos vein and the IVC proximal to the diaphragm. Just before clamping the aorta, one pulmonary vein should be incised to decompress the left side of the heart. The aorta and pulmonary artery should then be transected, leaving the donor heart attached only by the pulmonary veins. The heart is then elevated, allowing direct vision of the remaining pulmonary veins, which are transected intrapericardially at their entry into the left atrium (Figure 1).

Multiple organ procurement

Multiple organ procurement involving procurement of the lungs or liver may impair the integrity of the left atrium or IVC, respectively. If the liver is being excised, the donor IVC is often divided near or at the junction of the IVC with the right atrium. The donor free margin of the IVC (for subsequent suture to the recipient) may therefore consist of right atrial wall. The length of donor IVC available for anastomosis is never a problem as this anastomosis (in the recipient) can be performed between the right atrium (RA) of the donor and the remnant of the recipient IVC/RA (being more of an atrio-atrial anastomosis than a cavo-caval anastomosis). Therefore, if the liver team requires a long IVC, this does not preclude total OHT.

Problems can arise, however, with retrieval of a single lung or both lungs from the same donor. Depending on the lung transplant surgeon's skills and habits, the amount of left atrial cuff removed with the lung(s) will vary. This is obviously of the utmost importance to the possibility of performing total OHT, because sufficient posterior left atrial wall must remain with the heart to allow the total technique, even if the origins of the pulmonary veins have been excised with the lungs. However, at our own center, this technique aspects has never made the total OHT technique impossible to perform.

Preparation of the donor heart

In contrast to preparation of the donor heart for the standard procedure, both the SVC and the IVC are left open, with neither being ligated or oversewn. When the heart is harvested in the absence of lung retrieval, the left atrium clearly shows the origins of the four pulmonary veins (Figure 1). The bridging tissue between the left superior and inferior pulmonary veins is resected (as it is on the right), thus creating single left and single right pulmonary vein orifices (Figure 2). These orifices should be at least as wide as the mitral annulus in order to avoid restriction after anastomosis. The aorta is dissected from the pulmonary artery. Our own preference is to transect the pulmonary artery

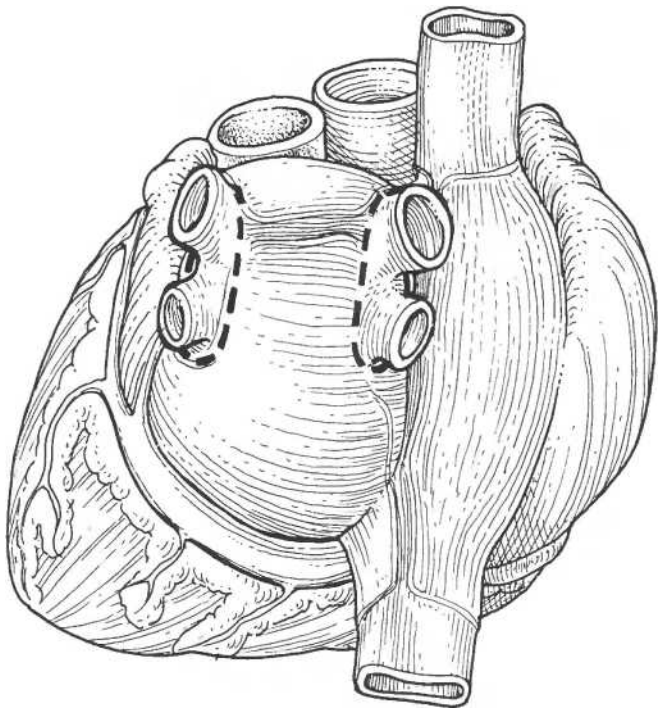

Figure 1 The excised donor heart. Note the integrity of all four pulmonary veins and the lengths of both superior and inferior venae cavae. The dotted lines demarcate the tissues to be excised to create two pulmonary venous orifices

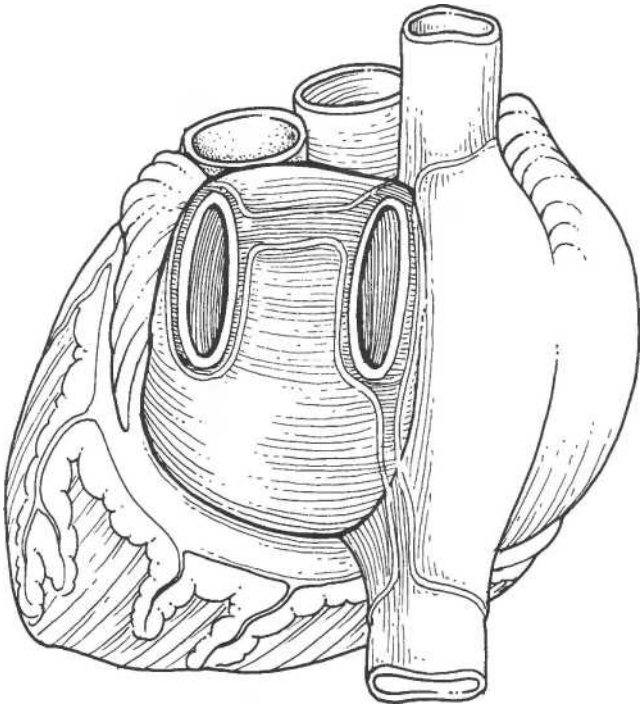

Figure 2 Preparation of the donor left atrium. The tissue bridge between the superior and inferior pulmonary veins is resected on each side, creating large right and left pulmonary orifices.

approximately 1 cm distal to the pulmonary valve (in order to avoid kinking after anastomosis to the recipient pulmonary artery).

THE RECIPIENT OPERATION

Cardiopulmonary bypass is initiated in a standard manner except that the SVC should be cannulated about 2 cm above its entry into the right atrium. The IVC should be cannulated via the lateral wall of the right atrium as close as possible to the diaphragm. After institution of cardiopulmonary bypass, both venae cavae are snared (snugged).

Excision of recipient heart

Excision is carried out as a two-step procedure. Firstly, the right atrium is opened as posterior as possible, close to both cannulae. The atrial septum is incised, which allows the left ventricle to

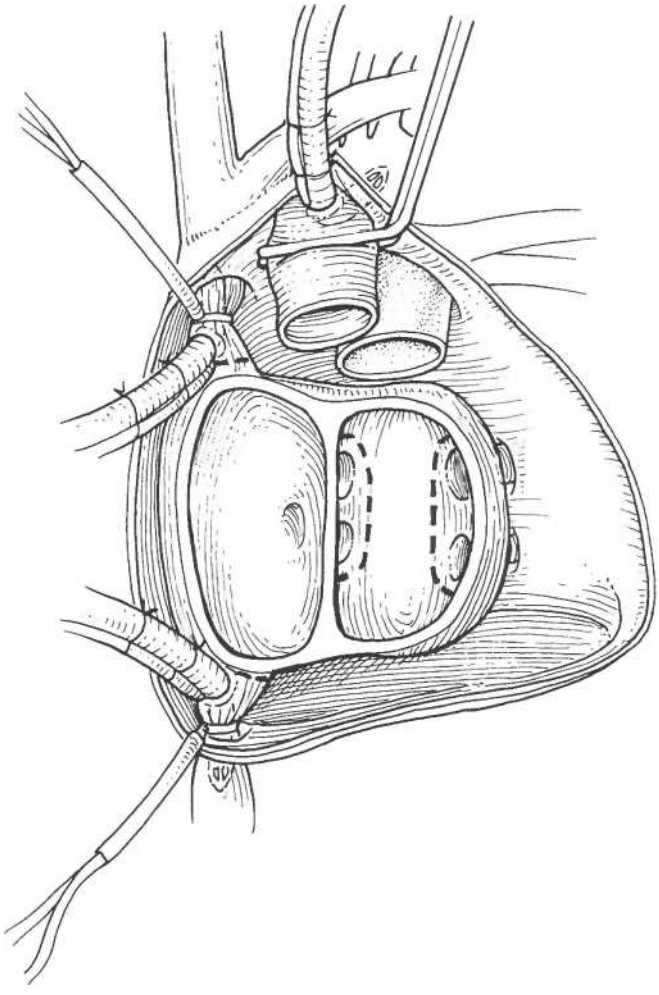

Figure 3 Excision of recipient heart. As a first step the heart is removed as for a standard orthotopic heart transplantation. This consists of excising both ventricles and all four valves. The dotted lines demarcate the left atrial venous cuffs that will remain *in situ*

empty via the mitral valve and left atrium. The aorta and pulmonary artery are transected. Finally, the left atrium is trimmed posterior to the left atrial appendage (Figure 3). At this point the recipient explantation follows that of the standard OHT technique.

Secondly, the posterior walls of both atria are excised. On the right this is performed by transecting both the SVC and IVC at their junctions with the right atrium. The right atrium should not be divided too close to the IVC cannula, as this may make the subsequent anastomosis with the donor IVC difficult. Therefore, the IVC cuff is, in fact, a right atrial cuff preserving at least 6–10 mm of atrial tissue beyond the IVC cannula. The right atrium remains attached only by the residual atrial septum. The posterior wall of the left atrium is freed from its pericardial attachment. This allows direct vision of the origins of the right and left pulmonary veins. The posterior aspect of the left atrium is trimmed, leaving a cuff on each side which includes the origins of the superior and inferior pulmonary veins. On the right side, the redundant left atrial wall is removed together with the remains of the atrial septum (Figure 4).

If the native left atrium is particularly large (as in dilated cardiomyopathy), or when there has been harvesting of a lung or both lungs from the same donor, care must be taken to leave large cuffs around the pulmonary veins.

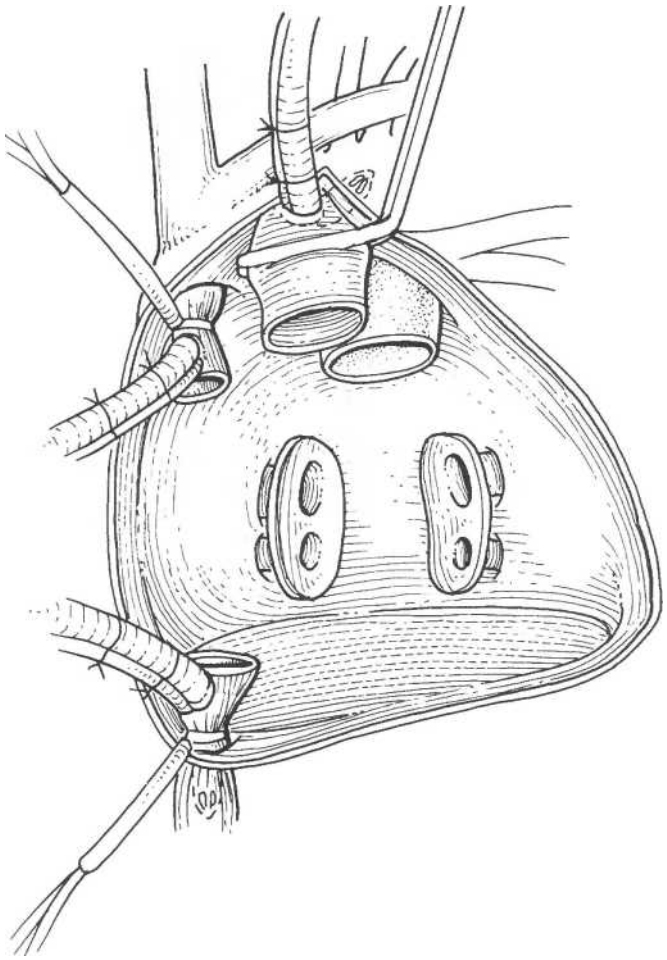

Figure 4 Excision of recipient heart. As a second step the remnants of both right and left atria are excised, leaving only two pulmonary venous cuffs and two caval cuffs

Anastomosis of left atria

As it is the most posterior of the suture lines that need to be performed, the first anastomosis is that between the left pulmonary venous orifice of the donor left atrium and the cuff around the recipient left pulmonary veins. To perform this, the donor heart is placed in the anatomic position. Two stay sutures are inserted to identify the cranial and caudal aspects of the rim of the donor left pulmonary venous orifice and of the corresponding recipient left atrial cuff. With the donor heart placed on its right side, and with its apex directed towards the right side of the pericardium (i.e. towards the surgeon, who is standing on the right side of the patient), the posterior wall suture line is performed in an end-to-end fashion (Figure 5). A running 5/0 polypropylene suture is begun inferiorly. Once the posterior wall is completed, the anterior wall suture line is carried out in the same manner.

The donor heart is then rotated to the left. Anastomosis of the recipient right pulmonary venous cuff with the rim of the donor right pulmonary venous orifice is performed in the same way as on the left (Figure 6).

These two anastomoses have to be performed with great care, as access to this region will be poor once the operation has been

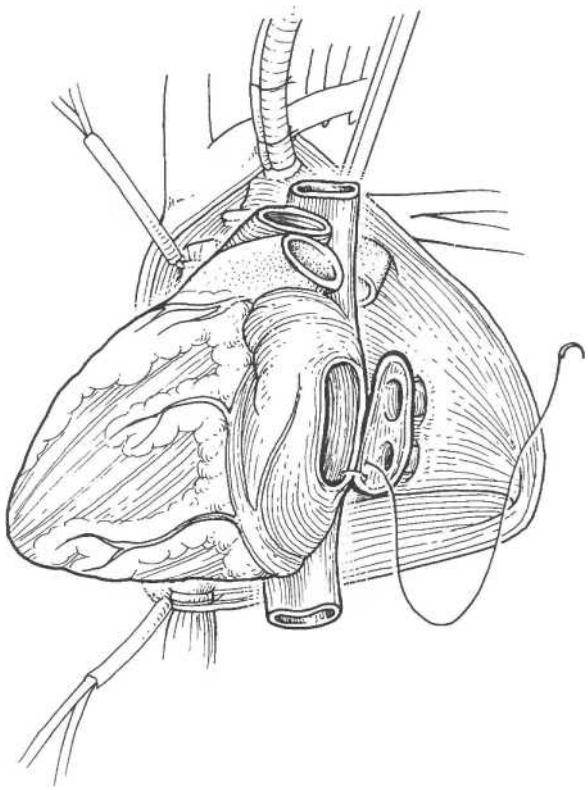

Figure 5 Anastomosis of left atria. The donor heart is rotated onto its right side with its apex directed to the right. The suture line begins inferiorly on the posterior aspect of the recipient left pulmonary venous cuff and rim of the donor left pulmonary venous orifice.

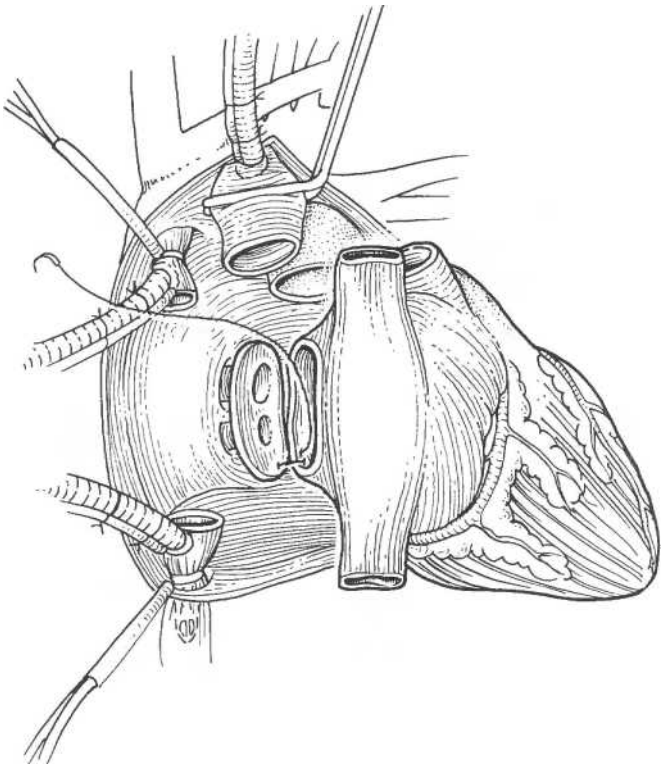

Figure 6 Anastomosis of left atria. The donor heart is rotated to the left. Anastomosis of the left pulmonary venous orifices has been completed. The recipient right pulmonary venous cuff is being anastomosed to the rim of the donor right pulmonary venous orifice.

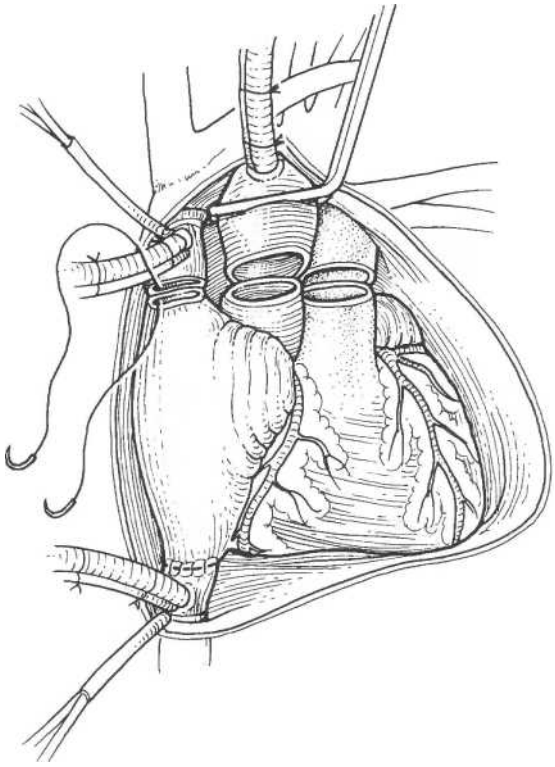

Figure 7 Anastomosis of venae cavae. The anastomoses of the venae cavae are performed in an end-to-end fashion. The IVC anastomosis is completed, and the SVC anastomosis is beginning

completed. However, if an extra suture requires placement, it has always been possible to gain access to the left atrial anastomosis either by retracting the ascending aorta forward or to one side, or by elevating the left ventricle.

Anastomosis of venae cavae

Both the SVC and the IVC are anastomosed in an end-to-end fashion (Figure 7). The IVC anastomosis is more of an atrial anastomosis than a caval anastomosis, as cuffs of right atrial tissue have been left both in the recipient and with the donor heart. This anastomosis is performed using a running 4/0 polypropylene suture. The recipient contribution to the SVC anastomosis is the recipient SVC, but the donor contribution can be either SVC or SVC-entry site into the right atrium (depending on the extent of dilatation of the native right heart and the size of the donor heart). (The presence of atrial cuffs in the recipient and on the donor heart has been recommended when there is considerable size mismatch between donor and recipient right atria[5].) The SVC anastomosis is performed with a running 5/0 polypropylene suture, and either can be performed immediately after the IVC anastomosis or, alternatively, in order to decrease ischemic time, can be delayed until the aortic anastomosis has been performed and the aortic cross-clamp has been removed (see Chapter 24). If the SVC anastomosis is to be delayed while the aortae are anastomosed, a clamp is placed on the donor SVC to prevent blood obscuring the field.

Anastomosis of pulmonary arteries

Both donor and recipient pulmonary arteries are trimmed to adequate length. Our personal preference is that the *donor* pulmonary artery should be cut short (just 1 cm above the pulmonary valve) in order to avoid any kinking of the pulmonary artery after anastomosis. (Alternatively, the *recipient* pulmonary artery can be cut short, although this renders access to the anastomotic site slightly more difficult.) We perform this anastomosis using a continuous 5/0 polypropylene suture (Figure 8).

Anastomosis of aortae

The aortae are trimmed to the required length and anastomosed using a running suture of 4/0 polypropylene (Figure 8). (This anastomosis can be performed before the pulmonary artery anastomosis if it is desired to reduce graft ischemic time.)

De-airing of the heart

As all cavities have been opened, de-airing of the transplanted heart remains crucial. Air needles should be placed after the SVC and IVC snares are released and ventilation is reinstituted. Our own routine is to place an air needle: (a) into the roof of the left atrium, (b) at the apex of the left ventricle, and (c) into the ascending aorta. A pad is placed posterior to the left ventricle, elevating the apex upwards to allow air to escape. Only then is the

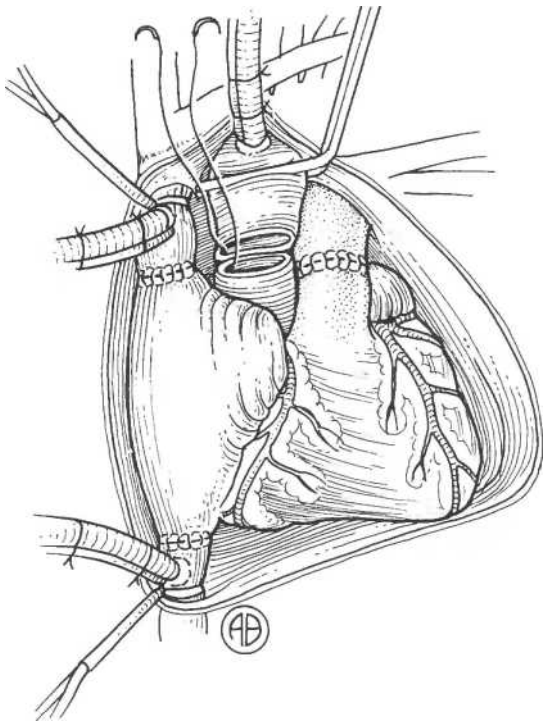

Figure 8 The pulmonary arteries have been anastomosed. The aortic anastomosis is beginning.

aortic cross-clamp released to allow reperfusion of the heart. When the heart either defibrillates spontaneously or is electrically defibrillated, both aortic and left ventricular needles are placed on suction for a few minutes to expel all air from the left side of the heart and to avoid distension.

Routinely, we initiate an isoproterenol infusion (at a dose of 0.05 $\mu g\ kg^{-1}\ min^{-1}$) at 10 min before unclamping the aorta. Pacemaker wires are routinely applied (even when the heart resumes sinus rhythm) to both ventricles and both atria, to allow sequential atrioventricular pacing if required (to prevent loss of atrial contraction if atrioventricular block occurs).

Discontinuation of pump-oxygenator support

The protocol for this part of the operation varies considerably between centers. As an example our own preference will be outlined. Both left and right ventricular function are monitored routinely by transesophageal echocardiography (TEE). After discontinuation of cardiopulmonary bypass we aim for a systolic blood pressure >100 mmHg, a heart rate <120/min, and a nondistended right ventricle (as judged by TEE). If hemodynamic status is compromised, pump-oxygenator support is resumed while pharmacologic adjustments are made (by increasing isoproterenol and adding epinephrine if necessary). When the right ventricle is distended, with or without pulmonary hypertension, we routinely use inhaled nitric oxide to assist in weaning from cardiopulmonary bypass.

Completion of operation

All suture lines are checked for bleeding, and extra sutures placed if required. (Access to the pulmonary venous anastomoses is poor.) The air needles are removed and the sites oversewn, if necessary. A metallic clip is placed at the margin of the apex of the right ventricle (just to the right of the left descending coronary artery) to assist in the performance of endomyocardial biopsy post-transplantation. The aortic and venous cannulae are removed. Protamine sulfate is administered. The pericardial cavity is drained using apical and basal drains. The sternum is closed.

COMMENT

The total technique can be considered an anatomical heart replacement. If care is taken when performing the SVC anastomosis to avoid a purse-string effect, the incidence of SVC stenosis is negligible. At our own center this operation has now been performed for many years with no incidence of SVC stenosis. However, the total technique is only an alternative to the standard technique, which has shown its efficacy for 30 years. Furthermore, the total approach is technically more demanding than the standard approach and, in general, takes rather longer to perform[6]. Others have modified the total approach, utilizing, for example, a single cuff of recipient left atrium incorporating all four pulmonary veins[7,8].

The bicaval anastomosis allows maintenance of the integrity of atrial conducting pathways, improving the likelihood of obtaining sinus rhythm, which is important for good early hemodynamics. A significant decrease in arrhythmias with improved atrial function has been shown after the bicaval technique[5,9]. The incidence of tricuspid regurgitation, and even of mitral regurgitation, is also reported to be lower than with the standard approach[6,10–12]. Early or late hemodynamic superiority, however, cannot yet be demonstrated conclusively, as many different factors (e.g. ischemic time, pulmonary vascular resistance, body surface area mismatch, etc.) play a role. Both exercise duration and exercise capacity, however, have been demonstrated to be improved in one study[10], and a higher cardiac index documented in the early postoperative period in another[5].

The introduction of TEE as a routine form of monitoring is fairly recent. It has been utilized by Angermann *et al.*[13] to demonstrate imperfections of the standard OHT technique. The following observations were made: (a) the atrial suture lines protrude into the respective atria, increasing the risk of thrombus formation (which proved more frequent than anticipated); (b) the presence of large recipient atrial remnants results in an abnormally large atrial volume (with an anteroposterior diameter up to twice the normal size); (c) the synchronous contractions between the recipient and donor atria lead to (i) pseudoaneurysmal behavior of the recipient atria and (ii) asynchronous opening and closing of both mitral and tricuspid valves.

Immediate Postoperative Care and Potential Complications

D.K.C. COOPER AND N.M. LIDSKY

IMMEDIATE POSTOPERATIVE CARE

The immediate postoperative care of a patient who has undergone heart transplantation, whether it be orthotopic or heterotopic, is similar to that of any patient who has undergone open-heart surgery. Precautions need to be taken, however, to minimize the risk of infection, and in general in the first few postoperative days there is greater concern over potential pump dysfunction and chronotropic inadequacy when compared with other cardiac surgical procedures. Maintenance immunosuppressive therapy is begun immediately before the operation and is continued afterwards.

Patient monitoring

The patient will return from the operating room intubated and ventilated with a volume-cycled ventilator capable of providing intermittent mandatory ventilation and positive end-expiratory pressure. *In-situ* arterial and central venous (CVP) cannulae allow monitoring of pressures, and other intravenous lines allow replacement of blood and fluid, as well as administration of vasoactive drugs if necessary. A urinary catheter and electrocardiogram (ECG) electrodes are also in position. A central temperature probe (blood, bladder or rectal) may be *in situ*. Drainage catheters will drain both the pericardial cavity and the anterior mediastinum. If either or both pleural cavities have been opened, it is preferable to drain these cavities independently.

A Swan–Ganz catheter to monitor cardiac output and pulmonary capillary 'wedge' pressure (or an oximetric catheter to give additional continuous information on the systemic venous oxygen – SVO_2) is an advantage, but not essential. Following orthotopic transplantation, if donor heart function is clearly satisfactory, we do not feel that measurements of left heart pressures or cardiac output are necessary. Such observations may be essential, however, if donor heart function is poor, or there is significant pulmonary vascular disease. The complex anatomy of heterotopic heart transplants renders measurement of cardiac output difficult, but information gained on pulmonary artery and 'wedge' pressures may prove valuable.

The nursing staff will monitor (either continuously or at frequent intervals) all vital signs, which will include arterial and central venous pressures, heart rate(s), peripheral pulses, temperature, respiratory rate and ventilator parameters. They will also keep careful records of blood loss from the drains, urinary output, and blood, plasma, and fluid input. Measurement of arterial blood gases, serum electrolyte levels (particularly potassium) and blood glucose will be carried out at intervals as in any patient who has undergone open-heart surgery, and appropriate steps taken to maintain these parameters within the normal ranges.

Most centers involved in heart transplantation consider it an advantage to extubate the patient as soon as possible, to minimize the risk of pulmonary infection and barotrauma. It is argued that the presence of an indwelling endotracheal tube, which prevents the normal cough reflex and mucociliary tracheal clearance, and provides a conduit for entry of microorganisms is, together with the intermittent introduction of tracheal suction catheters, a major factor that predisposes to infection. Extubation should be carried out as soon as the patient is awake enough to cooperate with the nursing and physiotherapy personnel, and can cough when requested, as long as his or her hemodynamic state is satisfactory. This typically occurs within 24 hours of admission to the intensive-care unit, and sometimes almost immediately. The parameters and guidelines for weaning from the ventilator and extubation are the same as for any patient who has undergone open-heart surgery. These criteria are standard, and include: (a) acceptable gas exchange on an F_iO_2 <50% with PEEP <5 cmH_2O; (b) normal pH and PCO_2 during a trial of spontaneous respiration (i.e. CPAP with or without low levels of pressure support); and (c) no signs of excessive work of breathing, such as tachypnea, tachycardia, or use of accessory muscles. Early postoperative pulmonary infections may occur in patients in whom, for one reason or another, there has been a delay in extubation until 48 hours have elapsed, but fortunately remain relatively uncommon. There is, however, a higher risk of pulmonary infection should the patient require ventilation beyond this time.

Chest drains are removed when there is no risk of further bleeding and, in heterotopic heart transplant patients, in the absence of a right pneumothorax or significant pleural effusion.

Removal can generally be carried out within 48 hours, but we have experienced no complications from leaving the drains in longer, if indicated.

Initially, chest radiographs are taken daily until the chest drains have been removed and the patient is being mobilized, and then at less frequent intervals (unless otherwise indicated) to augment the clinical examination of the chest. The radiographs are taken primarily to confirm bilateral lung re-expansion and absence of pleural effusion, particularly after heterotopic transplantation, and also to exclude the presence of areas of consolidation that might suggest infection. The proper position of central venous or Swan–Ganz catheters needs radiographic confirmation.

Precautions to prevent infection

Meticulous attention to sterility is required by the nursing staff for all procedures affecting the patient. All personnel attending the patient should wash their hands on entering the room. At most centers, however, it is no longer felt necessary for personnel to wear face masks when attending the patient. Staff with obvious infection should not be involved in the care of heavily immunosuppressed patients, and nursing staff should ideally not be caring for two patients if one of them has a significant infection, for fear of cross-infecting the other patient.

It is used to be our policy to send several specimens each day for laboratory study to monitor possible early infection. Tracheal aspirate or sputum, blood, urine and swabs from the throat and from around the various drains and cannulae were sent daily for the first few days for culture to exclude significant bacterial growth. Urine and throat swabs (or gargle culture media) were sent for virological studies. Blood cytomegalovirus titers were estimated weekly. This intensive monitoring for infection was not found to be cost-effective, and has been discontinued. Specimens are sent now only when clinically indicated.

The patient should preferably be nursed in a clean-air environment. The number of hospital personnel entering the room should be kept to a minimum, and at this stage only close relatives should be permitted to visit the patient. We no longer believe that it is essential for personnel to change into operating-room garments or cover their outer clothing with a clean surgical gown, but frequent handwashing is essential. If blood is required for transfusion, it should ideally be CMV-negative, leukocyte-poor, and irradiated to reduce the risk of transfer of CMV.

All arterial and intravenous cannulae are removed as soon as possible, to reduce the risk of introducing infection into the blood either through or alongside the cannulae. A CVP line can be kept *in situ* for several weeks, if require, in patients who require such a line for any purpose, such as the daily intravenous administration of antithymocyte globulin, but meticulous care of the skin entry site must be maintained. The surrounding skin should be cleaned with iodine or other effective antiseptic, and a new sterile dressing applied daily or on alternate days. The literature concerning routine (e.g. weekly) elective prophylactic replacement of central venous catheters is inconclusive as to whether it has a beneficial influence on the rate of infection. We are, however, aggressive in monitoring for any clinical features of infection associated with the presence of a venous cannula, whether these are local (at the site of infection) or systemic (e.g. when there are positive blood cultures or fever of uncertain origin). If infection is suspected, a new cannula should be inserted in an alternative site. The tips of all removed cannulae should be sent for microbiological culture.

The sternal wound dressing should be changed daily and the wound inspected for signs of infection.

Respiratory therapy and physical rehabilitation

To ensure early re-expansion of the lungs, and to keep the airways clear of secretions, respiratory therapy is commenced within 6 hours of operation (as long as the patient is hemodynamically stable), and continued every 4–6 hours for the first 1–2 days, and then as often as necessary until the patient is fully mobilized, at which time it may be reduced or discontinued altogether. In the event of hemodynamic instability, initiation of respiratory therapy should be delayed or at least modified. In the intubated patient, respiratory therapy takes the form of vibration of the thoracic cage, postural drainage, and hyperinflation of the lungs by manual Ambu bagging to expand the lungs and loosen secretions, followed by tracheobronchial suction. In addition, it is advantageous to utilize 3–5 cmH_2O PEEP to prevent lung derecruitment, as this amount of PEEP represents the equivalent of 'physiologic PEEP' in the non-intubated state. A mucolytic agent may be injected into the airways of patients with viscid secretions, as well as bronchodilators when indicated.

After extubation, the nursing staff should encourage incentive spirometry and assisted coughing every hour when the patient is awake. If the effort on incentive spirometry is poor or marginal (generally <75–1000 ml per effort in an average-sized individual), IPPB therapy can be prescribed until respiratory muscle strength improves or other contributory factors, such as chest wall pain, are adequately addressed. In some extubated patients, use of CPAP or BiPAP, followed by assisted expectoration, may be indicated to prevent atelectasis and to keep the airways free from excessive secretions.

Within 24 hours of operation, if the patient is hemodynamically stable, passive muscular exercises are introduced, particularly to the legs to prevent deep-vein thrombosis and to strengthen the musculature. Active exercises, such as straight-leg raising, are introduced as soon as the patient can cooperate. As soon as possible, usually within 48 hours, the patient should be assisted to sit and stand out of bed at intervals of a few hours, and encouraged to become fully mobile over the next few days.

These patients have frequently been relatively inactive, or even bedridden, for some weeks or months before transplantation due to their underlying myocardial failure. Their muscles may have become weak and atrophied. Furthermore, the corticosteroids given to prevent rejection, particularly if given in large doses, contribute in most patients to a further wasting of the musculature that is so extreme in some to warrant the description of 'steroid myopathy'. A similar form of myopathy is believed to occur in hypomagnesemic patients receiving cyclosporin. Frequent and regular attention is therefore required from the cardiac rehabilitation staff if this muscle wasting is to be kept to a minimum and eventually reversed.

Each patient is prescribed a program of exercises which he or she is expected to perform frequently (e.g. every 2 hours) throughout the waking hours. This exercise program especially concentrates on strengthening the legs. Walking is probably the best exercise at this stage, but is frequently restricted by the pres-

ence of monitoring leads and intravenous infusions. Static dynamic bicycle riding is a good alternative, and is generally begun under the therapist's supervision within the first 3 or 4 days, as long as the patient's general condition does not contraindicate this more vigorous form of exercise. Initially, the bicycle workload is set low, and the period of time the patient spends on it restricted to 2 minutes, but both factors are steadily increased as the patient's recovery continues. Bicycle riding is ideally carried out four times each day, and the period of exercise increased up to 15 minutes per session.

During a moderate acute rejection episode, when the myocardium is edematous and undergoing cellular infiltration and myofiber injury, we believe it is only sensible to restrict the exercise of the patient in an effort to minimize permanent myocardial damage and potentially dangerous dysrhythmias. Vigorous exercise, such as bicycle riding, should be omitted, though gentle exercise and walking may continue. When rejection is severe, particularly if it is causing hemodynamic instability, then bedrest is mandatory.

Fluid balance and dietary guidance

Once the initial post-cardiopulmonary bypass diuresis is completed, it is easy for the patient to become overloaded with fluid, leading to increased right and left heart pressures, which can lead to graft dysfunction, and peripheral and pulmonary edema. This can result from the relatively large number of intravenous infusions and drugs that are required, and can be exacerbated by the patient's usual thirst (and desire to quench it) that occurs after extubation. The use of loop diuretics may be necessary to normalize volume status; intermittent intravenous boluses of furosemide, bumetanide, and/or ethacrynic acid usually suffice. Hemodynamic status should be monitored carefully during such therapy.

A balance has to be sought between ensuring that the patient does not become overloaded (which might lead to right heart dysfunction) and yet does not become hypovolemic (which might exacerbate the renal dysfunction that is commonly seen in patients who have been in cardiac failure pretransplant and who are receiving cyclosporin).

In the early postoperative period the diet should be fairly liberal, although salt intake should be restricted. Once the patient is eating satisfactorily, attention should be paid to ensuring that he or she receives a low-fat, low-cholesterol diet (Chapter 16).

Prevention of psychological isolation and boredom

It is rare today for a patient to require isolation in an intensive-care unit for more than a few days, but should the patient need physical isolation for longer, it is important to prevent boredom by providing such facilities as television and/or video, which the patient may make use of if he/she feels inclined. The occupational therapist may play an important role at this stage. The medical and nursing teams must watch for symptoms or signs of depression, as this can occur in this patient population and may occasionally be severe enough to require specific psychotherapy and/or pharmacologic intervention.

DRUG THERAPY OTHER THAN IMMUNOSUPRESSION

Infection prophylaxis

Prolonged prophylactic antibiotic therapy is to be avoided in the immunosuppressed patient, as there is a greater risk of this leading to the growth of resistant bacteria or fungi. Patients should receive a suitable antibiotic (e.g. a cephalosporin) at the time of induction of anesthesia, with further doses after operation to cover the first 24 hours. Further antibiotics should be given only when signs of clinical infection are present, and when the causative organism has been identified, if this proves possible.

Nystatin mouthwash ('swish and swallow') is given after meals and at night to prevent oral or esophageal candida infection. Trimethoprim sulfamethoxazole (Bactrim) is begun within a few days as prophylaxis against *Pneumocystis carinii* infection. Bactrim prophylaxis has virtually eradicated this life-threatening infection.

Cytomegalovirus infection remains the most frequent post-transplant infection, though it usually does not develop during the first post-transplant month. Prophylaxis is generally considered to be beneficial, either by preventing the infection or by delaying its time of onset and its severity. The ideal prophylactic regimen has not yet been determined, but intravenous ganciclovir, oral acyclovir, and intravenous immunoglobulins are all advocated by different groups. Many various combinations of these options have been adopted, and there is no general agreement on the optimum regimen. The CMV status of donor and recipient may be important in the timing and specific nature of the anti-CMV prophylactic regimen chosen (Chapters 32 and 57).

Our own policy has been to initiate oral acyclovir therapy (800 mg t.i.d. or q.i.d., depending on the size of the patient) before the patient leaves hospital, and to continue this for 3 months. This is combined with intravenous administration of commercially available immunoglobulin (500 mg/kg) or CMV hyperimmune globulin (150 mg/kg) on two occasions on post-transplant days 7 and 35. In patients deemed to be at high risk, for example those who have received excessive immunosuppressive therapy for acute rejection episodes, we prefer a 2–3-week course of intravenous ganciclovir as prophylaxis, which can be continued orally (or switched to oral acyclovir) for 3 months. The doses of both acyclovir and ganciclovir need to be adjusted in patients with impairment of renal function. This important topic is discussed more fully in Chapters 11, 32 and 57.

Vasoactive drug therapy

If inotropic support is indicated, isoproterenol hydrochloride has the advantage of increasing donor heart rate, which is considered desirable as the transplanted heart depends significantly on an increase in heart rate to increase cardiac output in the early postoperative period. When cardiac function is poor, additional inotropic agents (e.g. dopamine or dobutamine) may be required or exchanged for isoproterenol. Epinephrine may be life-saving in occasional cases. Phenylephrine hydrochloride by continuous intravenous infusion in low doses ($<2.0\ \mu g\ kg^{-1}\ min^{-1}$ per hour) is frequently beneficial in increasing peripheral vasomotor tone sufficiently to maintain an adequate blood pressure, without being detrimental to the blood flow to such essential organs as the kidney. Higher infusion rates, however, should be avoided.

With the exception of isoproterenol therapy being administered for its chronotropic effect only, if multiple agents are required for more than brief periods, we advocate the insertion of a Swan–Ganz catheter for meticulous hemodynamic monitoring, with the aim of using the least toxic regimen that will normalize the circulatory status. The technology is now available to continuously monitor cardiac output, cardiac index, stroke volume, right ventricular ejection fraction, systemic and pulmonary vascular resistances, and systemic venous oxygen (SVO_2). The principal parameters indicating potential inadequacy of vital organ perfusion are cardiac output, arterial blood pressure, and SVO_2, and these are supplemented by physical and laboratory measures, such as urine output, mental status, capillary refill and serum lactate level.

The stimulatory effect of calcium on the myocardium should not be ignored, and the intravenous administration of 500–1000 mg of calcium chloride or gluconate not only increases myocardial contractility (and blood pressure) but may also improve conduction, particularly in cases of heart block or bradycardia, as well as possibly enhance peripheral vasomotor tone in cases of systemic hypotension.

Intravenous vasodilator therapy with, for example, sodium nitroprusside or nitroglycerine, may be indicated in the early postoperative period to reduce afterload, as in any patient who has undergone open-heart surgery. Other agents that can be administered intermittently in less urgent situations include intravenous hydralazine and nicardipine.

Cyclosporine therapy may result in hypertension, though it is relatively unusual for this to be a problem within the initial few postoperative days. Nifedipine (10 mg given sublingually) is usually effective in normalizing the blood pressure rapidly, and frequently in maintaining it at a desirable level for several hours, if hypertension becomes dangerously high. If the patient is absorbing drugs through the gastrointestinal tract, nifedipine (beginning at 10 mg every 8 hours) or other suitable antihypertensive therapy is generally effective in controlling hypertension continuously and, in our experience, is often associated with an increase in diuresis, presumably through a vasodilatory effect on the renal arteries.

The role of prostaglandins (eicosanoids) in the treatment of pathophysiologic states of the cardiovascular system is being increasingly investigated. Their metabolism, physiology, and pharmacology in relation to the cardiovascular system have been reviewed[1]. If severe right heart failure is present after orthotopic transplantation, and if this failure is secondary to a high PVR, prostaglandin E1 (PGE1) has been shown to have a beneficial effect, often dramatic, when given through a central venous catheter[2,3] (Chapter 20). PGE1 can be administered as an infusion of 500 μg in 100 ml of normal saline at a rate sufficient to bring about a reduction in systemic pressure, which is usually within the range of 0.1–0.4 mg/kg per minute. The patient should also be receiving 100% inspired oxygen. Pulmonary hypertension is relieved in large part by the vasodilating properties of the drug. Theoretically, 95% of injected prostaglandins is extracted by the lungs in a single pass through the pulmonary circulation[4], so that systemic hypotension requiring high-dose vasopressors can usually be avoided. PGE1 inhibits the release of thromboxane, a potent vasoconstrictor and potentiator of platelet aggregation[5], and has several other effects which make it of value in this situation[6]. If PGE1 is to be used, the insertion of a Swan–Ganz catheter is essential. (Prostacyclin (PGI_2) may prove to be more valuable for right ventricular failure, but in the USA is still at this time undergoing FDA investigation.)

It has long been known that plasma free triiodothyronine (T_3) is reduced in patients on cardiopulmonary bypass[7–9]. Laboratory and clinical research increasingly indicates an inotropic effect of T_3 following a period of myocardial ischemia on cardiopulmonary bypass[9,10]. Although this form of therapy remains highly controversial, it should be considered after heart transplantation if all other therapy (short of the placement of a mechanical assist device) appears to be failing. An initial dose of 0.1–0.2 μg/kg is usually sufficient, with further doses of 0.1 μg/kg at 4- or 8-hourly intervals, depending on hemodynamic response, for 24 hours.

If vasoactive drug therapy fails to support either right or left heart circulations, then some form of mechanical assistance will be required. This may take the form of an intra-aortic balloon pump in patients with predominant left ventricular failure, or a mechanical assist device for either left or right ventricular failure. Our general philosophy is to institute such mechanical therapies early, in order to prevent a deteriorating cascade of further ventricular overload and enlargement which leads to worsening pump function. If a period of such support is unsuccessful in allowing donor heart recovery, then retransplantation may be the only remaining alternative.

Pain relief and sedation

Large doses of morphine and other central nervous system or respiratory depressant drugs should be avoided. Fortunately, median sternotomy is not associated with a great deal of pain, and small doses of morphine (1–2 mg i.v.) or similar analgesic (e.g. buprenophine 0.1–0.2 mg i.v.) are usually all that is required to keep the patient comfortable. Such doses rarely cause significant respiratory or hemodynamic depression. Fentanyl, given continuously as an intravenous infusion or as intermittent boluses, has gained increasing popularity. Rarely, a morphine sulfate patient-controlled analgesic pump may be required. Non-steroidal anti-inflammatory agents should generally be avoided because of the increased risk of gastric irritation and bleeding.

After extubation, adequate pain relief or, preferably, pain avoidance is essential if the patient is to be encouraged to cough adequately to prevent secretion accumulation in his/her airways. It is unusual, however, for a patient to require more than the above doses of analgesia and, in many, mild oral analgesics may suffice.

Anxiety may be a problem in some patients, particularly while still intubated. Small doses of diazepam (1–2 mg) or similar relaxant, given intravenously, should be administered when necessary. Midazolam and lorazepam are good alternatives.

Dysrhythmias

Complete atrioventricular (AV) dissociation (third-degree heart block) is not uncommon in the immediate post-transplant period. Data suggest that approximately one patient in 10 will demonstrate a prolonged period of heart block. Pacing wires should therefore be inserted into the right ventricular myocardium in

every patient at the time of surgery, and should be tested in the operating room. In those with AV dissociation, pacing should be continued until the heart recovers. As heart block can clearly be life-threatening in such patients, two myocardial pacing wires should be inserted and one non-active wire should be inserted in the skin. In the event that one myocardial wire becomes ineffective, for whatever reason, the second wire may prevent a catastrophe. It is essential to test the pacemaker's efficiency in the operating room and to ensure that the wires and box are well protected when the patient is moved from the operating room to the recovery room, or from the recovery room to the intensive-care unit.

The continuous infusion of intravenous isoproterenol may diminish the period of time that the patient is pacemaker dependent. Once a spontaneous rapid rate has been achieved, then the pacemaker should be set on demand on a low rate (e.g. 60–80/min) in case heart block recurs.

There have been reports that the oral administration of slow-release theophylline may stimulate a change from block to sinus rhythm in some patients. The recommended oral dose is 150 mg every 12 h, and this dose should be titrated to keep the heart rate above 90 beats/min for at least 24 h. At that time the dose can be weaned slowly, and discontinued if the heart rate stays above 80–90 beats/min. A usual dose of 150–300 mg every 12 h is required. Rarely, dosing every 8 h is required. Theophylline levels should be measured throughout this therapy, and should be maintained between 10 and 15 μg/ml.

This therapy should be used with some caution, however, as potential complications of theophylline include seizures, interaction with H2 blockers, and tachycardia. These complications can generally be avoided if the blood levels are measured at fairly frequent intervals and maintained within the desired levels. However, even at these levels some patients complain of a feeling of nervousness and anxiety, and occasionally the drug cannot be tolerated for these reasons.

In our experience theophylline has occasionally appeared to stimulate an increase in heart rate, but not invariably so. If complete AV dissociation continues for more than 3–4 days despite isoproterenol and/or theophylline therapy, or a marked bradycardia (heart rate <50/min) persists when isoproterenol is discontinued, despite theophylline therapy, it has usually been our policy to proceed to insertion of a permanent pacemaker. This is done partly to ensure the safety of the patient, as temporary pacemaker wires always place the patient at some risk through detachment. Furthermore, if the patient's discharge home is delayed purely because of continuing bradycardia or pacemaker-dependence, then we have found it more cost-effective to insert a pacemaker at an early stage, allowing the patient to be discharged home 24 h later.

In the majority of these patients the heart rate subsequently increases, and they no longer become pacemaker dependent. However, the incidence of a return of heart block in the future or temporary bradydysrhythmias is uncertain, and we believe it places the patient at less risk if a permanent pacemaker has been inserted in such cases.

Serious rhythm disturbances are relatively common in donor hearts that have suffered damage from prolonged ischemia during implantation. Following heterotopic heart transplantation, dysrhythmias of the recipient heart may occur, though these can often be ignored, unless they lead to hemodynamic embarrassment of the donor heart, which is rare.

When prescribing therapy, it should be remembered that the response of the denervated donor heart to therapeutic agents that have an effect in correcting dysrhythmias may differ from that of an innervated heart (Chapter 27). Calcium antagonists, such as verapamil hydrochloride, and beta-blocking agents have a greater effect on the denervated heart than on the innervated heart, whereas the donor heart is less sensitive to some other drugs – for example, digoxin.

Fluid retention

Diuretic therapy is almost always necessary during the first few postoperative days, particularly in patients who were in severe cardiac failure (and fluid overloaded) before operation. The fluid-retention effect of corticosteroids is a factor in many patients. A temporary loss of right and/or left ventricular compliance immediately after transplantation also leads to raised jugular and/or pulmonary venous pressures, which in turn may result in peripheral and pulmonary edema.

There is usually a good initial diuresis as the patient excretes the 5% dextrose cardiopulmonary bypass machine prime given at the time of surgery. This frequently continues for several hours. If the immediate post-cardiopulmonary bypass diuresis is poor, consideration should be given to its cause. If the patient is hypotensive or hypovolemic, then these factors should be corrected by increased inotropic therapy and/or phenylephrine infusion and/or fluid or blood infusion. However, a diuretic such as furosemide or bumetanide is frequently necessary. A relatively large dose may be required in patients who have been taking large and frequent doses pretransplant. Mannitol (50 g i.v. given rapidly as a bolus) is frequently helpful in resistant cases, although care has to be taken in patients who are already hypervolemic, as pulmonary edema can be induced. Ethacrynic acid is also frequently successful in patients in whom furosemide fails. Intravenous diuretic therapy is clearly preferable in the early post-transplant period when gastrointestinal absorption is poor, and when a rapid response is required. Occasionally, we utilize a continuous intravenous infusion of furosemide, as the resulting diuresis is reliable, titratable, and more dose-effective. This is desirable in patients with marginal hemodynamics. Oral diuretic therapy can be initiated later if necessary. Some centers advocate 'renal dose' dopamine infusion at 0.5–2.0 μg/kg per minute.

Cyclosporin (CsA), particularly if given intravenously, may occasionally be associated with an acute oliguria, which may respond to diuretic therapy, though in addition, reduction in the CsA dosage (or even omission of this drug) may be required for a period of time. It may be difficult to distinguish between oliguria from CsA toxicity and acute tubular necrosis from other causes. Measurements of CsA levels are clearly helpful in differentiating these conditions. Additionally, CsA is sometimes associated with a relative mineralocorticoid deficiency, which can lead to hyponatremia and hyperkalemia. These abnormalities are not usually severe, and generally require no specific therapy; however, when necessary, they can be treated with drugs such as fludrocortisone acetate.

Prevention of peptic ulceration

Patients undergoing major surgical procedures and receiving corticosteroids are clearly at risk of developing peptic ulceration. An H2 antagonist or antacid is begun immediately after operation to help prevent gastric erosion or stress ulcer, and should be continued at least during the first 3 months after transplantation, by which time steroid dosage should have been substantially reduced. More powerful agents, such as omeprazole, may be indicated in patients deemed to be at high risk (e.g. judging by previous history), or in those who develop any features of peptic ulceration (e.g. falling hemoglobin associated with stool positive for blood). Therapy should be continued in those considered at high risk until steroids have been discontinued or at least reduced to a low maintenance level (e.g. <0.1 mg/kg per day). (Occasionally, endoscopy is required to locate the source of upper gastrointestinal tract bleeding.)

Anticoagulation

Full anticoagulation is unnecessary in patients with orthotopic heart transplants unless there are other specific indications. Some groups prescribe an anti-platelet agent for the first 6 weeks, and others continue such agents indefinitely in the hope of delaying or preventing the development of graft vasculopathy (chronic rejection) (Chapter 35). Aspirin therapy should ideally be avoided in the early post-transplant period, for fear of inducing peptic ulceration and bleeding complications.

In over 200 consecutive heart transplants at our center we have documented one small cerebral embolus (presumably from thrombus developing on the left atrial suture line) which fortunately resolved rapidly and resulted in no permanent neurological deficit. This patient was subsequently anticoagulated for 6 months. The need to anticoagulate all patients with heterotopic heart transplants is discussed in Chapter 37.

Prevention of graft vasculopathy (chronic rejection)

It is generally considered that a diet low in lipids may reduce the rate of progression of chronic rejection (accelerated graft arteriosclerosis), particularly in patients with hyperlipidemia (Chapter 35). This diet should be initiated as soon as practicable in the postoperative period (Chapter 16).

Hypercholesterolemia

In patients with underlying ischemic heart disease who are known to be hypercholesterolemic, therapy with a cholesterol-reducing agent may reduce the rate of progress of atheroma in peripheral vessels. It is rarely indicated to begin this therapy in the early postoperative period, and generally it would seem wise not to add non-essential drugs until the patient is successfully through the critical initial month or so after transplantation.

Some of the newer agents, such as lovastatin, however, should be used with caution, in view of the risk of rhabdomyolysis which has been reported when they have been used in association with CsA[11,12]. Dosages of lovastatin of up to 40 mg/day, however, seem well tolerated, and rarely cause problems when given to patients also receiving CSA.

Whether such cholesterol-lowering therapy slows the development of graft arteriosclerosis remains in doubt, and is discussed further in Chapter 35.

Antituberculous therapy

Long-term antituberculous therapy is essential in patients who have contracted this disease in the past. In patients with features on chest radiographs of previous tuberculosis infection it has become our policy to administer isoniazid for at least the first 6 months as prophylaxis against recurrence. As with other drugs that are not critical during the first few days, it is probably wise to withhold this drug until the patient's hemodynamic, renal and hepatic status is good.

Mineral replacement therapy

Many patients who undergo heart transplantation have osteoporosis induced by inactivity and diuretic therapy. Further bone loss may occur from corticosteroid therapy. An attempt should be made to prevent or reduce such loss by dietary supplements of calcium, possibly given in association with vitamin D supplementation.

CsA neurotoxicity is associated with a low serum magnesium[13,14]. Hypomagnesemia is common in heart transplant patients receiving CsA, and it is probably beneficial to administer dietary supplements of magnesium to all patients at least during the first several weeks or months.

MAINTENANCE IMMUNOSUPPRESSIVE DRUG THERAPY

Immunosuppressive drug therapy should be begun immediately pretransplant, and continued in the post-transplant period according to the protocol of the individual center. This topic is discussed in Chapter 8.

EARLY POSTOPERATIVE COMPLICATIONS

Any of the complications of open-heart surgery can, of course, occur following orthotopic or heterotopic heart transplantation. Technical complications are today fortunately rare.

Hemorrhage

Hemorrhage is a potential early complication that may occur following the operation of either orthotopic or heterotopic transplantation. In both procedures there are long suture lines involving both low pressure venous systems and high pressure arterial systems. With care, however, postoperative bleeding should not be a major problem, though it is more likely to occur in patients who have undergone previous cardiac surgical procedures, and in those with coagulopathies, possibly associated with impairment

of hepatic function from long-standing right heart failure or from pretransplant anticoagulant therapy.

Technical complications

In the preparation of the donor heart for both orthotopic and heterotopic transplantation, care must be taken to avoid the region of the sinoatrial node. In heterotopic heart transplantation the recipient sinoatrial node must also be preserved.

Inadequate surgical technique may lead to narrowing at anastomotic suture lines, the pulmonary artery anastomosis possibly being the most vulnerable.

Wound infection

Wound infection is fortunately relatively rare after major cardiac surgery, including transplantation, but can, of course, be potentially disastrous in the immunosuppressed patient. Its treatment in the transplant patient follows the guidelines for any patient who has undergone open-heart surgery.

Systemic and pulmonary emboli

Patients with poorly functioning orthotopic heart transplants (e.g. from acute or chronic rejection) are at risk of developing ventricular thrombi, which may be embolized into the pulmonary or systemic circulations. Pulmonary emboli have also been reported arising from a residual recipient right atrial appendage following orthotopic transplantation[15]; this appendage should be excised at operation.

A fatal paradoxical cerebral embolus (via an unnoticed patent foramen ovale in the donor atrial septum) resulted from a deep-vein thrombosis in one of the patients in the Cape Town experience; closure of a large patent foramen ovale in either donor or recipient atrial septum should therefore be carried out at operation.

Complications of immunosuppressive therapy

Both early and late complications of immunosuppressive therapy are discussed in Chapter 8. Complications such as acute tubular necrosis and bleeding peptic ulceration, that may occur after any major surgical procedure, may be even more problematic in patients receiving drugs such as CsA and corticosteroids.

Physiology and Pharmacology of the Transplanted Heart

J.B. YOUNG

INTRODUCTION

Heart failure is an extraordinarily complicated milieu. However, at the center of the difficulty is substantive impairment of cardiac pump function. Though the heart failure syndrome is characterized by profound perturbation of hormonal, humoral, neurologic, and cytokine systems, the root difficulty is impaired cardiac filling, decreased forward blood flow with peripheral organ hypoperfusion, and structural remodeling (hypertrophy and chamber dilatation)[1-3]. Many diseases cause myocardial injury that can impair normal cardiac contraction and relaxation. Therapies today have focused largely on ameliorating background difficulties prompting cardiac injury, and a great number of treatments used today attempt to interdict effects on perturbed humoral systems[4,5]. However, it has become clear that attenuation of peripheral physiologic abnormalities engendered by advanced heart failure cannot, alone, dramatically alter prognosis[6]. Replacement of the malfunctioning pump is necessary to significantly change long-term outlook.

Indeed, few things are more dramatic in medicine than observing the functional improvement that occurs when patients with advanced heart failure or cardiogenic shock undergo successful heart transplantation (HTx) with reversal of the heart failure syndrome[7]. Time has proven that HTx affords substantial physiologic rehabilitation in patients with severe heart failure. Functional limitations directly related to hemodynamic abnormalities improve dramatically and often resolve completely. It is clear that, in the strictly selected patient, HTx is vastly superior to any other therapy available to improve functional capacity and prolong life. Still, it is important to understand that cardiac allografts do not function entirely normally, and exercise tolerance in transplant recipients is less than one might anticipate[8]. Furthermore, because the transplanted heart represents a denervated organ system, response to many pharmacologic agents is not comparable to that noted in patients or individuals at large. It is important to understand the implications of altered cardiac physiology after HTx, particularly its relation to exercise physiology and pharmacotherapeutic intervention.

PHYSIOLOGY OF THE CARDIAC ALLOGRAFT

Factors affecting cardiac allograft function

Table 1 summarizes many factors which lead to alteration of cardiac allograft function. They include characteristic hemodynamic perturbations observed in HTx recipients, the important issue of afferent and efferent allograft denervation which persists after HTx, myocardial injury and maladaptation that can occur at the time of organ harvest, subsequent rejection injury, and preexisting donor cardiac pathology. It is fair to say that all cardiac allografts are abnormal to some extent and, with time, deterioration occurs because of rejection, drug toxicity, the often-present hypertension, and allograft vasculopathy (chronic rejection). The slope of functional deterioration is determined by static effects such as denervation and donor/recipient body size mismatch at implant, as well as dynamic factors such as intensity, severity, and chronicity of rejection and hypertension.

With respect to hemodynamic factors, one must remember that size of the donor, in relationship to size of the recipient, is extraordinarily important. Obviously, a heart geared to supplying output to an individual with a body surface area of 1.5 m^2 would behave differently when the demands of an individual of 2.5 m^2 present. Both afferent and efferent cardiac receptors are eliminated when the native heart is extirpated. Interdiction of normal neurohumoral control affects the manner in which cardiac output is regulated. Myocardial injury due to inflammatory assault is a constant issue in HTx recipients. This, combined with baseline injury occurring during donor organ preservation and recovery, complicated by acute and chronic ischemia (which seems ever present in cardiac allografts because of allograft vasculopathy), coupled with ventricular hypertrophy (developing because of hypertension), can cause significant organ dysfunction.

Insight gained from historic transplant paradigms

Initial models of HTx gave great insight into the function of these allografts. Indeed, Mann *et al.*[9] prophesied in 1933 that circulatory physiology after HTx would be 'excellent' if the 'bio-

Table 1 Factors affecting function of the transplanted heart

Hemodynamic issues
Donor/recipient atrial asynchrony
Early postoperative restrictive physiology
Late occult restrictive physiology

Allograft denervation
Afferent denervation
- Altered reflex control of peripheral vasocontraction/vasodilatation
- Altered Na^+/H_2O regulation via central-nervous-system-dependent vasopressin, renin, angiotensin, aldosterone secretion
- Absence of anginal syndrome during ischemia

Efferent denervation
- Absent vagal nerve control
- Rapid heart rate at rest
- Attenuated heart rate response to exercise

Hypersensitivity to circulating catecholamines
Exaggerated response to acetylcholine

Altered hormonal milieu
ANP secretion enhanced
Elevated exercise circulating catecholamines
Increased circulating paracrine peptides (endothelin)

Myocardial injury/maladaptation
Organ preservation and recovery injury
Intraoperative complications
Rejection
Ventricular hypertrophy
Hypertension (increased ventricular wall stress)
Allograft arteriopathy (ischemia)

Donor-related issues
Effect of brain death
Donor/recipient size mismatch
Age-related diastolic dysfunction
Pre-existing arteriosclerosis
Pre-existing hypertrophy
Pre-existing myopathy
Pre-existing structural heart disease

Modified from ref. 8.

logic factors' that invariably caused organ demise during experiments could be identified and controlled. Function of the transplanted heart was known at that time to be impaired virtually immediately postimplantation. It is likely that cell and humoral rejection caused rapid organ demise with systolic and diastolic dysfunction. Autotransplantation models, however, to effect complete cardiac excision with subsequent reimplantation, demonstrated the impact of cardioplegia, ischemia, denervation, and technical difficulties on replacement of the heart[10–13]. Indeed, these experiments were often performed to study the effects of innervation and denervation on the heart.

Observations after autotransplantation included the fact that right and left heart filling pressures were elevated (even in the absence of other known difficulties), gradually returning to more normal levels with time[14,15]. Interestingly, exercise tolerance in canine paradigms of autotransplantation approached that of control animals during follow-up[12,13]. Autotransplantation models also demonstrated that total blood volumes increased substantively compared with values obtained in control dogs[16,17]. A blunted diuretic and natriuretic response to volume expansion was also shown in these denervated canine auto-heart-transplant preparations[16]. It became apparent quite early that interruption of afferent neurocardiac innervation mediated, at least in part, circulatory system volume homeostasis. By interrupting the afferent neurofibers to the heart, a decrease in the opposition of sympathetic renal stimulation became apparent. This engendered a new volume steady state that subsequently translated into fluid retention with altered cardiac loading conditions[15–17]. We will subsequently detail these issues in human HTx, but it is apparent that the global circulatory milieu of cardiac allograft recipients is one of volume expansion. Very important was the observation that denervation of the heart caused myocardial catecholamine levels to diminish quickly[18,19] (as early as 1 week after autotransplantation), and this likely leads to loss of feedback inhibition of circulatory catecholamine increase. It is still important to remember that often transplanted dogs were able to exercise substantially, and for long periods, despite their cardiac physiology derangements.

Hemodynamics in human heart transplant recipients

Despite the fact that cardiac allografts are usually functioning more normally than the organs they replaced, hemodynamic derangement, sometimes extremely subtle, is generally apparent. Early reports of HTx in humans gave some insight into this, but these observations were confounded substantially by rejection. Initial studies[20] suggested that cardiac output was generally depressed in the early postoperative days, and that high central venous pressure was essential to maintain adequate flow. Atrial dynamics were quite abnormal[21–24], seemingly because of the mid-atrial anastomoses between donor and recipient hearts. This approach to allograft implantation allows varying portions of donor and recipient atria to be present, and the native atria do not contract synchronously with the allograft atria. Native sinus node electrical activity is not transmitted across the atrial suture line. Consequently, the normal atrial contribution to net stroke volume is generally less in the HTx patient than in normal subjects. Indeed, normally one would expect 15–20% of net stroke volume to be contributed by atrial systole. This does not appear to be the case in HTx recipients.

Recent reports suggest that improved left atrial transport and function can be achieved following orthotopic HTx by utilizing a bicaval and pulmonary venous anastomosis technique, the so-called, 'total' orthotopic HTx (Chapter 25). Freimark *et al.* recently reported[25] that HTx with this approach avoids the large atrial anastomoses of the standard biatrial implantation method. This group, utilizing Doppler echocardiographic techniques, suggested that greater ejection force and more normal atrial volume transmission could be achieved with this surgical approach.

Indeed, left atrial dimensions in the bicaval model are much smaller than in the biatrial anastomosis group, and the atrial ejection force is higher.

Early reports summarizing hemodynamics after HTx[26,27] generally noted that intracardiac pressures were normal at rest, but ventricular end-diastolic pressure increased rather dramatically during exercise. In fact, an evolutionary pattern of change in hemodynamics is characteristic of patients followed long term after HTx while receiving cyclosporine-based immunosuppressive protocols[28–30]. Again, complicating factors such as rejection and systemic hypertension have been emphasized in these reports. What has emerged is the fact that restrictive hemodynamic patterns are apparent early after HTx, but generally resolve within a short period of time (days or weeks)[30,31]. Despite the fact that the overt myocardial restrictive patterns disappear quickly, a subclinical and latent or 'occult' restrictive hemodynamic state persists. To observe this pattern, acute volume challenge is sometimes required[30]. A subtle abnormality is present in virtually every HTx recipient. The significance of this is not clear, but certainly it impacts on cardiac filling and likely contributes to biophysical remodeling. Persistently impaired ventricular filling, that is significant and overt, late after HTx can be seen in 10–15% of patients, and has been related to substantive allograft rejection[32,33].

It is important to remember that donor–recipient size mismatch may account for some of the restrictive hemodynamic patterns. Generally, donors are at least 70–80% of recipient weight, but variability can be greater. This would imply that most donor hearts are less than the desirable size for recipients. Hosenpud *et al.*[34] reported a significant negative correlation between donor–recipient weight ratio and resting heart rate, right atrial filling pressure, and pulmonary capillary wedge pressure at the 90-day observation point post-HTx. Individuals receiving a heart from a donor weighing substantially less had higher resting heart rates and ventricular filling pressures than those of other patients.

Many echocardiographic studies have been used to gain insight into anatomic and functional constraints of the cardiac allograft[32,35,36]. In studies performed when rejection (by endomyocardial biopsy) is not apparent, ejection fraction usually remains within normal limits over long-term (2–4-year) follow-up, but a substantially increased cardiac volume and end-systolic wall stress are apparent even in the absence of increased myocardial mass[31]. St Gore *et al.*[37] utilized Doppler echocardiographic techniques early after transplantation to assess left ventricular diastolic function serially and noted findings (isovolumic relaxation time, pressure half-time, and time-to-peak ventricular filling) that were suggestive of restrictive myocardial physiology. This compares nicely with right heart hemodynamic observations previously noted. Echocardiographic studies also demonstrated that these restrictive hemodynamic patterns normalize over the first postoperative month[30,31,35], and that the findings do not correlate well with preoperative pulmonary pressure or vascular resistance. Additionally, the restrictive myocardial changes were not influenced by cardiopulmonary bypass time, total ischemic time, or donor age.

In the absence of acute rejection, normal values for left ventricular ejection fraction during long-term follow-up are also, seemingly, normal. An elegant fluoroscopic analysis of radiopaque myocardial markers surgically implanted at the time of HTx[38,39] demonstrated that shortening fractions were within normal baseline ranges (obtained from non-transplant controls) and that an appropriate increase in cardiac output occurred during low-intensity exercise, resulting from augmentation of end-diastolic volume, with a subsequent increased left ventricular stroke volume. Utilizing resting radionuclide blood pool and angiography, Verani *et al.*[40] demonstrated that systolic ventricular performance of the transplanted heart, with respect to both right and left ventricular ejection fraction, was comparable to that of controls. Resting peak diastolic filling rates and time-to-peak diastolic filling rate were also normal. However, with exercise, significant increases occurred in left and right ventricular ejection fraction and peak diastolic filling rate, but the increases were significantly lower than in normal subjects. Again, these data correlate nicely with invasive hemodynamic and echocardiographic observations regarding cardiac function that indicate that cardiac allografts have mildly impaired ventricular function. Generally, stressing maneuvers are required to unmask these findings.

Though the effects of denervation on the cardiac allograft will be discussed separately, one consistent characteristic is that, without tonic vagal input, resting pulse rates are generally higher than noted in normal subjects[41]. Furthermore, rate acceleration with exercise is slower than in normal controls with lower peak heart rates achieved at similar degrees of exercise[35]. The higher resting pulse noted in cardiac allograft recipients does not respond to physiologic stimuli such as carotid sinus massage, Valsalva maneuver, or innervation-dependent pharmacologic therapy such as atropine infusion.

The exercise response of the cardiac allograft

Patients with cardiac allografts have diminished maximal exercise tolerance when compared with that of normal subjects. This is likely one effect of a subnormal ejection fraction and cardiac output during increased workload, as well as of an exaggerated increase in intracardiac volume[40,42–44]. The findings are generally subtle, and the longer the time period between HTx and observation, the less significant the hemodynamic perturbation may be, particularly if patients train aerobically. Elevated intracardiac filling pressure during exercise, in the setting of normal or reduced left ventricular volume, suggests that the cardiac allograft performs on a ventricular pressure–volume curve that is steeper and shifted to the left. This particular hemodynamic observation suggests that allograft ventricles are less compliant. Furthermore, allograft cardiac performance seems uniquely dependent on loading conditions, which in turn are clearly related to postural volume changes[42–44]. Rudas *et al.*[43,45] evaluated upright exercise hemodynamics 3 and 12 months after HTx, noting attenuated heart rate responsiveness, reflected by a slower heart rate acceleration, but rapid deceleration post-exercise after the first year. Compared to baseline studies, however, initial heart rate increase at 1 year seemed faster. Pulmonary capillary wedge pressure was lower at 1 year versus 3 months, both at rest and at peak exercise, with right atrial pressure also significantly lower at 1 year during exercise. This observation should be placed into the perspective of reports of exercise-induced hypoxemia in HTx recipients, because not all of the exercise and resting hemodynamic impairment noted in cardiac allografts is due entirely to changes within the heart.

Braith *et al.*[46] studied whether HTx was associated with an adverse effect on pulmonary diffusion capacity, and investigated the potentially deleterious effects of impaired pulmonary diffusion on arterial blood gas dynamics during exercise. The possibility exists that abnormal pulmonary diffusion occurred because of cyclosporine therapy, or because of pre-existing conditions known to affect diffusion adversely (such as congestive heart failure, primary lung disease, or pulmonary infection in an immunocompromised host). Patients underwent pulmonary function testing with bicycle ergometric exercise 3 months before and 18 months after HTx. Significant improvement in forced vital capacity, forced expiratory volume in 1 second, and diffusion capacity occurred; however, post-HTx vital capacity, forced expiratory volume, and diffusion were lower when compared with matched control subjects. Changes in arterial blood gases were similar among groups at 40% of peak power output, but at 70% of peak power output, arterial blood gases and blood pH were significantly lower in allograft patients having low diffusion capacities than in patients with normal diffusion and in control subjects. Cardiac index did not differ between the transplant patients with normal or low diffusion at rest or during exercise. Post-transplantation mean arterial pressure was related to exercise-induced hypoxia. It appears that abnormal pulmonary diffusion observed in patients before HTx can persist after the operation, with or without restrictive or obstructive ventilatory defects. When diffusion at rest is 70% of predicted, HTx recipients frequently experience exercise-induced hypoxemia. Obviously, this may have an effect on overall exercise capacity. Whether this is due to new infection, primary pulmonary disease, or a residual effect of heart failure is not clear[47–49].

Relating exercise performance post-HTx to other determinants of mobility, such as peripheral muscle function and performance, is also important. Patients with advanced heart failure often have skeletal muscle atrophy with metabolic abnormalities of muscle function[50–52]. Wilson *et al.*[52] recently studied this issue. Because the exertional dyspnea and fatigue associated with heart failure is frequently attributed to circulatory dysfunction, heart failure patients underwent hemodynamic monitoring during a maximal treadmill exercise test. The level of exercise intolerance perceived by patients with heart failure had little or no relation to objective measures of circulatory, ventilatory, or metabolic dysfunction apparent during the aerobic stress. This being the case, simply altering blood flow and pressure to more normal levels after HTx may not entirely address patient complaints of exercise intolerance. Intrinsic muscle oxidative problems may actually be exacerbated by immunotherapy post-transplant. Exercise testing focusing on peak oxygen utilization and time taken to reach anaerobic threshold is, then, often impaired post-transplant because of residual peripheral skeletal muscle difficulties originally created by the heart failure syndrome[50,51]. With increasing exertion, anaerobic metabolism is common quite early, and several studies have demonstrated that peak exertional oxygen utilization after HTx is surprisingly low. Savin *et al.*[53] demonstrated that HTx patients had higher peak lactate levels and ventilatory equivalents, but lower peak oxygen uptake and peak work rates, than those of normal control subjects. Exercise after HTx eventually induces tachycardia and an increased contractile state, but this takes time to develop and is seemingly related to the effects of increased circulating catecholamine levels. The dynamics of this exercise response may account for the fact that the maximal stress cardiac output after HTx is generally lower than seen in normal subjects[38,40,53]. However, transplant patients are capable of participating in most desired physical activities, and in comparison to their pretransplant state are dramatically improved.

The effects of cardiac allograft denervation

Human donor heart cardiectomy with subsequent HTx creates both afferent and efferent cardiac denervation[11,12,15]. Interruption of the afferent nervous pathways alters cardiovascular homeostasis by impairing renin–angiotensin–aldosterone regulation, and impeding the normal vasoregulatory response to changing cardiac filling pressure[54]. Loss of afferent nervous signaling is also the likely reason complaints of angina pectoris are absent in HTx patients experiencing ischemia or myocardial infarction. Chest pain in the cardiac allograft recipient is most often due to other etiologies[55].

Efferent cardiac innervation mediates sympathetic and parasympathetic nervous system effects on the heart. The absence, therefore, of vagal-mediated parasympathetic influences causes resting heart rate to be higher, and eliminates the influence on the heart of vasosignaling from the central nervous system[55–57]. Loss of autonomic innervation blunts the usual rapid changes in heart rate and contractility noted normally during exercise, hypovolemia, or vasodilation[35]. Also important is the fact that administration of beta-adrenergic blocking agents may have deleterious effects on the denervated heart. Because the denervated cardiac allograft relies on enhancement of ventricular performance through stimulation of myocardial beta-adrenergic receptors by circulating catecholamines[56,58], beta-blockade may blunt exercise-induced augmentation of cardiac function. Indeed, in a study by Verani *et al.*[58], beta-adrenergic blockade by propranolol administration produced a decrease in ventricular performance at rest, characterized by lower stroke volume index, lower cardiac index, and lower ejection fraction in both HTx patients and control subjects. Though the changes were similar in both groups, ejection fraction was significantly lower in the HTx patients. As the ejection fraction decreased, end-systolic volume increased substantially. In normal subjects there was a reduction in heart rate, but there was only a minimal reduction in ejection fraction and no change in end-systolic volume. These observations emphasize that, in the denervated HTx patient, circulating hormones appear crucial to maintaining reasonable exercise performance. Use of beta-blockers should be judicious.

The response of the denervated heart to other types of stress is also important to review. A canine model of the denervated heart studied by Tsakiris *et al.*[56] demonstrated that acute hypertension was well tolerated with only a slight decrease in cardiac output and a small increase in left ventricular end-diastolic pressure. Hypotension was less well tolerated with minimal reflex increase in cardiac output because of little, and late, heart rate responsiveness. Baroreflex-induced volume regulation after HTx has been demonstrated by Mohanty *et al.*[57] to be impaired. Central volume reduction (created by placing the lower body of the patient in a negative-pressure chamber) produced minimal reduction in forearm blood flow and only a slight increase in forearm vascular resistance (because HTx permits portions of

the native atria, with their accompanying sympathetic and parasympathetic innervation, to remain intact). This observation suggests that nerves arising in the ventricle rather than in the atrium or pulmonary vasculature constitute the afferent limb of this reflex. Additionally, it has been suggested that the inability to reduce blood flow (by vasoconstriction) to non-working muscles plays a role in limiting the maximal exercise capacity of HTx recipients[35]. Scherrer *et al.*[59] suggested that cyclosporine-induced hypertension (noted so frequently in HTx recipients) is associated with increased peripheral sympathetic nerve discharge, and that this effect may be exaggerated in HTx patients because of cardiac denervation.

There is evidence that reinnervation occurs in some patients after HTx. It has been demonstrated by immunohistochemical staining that human cardiac allografts contain viable intrinsic nerve fibers, though they remain extrinsically denervated[60]. Although ischemia-induced chest pain in the form of classic angina pectoris is said not to occur in HTx recipients, reports of this occurring in relation to ischemia are available[55]. This suggests that at least some HTx recipients undergo partial afferent reinnervation. Stark *et al.*[55] demonstrated a tyramine-induced cardiac epinephrine response suggesting reinnervation in two patients with angina pectoris and allograft arteriopathy. Wilson *et al.*[61], in a study of norepinephrine release in response to tyramine and sustained hand grip, concluded that it was likely that sympathetic reinnervation commonly occurred late after HTx, but that the pattern of reinnervation was widely variable.

More recently, Burke *et al.*[62] evaluated the functional effects of neuron reinnervation late (> 1 year) after HTx. Left ventricular and coronary hemodynamics in HTx and control groups were studied after stimulating sympathetic neurons with an injection of tyramine into the left coronary artery. Reinnervation was defined as the ability to measure cardiac norepinephrine release after the tyramine injection. Left ventricular pressure was also measured before and after tyramine infusion, as was coronary blood flow velocity, and coronary artery cross-sectional area (calculated by quantitative coronary angiography). In patients studied early after HTx, as well as those studied late, denervation was defined as no change in left ventricular function in response to tyramine. In HTx patients with reinnervation, left ventricular dP/dT rose significantly, but less than in control subjects. This serves to confirm the fact that cardiac allografts function abnormally, but subtly so, when compared to normal hearts. In both early- and late-denervated patients there was no change in coronary blood flow velocity in response to tyramine. These investigators concluded that, by stimulation of reinnervating sympathetic neurons with tyramine, a significant but subnormal increase in dP/dT and a transient decrease in coronary blood flow occurred, suggesting that reinnervating sympathetic neurons can produce physiologically meaningful changes in ventricular function and coronary artery tone. How frequent and what the physiologic significance is of reinnervation remains unclear.

Endocrine issues and the heart transplant

Atrial natriuretic peptide (ANP) is synthesized, stored, and released from myocytes of mammalian hearts, and has peripheral effects. The heart is thus an endocrine gland. Several observations in cardiac allograft recipients have given insight into the role cardiac innervation plays in the endocrine function of the heart. One hypothesis is that cardiac autonomic nerves trigger the release of ANP. Pepke-Zaba *et al.*[63] measured plasma ANP concentrations in the right atrium and main pulmonary artery, together with determination of pulmonary hemodynamics, in HTx recipients undergoing graded submaximal bicycle exercise testing during right heart catheterization. Pulmonary artery blood samples and hemodynamic measurements were obtained at rest, during peak exercise, and after recovery. Exercise significantly increased ANP levels in both the right atrium and the main pulmonary artery. It would appear that HTx recipients still retain the ability to increase ANP release in response to exercise, and that the mechanisms underlying ANP release are not entirely dependent upon the integrity of cardiac innervation. Unfortunately, these investigators did not determine whether partial reinnervation of allografts had occurred.

More recently, Bussieres-Chafe *et al.*[64] attempted to relate the influence of body posture and central hemodynamics on plasma levels of ANP. Central hemodynamics, mixed expiratory gas and ventilatory measurements, and venous blood for ANP determination, were obtained at rest and during graded cycle exercise. They also noted a change in exercise ANP from rest to exercise, and this change correlated with increases in pulmonary capillary wedge pressure, systolic pulmonary artery pressure, and right atrial pressure. There was no correlation between changes in ANP and peak oxygen consumption, heart rate, or mean arterial blood pressure. They concluded that in HTx recipients exercise is a stimulus for ANP secretion, and that augmentation in plasma ANP levels during exercise is modulated by changes in central hemodynamics. Again, the degree of reinnervation of these hearts was not determined.

Along these lines, Ationu *et al.*[65] studied expression of brain natriuretic peptide post-HTx. Observations in this group were determined over a broader time period (1–74 weeks post-HTx), and it was noted that a significant positive association between ventricular natriuretic peptide and time after transplant was apparent, suggesting that either a functional adaptation of the transplanted heart was occurring, or effects of reinnervation were present. The fact that, in HTx patients, plasma ANP levels may be elevated higher than expected by atrial stretch alone is a fascinating observation needing further clarification. The issue of immunologically mediated ANP secretion has not been resolved.

Other aspects of paracrine system perturbation are apparent in HTx patients. Indeed, cyclosporine-treated individuals exhibit a high incidence of systemic hypertension, and endothelin, a potent vasoconstrictor peptide of endothelial origin, may be important. Haas *et al.*[66] evaluated whether immunoreactive endothelin-1 detected in circulating plasma of HTx recipients was elevated, and if levels correlated with hemodynamic characteristics, cyclosporine concentration, or renal function. Indeed, plasma endothelin-1 was increased in the HTx population and this increase persisted during short-term follow-up. Endothelin-1 did not correlate with hemodynamic variables, serum creatinine, or cyclosporine levels. It seems, then, that endothelin-1 is increased after HTx for some reason, but there is no association with hemodynamics, renal function, or cyclosporine levels. This observation remains of

some concern because of the rather substantive hemodynamic effect of this paracrine peptide.

Electrocardiographic and electrophysiologic changes

Serial electrocardiographic (ECG) changes have been noted in the HTx recipient and, indeed, the earliest method of monitoring for HTx rejection utilized quantification of ECG voltage[67,68]. It is now generally accepted that this finding is not sensitive or specific enough to adequately diagnose allograft rejection. However, early observations noted substantive decrement in QRS voltage when rejection occurred. This undoubtedly reflected the attenuated electromechanical coupling that occurred when rejection was significant. Cyclosporine is said to alter this process.

Plainer ECG abnormalities are frequently noted post-HTx. Leonelli *et al.*[69] indicated that almost three-quarters of first postoperative ECG evidenced changes that would not be expected in normal patients, with a predominance of right bundle branch block being noted. Patient age, donor age, ischemic time, and prior drug therapy in recipients did not significantly differentiate between HTx recipients who had normal (as opposed to abnormal) early postoperative ECG. There are, seemingly, evolutionary changes taking place during the initial post-HTx hospitalization. Patients having progressive deterioration of the conduction system (manifest by widening QRS complexes) or worsening preexisting conduction defects have a higher early mortality. These changes therefore become an important prognosticator.

Approximately 20% of HTx patients during early postoperative follow-up demonstrate sinus node dysfunction with slow or no spontaneous depolarization[41,70]. Most frequently, these patients have junctional rhythms, with a lower resting heart rate (usually <70 beats/minute) than that of the majority of HTx patients[41]. Sinus node dysfunction may be caused by ischemic injury during graft harvesting, but rejection or, later, allograft vasculopathy may play a role. Furthermore, sinus node dysfunction has been described in patients who died in a sudden and unexpected fashion early and late after HTx[71]. Indeed, some patients have required permanent pacemaker implantation for persistent sinus node dysfunction[41,72]. In addition to the usual indications for permanent pacemaker implantation, some believe permanent pacing is indicated in HTx patients with unexplained recurrent syncope, or near syncope (particularly in the setting of allograft vasculopathy), as sinus node dysfunction may be intermittent and difficult to document[71].

Electrophysiologic studies performed after HTx demonstrate that atrioventricular node conduction times are similar to those of normal subjects both at rest and during pacing[73,74]. Atrial–His and His–ventricular intervals are also normal. Although the atrioventricular node alters conductivity relative to the rate of stimulation, this requires more time to occur in the transplanted heart[74]. Taken together, these observations emphasize that atrioventricular node impulse transmission control is an intrinsic function, with autonomic innervation enhancing this activity rather than being essential for underlying function.

It has been suggested that changes in atrial or ventricular pressure or chamber size modulate changes in electrophysiologic properties. Ellenbogen *et al.*[75] studied the coupling of mechanical and electrical alterations (termed mechano-electrical feedback) in the transplanted heart. This was done to avoid confounding influences of the autonomic nervous system on electrophysiologic measurements. Right atrial and ventricular pacing thresholds were measured using temporary epicardial pacing wires, with right ventricular monophasic action potential duration noted at 90% repolarization during right ventricular pacing at 600 and 400 ms. Also observed were donor heart rate, systolic, diastolic, and mean arterial and central venous pressures. Lower-body negative pressure was applied to change central volume and cardiac size. Lower-body negative pressure did not result in a significant change in any electrophysiologic variable despite significant changes in right atrial pressure. Thus, in the denervated transplanted human heart, unloading of the right heart results in no, or minimal, changes in atrial or ventricular pacing thresholds or ventricular monophasic action potential duration.

Ventricular arrhythmias in the HTx patient are not common. Arrhythmias tend to be either bradyarrhythmias or supraventricular tachycardia that is most often seen early post-transplant and usually in the setting of allograft rejection. Animal paradigms have suggested that cardiac denervation is an antiarrhythmic maneuver, particularly in terms of ischemia-related ventricular arrhythmias[76]. Indeed, there appears to be a low prevalence of ventricular tachycardia in long-term survivors of orthotopic HTx, with most agreeing that ventricular arrhythmias, when noted late, are associated more with development of allograft vasculopathy[75,77,78] and, when seen early, with acute rejection. The relationship of ischemic disease in the transplanted heart to bradyarrhythmias may actually be more important and ominous. Bradyarrhythmias should be considered when HTx patients complain of non-specific 'spells' or presyncopal episodes[71]. Importantly, it is an anecdotal impression that HTx patients do not sense their arrhythmias with the same frequency or intensity as non-transplant patients.

PHARMACOLOGY AND THE CARDIAC ALLOGRAFT

Primarily because of denervation, drugs affecting physiologic responses through autonomic nervous system stimulation are not usually useful in the transplanted heart. Atropine, for example, with its effects mediated by a parasympatholytic mechanism, does not speed the allograft ventricular rate when bradycardia is present[79]. Atropine is, mostly, a useless drug in HTx patients when bradycardia, sudden heart block or asystole develop. Direct-acting beta-adrenergic stimulating drugs such as isoproterenol or epinephrine must be used in these circumstances[79-81]. Likewise, edrophronium, a cholinesterase inhibitor, has no effect on heart rate[80]. Sympathetic agents, having direct effects on beta-adrenergic myocardial receptors, induce normal or even exaggerated effects on heart rate and cardiac contractility. Indeed, cardiac denervation may lead to an increased sensitivity of the denervated allograft to parenterally administered beta-adrenergic agents[81]. Exaggerated sensitivity to acetylcholine in denervated cardiac paradigms has also been observed[82]. Very importantly, because acetylcholine and the endogenous nucleoside adenosine have similar cardiac electrophysiologic effects, this drug must be used cautiously because of the greater changes noted in HTx recipients with denervated myocardial autonomic nodes[83]. The fact that a denervated sinus

node drives intrinsic heart rate means that care should be exercised to prevent bradyarrhythmia when the agent is used during diagnostic scintigraphic study, or to attempt cardioversion in patients having paroxysmal supraventricular arrhythmias (usually in the setting of rejection).

Because the electrophysiologic effects of digoxin are primarily on sinoatrial and atrioventricular nodes, but are mediated by sympathetic and parasympathetic nervous signaling, this agent has little electrophysiologic activity in the transplanted heart[84]. The inotropic effect of digoxin (which is not mediated by the autonomic nervous system) seems to remain intact. Utilizing digoxin to induce atrioventricular block in patients with atrial fibrillation after HTx is not usually effective. Furthermore, the effects of digoxin on baroreceptor mechanisms of blood pressure control will be minimal. Digoxin's role in patients developing systolic ventricular dysfunction after HTx (usually due to acute rejection (early) or allograft vasculopathy (late)) remains undefined, but is probably not great.

Certain antiarrhythmic agents (class IA drugs, such as quinidine and dysopyramide) have vagolytic effects that increase resting heart rate in non-transplant patients[85,86]. These changes are not observed in the denervated cardiac allograft and, instead, decreased sinus rate and increased atrioventricular conduction times often result when these drugs are administered.

Calcium channel blockers demonstrate attenuated responses with respect to electrophysiologic and electrocardiographic changes when compared to their effects in non-transplant patients. Diltiazem, a calcium channel blocker frequently used to control hypertension post-HTx (and believed by some to be effective in attenuating allograft vasculopathy), does not cause substantial decrease in heart rate in these patients[87,88]. Verapamil produces a slight increase in atrial–His interval[87]. The dihydropyrimidine calcium channel blocker, nifedipine, produces a minimal reflex increase in heart rate coincident with decrement in blood pressure, and has been shown to produce a slight decrease in the atrial–His interval[87].

HETEROTOPIC HEART TRANSPLANTATION

Heterotopic, or so-called 'piggy back', HTx has been performed much less frequently than orthotopic HTx, comprising <2% of all HTx reported to the Registry of the International Society for Heart and Lung Transplantation[89]. Nevertheless, there may be an important therapeutic place for this procedure and, particularly as donor-to-recipient size mismatch becomes problematic, it is likely to be performed more frequently[90–92]. The concept of utilizing a heterotopic HTx procedure is, in effect, using the allograft as a 'biologic' ventricular assist device[91] (Chapter 37). Generally, heterotopic HTx has been performed in the setting of very elevated pulmonary artery pressure, or when the donor size seems inadequate in relation to that of the potential recipient. Central circulatory hemodynamics are difficult to assess, since the heterotopic implant is placed in parallel to the existing circulation. Therefore, hemodynamic function of the heterotopic heart involves additional physiologic variables, such as the contribution to overall cardiac output by the native heart and the different loading conditions (such as pulmonary hypertension and ability/inability to fill the heterotopic right heart system). Because both donor and native hearts are beating in parallel but not synchronously, hemodynamic assessment of the relative contributions of the two hearts is difficult. However, heterotopic implants have been demonstrated to be capable of completely supporting a patient's circulation when the native heart becomes asystolic or develops ventricular fibrillation[91]. Additionally, with time, reduction in pulmonary hypertension may occur, and right heart hemodynamics that are similar to those following orthotopic HTx have been observed[92]. Heterotopic HTx can provide hemodynamic support sufficient to ameliorate many of the abnormalities seen in patients with advanced left ventricular dysfunction, and of considerable interest is the potential for the heterotopic HTx to reverse the biologic dysfunction of a dilated, failing native heart.

CONFOUNDING ISSUES REGARDING PHYSIOLOGY OF THE TRANSPLANTED HEART

Factors which may significantly alter function of the transplanted heart should always be considered. Possibly the most important is cell-mediated or humoral rejection, with its subsequent myocarditis. Mononuclear cellular infiltration and humoral antibody production, with concomitant complement system activation, can profoundly impair cardiac contractility, as well as affect coronary blood flow. The severity of these difficulties relates to the timing and dynamics of immunologic activity. During acute rejection, coronary vascular reserve is compromised and varying degrees of systolic and diastolic ventricular dysfunction can be observed. Profound reductions in cardiac output and ejection fraction with concomitant acute rise in ventricular filling pressure are frequently noted when rejection develops rapidly and is fulminant. Treatment of rejection often reverses these abnormalities, resulting in improved graft function[93,94]. However, permanent biventricular diastolic dysfunction may be the result of frequent, severe episodes of histologic rejection. It has been postulated that the restrictive hemodynamic patterns noted after HTx relate to histologic signs of rejection. Other long-term changes include increased left ventricular afterload and hypertrophy due to hypertension (which in turn contributes to the remodeling process and functional alteration noted in the long term).

Unfortunately, allograft vasculopathy remains frequent in HTx patients, and likely contributes to functional graft impairment. Left ventricular systolic dysfunction can occur in the setting of graft ischemic disease, and coronary angiography defines a high-risk subgroup for subsequent events such as acute myocardial infarction and heart failure[95]. Additionally, sudden cardiac death syndrome (frequently from bradyarrhythmic death) may be related to allograft vasculopathy.

Pre-existing disease in donor hearts may also account for dysfunction after transplantation. Older donor hearts, for example, may be at risk for having occult, but significant, coronary artery disease. Hypertension in the donor may have led to increased ventricular mass and diastolic dysfunction. It has recently been suggested that extending donor age to at least 50 years seems reasonably safe, but caution needs to be exercised when older donor hearts requiring significant inotropic support are used, particularly if the anticipated ischemic time is long[96]. This may put the patient at increased risk of receiving a poorly functioning allograft, with the attendant higher morbidity and mortality.

Confounding issues, such as pre-existing disease in the donor heart and rejection, may be important factors in failure of the allograft to perform adequately. Function of the heart is critically dependent upon eliminating or controlling these factors. Whenever one is evaluating function of a transplanted heart, the patient's status with regard to these confounding issues must be considered.

COMMENT

The transplanted heart is a denervated preparation that, in the absence of substantive rejection, significant allograft vasculopathy or hypertension, performs at rest in a similar but not identical fashion to a normal, healthy heart. Diastolic dysfunction is common early after HTx and may recur at later stages in some patients. This difficulty may be due to repeated episodes of acute rejection, hypertrophy and remodeling secondary to hypertension, or significant allograft vasculopathy. Cardiac reserve during exercise is usually adequate, but generally less than that seen in normal hearts. Augmentation of cardiac performance during stress is apparent, and is related to endogenous elevation of catecholamines and changes in diastolic loading conditions. In view of the preoperative functional limitations obvious in patients with advanced heart failure, cardiac allografts demonstrate a welcome degree of 'normal' physiologic function.

Pathology of Cardiac Allograft Rejection. 1: Vascular (Microvascular)

E.H. HAMMOND

INTRODUCTXION

Pathologic descriptions of allograft rejection of all solid organs have long recognized vascular involvement in the rejection process. Renal allografts, the earliest allografts to be studied, commonly display vasculitis involving the arteries and arterioles of the kidney cortex with or without cellular infiltrates invading tubules[1-3]. This vascular inflammatory process, often termed acute vascular rejection, is frequently associated with allograft loss in spite of increased immunosuppressive therapy[2,3]. Similarly, arteritis has been identified in cardiac allografts on endomyocardial biopsy, and has been associated with poor allograft survival[4,5].

In all these studies, emphasis has been placed on involvement of the arterioles and arteries rather than on capillaries or venules. Since venules and capillaries are the sites of lymphocyte trafficking, as well as being the most important sources of tissue oxygenation, it is also important to consider the changes in these vascular structures in allograft rejection[6,7]. Studies of allograft rejection in animals have shown that the microvasculature is the earliest structure to be destroyed during rejection[8,9]. Destruction of the microvasculature of human skin allografts has also been shown to be the central event in first-set rejection; in fact, the destruction of the capillary bed is likely more damaging to the graft than piecemeal destruction of the graft parenchyma[10]. Although endothelialitis of venules is considered evidence of moderate acute rejection in the liver, and capillaritis is considered as an important component of acute allograft rejection in the lung, the importance of microvascular changes in cardiac allografts has been ignored until recently[11-16].

Microvascular rejection is also the morphologic picture of rejection seen in treated and untreated experimental cardiac xenografts. Studies in several different animal model combinations, including porcine heart to primate models, have documented that hyperacute microvascular rejection is associated with vascular accumulation of immunoglobulin and complement, and results in rapid loss of the xenograft[17-20].

In this chapter, pathologic features of rejection involving the microvasculature (capillaries and venules) are described as they have been studied and reported from the Utah Transplantation Associated Hospitals (UTAH) Cardiac Transplant program (530 patients receiving cardiac allografts between 1985 and 1995). Most of these patients were treated with immunoprophylactic protocols, including anti-lymphocyte globulin (ALG) or murine monoclonal antibody against the CD3 receptor (OKT3)[21,22].

The morphologic observations in this chapter detail the types of microvascular changes that can be encountered in endomyocardial biopsies (EMB), explanted hearts, and autopsies from such patients[14,16,23]. The histologic appearance of acute cellular rejection (Chapter 29) and the typical appearance of coronary artery vasculopathy (Chapter 33) are addressed elsewhere. A chronic generalized form of microvascular rejection leading to heart failure in transplant patients is described here, since this type of chronic vasculopathy is frequently observed in patients with microvascular rejection. This process has been designated 'global myocardial ischemic damage'[16].

In all histologic investigations it is important to remember that our observations are static, and that the rejection processes are dynamic. Thus, the real importance of types of infiltrating cells in a biopsy or the presence of immune complexes, *if not demonstrated consistently over time*, may not be relevant to the mechanism by which rejection occurs. Earlier publications have focused on the relevance of CD8- or CD4-positive lymphocytes in the rejection process involving vessels[24-26]. These observations are flawed because they try to relate human vascular changes to those of well-characterized animal models. The relevance or any finding, isolated in time, to long-term outcome of a graft must be shown with clinical correlative studies. Of course, the impact of immunosuppression, and its effectiveness in treatment of rejection, must also be taken into account. This is a particular problem in relating the experience in untreated experimental allografts to those of treated human ones[8,9,26-28].

IMMUNOCYTOCHEMICAL AND MORPHOLOGIC DETERMINANTS OF MICROVASCULAR REJECTION

Initial criteria for the diagnosis of microvascular rejection of cardiac allografts were the demonstration of immunoglobulin and

complement components co-localized to the microvasculature of frozen sections of EMB samples[13]. These features were deemed diagnostic because they correlated with subsequent hemodynamic compromise of the allograft in the absence of cellular infiltrates diagnostic of cellular rejection[13,14,23]. Frequently the biopsies also exhibited vascular and interstitial fibrin accumulation[13,16,23].

Since the original publication of the first prospective series of patients with microvascular rejection, other investigators have confirmed and extended these observations to include other immunocytochemical markers of microvascular alteration[29–34]. Faulk and Labarrere have reported elegant studies documenting the relevance of immunocytochemical studies of anticoagulant and fibrinolytic pathway markers in assessing microvascular damage. They have noted that antithrombin III (ATT), a marker of the natural anticoagulant pathway, is normally expressed by the arterioles and venules, and is lost in instances of microvascular damage[29]. Furthermore, tissue plasminogen activator (tPA), normally present in smooth muscle cells of myocardial arterioles, is similarly lost in allograft microvascular injury. Associated with this loss of tPA is the accumulation of microvascular complexes of tPA with plasminogen activator inhibitor-1 (PAI-1)[15,29,30]. Fibrin and plasmin are found in the interstitium of such biopsies. Whether these changes of anticoagulant and fibrinolytic pathway expression are results of, or precursors to, a vascular endothelial-specific immune response is unknown. However, the alteration of the expression of these molecules clearly precedes permanent microvascular injury of cardiac allografts and has been correlated with cardiac allograft loss[29,30].

Lones and his colleagues have also noted that EMB with microvascular rejection have a large number of intravascular macrophages accumulating in the microvessels, which are often confused with activated endothelial cells[31]. Immunocytochemically, using antibodies directed against macrophage antigens KP-1 and CD68, these cells can be shown to be macrophages. Antibody directed against factor-VIII-related antigen (FVIII ra) or CD34 can be used to highlight endothelial cells[16,31,35,36]. The prominence of intravascular macrophages has been documented by ultrastructural examination of EMB[32,33]. The association of prominent intravascular macrophages and dysregulation of fibrinolysis and anticoagulation is potentially important to our understanding of this process: macrophages are able to alter fibrinolytic processes directly and indirectly, at least in atherosclerotic lesions. Tipping *et al.* have reported that macrophages from these lesions are able to make PAI-1 and also stimulate production of PAI-1 by endothelial cells (but not stimulate tPA production), probably through augmented secretion of interleukin-1 (IL-1) and tumor necrosis factor alpha (TNF-α)[37].

In the following classification of microvascular rejection, both the light microscopic and immunocytochemical findings will be described, since both are used to arrive at the appropriate classification. The methodology used for immunocytochemistry by immunofluorescence is the standard methodology used for investigation of renal biopsies and includes: (1) direct immunofluorescent examination of frozen unfixed endomyocardial biopsy sections with IgG, IgM, C3, C1q and fibrin, and (2) indirect determination of the presence of HLA-DR (MHC class II), ATT, and tPA[30,38].

It is not recommended that the sections be stained with antibody directed against the MHC class I backbone determinates since they are so pervasively present[39]. We do not recommend that EMB be routinely evaluated for immunophenotyping of lymphocytes, since studies of this type have not yielded clinically useful information[24–26]. Immunocytochemical demonstration of macrophages using antibody directed against KP-1 or CD68 may be a useful adjunct to show the intravascular localization. Antibody directed against FVIIIra or CD34 may also be used to highlight the endothelial cell changes in these biopsies. Since these later antibodies are used to extend histologic observations, they are best performed on unstained sections of paraffin blocks of the biopsies by immunoperoxidase techniques[16,35,36].

Other immunocytochemical studies may prove useful in the future. It has been suggested that the evaluation of biopsies for macrophage activation (CD14) and markers of lymphocyte activation, IL-2R (CD25) may yield important information relevant to prediction of rejection[40,41]. Others have evaluated vascular adhesion marker expression in cardiac allografts. A recent longitudinal study of 20 allograft recipients suggested that increased expression of vascular cell adhesion molecule-1 (VCAM-1) and intercellular adhesion molecule-1 (ICAM-1) on the microvasculature is found temporally related to cellular rejection[42].

VCAM expression was restricted to venules surrounded by infiltrating CD3-positive lymphocytes, which may provide a necessary co-factor for its expression. The temporal relationship of ICAM-1 to rejection events is consistent with the proposed role of this adhesion molecule as a mediator of high-affinity binding and transmigration events, as well as its co-stimulator function in antigen-dependent activation of T lymphocytes[43]. Since ICAM can also be induced in ischemic injury, its presence may be somewhat non-specific. *In vitro* studies have shown that anti-HLA antibodies can also stimulate ICAM expression by cultured endothelial cells[44]. By contrast, endothelial leukocyte adhesion molecule-1 (ELAM-1 or E-selectin) preceded cellular rejection and was only expressed transiently. Its expression was highly correlated with subsequent rejection. In animal models of allograft rejection, ICAM-1 and VCAM-1 expression has been demonstrated during rejection using PER to detect mRNA; antibodies directed against VCAM-1 were efficacious in abrogating the rejection[45–48]. This finding is confirmatory of the relationship of lymphocyte adhesion and infiltration, but is not diagnostically useful.

If up-regulation of these adhesion molecules can be consistently demonstrated before infiltration of lymphocytes, or can be correlated with need for treatment, they may become important monitoring criteria. Similarly, studies in human and animal allografts have attempted to characterize cytokine expression using PER to detect mRNA. Even in isografts, mRNA of IL-1, IL-6, TNF, LT, and TGFb can be found. By contrast, mRNA of IL-2, IL-4, and interferon-gamma (IFN-γ) were found only in allografts. Use of this information in monitoring human allografts for rejection must await further study[49,50].

The archiving of frozen tissue on all EMB will be crucial to these approaches, since all of these markers can be found only on frozen sections using immunofluorescence, immunoperoxidase, or PER techniques.

These studies highlight the crucial importance of the endothelial cell in all rejection processes. Expression of adhesion molecules, cytokines, ATT, and PAI-1 is limited to microvascular

endothelium. Studies have shown that lymphocytes adhere only to these structures within the myocardium[43]. In addition, recent experimental evidence has shown that endothelial cells, stimulated by IFN-γ possess the necessary signaling capacity to cause T lymphocyte proliferation, without the addition of macrophages[44].

CLASSIFICATION OF MICROVASCULAR REJECTION

Microvascular rejection can be evaluated descriptively or semiquantitatively by immunocytochemistry. Categories are described below on the basis of histologic and immunocytochemical findings. Such features have been seen in human allografts as well as treated animal xenografts in which acute vascular rejection has been prolonged to several days or weeks[17–20].

The value of a classification of microvascular rejection is unknown. It is offered here to provide a framework for evaluation of biopsies. Criteria are summarized in Table 1. Specifically, there may not be any significance to the designation of *mild* versus *moderate* microvascular rejection. Morphologically they appear as a spectrum of rejection of increasing severity: they are distinct from *severe* microvascular rejection which is identical morphologically to severe cellular rejection (International Society for Heart and Lung Transplantation (ISHLT), grade 4)[51,52]. The designation of *equivocal* is offered to explain changes that may be found which are not diagnostic but may cause confusion.

No evidence of microvascular rejection

In this category are included all EMB which show no light or immunofluorescent evidence of vascular rejection. By light microscopy such biopsies show no endothelial cell swelling, endothelial cell necrosis, thrombosis or inflammatory infiltrates in the walls of microvessels. Interstitial edema and hemorrhage are not present (Figure 1).

By immunofluorescence, negative biopsies show no significant MHC class II expression by endothelial cells. Furthermore, no vascular accumulation of immunoglobulin or complement components is detected. Leakage by fibrin and albumin, which would indicate increased vascular permeability and endothelial cell activation and/or injury, is not seen. Examination of the biopsy for evidence of anticoagulant pathway expression shows strong uniform ATT expression of arterioles and venules without expression by capillaries (Figure 2). This is the normal pattern of expression in the heart[29]. Tissue plasminogen activator (tPA) is expressed exclusively by smooth muscle cells of the arterioles within the heart, also the normal pattern of expression[30]. The sites of these substances in allografts without rejection have been confirmed by double-labeling experiments[29,30].

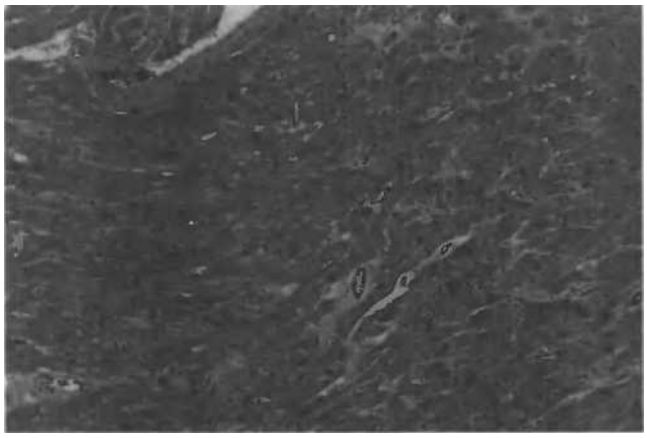

Figure 1 Photomicrograph showing the histologic features of an allograft biopsy without rejection or microvascular alteration. The capillary and arteriolar endothelial cells are flat. No interstitial edema or hemorrhage is present (magnification × 75). Used with permission from ref. 16

Equivocal evidence of microvascular rejection

By light microscopy, equivocal biopsies show histologic endothelial cell activation or damage with/without associated edema or hemorrhage. No inflammation or thrombosis is demonstrated in the walls of any capillaries, venules, or arterioles within the sample. Histologically, such biopsies are ISHLT grade 0. Since these features are very subjective, microvascular rejection can only be suspected on the basis of these findings (Figure 3). Similar equivocal findings can be seen in patients with systemic viral illnesses, especially those caused by cytomegalovirus[16,38].

Table 1 Vascular rejection criteria using immune complexes, fibrin, ATT and tPA

ISHLT Grade	*Vascular grade*	*Light microscopy*	*ATT/tPA*	*Fibrin*	*Ig/C*
0	Negative	Negative	Normal	0	0
0	Equivocal	Endothelial activation, edema, hemorrhage	Normal or equivocal	0	Ig or C
0	Mild	Endothelial activation, edema, hemorrhage, or focal vasculitis	Normal or absent	0 – 1+	Ig and C in BV 1+
0	Moderate	Endothelial activation	Absent	1 – 3+, also interstitial	Ig and C in vessels 2+
4	Severe	Diffuse aggressive polymorphous ± edema ± hemorrhage ± vasculitis	Absent	2 – 3+, vessels, interstitial with necrosis	Ig and C in vessels and interstitial

ATT = antithrombin III; tPA = tissue plasminogen activator (see text for explanation); Ig = immunoglobulin; C = complement

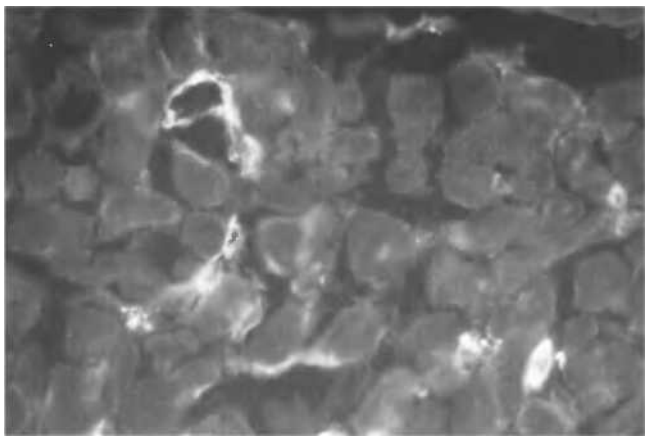

Figure 2 Photomicrograph of the usual appearance of antithrombin III staining of the vasculature of a normal endomyocardial biopsy. Strong staining by arterioles and venules is seen (× 187)

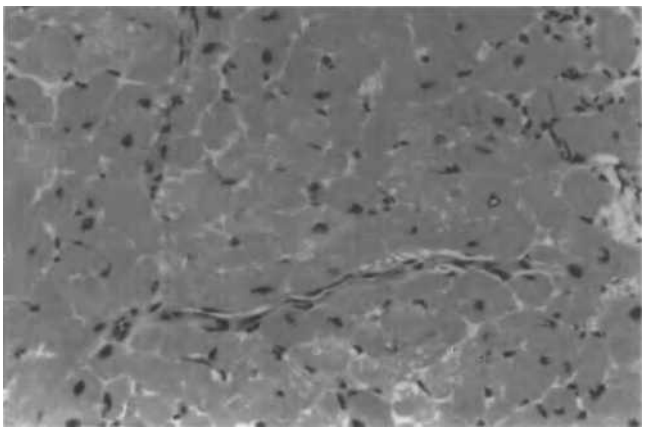

Figure 3 Equivocal histologic evidence of microvascular rejection or damage. Biopsy shows endothelial activation characterized by swelling of the capillary endothelium. No cellular rejection is seen (H&E × 187). Used with permission from ref. 16

Another equivocal histologic feature is the presence of focal myocyte necrosis or healing necrosis with granulation tissue. Focal ischemic injury is commonplace in the first weeks post-transplant in some transplant programs, and cannot be used to diagnose microvascular rejection. By contrast, the finding of myocyte necrosis, of either coagulation or contraction band type in the interval of months to years post-transplant, is a feature strongly suggestive of either allograft vasculopathy or global ischemic damage which is a consequence of long-standing microvascular rejection[14,16].

By immunofluorescence, such equivocal biopsies may show microvascular accumulation of immunoglobulin or complement components, but not both (Figure 4). Furthermore, vascular leakage may be demonstrated by seeing extravasated albumin in the absence of vascular immune complexes[38]. These features indicate that diffuse vascular permeability is present. Thus, these features are quite non-specific and cannot be used to specifically diagnose vascular rejection or vascular damage. MHC class II

Figure 4 In this immunofluorescent photograph, equivocal staining of vessels is seen with fluoresceinated antibody directed against IgG. Compare with the staining present in mild or moderate vascular rejection, seen in Figure 10 (× 178). Used with permission from ref. 16

antigen expression may be up-regulated on the microvasculature. Expression of ATT is of equivocal significance if loss of ATT is from venules but not arterioles. Tissue plasminogen activator may show focal loss from arteriolar smooth muscle[29,30].

These changes are ubiquitous in the first weeks post-transplant in patients undergoing induction immunosuppression with monoclonal anti-CD3 (OKT3) which has been shown to produce transient lymphocytic activation and release of cytokines, such as tumor necrosis factor (TNF) and interleukin-1[53,54]. Since these factors lead to vascular permeability and endothelial activation, it is not surprising that patients show these features during OKT3 therapy[54–58]. The clinical syndrome associated with OKT3 can be abrogated by treatment of patients with antibody directed against TNF[46,47]. This provides evidence of the importance of this cytokine in mediating these effects.

Mild microvascular rejection

The presence of leukocytoclastic vasculitis, in the absence of cellular rejection, qualifies the EMB for a diagnosis of mild vascular rejection. This vasculitis involves venules and capillaries, but spares arterioles. The vessels may show prominent accumulation of nuclear dust, and the invading inflammatory cells are lymphocytes and macrophages and rarely neutrophils (Figure 5). Alternatively, the biopsy may be deceptively innocuous, showing only interstitial edema and/or hemorrhage with endothelial cell activation (which may be partially activated macrophages) and no inflammation (Figure 6). This is the type of biopsy in which immunofluorescence is particularly useful, since one can be misled by the light microscopic appearance, which is indistinguishable from the appearance of equivocal biopsies.

By immunofluorescence the EMB will show co-localization of immunoglobulin and complement components in capillaries and venules, with possible intravascular localization of small amounts of fibrin (Figure 7). Rarely, vasculitis can be caused by cellular immune mechanisms and, in such cases, immune complexes in vessel walls are not demonstrated. We have seen this pattern of

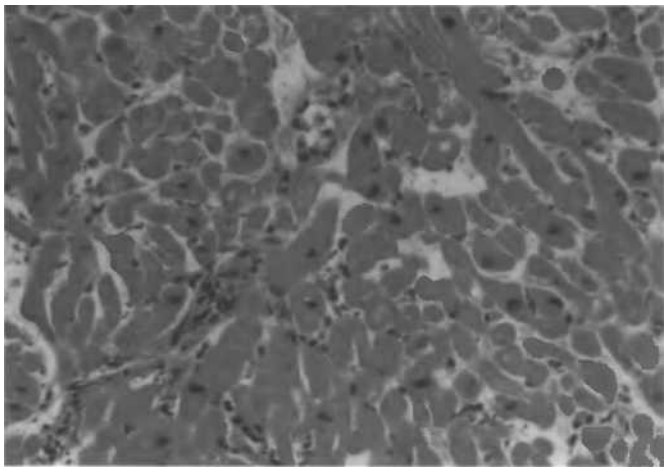

Figure 5 In addition to endothelial activation, capillaries in this biopsy show vasculitis. No cellular rejection is seen. Interstitial edema is obvious (H&E × 175)

findings in only three of 75 patients with vascular rejection, but it has been more frequent in the experience of others, especially in the absence of immunoprophylactic therapy[15,59,60].

Biopsies with mild vascular rejection consistently demonstrate alterations of the natural anticoagulant and fibrinolytic pathways. The microvasculature exhibits partial loss of ATT (on venules) and tPA (in smooth muscle cells of arterioles) or complete loss of ATT on all arterioles and venules and loss of smooth muscle tPA[15,29,30]. Up-regulation of MHC class II is also uniformly seen[16,61].

Moderate microvascular rejection

In this category, vasculitis may be extensive and arteriolitis may be found (Figures 8 and 9). Alternatively, patients with moderate microvascular rejection may show no vasculitis and may only show severe interstitial edema with a blue fibrillar appearance of

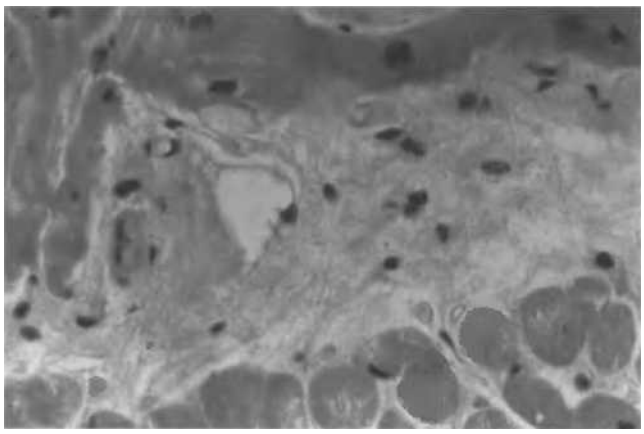

Figure 6 In this photomicrograph, at high magnification, an edematous area of interstitium is visualized. The fibrillar character of this edematous change is evident. Patient had positive immunofluorescence for immunoglobulin and complement (H&E × 30). Used with permission from ref. 16

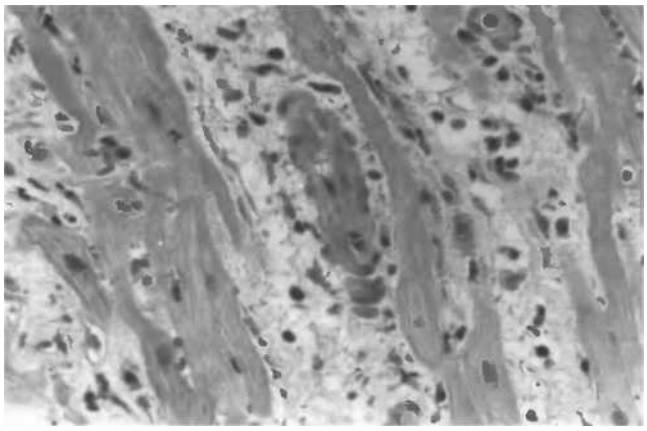

Figure 8 Biopsy with moderate vascular rejection. Capillaries, venules and arterioles, such as this one, had vasculitis. Interstitial edema and hemorrhage are seen. Particulate debris surrounding the arteriole is apparent. No cellular rejection is present (H&E × 300). Used with permission from ref. 16

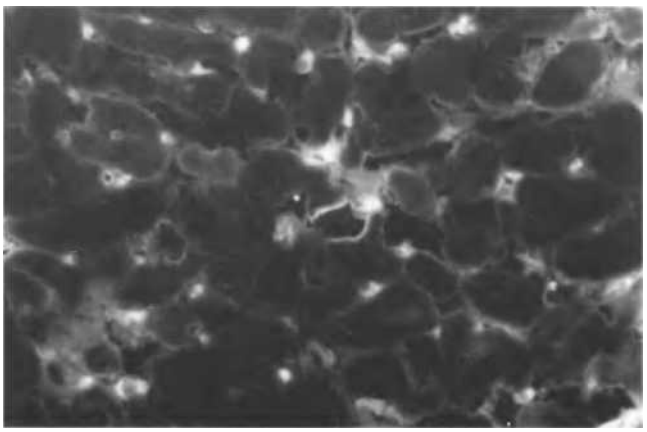

Figure 7 Frozen myocardium from patient with mild vascular rejection. Tissue was reacted with fluoresceinated antihuman IgG. There is a punctate pattern of staining, indicating vascular localization in round vessel profiles. Complement was present in an identical distribution. Compare with Figures 4 and 10 (× 178). Used with permission from ref. 16

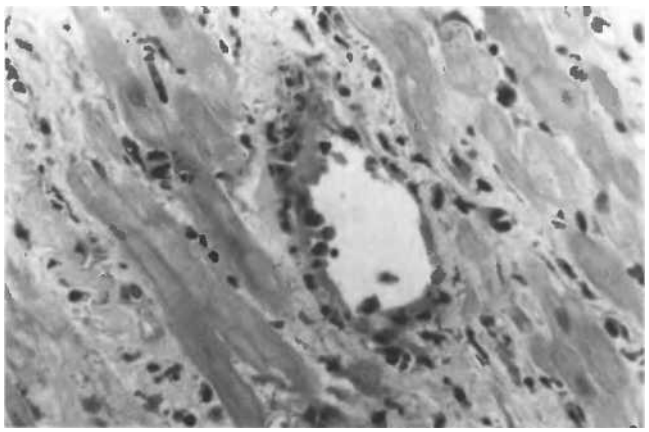

Figure 9 Moderate vascular rejection. This venule shows obvious inflammation. Interstitial edema is prominent. The immunofluorescence examination showed vascular accumulation of IgG and complement in capillaries and fibrin within the interstitium (see Figure 10). Used with permission from ref. 16

the interstitium, which has been shown to be associated with fibrin accumulation (Figure 6). In such patients it is critical to review the previous biopsy, to see whether or not the process is worse or better, in order to make an adequate assessment.

By immunofluorescence, moderate microvascular rejection usually shows obvious accumulations of immunoglobulin and complement components diffusely within capillaries and venules (Figure 10). In some cases, particularly in long-standing vascular rejection, only intravascular and interstitial fibrin is detected[14,16] (Figure 11). In biopsies of patients with moderate microvascular rejection, ATT and tPA are usually completely lost, and tPA–PAI-1 complexes are often present. This pattern of expression is often associated with clinical hemodynamic compromise[15,29,30] (Figure 12). Immunofluorescence is helpful in this setting because light microscopy may merely show interstitial edema without evidence of vasculitis. Such EMB may show piecemeal myocyte necrosis or subendocardial infarction, either

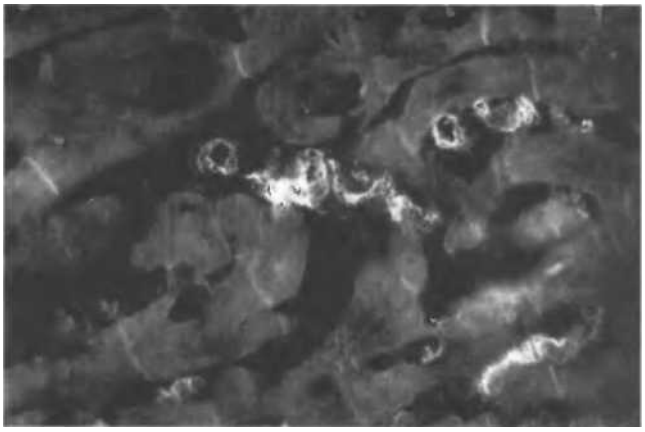

Figure 10 Immunofluorescent findings in moderate vascular rejection. Capillaries showed co-localized IgG and C3. The complement staining is shown here. Fibrin was abundant in the interstitium, and antithrombin-III was not found on arterioles or venules, consistent with moderate vascular rejection (× 178). Used with permission from ref. 16

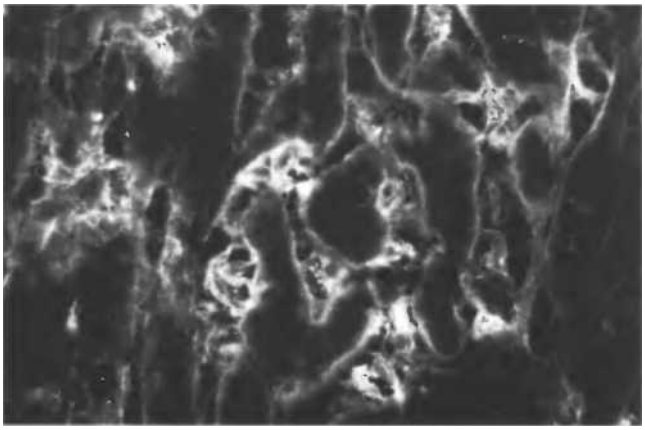

Figure 11 Fibrin localized by immunoflurescence is illustrated. Frozen myocardium is stained with fluoresceinated antibody directed against fibrin. Same biopsy as Figure 10 (× 178). Used with permission from ref. 16

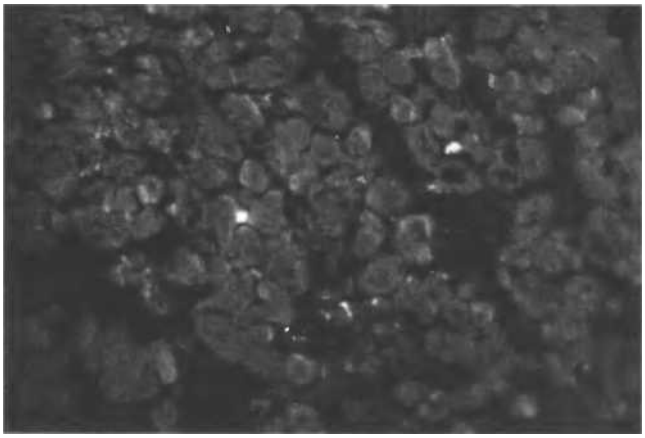

Figure 12 This photomicrograph of tissue reacted with antibody against antithrombin-III shows no staining of venules in the biopsy. Only two fluoresceinated dots are seen, which are artifactual. Compare with Figure 2, the normal distribution for ATT. Both slides were exposed for 30 seconds at the same magnification (× 178)

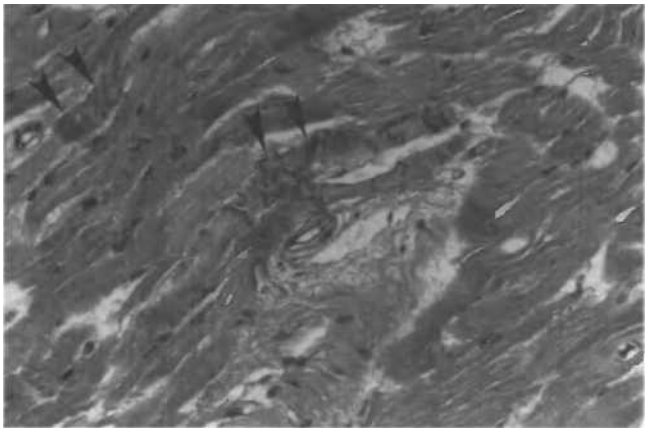

Figure 13 This biopsy from a patient with persistent vascular rejection for several weeks shows contraction band necrosis of myocytes without surrounding inflammation (arrows, H&E × 300). Used with permission from ref. 16

of which is evidence that larger arterioles, not included in the biopsy, may have vascular compromise (Figure 13). This is particularly true in the early months post-transplant, when it is very unlikely that the process could be related to epicardial coronary vasculopathy. Myocyte necrosis without inflammation, detected in the first few weeks post-transplant, may be caused by prolonged ischemic time or perisurgical hypoxia[62]. In our program such myocyte necrosis is very uncommon; other programs have reported that as many as 80% of early biopsies show this feature.

Severe microvascular rejection

Severe microvascular rejection is morphologically indistinguishable from severe cellular rejection (ISHLT grade 4). It is the end-result of any severe rejection process. The EMB shows a diffuse, mixed leukocytic infiltration including neutrophils and eosinophils (Figure 14). Myocyte necrosis and interstitial edema and hemorrhage may be prominent. Vasculitis is obvious.

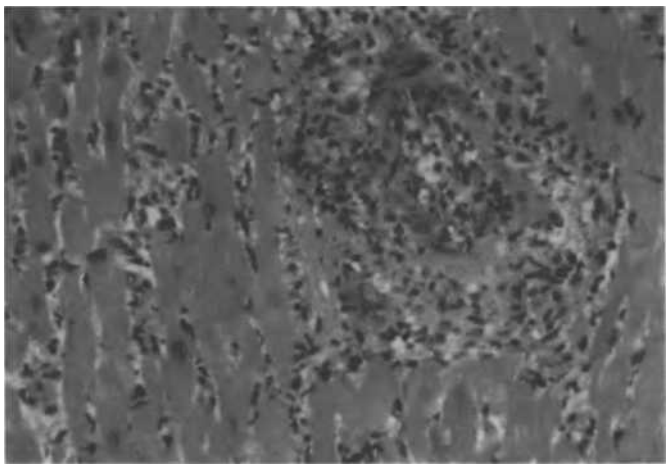

Figure 14 Histologic appearance of severe cellular and vascular rejection: arteriolitis is seen as well as other vasculitis. There is a mixed cellular infiltrate with myocyte necrosis and prominent intercellular edema. Immunofluorescence showed loss of antithrombin-III and extensive fibrin, immunoglobulin and complement in vessel walls (H&E × 175)

Immunocytochemically, biopsies with severe cellular/vascular rejection will often have vascular deposits of immunoglobulin and complement, as well as interstitial and vascular accumulation of fibrin. Complement components may also be distributed in the interstitium. Examination of biopsies for ATT and tPA will show loss of these reactants. Some tPA–PAI-1 complexes may be present[15,29,30]. The microvasculature may paradoxically show lack of MHC class II expression, resulting from the relentless vascular injury. This can be highlighted by immunoperoxidase staining of vessels with factor VIIIra[16]. In severe rejection, endothelium is ragged or frayed, or may show areas where endothelial cells are missing[14,16] (Figure 15).

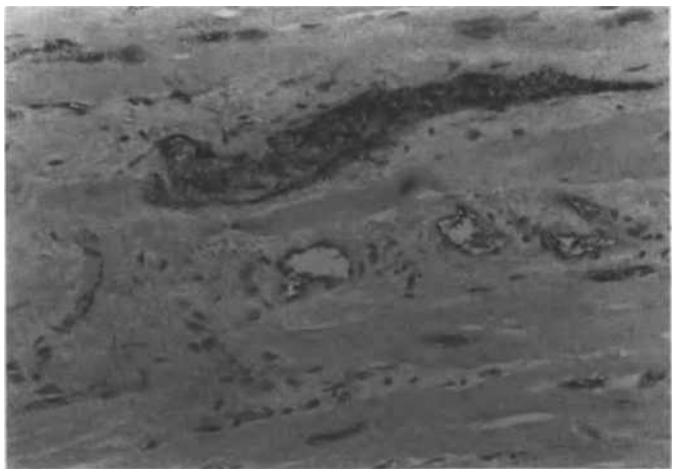

Figure 15 Vessels in this case of moderate microvascular rejection show ragged endothelial surfaces in this factor-VIIIra-stained section. The vessels from a biopsy with severe microvascular or hyperacute rejection would appear identical. (Immunoperoxidase method, counterstained with hematoxylin × 280). Used with permission from ref. 16

Severe hyperacute (microvascular) rejection

Hyperacute rejection of cardiac allografts is very rare and catastrophic. Acute cardiac dysfunction results from deposition of preformed antibody (IgG or IgM) and complement components in the microvasculature of the allograft[63]. This process has been reported to occur even in the presence of a negative lymphocytotoxic crossmatch[64]. Allograft dysfunction results from endothelial damage, vascular permeability, interstitial edema and hemorrhage, which cause myocardial ischemia. If the process persists for several hours an infiltrate of neutrophils within and around vessels can be seen.

Untreated xenotransplantation routinely leads to hyperacute rejection in discordant animal species where it has been investigated most thoroughly[17–20] (Chapter 81). The pathologic process is characterized by prominent interstitial edema followed by interstitial hemorrhage and swelling of the capillary and venular endothelium. Inflammatory infiltrates are not a feature, because of the rapid time-course of the process which leads to xenograft loss within minutes or hours. Hyperacute rejection is mediated by deposition of xenospecific antibodies in the donor heart. If the process is abrogated by depletion or inhibition of natural antibodies, or inhibition of complement activation, the histologic findings often include inflammation and venular thrombosis. Ischemic myocyte injury with myocytolysis and eventual coagulative necrosis is seen in xenografts surviving several weeks. A pattern of rejection identical to severe mixed acute cellular and vascular rejection (ISHLT grade 4) is observed in xenografts in which complement function returns (after 25 days)[17,19].

RELATIONSHIP OF MICROVASCULAR REJECTION TO ISHLT GRADING

The current ISHLT grading scheme for cardiac allograft rejection does not include provision for grading of the above-described processes[51,52]. The relationships between these microvascular grades of rejection and the ISHLT grading schema (revised in 1995) are shown in Table 2[52]. Because features of the microvasculature are ignored in this grading schema, the presence of microvascular changes causes difficulty in interpretation, and leads to interpretive disagreements, even among experienced pathologists[65]. However, since the incidence of microvascular rejection and the proper treatment for this pathologic entity are

Table 2 Comparison of UCTP and ISHLT grades

Cellular rejection: variations of ISHLT and UCTP grades
Focal mild rejection: ISHLT 1A
Mild rejection: ISHLT 1B and 2
Moderate rejection: ISHLT 3A or 3B
Severe rejection: ISHLT 4
Vascular rejection: variations of ISHLT and UCTP grades
Mild vascular rejection: ISHLT 0
Moderate vascular rejection: ISHLT 0
Severe vascular rejection: ISHLT 4
Mixed rejection: all considered as corresponding ISHLT cellular grade

UCTP = Utah Cardiac Transplant Program; ISHLT = International Society of Heart and Lung Transplantation

unknown, it is of less importance that a uniform grading schema for these changes be adopted. It was felt by the panel of pathologists, including this author, that these features should be further studied before being incorporated into a grading schema to be uniformly adopted.

Furthermore, it may not be useful at this time to adopt a classification of microvascular rejection into mild, moderate and severe subcategories, since no outcome or treatment differences between the groups have been established. Acute increases in immunosuppressive therapy are not undertaken on the basis of this information unless hemodynamic compromise is present[66]. Such hemodynamic compromise is much more common in patients with multiple episodes of microvascular rejection (vascular rejecters). These patient also have associated echocardiographic evidence of diastolic dysfunction[67].

CLASSIFICATION OF MIXED (CELLULAR AND VASCULAR) REJECTION

Mixed cellular and microvascular rejection may occur in an EMB simultaneously[13,14,16]. Independent grades of each process are assigned in our program. The cellular grading criteria are shown in Table 2, along with the corresponding ISHLT grades according to the revised ISHLT grading schema. Vascular grades are assigned according to the criteria described in Table 1. Mixed rejection, as defined in this chapter, is not recognized in the ISHLT schema; such biopsies are designated only by their cellular grade. Vasculitis is often ignored in the ISHLT schema except in severe rejection (grade 4), where it is the rule[52] (Figure 16).

DESIGNATION OF DOMINANT PATHOLOGIC REJECTION PATTERN

We have found it prognostically useful to designate patients according to their predominant form of histologic rejection[13,14,16,23]. Three separate clinical correlation evaluations of our patients have shown that these designations by predominant rejection type are prognostically important[13,14,23]. Patients with microvascular rejection have a significantly worse survival than patients with cellular or mixed rejection patterns, prospectively assigned in the first 3 months post-transplant (Figures 17 and 18)[14,23].

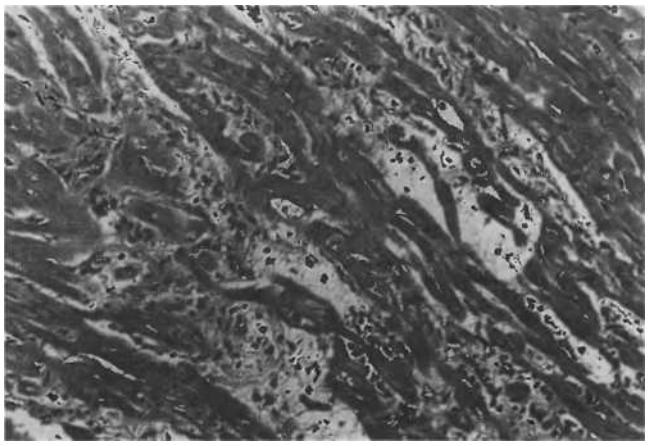

Figure 16 Histologic picture of moderate mixed rejection. Vasculitis and a space-occupying infiltrate of cells are seen, associated with myocyte damage. By ISHLT grading this biopsy would be considered 3B or 4, depending on the extent of the involvement of the biopsy with this process (H&E × 178). Used with permission from E.H. Hammond, editor. Solid Organ Transplantation Pathology vol.30 in series, Major Problems in Pathology, 1994

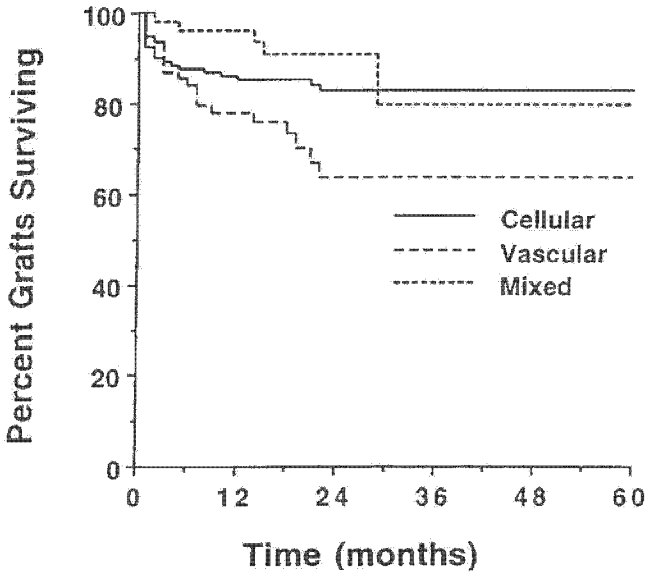

Figure 17 Kaplan–Meier graft failure curves are shown for each type of rejection group. Tarone Ware test was significant ($p = 0.027$) and the proportional hazard regression model showed the patients with vascular rejection had significantly different survival ($p = 0.012$) from patients with combined cellular and mixed rejection. Used with permission from ref. 14

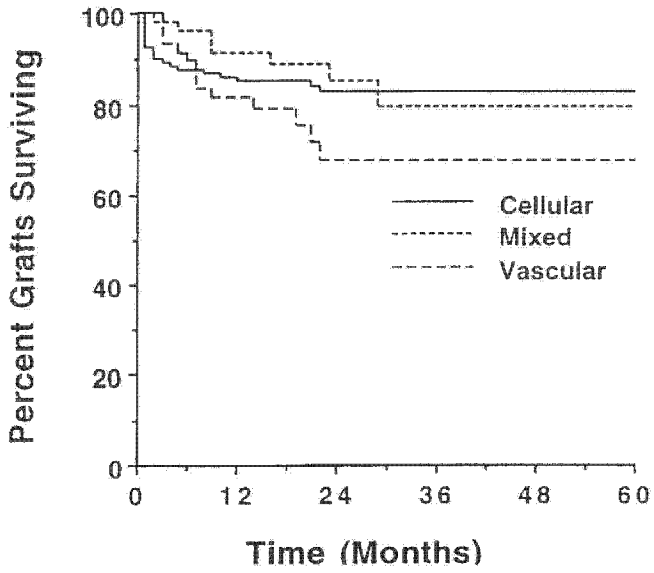

Figure 18 Kaplan–Meier graft failure curves are shown for each type of rejection group when OKT3-sensitized patients were eliminated from the analysis. Tarone Ware test for these data was not significant ($p = 0.223$). Used with permission from ref. 14

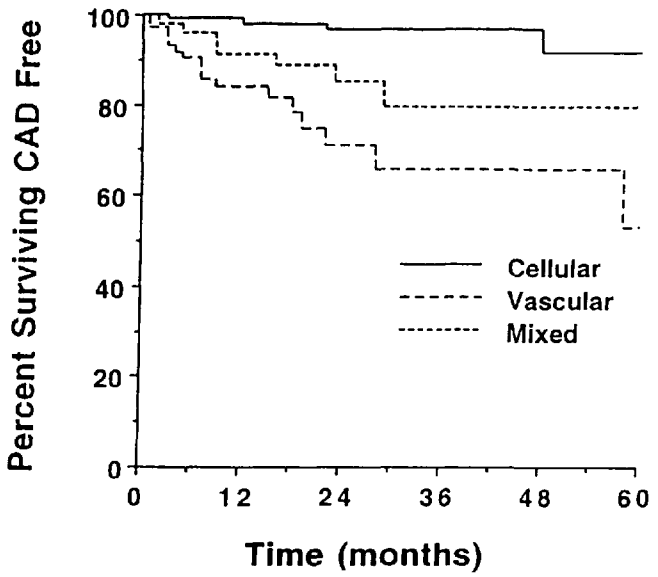

Figure 19 Kaplan–Meier coronary-free survival curves are shown for each type of rejection group. Tarone Ware test was significant among groups regardless of whether OKT3-sensitized patients were included ($p = 0.014$). The proportional hazard regression model showed that patients with the vascular pattern ($p = 0.0001$), as well as those with the mixed pattern ($p = 0.014$), were significantly different from cellular pattern patients. Used with permission from ref. 14

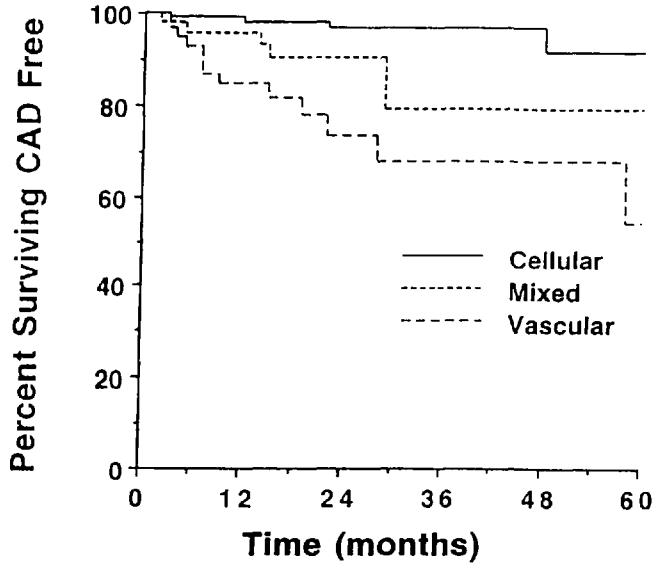

Figure 20 Kaplan – Meier coronary-free survival curves are shown for each type of rejection group. Tarone Ware test was significant among groups ($p = 0.001$). OKT3-sensitized patients were excluded from this analysis. The proportional hazard regression model showed that patients with the vascular pattern ($p = 0.0001$), as well as those with the mixed pattern ($p = 0.011$), were significantly different from cellular pattern patients. Used with permission from ref. 14.

Interestingly, although patients with mixed rejection have a survival rate similar to that in patients with cellular rejection, they have a 4-fold higher risk of developing allograft coronary artery disease; vascular rejection patients have an 8–9-fold greater risk (Figures 19 and 20). These risks are irrespective of the time post-transplantation[14]. The relationship of these rejection patterns to the occurrence of coronary artery vasculopathy is very impressive, especially when reviewed in the light of other published associations of coronary artery vasculopathy risk. Modest increases in risk of allograft coronary artery disease have been associated with: (a) degree of HLA mismatch, (b) HLA antibodies, (c) antiendothelial antibodies, or (d) panel-reactive antibodies detected in the serum of the patient post-transplant, (e) CMV infection, (f) donor–recipient mismatching for sex, (g) cellular rejection frequency, and (h) forms of hyperlipidemia (increase in total cholesterol, LDL cholesterol, or elevated plasma triglycerides). These data were recently reviewed by Marboe[68].

Faulk and Labarrere have presented compelling evidence that abnormalities in the expression of natural anticoagulant and fibrinolytic molecules are also associated with early graft loss; this loss, however is often very early, and is associated with acute myocardial infarction rather than diffuse coronary artery vasculopathy[29,30].

ALLOGRAFT CORONARY ARTERY VASCULOPATHY – RELATIONSHIP TO DIFFUSE CHRONIC VASCULOPATHY (GLOBAL MYOCARDIAL ISCHEMIA)

Elsewhere in this book are descriptions of the pathologic (Chapter 33) and clinical (Chapter 35) aspects of allograft coronary artery vasculopathy. One form of this vasculopathy will be discussed in detail here because of its prevalence in patients with multiple episodes of microvascular or mixed cellular and microvascular rejection. This form of chronic vasculopathy, studied in detail in explant and autopsy hearts from our transplant patient population, involves penetrating arteries and arterioles within the myocardium as well as the epicardial coronaries. The history and pathologic features are quite specific when present. The patient develops evidence of heart failure manifested by a decreasing left ventricular ejection fraction and the usual symptoms and signs. EMB is performed to rule out acute rejection as a cause of the patient's clinical symptoms.

On EMB a distinctive group of morphologic features is demonstrated. The biopsy shows focal areas of myocyte dropout in which myocytes are replaced by loose connective tissue and eventually collagen. Surrounding myocytes are often hypertrophied and vacuolated. Inflammatory cells such as lymphocytes and macrophages may be seen, but they are limited to the areas of myocyte dropout or scarring. Capillaries are difficult to find, and no endothelial activation is present (Figure 21)[14,16,69,70].

The patchy nature of this process, and its predilection for the subendocardial region, suggests that the myocyte loss is due to generalized microvascular damage, which includes small arteries and arterioles outside of the field of examination on endomyocardial biopsy. This observation has been documented on autopsy and explant evaluation of such hearts[14,16]. The changes are also seen in patients with allograft coronary vasculopathy. If these changes are encountered on repeated EMB in patients with slowly worsening cardiac function, they are an ominous sign. Such

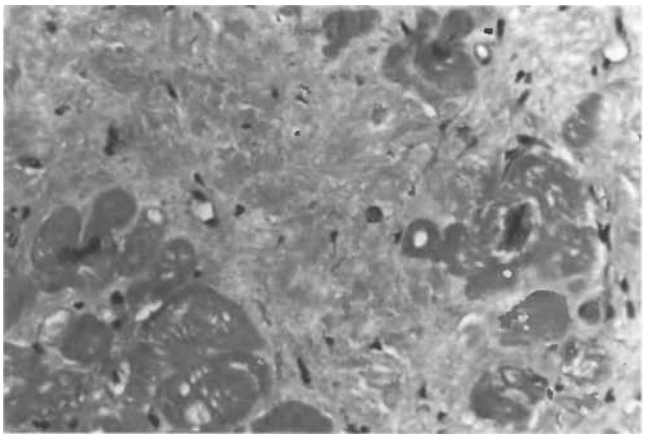

Figure 21 Histologic findings in a biopsy with changes suggestive of allograft coronary vasculopathy or global myocardial ischemia. Biopsy shows irregular areas of scarring surrounded by hypertrophied myocytes, suggesting that this area was a microinfarct which was healed. These small scarred regions were not in relationship to the endocardium as expected for biopsy site remnants. Note the prominent vacuolization of the surrounding myocytes. Patient had a history of repeated episodes of microvascular rejection over several years post-transplant (H&E × 178). Used with permission from ref. 16

patchy myocyte loss is distinctive from the loss usually associated with myocardial infarction, in which large zones of myocyte necrosis are ultimately replaced by dense scarring. When we recognize this change suggestive of diffuse myocardial ischemia at intervals after the first few months post-transplant, we note it in our reports. All patients in whom this finding was present on biopsy, and who have come to allograft replacement or autopsy, have had global myocardial ischemic damage in the heart as the predominant explanation of their cardiac failure[14,16,70]. Coronary artery involvement with vasculopathy was often also seen, but areas of complete occlusion of coronary vessels were absent (Figure 22)[14,16] (personal unpublished observations).

By immunocytochemistry, patients with global myocardial ischemia or allograft coronary vasculopathy usually show generalized increased MHC class II (HLA-DR) staining of microvasculature of EMB in the absence of other pathologic evidence of acute rejection[14,16]. The immunocytochemical findings of microvascular immunoglobulin and complement components may be decreased from previous biopsies, or may be totally absent. ATT is often absent in the microvasculature and tPA is undetectable in smooth muscle. This pattern of ATT and tPA expression was detected in seven of 11 hearts examined at autopsy in which global ischemic changes were the predominant cause of heart failure (unpublished observations). We have seen biopsies from several patients who lack microvascular damage but have coronary vasculopathy; ATT and tPA staining were not diminished. The amount of fibrin staining is often decreased over previous biopsies.

We believe that these altered morphologic expressions in the microvasculature may be the results of attempted repair of chronic damage of the microvasculature. In such patients it is only the observation of serial EMB, plus a careful examination of the light microscopic findings, which will lead to the correct pathologic diagnosis of global myocardial ischemia.

Ultrastructural observations of EMB from patients with histologic evidence of chronic damage of large and small blood vessels have shown changes analogous to those found in ischemic hearts of experimental animals; these hearts show a prominent loss of actin over myosin in myofilament bundles that are intact, giving a coarse appearance to the myofilaments (Figure 23)[16,70]. In addition, large numbers of myocyte cytoplasmic organelles are often scattered around in the interstitium, associated with a patchy and haphazard collection of collagen fibrils. The vessels usually have irregular profiles and may show irregular endothelial cell swelling[16,70].

Figure 22 This epicardial coronary artery was sectioned at the time of autopsy 4 months after transplant. The patient had multiple episodes of acute microvascular rejection which were not associated with hemodynamic compromise and were not treated prior to death. Marked narrowing of the vessel with subintimal fibrosis is seen. Numerous inflammatory cells were found in this region, consisting of macrophages and lymphocytes (H&E × 75). Used with permission from ref. 16

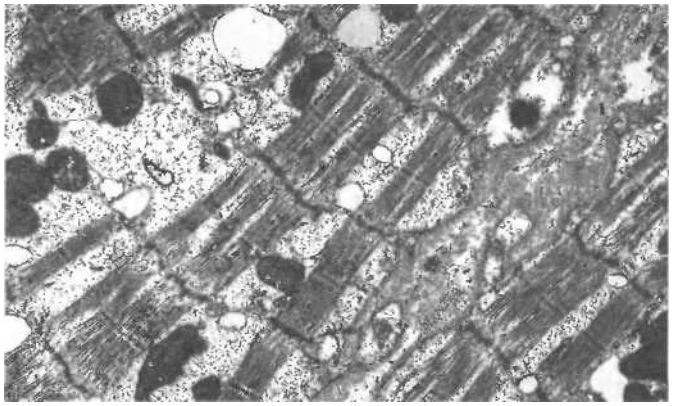

Figure 23 Ultrastructural appearance of myocytes from a biopsy showing histologic evidence of global myocardial ischemia. Myofilament structure appears coarse, due to the predominant loss of actin filaments. Original print magnification × 10,000. Used with permission from ref. 16

DRUG-INDUCED VASCULAR PROCESSES SIMULATING VASCULAR REJECTION

In patients treated with antibodies raised in various animal species, such as horse, rabbit, sheep or mice, an immune-complex-mediated response to these foreign proteins may develop[71-73]. In patients who develop these reactions the immunosuppressive function of the monoclonal antibody is abrogated by the production of antibodies against the immunosuppressive agent. Such patients may show early rejection because of lack of immunosuppression[74]. Alternatively, patients may show a serum-sickness-like process within their cardiac vessels related to the deposition of immune complexes of the monoclonal antibody and the host antibody directed against it[75]. Usually these antibodies are anti-idiotypic antibodies directed against the foreign protein.

In our institutions, where the vast majority of patients have been treated with OKT3 (a mouse monoclonal antibody), all patients are routinely evaluated by immunocytochemistry for the accumulation of mouse immunoglobulin (the antigen) in cardiac vessels[76]. Typically, the efficacy of OKT3 therapy is monitored by following total daily T lymphocyte counts or, in the case of OKT3, CD3 lymphocyte counts. This method is an insensitive way to detect early anti-idiotypic antibody accumulation. A better method is the flow cytometric assay described by Wittwer *et al.*, which detects declines in steady-state plasma levels of the OKT3 (due to complexing of antigen with anti-idiotypic antibody) 1–3 days earlier than the return of $CD3^+$ cells in the serum[77]. The value of early detection of OKT3 sensitization (anti-idiotypic antibody activity sufficient to cause plasma OKT3 levels to fall significantly) is that the patient can be immediately withdrawn from OKT3 therapy and placed on alternative immunosuppression.

We have demonstrated that maintaining the patient on OKT3 in the presence of anti-idiotypic antibodies leads to humorally mediated microvascular alterations in every case[76]. Since this is associated with severe hemodynamic consequences, it should be avoided. A subsequent study, in which patients sensitized to OKT3 had therapy promptly aborted, has led to dramatic improvement in allograft survival[78]. Eleven of 12 patients shown to be sensitized, and removed from therapy at the time of sensitization, have not lost their allografts acutely. In this later report, patients without OKT3 sensitization during induction treatment also did not develop sensitization if retreatment was necessary. This is another situation in which routine immunocytochemical monitoring is very helpful in understanding the nature of the immunologic response.

Morphologically, EMB have features of microvascular alteration identical to those found in vascular rejection patients. The only different feature is the presence of mouse, horse or rabbit immunoglobulin in a distribution identical to the human immunoglobulin and complement components which serves to distinguish it from vascular rejection. There are no direct data concerning the distribution of altered ATT and tPA expression in these patients, since most of the sensitized patients were studied prior to routine use of these reagents. However, fibrin was found in an interstitial and vascular distribution in all of the biopsies, suggesting that ATT and tPA would be expected to be missing from the microvasculature[15].

PATHOGENESIS OF MICROVASCULAR REJECTION

The changes described in this chapter suggest that endothelial cell activation, vascular permeability, and subsequent myocyte degeneration are prominent features in patients displaying light microscopic and immunocytochemical alterations associated with microvascular rejection. These morphologic features suggest that the endothelial cell plays a pivotal role in this rejection process. In-depth investigations of endothelial cell biology have shown that, rather than being non-specific targets of injury, endothelial cells are capable of many important functions which can be altered in the allograft[55-58,79-83].

Endothelial cells provide a natural anticoagulated surface through their binding of antithrombin III and thrombomodulin, although the evidence in cardiac transplants suggests that the former pathway is more important than the latter[15,29]. Endothelial cells produce diverse cytokines which can modulate the biologic behavior of cells in the myocardial tissue. These cytokines are produced in inflammation, ischemia, and many other circumstances commonly operative in transplantation, such as infection and lymphocyte activation[55]. There is good evidence that endothelial activation can be the result of immunosuppression or immunoprophylaxis utilizing monoclonal anti-T-cell antibodies. The therapy can generate T cell activation, as a result of interaction of the antibody and the CD3 or T cell receptor antigen on the lymphocyte surface[54,55,74,84]. A predominant cytokine released is tumor necrosis factor alpha; antibody directed against this cytokine is effective in abrogating the first dose response commonly seen in these patients[85,86]. Other reports suggest that such lymphocyte activation leads to increased release of IL-2 and IFN-γ, which promotes further endothelial cell activation, as has been elegantly shown by the *in vitro* studies of Pober and colleagues[55-58].

We have observed that patients with the morphologic pattern of microvascular rejection (vascular rejecters) include patients sensitized to OKT3 while undergoing immunoprophylaxis. This type of microvascular rejection is related to humoral immune responses with probable altered B-lymphocyte immune regulation or polyclonal B-lymphocytic activation[52,54]. The morphologic changes are very similar to those described in reports detailing humorally mediated vascular rejection in: (a) renal transplant recipients, (b) patients with serum sickness, and (c) experimental animals with leukocytoclastic vasculitis, (d) the Arthus phenomenon, and (e) animals rejecting xenografts in which there has been a decrease in antibody levels or complement activity[17,79-81,87-89]. The pathogenic mechanisms responsible for these vascular inflammatory processes (where an antigen–antibody complex process is definitely implicated) involve complement activation, cytokine release, and chemotaxis and activation of neutrophils and macrophages.

Recent work has shed light on the pathogenesis of this process in our allograft population. We examined the incidence of vascular rejection pattern related to the duration of OKT3 induction immunoprophylaxis (Table 3). We found a statistically significant association of the vascular rejection pattern with duration of OKT3 greater than 7 days. The percentage of patients developing microvascular rejection increases in direct proportion to the length of OKT3 therapy. Unfortunately, the number of patients treated with standard triple immunosuppression is too small to

Table 3 Relationship of duration of OKT3 induction to vascular rejection pattern

Duration of OKT3 prophylaxis[*]	*Total no. of patients*	*Vascular rejection pattern (percentage of total)*[†]	*Lost grafts*
7 days	53	6 (11)	3/6
10 days	26	8 (31)	4/8
14 days	208	56 (27)	24/56
21 days	13	6 (46)	4/6

[*] Duration of OKT3 induction determined retrospectively by chart review (Dr Hong Ma). Patients sensitized to OKT3 as determined by the flow cytometric assay were excluded from this analysis. Sensitization also documented by chart review.

[†] Vascular rejection pattern prospectively determined during first 3 months post-transplant. Patient had at least three episodes of vascular rejection without cellular rejection and prior to other rejection episodes, including cellular infiltrates. See text.

include in the analysis; the number of these patients with the vascular rejection pattern was not significantly different from the patients treated with 7 days of OKT3 immunoprophylaxis. This association, in multivariate analysis, was independent of: (a) patient sex, (b) age, (c) positive crossmatch, and (d) positive panel-reactive antibody status, which were all previous predictors of vascular rejection pattern in this patient population. Patients with OKT3 sensitization were also excluded from the analysis[90]. The association of vascular rejection pattern with durations of OKT3 immunoprophylaxis >7 days suggests that anti-idiotypic antibody production, which occurs to some degree in all patients after 7 days of induction, synergizes with the humoral rejection response so that it becomes the predominant pattern in susceptible patients.

An alternative hypothesis is that the OKT3 induction for >7 days alters cytokine production, such as TNF. It is well recognized that TNF is the cytokine responsible for the first-dose OKT3 reaction. Recent studies have shown that TNF may play a significant role in allograft rejection[46,47,49]. TNF recruits cells to the site of antigenic challenge, activates immunocompetent cells, augments the expression of MHC class I and class II antigens, and induces the production of other cytokines. Lymphocytes, macrophages, and endothelial cells are all able to produce TNF-α, and are activated by its actions. Elevation of mRNA for TNF-α is detected in rat cardiac allografts in advance of clinical rejection[46,47]. Antibody against TNF-α has also been shown to be effective, in combination with cyclosporin, in prolonging rat cardiac allograft survival. Elevation of circulating levels of TNF has been detected in cardiac and renal transplant recipients[91,92,93].

Thus, it is likely that TNF is produced concomitantly with each dose of OKT3 that is given, so that the amount of TNF produced in patients induced for 14 or 21 days is significantly greater than in patients receiving the drug for only 7 days. Furthermore, activation of macrophages and endothelial cells, which promote further TNF production, is accelerated by binding of these cells to immune complexes, like complexes of OKT3 and its anti-idiotypic antibody. Thus, circumstances are favorable for the increased production of TNF in patients receiving prolonged OKT3 induction. TNF enhances immunologic responsiveness, and would be expected to accelerate rejection responses in patients as it has been shown to do in experimental animals. If this hypothesis is correct, antibody directed against TNF-α may be an effective strategy to prevent microvascular rejection in this patient population.

The likelihood that microvascular rejection is mediated by TNF or other cytokines in addition to humoral immune mechanisms cannot be differentiated by the present or previous studies[79,83,87,88]. We have consistently seen up-regulation of HLA-DR on the large and small vessels of the allograft which, at least in experimental situations, is produced exclusively by interaction of endothelial cells with IFN-γ[79]. This finding, as well as the prominent fibrin deposition and endothelial activation, suggests that cytokine-mediated (delayed-type) hypersensitivity may be implicated in this process[10,94].

The consequence of either a humoral or cellular immune response directed against the vascular endothelium would ultimately be compromised myocardial oxygenation. Important inflammatory participants in this process include neutrophils and macrophages which can be activated by immune complexes, cytokines, complement components, endotoxin, and platelet-activating factor[77–79]. Such activation can result in the production of various leukotrienes, arachidonic acid metabolites, and a variety of cytokines which lead to vascular permeability, leukocyte adherence via various specifically induced adhesion molecules, and the activation of proteolytic enzymes such as protein kinase C. The ability of endothelial cells to express adhesion molecules (ELAM-1, ICAM-1, VCAM-1) in response to inflammatory stimuli or cytokine release, such as IL-1, can create the morphologic expression of vascular rejection, including endothelial activation and capillaritis. The consequences of this process include compromised myocardial oxygenation, diffuse myocardial damage, hemodynamic compromise, and allograft loss.

Pathology of Cardiac Allograft Rejection. 2: Acute Cellular

A.G. ROSE

INTRODUCTION

Cardiac transplantation has become firmly established as a treatment for terminal cardiac failure. The early experimental work in animals[1–7] that preceded the first human-to-human cardiac transplant in 1967 is now mainly of historical interest. Thomson[8] documented the pathological findings in the donor heart of Louis Washansky, who was the recipient in this first historic operation. Shortly thereafter Lower *et al.*[9] reported their experience with human cardiac transplantation.

Despite advances in patient selection, donor heart procurement and preservation, and immunosuppressive therapy, acute rejection remains an important cause of graft loss and recipient mortality.

MACROSCOPIC APPEARANCE OF ACUTE REJECTION

Mild or moderate acute rejection usually fails to produce detectable naked-eye changes in the donor heart apart from an increased organ mass (Figure 1)[10,11]. Cyclosporine-induced systemic hypertension may also contribute to the cardiac hypertrophy. Such hearts are seldom examined pathologically unless the recipient has died of other causes.

Severe acute rejection may produce a swollen, mottled myocardium with scanty subendocardial hemorrhages. A heterotopic transplant which has undergone irreversible, severe rejection may not lead to the death of the recipient if the latter's own heart has enough residual function to support the circulation.

Figure 1 Transverse slices of recipient heart (left) and donor heart (right) 21 days after heterotopic transplantation. The severely rejected donor myocardium presents a pseudohypertrophied appearance. (Reproduced with permission from ref. 10)

Explanted heterotopic grafts usually show very severe acute rejection since immunosuppression is often reduced in the period between cessation of graft function and surgical excision of the graft. Such hearts (Figure 2) have a severely hemorrhagic, mottled appearance. Geographic zones of pale-colored, focal infarction stand out against the plum-colored, hemorrhagic, but still viable myocardium. Stasis thrombi may be present within the cardiac chambers. Orthotopic transplants that have failed primarily due to acute rejection usually show less obvious naked-eye alterations despite the presence of severe acute rejection histologically.

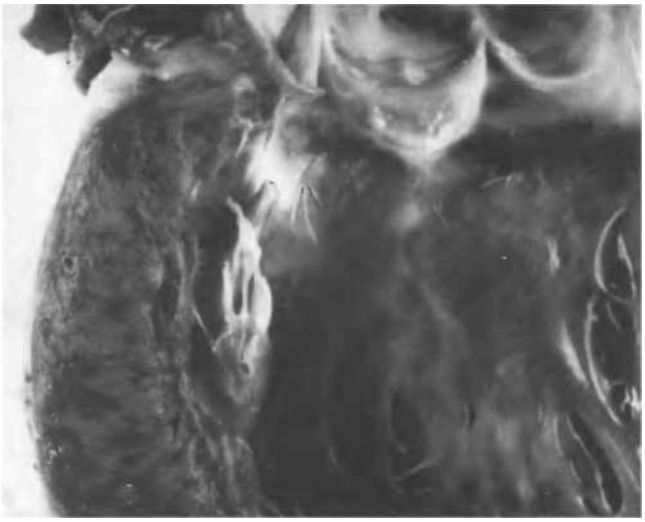

Figure 2 Close-up view of donor heart left ventricular outflow tract. Severe acute rejection has produced diffuse intramyocardial hemorrhage and the myocardial cut surface shows pale areas of necrosis which contrast with the hemorrhagic background

ROLE OF ENDOMYOCARDIAL BIOPSY IN THE DIAGNOSIS OF ACUTE REJECTION

Endomyocardial biopsy histology with grading of the severity of rejection continues to be the so-called gold standard for the diagnosis of acute rejection. Usually biopsies are performed weekly during the first 6 weeks post-transplantation and then fortnightly for the next few months. Gradually therafter the intervals between the biopsies are increased until a stage is reached at which the biopsies are done approximately every 3 months.

Non-invasive methods for diagnosing acute rejection, such as magnetic resonance imaging, assessment of peripheral blood lymphocytic activation and soluble interleukin-2 receptor levels, have failed to live up to expectations and have not superseded graft histology. It remains to be seen whether other non-histologic modalities, e.g. radioimmunoassay assessment of vascular adhesion molecules[12] in endomyocardial biopsies, may play a role in the routine management of cardiac transplant patients. The latter invasive procedure is still dependent on the taking of endomyocardial biopsies.

Earlier criticism of endomyocardial biopsy has focused primarily on the possibility of sampling error and the subtlety of the histologic changes in diagnosing rejection[13,14]. One study[15] attempted to validate the technique by examining 'biopsy' samples taken with a bioptome from formalin-fixed explanted human donor hearts, and comparing these in a blind fashion with standard histologic sections taken from the same hearts. Agreement of results between the bioptome samples and the routine sections was found in 86% of cases. False-negative results were less than 1%. Acute rejection involved both ventricles equally.

Due to the rigidity of the bioptome catheter, endomyocardial biopsy usually only samples the septal wall of the right ventricle towards the apex. Four or five tissue samples are regarded as adequate[16]. In practice most pathologists usually receive three or four endomyocardial samples per biopsy procedure. In the study referred to earlier, it was found that even as few as two endomyocardial samples revealed the presence of acute rejection[15]. If fewer samples are received this should be noted in the pathologic report, since it holds the implication that significant rejection may be missed (false-negative biopsy). In the light of other clinical and laboratory parameters, the cardiac surgeon has to decide whether an immediate or earlier than usual repeat biopsy is indicated. The size of the biopsy specimen varies according to the bioptome used. If the biopsy specimens are small, then a suboptimal number of samples has more severe implications than would be the case if the samples were large.

At some centers the endomyocardial biopsies are submitted to the laboratory in 5% buffered glutaraldehyde to facilitate subsequent ultrastructural examination of one of the fragments, if this is deemed necessary. Selected fragments for light microscopic assessment of rejection are transferred into 5% buffered formaldehyde and processed in a hypercenter tissue processor for expedited handling.

Paraffin-embedded sections are stained by the hematoxylin–eosin, Masson's trichrome, elastic van Gieson, and Unna-Pappenheim methods. One or two biopsies may also be submitted unfixed for immediate frozen section. This gives immediate information regarding the presence of rejection, and additional sections may be cut for the determination of lymphocyte subsets. The latter is performed more for research purposes than for influencing management of the patient. Electron microscopy and immunofluorescence microscopy play only a small role in the routine diagnosis of acute rejection.

HISTOPATHOLOGY OF ACUTE REJECTION

One of the earliest changes observed in acute rejection is the development of interstitial edema (Figure 3), which is most prominent perivascularly and less evident in the endocardium, which has a denser connective tissue component. The edema is probably a result of microvascular damage. Interstitial edema is less severe in patients receiving cyclosporin compared to the earlier, steroid-based immunosuppression. The vascular endothelium is that portion of the graft which first encounters the host lymphocytes which are attracted into the graft, since these cells reach the graft via the bloodstream.

In the early stages of acute rejection the small blood vessels within the graft contain increased numbers of mononuclear cells (Figure 4), which may also be seen to be passing through the vessels' walls into the surrounding myocardium. The early

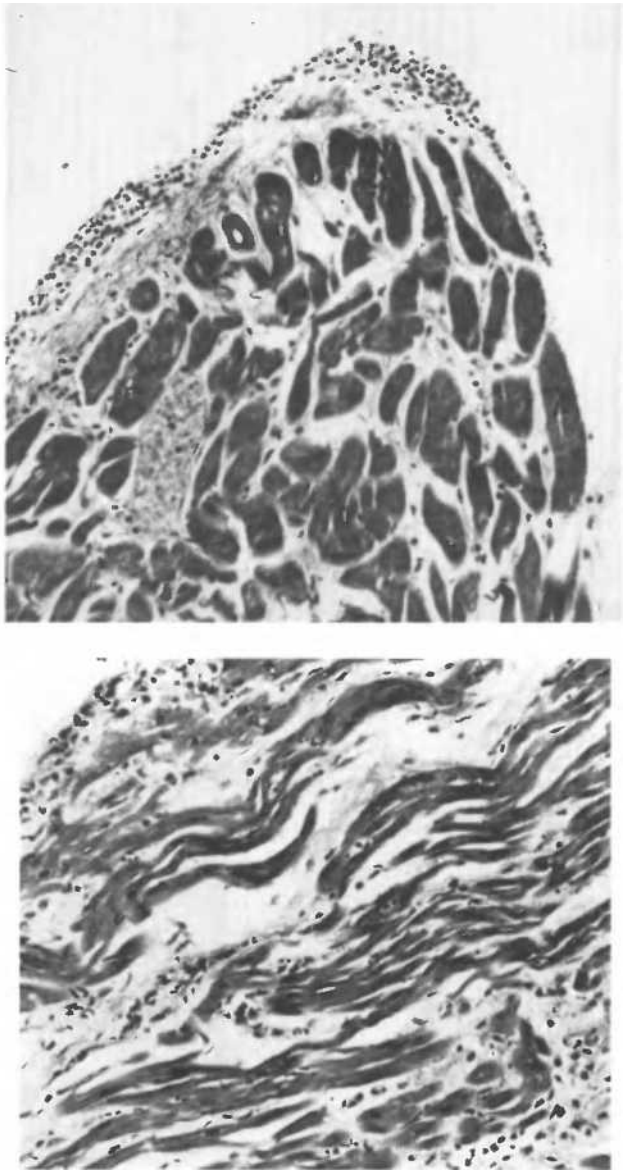

Figure 3 **A**: Early acute rejection (grade 1A of ISHLT). Mild interstitial edema spares the endocardium, which contains a more florid lymphocytic infiltration than is seen in the myocardial interstitium (H&E, × 135). **B**: Scanty interstitial lymphocytic infiltrate of mild acute (grade 1B of ISHLT) rejection (H&E, × 60)

infiltrating cells (Figure 5) consist mainly of non-activated lymphocytes and small unidentified mononuclear cells of lymphoid type, together with histiocytes and scanty neutrophils plus eosinophils. The cellular infiltration of mild acute rejection (Figure 6) has a focal, mainly perivascular distribution. The lymphocytes soon develop a prominent cytoplasmic pyroninophilia (activated or aggressive lymphocytes), as do the endothelial cells of the small blood vessels. Focal infiltration by similar cells is also noted in the endomyocardium. Cardiac histiocytes (Anitschkow myocytes), presumably of donor heart origin, also appear activated and prominent.

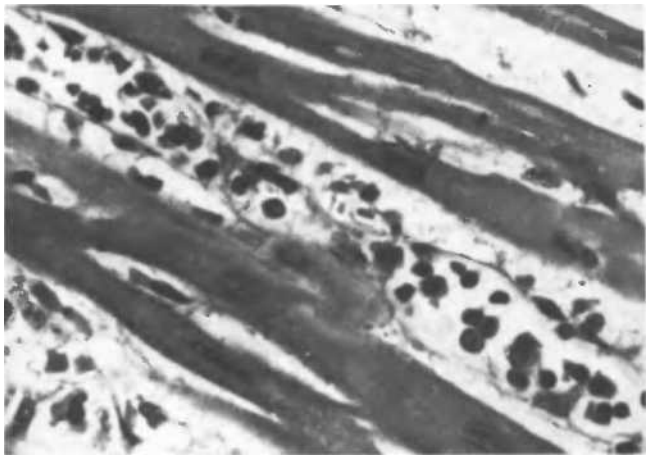

Figure 4 A capillary contains numerous mononuclear cells. Similar cells are present in the edematous interstitium of this rejecting graft (H&E, × 420)

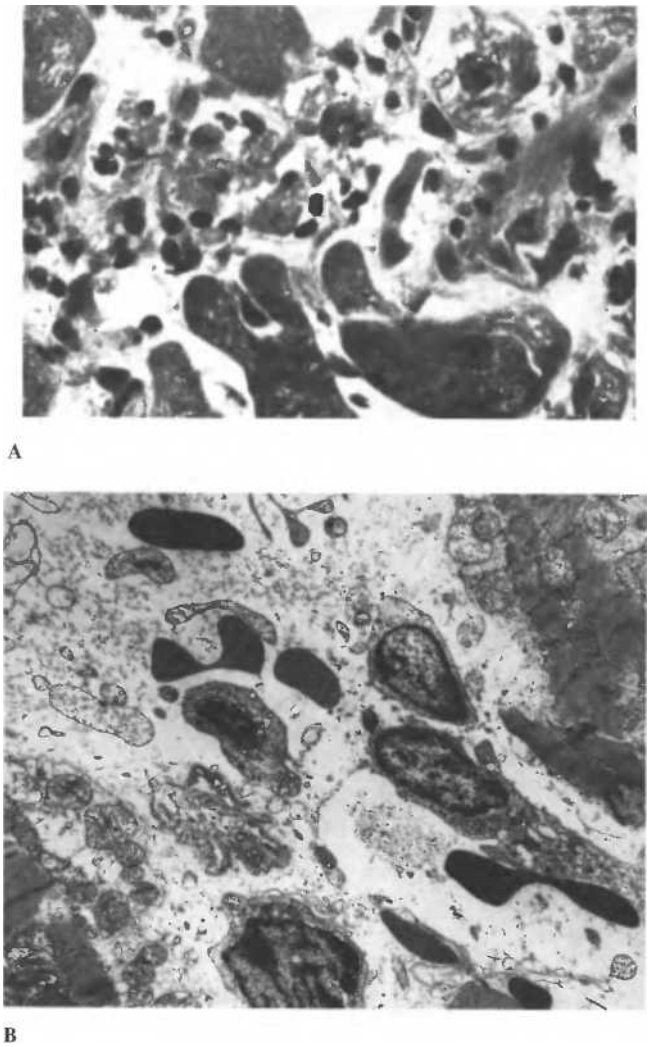

Figure 5 **A**: Donor heart biopsy shows numerous lymphocytes in relation to necrotic myocytes (H&E, × 420). **B**: The edematous interstitium between two myocytes (top right and bottom left) contains activated lymphocytes and some free-lying erythrocytes. (Lead citrate and uranyl acetate, × 2400)

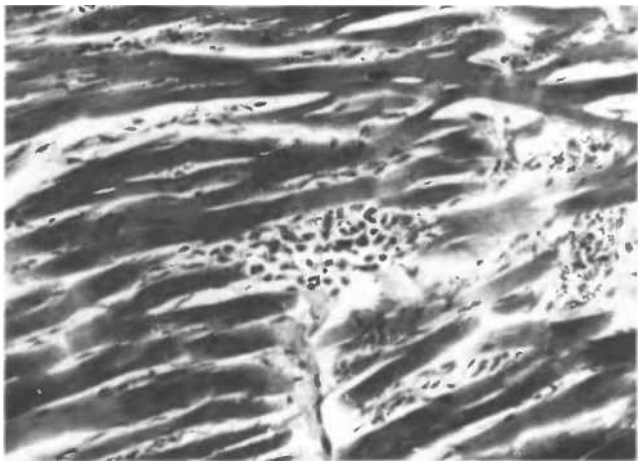

Figure 6 Mild acute rejection (grade 1A of ISHLT); focal lymphocytic aggregation without myocyte damage

If untreated, one may have the development of moderate (Figures 7 and 8) and severe (Figure 9) acute rejection. In such a case all of the above changes will progress and increase in intensity, and will be accompanied by damage to the myocytes and blood vessels. Thus, interstitial edema increases and interstitial fibrin deposition may also occur. Fibrinolysis may render the latter inconspicuous microscopically. The most reliable indication of progression in severity of acute rejection is more intense and widespread lymphocytic infiltration of the graft. With time there is enlargement of the nuclei and cytoplasm of the lymphocytes, which now have the appearance of immunoblasts (Figure 10). Similar lymphoid cells infiltrate the intima of intramyocardial blood vessels where they are admixed with proliferating endothelial and intimal cells. Fewer lymphocytes may also be seen within the media and the adventitia (Figure 11).

Herskowitz *et al.*[17] identified interstitial edema, perivascular keryorrhexis, and perivascular lymphocytic infiltration with intermyocyte extension as three histologic abnormalities that help predict the future development of more severe acute rejection associated with myocyte necrosis.

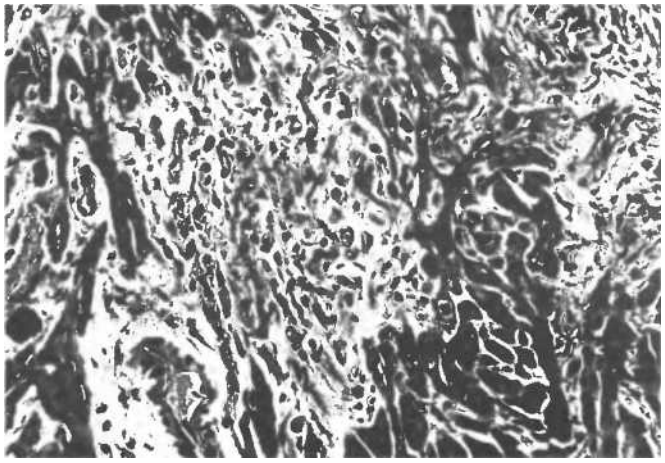

Figure 8 Moderate acute rejection (grade 3B of ISHLT). A diffuse lymphocytic infiltration is present together with focal myocyte necrosis (H&E, × 84)

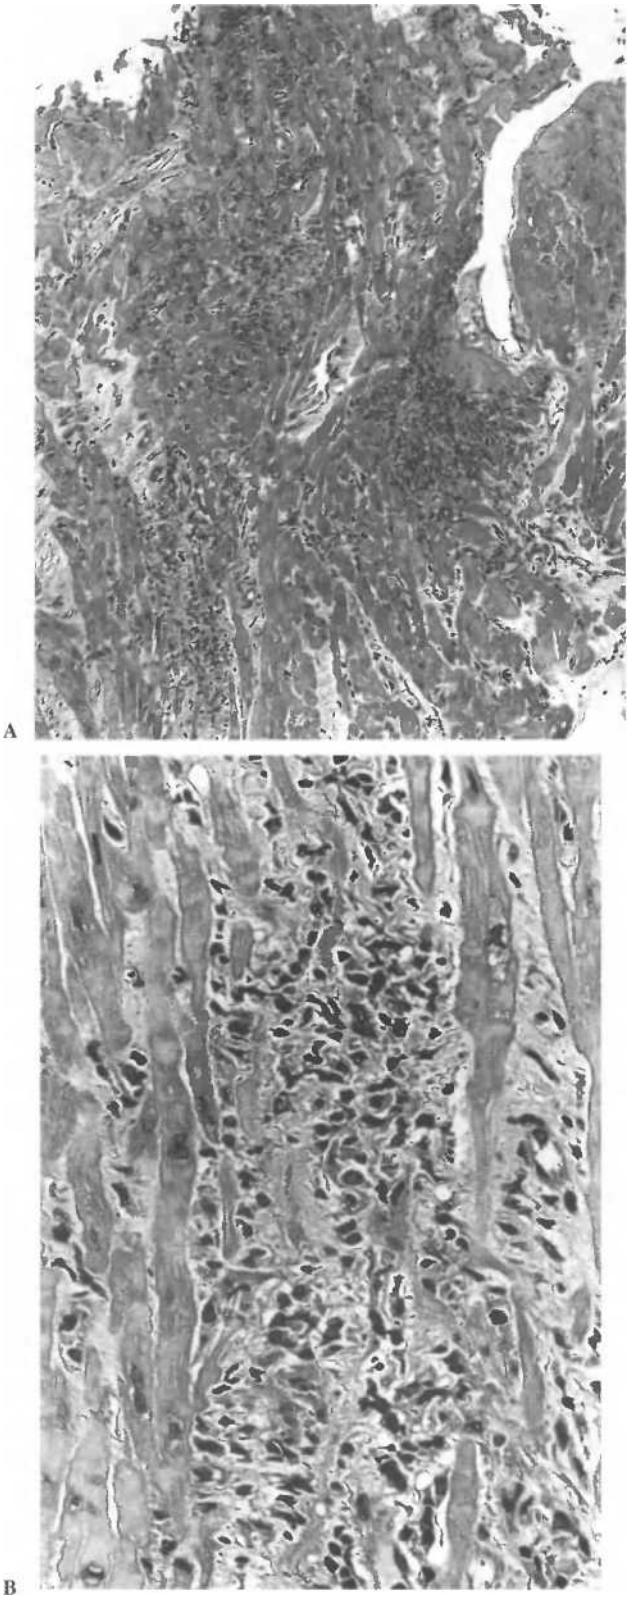

Figure 7 **A**: Grade 3A (ISHLT) acute rejection is characterized by multifocal lymphocytic infiltration of the myocardium (H&E, × 40). **B**: Higher-power view of same biopsy shows myocyte necrosis in relation to an intense mononuclear cellular infiltration. The presence of necrosis steers the grading towards grade 3B (H&E, × 280)

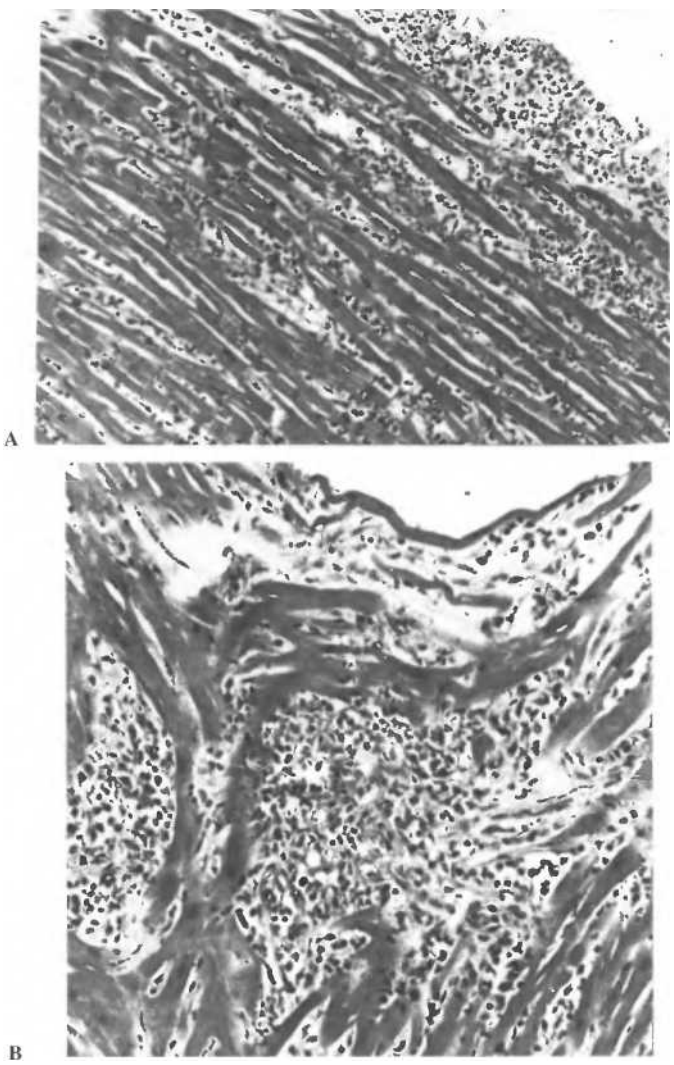

Figure 9 A: Severe acute rejection (grade 4 of ISHLT) exhibits severe interstitial lymphocytic infiltration and focal myocyte necrosis (H&E, × 100). B: Different area of the same biopsy shows focal loss of myocytes and masses of lymphocytes plus scanty haemorrhage (H&E, × 200)

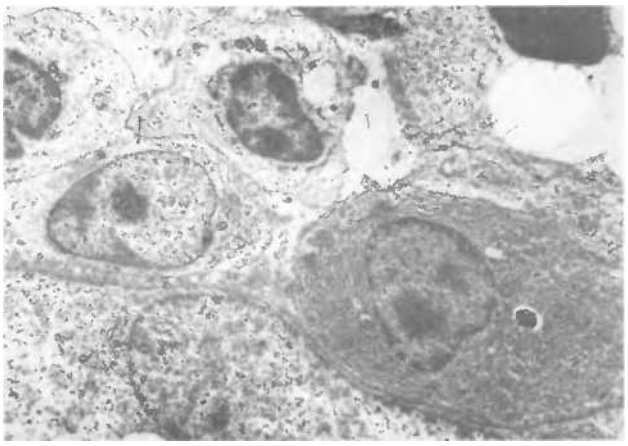

Figure 10 Electron micrograph in acute rejection. A group of activated lymphocytes occupies the myocardial interstitium. A plasma cell is present (lower right) (Lead citrate and uranyl acetate, × 1350)

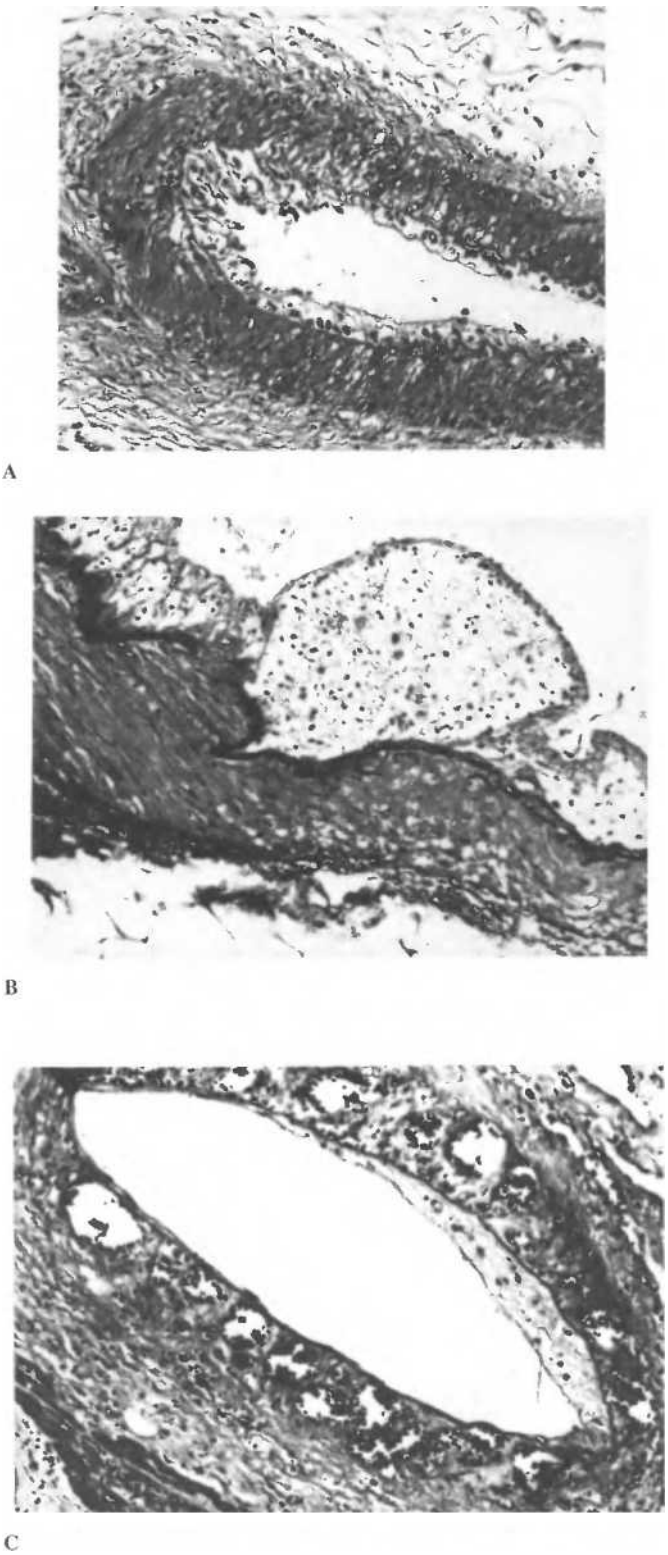

Figure 11 Coronary arterial alterations in severe acute rejection. A: Acute rejection has caused subendothelial intimal edema in a small epicardial coronary artery. B: At times the edema can be quite striking. C: Small coronary artery shows outer medial defects of the kind associated with an immune-mediated arteritis (All H&E, × 100)

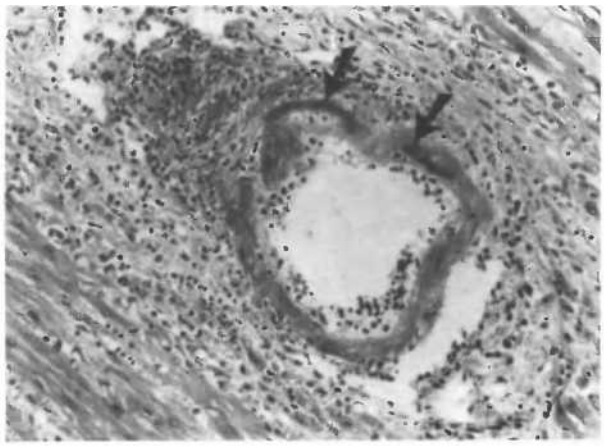
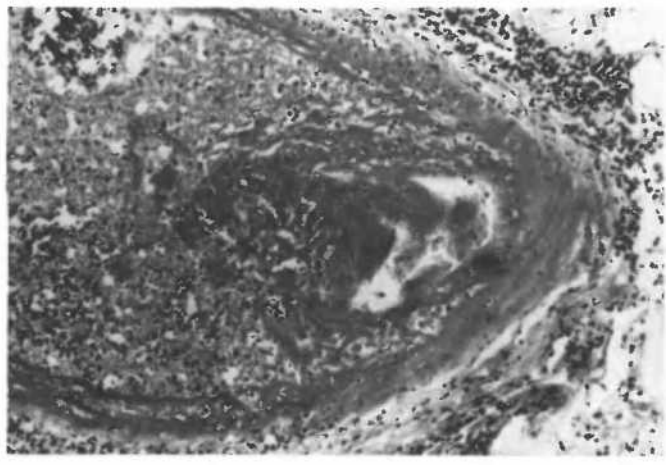
Small-vessel thrombi have been an inconspicuous feature of mild and moderate acute rejection in human cardiac transplants, but they have been encountered by others in canine cardiac allografts[18]. The occurrence of such thrombi in severe acute rejection in humans is not surprising, since there is evidence that rejection may activate the coagulation mechanism[19,20]. The cardiac veins and venules are seldom affected by florid acute rejection changes[7].

The above-described microvascular changes, together with the cytotoxic effects of the infiltrating immunoblasts, combine to produce deleterious effects on the myocardium. Thus, the myocytes may show a range of appearances from normal through cytoplasmic swelling, lipid vacuolation to focal necrosis. The presence of zonal myocytolysis or coagulative necrosis usually indicates graft arteriopathy (chronic rejection) rather than acute rejection. Rarely, fibrinoid necrosis of coronary arteries (Figure 12) associated with very severe acute rejection may lead to zones of myocytolysis or coagulative necrosis in the donor ventricles. Associated focal interstitial hemorrhages may also occur in such cases. It will be necessary to avoid confusion with delayed vascular rejection, but lymphocytic infiltration is not a feature of the latter process in its pure form.



A



B

Figure 12 Severe acute rejection. **A**: Early fibrinoid necrosis (arrows) of wall of an intramyocardial coronary artery. **B**: Advanced fibrinoid necrosis of a small coronary artery with superimposed thrombosis (Both H&E, × 100)

Focal myocyte necrosis is not a uniform finding in severe acute rejection. Lesser changes indicative of myocyte damage are often noted, e.g. hypereosinophilia of individual myocytes, blurring of the edges of myocytes, attenuation of myocytes, reduction in visibility of cross-striations and vacuolization of the cytoplasm. Damaged myocytes often have lymphocytes closely applied to their sarcolemmal sheaths. It has been claimed that the myocyte injury in acute rejection is reversible[21] and that the injured myocytes in acute rejection are capable of reconstitution[22].

HISTOLOGIC GRADING OF ACUTE REJECTION

A variety of histologic grading systems for acute rejection have evolved at various centers worldwide[23–27]. No matter which grading system has been used the essence of its successful application has been frequent and clear dialogue between the pathologist and the clinicians looking after the recipient. The pathologist must clearly indicate the degree of rejection present. The use of a grading system has the advantage that the severity of rejection can be swiftly communicated without going into descriptive histologic details which may confuse the clinician. The pathologist examining the biopsy should be experienced in the interpretation of endomyocardial biopsies, since the unwary may read too much into biopsy-induced artefacts with possibly untoward results for the patient if such artefacts are interpreted as being due to rejection.

STANDARDIZED GRADING SYSTEM FOR HISTOLOGIC ASSESSMENT OF DONOR HEART ENDOMYOCARDIAL BIOPSIES

A standardized grading system was established by the International Society for Heart and Lung Transplantation (ISHLT)[28] in order to facilitate multicenter trials, and for uniformity in publications, so that results from different centers may be compared effectively. The Working Formulation for the Standardization of Nomenclature in the Diagnosis of Heart Rejection[28] acts as a Rosetta Stone by which gradings in one scheme can be compared with the gradings of another. Whilst the aim was not to replace the pre-existing individual grading schemes, many centers have adopted the proposed Working Formulation in their day-to-day practice.

The various categories within the standardized cardiac biopsy grading system are given in Table 1. This grading system for acute rejection may be paraphrased as follows.

Grade 0 (no acute rejection): this indicates the absence of acute rejection or of any feature of myocyte damage in the sample. Equivocal findings of rejection are similarly graded as 0.

Grade 1A (focal, mild acute rejection): one or more samples may show focal, interstitial or perivascular infiltrates of lymphocytes unassociated with myocyte damage (Figures 3A and 6).

Grade 1B (diffuse, mild acute rejection): a more diffuse infiltration (Figure 3B) of a similar intensity to that seen in 1A is present. Not all samples need to show features of rejection.

Table 1 Standardized cardiac biopsy grading

Grade	*'New' nomenclature*	*'Old' nomenclature*
0	No rejection	No rejection
1	A = Focal (perivascular or interstitial) infiltrate without necrosis B = Diffuse but sparse infiltrate without necrosis	Mild rejection
2	One focus only with aggressive infiltration and/or focal myocyte damage	'Focal' moderate rejection
3	A = Multifocal aggressive infiltrates and/or myocyte damage B = Diffuse inflammatory process with necrosis	'Low' moderate rejection 'Borderline/severe'
4	Diffuse aggressive polymorphous ± infiltrate ± edema, ± hemorrhage, ± vasculitis, with necrosis	'Severe acute' rejection

'Resolving' rejection is denoted by a lesser grade. 'Resolved' rejection is denoted by grade 0.

Grade 2 (focal, moderate acute rejection): this is indicated by the presence of only one focus of lymphocytic infiltration which is sharply circumscribed. Architectural distortion with myocyte damage within the focus is listed as an additional prerequisite.

Grade 3A (multifocal moderate acute rejection): multifocal inflammatory infiltrates (Figure 7) made up of large, aggressive-looking lymphocytes with or without eosinophils involve one or more of the endomyocardial samples.

Grade 3B (diffuse, borderline, severe, acute rejection): diffuse lymphocytic infiltration (Figure 8) is observed within several of the biopsy samples. Myocyte damage is noted. Scanty eosinophils and the occasional neutrophil may be seen. Hemorrhage is usually absent.

Grade 4 (severe acute rejection): the hallmarks of this grade (Figure 9) are a diffuse, polymorphous inflammatory infiltration composed of 'aggressive' lymphocytes, eosinophils and neutrophils. Myocyte damage or even necrosis is 'always' seen. Edema, hemorrhage and vasculitis are often present too.

It is recommended that 'resolving' acute rejection (Figures 13 and 14) should be indicated by denoting a lesser grade than that given in the previous biopsy. (The term 'resolving' may also be used in parenthesis after the given numerical grade). Similarly, 'resolved' acute rejection is diagnosed as grade 0. ('Resolved' may also be given in parenthesis after the grade).

Additional information that should be included in the pathologic report includes the following: (a) the number of endomyocardial samples supplied for the biopsy (four or more are considered adequate); (b) presence of humoral (antibody mediated) rejection; (c) presence of a Quilty effect (endocardial lymphocytic infiltration) ± myocyte encroachment; (d) ischemic changes (early on related to donor heart procurement and late due to graft arteriopathy), early on catecholamine-induced brain death effects may also be encountered; (e) infection present – biopsy cannot be interpreted for rejection; (f) lymphoproliferative disorder; (g) other (to be specified).

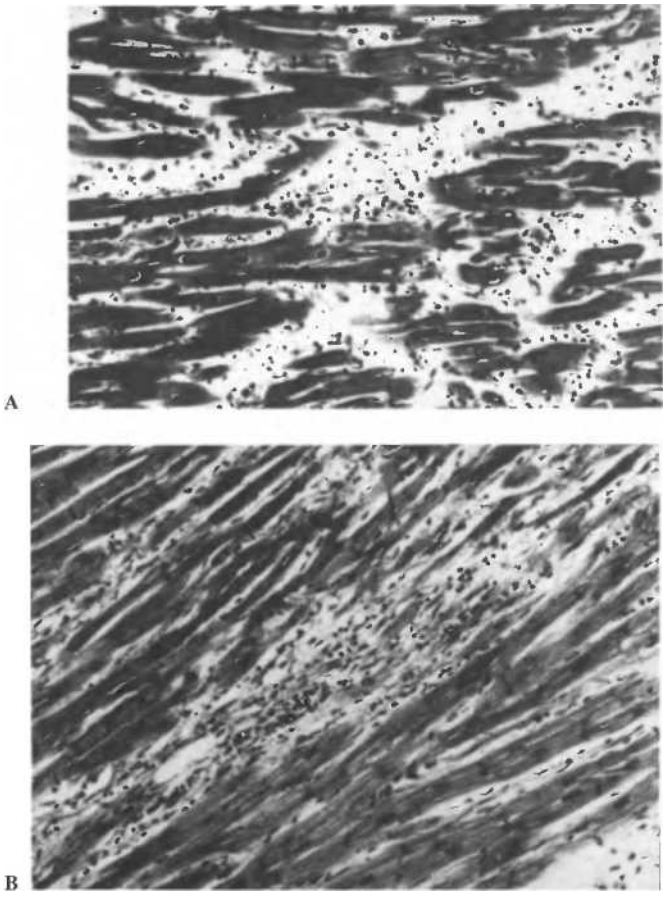


Figure 13 **A**: Prominent interstitial edema accompanies a moderate lymphocytic cellular infiltration of early-resolving acute rejection (H&E, × 120). **B**: Late-resolving acute rejection shows few mononuclear cells and early stromal collapse fibrosis where some myocytes have been lost (H&E, × 110)

PROPOSED REVISION OF THE ISHLT GRADING SYSTEM

As may be expected, practical use of the ISHLT grading system has highlighted its inherent deficiencies. The following revision to the ISHLT grading system (Table 2) was proposed at the 15th Annual Meeting of the International Society for Heart and Lung Transplantation held in San Francisco, 5–8 April 1995. *Grades 0 and 1 (1A and 1B)* remain as before. *Grade 2* has been abolished. *Grade 3* is divided into *Grade 3A* (two or more multifocal, discrete lymphocytic infiltrates with focal, occasional eosinophils) and *Grade 3B* (diffuse mononuclear cellular infiltration in several or all of the biopsy fragments; at least two samples show evidence of myocyte damage). *Grade 4* (all of the biopsy samples show edema, hemorrhage and vasculitis with rare areas of normality).

Footnotes to this revised grading system include the following:

(1) An inadequate sample is less than four pieces. Four to six samples are the optimum to be aimed for. If less than three samples are received, the pathologist cannot rule out the presence of rejection if appearances are negative. If less than

Figure 14 Early-organizing fibrin thrombus (top) covers the surface of a previous right ventricular endomyocardial biopsy site (H&E, × 150)

two samples are positive for rejection, one cannot rule out a higher grade of rejection.

(2) No immunofluorescence is needed.

(3) Quilty change is noted if present, but is not characterized further.

(4) Ischemic changes, both early (<3 months post-transplantation) and late (>3 months) are looked for and noted.

(5) The grading should not be applied to autopsy material.

(6) The worst area in the sampled myocardium should be used to choose the grading number.

GENERAL COMMENTS ON THE PATHOLOGIC DIAGNOSIS OF ACUTE CARDIAC REJECTION

Myocyte necrosis in acute rejection

The presence of myocyte necrosis is taken as a firm indicator of clinically significant acute cardiac rejection in most grading systems used for assessing endomyocardial biopsies[24,29]. Multiple foci of necrosis have more significance than only a single such focus. Such necrosis is rare in my experience, even in patients with florid lymphocytic infiltrates.

Ratliff *et al.*[21,22,30] have performed extensive electron microscopic studies of myocytes that appear to be necrotic by light microscopy, and they report that such myoctes show a unique form of reversible myocyte injury. Centralization of the myofilaments occurs and the latter are surrounded by a radially orientated bundle of myofilaments. They suggest that the myocyte injury of transplant rejection is generally reversible and is similar to apoptosis.

Resolving acute rejection

Augmented immunosuppresion usually leads to abolition of an acute rejection episode. This process, which may take days to weeks to reach completion, is termed resolving acute rejection (Figure 13). Since the clinical concern is whether rejection has been controlled, this is a period in which further biopsies are often taken.

In patients receiving cyclosporin-based immunosuppression less rapid dissolution of the lymphocytic cellular infiltration occurs when pulsed doses of corticosteroids are given to overcome acute rejection, compared to patients receiving the previous steroid-based immunosuppressive regimen[31]. Thus, acute rejection in patients treated with cyclosporin resolves slowly. Myocyte damage may persist for about 2 weeks despite increased immunosuppression[32]. With resolution of acute rejection the remaining lymphoid cells show minimal pyroninophilia, and the removal of dead myocytes leads to early replacement fibrosis.

Table 2 Revised standardized cardiac biopsy grading

0	No rejection
1	A = Focal (perivascular or interstitial) infiltrate without necrosis B = Diffuse, but sparse infiltrate without necrosis
2	Has been abolished/no longer exists
3	A = Multifocal, discrete lesions, focal occasional hypereosinophilia B = Diffuse mononuclear cells in several or all fragments. Two samples show myocyte damage
4	All biopsy samples show edema, hemorrhage, vasculitis with rare areas of normality in the sample

Less than four pieces is an inadequate biopsy. Three pieces cannot rule out rejection. If two pieces are positive rejection can be diagnosed, but cannot rule out a higher grade. At least three levels should be cut on each block.
The worst area is the keynote area for grading.
No immunofluorescence is needed.
Quilty (not Quilty A or B).
Ischemic changes may be noted early (< 3/12) or late (> 3/12). The grading is not for use in autopsy or explanted material.

Detection of possible over-immunosuppression

If repeated biopsies are totally negative for the presence of any lymphocytes within the myocardium, this should be brought to the attention of the clinician caring for the recipient, as there is the possibility of over-immunosuppression and an attendant danger of infection. This dictum is especially important in patients receiving cyclosporin, since endocardial lymphocytic infiltrations are commonly seen.

Immunofluorescent studies

Immunofluorescent studies for the immunoglobulins IgG, IgM, and IgA, and complement (C3) on biopsy and autopsy material from human and animal donor hearts yielded unhelpful results by both direct immunofluorescence and immunoperoxidase methods in acute rejection. Moderate amounts of fibrinogen and C3 may be found within the walls of some intramyocardial blood vessels. Immunofluorescence may be useful in some circumstances[33] and it has also been used for the detection of microvascular rejection[34].

Lymphocyte subpopulations in acute cardiac rejection

T lymphocytes are the predominant cell type in acute cardiac rejection. The ratio of helper to suppressor T lymphocytes in the cardiac biopsy does not correlate with rejection. However, the greater the number of lymphocytes in the biopsy, the greater is the likelihood of significant acute rejection. B lymphocytes are seldom present in endomyocardial biopsies and, if present, are seen in very scanty numbers only. Macrophages are more prominent in resolving acute rejection.

Cyclosporine suppresses the generation of inducer T cells, but allows the generation of suppressor cells. Monoclonal antibodies, which destroy the T3 cell subset, are playing a small, but possibly increasing, role in the treatment of acute ejection.

Electron microscopy

In the early stages of acute rejection there is a preponderance of mononuclear cells of undistinguished appearance. In biopsies of cardiac allografts implanted in baboons, unidentified mononuclear cells composed 53% of the interstitial cellular infiltrate overall in acute rejection[10]. Later activated lymphocytes predominate (Figure 10); occasional histiocytes, neutrophils and eosinophils may also be seen. In resolving acute rejection a few plasma cells may also be observed. The latter cells are characterized by the presence of numerous polyribosomes and cisternae of rough-surfaced endoplasmic reticulum. Such cells stain weakly with the Unna-Pappenheim stain.

The myocytes of donor heart biopsies may show a variable loss of myofilaments leaving free-lying Z-bands within the sarcoplasm. Some Z-bands have a widened, smudgy, ill-defined appearance. As detailed above, Ratliff *et al.*[30] report an unusual, reversible form of myocyte damage, characterized by radially arranged myofilaments. Severe acute rejection associated with vasculitis may cause complete myocyte destruction. Other ultrastructural features of note include swollen mitochondria, dilated T tubules, cytoplasmic lipid vacuoles and swelling or necrosis of capillary endothelial cells. Severe acute rejection associated with vasculitis may cause complete myocyte destruction.

SPECIAL PROBLEMS REGARDING THE LIGHT MICROSCOPIC DIAGNOSIS OF ACUTE REJECTION

Certain special problems may be encountered in interpreting donor heart endomyocardial biopsies[27,35,36].

Inadequate biopsy

The rejection process in cyclosporin-treated patients is more focal than that seen in steroid–azathioprine-treated patients[37]. At least three to five tissue samples from different areas of right ventricular endomyocardium should be obtained at each biopsy procedure, in order to accurately assess the degree of rejection present. Personal experience with steroid–azathioprine immunosuppression is that the rejection changes are not uniformly distributed throughout the myocardium, but endomyocardial sampling is representative of the overall situation[15]. In the Standardized Grading System of the ISHLT four or more samples of endomyocardium are considered adequate (see above).

Thrombus obtained on biopsy

Occasionally, one or more endomyocardial samples are found to consist solely of fibrin thrombus. The source of the latter is not always clear. Possible sites of origin include the biopsy catheter itself, endocardial thrombus, thrombus at the vein entry site, or even a previous biopsy site.

Previous biopsy site

Since right ventricular endomyocardial biopsy samples a limited area of the apical portion of the interventricular septum, there is a possibility that the thrombus may even be derived from a previous biopsy site if serial biopsies have been taken[35,36]. A localized lymphocytic response and/or even myocyte necrosis may also be evoked by the biopsy procedure, and this may lead the unwary to consider the presence of rejection[27,36]. The presence of organizing thrombus (Figure 14) or hemosiderin deposits should provide a clue as to the correct diagnosis. Myocytes running vertically into an organizing thrombus are also characteristic of a previous biopsy site.

Presence of fibrous tissue

Another problem is the sample that is composed solely of fibrous tissue. While such a finding raises the possibility of chronic rejection, it should be borne in mind that chronic rejection commonly spares the myocytes that lie immediately below the subendocardium[23]. If the donor heart has a greatly reduced ejection fraction, and biopsy reveals no evidence of acute rejection, then chronic rejection is high on the list of possibilities.

Sometimes the fibrous tissue is easily identifiable as a portion of the tricuspid valvular chordae tendineae. Usually such removal of tricuspid valvular tissue does not result in significant valvular dysfunction. Occasionally the bioptome may penetrate the right ventricle and sample the fibrosed epicardium, with or without small epicardial blood vessels. A healed previous biopsy site may also show abundant fibrosis.

Infection of the donor heart

Although infection of the donor heart is very rare, the pathologist should be constantly on the alert for such a possibility. Infections include toxoplasmosis, coccidioidomycosis, cytomegalic inclusion disease, and Chagas disease. *Sarcocystis* species, which may occasionally infect humans, can produce a similar appearance to that of toxoplasmosis in the heart. These myocardial infections may elicit a mononuclear cellular infiltration that may be confused with acute rejection.

I have encountered two cardiac transplant patients with toxoplasmosis. In one patient with a heterotopic allograft a diagnosis of infection of both the donor and the recipient hearts by *Toxoplasma gondii* was made by endomyocardial biopsy (Figure 15A). Electron microscopy (Figure 15B) and serology served to confirm the diagnosis[38]. The infection had been transmitted to this recipient via the donor heart. Toxoplasmosis has also been reported from several other centers[39,40].

The interstitial mononuclear cellular infiltration that follows release of the *Toxoplasma* organisms from the cysts within myocytes is similar to that seen in acute rejection despite its supposedly more mixed nature (presence of plasma cells, as well as histiocytes and scanty eosinophils). In acute rejection the cellular infiltrate consists almost entirely of activated lymphocytes[33].

Despite these theoretical differences there is no certain way of diagnosing acute rejection in the presence of an active cardiac infection by *Toxoplasma*. Since our first patient with toxoplasmosis, referred to above, had a heterotopic transplant, the recipient heart served as a control for chemotherapy and for deciding whether a mononuclear cellular infiltration of the donor heart was likely to be due to acute rejection or toxoplasmosis.

Figure 15 **A**: Partially ruptured intramyocyte cyst of *Toxoplasma gondii* is evoking an early, mixed chronic inflammatory cellular response (H&E, × 250). **B**: Electron micrograph of donor heart biopsy shows numerous *Toxoplasma* within a myocytic cyst (Lead citrate and uranyl acetate, × 5180)

Myocardial ischemia

Early ischemia

Early myocardial ischemia may be encountered if the donor heart has not been adequately protected prior to implantation. The paucity of human donor hearts available for transplantation has led to distant heart procurement, whereby the excised donor heart may be stored and transported in a cardioplegic solution in ice, or by using a portable hypothermic perfusion system. A prolonged transplantation operation itself may cause myocardial damage. If preservation is unsatisfactory, various forms of myocardial necrosis (coagulative, myocytolytic, and contraction band) may be observed. Widespread interstitial hemorrhage indicative of a reperfusion-type infarction may also be observed. Subsequent stromal collapse fibrosis may be evident in 1–2 weeks.

Late ischemia

Late ischemic changes in the myocardium may be related to chronic rejection. The presence of a band of extensive coagulative necrosis or myocytolysis (Figure 16) in an endomyocardial biopsy in a patient who has survived longer than 3 months after transplantation may indicate graft arteriopathy (chronic rejection).

Similarly, healed infarction of the right ventricle may yield an endomyocardial sample which consists almost entirely of fibrous tissue with a band of surviving myocytes three to five myocytes thick immediately deep to the endocardium.

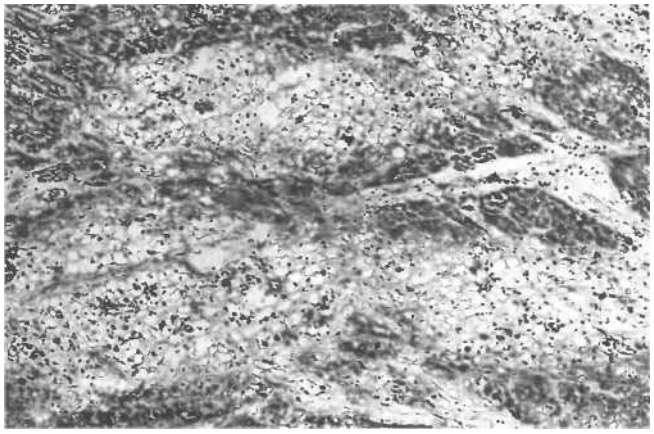

Figure 16 Late ischemic necrosis of right ventricle due to graft arteriopathy. Pale areas show myocytolytic necrosis and darker staining myocytes show coagulative necrosis (H&E, × 45)

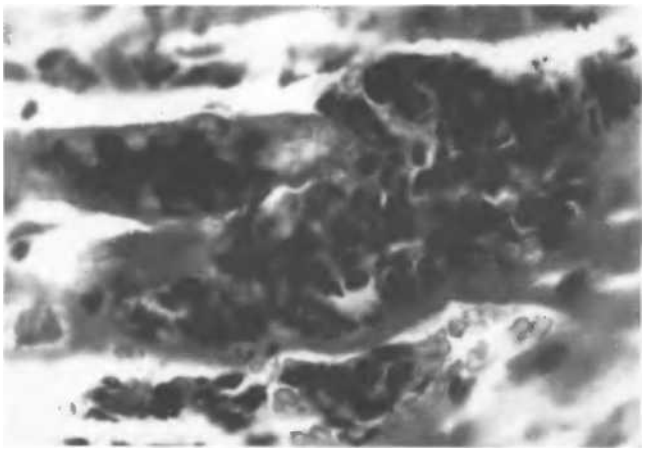

Figure 18 Numerous lymphocytes are applied to the surface of a necrotic myocyte in severe acute cardiac rejection (H&E, × 480)

Effects of donor brain death

Donor hearts are seldom biopsied in the first week following transplantation. Contraction banding of myocytes is a frequent biopsy-induced artefact, particularly at the margins of the biopsy. The presence of very numerous contraction bands has been taken as a sign of rejection by Kemnitz *et al.*[25]. Catecholamine overproduction associated with brain death produces myocyte injury[41–43], which consists of heightened cosinophilia of myocytes, contraction banding, focal coagulative necrosis, and application of mononuclear cells to the surface of damaged myocytes (Figure 17). The appearances can be similar to myocyte necrosis induced by acute rejection (Figure 18).

Localized endocardial lymphocytic infiltration (Quilty lesion)

Focal collections of lymphocytes which have been attracted to the endocardium are not an unusual finding in patients treated with

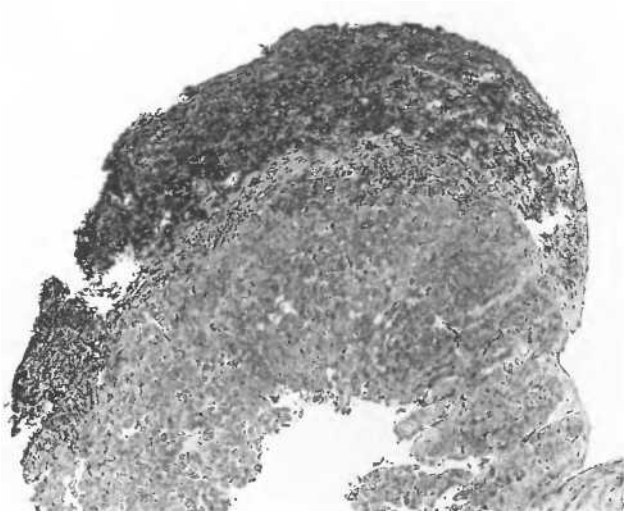

Figure 19 Endocardial lymphocytic infiltration with extension into the underlying myocardium (so-called Quilty B lesion). (Immunoperoxidase stain for T lymphocytes, × 20)

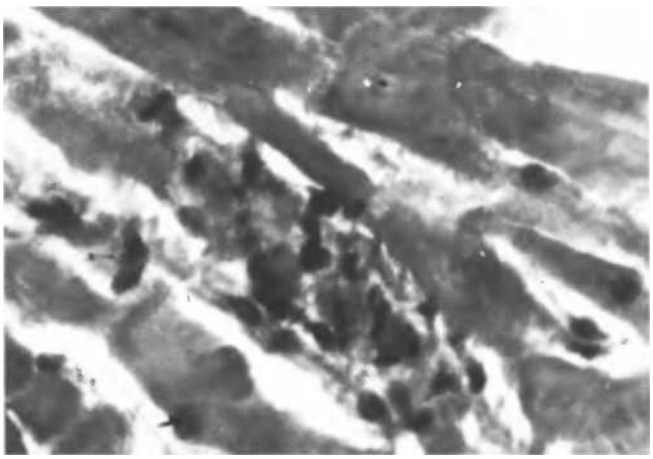

Figure 17 Mononuclear cellular response to necrotic myocyte in human donor heart damaged by brain-death-induced catecholamine excess (H&E, × 490)

cyclosporin. If the lymphocytic infiltration becomes florid it may lead to exophytic thickening of the endocardium, or it may extend into the underlying adjacent myocardium (previously termed an aggressive Quilty effect (Quilty B). The Quilty lesion (Figure 19) does not represent significant acute rejection, and augmented immunosuppression is not warranted. The response is more frequent in the paediatric age group.

Vascular (humoral/antibody-mediated) rejection

Vascular rejection may take one of two forms[44,45]: hyperacute rejection which occurs within 24 hours following transplantation, or delayed vascular rejection which is a similar process occurring later due to immunosuppression. The earliest features consist of swelling of capillary endothelial cells, venous thrombosis (seldom observed in endomyocardial biopsy), capillary con-

gestion, interfascicular followed by interstitial edema, and interstitial hemorrhage.

Lack of correlation with hemodynamic data

Hemodynamic function and inflammation or fibrosis detected on biopsy show a poor correlation. Greenberg *et al.*[46] found no significant difference in mean ejection fraction and left ventricular end-diastolic pressure between patients with and without fibrosis on biopsy, or between those with and without inflammation. At Groote Schuur Hospital, Cape Town, a good correlation was noted between changes in left ventricular volumes and histologic semiquantitative scores for acute rejection[47].

ALTERNATIVES TO ENDOMYOCARDIAL BIOPSY

As indicated earlier, several methods are being explored with the purpose of finding an acceptable substitute for endomyocardial biopsy in the diagnosis of acute cardiac rejection (Chapter 30). These include magnetic resonance imaging, assessment of peripheral blood lymphocytic activation, soluble interleukin-2 receptor levels[48] and induction of vascular adhesion molecules[49]. For the foreseeable future, graft histology will remain the gold standard for the early diagnosis of acute rejection.

Clinical Diagnosis of Acute Rejection

M.R. COSTANZO

INTRODUCTION

The alloimmune response of the recipient against the transplanted heart can injure the constituent cells of the graft, impairing their function[1]. The potential target cells for injury include not only the myocytes, whose destruction forms the basis for rejection surveillance and treatment, but also the cells of the vasculature, which provide the interface between donor and recipient. The alloimmune response involves the presentation of donor antigen, by vascular endothelial cells and/or by passenger leukocytes, leading to the activation and clonal proliferation of T cells that specifically recognize alloantigens[1] (Chapter 7). These events, as well as recruitment of macrophages and the up-regulation of cell surface antigens for adhesion of inflammatory cells, lead to the release of cytokines and the up-regulation of their receptors. The consequence of these events is the release of powerful biologic effectors of cell injury[1]. Myocyte injury and necrosis occurring during this process are readily recognized by histologic examination, and form the cornerstone of rejection surveillance in heart transplant (HTx) recipients.

Acute rejection is not a steady phenomenon, but occurs in sporadic waves, extending over a few days or a week or two. Since the introduction of cyclosporin (CsA) as an immunosuppressive agent, severe acute rejection episodes have become relatively rare. Mild acute rejection (cellular infiltration) is seen fairly frequently, but many groups would not increase therapy in such cases. It is impossible to predict whether or not any individual patient will experience episodes of rejection and, when it occurs, it may be impossible to make the diagnosis on clinical evidence until it is extremely advanced.

The frequency and severity of acute rejection episodes tend to diminish with time, the recipient's immune system appearing to adapt to the presence of the donor organ and its histocompatibility antigens. A state of relative unresponsiveness is frequently achieved, and maintenance immunosuppressive therapy may be progressively reduced. A few patients have been weaned from immunosuppressive therapy entirely, usually in the presence of lymphoproliferative disease or severe infection, and there are anecdotal reports of patients surviving months or years when not receiving immunosuppressive drugs. However, it would appear that the possibility of an acute rejection episode is almost always present, even some years after HTx, particularly if a patient fails to take his/her medication regularly.

DIAGNOSIS OF ACUTE REJECTION

The patient may feel completely well until the rejection episode has progressed for some days and donor heart function has deteriorated (sometimes irreversibly) to the point that cardiac failure occurs. (Identification of features of cardiac failure from acute rejection may prove more difficult in a patient with a heterotopic HTx, in whom the recipient heart may assist the cardiac output for a considerable period of time, delaying the onset of symptoms and signs of cardiac failure.) Irreversible damage of the myocardium may occasionally occur before clinical features become manifest. For successful therapy to be initiated at an early stage, the diagnosis must therefore be made before clinical features of cardiac failure occur.

Endomyocardial biopsy remains the most reliable method of confirming rejection. The search for a simple, noninvasive method of detecting acute rejection in its early stages (or even of predicting rejection in advance) has continued for a number of years. Such methods are reviewed below. There are, however, some clinical features and simple investigations that may make the attending physician suspicious that a rejection episode is developing.

Clinical features

Acute rejection is frequently totally asymptomatic, particularly in its early stages. In a patient with an orthotopic allograft the clinical diagnosis of rejection relies mainly on symptoms and signs indicating cardiac failure, particularly of right ventricular failure due to the decreased compliance associated with cellular infiltration and edema of the graft. In the early stages following HTx, however, several other factors may affect the performance of the right ventricle, e.g. inadequate preservation of the heart

during transportation and transplantation, an increased pulmonary vascular resistance, and fluid overload (secondary either to steroid therapy or to impairment of renal function from CsA therapy). These factors may make a clinical diagnosis of rejection uncertain.

In the heterotopic HTx, however, due to the support given by the patient's own right ventricle, evidence of right ventricular failure may not occur during rejection and, therefore, such symptoms and signs cannot be relied upon in the diagnosis of this complication.

The onset of features of cardiac failure, however, should always be considered to be due to acute rejection until proved otherwise. If acute rejection is confirmed, the treatment is primarily increased immunosuppression rather than anti-failure therapy, though this may be indicated also.

Clinical features suggesting a reduction in cardiac output (e.g. weight gain, diminished pulse volume, cold extremities), muffled or reduced-amplitude heart sounds, the development of a pericardial friction rub, tachycardia or gallop rhythm, or a dysrhythmia (in the absence of electrolyte or acid–base disturbance) should be viewed suspiciously until acute rejection has been excluded. Very occasionally, patients complain of vague chest discomfort or are feverish during an acute rejection episode.

Radiographic appearances

Radiographic evidence of rejection consists of progressive cardiomegaly, increasing pulmonary plethora and, rarely, pulmonary edema. An increase in cardiac volume of more than 10% or 100 ml compared with the previous measurement, and a simultaneous increase of the cardiothoracic ratio, have been suggested as confirmation of acute rejection[2]. Using these criteria, sensitivity and specificity were 76% and 97%, respectively. Predictive values of a positive or negative test for the presence or absence of rejection were 82% and 96%, respectively. Such radiographic changes may well make the physician suspicious that rejection is occurring, but should not be relied upon exclusively.

Occasionally, the appearances are those of an exudate from the epicardium. Following orthotopic HTx, fluid exuding from the epicardium may show up as a pericardial effusion (and may be associated with clinical features suggestive of subacute tamponade); after heterotopic HTx, it may present as a right-sided pleural effusion. The presence of a pericardial or pleural effusion should be considered suggestive of acute rejection until proved otherwise. A pleural effusion may, of course, suggest an underlying infective condition of the lung, which should also be aggressively sought. With satisfactory treatment of the acute rejection episode, these effusions will regress and disappear.

Effusions, however, may be absent in patients with severe acute rejection, or may appear very late in the episode. Their development cannot be awaited, therefore, as a reliable diagnostic aid in the recognition of early rejection.

Endomyocardial biopsy (EMB)

Survival after HTx has improved steadily over the past decade, with mortality at 1 year falling to as low as 10% in many centers[3]. This improvement in survival is owed in part to better, more specific immunosuppression, but also, to a large extent, to surveillance endomyocardial biopsy (EMB), which allows diagnosis of rejection to be made, in most instances, before the development of allograft dysfunction[4]. Early diagnosis is exceedingly important due to the high mortality in patients with acute rejection associated with consequent allograft dysfunction[5]. The histologic diagnosis of cardiac allograft rejection is obtained by light microscopy examination of the specimens obtained by transvenous EMB, which is performed at regular intervals after HTx. In many centers, EMB are performed weekly for the first 4–6 weeks, biweekly for the subsequent 2 months, then at progressively longer intervals until a frequency of ≤ 3 EMB per year is reached[6].

EMB can be performed with a variety of bioptomes which are inserted through the internal jugular, subclavian or femoral veins, and advanced, under radiologic or echocardiographic control, to the apical portion of the right ventricular septum[7]. Adequate sampling and proper handling of EMB specimens are critical to obtain accurate diagnoses. Because rejection is often a focal process, three to five specimens are necessary to achieve a sensitivity ranging between 75% and 98%[8,9]. Once six specimens are examined, obtaining additional tissue does not significantly increase the diagnostic yield[9]. The specimens should be fixed in 10% formalin for light microscopy (Chapter 29). The tissue is processed for paraffin embedding, serially sectioned at 4 μm, and stained with hematoxylin and eosin and Masson's trichrome[6]. Electronmicroscopy, immunohistochemistry and immunofluorescent studies are performed at some centers as part of research protocols (Chapter 28), but are not mandatory for the routine diagnosis of acute rejection[6].

Since the Stanford original histopathologic classification of acute rejection[10], many modifications have been proposed (Table 1). The feature common to all classifications is that severity of rejection is graded according to increasing degrees of inflammatory infiltrates and increasing damage to the myocardium. The categories of mild and moderate rejection are often subdivided into focal and diffuse, in an attempt to predict which subset of patients within each category is most likely to progress to the next

Table 1 Comparison of individual centre grading systems for acute rejection

Stanford	None	Mild	Moderate	Severe
Texas	0 1 2 3 4		5 6 7 8 9	10
Hannover	A 0	A 1 A 2	A 3	A 4
Boston	0	1 2	3 4	5
Loyola	None	FM Mild	FMod Mod	Severe
Pittsburgh	0 1	2	3	4
Utah	1 2	2.5 3	4	5

From Ref. 6.

Table 2 International Society for Heart and Lung Transplantation (ISHLT) standardized cardiac biopsy grading

Grade	*Description*
0	No rejection
1A	Focal perivascular or interstitial infiltrate without myocyte damage
1B	Diffuse but sparse perivascular and/or interstitial infiltrate without myocyte damage
2	One focus only with aggressive infiltration and/or focal myocyte damage
3A	Multifocal aggressive infiltrates and/or myocyte damage
3B	Diffuse inflammatory process with myocyte damage
4	Diffuse aggressive polymorphous infiltrate ± edema ± hemorrhage ± vasculitis, with necrosis

From Ref. 13.

higher grade and should, therefore, be monitored more closely and/or receive increased immunosuppression[11,12]. The key histologic feature which differentiates 'moderate' from 'mild' rejection is the presence of myocyte damage since, in general, the presence of this finding warrants augmentation of immunosuppression. At present the rejection grading system introduced by the International Society for Heart and Lung Transplantation (ISHLT)[13] is the most widely accepted among transplant centers (Table 2).

Undoubtedly, standardization of cardiac allograft rejection criteria has greatly improved the ability of HTx centers to compare rejection rates, severity and thresholds for treatment. Accurate comparison of EMB results between institutions is also essential to the conduct of multicenter immunosuppressive trials. However, even the ISHLT grading system is not exempt from criticism. It has been pointed out that the ISHLT classification of rejection does not immediately convey information on whether the histologic changes detected in an individual EMB represent ongoing or resolving rejection. Criteria for the diagnosis of chronic and 'humoral' rejection are classified as 'additional information' rather than separate entities. The ISHLT classification does not account for the fact that the significance of a given histologic finding may change over time. For example, grade 2 detected early after transplantation may forecast impending rejection of greater severity, whereas the same rejection grade detected beyond the third postoperative month may be an entirely benign, self-limiting finding[12]. The relative severity of grades 1B and 2 remains unclear; recent studies on the evolution of untreated rejection have shown that *diffuse* cellular infiltrates *without* myocyte damage may progress more often than an *isolated* cellular infiltration associated *with* myocyte damage[12].

In addition to the specific limitations of the ISHLT rejection classification, other factors can complicate the histopathologic interpretation of EMB specimens (Table 3). Some of these are related to the procedure and tissue processing, some to tissue sampling, and others to transplantation-related effects[6]. Since the average HTx recipient undergoes 15–20 EMB in the first postoperative year, and the bioptome tends to follow the same path due to the structure of the instrument and the configuration of the right ventricular trabeculae, it is common to take an EMB specimen from a previous EMB site. EMB site changes, which can be present in 16–69% of surveillance EMB specimens, range from a fresh thrombus overlying an area of myocyte injury and hemorrhage in a recent EMB site, to granulation tissue, often containing mononuclear inflammatory cells and myocyte disarray at the periphery of the EMB site, to dense fibrous tissue in a fully healed EMB site[6,14].

It remains unclear whether endocardial infiltrates (Quilty effect), which are found in 5–10% of adult recipients and up to 50% of pediatric recipients receiving cyclosporin, forecast impending rejection, or are benign collections of lymphocytes[15,16]. In some cases it is difficult to distinguish Quilty lesions from rejection, particularly when the lesion extends into the subadjacent myocardium and encroaches upon, surrounds, and damages myocytes. Contiguity of the endocardial and myocardial components is the key histologic feature which confirms the presence of a Quilty lesion and excludes acute rejection[15].

Opportunistic infections
Post-transplantation lymphoproliferative disorder

Adapted from Ref. 6.

Histologic evidence of ischemia detected in the first few postoperative weeks may result from the use of pressor agents in donor and/or recipient, preservation injury, or microinfarcts due to air bubbles entrapped in the coronary circulation during the operation[17]. In ischemic injury the degree of myocyte damage appears to be disproportionate to the sparse infiltrate, which is composed of neutrophils in the early stages and of macrophages, histiocytes and granulation tissue in the organizing phase[6,18]. Differentiation of ischemia from acute rejection during the early postoperative period can avoid unnecessary intensification of immunosuppression. However, ischemia, when present later after HTx, may unveil cardiac allograft vasculopathy[19].

Other potential pitfalls of EMB include sampling error, which leads to a falsely negative diagnosis of rejection in 15% of cases, recovery of insufficient tissue in 6% of cases, and incorrect interpretation of entities that may mimic rejection, such as infections and post-transplantation lymphoproliferative disorder (PTLD)[6]. Careful search for infectious organisms is warranted. The two organisms most likely to be encountered in EMB are *Toxoplasma gondii* and cytomegalovirus. When the myocardium is involved with PTLD, the distinction between this infiltrate and reactive T lymphocytes of acute rejection can prove very difficult[6]. The presence of atypical lymphocytes, lymphoplasmacytoid or immunoblastic mononuclear infiltrates, necrosis and frequent mitotic figures should suggest the possibility of PTLD.

Immunohistochemical studies for light chain restriction, gene rearrangement for clonality and *in-situ* hybridization for EBV are useful diagnostic studies[20].

Recently, investigators have observed clinical examples wherein patients with hemodynamic and echocardiographic evidence of allograft dysfunction lack the classic histopathologic findings of cellular infiltrates and myocyte injury on EMB specimens[21]. The EMB specimens instead display evidence of endothelial activation and injury in the capillaries, venules, and arterioles of the myocardium[22]. The earliest findings include enlarged, prominent, swollen endothelial cells and interstitial edema. In the later phases vasculitis is observed with infiltration of the vessel wall by lymphocytes, macrophages and neutrophils. This has been designated as acute vascular or humoral rejection[22] (Chapter 28). In addition to these microscopic findings, immunofluorescent studies are required to establish the diagnosis. Vascular injury is characterized by deposition of immunoglobulin (IgG or IgM), complement (C1q or C3) and fibrinogen in linear or circular patterns indicative of deposition within the vessels[22]. Accurate diagnosis of humoral rejection is important, since this entity may require, in addition to high-dose pulsed corticosteriod therapy, the use of plasmapheresis and cyclophosphamide. Furthermore, patients with humoral rejection may be at higher risk of developing cardiac allograft vasculopathy[23].

The contribution of surveillance EMB to the improved outcome of HTx recipients is undeniable. However, some limitations of EMB cannot be ignored. The EMB is an invasive procedure which is associated with a rate of complication ranging between 0.3% and 1.3%[5,6]. Processing and interpretation of EMB specimens may delay diagnosis of rejection for 8–24 hours. EMB is performed at progressively longer intervals after HTx. Thus, since the detection of rejection is highly dependent upon the frequency of EMB, it is very difficult to estimate the duration of a rejection episode. Indeed, the EMB provides only 'snapshots' of the rejection process, while the immune response of the recipient against the allograft and the resulting effects on allograft function are continuously ongoing. Another important limitation of EMB is its expense, an increasing concern in this era of health-care rationing and cost containment. The limitations of EMB summarized above have spurred the search for reliable, safe and less expensive noninvasive methods for the diagnosis of rejection.

Electrocardiographic methods

During the initial decade of HTx the results of several studies suggested that changes in the amplitude of the QRS complex measured from the standard 12-lead electrocardiogram (ECG) could be used to detect rejection[24]. However, since the introduction of CsA, QRS voltage reductions on the standard 12-lead ECG are typically absent[25]. Possible reasons for this include minimal interstitial edema, earlier detection by surveillance EMB of rejection before it can cause hemodynamic and ECG changes, and the occurrence, in CsA-treated patients, of rejection that progresses more slowly and is more easily treated. Several investigators have therefore studied the potential of ECG methods, other than the standard 12-lead ECG, for the early noninvasive diagnosis of rejection (Table 4).

Table 4 Electrocardiographic methods evaluated for the diagnosis of cardiac allograft rejection

Authors/year (ref.)	*Echocardiographic method*	*Echocardiographic rejection criteria*	*Sensitivity (%)*	*Specificity (%)*
Keren *et al.* 1984[26]	SAECG	Decreased total QRS vector voltage amplitude	82	81
Lacroix *et al.* 1992[27]	SAECG	11% decrease of QRS voltage between two consecutive recordings	88	78
Haberl *et al.* 1987[28]	SAECG (FFT)	Increased frequency content of QRS complex 70–110 Hz	90	–
Warnecke *et al.* 1992[29]	Intramyocardial ECG transmitted by implanted telemetric pacemaker	15% decrease of QRS voltage from control	88	96
Grace *et al.* 1991[30]	Epicardial paced evoked response	Decrease in evoked T wave amplitude	92	100
Sands *et al.* 1989[31]	Power spectral analysis of heart variability	Increased heart rate variability	–	–
Picano *et al.* 1990[32]	Dipyridamole ECG	> 0.1 mV ST segment depression	72	94

High-frequency signal-averaged ECG (SAECG) is a technique that enhances the signal-to-noise ratio and excludes the low-frequency signals of the standard ECG by electronic filtering methods. With this technique the averaged QRS complex can be analyzed: (a) in the time domain, using a high-pass filtering technique, and (b) in the frequency domain, using fast Fourier transformation (FFT) techniques.

In one study of 20 CsA-treated HTx patients a decrease in the total high-frequency voltage amplitude of the QRS predicted EMB histologic findings consistent with definite rejection, with a sensitivity and a specificity of 82% and 81%, respectively[26]. The method, however, was inadequate in monitoring patients during the early postoperative period and in detecting mild forms of rejection in the late postoperative phase. In another study an 11% decrease in the QRS voltage between two consecutive recordings predicted rejection with a sensitivity and a specificity of 88% and 78%, respectively[27]. In contrast, in other studies, frequency domain analysis, but not time domain analysis, of the QRS complex provided useful information for the noninvasive diagnosis of rejection. A single-beat analysis of the QRS complex by FFT revealed a progressive change of the spectral morphology (increase in the frequency content between 70 and 110 Hz) on the days of rejection in 19 of 20 patients[28]. A decrease in the amplitude of the QRS complex was not a reliable predictor of rejection[28].

In a further effort to identify an ECG correlate to rejection, intramyocardial electrograms have also been compared with EMB. In a preliminary report using intramyocardial electrocardiography transmitted by an implanted telemetric pacemaker, a voltage reduction >15% of control had 88% sensitivity and 96% specificity[29]. Unfortunately, the value of this approach has been tested only in small series, and has not been confirmed by other investigators.

An alternative ECG technique is to measure the evoked T wave amplitude using an externalized QT-driven rate adaptive pacemaker[30]. This technique uses direct measurements from the heart rather than body surface recordings, and assesses the repolarization rather than the depolarization phase of the cardiac cycle. A significant fall in the mean evoked T wave amplitude from 1.3 mV to 0.6 mV ($p<0.005$) preceded by an average of 2 days the EMB diagnosis of rejection in 11 of 17 patients[30]. Since evoked T wave amplitude did not fall in the absence of rejection, and remained unchanged in only one rejecting patient, the sensitivity and specificity of this noninvasive method for the diagnosis of rejection were 92% and 100%, respectively[30]. The above observations, however, were limited to the first 20 postoperative days, and whether a fall in the evoked T wave amplitude predicts rejection late after HTx remains unknown[30].

Since denervation of the heart reduces heart rate variability, some investigators have studied beat-to-beat heart rate variability by power spectral analysis to determine if changes in this parameter might be a noninvasive marker of rejection. One study showed that the development of rejection was associated with a significant increase in heart rate variability[31].

Since characteristic ECG changes occur in response to dipyridamole infusion in conditions associated with a decreased coronary reserve, one study sought to establish whether acute cardiac allograft rejection might induce ECG alterations during dipyridamole infusion[32]. A dipyridamole-induced ST segment depression >0.1 mV detected EMB-proven acute rejection with a sensitivity and a specificity of 72% and 94%, respectively[32]. As with other ECG markers of cardiac allograft rejection, dipyridamole-elicited ST segment changes were studied only in the first few postoperative weeks, and it is not yet known whether this technique would continue to predict rejection later after HTx[31].

Echocardiographic methods

A variety of echocardiographic techniques have been used to characterize the transplanted heart from both an anatomical and a functional standpoint. Anatomic changes, such as the presence of a pericardial effusion, and quantitative changes, such as an increase in left ventricular (LV) mass, can be evaluated by echocardiographic techniques[33]. The EMB histologic abnormalities typical of acute rejection which produce qualitative and quantitative echocardiographic changes include edema, cellular infiltrates, and myocyte damage. In addition, since cells of the microvasculature express foreign antigens and produce cytokines, they may become the target of alloimmune responses. This microvascular damage, in turn, may produce acute diastolic dysfunction, a process that would go unrecognized by conventional histologic evaluation, but could be detected by echocardiography[34]. The cardiac allograft anatomic and functional variables and the echocardiographic techniques that detect them are summarized in Table 5.

Table 5 Echo cardiographic methods evaluated for the diagnosis of cardiac allograft rejection

Authors/year (ref.)	*Echocardiographic method*	*Echocardiographic rejection criteria*	*Sensitivity (%)*	*Specificity (%)*
Dawkins *et al.* 1984[37]	M-mode and phonocardiography	10% decrease of IVRT	87	90
Valantine *et al.* 1991[40]	Doppler	Decreased IVRT and PHT	82	79
Dodd *et al.* 1993[42]	M-mode and Doppler	Echocardiographic score ≥ 4 (LVEEDV, filling velocity LVPW, velocity of LVPW thinning)	100	75
Park *et al.* 1992[46]	Digitized M-mode	20% increase of time interval (Te) over prerejection values	80	94
Masuyama *et al.* 1990[43]	Ultrasonic backscatter instrumentation	Decreased cyclic variation of integrated ultrasonic backscatter	86	85
Lieback *et al.* 1994[44]	Texture analysis	Change in three texture parameters	89	84

In patients who underwent HTx before the introduction of CsA, increases in wall thickness and LV mass measured by M-mode echocardiography were reported to occur during episodes of acute rejection[35]. Subsequently, a decreased LV lengthening rate and posterior wall thinning rate consistent with significant LV dysfunction were reported in association with episodes of acute rejection[36]. In a prospective study of 20 patients, using M-mode echocardiography and phonocardiography, a 10% decrease in isovolumic relaxation time was 87% sensitive and 90% specific for the diagnosis of acute rejection[37]. After the introduction of Doppler echocardiography, Doppler indices of diastolic function have been applied to the diagnosis of acute rejection, since this process appears to be characterized by the onset of 'restrictive physiology'[38].

This has been defined as a decrease in either isovolumic relaxation time (IVRT) or pressure half-time (PHT), as determined by the analysis of the Doppler mitral flow velocity curve[39]. The discrete signal of aortic valve closure may be recorded with the transducer oriented to encounter both mitral and aortic flow velocities. IVRT is measured from aortic valve closure to the onset of mitral flow[39]. Peak early mitral valve flow velocity (M1) is measured vertically from the baseline to the maximum recorded velocity. The maximum velocity is related to the rate of decrease of pressure difference across the mitral valve[39]. The PHT is the time taken by the peak pressure difference to decline by one half[39]. In some studies a 15% decrease in either IVRT or PHT had a sensitivity in excess of 80% and a specificity of 70% in the diagnosis of acute rejection[39]. Analysis of the factors that contribute to an incorrect Doppler echocardiographic diagnosis of rejection revealed that while false-negative studies occur most frequently when rejection is already being treated with intensified immunosuppression, restrictive physiology preceding biopsy evidence of rejection accounts for a large proportion of Doppler false-positive studies. These observations suggest that positive Doppler echocardiography in the absence of concurrent rejection by EMB is a strong indication for an earlier follow-up EMB[40].

Other investigators have challenged the value of Doppler echocardiography for the diagnosis of acute rejection due to a wide overlap of measurements in individual recipients with or without rejection[41]. Factors which may be responsible for this overlap include a variety of hemodynamic factors (pulmonary hypertension, perioperative ischemia, hypertension) which affect diastolic function and are superimposed on the restrictive left ventricular filling pattern caused by rejection and LV hypertrophy[41]. Differences in patient selection, duration of follow-up, antihypertensive therapy, and immunosuppression may also influence the outcome of Doppler echocardiographic studies[33].

To accommodate differences between patients and between serial studies in the same patient, some investigators have combined multiple echocardiographic parameters into a scoring algorithm[42]. Such an algorithm is based on echocardiographic indices of LV chamber size, diastolic function and LV mass obtained by computer-assisted digital analysis of two-dimensional-guided M-mode echocardiograms. When applied prospectively to 49 studies, an echocardiographic score ≥ 4 detected rejection with a sensitivity of 100%, a specificity of 75%, and a negative predictive value of 100%[42].

Based on the assumption that abnormalities in microscopic tissue structures are identified by their acoustic properties, some investigators have evaluated the ability of texture analysis of echocardiograms to detect morphologic changes in the myocardium caused by rejection. In some studies abnormal patterns of echocardiographic myocardial texture detected rejection with a sensitivity and specificity of approximately 85%[43,44].

In summary, the main advantages of echocardiography in the diagnosis of rejection are the noninvasive nature of the technique, the ability to obtain results immediately, and its value as an adjunct to EMB. Echocardiographic changes consistent with rejection may prompt an earlier EMB, leading to an earlier diagnosis of rejection. Conversely, absence of echocardiographic changes consistent with rejection may reduce the frequency of EMB[45–48]. However, the ability of echocardiography to detect rejection is limited by: (a) insufficient sensitivity, (b) effect of image quality, (c) need for serial studies, (d) inter-observer variability, and (e) occurrence of echocardiographic changes resulting from conditions distinct from rejection[33].

Radionuclide methods

Different radionuclide techniques have been evaluated to determine their usefulness for the noninvasive diagnosis of cardiac allograft rejection[49]. These include myocardial function studies, imaging with radioisotopes which assess myocardial perfusion or detect inflammation, and imaging with radiolabeled blood cellular elements or radiolabeled monoclonal antibodies. Functional studies are not sensitive enough unless further investigation on quantitative ventricular volume changes shows a consistent correlation with acute rejection[49]. Routine myocardial imaging agents such as ^{67}Ga, ^{99}TcPP, or the perfusion agent ^{201}Th are clearly not specific enough to detect rejection until the allografts are nearly lost[49]. Use of radiolabeled lymphocytes may hold some promise. However, this technique is limited by an unacceptably long radiation exposure, and by the inability to discriminate between rejection episodes that require intensified immunosuppression versus those that do not[49].

^{111}Indium-radiolabeled Fab fragments of monoclonal antimyosin antibodies have been shown to specifically detect myocyte necrosis that occurs at the microscopic level. In one study the sensitivity, specificity, and overall accuracy of this technique in detecting cardiac allograft rejection were 80%[50]. In another study in which ^{111}indium antimyosin imaging had a sensitivity of 100% and a specificity of 67% in detecting cardiac allograft rejection, falsely positive images were obtained in patients that had myocyte necrosis attributable to ischemic rather than rejection-induced myocyte injury[51]. However, because of the high sensitivity of antimyosin scintigraphy, EMB can be avoided in the presence of a negative scan. Using the heart/lung (H/L) ratio as a measure of ^{111}indium antimyosin antibody uptake, a H/L ratio ≥ 1.6 was 93% sensitive and 98% specific in detecting rejection[52]. The results of more recent studies suggest that ^{111}indium antimyosin antibody scintigraphy predicts the occurrence of rejection-related complications in the early postoperative period and of subsequent rejection episodes ≥ 12 months after HTx[53,54]. Based on the latter finding, the authors recommend that, if the antimyosin scan is negative ≥ 1 year after HTx, rejection surveillance be carried out noninvasively; in contrast, if the antimyosin scan performed ≥ 1 year postoperatively is positive (H/L ≥ 1.55), EMB should be performed at 4-month intervals[54].

Despite these encouraging results the limitations of ^{111}indium should not be underestimated. These include: (a) the slow blood clearance of antimyosin antibodies which delays scanning and diagnosis; (b) the long half-life of ^{111}indium which limits the ability to repeat injections at clinically required intervals; (c) the hepatic uptake of ^{111}indium which may obscure the uptake in the adjacent myocardium; (d) the production of human anti-mouse antibodies; and (e) the binding of antimyosin antibodies to dying myocytes regardless of the etiology of myocyte injury[49].

Based on the knowledge that expression of class II major histocompatibility complex (MHC) antigens increases in rejecting organs, experimental work in a rat heterotopic HTx model has evaluated the ability of ^{111}indium-labeled anti-MHC class II monoclonal antibodies to detect *in-vivo* induction of MHC class II antigens and, therefore, rejection[55]. Radiotracer uptake in the grafts was significantly correlated with the presence and severity as defined by histologic abnormalities. Furthermore, increased expression of MHC class II antigens was detected in the presence of cellular infiltrates *before* the occurrence of myocyte necrosis[55]. These experimental results are encouraging, but scintigraphy with ^{111}indium-labeled monoclonal antibodies directed against the constant region of MHC class II antigens still awaits clinical application.

Magnetic resonance imaging

The possibility that magnetic resonance imaging (MRI) might be a useful tool for the noninvasive diagnosis of rejection is based on the assumption that cellular infiltrates, hemorrhage, and myocyte damage may alter MRI relaxation times[56]. Prolongation of T2 has been reported in rejecting heterotopic canine heart allografts[57]. To date only a few clinical studies conducted in a very small number of patients have been published on rejection surveillance with MRI[56,58]. The results of these studies suggest that MRI is of limited utility for the diagnosis of rejection in human HTx recipients. Limitations of MRI include: (a) a lack of diagnostic value in the early postoperative period when T2 values are uniformly increased by myocardial edema[57]; (b) a large degree of overlap in T2 values when T2 measurements are sorted according to EMB grade; (c) the difficulty in monitoring critically ill patients in a high magnetic field; and (d) the limited availability of MRI equipment[56–58].

Cytoimmunologic monitoring

A steady and progressive rise in the white blood cell (WBC) count, or in the total lymphocyte count, or, particularly, in the T-11 lymphocyte subset, may, on occasion, indicate that a rejection episode is occurring, but is unreliable[59]. A rise in the T cell fraction has been considered helpful, and there is some evidence that fluctuations in the number of circulating T cells may reflect an earlier phase of the host immune response to the cardiac allograft than that provided by endomyocardial biopsy[60,61]. This Stanford experience, however, was documented before the introduction of CsA, at a time when antithymocyte globulin (ATG) was administered regularly for several weeks post-HTx. A rapid expansion of the circulating T-lymphocyte population, after discontinuation of ATG, was shown to correlate closely with the development of acute rejection. As CsA does not depress the number of circulating T lymphocytes, monitoring of the T cell fraction has not been put forward as an indicator of acute rejection in patients receiving this drug. A persistent rise in the T cell fraction in the early post-transplant period, however, reflects the fact that the host's immune system is responding to the presence of the foreign tissue, and may therefore suggest that acute rejection is occurring, but is not reliable.

Numerous cytoimmunologic variables have been measured in an attempt to identify a highly sensitive, easy-to-administer repetitively, and inexpensive noninvasive index of cardiac allograft rejection (Table 6). The earliest studies involved the measurement of urinary polyamines that reflected increased cellular proliferation or degeneration[62,63]. Later, changes in prolactin levels were measured as an indicator of immune activation[64]. The sensitivity of these measurements never exceeded 80%. With improved understanding of the immune response, lymphocyte subsets, and activation markers, along with the development of flow cytometry techniques, several groups have investigated the possibility that assessment of activation antigens on circulating lymphocytes, cytokines[65] (plasma tumor necrosis factor alpha levels)[66–68], cytokine receptors (serum interleukin-2 receptor levels)[69–74], and components of MHC class I antigens (serum β-2 microglobulin levels)[75,76] might predict rejection. Although one group reported a sensitivity of cytoimmunologic monitoring of 94% in the detection of rejection[77], these striking results have not yet been reproduced by others[69,78].

Important limitations of cytoimmunologic monitoring include: (a) the possibility that events occurring in the periphery may not reflect immunologic activity in the allograft; (b) the observation

Table 6 Cytoimmunologic monitoring methods evaluated for the noninvasive diagnosis of cardiac allograft rejection

1. Lymphocyte subsets in the peripheral blood
2. Urinary polyamines
3. Serum prolactin levels
4. Plasma tumor necrosis factor alpha
5. Serum interleukin-2 receptor levels
6. Serum β-2 microglobulin levels
7. Interleukin-2-driven growth of graft infiltrating cells
8. Cytotoxicity of graft infiltrating cells
9. Expression of adhesion molecules (VCAM-1, E-selection, ICAM-1) in the graft
10. Frequency of alloreactive cytolytic T lymphocytes in the peripheral blood
11. T cell receptor subsets
12. Phosphotyrosine levels in peripheral blood mononuclear cells

that single determinations correlate poorly with EMB findings; and that (c) values are not reliable in the early postoperative period because abnormalities may be due to preoperative illness, surgical trauma and ischemic injury; and (d) abnormalities induced by rejection may be indistinguishable from those occurring as a result of infection[5,69,78].

Other immunologic approaches have recently been proposed either as adjuncts to the EMB histologic diagnosis of cardiac allograft rejection, or as noninvasive diagnostic alternatives to EMB. A correlation has been found between the frequency of IL-2-driven propagation of graft-infiltrating lymphocytes and the degree of cellular infiltration in EMB specimens. Furthermore, a positive correlation was found between the growth of alloreactive lymphocytes from histologically negative EMB and the incidence of subsequent histologic rejection[79].

In another study in which lymphocyte cultures established from EMB (taken before, during, and after rejection episodes of ISHLT grade ≥ 1) were assayed for cytotoxicity, the patients whose cultures remained cytotoxic after a rejection episode went on to develop further rejection episodes[80]. These results suggest that both the growth of alloreactive T cells and persistent cytotoxicity of IL-2-responsive T lymphocytes in EMB may be useful prognostic indicators of future rejection episodes[80].

Other studies have shown that increased expression of adhesion molecules in EMB specimens may be a marker of rejection, necessitating augmentation of immunosuppression, and that expression of inducible endothelial cell adhesion molecules may predict impending clinically significant rejection[81–84]. In one study a percentage of ICAM-1-positive vessels $\geq 80\%$ predicted the presence of rejection necessitating treatment, with a sensitivity and specificity of 85% and 95%, respectively[81]. In another study, increases in E-selectin and ICAM-1 were most likely to occur in EMB just prior to rejection episodes[82].

Some investigators have used limiting dilution analysis (LDA) technology to monitor the frequency of donor-reactive cytolytic T lymphocytes in the peripheral blood of cardiac allograft recipients. In one study the frequency of donor-reactive cytolytic T lymphocytes was significantly higher ($p<0.05$) in blood samples from patients whose simultaneous EMB showed histologic evidence of cardiac allograft rejection than in patients showing no evidence of rejection[85]. Although this method is noninvasive, and the results do not seem to be influenced by infection, the 10-day culture period required for LDA makes it impractical when a rapid diagnosis of rejection is needed.

Based on the hypothesis that quantitative changes in T cell subsets can be detected in the peripheral blood, and that these changes correlate with rejection, some investigators performed T cell subset analysis by flow cytometry using monoclonal antibodies recognizing six isotypic epitopes of the T cell receptor β-chain variable (V) region. In this study, regression analysis showed a significant ($p<0.001$, $R=0.91$) temporal association between cellular rejection and abnormal subset fluctuations[86]. Although this approach holds potential for the noninvasive diagnosis of rejection, much remains to be learned about the physiological mechanisms underlying changes in T cell receptor subset expression in the peripheral blood. Furthermore, it remains to be established whether there is a relation between receptor subset expression in the peripheral blood and T cell subsets that infiltrate the blood.

Tyrosine phosphorylation is an early critical event in lymphocyte signal transduction and activation. In a porcine HTx model, levels of phosphotyrosine in peripheral blood mononuclear cells were increased 2–5 days before histologic signs of allograft rejection[87].

Thus, future methods for the noninvasive diagnosis of rejection may focus on the detection of molecular events participating in T cell activation.

COMMENT

There are some clinical, electrocardiographic and radiographic features that suggest that an acute rejection episode may be occurring, but EMB represents the only generally accepted reliable method of confirming the presence or absence of rejection. Even EMB can be misleading on occasions, however, and if biopsy proves negative and yet clinical suspicion of rejection is high, then EMB must be repeated as a matter of urgency. There are occasions when the result of the EMB, if negative, should be ignored and, if the physician's suspicions are high, the patient should be treated for rejection even in the absence of confirmation.

The procedure of EMB is unpopular with the majority of heart transplant recipients, and is not without risk. The search for noninvasive techniques for diagnosing the presence of early rejection (or preferably for predicting the onset of rejection) should therefore continue. Further investigations and trials are required, however, before any noninvasive technique can be accepted as being totally reliable; only then will EMB prove unnecessary.

Treatment of Cardiac Allograft Rejection

L.W. MILLER

INTRODUCTION

The development of the endomyocardial biopsy by Caves *et al.*[1] was one of the most important developments in the management of heart transplant recipients, and remains the gold standard today for the diagnosis of allograft rejection. Subsequent investigation has shown that a minimum of four and preferably five adequate pieces of endomyocardium are required to achieve satisfactory diagnostic accuracy[2]. The samples should be taken from as many different locations as possible for maximum sensitivity, a task perhaps made easier by use of echocardiography (versus fluoroscopy) to guide the bioptome and allow safe sampling from the anterior free wall and apex[3].

The decision or threshold to initiate bolus therapy for treatment of cardiac allograft rejection has evolved over time. In the mid-1980s low-grade rejection (grades 1B and 2) was routinely treated in many programs[4]. However, a number of investigators have shown that as many as 80–85% of both diffuse mild and focal moderate rejections resolve spontaneously, or with a simple increase in maintenance immunosuppression[5–8]. Although there is increasing evidence of a strong correlation between the occurrence of even one rejection episode and the development of chronic rejection in kidney transplant recipients[9,10], there are few data demonstrating a correlation between the incidence, severity, or time to first rejection and the development of chronic rejection or allograft coronary disease in heart transplant recipients[11–13]. As a result the pendulum has swung to a more conservative approach or threshold to treat cardiac allograft rejection over the past 5 years.

Most recently, however, data from Kobashigawa and the CVIS investigators[14], involving over 250 patients, demonstrated a correlation between the average biopsy score (ABS), which takes into account all low-grade untreated as well as treated rejection during the first 3 months post-transplant, and the development of coronary intimal thickening (chronic rejection) as measured by intravascular ultrasound. Of note, the incidence of treated rejection episodes did not correlate with intimal thickening. In addition, Anguita *et al.*[15] have recently reported that repetitive episodes of untreated grade 1B or 2 rejection impair long-term cardiac graft function. These important data suggest a need to re-evaluate the threshold for initiating treatment of even mild rejection, and studies are needed to compare the morbidity of a more aggressive approach.

The risk factors for early and late cellular rejection have been reviewed[16–18], and a number of factors have been identified which additionally impact on the decision to treat a given biopsy, including: (a) grade of the previous biopsy; (b) time post-transplant – data from a large review from Stanford[19] have shown that rejection is much more likely to progress to a higher grade if untreated early (<9 months) post-transplant than later (>9 months); (c) level of other maintenance immunosuppressive medications; and (d) clinical signs or symptoms.

Many patients are treated for rejection with <grades 1B or 2 histologic criteria on biopsy. The CTRD database on over 900 patients transplanted between January 1990 and January 1993 indicates that 12% of treated rejection episodes had grade 0 or 1A biopsy score[17]. Often the most compelling reason to treat low-grade evidence of rejection is hemodynamic compromise. Possible explanations for the disparity between histologic findings and clinical signs or symptoms include sampling error on biopsy, passage of cytotoxic lymphocytes out of the allograft after initiating damage, or the possibility that the primary mechanism associated with acute allograft dysfunction is not cellular but humoral[19–21]. Many centers give a course of corticosteroids for patients with acute graft dysfunction, even with limited evidence of cellular rejection[19], followed by more aggressive therapies if no response is evident[20] (see discussion on humoral rejection below).

The following is a review of the numerous options for the treatment of cardiac allograft rejection, including doses recommended and associated side-effects. Comments regarding treatment of rejection in pediatric patients are combined with discussion of adult treatment. This review will not deal with strategies or agents used as prophylaxis against rejection.

TREATMENT OF ACUTE CELLULAR REJECTION

Corticosteroids

Acute cellular rejection is the most common form of cardiac allograft rejection, and corticosteroids have been the most commonly employed treatment[22]. There is, however, no uniform agreement on the amount or route of administration for this agent in the treatment of acute cellular rejection. The most common route has been intravenous, utilizing doses of 1 g of methylprednisolone per day for three consecutive days[22]. However, the dose of 3 g in 3 days is frequently suprapharmacologic, especially for patients of small body size. Heublein *et al.*[23], in fact, performed a randomized prospective/retrospective study of 512 biopsies in 128 patients, comparing the 3 g dose to a dose reduced by 50% (i.e. 0.5 g/day for 3 days) and found no increased efficacy in reversing rejection or the rate of subsequent rejection with the higher dose.

Perhaps the most reasonable approach is to individualize the dose by kilogram body weight in order to minimize unnecessary steroid side-effects in smaller patients, and provide equivalent dosing to all patients. The dose of i.v. methylprednisolone used at St Louis University Health Sciences Center for the past 5 years has been 10 mg/kg per day for 3 days. Miska *et al.*[24] have shown the feasibility and practical advantage of giving the intravenous steroids as an outpatient. While there are clear side-effects of high-dose i.v. steroids[25], especially if given too rapidly, most patients can be treated safely as outpatients.

In contrast, many centers now use oral steroids to treat all rejections not associated with hemodynamic compromise that occur more than 3 months post-transplant[26,27]. Kobashigawa *et al.*[26] performed a randomized study comparing an oral dose of 100 mg/day for 3 days (plus an oral taper over 2 weeks) to a conventional dose of 1 g/day × 3 days of intravenous methylprednisolone in 41 asymptomatic patients with grade 3A rejection. They showed no difference in rate of resolution of the biopsy (95% with i.v. vs 91% oral) at 4 weeks post-treatment, and no difference in infection. However, cost was significantly lower with oral therapy ($6.30 vs $180). Unfortunately, there are no prospective trials comparing the dosage required for treatment of rejection with oral steroids, but the most common dose reported has been 100 mg/day for 3 days[26,27].

The use of a 'taper' of the steroid dose after the bolus dose is also controversial. Lonquist *et al.*[28] showed no statistically significant difference in the incidence of rejection over the next 3 months or the number of rejections requiring additional therapy to achieve resolution in patients returned directly to pre-bolus steroid dose (no taper) versus the group that had the steroid dose tapered from 200 mg/day to 30 mg/day over 2 weeks. These data raise questions about the need for further steroid exposure by routine use of a taper over 1–4 weeks. Oral steroids have become the standard therapy for uncomplicated rejection in many programs, but generally only after the first 3 months, during which period i.v. steroids remain the more common practice.

The response rate to a course of steroids for the treatment of grade 3A rejection may be as high as 85% with one course[26,29]. Patients who fail to demonstrate an improvement on biopsy after a course of steroids generally receive a second course of steroid therapy, typically i.v., if there is no evidence of graft dysfunction. Patients who fail to improve with the first course of corticosteroids have approximately an 80% chance of improving with a second course[29]. Most programs have evolved to waiting a minimum of 7 days, and most commonly 14 days, before repeating the biopsy in patients with no evidence of hemodynamic compromise, to allow adequate time for histologic evidence of improvement in biopsy grade. Biopsies performed at <1 week may give a false impression of persisting rejection where, without further treatment, the biopsy may be substantially improved after another 7–10 days. However, patients whose grade 3A biopsy progresses to a grade 3B or greater are at higher risk of not responding to a second course of steroids[29]. In these cases consideration should be given to cytolytic therapy with agents such as OKT3, particularly if there are any signs of hemodynamic compromise and the doses of cyclosporin and azathioprine are considered to be at the maximum tolerated. The response rate with OKT3 in this setting may be as high as 80%[30].

Many programs administer prophylactic antimicrobial therapy during or following a course of rejection therapy, as a course of antirejection therapy has been shown to significantly increase the risk of infection[31]. Common strategies include Mycelex (one tab. b.i.d.) for prophylaxis against *Candida* infection, and acyclovir (400 mg t.i.d.) to prevent exacerbations of herpes simplex virus during and/or for 1 week after a course of steroid therapy for rejection. Following antirejection therapy, patients should be carefully monitored for signs or symptoms of infection, as high-dose steroids may significantly inhibit typical signs of inflammation and pyrexia.

Cyclosporine

Cyclosporine (CsA) is not typically considered an agent for the treatment of acute cellular rejection, but several investigators[32,34] have documented successful use of high-dose oral or i.v. CsA for the treatment of mild to moderate acute allograft rejection. This approach would seem counterintuitive to our understanding of T cell activation which has progressed to acute cellular rejection in terms of the ability of CsA to turn off IL-2 generation and allow clearing of rejection.

However, Kobashigawa *et al.*[33] have shown that only one of 21 patients (5%) with mild rejection who had at least a 50% increase in CsA level (169–413 ng/ml) progressed to moderate rejection. Radovancevic and Frazier[34] reported an 81% response rate in a series of 24 patients with moderate rejection treated with high-dose oral and i.v. CsA (14 mg/kg per day of oral CsA plus 1–3 mg/kg i.v.). These patients were compared to a group treated with i.v. steroids over a similar time, and no significant difference was found in resolution of rejection, but there was a significantly lower incidence of infection with the high-dose CsA. Surprisingly, there was no irreversible liver or kidney damage with use of these high doses.

FK506 (tacrolimus)

Recently, the new immunosuppressant drug FK506, now known as tacrolimus, has been investigated in cardiac transplant recipients as a primary therapy for refractory cellular rejection[35], as well as maintenance immunosuppression[36]. Despite a nearly identical mechanism of action as CsA (inhibition of IL-2 syn-

thesis), in current doses this drug has been shown to be effective in reversing rejection in patients previously receiving CsA. The dose of tacrolimus for treatment of rejection is 0.15–0.30 mg/kg per/day p.o. in two divided doses. CsA should be held for 24 h before initiating tacrolimus due to the strong overlap of mechanism and side-effects. The target level for tacrolimus by the commercial kits now available is 15–20 ng/ml. The main side-effects are neurologic and renal toxicity.

Methotrexate

The folic acid analogue, methotrexate (MTX), has been utilized for reversal of refractory[37,38] or recurrent acute cellular rejection with reasonable success[37–43], including pediatric patients[38,44]. By blocking the conversion of dihydrofolic acid to tetrafolic acid this agent inhibits purine synthesis which is essential to DNA synthesis and cell division, especially in rapidly dividing cells. MTX is an antiproliferative that affects both cellular and humoral immunity.

Reports by Costanzo-Nordin *et al.*[37] and Bourge *et al.*[39] demonstrated resolution of acute rejection in nearly 90% of patients treated with high doses of MTX (15–50 mg/week i.v. or 10–30 mg/week p.o.) over 1–3 days/week for 3–6 weeks. However, nearly half of these patients had recurrent rejection after MTX was discontinued, but again responded to a second course of the drug. Given the efficacy of a short course of MTX, but the high incidence of rebound rejection, Jennison *et al.*[44] reported safe administration in 27 patients who received the drug for an average of 16 months (range 1–43 months). There was no significantly increased risk of infection with MTX, and the incidence of rejection was significantly reduced during the period of administration (compared to the pre-MTX incidence). Currently its most common usage is in patients with persisting grade 1B or grade 2 rejection[40,43,44], particularly without hemodynamic compromise.

MTX is usually given 2 days per week, either on 2 consecutive days (e.g. Saturday and Sunday) or split (e.g. Monday and Thursday) with doses ranging from 2.5 to 7.5 mg/day based on white blood cell count. Side-effects include gastritis and neutropenia, and occasionally patients describe a fatigue syndrome which may improve by separating the dose by a number of days. Bourge *et al.*[39] noted that the risk of neutropenia with MTX correlates with: (a) the dose of MTX, (b) the WBC before starting MTX, and (c) the WBC 1 month after therapy. Protocols vary with respect to whether the dose of azathioprine is reduced or discontinued entirely during MTX therapy.

Mycophenolate mofetil

The newest immunosuppressive agent which has been used for the treatment of recurrent or persistent cardiac rejection is mycophenolate mofetil[45]. This drug is a derivative of mycophenolic acid which inhibits the *de-novo* pathway for purine synthesis of activated lymphocytes[46]. Its ability to reverse recurrent cardiac rejection was evaluated in a multicenter study of 17 patients[45]. Rejection was controlled in all 14 patients who were able to receive the drug long-term at a dose of 3 g/day p.o. The incidence of rejection decreased from 0.67 to 0.27 episodes/month ($p<0.0001$), with no increase in the incidence of infection. The major side-effects are neutropenia and gastrointestinal symptoms. This drug is designed primarily as a maintenance immunosuppressive medication, but it may be effective as therapy for acute rejection, especially in patients not currently receiving it.

Total lymphoid irradiation

Total lymphoid irradiation (TLI) has been used as a form of immunosuppression since the 1960s, but largely as prophylaxis. Salter *et al.*[47] recently reported on the use of TLI as a primary therapy for the treatment of recurrent or persisting early severe cardiac allograft rejection. This therapy was able to reverse acute rejection in 18 of 19 patients. The authors also demonstrated a highly significant reduction in the incidence of subsequent rejection, from 1.3 to 0.07 episodes/month ($p<0.0001$). The usual dose is 800 cGy in divided treatments 2 days/week for 5 weeks. The major side-effects are neutropenia, which is correlated with a lower tolerated dose of azathioprine pre-TLI, and infection. The course of treatment may require several interruptions, each for 5–7 days, if neutropenia (WBC<3000 cells/mm^3) develops. Reversal of rejection is not very rapid with TLI, and it is therefore not designed for the treatment of severe or symptomatic rejection, but may be very effective in the long-term control of recurrent or persisting rejection, even if refractory to cytolytic agents[48,49]. TLI may also be effective in pediatric patients[50].

Photochemotherapy

Recently, a new form of therapy for the treatment of acute rejection has been reported which is termed photopheresis (PH) or photochemotherapy[51–53]. This technique requires patients to receive pretreatment with a photoactivating agent, 8-methoxypsoralen, either p.o. or i.v. The patient's mononuclear cells are then pheresed and extracorporeally exposed to UV-B irradiation in a flat field, which alters the cytotoxicity of the photomodulated cells. One treatment requires 3 hours to complete, which usually involves 1×10^6 cells. The exact mechanism of this modulation is unclear. Results of a randomized prospective study of 12 patients with 16 episodes of grade 2 or 3A rejection showed PH to be as effective as oral or i.v. steroids for reversing rejection, and there was minimal or no toxicity with PH. This therapy may have more of an application for the prevention of rejection than acute treatment[54].

RESCUE THERAPY FOR ACUTE CELLULAR REJECTION

OKT3

The use of cytolytic therapy with agents such as OKT3 is generally reserved for patients with allograft rejection that is refractory to multiple courses of conventional agents, or is associated with hemodynamic compromise[30,55–58].

OKT3 is a murine monoclonal antibody directed against the CD3 receptor which is intimately linked to the T cell recognition complex[45] on the surface of most circulating lymphocytes. The binding of OKT3 to the surface receptor causes loss and/or internalization of the T cell receptor–CD3 complex, thereby

rendering the T cell incapable of recognizing foreign antigen. In addition, there is loss of usual T cell functions, such as CD4 proliferation, CD8 cytotoxicity, and B cell proliferation, essentially inhibiting the entire immune response to antigen recognition. Coating or complexing of the CD3 complex with OKT3 leads to opsonization of the $CD3^+$ cells from the circulation by the reticuloendothelial system[59]. The count of $CD3^+$ cells falls dramatically within 12–24 hours of administration (usually to <100 cells), and biopsies have also demonstrated rapid clearance of lymphocytes from the myocardium.

The standard dose is 5 mg given over 15 seconds once a day. Smaller doses (2.5 mg/day) have been found to be effective in reversing rejection[60], especially in children, and there are anecdotal reports that the CD3 count may in fact remain <100 cells with only one or two doses. Additional empiric doses of OKT3 may only increase morbidity without enhancing clinical efficacy. However, the major concern of abbreviated, interrupted, or reduced dose therapy is enhanced sensitivity to the agent (development of human anti-mouse antibodies) or further immune activation[59–62].

The binding of the OKT3 to the surface receptor triggers a release of cytokines (particularly TNF and IFN-gamma) and, potentially, prostaglandins, which result in a clinical entity called cytokine release syndrome[63–65]. This syndrome, which may be manifest by fever, chills or even rigors, vasodilatation, hypotension, and a capillary leak syndrome with a pulmonary edema picture, particularly if the patient is volume-overloaded, can be avoided by pretreatment with a combination of 1 g of intravenous methylprednisolone, acetaminophen (650 mg p.o.), diphenhydramine (50 mg p.o.), and a dose of a non-steroidal anti-inflammatory agent such as indomethacin (50–75 mg p.o.) 60 minutes *prior* to giving the first dose of OKT3. This pretreatment should be continued for at least the first 3 days, although the dose of steroids can be reduced to 500–750 mg on day 2, and 250–500 mg on day 3. The steroid dose should then be converted to a dose of 0.3 mg/kg/per day p.o. from day 4 to completion of the course of OKT3, when the dose is again increased to 1 mg/kg/per day and tapered by 5 mg/day to the usual level at the time post-transplant. This post-OKT3 steroid bolus and taper are to prevent 'rebound' rejection with cessation of OKT3. Other side-effects include: (a) secondary infection, especially CMV, pneumocystis, and other opportunistic infections; (b) aseptic meningitis; and (c) seizures.

The overall success of OKT3 therapy to reverse allograft rejection varies from 70% to 95%[55–58]. Lower success[66] seems to be related to lack of the use of a pulse and taper of oral steroids at the completion of the 7–10-day course of OKT3, to prevent the rebound rejection which may occur due in part to the inherent property of OKT3 to activate the immune system[62]. This drug may allow substantial improvement in hemodynamic function within 1–2 days of initiating therapy.

Therapy with OKT3 is monitored by either serum levels of OKT3 or counts of $CD3^+$ cells[67]. Levels should be >800 ng/ml and CD3 counts should drop <100 cells with effective therapy. Prior use of this agent, such as perioperative 'induction' therapy to prevent rejection, may result in development of human anti-mouse antibodies (HAMA) which can inactivate OKT3 and reduce the response to treatment of rejection[57,61]. These antibodies can be screened for: (a) prior to initiating a second course or (b) in patients whose OKT3 levels fall, or CD3 counts rise, during therapy. Demonstration of rising CD3 counts during therapy requires use of an alternative therapy.

Antithymocyte globulin

The first cytolytic agent used for rejection rescue therapy was the polyclonal preparation antithymocyte globulin (ATG). This is currently used more for prophylaxis than rescue therapy. This agent is made by injecting human thymocytes into the animal host (a horse or rabbit), and then harvesting, pooling, and purifying the host plasma, which is rich in antithymocyte immunoglobulin. Side-effects of ATG include pyrexia and even serum sickness reaction, variable efficacy between lots, and contamination with other immunoglobulins (such as antiplatelet antibodies)[68]. Numerous studies have compared the efficacy of ATG and OKT3[69–73], but primarily as prophylactic (induction) therapy. The dose of ATG for rescue therapy is usually 10–15 mg/kg/per day i.v. or i.m. (in one or divided doses) for 7–10 days, with smaller doses used in pediatric patients[69]. Pretreatment with steroids, acetaminophen, diphenhydramine, and non-steroid anti-inflammatory agents (see above *re* OKT3) is recommended. Blood level details are not available.

TREATMENT OF HUMORAL (VASCULAR) REJECTION

The role of the humoral immune system in cardiac allograft rejection has been recognized only recently[21,74–76]. This type of rejection is relatively uncommon, but may be the cause of much of the acute hemodynamic compromise that may occur with cellular rejection. It is very uncommon for vascular rejection to occur alone (i.e. without evidence of cellular rejection) with the exception of hyperacute rejection, which usually presents in the operating room at the time of transplant and is due to circulating antibodies against one or more antigens on the donor endothelium. The treatment of hyperacute rejection is discussed below.

The graft dysfunction that may occur with humoral rejection is largely a result of thrombosis and/or vasospasm of the coronary arteries due to an antibody-mediated arteritis. Vascular rejection usually occurs within the first month post-transplant and should be anticipated in patients with a positive donor-specific cross-match[76]. The diagnosis is confirmed by histologic evidence of arteritis on routine endomyocardial biopsy and immunofluorescent staining of immunoglobulin deposition on the coronary endothelium[74]. The immunoglobulin(s) or antibody is (are) directed against foreign donor antigens located on the surface of the coronary arteries[77,78].

The treatment of this form of rejection is focused on: (a) removing circulating antibody and (b) suppressing new antibody formation. The recommendations that follow are based on clinical experience in a number of centers, but there are no prospective studies comparing various forms of therapy in heart transplant recipients.

The most rapid and effective therapy for humoral rejection is plasmapheresis[76,79–81]. This requires placement of a percutaneous,

dialysis-type central venous catheter to allow pheresis and exchange of the patient's plasma. The patient's weight is used to calculate the total plasma volume, and a single plamsa volume exchange is performed. The replacement fluid is usually a mix of 50% type-specific fresh-frozen plasma and 50% albumin. The exchange requires approximately 3 hours to perform, but rarely results in hypotension or any hemodynamic deterioration. Ionized calcium is monitored and replaced as needed. Due to the documented alteration in local plasminogen activators and significant coronary endothelial inflammation, patients are usually placed on full heparinization to minimize coronary thrombosis. This procedure should be repeated daily for a minimum of 3 days and can be done for 5–7 days or until the circulating antibodies (usually multiple) are reduced to very low titer, as demonstrated by repeated donor-specific crossmatch or panel-reactive antibody (PRA) assay. This therapy may be lifesaving, has very little associated morbidity and should be initiated as soon as possible when this diagnosis is confirmed.

A second alternative method for removing circulating antibody is with use of an immunoadsorption column (protein A column, Prosorba, IMRE Corp.). As with plasmapheresis, plasma is pheresed from the patient, but is then passed over the column which is covered with immunoglobulin that absorbs the circulating antibodies from the plasma, which is then reinfused to the patient. Olivari *et al.*[82] reported successful reversal of acute vascular rejection in three patients with significant hemodynamic compromise that was unresponsive to high-dose i.v. steroids and cyclophosphamide. After several courses of immunoadsorption the left ventricular ejection fraction improved from 23% to 56%. The PRA titer fell to <5%. The patients had no further vascular rejection. There are no data comparing the efficacy of the two forms of antibody removal.

The second goal of treating vascular rejection is to suppress antibody production. A combination of lympholytic agents is typically used, including high-dose i.v. methylprednisolone (1–1.5 g/day × 3–4 days), and substitution of cyclophosphamide[79] for azathioprine. The dose of cyclophosphamide ranges from 1 mg/kg per/day to 1000 mg/day, and several centers have noted improved efficacy with the higher dose for the first several days. Finally, most centers also use OKT3 to help resolve any component of cellular rejection and help turn off B cell proliferation[79–83]. There are a few anecdotal reports of additional improvement with conversion from CsA to FK506. Antimicrobial prophylaxis, as described above, is also recommended during and after this aggressive therapy.

The prognosis with vascular rejection (especially the hyperacute form) is worse than with cellular rejection.

COMMENT

There are new monoclonal antibodies directed against a variety of cytokines and surface receptors, and other agents such as rapamycin and leflunomide, that may offer improved or additional strategies to manage acute cellular and/or vascular rejection in the future. Progress is still needed to help manage an entity which continues to be one of the leading causes of death in heart transplantation.

32
Infection in Relation to Thoracic Transplantation

K. LOVE

INTRODUCTION

Although the advent of focused and therefore superior immunosuppressive regimens has greatly decreased the incidence of infection in the thoracic transplant recipient, infection remains the leading cause of death in many centers[1–5]. Infection is acquired exogenously through usual nosocomial and community modes of transmission, and through transfusion, or is donor-transmitted. It can also result from endogenous reactivation of latent organisms within the recipient (Table 1).

Table 1 Organisms causing infections after thoracic organ transplantation

Bacteria	
Community-acquired bacteria	Various infections
Nosocomial bacteria	Nosocomial infections
Donor trachea flora*	Anastomotic infection in LTR
Legionella species	Pneumonia
Listeria	Meningoencephalitis
*Mycobacteria**†	Pulmonary/extrapulmonary disease
Mycoplasma hominis	Sternal wound infection
Nocardia species	Pulmonary/extrapulmonary disease
Rhodococcus equi	Pneumonia
Miscellaneous unusual	*Bartonella* (*Rochalimea*)
Fungi	
Candida species	Mucocutaneous candidiasis Mediastinitis, sternal infection
*Cryptococcus neoformans**†	Meningitis, extraneural disease
*Coccidioides immitis**†	Meningitis, extraneural disease
*Histoplasma capsulatum**†	Pulmonary, disseminated disease
Viruses	
Herpes simplex 1, 2†	Mucocutaneous vesicles
Varicella-zoster†	Chickenpox, shingles
Epstein–Barr virus*†	Lymphoproliferative disorders
Cytomegalovirus*†	CMV syndrome, enteritis, pneumonitis
Human herpesvirus 6†	? lymphoma, ? other
Hepatitis B, C*†	Liver disease, hepatoma
Retroviruses*†	AIDS, leukemia, lymphoma, paraparesis
Polyomaviruses†	JC Virus progressive multifocal leukoencephalopathy
Papillomaviruses*†	Warts, ? malignancy
Respiratory viruses	Respiratory syncytial virus, adenovirus, parainfluenza virus, influenza A, B
Parasites	
Pneumocystis carinii†	Pneumonia
*Toxoplasma gondii**	Myocarditis, encephalitis, pneumonia
*Trypanosoma cruzi**†	Myocarditis, disseminated disease
Strongyloides stercoralis†	Disseminated disease
Cryptosporidium	Diarrhea

* Potentially donor-transmitted.
† Reactivated latent infection in the SPR.
All infections can be exogenously acquired.
LTR = lung transplant recipients; JC = Jacob Creutzfeldt virus.

The type of infecting organism and severity of disease produced is determined by factors such as the age of the patient, the intensity and duration of immunosuppression, pre-existing diseases such as bronchiectasis, timing after transplant (Table 2), and whether disease is due to primary infection or reinfection with a donor strain, or reactivation of latent infection in the recipient.

The net state of immunosuppression

Rubin has aptly pointed out that it is the 'net state of immunosuppression' that determines the risk of infectious disease in the transplant recipient[6]. This concept takes into account the duration of immunosuppression and the contribution from immunomodulating viruses such as cytomegalovirus (CMV), Epstein–Barr virus (EBV), hepatitis viruses, and retroviruses. The intensity of pharmacological immunosuppression, especially the contribution from corticosteroids, is greatest during the first 3–6 months after transplant and after treatment for rejection. These are the periods in which most acute infections are seen.

Timing of infection after transplantation

First month

In the first month after transplant, nosocomial bacterial and fungal infections (pneumonia, intravascular device-related sepsis, urinary tract infection, wound infection, and *Candida difficile* diarrhea) predominate and are directly related to breeches of integumentary and mucosal integrity by invasive devices and wounds, as in any other ICU patient. Handwashing with an antibacterial soap and other fundamental infection control measures are indicated. There is no literature to support the use of barriers, such as masks and gowns that were a part of traditional 'protective isolation'. This has been studied in both the neutropenic[7,8] and the transplant patient[9]. Special air handling and procedures designed to minimize exposure to fungal spores are warranted (refer to the section on *Aspergillus*). Herpes simplex virus reactivation occurs in this time frame as well but, with the widespread use of acyclovir prophylaxis, is either delayed or suppressed.

Sternal wound infection and mediastinitis are particular problems early after thoracic transplantation; unusual causative organ-

Table 2 Timing of infection after transplant by type of disease

Site/type of disease	*Early (within 3 months)*	*Late (after 3 months)*
Pneumonia	Nosocomial pathogens Cytomegalovirus (CMV) *Legionella* *Aspergillus* *Toxoplasma gondii*	*Pneumocystis carinii* *Nocardia asteroides* CMV Community-acquired bacterial, viral, fungal pneumonia
Sternal and mediastinal infection, empyema	Staphylococci, GNB Donor trachea flora *Candida* *Mycoplasma* Mycobacteria	
Myocarditis	*Toxoplasma gondii* CMV *Trypanosoma cruzi*	
Central nervous system	*Aspergillus* *Toxoplasma gondii*	*Listeria monocytogenes* *Cryptococcus neoformans* *Nocardia asteroides* *Toxoplasma gondii* PML
Gastrointestinal tract	CMV, HSV esophagitis CMV enteritis Hepatitis *Strongyloides*	CMV enteritis Cholecystitis *Strongyloides*
Mucocutaneous	*Candida* species HSV Disseminated fungal infection Disseminated mycobacteriosis	*Candida* VZV Disseminated fungal infection
Malignancy	EBV-LPS	EBV-LPS Accelerated course of solid tumors. Hepatoma. Cervical cancer (? papillomavirus) EBV or retrovirus associated T-cell
Mononucleosis syndrome	CMV EBV HBV, HCV Retroviruses *Toxoplasma gondii*	EBV Community acquired virus

Disseminated infection can occur with most of these organisms

isms such as *Candida* species and mycoplasma have been reported[10]. At the Minneapolis Heart Institute the overall deep sternal wound infection/mediastinitis rate in 189 thoracic transplant-related sternotomies as of December 1994 was 3.2%, representing 4/177 (2.3%) heart transplant recipients, 1/6 heart–lung and 1/6 double lung transplant recipients, respectively. Literature rates with which to compare are not readily available. Usual perioperative antibiotic prophylaxis regimens are used (Tables 3 and 4).

In the lung transplant recipient, mediastinitis and pleural space infection can also result from contamination of the bronchial anastomosis by recipient and donor trachea flora, and can be prevented by pre-emptively treating the recipient with antibiotics directed against organisms grown in tracheal cultures, and monitoring and treating organisms cultured from chest tubes.

Despite the multiple suture lines involved and the immunosuppression, there are only two cases of endocarditis reported in heart transplant recipients[11,12], one at day 8 and the other at 7 months after transplant. Given the usual time to endothelialization of these anastomoses, it seems logical to provide antibacterial prophylaxis for dental, genito-urinary and gastro-intestinal

Table 3 Prophylaxis and prevention of infection

Organism/infection	*Prevention/prophylaxis*
Sternal wound infection/mediastinitis	Perioperative prophylaxis with cephalosporin or vancomycin to PCN allergic patients
Mediastinitis/anastomotic infection in LTR	Perioperative prophylaxis with Imipenem or Clindamycin/Aztreonam for PCN allergic patients, pre-emptive treatment of donor trachea isolates post-transplant
Legionella species	Water treatment for control of nosocomial transmission
Listeria monocytogenes	Recommendations in the text, TMP–SMZ prophylaxis
Mycobacteria	Testing and treatment for TB pretransplant Avoid exposure to aquaria (*M. marinum*)
Nocardia species	TMP-SMZ prophylaxis
Candida species	Clotrimazole troches or mycostatin S&S q.i.d. × 1 month Fluconazole 200–400 mg/day × 14 days for + donor trachea culture Daily ingestion of 8 oz of *L. acidophilus* + yogurt for females with recurrent vaginitis
Aspergillus	See Table 4
Herpes simplex 1, 2	Acyclovir 400 mg b.i.d.–t.i.d. for frequent recurrences
Varicella–zoster	Active immunization of SNR Post-exposure VZIG for exposed susceptibles
Cytomegalovirus	CMV-negative blood products, high dose p.o. ACV or GCV ± CMVIG for SNR of SPD and SPR × 3 months
Epstein–Barr virus	Optimal immunosuppression. ? ACV or GCV, CMVIG
Hepatitis B	HBV vaccine + hepatitis immune globulin (HBIG)
HIV	AZT as soon as possible
Pneumocystis carinii	TMP–SMZ × 1 year
Toxoplasma gondii	TMP–SMZ or pyrimethamine 25 mg/day × 6 weeks for mismatch
Trypanosoma cruzi	Benznidazole or nifurtimox probably indefinitely
Strongyloides stercoralis	Thiabendazole

SNR = seronegative recipient; VZIG = varicella zoster immune globulin; PCN = penicillin.
LTR = lung transplant recipient

Table 4 *Aspergillus* precautions

The patient is in a private room with positive ventilation and at least 10 air exchanges per hour.
At least 90% of particles over 0.5 μm in size are filtered from air entering the room.
Not allowed: plush toys, balloons, pepper for food, artificial or real flowers or plants.
All horizontal and other surfaces capable of gathering dust are damp-cleaned daily.
The patient wears an 8710 dust–mist respirator mask (3M) when out of the room and for 30 minutes after cleaning of the room.
All construction projects are reviewed in advance by the Infection Control Department and suitable barriers and removal systems implemented; some projects are postponed until there are no transplant patients in the area.
These precautions are in effect until the prednisone dose is down to 30 mg/day or, if the patient is discharged before that target is reached, wearing of the mask is encouraged for coming to the hospital because of constant renovation, and on windy days and being near excavation or construction sites for 3 months post-transplant.

procedures for only 3 months after transplant. The American Heart Association recommendations for antibiotic prophylaxis to prevent infective endocarditis are appropriate for this indication[13].

One to six months

In the 1–6 months after transplantation, cytomegalovirus is far and away the most common and important of the immunomodulating viruses which become active during this period and pave the way for other opportunists such as *Aspergillus*, *Nocardia*, *Pneumocystis*, and *Listeria*.

After six months

According to Rubin[6], after 6 months 75% of patients are doing well, and 10% have chronic infection with immunomodulating viruses, which eventually leads to destruction of the infected organ or to malignancy. Fifteen percent have poor allograft function due to both acute and chronic rejection, and have received repeated and prolonged intensive immunosuppression, complicated by chronic viral infection, making them prone to opportunistic infection with *Listeria*, *Cryptococcus*, *Pneumocystis*, and *Nocardia*. Varicella–zoster reactivation is also a late infection.

Primary infection, reinfection, reactivation

Primary infections occur with varying frequency in previously uninfected persons who receive the blood or organ of a previously infected donor, and tend to cause disease more often and with greater severity than reinfection or reactivation. Primary infections are usually diagnosed as such by serological testing, whereby the seronegative recipient (SNR) becomes seropositive after exposure to the seropositive donor (SPD). Primary infections are more common in pediatric transplantation.

Reinfection can occur in the seropositive recipient (SPR) who acquires a donor strain of an organism with the donated organ or transfusion that is different from the recipient strain. Disease following reinfection is usually less severe than that following primary infection. Molecular techniques are required to prove reinfection.

Endogenous reactivation of a SPR's latent organisms, such as herpesviruses, causes milder disease or none at all.

SPECIFIC INFECTIONS

Where cell-mediated immunity is impaired, infections with organisms which are engulfed but not killed by leukocytes ('intracellular parasites') may either occur more frequently or, though not more common in the immunocompromised host, be particularly invasive, disseminated, and severe ('hyperinfection').

BACTERIAL INFECTION

Legionella

Legionella is a Gram-negative rod aerosolized in a variety of hot and cold water sources, including evaporative condensers and cooling towers[14–18], showers[19], whirlpool spas[20], respiratory therapy equipment[21], and grocery store mist machines[22]. Microaspiration of contaminated water via nasogastric tubes has also been implicated in some outbreaks. *Legionella* has been found in 1–30% of home water heaters, especially electric units.

Legionella species cause <1–5% of cases of pneumonia in adults, but there is a marked geographic variation in the incidence[23,24]. In a 1988 survey of 28 centers with 2274 heart transplants, representing 73% of the cardiac transplants done in the USA as of 1986, the incidence of legionellosis was 2% (0–>5%)[23].

The 'classic' syndrome consists of lobar pneumonia with nonproductive cough, pulse–temperature dissociation, rigors, diarrhea, myalgia, confusion, abnormal liver function tests, hyponatremia and hypomagnesemia, but this presentation represents only a small subset of patients with the disease. Prospective studies have shown that the usual case consists of non-specific clinical, roentgenological, and laboratory manifestations of lower respiratory tract infection[24,25]. Rarely, *Legionella* can cause extrapulmonary infection[26,27].

The diagnosis is confirmed by culture of sputum, blood, or other clinical material; unfortunately, many otherwise sophisticated laboratories are not able to culture *Legionella* as they do not routinely use the selective media and techniques required. It is therefore necessary to obtain cultures before institution of antimicrobial therapy, and to alert the laboratory to the possibility of the diagnosis.

Antigenuria can be assayed with a very quick and sensitive commercially available radioimmunoassay that detects only *L. pneumophila* serogroup 1, but as 70–90% of all cases of Legionnaire's disease are probably caused by this serotype, it is still a useful test. In many laboratories it has replaced direct fluorescent antibody (DFA) testing of clinical specimens, which is technically difficult and suffers from a lack of specificity and sensitivity. DNA probe methods are about as accurate as DFA tests, are easier to perform, and detect all species of *Legionella*; however, they have no practical advantages over the antigenuria test. Polymerase chain reaction techniques hold great promise, but more experience is needed.

Serology is widely used for diagnosis, but the specificity of seroconversion may be unreliable for species other than *L. pneumophilia* serogroup 1, and false-positives occur due to cross-reactivity with other organisms, such as *Escherichia coli*. Also, seroconversion may take as long as 9 weeks.

In-vitro sensitivity testing is not relevant, as activity of an antibiotic against *Legionella* depends on its ability to enter the infected cell. In the past the preferred treatment was with erythromycin 1 g intravenously every 6 hours with rifampicin added for severe cases. Both of these drugs have major interactions with cyclosporin (CsA) which can result in renal failure. For this reason (and because in *in-vitro* models the new macrolides, azithromycin and clarithromycin, are much more active) these, and the fluoroquinolones, ciprofloxacin and pefloxacin, are probably the drugs of choice. They, too, have some interaction with CsA, but it is not so pronounced as with erythromycin, and careful monitoring of CsA levels will avoid toxicity. With the exception of azithromycin, which is given in a dose of 500 mg on day 1, followed by 4 days of 250 mg/day, antibiotic therapy should be given for 3 weeks.

Though conventional wisdom dictates that imipenem–cilastatin should not be effective, we have had good experience with three cases of culture-proven *Legionella* pneumonia treated empirically with this drug before the diagnosis was confirmed; after initial improvement these patients were sent home on oral ciprofloxacin, with complete resolution.

Prevention of infection with *Legionella* consists of monitoring water sources in areas where it is a prevalent pathogen in the transplant population; superheating water to 55–60°C is required to eradicate it. Sterile water should be used to irrigate nasogastric tubes, and for any respiratory therapy activities such as washing nebulizers, tubing or humidifiers, unless this equipment is to undergo subsequent sterilization. Samples from home water heaters could be cultured and, if positive, the transplant recipient could be advised either to replace an electric heater with a gas-fired one or to increase the temperature of the water heater, taking care to avoid scalding injuries.

Listeria

Listeria monocytogenes is a Gram-positive bacillus found in dairy products, raw vegetables, and undercooked meat and poultry[28], which colonizes the gastrointestinal tract in 5–10% of people and causes systemic infection in an estimated 7.0 per million population in the USA per year[29].

In a recent review of 74 Finnish cases, between 1971 and 1989, Skogberg *et al.* found that around 50% of all patients had primary bacteremia[30]. In an exhaustive analysis of 178 cases in the English literature between 1968 and 1978, Nieman and Lorber[31] recorded primary bacteremia in ~25% of patients. Acute, or rarely subacute or chronic[32] meningitis or meningoencephalitis occurred in 55% and encephalitis without meningitis in another 6.5%. Other sites of infection were described in 12 patients, and 14 patients were diagnosed as having endocarditis. Prominent CNS features consisted of nuchal rigidity (85% of meningitic cases), ataxia, tremors, seizures, and fluctuating consciousness, with positive blood cultures in 75% of cases. The cerebrospinal fluid profile was variable; the average leukocyte count was >1000 with 66% polymorphonuclear cells and counts did not correlate with outcome. The glucose was normal to depressed (average 60 mg/dl) and low levels (<40 mg/dl) seemed to predict a poor prognosis. The average protein level was around 200 mg/dl and values >300 mg/dl also appeared to portend a poor result. The Gram stain was positive in ~40%, and was misleading in some cases, as has been previously described by Buchner and Schneierson[33], because the organism is often mistaken for a diphtheroid contaminant or a streptococcus. Over-decolorization of the Gram stain can lead to the erroneous identification of Gram-negative bacilli. It is therefore necessary to have a high clinical suspicion for this organism in patients with compromised cellular immunity, including alcoholics, pregnant females, and neonates.

On CT scanning, localized abscesses of cortex, spinal cord or brainstem, and hydrocephalus can be seen, and generalized encephalitis may be diagnosed on biopsy or at autopsy.

Treatment of choice consists of ampicillin 2 g every 4 hours i.v., or penicillin G 3–4 million units every 4 hours i.v., with or without an aminoglycoside, for 14–21 days. Cephalosporins are ineffective. Patients with a history of life-threatening penicillin reactions can be treated with trimethoprim-sulfamethoxazole, 10–15 mg/kg every 8 hours, i.v. or p.o.[34,35] or, if also intolerant of sulfonamides, desensitized to penicillin and then treated as above[36]. Vancomycin is an alternative, but CSF levels should be monitored, as the drug has variable blood–brain barrier penetration.

Efforts at prevention should focus on educating transplant recipients as to avoidance of high-risk foods. Schuchat *et al.*[37] make the following dietary recommendations for persons immunocompromised by disease or medication, pregnant women, and the elderly (adapted):

(1) Avoid eating raw or partially cooked foods of animal origin.
(2) Avoid cross-contamination between raw and cooked foods during food preparation and storage.
(3) Reheat leftovers until too hot to touch.
(4) Avoid soft cheeses such as feta and Mexican-style cheeses; eat hard cheeses, cottage cheese, and cream cheese.
(5) Wash raw vegetables thoroughly before eating.

Trimethoprim-sulfamethoxazole is used as prophylaxis against *Pneumocystis* in most transplant programs today. It is likely that this drug also offers protection against *Listeria*.

Mycobacteria

As of 1993, only nine cases of mycobacteriosis complicating lung transplantation had been reported[38–42,49]. At least seven articles report on experience in heart transplant recipients[43–49]. Tuberculosis (TB) can be donor-transmitted, reactivated in the previously infected recipient, or acquired through exposure to persons with pulmonary TB. Non-TB mycobacteria are acquired from environmental sources, such as soil and water, and are not transmitted between humans.

In a world-wide literature review of renal transplant recipients before 1983, only 47 mycobacterial infections (23 cases of tuberculosis) were identified[50]. The overall incidence in western countries is between 0.3% and 2.3%, but up to 9.5% in high-prevalence areas[50–53].

Mycobacterium tuberculosis

With the recent resurgence of tuberculosis (TB) in North America, it seems likely that the incidence of this disease, and of drug resistance, will increase in transplant recipients. Most of the clinical experience has been with renal transplant recipients in whom the full gamut of pulmonary, extrapulmonary, and disseminated disease has been seen; the only exceptional feature seems to be a propensity for bone and joint involvement[54].

Diagnosis is made by isolating *Mycobacterium tuberculosis* from clinical material, but as the sensitivity is variable depending on the source, it is important to look for acid-fast bacilli on special stains and for granulomata on histology. With the advent of newer methodologies, mycobacteria will grow within 10–14 days and *M. tuberculosis* can be identified promptly by DNA probe.

There are no definitive studies on the optimal treatment of TB in the transplant recipient. Rubin[6] advocates a 12-month course of treatment with isoniazid (INH) and rifampicin (RFM) or pyrazinamide (PZA), which would suffice for patients with a low likelihood of having INH-resistant, or multidrug-resistant TB (MDRTB, resistant to at least INH and rifampicin), later confirmed

with sensitivities. This approach may minimize the toxicity of short-course regimens which require initial treatment with INH, RFM, and PZA for 2 months, followed by 4 months of INH and RFM. Both INH and RFM induce hepatic microsomal enzymes which increase steroid catabolism. RFM, and possibly also INH, competes with CsA for the cytochrome P450 enzyme system, thus decreasing CsA levels. Rejection has been reported in this circumstance[38,55–59] as even massive increases in doses of CsA may not overcome the RFM effect.

However, the short-term regimens are attractive because of their duration, and it may seem reasonable to try them. If RFM cannot be used, the patient should receive 12 months of INH and PZA[6] or 18 months of INH and ethambutol (EMB).

In communities or areas of the world where there is >4% primary resistance to INH, EMB or streptomycin (SM) must be added to the initial regimen, pending results of sensitivity tests. If the organism turns out to be resistant to INH, this drug should be discontinued and 6 months of therapy should be completed with RFM, PZA, and EMB or SM, or 12 months of RFM and EMB. Where MDRTB is prevalent, or where the patient with active TB has been exposed to someone with MDRTB, therapy with five or six antituberculous drugs must be initiated, and when sensitivities are available, at least three new drugs to which the organism is susceptible should be started. This polypharmacy must be continued until culture conversion occurs, after which 12–24 months of two-drug therapy is indicated. Pyridoxine should be given to prevent INH-induced peripheral neuropathy in this high-risk population. Other aspects of treatment and management are extensively covered in the Center for Disease Control's Core Curriculum on Tuberculosis[60].

The issue of whether or not to give Mantoux-positive transplant candidates INH chemoprophylaxis before transplant is controversial. The official recommendations of the Centers for Disease Control (CDC) state that, assuming active TB has been ruled out, tuberculin-positive persons on, or about to go on, prolonged therapy with immunosuppressive medications receive INH prophylaxis, preferably for 12 months, though 6–9 months' treatment is often used[61].

Rubin[6] maintains that prophylaxis should be reserved for Mantoux-positive transplant candidates who have other risk factors such as: (a) recent tuberculin conversion, (b) Asian, African, or Native American heritage, (c) other immunosuppressing conditions, (d) a history of inadequately treated active TB, and/or (e) significant abnormalities on chest radiograph. This is based on the fact that TB reactivated in only one of 73 Mantoux-positive renal transplant recipients, none of whom received pretransplant INH prophylaxis, and that patient was easily treated. This approach seems logical in low-prevalence areas of the world, though geographic risk also should include Mexico, Central and South America, Mediterranean countries, and central and eastern Europe. As the risk of INH hepatitis may be higher than the risk of TB in transplant recipients[62,63], every effort should be made to complete the prophylaxis before transplantation.

Non-TB mycobacteria

In a review of 17 years' experience with heart transplant patients, the Stanford program[49] reported on 14 patients with atypical mycobacterial disease, 11/200 maintained on azathioprine and prednisone and 3/302 on CsA-containing regimens ($p = 0.004$), who presented at 86 days to 11.5 years after transplant. Twelve patients had lung and/or skin involvement, and two developed lesions at the site of prosthetic devices, with *M. kansasii* in six patients, *M. avium-intracellulare* (MAI) in five, and *M. fortuitum* and *M. thermoresistibile* in one each. The fourteenth isolate was an unidentified Runyan group II scotochromagen. In recent years MAI has become the most common isolate. A fifteenth patient, with mycobacterial coronary arteritis, was reported elsewhere[48]. Other reports describe pulmonary and/or skin infections with *M. chelonae*[41] and *M. scrofulaceum*[44].

Treatment of these infections is variable, depending on sensitivities[64].

Nocardia

Nocardia is a partially acid-fast filamentous bacillus; the species *N. asteroides* and *N. brasiliensis* most commonly cause disease, usually late after transplant[65–67]. Transplant recipients accounted for 13% of the 500–1000 cases reported annually in one report from 1976[68]. The reported incidence among renal transplant recipients varies from 0% to 20%[66,69,70] and in one older study of heart transplant recipients was 21%[67]. The incidence has decreased in the CsA era independently of the use of routine trimethoprim-sulfamethoxazole prophylaxis for *Pneumocystis carinii* pneumonia (PCP)[66], though this might be as expected, as many cases of nocardiosis occur after prophylaxis has been discontinued.

Though some patients can present with dry cough and fever, pulmonary nocardiosis in transplant recipients is often asymptomatic and detected only on incidental chest X-rays showing single or multiple nodules with or without cavitation. Diffuse pulmonary infiltrates can also occur. Dissemination from the lung produces abscesses in skin, brain, and other tissue[71]. Primary skin inoculation can also occur[64].

Sulfonamides, either alone or in combination with trimethoprim, are the drugs of choice for treatment of nocardial infections[72]. For the allergic or intolerant patient, amoxicillin with or without clavulanate, and minocycline are good oral alternatives for susceptible strains[73]. Where parenteral therapy is indicated, imipenem–cilastatin, ceftriaxone, cefotaxime, and amikacin are effective[73–75]. Because of the propensity for secondary CNS involvement, CT or MRI scans should be done in any case of nocardiosis before starting therapy, as a positive result has several implications for management:

(1) The duration of therapy should be extended from 6 months to 12 months.
(2) Brain abscesses, which are large and accessible or do not respond to, or progress in spite of, medical therapy, should be evacuated.
(3) CNS lesions may develop on therapy without adversely affecting the prognosis or dictating a change in antibiotics, therefore it is useful to have baseline CT scan[76].

Miscellaneous bacterial infections

Rhodococcus equi

The first case of infection in a heart transplant recipient has been reported[77]. This aerobic, Gram-positive, weakly acid-fast cocco-

bacillus is a soil actinomycete which causes pleural-based, cavitating pulmonary nodules or, less often, lobar pneumonia, in immunosuppressed hosts. Half of the patients not infected with the human immune deficiency virus have a history of exposure to horses, swine, or cows or their products[78,79]. Fever, cough, with or without hemoptysis, dyspnea, pleuritic pain, and wasting come on insidiously in days to months. Recommended treatment includes up to 6 months of at least two lipophilic bactericidal antibiotics, the choice based on sensitivity testing. Vancomycin is widely used, with a quinolone or amoxicillin–clavulanate, or a macrolide.

Treponema pallidum

Reports of syphilis in modern transplantation literature are rare[80]. Clinical manifestations of this disease are extremely variable and diagnosis can be difficult. Testing of donors for syphilis is routine, but there is no consistent practice for recipient candidates. Storing pretransplant recipient serum for future testing can be very useful in making this and other obscure diagnoses, and it is more cost-effective than obtaining all possible serologies. Many cases of latent syphilis may well be treated by virtue of the frequent contact most people, especially transplant recipients, have with antibiotics. Donor seropositivity need not be a contraindication to transplantation, as good results have been obtained with antibiotic prophylaxis[81].

FUNGAL INFECTION

In a recent review by Paya[82], the incidence of fungal infection in the CsA era is cited as 0–21% for heart transplants[83–85] with *Aspergillus* predominating[84,86] and 15–35% for heart–lung and lung transplants[87,88], with *Candida* as the most common fungal pathogen[85,87,88]. Infections usually occur early after transplantation, with a median of 23 days for *Aspergillus* and 44 days for *Candida*[84], and a resultant mortality of between 40% and 70% for heart–lung and lung transplant recipients[85,87,88] and an almost universally fatal outcome for heart transplant recipients with aspergillosis despite amphotericin B treatment[84,89], though other reviews quote a better survival rate for isolated pulmonary aspergillosis (see below).

Several factors may contribute to the high mortality of these infections: (a) difficulty in making an early diagnosis and unavailability of reliable non-invasive tests such as serology[90]; (b) lack of effective therapy for *Aspergillus*, (c) toxicity of amphotericin B and the interaction of antifungal drugs with CsA, making treatment an ordeal, and (d) limited data on the efficacy of available antifungal prophylaxis[81].

Candida

Conditions which facilitate *Candida* colonization of the skin and gastrointestinal tract, such as antibiotics, intravascular and urinary catheters, malnutrition, and breaches of mucosal integrity, conspire with impaired neutrophil and macrophage number and function to establish *Candida* as an invasive pathogen. Suppressed cell-mediated immunity tends to be complicated by the mucocutaneous forms of the disease.

Candidiasis is usually caused by *C. albicans* and can be classified as mucocutaneous (thrush, vaginal candidiasis, intertrigo, and esophagitis), urinary, invasive (sternal osteomyelitis, localized abscesses) and disseminated (candidemia with or without organ involvement, endophthalmitis). Dissemination, with the potential for visceral involvement, results from transient candidemia in >50% of immunosuppressed patients as compared with 5% in immunocompetent hosts[91]. Pulmonary involvement is rare, and then occurs only in the context of disseminated disease. Culture of *Candida* from multiple sites usually accompanies disseminated disease, but is not specific for it.

Unique to thoracic transplantation is mediastinal abscess complicating dehiscence of the infected bronchial anastomosis[88] and fatal rupture of mycotic aneurysms of the aortic anastomosis[91–93]. These latter two disasters can be prevented by pre-emptively treating recipient and/or donor trachea cultures positive for *Candida* with fluconazole; there are no data as to the appropriate duration.

Until further data are available, invasive and disseminated disease in this population should be treated with amphotericin, not fluconazole, though after an initial course of 300–500 mg as 'induction therapy', the responding patient can receive 'consolidation therapy' with fluconazole if the organism is not *C. krusei* or *C. glabrata*, as these species cannot be assumed to be sensitive to fluconazole. Candidal sternal wound infections must be aggressively debrided and treated with amphotericin. Fluconazole does not achieve good levels in bone[94]. Candiduria can be treated with daily or continuous amphotericin bladder instillations or fluconazole, but none of these works if the catheter is not removed. Fluconazole is effective treatment for esophagitis and for other forms of mucocutaneous candidiasis that are not responding to topical antifungals, such as clotrimazole troches.

Increasing resistance is a concern; *C. glabrata* develops resistance on therapy and *C. krusei* is minimally susceptible[95,96]. Itraconazole is often effective in this circumstance. Antifungal therapy is discussed in more detail below.

Prophylaxis with topical antifungals has produced inconsistent results in other populations[97] but is standard in most transplant programs; 1–3 months seems long enough. While a limited number of studies suggest that fluconazole prevents both colonization and disease in neutropenic bone marrow transplant recipients and leukemics[98,99], routine prophylaxis in thoracic transplant recipients would be expensive, and carries the potential to induce more resistance and to increase the incidence of infection with *C. krusei* and *C. glabrata*[100]. Daily ingestion of 8 ounces of yogurt containing *Lactobacillus acidophilus* decreased the incidence of both colonization and candidal vaginitis in a population of women with recurrent vaginal candidiasis[101]. Surveillance cultures have a good negative predictive value but a poor positive predictive value, as it is often difficult to differentiate colonization from invasive disease and, as such, are not cost-effective.

Aspergillus

Spores of this ubiquitous mold are inhaled, and can colonize the respiratory tract or cause invasive pulmonary aspergillosis with the potential for extrapulmonary dissemination. For aspergillosis confined to the lung, survival rates are 28–82%[102–104]. The organ-

ism is highly angioinvasive. Clinical presentation can be insidious or acute and consists of:

(1) a pulmonary embolus-like syndrome with pleuritic chest pain, dyspnea, fever, pleural rub and peripheral cavitating nodules on chest X-ray;
(2) diffuse pulmonary infiltrates;
(3) pulmonary aspergilloma: a focal area of *Aspergillus* necrotizing pneumonia with cavitation in which saprophytic fungal growth occurs ('fungus ball');
(4) single or multiple brain abscesses;
(5) oculo- or otomycosis;
(6) disseminated disease.

It has been suggested that transplant recipients with *Aspergillus* infection can be treated with lower doses than the 1.0–1.5 mg/kg per day recommended for neutropenic patients. However, a significant number of the treatment failures in this review occurred in the patients receiving lower doses (<30 mg/day). Recommendations as to total doses of amphotericin B range from 1.5 to 4.0 g depending on the rate of radiologic resolution of lesions, and bone marrow recovery in neutropenics[105]. The role of surgical resection of isolated aspergillomas, pulmonary nodules and infiltrates is crucial and underemphasized in the literature[102,106,107]. Four heart transplant recipients in the Minneapolis Heart Institute program have been diagnosed with invasive aspergillosis (2.2%): two died with CNS dissemination and concomitant CMV infection, one did well after resection of a right upper lobe aspergilloma and a short course of amphotericin, and one with multiple pulmonary nodules is doing well on amphotericin, after at least 2 g of which he will be maintained on itraconazole.

Nosocomial outbreaks of aspergillosis in solid-organ transplant recipients have been related to local construction work and to contaminated ventilation systems[84,108–112]. Special air-handling systems have been shown to reduce the incidence of colonization and disease with *Aspergillus* in bone marrow transplant recipients[108,113–115] and in renal transplant patients[108]. Preventive measures at our institution consist of special ventilation with HEPA-filtered air under positive pressure, exchanged at a rate of at least 10 times per hour. Additional '*Aspergillus* precautions' are detailed in Table 4. Systems are monitored on a regular basis, but positive pressure can be easily checked with a smoke stick.

Cryptococcus neoformans

Cryptococcosis occurs infrequently in thoracic transplant recipients. It constitutes 20% of fungal infections seen in this population, but is the commonest cause of CNS infection in transplant recipients overall[6]. Although the potential for *C. neoformans* to be passed on in donor lungs is real, the few infections reported in heart–lung and lung transplant recipients are thought to have been acquired from environmental exposure[82].

C. neoformans is a yeast carried in bird feces, and spores are inhaled. It causes pulmonary infiltrates or nodules and, from there, disseminates to the CNS, skin, and urinary tract. All skin lesions and areas of cellulitis should be considered for biopsy, and sterile pyuria investigated. The presence of cryptococcal antigen in the blood is very helpful[6]. All patients with extraneural cryptococcosis should undergo lumbar puncture before starting therapy, as the likelihood of CNS involvement is high, even in the absence of clinical signs and symptoms. The typical CSF profile consists of <100 WBC, mostly mononuclear cells, glucose between 20 and 40 mg/dl, and a positive cryptococcal antigen.

Treatment of meningitis has traditionally consisted of 6–10 weeks of amphotericin B, 0.3 mg/kg per day, and 5-flucytosine[116], and that remains the therapy of choice for the acutely and severely ill; once stabilized, treatment can be completed with fluconazole. Ketoconazole and itraconazole do not cross the blood–brain barrier. Given the toxicity of amphotericin in the transplant population, many are using fluconazole as primary therapy in the subacutely ill patient[117]. In both cases the drug is given for 2–4 weeks after the last positive culture and cryptococcal antigen test. Sequential measurement of the cryptococcal antigen titer is helpful in monitoring the efficacy of therapy[6]. Extraneural cryptococcosis can be treated with fluconazole, 400 mg/day or an equivalent dose adjusted for renal function, using the same parameters for duration.

The dimorphic fungi (*Coccidioides, Histoplasma,* and *Blastomyces*)

Common to all of these organisms is a defined geographic distribution and the fact that, although infection is probably no more common than in normal hosts, immunocompromised persons are more likely to develop disease, and disease is more often disseminated and severe (hyperinfection). They exist in nature in mycelial forms and in the body as yeasts; hence the classification as dimorphic.

Coccidioides immitis

This fungus exists only in the Sonoran desert ecosystem in seven southwestern American states and in the Mexican northwest. Spores are inhaled and, 1–3 weeks later, cause symptomatic pneumonitis, often with pleuritis, in 40%, accompanied by a nonspecific febrile illness with arthralgias; associated erythema nodosum or multiforme is 2–10 times as common in women. Five percent have residual pulmonary nodules or cavities which can calcify. Chronic cavitary disease occurs more commonly in immunocompromised patients. Dissemination to musculoskeletal and central nervous systems and to skin occurs in 0.5% of all infected persons, this being much more likely to complicate immunosuppression, particularly when lymphopenia is present. Although reactivation disease can occur, primary infection is more likely to cause dissemination in transplant recipients[118].

Serum IgM precipitins can be detected in 75% of patients 1–3 weeks after the onset of symptoms of primary coccidioidomycosis and disappear within 4 months; persistence is a marker of progressive disease. They can also be measured in some cases of reactivation. At 3 months, 90% of patients are positive for IgG antibodies either by tube precipitin or complement fixation (CF) tests, and they may persist for 6–8 months. With the exception of meningitis, 61% of patients with disseminated disease have CF antibody titers of >1 : 32 and 41% have levels of at least 1 : 64[118]. The serologic response in im-

munocompromised patients appears to be at least qualitatively intact.

Coccidioidomycosis in heart transplant recipients has been sporadically reported before the CsA era[119,120]. Copeland's group in Tucson, Arizona, reported on their experience in the triple-drug immunosuppression era[121]. Six patients had a history of infection prior to transplant and were put on ketoconazole afterwards; none had recurrences. The rate of presumed coccidioidomycosis occurring after transplant was 4.5% or 1.5 episodes per patient-year, a rate that was half that seen in the pre-CsA era. Onset of disease occurred at a mean of 174 days (range 19–410 days) after transplant. Seven of the nine patients had only pulmonary disease, and dissemination from the lungs to blood, genito-urinary tract, joints, and skin occurred in the other two. Interestingly, no central nervous system disease was found. All patients were treated with 1 g of amphotericin B and then maintained on ketoconazole, 200 mg p.o. twice a day. Two of the nine had recurrent disease under circumstances which required the discontinuation of ketoconazole, a phenomenon that was also reported in previous studies[120,121]. Given the overall prevalence of coccidioidomycosis in that part of the continent, their practice is to screen transplant candidates, giving prophylaxis indefinitely to those with either a positive history or serology.

All transplant recipients with acute coccidioidomycosis should be treated with fluconazole, to prevent dissemination. Neither ketoconazole nor itraconazole crosses the blood–brain barrier, and meningitis has occurred in patients on ketoconazole. Although there is little specific data in the thoracic transplant literature on the preferred treatment of disseminated disease, patients with meningitis can probably be effectively treated with fluconazole. Extraneural disease can be treated with either fluconazole or itraconazole[122]. All patients should receive lifelong suppressive therapy. Doses of 400 mg/day are appropriate. Critically ill patients may need initial therapy with 0.5–1 g of amphotericin B followed by azole therapy and suppression. Intrathecal drug may be required to treat meningitis in such patients.

Where disease is confined to the lung, immunosuppressed patients do as well as their immunocompetent counterparts. Surgery may be indicated for some patients with cavitary disease[123].

Histoplasma capsulatum

This fungus exists in mycelial form in the soil of the east central United States, especially where concentrations of avian or bat feces are heavy. As in most other clinically significant fungal infections, the organism is inhaled and, in immunocompromised hosts, causes pulmonary disease with or without dissemination to skin, bone marrow, liver, and other organs. Presentation as acute (APDH), subacute, or chronic progressive disseminated histoplasmosis (CPDH) is dependent on the degree of parasitemia of the mononuclear phagocyte system, with high fevers, pancytopenia, visceral lymphadenopathy, pulmonary/gastrointestinal disease and hepatosplenomegaly characterizing APDH[124], and chronic wasting with focal disease the chronic form. Subacute disease is intermediate between the two. In all forms a careful search for skin or oral mucous membrane lesions is crucial as the diagnostic yield on biopsy of such lesions is higher than for any other site. Bilateral adrenal gland enlargement in the appropriate clinical setting should strongly indicate the diagnosis of disseminated histoplasmosis, and patients can become Addisonian.

Wright stain of peripheral blood is positive in 30–45% of AIDS patients with acute presentations[125]. Silver stain of the blood buffy coat and bone marrow biopsy specimens increases that yield, and is always positive on biopsies of oropharyngeal lesions. Rates of isolation from blood culture have been increased by lysis-centrifugation techniques[126]. Yield from cultures of clinical material depends on the presentation and the experience of the laboratory. Sputum culture is positive in only 10–15% of cases of acute pulmonary histoplasmosis[127]. Detection of a polysaccharide antigen in urine and blood is sensitive and specific for the diagnosis of APDH in AIDS patients, but less so in other hosts[125,128]; data for transplant recipients are needed. Complement-fixing antibodies (CFA) appear 3 weeks after exposure in 5–15%, and at 6 weeks in 75–95%. A titer of >1:32 is highly indicative of active histoplasmosis, titers of >1:8–1:16 are not as specific but are considered positive, and are more in the range of the level of response expected in the immunosuppressed[125,129]. Precipitin to the 150 kDa M antigen can be detected by immunodiffusion 2–4 weeks after CFA in 50–80% of patients but persists for years, thus losing its sensitivity as a predictor of active disease. It is present in 50% of chronic pulmonary or disseminated disease. Precipitin to a 120 kDa H antigen is highly specific and persists for only 6 months, but is present in <20% of patients[125,130]. Amphotericin B, 35 mg/kg or 2.0–2.5 g total, at a dose of 0.7–1.0 mg/kg per day, is indicated for the treatment of patients who are immunosuppressed, or either not responding to azoles or relapsing off them. Another approach is to give an induction course of 20–25 mg/kg of amphotericin B followed by itraconazole. It is not clear whether transplant recipients, like AIDS patients, require lifelong azole suppression[126,131]. Itraconazole has been effective as primary therapy in patients who are not intensely immunosuppressed, in a dose of 200–400 mg/day for 6–12 months[126,132–134].

Work continues on the development of a vaccine[135,136].

Blastomyces dermatitidis

Geographic distribution for this fungus includes the east central USA with extension along the St Lawrence River and into the territory around the Great Lakes. Most cases of blastomycosis are not associated with immunosuppression. In a case report of recurrent blastomycosis in a heart transplant recipient and a review of the literature[137], Serody *et al.* found only four, or possibly five, additional cases of blastomycosis in transplant recipients[138–142], one of which was a heart transplant recipient. Onset was from 3 weeks to 4 years after transplant, and disease was not associated with any particular immunosuppressive regimen. Pulmonary disease was active in all, with skin involvement in two, and eye lesions in one. Diagnosis was made by skin biopsy or bronchoscopy. Their patient responded to 1 g of amphotericin B, followed by 9 months of ketoconazole, but relapsed and was retreated with 1 g of amphotericin B with partial response, and worsened on ketoconazole.

Itraconazole is now the drug of choice for treatment of blastomycosis in the non-critically ill patient, but data on cures in transplant recipients remain to be accumulated.

Paracoccidioides brasiliensis

Dynamic population shifts can be expected to introduce cases of South American blastomycosis, the disease caused by this agent, into North American medical experience. As reactivation of dormant infection can occur in immunosuppressed hosts, this entity should be kept in mind in patients who have resided in endemic areas. Brazil is the focus of the geographic distribution, with some spillover into Colombia, Venezuela, and Argentina, and infrequently in the rest of Latin America from latitude 23 degrees north to 34 degrees south. The lungs are the site of primary infection, but dissemination to skin, mucous membranes, reticuloendothelial system, and adrenals is frequent[143,144].

Miscellaneous unusual fungi

Pseudallescheria boydii infection is often clinically and morphologically mistaken for aspergillosis, and includes otomycosis, oculomycosis, sinusitis, fungus balls, and angioinvasive pulmonary disease with dissemination. It has an array of clinical presentations according to sites of trauma and is a cause of eumycetoma. It is important to differentiate this organism from *Aspergillus* by culture, however, as it is resistant to amphotericin B, though responsive to azoles. Concomitant surgical management is necessary[145–148].

Mucormycosis, with rhinocerebral, pulmonary, cutaneous, gastrointestinal and central nervous system presentations, is very rare in transplant recipients[149–154], and there are no data for thoracic transplant recipients.

Phaeohyphomycosis is a term that applies to infections other than chromoblastomycosis and eumycotic mycetomas, caused by dematiaceous fungi present as saprophytes in nature, and seen with increasing frequency as the prevalence of immunosuppression rises. McGinnis has categorized these infections into superficial, cutaneous/corneal, and subcutaneous cystic forms initiated by direct inoculation, and systemic disease where widespread dissemination, often from a lung source, occurs[155]. Sudduth *et al.* reported the first case in a cardiac transplant recipient who had a subcutaneous abscess on the arm, from which *Exophilia jeanselmei* was isolated[156]. An excellent review of the *Exophilia* infections is presented. Other rare fungal agents causing infection in transplant recipients include *Trichosporon beigelii*[157,158] and *Fusarium*[146].

Antifungal therapy

Amphotericin B is the tried and true gold standard for the treatment of most serious fungal infections, despite its legendary toxicities. Management of amphotericin B therapy in patients on nephrotoxic immunosuppressive medications such as CsA and FK506 is particularly arduous, as serum creatinine may rise precipitously[159,160], even after just one dose. Salt loading and good hydration may help[161]. Starting with lower doses, and increasing the dose more gradually than usual, do seem to prevent big jumps in creatinine, but theoretically delay the response to treatment for seriously ill patients with virulent infections such as invasive/disseminated aspergillosis. The ability to change to the less toxic azoles after an initial induction period with amphotericin B helps to minimize the cumulative toxicity.

Liposomal encapsulated amphotericin B appears to be less nephrotoxic; thus higher doses can be given[162,163]. However, although data from open trials indicate equal or superior efficacy and less toxicity in the treatment of *Candida* and *Aspergillus* infections in neutropenic and bone marrow transplant patients[163–170], the safety profile remains to be established in solid organ transplantation, and the benefits may not extend to patients on CsA. Preliminary results indicate the potential in some situations[171].

Ketoconazole has no place in the treatment of mycoses in the transplant population, but itraconazole and fluconazole have added greatly to the management of fungal infection, either as primary therapy or after an induction phase of amphotericin B. Itraconazole down-regulates the cytochrome P450 hepatic enzyme system and raises CsA levels, but to a lesser extent than ketoconazole[159]. Prompt halving of the CsA dose can offset this effect. Fluconazole elevates CsA levels only at doses in excess of 400 mg/day[172]. Itraconazole cannot be given down a nasogastric tube and only fluconazole comes in an intravenous formulation. Itraconazole is useful for the continuation of treatment of aspergillosis after amphotericin B, and for primary or subsequent treatment for histoplasmosis, blastomycosis, and pulmonary coccidioidomycosis. It does not cross the blood–brain barrier, so is not useful for meningeal disease. Fluconazole does penetrate the cerebrospinal fluid and is useful for the primary treatment of the non-emergently ill patient with cryptococcosis, coccidioidomycosis, oral/esophageal candidiasis, and candiduria, and for the subsequent treatment of invasive/disseminated candidiasis with sensitive strains[82,117,173–178]. Saperconazole is a new azole which has excellent *in-vitro* activity against *Aspergillus*[177,178] but is still in trials.

VIRAL INFECTION

Human herpesviruses

Cytomegalovirus

Cytomegalovirus (CMV), or human herpesvirus 5, is a DNA virus that causes the most morbidity and mortality in transplant recipients[185]. The Stanford group has shown that CMV infections in heart transplant recipients constitute a risk factor for more frequent episodes of rejection, more frequent and severe graft atherosclerosis, and a greater risk of death (see below). Some of the reasons for this association include the fact that CMV is ubiquitous; seropositivity rates in Western European and North American populations are 15% by age 2, 30% in young adults, and 50–60% over age 50. Higher rates are seen in low socioeconomic groups, gay males, sexually promiscuous heterosexuals, and recipients of blood transfusions[179]. Day-care-age children and their parents are also at higher risk[180]. In addition to directly causing clinical disease, CMV infection has a number of indirect consequences: it is associated with, and may cause, rejection; it is immunosuppressive, thereby adding to pharmacologic immunosuppression and facilitating superinfection by other opportunists; it may be oncogenic.

Ninety percent of primary CMV infections in transplant recipients are due to reactivation of latent virus in the cells of the donor organ in a SNR, and 10% to transfusion of CMV-positive blood products. SPR can be primarily reinfected with donor strains different from their own, and subsequent disease is due to the donor

strain 50% of the time (as demonstrated by DNA-restricted enzyme analysis). Reactivation of recipient strains accounts for the balance of the 90% of CMV infections that occur in the first 1–4 months after transplant. Late-onset primary infections are community-acquired. Primary infection can be documented by seroconversion, and all forms by detection of virus in oropharyngeal secretions, urine, and blood. Disease results from 25–60% of the primary infections and in at least 20% of SPR[6,84,87,179,181–191], but there appears to be no difference in mortality.

Viral pathogenesis

CMV replicates best in fibroblasts and less well in epithelial and other cells. In the first 4 hours after cellular penetration (the immediate–early phase), proteins which regulate expression of viral genes are synthesized. The next 8 hours (the early phase) result in the production of DNA polymerase. In the final 6 hours of the 18–24-hour replicative cycle (the late phase) whole viral particles are assembled for release[192], which may not occur for 4 days[179]. The fact that multiple replicative cycles are required to detect the typical cytopathic effect on fibroblast monolayer cultures 3 weeks later (range 1–6 weeks) may explain the long incubation period until infection and disease can be detected after transplant.

The end-result is cytolytic or productive infection where new virus particles released from the lysed host cell are capable of infecting new host cells, or persistent or non-productive infection where, in the case of CMV, virus persists in circulating monocytes and polymorphonuclear leukocytes in a non- or intermittently replicative, latent state[193–195]. Viral persistence may also be manifested by chronic, replicative, cytolytic infections that are subclinical and do not impair organ function[196] and by slowly progressive, destructive infections such as progressive multifocal leukoencephalopathy caused by papovaviruses[197] (see below).

Immunosuppressive regimens interfere with the cell-mediated mechanisms that check the activation and expression of, and later destroy, virus-infected cells. Recovery from CMV disease is dependent upon the host's ability to elaborate MHC-restricted CMV-specific cytotoxic T8 cells and natural and antibody-dependent killer cells[198,199]. Specifically, the effects of antilymphocytic and cytotoxic agents facilitate reactivation of latent virus, while those of CsA, rapamycin, and FK506 allow the dissemination and amplification of actively replicating virus. Though the frequency of CMV infections has decreased in the cyclosporin era, particularly with low-dose triple regimens[200,201], spontaneous recovery is no longer seen, and relapsing CMV infections are now a problem in some transplant populations. Rubin[6] states that the addition of any antilymphocyte therapy to an immunosuppressive regimen causes an increased incidence of CMV disease and a decreased effect of preventive measures against it, such as interferon, acyclovir, or CMV immune globulin[182,188,201–209]. This conclusion comes mainly from the experience in renal transplant recipients; in thoracic transplantation there is some conflicting evidence that antithymocyte globulin or induction OKT3 results in a higher incidence of CMV[210–214].

Clinical syndromes

The mean time of onset of CMV disease after transplant is 5.5 weeks[215]. In a recent multi-institutional study[214] of 1553 heart transplant recipients at 26 centers, there were 230 episodes of CMV disease in 200 patients for an incidence of around 13%, with a 12% rate of recurring disease. Ninety-nine percent of the episodes were treated with ganciclovir, with a 93% resolution rate. Blood cultures were positive in 43%. Disease involved the lung in 30% of episodes, 13% of which were fatal, and the gastrointestinal tract in 23%, for a 6% mortality rate. Donor–recipient serostatus and cytolytic induction therapy were risk factors for disease occurring earlier in the post-transplant period, but fatal outcome was influenced only by preceding or concomitant infections with other organisms.

CMV infection in lung transplants is more problematic as it usually involves the lungs. Experience varies widely[216–218], with the Toronto group[216] reporting an incidence of CMV pneumonitis of 7.7% (fatal in 2%) in 57 single lung transplants (SLTx) and double lung transplants (DLTx) performed between 1983 and 1990, and the Pittsburgh group citing a 27.6% incidence (13.8% fatal) in 59 heart–lung transplants (HLTx), DLTx and SLTx transplanted between 1982 and 1989[217]. In the latter study, although 19/20 (95%) SPR showed evidence of active infection, with a 5% mortality rate, only six developed disease. Primary infection and disease developed in 13/38 SNR (38%) and was fatal in 7/13 (54%). Sixteen of the 19 patients with CMV disease had pneumonitis: 11 SNR (85%) and five SPR (26%). More SNR than SPR had severe pneumonitis (8/11 vs 1/5), and pulmonary superinfections with other organisms occurred at a significantly higher rate in the first year post-transplantation in SNR. Actuarial survival was also worse. Only 6/16 patients with pneumonitis were treated with ganciclovir. The higher incidence of CMV pneumonitis in LTx than in heart transplants (HTx) may be attributable to the younger age, and therefore greater proportion of seronegativity, of the recipient population, and the much larger inoculum of latent virus associated with the large amount of tissue transferred with a heart–lung block.

Singh *et al.*[184] have provided a standardized classification of CMV disease:

(1) CMV syndrome: Fever of 38 degrees C for a least 1 week without any other source. Laboratory evidence of CMV infection (see Diagnosis). One or more of the following:
   (a) white blood cell count $\leq 4000/mm^3$;
   (b) platelets $\leq 100\,000/mm^3$;
   (c) atypical lymphocytes $\geq 3\%$.
   Myalgias, arthralgias, and headache are non-specific but often present, as in anemia.
(2) Localized CMV disease: Tissue invasion of a single organ, proven histologically; and/or by positive tissue culture.
(3) Disseminated CMV disease: Tissue involvement of two or more non-contiguous sites.

There is likely much overlap, and empiric esophagogastroduodenoscopy (EGD) will often demonstrate the characteristic findings of CMV enteritis in patients with no localizing symptoms[219]. This can be a useful finding in confusing situations, so the threshold for doing endoscopy should be low[217].

CMV enteritis is a common manifestation of CMV infection in thoracic transplantation; pneumonitis is seen almost exclusively in lung and heart–lung, and myocarditis in heart/heart–lung, recipients. CMV retinitis is rare and denotes chronic CMV viremia[220,221].

Enteritis

Cytomegalovirus can cause mucosal disease anywhere along the gastrointestinal tract[222], but the stomach, duodenum, and right colon are most frequently involved. Esophagitis presents as dysphagia and gastroduodenitis with epigastic pain, often exacerbated by movement, nausea, vomiting, early satiety[223], and anorexia[224]. Diarrhea, sometimes with blood, and lower abdominal pain are characteristic of colitis[225–228], and perforation can be a serious complication. CsA levels tend to decrease, reflecting absorption abnormalities. Fever is not necessarily present. Diagnostic endoscopy reveals non-specific inflammation with erosions, and aphthous ulcerations and biopsy show characteristic perinuclear inclusion bodies.

Pneumonitis

Patients with pneumonitis present with constitutional illness, dyspnea, tachypnea, dry cough, and bilateral peribronchial interstitial and alveolar infiltrates of the lower lobes on chest roentgenogram in 70%. Focal infiltrates, nodules, and lobar consolidation occur less frequently. Although the diagnosis of CMV pneumonitis should be based on demonstration of typical histology and detection of CMV in lung tissue, seeing inclusions and/or detecting CMV on bronchoalveolar lavage is cited as sufficient indication for treatment[6,229].

Disseminated infection

CMV can cause disease of almost any organ, and viral septic shock is associated with an increased cardiac index, decreased systemic vascular resistance, and elevated oxygen delivery during both early and late phases. In contrast to bacterial sepsis and endotoxemia, pulmonary resistance is normal[230].

Miscellaneous sites

CMV has been identified as causing endometritis[231], encephalitis[232], transverse myelitis[233], Guillain-Barré-type polyneuropathy[234], cutaneous vasculitis[235], hemorrhoiditis[236], hepatitis[237], nephritis[238], epididymitis[239] and coronary thrombosis[240].

Diagnosis

Pathology

Positive biopsies are those which show CMV inclusions and focal inflammation and/or antigens of CMV by monoclonal antibody staining or CMV DNA by *in situ* hybridization[241].

Serology

CMV IgG antibody tests are useful only to establish the serostatus of the recipient and the donor, and to identify candidates for prophylaxis (Table 5). For that purpose, complement-fixation tests using a glycine-extracted antigen are sensitive and specific at >1:8[188]. Newer immunofluorescent, ELISA, and latex agglutination techniques are being used by many laboratories as they are faster, less labor-intensive, and cheaper. However, there is no standardization, except at a local experiential level, as to what constitutes a positive test, and low-level positives can be falsely so. Chou has reviewed the advantages and problems of these tests[241]. IgM antibody, an indicator of active infection, has poor sensitivity and specificity, especially in immunosuppressed patients[241]. Measurement of anti-CMV neutralizing antibody is cumbersome and unhelpful[242].

Viral isolation

Detection of CMV in blood, body fluids, and tissue offers the best sensitivity for diagnosis of disease, when matched with clinical assessment. Viremia is the best overall marker for both acute and chronic infection[182,188,206]. The 'gold standard' test is the demonstration of the typical cytopathic effect on a fibroblast culture 1–6 weeks after inoculation. Rapid diagnostic techniques have evolved, and have contributed greatly to improved outcomes in patients with CMV disease. Using the shell vial technique, the 72 KDa immediate–early antigen can be detected 24–48 hours after inoculation of fibroblast monolayers, using monoclonal antibody and immunofluorescence[243]. The major drawback is that, due to technical difficulties, false-negative blood buffy coat cultures can occur in up to 50% of patients[244].

The antigenemia assay of The *et al.*[245] involves direct immunoperoxidase staining of buffy coat preparations using a monoclonal antibody to the 65 kDa lower matrix phosphoprotein, a late antigen, and yields a diagnostic sensitivity and specificity of 95%. As it is a semi-quantitative technique it can be used to determine when pre-emptive therapy might be indicated, as rising titers and sustained antigenemia have been shown to herald the onset of disease. It is therefore also of value in monitoring the effects of therapy. Other antigenemia assays based on different antigens and monoclonal antibodies have proven to be less sensitive and specific[246–255]. A similar technique can be used on bronchoalveolar lavage (BAL) material[254,256].

In-situ DNA hybridization can detect CMV genome copies in clinical material[257]. Polymerase chain reaction (PCR) allows selected amplification of specific nucleic acid sequences, and is as good as the antigenemia assay but technically more difficult[258–260].

Table 5 Pretransplant work-up: donor

Infection risk	*Specifics*	*Action*
Viral	CMV IgG SPD	Prophylaxis of SNR
	EBV VCA IgG SPD	May dictate matching to SPR
	HBV surface antigen SPD	Exclude
	HCV 2nd or 3rd generation ELISA and immunoblot test SPD	May need to exclude or to use only in SPR
	Retrovirus SPD or SND at high risk	Exclude
Parasites	*Toxoplasma gondii* IgG SPD	Treat SNR
	Trypanosoma cruzi risk or SPD	Exclude

A newer technique is reverse transcription PCR, that can detect viral transcripts which code for different CMV proteins[261]. This could improve the sensitivity of diagnosis as existing techniques rely on single antigens, whereas CMV has genomic and antigenic heterogeneity.

Treatment

The advent of ganciclovir (GCV) has had a great impact on the previously poor outcome of CMV disease in transplant recipients. The 7% mortality rate from GCV-treated CMV disease reported by the Cardiac Transplant Research Database Center[214] compares favorably to the 25–70% mortality rates quoted before the drug became readily available[210,229,262]. Other groups have confirmed this experience[262–270].

CMV enteritis is usually successfully treated with 5 mg/kg every 12 hours (adjust for renal dysfunction) for 2 weeks.

Optimum therapy of CMV pneumonitis consists of GCV plus intravenous immune globulin (IVIG) or hyperimmune CMV immune globulin (CMVIG)[271–274] for 4 weeks. A beneficial effect of humoral responses on symptoms not attributable to a major reduction in viral replication has been noted in the mouse model[275]. CMV hyperimmunoglobulin (CMVIG) alone has not proved beneficial in treating CMV disease[271].

Concomitant decrease in doses of immunosuppressive drugs, particularly azathioprine, may be advisable and necessary, as leukopenia is the commonest side-effect of GCV. Care must be taken to reinstitute higher doses when the infection and its immunosuppressive effects are resolving, as rejection can occur.

Although not much resistance to GCV has been experienced, the increase in the use of this useful drug for prophylaxis and pre-emptive therapy can be expected to result in more. Erice *et al.*[275] reported three patients (two with AIDS, one with chronic lymphocytic leukemia) in whom GCV-resistant CMV was isolated; in one, resistance emerged on therapy. GCV was ineffective in eradicating CMV from the blood and all three patients died.

Trisodium phosphonoformate (Foscarnet, Astra), a virostatic agent, has been used with some success in the treatment of CMV disease in immunocompromised hosts, including a heart transplant recipient[276,277]. This drug could serve as an alternative in the patient with GCV-resistant or GCV-unresponsive CMV.

Prevention

A number of measures to prevent CMV infection and disease have been tried for many years, with mixed results:

(1) Matching D : R serostatus.
(2) CMV-negative blood products or leukocyte filters.
(3) Passive immunoprophylaxis.
(4) Active immunoprophylaxis.
(5) Chemoprophylaxis.
(6) Combinations of the above.
(7) Pre-emptive therapy.

1. Matching serostatus. Matching donor and recipient by CMV serostatus (SNR/SND) significantly reduces the incidence of CMV disease[216,278,279]. Even in the absence of documented CMV infection, survival and functional status are better than in seromismatched pairs[216]. The shortage of donor hearts and our ability to maintain a relatively low morbidity and mortality from CMV disease in HTx have made this an unattractive strategy, though evidence is mounting that the greatest toll of CMV infection may be its contribution to chronic rejection as manifested by accelerated atherosclerosis. The stakes are higher in LTx and HLTx however, as CMV pneumonitis develops in at least 75% of SNR of SPD lungs, and preventive tactics tried so far have been relatively ineffective. Some lung transplant programs are therefore trying seromatching[280].

2. CMV-negative blood products. Approximately 20% of SNR of SND hearts develop CMV infection, presumed to come mainly from blood transfusion[181,281]. About 10% of seropositive blood donors transmit infection[282,283] and positive IgM antibody is a marker of transmissibility[284]. The estimated risk, based on older studies, is 2.7% per unit of blood[285]; in more recent studies the numbers are much lower[286]. It is more cost-effective to screen for CMV antibody than to administer all blood products with high-efficiency leukocyte filters[6], though these work well and offer the additional advantage of possibly also removing Epstein–Barr virus (EBV) and human herpesvirus 6 (HHV-6) infected cells[287,288]. Exclusion of CMV IgM-positive (6%) blood products reduced the incidence of transmission-associated disease in one study[289].

3. Passive immunoprophylaxis. There is evidence from bone marrow (BMTx) and renal transplantation after that although various hyperimmune (CMVIG) and unselected CMV globulins do not prevent infection, they significantly modify the severity of CMV disease and prevent the complicating superinfections[281,290–295]. For example, in one multicenter trial using CMVIG in SNR of SPD kidneys, only 21% of CMVIG-treated patients developed CMV disease as opposed to 60% in controls; 4% of CMVIG recipients had CMV pneumonitis vs 17% of placebo controls. Fungal and parasitic infections were seen in 20% of controls but in none of the CMVIG group. Results in thoracic and liver transplant recipients are mixed[216,218,296–298].

The definition and delivery of protective titers of antibody are complicated by the heterogeneity of CMV, the antibody titer variation between and within IG preparations[299–301], the fact that antibody titers measured by ELISA do not correlate with *in vivo* neutralizing titers[300], and, finally, the fact that it is not known which antibody response is protective against CMV[196]. Prophylactic and therapeutic trials of human monoclonal CMV antibodies with high levels of neutralizing activity have been proposed[301,302], but neutralizing antibodies do not correlate with recovery from CMV disease, nor do they confer protection[303].

There is no evidence that CMVIG is superior to IVIG for this purpose, and various unselected globulin preparations have been shown to have equal neutralizing activity[300,301]. The advantages of CMVIG, now marketed as Cytogam (MedImmune, Inc., Gaithersburg, MD), are that there is lot-to-lot consistency in antibody titers and that, because titers are high, less infusion volume is required so that cost is also less. Nonetheless, the cost in one Snydman study was $4800 per patient, $29 800 per life saved for those at risk of primary disease[304], or $13 000 per case of CMV disease prevented following lung transplantation[297]. Also, at least one preparation of IVIG has been associated with the trans-

mission of hepatitis C virus as far back as 1992, and has been taken off the market[305].

It has also been shown that CsA and, more so, antilymphocyte rejection therapy attenuate the beneficial effects of CMVIG[295,297].

In HTx, the role of CMVIG prophylaxis is definitely not clear, but in HLTx/LTx the combination of this and chemoprophylaxis needs careful study.

4. Active immunization. Plotkin's work with a live human CMV (Towne strain) vaccine[306-309] has shown that the incidence of CMV infection and disease was not altered, but the frequency of severe disease was markedly decreased in vaccinated vs. placebo-treated SNR of SPD kidneys ($p<0.05$) in one study[306]. Both groups received similar regimens to prevent and treat rejection, and had the same average number of rejection episodes. One-year and 5-year actuarial survival rates for cadaver renal allografts were 73% and 62% for vaccinees vs 40% and 25% for placebo patients. A cell-mediated immune response demonstrated in vaccinees pretransplant disappeared with the introduction of immunosuppressive therapy after transplant. Vaccine strain did not reactivate. These observations were not corroborated by a Minnesota study using the same vaccine[310].

A subunit glycoprotein B vaccine has been developed; it produces neutralizing antibodies and the CMV-specific cytotoxic T cell proliferation, though this seems to wane in the face of immunosuppressive therapy[311].

It may prove difficult to develop a vaccine that accounts for the heterogeneity of CMV. There is also concern over the potential oncogenicity of CMV and over the possibility of chronic disease related to its latency.

5. Chemoprophylaxis

(a) *Acyclovir (ACV).* Balfour *et al.* reported a significant decrease in the incidence of CMV disease, particularly primary disease, in renal transplant patients taking ACV 800 mg q.i.d. for 3 months post-transplant[312]. Dummer *et al.* noted no benefit in HTx and three of 10 patients succumbed to CMV pneumonia after the drug was discontinued[210]. In our own experience with HTx randomized to this protocol, or to a no-prophylaxis group, there has been no difference in the incidence or severity of CMV disease regardless of donor– recipient serostatus.

(b) *Ganciclovir (GCV).* This highly active nucleoside analog is more toxic than ACV and therefore is less appropriate for prophylaxis. It has been shown to be effective in reducing the incidence and severity of CMV disease in BMTx, though neutropenia was a troublesome side-effect in this population[313,314]. Merigan *et al.* reported success in preventing disease in SPR but not primary disease in SNR using GCV for 1 month post-heart transplant[315]. Bailey *et al.* documented failure of prophylactic GCV in LTx[316]. Martin *et al.* showed that 2 weeks of GCV followed by high-dose ACV was superior to ACV alone in liver recipients[317]. An oral preparation is now available; it is not well absorbed and in half of the patients in whom we have used it to suppress disease, clinical and histologic evidence of CMV enteritis was still present after 1 month of therapy.

6. Pre-emptive therapy. Once-daily dosing with GCV when preclinical CMV infection is demonstrated by virological monitoring techniques has been shown to be effective in preventing CMV pneumonia in BMTx[318,319]. The rate of CMV disease seen after treatment of rejection with antilymphocyte agents in renal transplant was reduced in GCV recipients[6,320-322]. LTx may well benefit from this approach given the inadequacy of other preventive modalities. Each center should assess its own experience with CMV disease in HTx, as there is so much variation in immunosuppressive regimens. Rubin predicts that, in the future, patients at risk for primary disease will receive prophylaxis, and pre-emptive therapy will be given after treatment of rejection and for patients with presymptomatic viremia detected by periodic monitoring[6].

CMV and rejection

Simmons was the first to recognize a possible association between CMV infection and rejection in 1970[323] and since then a relationship has been demonstrated in LTx[324], liver transplantation[325,326], and renal transplantation[327,328], but the most compelling evidence comes from HTx, where CMV infection has been linked to both acute and chronic rejection[329-332].

Accelerated atherosclerosis is the hallmark of chronic rejection in HTx and severely limits long-term survival[329]. Koskinen *et al.* documented arteriolar endothelial cell accumulation and increased intimal thickness of intramyocardial vessels significantly more frequently in the 1-year endomyocardial biopsy (EMB) specimens of CMV-infected HTx, indicating a CMV-associated acceleration of allograft vasculopathy. At 2 years the endothelial cell response had subsided, but the intimal thickening had progressed. Thereafter there was no difference in histologic findings between CMV-infected and non-infected[333]. Other organisms have been associated with atherosclerosis[344] and human herpesviruses have been detected in atheromatous lesions in major arteries by DNA hybridization and immunoperoxidase staining for specific viral antigens[345].

In LTx, increased donor alloreactivity and obliterative bronchiolitis is seen in CMV-infected patients, but the process is thought to be multifactorial and is not statistically significantly CMV-associated[217,334-336].

The most detailed studies are in renal transplant patients, where a characteristic glomerulopathy distinct from classical rejection is associated with CMV infection. The lesion consists of increased numbers of $CD8^+$ cells and activated mononuclear phagocytes, and the glomeruli stain more intensely for MHC class-I antigen than do the tubules which are maximally involved in classic rejection. The lesion is less likely to respond to antirejection therapy, and GCV appears to decrease its incidence.

Proposed mechanisms could be direct and/or indirect[329,333]:

1. Direct

(a) CMV infection of vascular endothelial and smooth muscle cells[337] and the resultant inflammatory and immunologic responses render allograft blood vessels vulnerable to chronic injury[343].

(b) Virus may transform cells by incorporating into the cell genome and inducing local proliferation and changes in cellular metabolism of these cells, e.g. growth factors[338,339], thus causing endothelial and medial cell hyperplasia.

The hypothesis that latent CMV infection of the coronary arteries is associated with graft atherosclerosis has been refuted by Skowronski *et al.*, who found CMV by PCR in only two coronary artery specimens from one HTx with no post-mortem evidence of graft atherosclerosis and a history of CMV infection. They found CMV in stomach, kidney, and lung of only one other patient in the study, despite the presence of both clinical CMV infection and graft atherosclerosis[355].

2. *Indirect*

(a) There appears to be down-regulation of MHC class I antigens in CMV-infected cells, whereas in the surrounding uninfected cells there is up-regulation of these antigens and of the adhesion molecules ICAM-1 and LFA-3; together, they modulate a local immune attack on infected allograft endothelium.

(b) Immediate–early antigens have sequence homology and immunologic cross-reactivity with HLA-DR beta-chain[340], and CMV encodes a glycoprotein homologous with the heavy chain of MHC class I molecule[341,342]. This 'molecular mimicry' could provoke immune-mediated damage to cells displaying these antigens[341–348]. DR-matched transplants may result in more CMV disease[349,350] as studies in the mouse model suggest that the MHC locus equivalent may represent a receptor for CMV.

(c) CMV infection is associated with the activation of T cells and the release of interferons (especially gamma) which up-regulate the display of MHC class I and II antigens on the allograft[351–354]; this provides another opportunity for immune-mediated attack on the graft[348]. In the mouse model, CMV infection exacerbates graft vs host disease and increases the cytolytic T cell response to alloantigens[346,347].

CMV infection is immunosuppressive

Another by-product of the down-regulation of class I MHC antigens in CMV-infected cells is impairment of the presentation of viral antigen to the T lymphocyte so that cytotoxic T cell killing of virus-infected cells is also impeded. The function of both monocyte and natural killer (NK) cells is impaired in CMV infection, and the end-result is monocyte-induced suppression of lymphocyte function[347,356–360]. As with HIV infection, both CMV and EBV cause reversal of the CD-4 (T-helper cells) and CD-8 (T-cytotoxic/suppressor cells) ratio. Clinically this translates into 'superinfection' with other organisms, including opportunists such as *Aspergillus, Pneumocystis, Listeria*, and *Toxoplasma*[6,214,329,361,362].

CMV oncogenesis

Portions of the CMV genome are homologous to the myc oncogene[363]. Transformation in certain cell lines does occur, and malignancies have been produced in animal models[188]. In humans, CMV has been most closely linked to Kaposi's sarcoma[188,364].

Epstein–Barr virus (EBV)

EBV causes post-transplantation lymphoproliferative disorders (PTLD) or lymphoproliferative syndromes (LPS), ranging from active viremic disease to lymphomas[365–368] caused by oncogenic transformation of virus-infected cells. Primary infection in the SNR results from intimate contact with infected respiratory secretions or transfusion or transplantation from SPD, and is responsible for 50% of the EBV infection in pediatric transplant recipients and 80% in SNR overall. As >90% of adults are seropositive, reactivation, which is estimated to occur in 40% of SPR, is the most common precursor of disease in adult transplant populations, but reinfection of the SPR is also possible since there are two strains of EBV (1 and 2). Primary infection causes 70% of PTLD[368].

Stanford University reported a 7% incidence of lymphoma in HTx in the pre-CsA era[369]; this increased to 13% in the early years of CsA use[370], but familiarity with the drug and the ability to monitor blood levels resulted in a drop in this rate[371]. Ten years of experience with cyclosporin-based immunosuppression at the University of Pittsburgh yielded a rate of 4% for all thoracic transplant recipients surviving more than 30 days; 3.4% in HTx and 7.9% in HLTx/LTx. Peak occurrence was at 3–4 months post-transplant. Early-onset PTLD (<1 year) was characterized by presentation with disseminated disease in 23%, an 89% response to reduction in immunosuppression, and a 36% mortality rate from lymphoma. Late disease was associated with disseminated infection (86%), no response to reduced immunosuppression, and a mortality rate from lymphoma of 70%. Most infections were primary[375]. It has been stated that there is a substantial increase in PTLD in those receiving antilymphocyte therapy in addition to triple-drug immunosuppression[6,372–374,401]. This has not been our experience, nor that of others[375–378].

Viral pathogenesis

The virus binds to the complement receptor C3d (the CD21 molecule) on B lymphocytes, developing T lymphocytes, non-T, non-B lymphocytes, and epithelial cells[379,380]. Productive infection takes place in the epithelial cells of the upper respiratory tract. Non-productive, latent infection in B lymphocytes predominates in normal hosts[371,372,382] and is characterized by the persistence, in circular episomal form, of EBV genomes. The best marker of latency is the detection of small mRNA encoded by the EBER-1 gene[387].

Infected cells undergo polyclonal or monoclonal transformation into lymphoblastoid cell lines (LCL) in which viral genomes are replaced in constant balance with host cell DNA[371,372,381–384]. EBV-1 appears to be a more potent transformer than EBV-2 and has been associated more strongly with lymphoproliferative disease[384–386]. These LCL produce their own B cell growth factors, including interleukin-6 and lactic acid[372], and grow indefinitely (immortalization); they not only perpetually produce viral antigens but also secrete immunoglobulins and may facilitate augmented transcription of cellular oncogenes. Other processes associated with the elaboration of cytokines and growth factors, such as rejection and CMV infection, may enhance the lymphoproliferative response[388]. Recent evidence has emerged that a protein product of the BCRF-1 region of the EBV genome has extensive homology with interleukin-10, and these molecules appear to inhibit IFN-γ secretion, which suppresses T cell proliferation and may interfere with the elimination of EBV-infected cells[6,372,389]. Recent evidence suggests that elevated levels of

interleukin-6 play an important role in the pathogenesis of PTLD[372].

Viral expression in transformed cells is continually checked by MHC-restricted, EBV-specific, cytotoxic T cells, which suppress the outgrowth of LCL and virus-associated immunoglobulin synthesis. CsA interferes with interleukin 1 and 2 production, which precludes this response to EBV[390]. OKT3 abrogates cytotoxic T cell effector functions by modulating the T3–Ti complex on all mature T lymphocytes until the receptor complex reappears[391]. In addition, maintenance immunosuppression increases the incidence of viral shedding to 30%, and the addition of anti-lymphocyte therapy raises this to 80%. Higher rates of viral shedding are associated with primary disease and with the development of PTLD[384,392].

EBV has also been linked to T cell lymphomas[393,394].

EBV is immunosuppressing[6] and may contribute to chronic allograft dysfunction[395]. Co-infection with CMV may cause additive effects[388,404].

Clinical syndromes

Hanto *et al.*[396] provide a clinical and pathologic approach to classification of EBV LPS (Table 5), but the clinical presentation can be protean and non-specific including fever of unknown origin, a mononucleosis-like illness sometimes with sepsis syndrome, enteritis/hepatitis, central nervous system dysfunction and focal disease, and focal tumors in various extranodal locations[365,373].

Group I patients (mean age 23 years)[371] present within the first year post-transplant, may have acyclovir-responsive disease and may not require reduction in immunosuppression. *Group II* patients are similar to group I but pathologically show evidence of malignant transformation. The B cell proliferation is still considered to be acyclovir-responsive, but concomitant reduction in immunosuppression is needed, and serial biopsies are indicated to monitor for monoclonal transformation. Patients in this group often succumb to aggressive disseminated disease with lactic acidosis and intravascular coagulopathy. *Group III* patients tend to be older (mean age 48 years) and present longer after transplantation (average 6 years) with acyclovir-insensitive solid tumors, presumably composed of latently infected B cells of monoclonal origin. The prognosis is poor, with a mortality rate of >80%[396].

Patients in all groups may be asymptomatic at presentation. Ho *et al.* found no difference in the clinical course according to age, time of onset, or clonality[367]; however, their patients fit well into Hanto's clinicopathologic groups[368].

Diagnosis

Serology

The normal host generates high levels of IgG and IgM antibody to viral capsid antigen (VCA-IgG, VCA-IgM) during acute infection along with transient levels of antibody to the diffuse component of early antigen (EA-d). Weeks to months later, antibody to EBV nuclear antigen (EBNA) develops, and is a marker for EBV immortalization. In some patients with protracted illness, EA-r (restricted component) antibody may emerge when EA-d lapses. The only reliable marker of infection in transplant recipients is seroconversion or a four-fold rise in VCA IgG. Some patients may generate an IgM response and some may also develop persistent EA-r antibody. None manifests heterophile antibodies[203].

Other studies

Lymphoproliferative lesions should be examined histologically and surface markers of lymphoid cells studied to determine clonality. EBNA staining of touch imprints and frozen sections using appropriate controls and DNA hybridization studies on fresh tissue frozen at –70°C to detect EBV genomes, help to establish EBV causality[366]. Detection of EBER-1 RNA in tissue is confirmatory[372,384,387]. Karyotypic analysis also helps to detect the presence of cytogenetic abnormalities such as oncogenic translocations.

Treatment

Reducing immunosuppression

In 1984 Starzl *et al.* described 17 recipients of various organs who subsequently developed LPS while on regimens containing CsA. In patients in whom LPS was diagnosed pre-mortem, immunosuppression was decreased in all but one. Eight patients had combinations of surgical excision, irradiation, chemotherapy, and acyclovir[397]. Overall, tumor-free survival occurred in 11, six of whom had reduction of immunosuppression as the only treatment. At the University of Pittsburgh the usual approach to patients with EBV-LPS is to decrease CsA to a dose that provides serum levels of 50–100 ng/ml by high-density liquid chromatography (HDLC). If an organ is expendable, immunosuppression may be stopped altogether. Acyclovir is reserved for unresponsive lesions.

Acyclovir

The University of Minnesota has been the main proponent of acyclovir therapy (500 mg/m^2 every 8 hours) for patients with group I or group II LPS[390,398]. Other investigators have reported no benefit[399,400]. However, although acyclovir inhibits EBV replication, reduces the number of VCA-positive cells, decreases the number of viral genomes per cell *in vitro*, and suppresses oral EBV shedding *in vivo*, the effects persist only during the course of therapy. Return of viral replication and clinical LPS occurs when acyclovir is stopped. Of particular concern is the possibility that acyclovir therapy may facilitate the transition from polyclonal to monoclonal B cell lymphoma; such tumors contain latently infected LCL which are acyclovir-insensitive because there is no active production of DNA polymerase for acyclovir to inhibit[397].

Ganciclovir

Ganciclovir is more potent than acyclovir *in vitro* against EBV. Pirsch *et al.*[400] reported two patients with severe polyclonal LPS, unresponsive to reduction of immunosuppression plus acyclovir, who were treated with ganciclovir at a dose of 3 mg/kg every 12 hours. One patient survived and is free of evidence of LPS

6 months after transplant nephrectomy. More data are clearly needed.

Monoclonal antibodies

Blanche *et al.* reported success with the treatment of two children with EBV polyclonal LPS following HLA-mismatched bone marrow transplantation with T cell depletion. Two antibodies were used: (a) CD24, which binds B cells at all steps of differentiation; and (b) CD21, an anti-C3d (anti-CR2) receptor antibody. Both patients had failed cessation of CsA, but had complete resolution of abnormalities over 2–3 weeks after antibody infusions, and remain well after 1 year of follow-up[401]. The authors reported further experience with 26 BMTx and solid-organ transplant recipients; the treatment was ineffective in patients with monoclonal B cell proliferation, but was successful in all patients with oligiclonal B cell proliferation who did not have CNS involvement[402].

Other modalities

Success has been reported in treating polyclonal and monoclonal PTLD with IFN-α and IVIG[403]. Monoclonal lymphomas do not respond well, though surgery, chemotherapy and/or radiation are indicated[373,375].

Prevention

The Mayo Clinic has established that EBV SNR in a study of 381 non-renal solid-organ transplant recipients have a risk of developing PTLD that is 24 times that of SPR, and that this risk is further amplified 4–6-fold by concurrent CMV mismatch and/or antilymphocyte therapy. Together, all three risk factors acted synergistically to increase the incidence rate of fatal or CNS PTLD by a factor of 654 over that of patients with none of these risk factors, regardless of the aggressive chemoprophylactic and immunoprophylactic regimens they used. The EBV SNR is being rejected for lung transplantation at their institution, and they have suggested that dual EBV/CMV seronegativity be considered a potential contraindication to transplant[404].

Antiviral chemoprophylaxis or pre-emptive therapy with ACV or GCV may be of some use to suppress low levels of viral replication such as exist in early reactivation during time of more intense immunosuppression. CMVIG also contains high levels of anti-EBV antibodies (Specialty Laboratories, Santa Monica, California) and needs to be looked at as an immunoprophylactic approach, either alone or in combination with chemoprophylaxis.

Given that the transplanted organ is often the focus of viral replication and disease, one approach would be to monitor the number of EBER-1 RNA-positive cells in routine post-transplant biopsies and begin immunosuppression reduction and/or pre-emptive therapy before malignant transformation occurs[387].

Herpes simplex virus (HSV)

HSV1 and 2 infections are not problematic in HTx and are easily treated with oral ACV. There have, however, been several reports of HSV pneumonitis, with some fatal outcomes, in early publications on HLTx/LTx[87,405]. In a study of 51 HLTx, Smyth *et al.*[406] reported six episodes of pneumonitis in five of nine HLTx with clinical HSV out of 23 SPR. Four patients were co-infected with CMV. No disease developed in SNR. Prophylactic ACV and GCV, as given to prevent other herpesvirus infections, are highly effective in suppressing HSV activity[407], and have been recommended for the HSV SPR in lung transplantation[406]. One case report of primary HSV infection in two recipients of kidneys from the same donor suggests that donor-transmitted disease can also rarely occur[408].

Varicella–zoster virus (VZV)

By the age of 15 years >85% of the population has had varicella, so that this infection is mainly a problem of pediatric transplantation, especially BMTx[409]. A live, attenuated varicella vaccine is now available[410], and SNR should receive it prior to transplantation. Vaccinees shed virus for approximately 30 days, which poses a potential risk for transplantation occurring in that time period; as yet the risk is unknown, but pre-emptive ACV, ± varicella–zoster immune globulin (VZIG), should be effective. The problem of exposure of a susceptible (SNR) immunosuppressed patient to a recently vaccinated household contact has not been addressed, but options include forgoing varicella vaccination, avoiding contact for 30 days, or giving chemoprophylaxis with or without VZIG. Post-exposure prophylaxis with VZIG is indicated for the SNR with significant exposure to a diagnosed case of varicella and should be given within 72 hours[411]. Assuming that pretransplant immune status has been established by ELISA, fluorescent antibody to membrane antigen (FAMA), or immune adherence hemagglutination[412], SPR do not have to avoid contact with either varicella or zoster.

Untreated clinical disease in this population is often complicated by hemorrhagic pneumonia, hepatitis, encephalitis, and death[413], and there is some evidence for allograft injury similar to that caused by CMV[414]. Intravenous ACV, 10 mg/kg every 8 hours, or 500 mg/m^2 for children, should be started within 24 hours of onset[415].

Reactivation of varicella in the SPR occurs late after transplantation and causes zoster (shingles). While immunosuppressed patients can have unilateral pain and no skin findings, the usual presentation with dermatomal lesions with or without pain is most common. The process can take significantly longer to resolve, even with treatment. Neither the duration of acute pain nor the occurrence of post-herpetic neuralgia is affected by ACV, but an abbreviated evolution of cutaneous lesions results from starting ACV (in a dose of 800 mg four times daily for children and five times for adults) within 4 days of onset, and treating for 10–14 days. Patients should therefore be educated to report radicular pain and/or lesions immediately. Treatment is particularly indicated for ophthalmic, sacral, and multidermatomal zoster. Oral ACV does not achieve blood levels that correlate with inhibition of viral replication *in vitro* and immunosuppressed patients with VZV infections should be watched closely for signs of visceral dissemination that would dictate prompt initiation of intravenous ACV at a dose of 10 mg/kg every 8 hours[415–420].

Human herpesvirus-6 (HHV-6)

HHV-6, tropic for B lymphocytes, normal CD4+ T lymphocytes, and T-cell-derived lines[421], has no defined role in transplant patients, though both primary and reactivation infections have been documented in recipients by serology, positive blood cultures, and evidence of viral replication in circulating mononuclear cells[422]. Seroprevalence nears 100% by age 2–3 years[423]. There is significant sequence homology with CMV[424], which causes serologic cross-reactivity, and co-infection is common. HHV-6 has been linked to non-specific febrile illnesses after transplant[425], to exanthem subitum (roseola infantum) in children[426], and to lymphoproliferative processes[427,428].

Recently HHV-7 has been described; its clinical significance remains to be elucidated.

Hepatitis viruses

Hepatitis viruses A–E have now been described. Only hepatitis B (HBV) and hepatitis C (HCV) have an impact on thoracic transplantation; delta virus (HDV) replication requires co-infection with HBV, and results in fulminant hepatitis in countries such as Italy, where seroprevalence is high[429]. Primary infection in transplant recipients results from transfusion and transplantation from SPD to SNR, and through intimate contact with infected secretions, in which case HBV is a much more efficient infective agent than HCV. Immunosuppression of SPR causes active viral replication; reinfection with donor strains also occurs. All infected patients have the potential to proceed to chronic hepatitis, liver failure, and hepatocellular carcinoma[430–432].

The issues in transplantation are whether or not to transplant a SPR, and whether to use a SPD for either a SNR or a SPR. Protection of the SNR from exposure to contaminated blood products and sexual transmission is the same as for the population at large. Screening of blood donors and exclusive use of volunteered donations has reduced the incidence of post-transfusion HBV infection by 80%, so that >90% of transfusion-associated hepatitis is now caused by HCV or as yet unidentified agents[429]. At the present time the incidence of HBV infection after transfusion or transplant is approximately 0.002% per exposure[433].

HBV

HBV is a DNA virus which replicates by reverse transcription, a mechanism which is unusual for a DNA virus and is unique to the hepadnaviruses and a plant virus[429]. Hepatitis B infection results in persistent viral replication in 0.1–20% of infected patients[434], depending on geographic location and age; the average carrier rate in the USA is 10%. Persistent infection is characterized by detectable hepatitis B surface antigen (HBsAg), HBe antigen (25–50%), HBcAg (core antigen), HBV DNA, and/or DNA polymerase activity. HBsAg-negative persistent HBV infection attributable to levels of HBsAg lower than those measurable by the radioimmunoassay (RIA) test has been blamed for rare instances of transmission of HBV via seronegative blood products[435–437]. Although hepatitis B surface antibody (anti-HBs) confers protection against reinfection, renewed HBsAg positivity has been documented, both spontaneously and after immunosuppression in HBsAb+ patients[438,439].

Primary infection after transplantation causes fulminant hepatitis. It is not common practice to immunize thoracic transplant candidates with HBV vaccine, which would take 6 months to complete, or 2 months to achieve 90% immunogenicity. There are therefore no data on the efficacy of this plus hepatitis B immune globulin (HBIG) in preventing or attenuating hepatitis B in this situation; therefore, HBsAg positivity renders the donor unacceptable for the SNR.

Since a determinant of the HBsAg complex gives protective immunity against virus of any subtype[429], it seems feasible that the HBsAb+ recipient could accept an organ from a HBsAg+ donor, especially a HBsAg and HBV DNA negative one.

Initially, the HBsAg+ transplant recipient may actually seem to improve in terms of liver function tests and biopsy appearance, but after 2 years, liver damage usually proceeds relentlessly and/or hepatocellular carcinoma develops[430,440–443]. Corticosteroids particularly stimulate viral replication. The prognosis in renal transplant patients has improved with the advent of CsA-based regimens using reduced doses of prednisone but, prior to that, 38% had chronic progressive hepatitis, 38% had chronic active hepatitis, 42% had cirrhosis, and 54% died of liver failure in one study[440]. The subset of patients with evidence of liver disease, or with HBeAg and/or HBV DNA in the blood, has been shown to do much worse, so that HBsAg positivity itself may only be a relative contraindication to transplantation, and decisions as to candidacy should be individualized[6,440,444,445].

Treatment with IFN-α has not been as successful in transplant recipients as it has been in nonimmunosuppressed hosts[446]. Prolonged immunoprophylaxis with HBIG has been shown to be of some benefit in liver transplant patients, but is very costly[447].

HCV

HCV is an RNA virus of the flavivirus family that causes 80% of the progressive liver failure in both liver and non-liver transplant recipients[430] and has been linked to hepatocellular carcinoma as well[447,448,474]. The virus is acquired by parenteral contact with blood, by infusion of certain IVIG products[305], by transplantation[449–455], and inefficiently by sexual intercourse[432]. As with the herpesviruses, virus-specific cytotoxic CD8 T cells are responsible for lysing infected cells, a mechanism that is abrogated by immunosuppressive therapy, permitting persistent infection to go unchecked[461].

In one study, transmission by transplantation was infrequent and the resulting infection relatively inconsequential[451]. Diethelm *et al.*[452] and Vincenti *et al.*[451] have challenged the premise of Pereira *et al.*[449] that HCV is transmitted by this route. In Pereira's studies[449] of the outcome of 29 recipients of organs from 12 confirmed SPD (1.8% seroprevalence) of kidneys, hearts, and livers, 75% of SPD-transmitted HCV and liver disease was documented in 14 recipients (48%) by 6 months (mean 3.8± 1.5 months), with no difference in rates according to organ transplanted. Chronic liver disease developed in 12 (86%) and subfulminant liver failure in two (14%). Liver biopsies showed chronic active hepatitis in six and cirrhosis in two. Liver failure eventually occurred in four (29%) and contributed to death in two (14%). In two other studies of renal transplant patients[430,439], clinical liver disease was unusual in the first 2 years after transplant, and the main effect of the infection during this time period was to

add to overall immunosuppression. After 2 years, infected patients went on to progressive liver disease. HCV has also been linked to aplastic anemia in this population[456–459].

Viremia develops within a few days of exposure. Symptoms occur at 6–7 weeks and correlate with elevated transaminases. Antibodies to HCV can be detected by second-generation ELISA ~2 weeks after that[460–464]. HCV RNA can be detected earlier by PCR, but a simpler and cheaper antigenemia test is needed. Antibody tests have gone through an evolutionary process aimed at improving the sensitivity and specificity. Of patients with well-documented chronic hepatitis C, 75–90%, and almost 100%, have positive first- and second-generation ELISA tests (EIA-1 and EIA-2), respectively[461]. A recently developed multiantigen enzyme immunoassay is the most sensitive assay to date, and will detect antibodies in immunosuppressed patients for whom conventional assays have been suboptimal[462].

The specificity of current tests is still, however, problematic, with false-positives seen in regular blood donors and in patients with hyperglobulinemia. The positive predictive value for the viral carrier state is still only ~0.5 among blood donors screened with a third-generation ELISA[463]. Confirmatory recombinant immunoblot assays (RIBA), of which the best one available is RIBA-3, are therefore important, especially in low-seroprevalence populations, though they are subject to misinterpretation. Indeterminate results, as indicated by the manufacturer, may in fact be positive when cross-checked with PCR for HCV DNA. With the EIA-2 or EIA-3 and the RIBA-3, seroconversion can be detected in the majority of patients within 4 weeks of onset of clinical disease. A core IgM antibody test is being evaluated[464].

Treatment with IFN-α has resulted in a fall in transaminase and HCV RNA levels in 40–50% of immunocompetent patients[465,466], but this success has not been duplicated in transplant recipients[203,430]. Ribavirin may decrease viral replication, but the response is not sustained. Recent data suggest synergistic benefit from a combination of the two modalities[467–469].

There is no known effective prophylaxis against HCV. Antibody to HCV is not protective against reinfection with either homologous or heterologous strains[470,471]. This, plus the fact that HCV displays antigenic drift, raises serious concerns about the possibility of developing a vaccine[464]. The present recommendation of the US Public Health Service is to limit the use of organs from HCV-positive donors to 'life-saving' transplant procedures, which include thoracic transplants[432]. Others[6,449,472] advocate not using them at all, even for SPR, because reinfection of the SPR with a donor strain could occur. The experience of many centers does not seem to reflect the findings of Pereira *et al.*, and, given the shortage of donors, they continue to transplant SPD organs into SPR[451–455]. Reactivated or up-regulated infection in the SPR appears to cause mild disease, but the long-term sequelae are not yet known.

Policies regarding SPD and SPR of thoracic organs are inconsistent across a wide range of centers responding to a survey published by Milfred *et al.*[472], though a follow-up survey 2 years later showed a marked increase in the number of centers which would not transplant SPR and would use a SPD organ only for SPR or status I candidates[473]. The presence of HCV RNA in the serum of the donor is the best predictor of transmission, and there is a much lower prevalence of HCV infection and clinical liver disease in the recipient of an EIA2-positive/HCV RNA-negative donor liver[474], suggesting that such organs can be used for transplantation especially in the case of urgent need. Until such time as a rapid test for HCV RNA becomes available, it seems reasonable to forgo transplanting SPD organs into SNR, but to continue to transplant SPD organs into SPR, with ongoing study, preferably on a multicenter basis, to further characterize the outcome of all types of HCV infections.

Retroviruses

HIV

Since routine serological screening did not became available until 1985, there has been much experience with primary infection as acquired by SPD of blood and/or organs and by high-risk behaviors in the community, and also with the course of disease in SPR[476–483]. Inadvertent transplantation of infected organs has occurred, presumably during the 6–8-week 'window period' when newly infected persons are viremic and have not yet produced detectable antibodies[483–486]. In some individuals, especially if immunosuppressed, this may take as long as 1 year[480,484,487,488]. False-negative results are also possible after massive blood transfusion, which can dilute antibody, as reported by Bowen *et al.*[478].

In a case report and review of the literature, Erice *et al.* noted that 28% of 88 HIV-infected transplant recipients described between 1985 and 1990 developed acquired immune deficiency syndrome (AIDS) at a mean of 27.5 months, and 80% of these died within 23.9 months of transplantation. Another 10% had, at the time of the report, developed HIV disease[482]. Seroconversion occurred within 2 months of transplant (range 5 to >135 days) and was associated with a non-specific febrile mononucleosis-like illness in some. SPR developed AIDS within 17 months as opposed to 32 months after primary infection in SNR. AIDS-defining conditions were similar to those in non-transplant patients, though a lower incidence of *Pneumocystis carinii* pneumonitis was probably attributable to routine post-transplant TMP–SMZ prophylaxis. Graft survival was not affected and, in fact, due to the immunosuppressive effects of HIV infection, many patients could be maintained on low-dose immunosuppressive regimens. Overall, the clinical course of HIV infection in transplant recipients does not differ much from other patients with HIV, except for earlier onset of AIDS.

Prompt treatment with azidothymidine (AZT) did not prevent infection of the SNR[478]. Current recommendations are to start AZT at lower doses (500–600 mg/day) when $CD4^+$ lymphocyte counts drop below 500/mm^3. Concomitant reduction in dosages of immunosuppressive medication will help to avoid bone marrow toxicity[482]. Other aspects of management are the same as for non-transplant patients infected with HIV.

Since serological testing can still miss infected donors, it is important to take a good history for any risk factors for HIV infection, which, if present, are a contraindication to donation.

Other retroviruses

Human lymphotropic virus 1 and 2 (HTLV-1, HTLV-2) and HIV-2 have similar modes of transmission to HIV-1[489]. HTLV-1 is endemic in Japan, the Caribbean, Africa, the southeastern USA, and South America[490], and causes T cell lymphoma/leukemia and

spastic paraparesis in a small percentage of infected individuals[490–495]. A case of rapidly progressive myelopathy resulting from transmission of HTLV-I from a blood transfusion during cardiac transplantation has been reported[496]. HTLV-2 has been linked to hairy-cell leukemia[497] and HIV-2 causes AIDS[498]. Screening for these viruses needs to be part of the work-up of donors.

Papovaviruses

These include the papillomaviruses, which can cause disfiguring warts in transplant recipients, and the polyomaviruses BKV and JC virus which infect most people during childhood and rarely result in disease in normal hosts, but cause progressive multifocal leukoencephalopathy in immunosuppressed patients[500], many of whom shed these viruses in secretions and urine. BKV has been associated with urethral stricture in renal transplant patients. Both may be oncogenic[499].

Community-acquired respiratory viruses

Adenovirus, RSV, parainfluenzavirus (PIV), and *influenza viruses A and B* all seem to cause more severe diffuse interstitial pneumonitis, associated with complications, in the transplant recipient, though this has not been well studied[6]. Adenoviruses also cause hepatitis, enteritis, nephritis, encephalitis, and hemorrhagic cystitis mainly in BMTx recipients[501–504]. RSV should be especially considered in pediatric recipients and should be treated with ribavirin[505,506]. Pneumonia due to parvovirus B19 has recently been reported in a HTx patient[507]. Yearly influenza vaccination is indicated in this population. Nosocomial spread may play a prominent role in transmission.

PARASITIC INFECTION

Toxoplasma gondii

The life cycle of the protozoan *Toxoplasma gondii* is completed in the cat, the only animal known to excrete the infectious oocyst[508], which is ingested by a variety of intermediate hosts, including domestic animals, whose meat and organs contain encysted parasites[509]. Humans acquire toxoplasma by ingesting soil contaminated with oocysts while farming, gardening, or changing cat litter, or by eating undercooked meat or possibly by drinking unpasteurized milk[510].

Less commonly, the organism can be transmitted via blood transfusion. *Toxoplasma gondii* remains viable in banked blood for 50 days at 5°C and can be isolated from buffy coat leukocytes over long periods of time in asymptomatic patients[511]. Because cysts persist in muscle, heart, brain, leukocytes, and lymph nodes for years, the organism can also be transmitted by transplantation[512]. HTx recipients have a higher incidence of toxoplasmosis (4–12%) than do other transplant recipients[513–517].

Clinical syndromes

Prevalence of antibody to *Toxoplasma gondii* varies with age and geographical location. In the usual thoracic organ donor population in the USA, approximately 15–30% will have had toxoplasmic infection (data adapted from Feldman[518]), and the transplantation of a heart from a SPD into a SNR has been estimated to occur 10% of the time[519].

Clinical disease is most prominent in HTx recipients and results from primary infection; it is rarely due to reactivation[520]. Symptoms can coincide with seroconversion at 4–6 weeks post-transplant or can follow as much as 10 months later, and represent CNS involvement with encephalitis, meningoencephalitis, or mass lesions accompanied by cerebrospinal fluid mononuclear pleocytosis with high protein concentration, or myocarditis simulating graft rejection. Pneumonitis can occur concomitantly[519–521].

Diagnosis

Strict pathologic and serologic criteria for the diagnosis of active infection and disease have been advocated by Remington and colleagues[520,521] and, as applied to thoracic transplantation, include:

(1) Compatible clinical manifestations.
(2) Histologic demonstration of toxoplasma tachyzoites in body fluid tissue or in association with numerous cysts in a localized area of tissue.
(3) Isolation of *Toxoplasma gondii* from blood or body fluids.
(4) Conversion of toxoplasma IgG antibody from negative to positive.
(5) High toxoplasma IgM titers with a single high-titer IgG antibody test.

Tests in common usage include the indirect fluorescent antibody test (IFA) which measures IgG antibodies, and the IgM immunofluorescent antibody test (IgM-IFA). Significant (≥4-fold) rises in antibody titer can occur without symptoms in transplant patients, and many will not generate an IgM response. Empiric endomyocardial biopsy may yield the diagnosis even in the absence of clinical myocarditis, but the pathologist must be alerted to look for toxoplasmosis[522].

Treatment

Pyrimethamine and sulfadiazine or triple-sulfa constitute successful therapy in most cases. Complete blood and platelet counts must be followed closely; hematologic side-effects can be countered with oral folinic acid (leukovorin). The regimen is given for 4–6 weeks after the resolution of symptoms, often resulting in therapy for 6 months or more. Approximately 80% of patients improve[519,521].

Prevention

In low-prevalence areas it is cost-effective to test frozen recipient serum only if donor serology is positive, and then to give prophylaxis to mismatches. Patients already on prophylaxis with TMP-SMZ are very likely protected against toxoplasmosis[515,523], but pyrimethamine prophylaxis (25 mg/day for 6 weeks) is what is recommended[6,516,517]. Monitoring toxoplasma IgG and IgM antibody tests with pre-emptive pyrimethamine and sulfa treatment given to seroconverters for 6 weeks is another approach. SNR of

SND organs should be taught to avoid activities that would expose them to *Toxoplasma*: (a) use gloves when handling raw meat, (b) eat well-cooked meat, (c) delegate litter-box duty to another, and (d) avoid cat feces while gardening or in children's sandboxes.

Pneumocystis carinii

Whether a fungus or a protozoan, this organism causes pneumonitis (PCP) and, rarely, disseminated infection in hosts with impaired cell-mediated immunity. Before the implementation of routine prophylaxis with TMP-SMZ, attack rates were 5–41% for HTx recipients[84,524–526] and 16–43% for HLTx/LTx recipients[85,527,528]. Hughes *et al.* definitively established low-dose TMP-SMZ as effective for the treatment and prevention of PCP[529–531]. The recommended duration of prophylaxis varies from at least 4–6 months post-transplant[6,532]. In those patients who require more prolonged or repeated immunosuppression to treat rejection, it should be continued for 12–18 months[532]. Dose recommendations vary widely[527,532,536]. Alternatives include dapsone and aerosolized pentamidine[536].

PCP without HIV infection has been particularly related to corticosteroid therapy[533,534]. In one retrospective study of 142 cases of PCP[534], the median time on steroids was 2 months (at a maximum dose of 40 mg/dl) and the risk appeared to be dose-related[534,535].

PCP in transplant patients presents more acutely than it does in AIDS patients, with fever, non-productive cough, dyspnea, interstitial infiltrates on chest radiograph, and hypoxemia out of proportion to the auscultatory or radiological findings. Diagnosis is confirmed with induced sputum[537] or bronchoalveolar lavage (BAL); biopsy should be done if the BAL is negative. Sensitivity has been improved with the use of monoclonal antibodies[538]. Co-infection with CMV is not uncommon and may facilitate PCP. Treatment with 15–20 mg/kg of the TMP component can lead to CsA interaction and renal failure[6].

Strongyloides stercoralis

Residence in or extended travel to endemic parts of the world (Latin America, Mexico, southern USA, and all countries outside of northwestern Europe) may expose patients to this nematode which can remain in the gastrointestinal tract for years without symptoms. With immunosuppression, fever, diarrhea, and disseminated disease can occur. Transplant candidates with a significant travel history or geographic origin should be screened with three stools for ova and parasites or empirically given a 2-day course of thiabendazole[539,540].

Trypanosoma cruzi

This protozoan, transmitted by the bite of the reduvid bug, causes American trypanosomiasis, or Chagas' disease, which is a lifelong infection. It is endemic in all Latin American countries, including Mexico, and it is estimated that 16–18 million persons are chronically infected[541]. Transmission by transfusion is a major problem in endemic areas[542,543], with a risk of 13–23% per unit of blood transfused in Brazil[544]. Acquisition through kidney transplantation has also been reported[545–547]. Seroprevalence in Santa Cruz, Bolivia, approaches 50%[548].

In the USA vector transmission occurs rarely, despite the fact that many insects and wild mammals of the south and southwest are infected. With the continued influx of Mexican and Central American immigrants, acquisition by blood transfusion[549] and transplantation is likely to be more common. Transfusion-related trypanosomiasis has occurred in two Americans and one Canadian[550–552]. The seroprevalence in a group of Salvadoran and Nicaraguan immigrants living in the Washington, DC area was 5%, and extrapolation of these data suggests that there are 50 000–100 000 persons with chronic infection in the USA today[544].

Cardiac transplantation for end-stage Chagas' cardiomyopathy has been reported in 31 Brazilian[553,554] and six American patients[555], as of the time of publication of Kirchhoff's excellent review article[544], and results are summarized there. Outcome data on 12 of these patients indicate a high incidence of reactivation of disease (8/12) which responds to benznidazole or nifurtimox, but relapses off treatment. Lifelong suppressive therapy after transplantation may be effective. The toxicity of this is not known, except that both drugs cause lymphomas in rabbits[556]. Kirchhoff advocates avoiding transplantation for end-stage Chagas' cardiomyopathy.

Available tests have lacked sensitivity and specificity, but ELISA tests seem to be best[544,548]. Presence of IgM antibody may correlate with the infectivity of a unit of blood. With the low seroprevalence in the USA at this time there is no prospect for routine screening. However, Kirchhoff and co-workers found that eliminating high-risk blood donors in the Los Angeles area by questionnaire reduced the blood supply by only 2.1%[544] and correlated well with seropositivity. The seroprevalence of donors at that blood bank is 0.1%.

Organs from donors deemed to be at risk should not be transplanted unless shown to be seronegative by a reliable test.

Cryptosporidium

In immunocompetent hosts, this protozoan causes a self-limited diarrheal illness, but in the immunosuppressed patient, chronic disease with voluminous, watery diarrhea can result in progressive wasting and death[557,558]. The organism may be acquired through contact with infected domestic animals and contaminated water. Person-to-person spread has been described in day-care centers[559] and within families[560], and by sexual transmission[561].

Although transplant recipients would seem to be at risk for severe disease, there are no reports in HTx or HLTx/LTx patients. Collier *et al.*[560] reported on one BMTx recipient who did well with spiramycin treatment. High-dose azithromycin is an alternative, but may interact with CsA. Transplant recipients should be instructed in infection control measures to prevent acquisition of enteric pathogens.

COMMENT

Great strides have been made in transplantation. Continued improvement in the outcomes of the patients we transplant will

Table 6 Pretransplant work-up: recipient

Infection risk	*Specifics*	*Action*
Tuberculosis	Immigration from a high-prevalence country. Ethnic origin associated with high-prevalence, high-risk lifestyles/behaviors. Exposure to persons TB. Hx of a positive Mantoux	Place Mantoux skin test with controls and read at 48–72 h. Treat positives according to CDC guidelines[60]
Herpes simplex 1, 2	Hx of orolabial or genital lesions	Give prophylaxis only for frequent recurrences
Varicella–zoster	Hx of chickenpox or shingles	Varicella immune status by reliable test
Epstein–Barr virus	Hx is often negative though >90% of adults are VCA-IgG positive	Serology is not helpful unless donor : recipient matching or prophylaxis is planned. Testing stored sera may aid diagnosis later
Cytomegalovirus	Hx of blood transfusions	Positive CMV IgG may dictate post-transplant prophylaxis
Hepatitis	Hx of blood transfusions, high-risk behavior	HBV and HCV serology indicated in all candidates. Positive HBV serology is a contraindication to transplant. HCV ELISA+/RNA – organ may be safe to transplant, especially in a HCV+ recipient
Toxoplasmosis	Cats, undercooked meat ingestion	Do toxoplasma IgG on stored sera if donor is positive. Treat SNR with pyrimethamine or TMP/SMZ × 6 weeks.
Geographic exposure Hx	SW USA (coccidioides) Third world travel/residence	Work up any diarrheal or other illness that seems travel related. Stools × 3 for *Strongyloides* or empiric thiabendazole. HIV-2, HTLV-1 antibody
	Mexican, Central or South American	*Trypanosoma cruzi* serology × 2 transplant contraindicated for SPR
Hx of recurrent infection	UTI, upper and lower respiratory infection dermatitis, dental status	Assess for potentially corrective measures
Pets/hobbies/habits	Who changes the cat litter? Bird exposure? Spelunking? Aquarium cleaning? Eating habits: unpasteurized dairy products, undercooked meat?	Lifestyle changes, avoidance of high-risk exposure, barrier precautions
High-risk behaviors for HIV: male to male sexual intercourse, IV drug abuse, birth to an HIV+ mother, intercourse with an HIV+, blood transfusion before 1985, never tested	Candidate could be in the seronegative 'window' period Risk factors for other retroviruses include geographic exposure and drug abuse	HIV antibody indicated for all candidates; transplantation not advisable for SPR. Consider exclusion of the high risk candidate until repeat test at 3–6 is negative HIV–2, HTLV–1 and 2 antibody
Immunization Hx	All candidates: Tetanus–diphtheria booster in past 10 years. Pneumococcal 23 serotype vaccine Influenza vaccine this year	No? Update No? give Give if seen between October and February
	Children/young adults: Childhood immunizations MMR booster Varicella non-immune	Complete DPT, OPV, MMR, HBV No? Give ? Give varicella vaccine

Store a sample of serum to help with diagnosis and/or studies later.

depend on further innovations that decrease net immunosuppression[6] and prevent infection. An approach to screening donors (Table 5) and recipients (Table 6) and preventing infection and/or disease (Tables 3 and 4) is summarized above. Collaborative clinical research is desperately needed to arrive at standard approaches to these issues, given the sample sizes that exist in any one center.

33
Pathology of Cardiac Allograft Vasculopathy (Chronic Rejection)

A.G. ROSE

INTRODUCTION

In the quarter-century since the first human heart transplant was performed by Barnard in 1967[1], this operation has become a well-established therapy for treating irremediable cardiac failure. Survival rates have progressively improved[2,3] (Chapters 43 and 44) and the 1-year survival following the operation is 80% or greater. Over 20 000 heart transplants have been performed worldwide. In patients who die in the first few months after cardiac transplantation when immunosuppression is maximal, infection is a major cause of death[4,5] (Chapter 32). Rejection is also an important factor which, if not primarily responsible for the patient's death, contributes significantly to it, even when overwhelming infection is present[6,7]. The clinical pattern of acute cardiac rejection, and the role of endomyocardial biopsy in its diagnosis, have been outlined in Chapter 30.

Acute rejection may be encountered beyond the first few weeks post-transplantation, and may be seen in patients who die years after transplantation. With longer survival one has the progressive development of a chronic rejection response that is dominated by obliterative lesions affecting both the large, epicardial coronary arteries and their intramyocardial branches.

In 1968 Lower and his colleagues were the first to draw attention to the proliferative and obliterative intimal changes of chronic vascular rejection in the epicardial coronary arteries of long-surviving canine transplants[8]. The first description of a human heart with the obliterative vascular changes of chronic rejection was in 1969, when Thomson described the donor heart of Barnard's second cardiac transplant patient who had survived almost 20 months after transplantation[9]. In 1970 Bieber *et al.*[10] described their experience with graft coronary disease. Since then, with longer survival times, this lesion has been recorded with increasing frequency[6,7,10–17]. Graft arteriopathy is currently the major factor limiting the long-term success of cardiac transplantation.

MACROSCOPIC APPEARANCES

The donor heart with chronic rejection may show a variable spectrum of macroscopic appearances (Figures 1 and 2). The anastomotic sites usually show signs of complete healing within a few weeks. The sutures are often buried in connective tissue with smooth endocardial surfaces (mostly comprising compacted fibrin) overlying the surface of the anastomoses. In none of our patients have these been the site of macroscopic thrombus formation or infection. Depending on the degree of chronic rejection, the ventricular myocardium in some appears near-normal, while in others a varying extent of scarring (Figure 1), similar to healed infarction, is noted. In yet others there is evidence of

Figure 1 Bisected, explanted cardiac transplant of 18 months duration shows white stasis thrombi filling the apices of the left ventricle (left) and the right ventricle (right). Ventricular dysfunction was due to graft arteriopathy which had led to extensive fibrosis of both ventricles

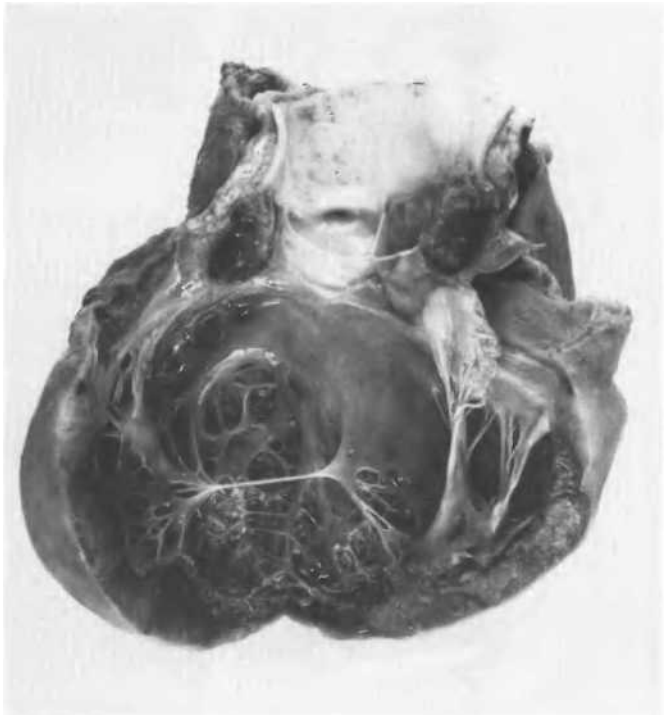

Figure 2 Stasis thrombus fills the left aortic valvular pocket. Extensive infarction of the left ventricular free wall is present. Prior organization of thrombus between the non-coronary and the right coronary leaflets has led to the development of an acquired bicuspid aortic valve

superimposed acute infarction caused by superimposed thrombotic obstruction of the coronary arteries (Figure 2). This is particularly prominent in heterotopic transplants which have ceased to function for some time before the patient's death, or before surgical extirpation of the heart.

In such hearts the coronary arteries appear macroscopically strikingly abnormal. The main coronary arteries and their epicardial branches are thickened, have a yellow-orange color due to lipid deposition in the vessel wall and, on transverse section, show a marked reduction in lumenal cross-sectional area, sometimes with accompanying thrombotic occlusion. In heterotopic transplants with chronic rejection examined at autopsy, mural stasis thrombus often occupies a large portion of both ventricular cavities of the donor heart. Stasis thrombi may also fill the valve pockets and occlude coronary ostia. The epicardial surface is bound by fibrous adhesions to adjacent structures, while the pulmonary arteries and aorta usually appear macroscopically unremarkable.

MICROSCOPIC APPEARANCES

Some microscopic changes of chronic rejection may be detectable as early as 1 month postoperatively. In one of our cases the intimal thickening of early chronic vascular rejection was observed as early as 20 days after transplantation. It should be borne in mind that a donor heart, even from a young person, may occasionally exhibit significant focal coronary atherosclerosis before transplantation.

A gradual development of the changes characterizing chronic rejection may be observed in the donor heart, depending upon the survival time of the recipient and whether death was primarily due to infection, late acute rejection, or chronic rejection. Even in patients who survive periods from 1 to 20 years, a proportion of the hearts examined at autopsy show evidence of coexistent acute rejection. These changes, similar to those already described (Chapter 29), take the form of infiltrates of lymphoid cells in the interstitium and subendocardial connective tissue. Many of these cells acquire abundant RNA-rich pyroninophilic cytoplasm. Such lymphocytic infiltrates may be difficult to distinguish from focal lymphocytic infiltration that may accompany previous zones of myocardial infarction on an ischemic basis.

Acute vascular rejection, presenting as fibrinoid necrosis of the walls of large and medium-sized coronary artery radicles, associated with an infiltrate of lymphoid cells, infrequently coexists. Evolving graft arteriopathy is often characterized by a lymphocytic infiltration in the subendocardial portion of a progressively thickening intima (Figure 3), as well as focally on the endothelial surface.

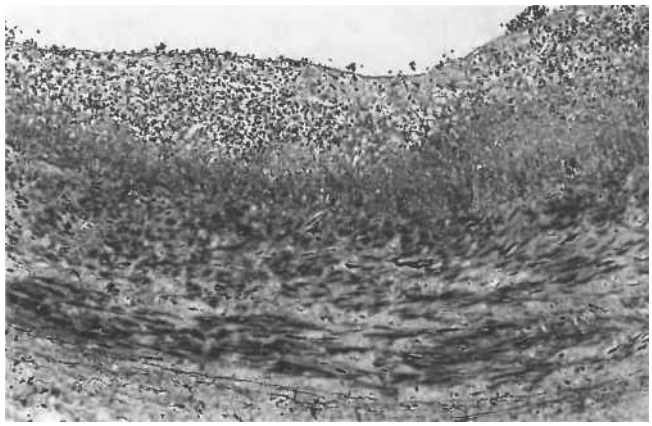

Figure 3 Evolving graft arteriopathy shows a lymphocytic infiltrate which is most marked within the upper portion of the intima (top). Lymphocytes are also seen within the adventitia (bottom) (H&E, × 24)

The most striking and significant component of chronic rejection is the process of graft arteriopathy which, due to continued proliferation of myointimal cells, leads to progressive obliteration of the lumena of the epicardial branches of the main coronary arteries (Figures 4–11), their penetrating branches and some intramyocardial, small coronary arteries. It should be noted that the latter (penetrating and smaller intramyocardial) arteries are usually unaffected by ordinary atherosclerosis. Lipid deposits are seldom seen in the thickened intimas of the intramyocardial vessels in chronic rejection. The intimal thickening in the epicardial coronary arteries may be concentric or eccentric (Figures 5 and 6), whereas the intramyocardial arteries usually show concentric intimal thickening.

Since the arterial changes in chronic rejection appear to be an accelerated form of atherosclerosis, understanding of the pathogenesis of atherosclerosis may be enhanced if the reason for this differential involvement of the penetrating branches of the epicardial coronary arteries could be elucidated.

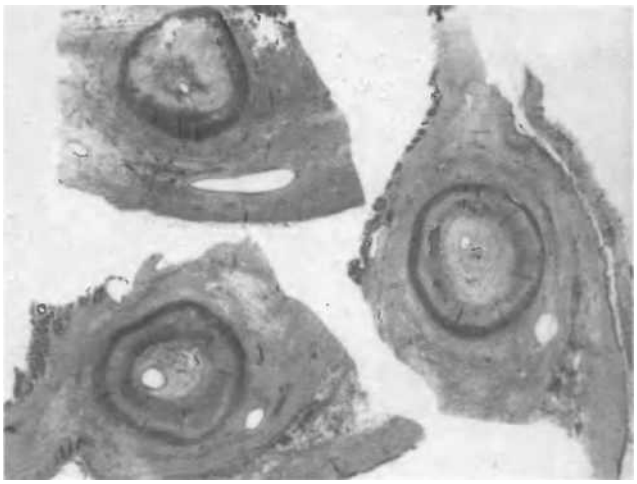

Figure 4 Chronic vascular rejection. These epicardial coronary arterial branches are almost totally occluded by concentric intimal thickening which mimics natural atherosclerosis. Graft survived 12.5 years (H&E, × 4)

Figure 6 Eccentric intimal thickening in another coronary artery in the same donor heart illustrated in Figure 5 (H&E, × 8)

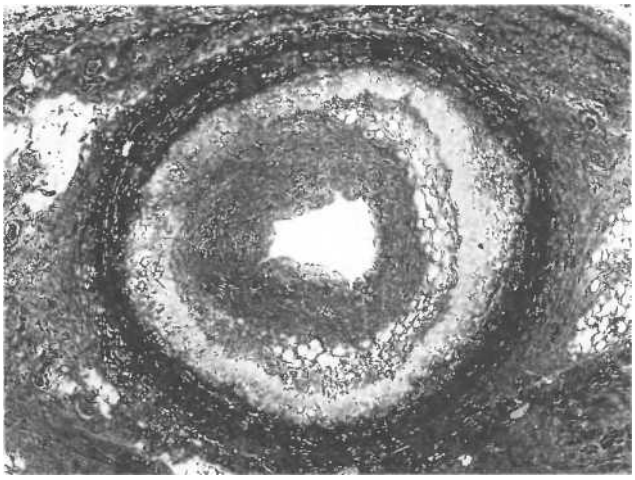

Figure 5 Concentric coronary arterial intimal thickening in a 537-day-old cardiac allograft. The intima has a lipid-rich deeper portion which is covered by a circumferential, thick fibrous cap (H&E, × 10)

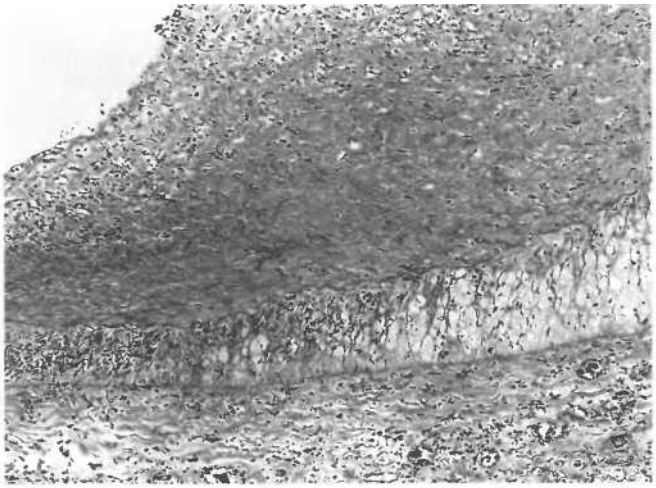
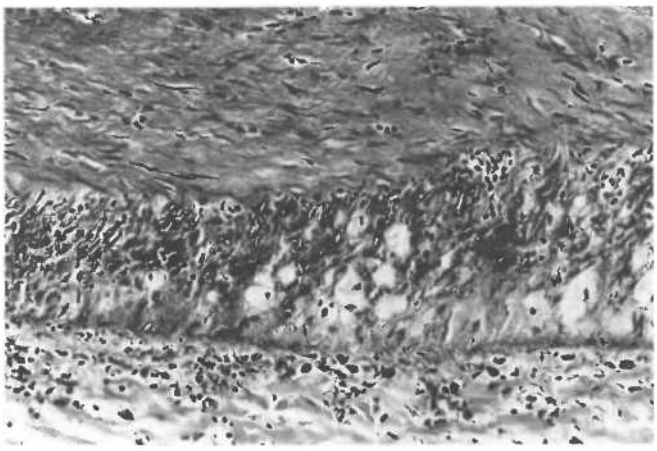


A



B

Figure 7 Foam cell transformation of donor coronary arterial media in graft arteriopathy. The thickened intima (top), the media (middle) and the adventitia (bottom) contain variable numbers of lymphocytes (both H & E, A × 34 and B × 80)

Initially, the lipid deposits in the major epicardial coronary arteries are observed in myofibroblasts and macrophages. Later these cells disintegrate and release free-lying lipid. There is a variable lymphoid cellular infiltration of the walls of the affected vessels. Endothelialitis is a term currently in vogue, but its relationship to the subsequent development of graft arteriopathy is still an open question. The internal elastic lamina may be fragmented, and occasionally large gaps in both the elastic lamina and the media may result from healed arteritis.

These lesions of chronic rejection in the large coronary artery branches, particularly when associated with abundant lipid deposition in the thickened intima, bear a close resemblance to ordinary advanced atherosclerosis of native coronary arteries. The smaller coronary artery branches more often show reparative fibrosis of previous medial necrosis, giving the lesion the appearance of a healed arteritis. Mostly the intramyocardial coronary

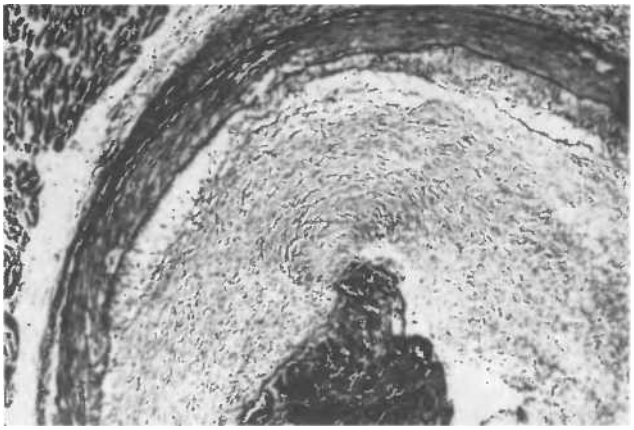


Figure 8 Graft arteriopathy (2.7 years post-transplantation) with superadded recent occlusive thrombus (H&E, × 40)

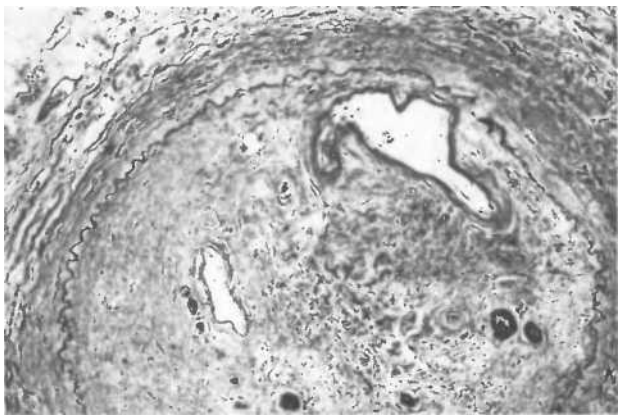

Figure 9 Advanced graft arteriopathy with organized, partially recanalized, occlusive thrombus. Graft survived 2.2 years (H&E, × 40)

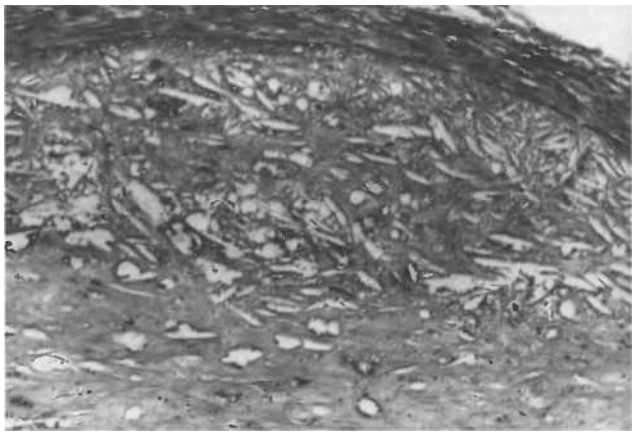

Figure 10 Natural atherosclerosis-like appearance of coronary artery in chronic rejection in a 4.2-year-old allograft (H&E, × 110)

arteries (Figures 12 and 13) show prominent, concentric intimal fibrosis of a marked degree.

Graft arteriopathy in the more severely affected large coronary arteries predisposes to superadded thrombosis, which appears as

Figure 11 Calcification within accelerated atherosclerosis-like plaque in left coronary artery of a 2656-day-old allograft (EvG, × 9)

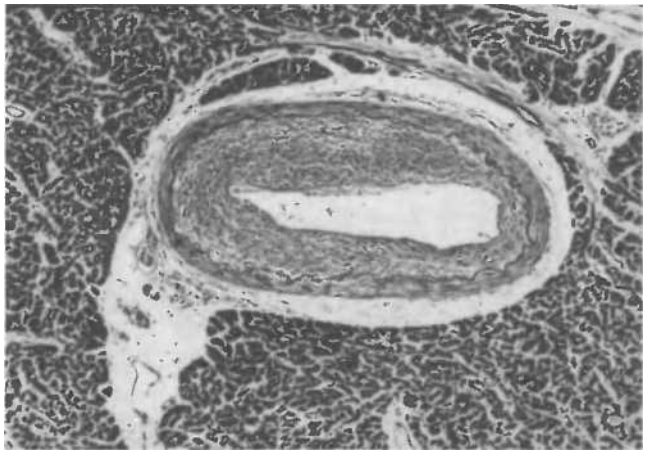

Figure 12 Small, intramyocardial coronary artery shows moderate lumenal stenosis due to almost circumferential intimal thickening caused by intimal smooth muscle cellular proliferation with fibrosis. Graft survived 12.5 days (H&E, × 60)

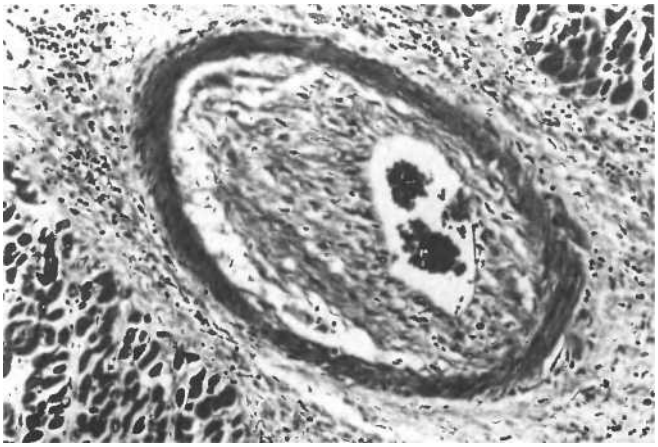

Figure 13 Intramyocardial coronary artery, which is slightly obliquely sectioned, shows severe lumenal stenosis due to intimal thickening. Scanty foam cells are present in the deeper portion of the thickened intima (H&E, × 75)

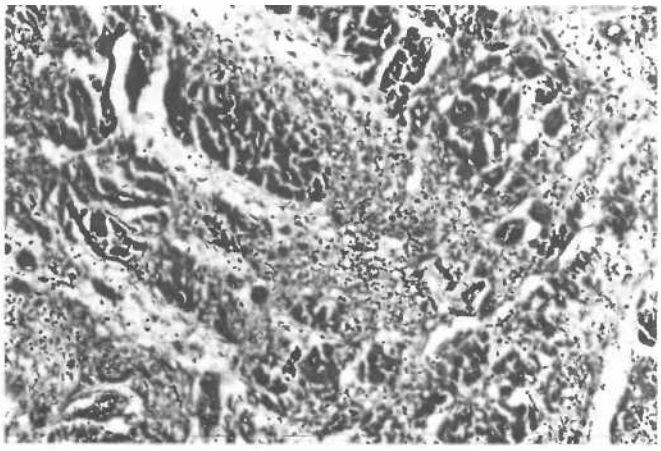
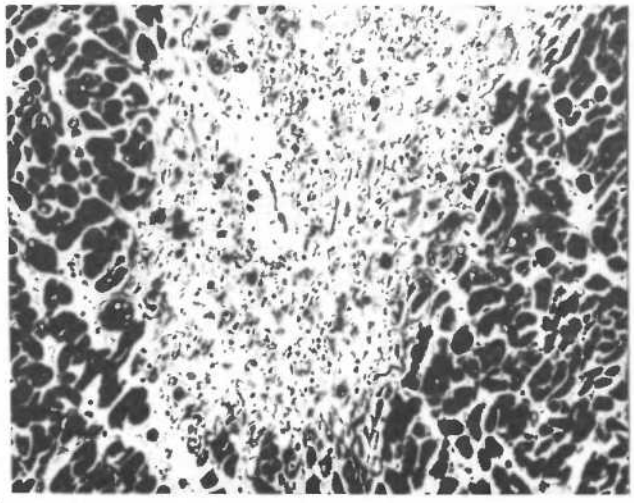
fresh thrombus in a few cases (Figure 8), but in the majority as old occlusive thrombus, which has undergone fibrous replacement and recanalization (Figure 9). Veins are seldom affected by this process and such involvement when present does not produce more than modest intimal fibrous thickening.

Frequent scars are noted in the myocardium. In some, the remnants of degenerate myocytes occurring in collapsed stroma in the presence of a lymphoid infiltrate suggest previous foci of myocytolysis (Figures 14 and 15). In others the appearance of large acellular scars is indicative of fibrous replacement of ischemic infarcts (Figure 16). Extensive acute infarcts may be observed in heterotopic transplants with thrombotic occlusion of severely narrowed coronary arteries.

The obliterative vascular changes may lead to extensive loss of ventricular myocardium, and the resultant massive fibrous replacement is often most evident in the right ventricle (Figure 17). Subendocardial myocytes (Figures 17 and 18) are kept alive by intra-cavity blood. This may be a cause of misleading results on endomyocardial biopsy, since the biopsy may show relatively normal myocytes at a time when much of the ventricle exhibits replacement fibrosis.



A



B

Figure 14 **A**: Multiple foci of myocytolysis caused by graft-arteriopathy-induced partial ischemia have evoked a lymphocytic response (H&E, × 105). **B**: Scar showing remnants of degenerate myocytes and persisting lymphoid infiltrate suggestive of previous myocytolysis. Graft survived 2.7 years (H&E, × 130)

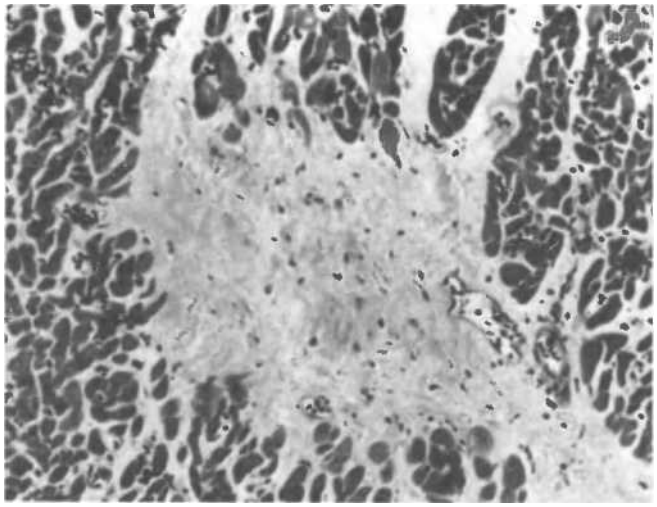


Figure 15 Small, dense, hypocellular scar, possibly due to previous myocytolysis with stromal collapse fibrosis due to ischemia caused by chronic rejection in a 1.6-year-old graft (H&E, × 170)

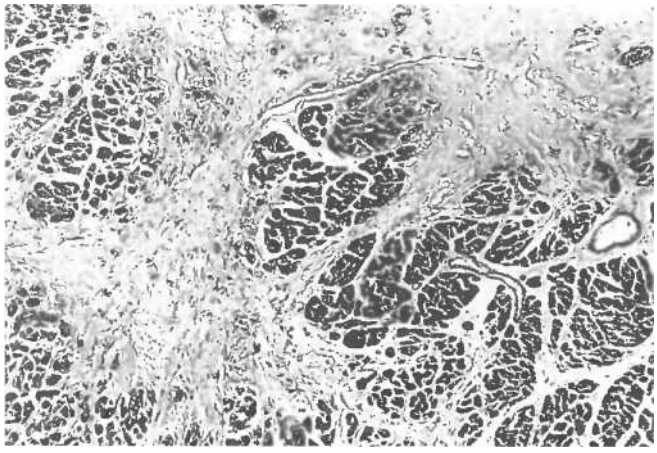

Figure 16 Large, acellular, fibrous scar of healed myocardial infarction. Graft survived 12.5 years (H&E, × 48)

Other cardiac structures are surprisingly little affected. Intimal fibrosis of modest degree with some loss of medial smooth muscle may be observed in both the aorta and the pulmonary arteries, with little accompanying cellular infiltration. Only in the presence of severe acute rejection are the valves affected by a focal lymphoid infiltrate. Chronic rejection does not appear to produce any specific changes in the heart valves.

INCIDENCE OF CHRONIC REJECTION

The frequency with which chronic rejection changes occur in long-surviving cardiac transplants is illustrated by a personal

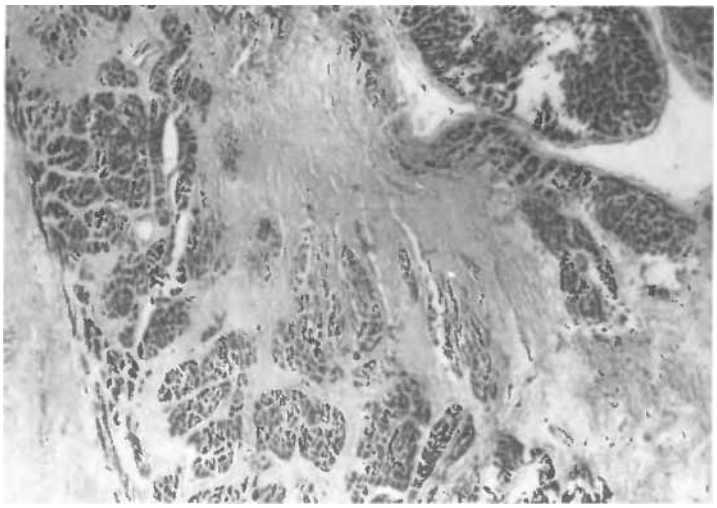

Figure 17 Massive replacement fibrosis of the right ventricle due to chronic rejection in a 12.5-year-old graft. Note the survival of subendocardial myocytes (H&E, × 3.4)

study of 12 patients with 14 cardiac transplants with survival times greater than 1 year[18]. These consisted of three orthotopic and nine heterotopic transplants examined at autopsy, and two surgical specimens from patients who underwent heterotopic retransplantation. The grafts survived 1.1–12.5 years with a mean of 2.7 years.

Histologically, 29% of hearts showed evidence of persisting acute rejection, and 93% showed signs of significant chronic rejection. In the response of chronic vascular rejection, severe myointimal proliferation was present in most cases (86%), while a cellular infiltration of the vessel wall was generally absent (72%).

The degree of vascular occlusion of chronic rejection bore no relationship to the frequency or severity of previous acute rejection episodes. Severe lumenal encroachment of between 51% and 100%, resulting from these changes, was frequently present (79%), while superadded thrombosis of the affected arteries was present in 72% of cases. Myocardial scars were present in 92% of hearts, while extensive acute infarction was present in 43% of heterotopic transplants. Further, it is striking that in all of the cases with chronic rejection there was an almost complete absence of infective lesions. A significant degree of rejection was responsible for the patient's death or graft failure in 79%.

FEATURES DISTINGUISHING GRAFT ARTERIOPATHY FROM ORDINARY ATHEROSCLEROSIS

In a later personal study of 43 human allografts with graft arteriopathy[19] the coronary arteries showed purely concentric narrowing in 56% of patients and eccentric narrowing in 44%. Others[20] stress the concentric nature of graft coronary disease compared to naturally occurring atherosclerosis, but this differs from our experience even in grafts with a mean duration of only 2 years.

Whilst many vessels affected by graft arteriopathy showed changes indistinguishable from ordinary atherosclerosis, certain pathologic features separate graft arteriopathy from usual atherosclerosis: (a) the presence of either active or healed vasculitis in some of the affected vessels, (b) a prominence of outer medial defects due to mediolysis and/or foam cell transformation in the major coronary arteries, (c) the diffuse nature of the atherosclerosis-like changes, (d) obliterative narrowing of the intramyocardial coronary arteries and (e) calcification being observed less frequently in graft arteriopathy compared to usual atherosclerosis.

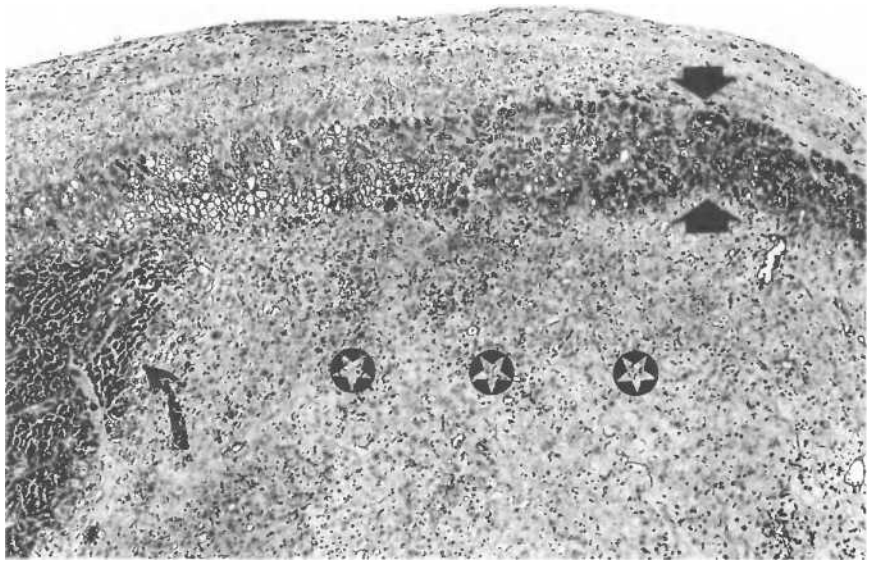

Figure 18 Graft arteriopathy has produced severe ischemic damage in the donor right ventricular subendocardium. A thin layer of surviving subendocardial myocytes (between the two arrows) contrasts with a paler, deeper zone of extensive myocytolysis (stars) and an adjacent zone of coagulative necrosis (curved

COMMENT

It is not safe to assume that the donor heart that is transplanted is always free of (significant) coronary atherosclerosis even with a young donor age. Pre-existent donor coronary arterial disease is easy to detect if the recipient dies (or if the graft is explanted) shortly after transplantation. If the graft lasts for a longer period, pre-existent natural atherosclerosis will be difficult to distinguish from graft arteriopathy despite the more often focal distribution of the naturally occurring disease. In a personally studied series[21] of 47 patients who died within 30 days following cardiac transplantation, pre-existent coronary atherosclerosis was found in 19% of the hearts (Figure 19).

The appearances of the vascular lesions of graft arteriopathy are those of a reparative process following immune-mediated intimal and medial arterial damage. The entire length of the coronary artery is affected by the immune insult, but the resultant lesions may show regional differences in severity.

The severity of these lesions bears no constant relationship to the survival time of the graft or patient. Graft arteriopathy may be detected as early as 3 months after transplantation. It is detected angiographically in over 50% of recipients 5 years postoperatively[22]. The incidence has even been put as high as 90% after 5 years[23]. It remains to be seen what effect on the prevention of allograft arteriopathy will be achieved by newer drug therapy with agents such as the calcium antagonist dilitiazem[24] and pravastatin[25,26] following grafting. Angiography tends to underestimate the severity of histologic determination of graft arteriopathic narrowing[27]. Myocardial bridges are also more frequently demonstrated in transplanted hearts angiographically[28], possibly due to increased myocardial stiffness and myocardial hypertrophy.

Von Scheidt and Erdman[29] reported a specific subtype of allograft coronary disease which they termed dilated angiopathy. This unique angiopathy, in which the dilated coronary arteries exceeded the diameter of adjacent vessels by at least 50%, was observed in 7.3% of their cardiac transplant patients. This angiopathy was as frequent as diffuse vessel obliteration in their patient population.

Inflammatory weakening of the media of the affected coronary arteries is the postulated etiology of dilated angiopathy. In this regard we found microscopic evidence of coronary vasculitis in 60% of our patients with chronic rejection[19]. Active vasculitis was evident in 21%, both active and healed vasculitis was present in 19%, and healed vasculitis was seen in 21%. As far as I am aware, no pathologic study has been performed to define the microscopic features of dilated angiopathy. Dilated angiopathy has a better prognosis than its obliterative counterpart[29].

Gravanis[30] considers cell-mediated immunity to be the basis for graft arteriopathy. This proliferative arterial lesion is not unique to cardiac allografts[31], but has been described in every organ grafted, including the kidney, liver and lung. Libby *et al.*[32] have advanced a unique hypothesis for cardiac allograft vascular disease. They observed a significant deposition of CD4 lymphocytes and macrophages plus smooth muscle cells just below an intact endothelial cell layer in patients with allograft coronary disease. These vascular wall cells have important immunologic capabilities not only in presenting antigen, but in stimulating the release of growth factors and cytokines, which might result in a chronic, local delayed-type hypersensitivity reaction. Others are paying attention to factors derived from endothelial cells (e.g. endothelin-1 mRNA and peptide expression) that are up-regulated in allografts with rejection and graft arteriopathy[33].

Since T-lymphocyte depletion has been used effectively to prevent graft-versus-host disease in bone marrow transplantation, it has been suggested that this therapy may be applied to cardiac transplantation in order to prolong graft survival[34].

Not all vessels in the donor heart show accelerated atherosclerosis, which is surprising in view of the suspected immunological etiology. The determining factor for graft survival, in the presence of chronic rejection, is myocardial ischemia, manifesting as extensive recent or old infarction. The fact that donor hearts are generally procured from young people further underlines the significance of this event. This situation is ironic, since ischemic heart disease is a frequent indication for cardiac transplantation.

While endomyocardial biopsy is an effective means of monitoring acute rejection episodes, it is of less use in chronic rejection. Experience has shown that extensive RV myocardial fibrosis may exist, which is not detected in a superficial endomyocardial biopsy, in which the subendocardial myocytes remain viable since they are nourished by the RV intra-cavitary blood. Similarly, the biopsy does not include coronary arteries, which are the vessels affected by the process of chronic rejection. Chronic rejection (graft arteriopathy) continues to be the major factor limiting the long-term success of cardiac transplantation.

Figure 19 Pre-existing, natural atherosclerosis of a donor heart's left anterior descending coronary artery. The donor heart, which came from a 47-year-old female, had only been implanted for 7 days (H&E, × 12)

Pathogenesis of Cardiac Allograft Vasculopathy (Chronic Rejection)

B. ARKONAC AND J.D. HOSENPUD

INTRODUCTION

Despite the dramatic improvement of early and 1-year survival following cardiac transplantation, long-term mortality has not been substantially impacted[1]. The major cause of late mortality is an accelerated obliterative coronary artery disease, presumably a manifestation of chronic rejection[2], which will be referred to in this review as cardiac allograft vasculopathy (CAV). The incidence of CAV is between 10% and 15% per year, with a prevalence of as high as 45% at 5 years based on angiographic diagnosis[3]. With the more sensitive intravascular ultrasound, some investigators have reported virtually 100% prevelance of the disease[4]. This review will focus on the pathophysiology and immunologic mechanisms proposed for CAV, as well as current diagnostic and potential therapeutic interventions for the disease.

PATHOLOGIC FINDINGS

The pathologic features of CAV (Chapter 33) differ from the native coronary artery arteriosclerosis in many aspects, especially early in the disease process (Table 1). In native coronary arteriosclerosis, typically the lesions are focal, predominate at the proximal bifurcations of the coronary system, and are eccentric in their distribution. The lesions frequently contain calcium, and the internal elastic lamina is disrupted. This process usually takes several years even in its most aggressive manifestations as seen in patients with multiple risk factors, including familial hyperlipidemia[5].

The pathologic findings of end-stage CAV may eventually match the above features, but the initial presentation differs. Typically, the endothelial layer is intact and, as demonstrated in Figure 1, there is a significant concentric intimal hyperplasia[6]. The internal elastic lamina is also intact until very late in the disease process, when it may be disrupted. Calcium deposits are rarely present. Although originally described as a bland proliferative lesion, more careful examination has demonstrated an inflammatory cell infiltrate, typically subendothelially[7]. Rarely, a frank vasculitic picture is observed[8,9].

The strongest evidence for this process being immune-related is its exclusive confinement to the allograft. In addition to the coronary tree, intimal thickening occurs in the coronary veins[10] and the great vessels up to, but not extending beyond, the suture line[11]. CAV is therefore a true vasculopathy, involving all of the vessels of the allograft, rather than solely an arteriopathy. Although this disease characteristically is diffuse, with greatest involvement of distal vessels[6], a more recent investigation has demonstrated that the appearance of increased severity in the distal vasculature is an anatomic phenomenon due to branching, rather than a physiologic difference[12]. Furthermore, nearly half of these patients have focal epicardial stenoses, more typical of the non-transplant-associated coronary artery disease[13,14]. In CAV, possibly as a result of the distal vessel obliteration, the coronary collateral formation develops in an atypical form, and has been described as a 'blush pattern'. This pattern may represent an angiogenic response to microvascular ischemia[15].

Table 1 Pathologic differences between CAV and CAD

Histologic attribute	*Cardiac allograft vasculopathy*	*Coronary artery disease*
Angiographic localization	Diffuse, distal	Focal, proximal
Intimal proliferation	Concentric	Eccentric
Calcium deposition	Rare	Frequent
Internal elastic lamina	Intact	Disrupted
Inflammation	Present	Rare

CLINICAL FEATURES

In contrast to traditional atherosclerosis, the time-course for the development of CAV is measured in months rather than years. Due to initial cardiac denervation at the transplant operation, clinical signs and symptoms of ischemia may be minimal. Generally, recipients who lack afferent cardiac innervation will not experience typical angina pectoris. There are, however, reports of patients late following cardiac transplantation experiencing chest pain, which is presumably anginal[16] and, more recently, chemical and physiologic evidence of partial autonomic reinnervation has been reported[17]. The problem of inability to experience angina is most important in CAV, but increasingly relevant is the transmission of pre-existing coronary artery disease due to the use of older donors. Tuzcu *et al.* demonstrated a high frequency of donor atherosclerosis in their series of 50 cardiac allograft recipients studied early post-transplantation by angiography and intravascular ultrasound[18].

Depending on whether there is a discrete clinical event such as a myocardial infarction, or more commonly progressive global myocardial ischemic dysfunction, clinical presentation can be quite insidious. Symptoms range from those as nondescript as malaise or decreased exercise tolerance, to overt congestive heart failure. Alternatively, the initial presenting finding can be arrhythmia or sudden cardiac death. Thus, the practice of performing annual screening coronary angiography is routine in most cardiac transplant programs. Currently, given limited intervention for this disease, this screening is used for prognostic purposes and the timing of repeat transplantation if this procedure is considered.

DIAGNOSIS

As stated above, although coronary angiography is the most widely used surveillance method internationally, it has been criticized for greatly underestimating the prevalence of CAV[19,20]. Despite this criticism, Everett *et al.*, in a small series of 28 cardiac allograft recipients, demonstrated that at 1 year the specificity of normal qualitative angiography in predicting absence of cardiac allograft vasculopathy is 81%[21], based on a change of luminal diameter by quantitative angiography.

When a more sensitive technique such as intracoronary ultrasound is compared with qualitative coronary angiography, however, 70–90% of transplant recipients who had normal coronary angiograms had significant intimal thickening[22,23]. Ventura *et al.*[24] compared routine coronary angiography, intracoronary ultrasound and percutaneous coronary angioscopy. The sensitivity for detecting plaque was 79% for percutaneous coronary angioscopy and 10% for angiography, and for detecting stenosis was 24% and 3%, respectively. For intracoronary ultrasound versus

angiography for plaque and stenosis detection, the sensitivities were 76% vs 10% and 45% vs 3%, respectively. The authors concluded that intracoronary ultrasound, when compared with percutaneous coronary angioscopy, is more accurate in assessing the severity of stenosis (45% vs 24%), and that intracoronary ultrasound could better detect calcification and presence of intimal thickening[24].

It is, however, unclear what prognostic significance ultrasound-diagnosed intimal thickening has in the face of normal angiography. To address this issue, Anderson *et al.*[25] assessed the functional significance of intimal thickening detected by intravascular ultrasound by investigating endothelial-dependent and independent vasodilatation in 40 patients 1–8 years post-transplantation. Endothelial dysfunction occurs early, even before intimal thickening, yet may recover in recipients that survive more than 5 years even in the presence of moderate intimal thickening. Recently, Heroux *et al.*[26] investigated the coronary vasodilatory response to intracoronary papaverine, and demonstrated that all the patients with intimal thickening by intracoronary ultrasound had blunted response to intracoronary papaverine, suggesting intimal injury resulting in decreased coronary EDRF production.

IMMUNOLOGIC MECHANISMS

Cocanougher *et al.*[27], using death due to CAV proven by autopsy as an endpoint, demonstrated in 101 patients that worse HLA match was associated with severe CAV. The association with HLA matching has also been suggested by Costanzo-Nordin[28], who demonstrated that complete HLA-B and DR mismatch is associated with a higher incidence of CAV. The general assumption is that CAV represents a chronic alloimmune response to the vasculature. Given this assumption, the likely target for the immune response is the vascular endothelium, which is appropriately located at the blood vessel interface, expresses both MHC class I and II antigens *in vivo* and *in vitro*[29–33], and can also serve as antigen-presenting cells, capable of presenting either alloantigen or nominal antigens such as microbiological antigens[34–39]. Finally, endothelial cells either express constitutively or can be induced to express a variety of adhesion molecules, such as intracellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1), necessary for the adherence of various classes of white blood cells to initiate the immune response[40,41].

Whether the vascular smooth muscle cells are capable of expressing appropriate antigens to augment an allogeneic response is still not clear. Salomon *et al.*[42] showed *in vitro* that there is no lymphocyte activation in a co-culture of interferon-pretreated arterial smooth muscle cells. In addition, Theobald *et al.*[43] demonstrated that, despite an increase in MHC class I and II antigen and an increase in ICAM-1 in response to IFN-γ, smooth muscle cells isolated from human umbilical veins were poor stimulators of lymphocyte proliferation. Contrasting these studies, Fabry *et al.*[44] demonstrated that both syngeneic and allogeneic rat splenocytes proliferated in response to brain microvascular smooth muscle cells, though the syngeneic response was greater than the allogeneic one.

Cellular versus humoral immunity

In general, most studies have been unable to find a correlation between typical cellular rejection and the ultimate development of CAV, with few exceptions[45,46]. Thus CAV was thought to be a manifestation of humoral immunity. This widely accepted opinion began to shift with the emergence of a number of animal studies using heterotopic models of heart and aortic transplantation. They all demonstrated the ability to reliably produce vasculopathic lesions which consisted of extensive mononuclear cell infiltration associated with smooth muscle cell proliferation and intimal thickening. A number of rat strain combinations have been investigated, which vary from mismatches at MHC class I, class II or minor histocompatibility antigens[47,48]. Recently, Adams *et al.*[49], using Lewis rats as donors and F344 rats as recipients (which match for MHC and differ for non-MHC), demonstrated diffuse arteriosclerotic lesions which were identical in appearance to those seen in human allografts. Their series demonstrated 20% acute rejection within 3 weeks, 50% surviving at least 3 weeks, and 25% surviving indefinitely. Rejected allografts demonstrated intense mononuclear cell infiltration and necrosis. Indefinitely surviving grafts demonstrated moderate mononuclear cell infiltration and myocyte destruction. More than 90% of all arteries present in allograft cross-sections demonstrated marked coronary intimal lesions. Early lesions consisted of subendothelial accumulations of mononuclear cells, while later lesions demonstrated diffuse fibrotic intimal thickening with occasional focal cellularity that was identical in appearance to CAV seen in humans[49].

Cramer *et al.*, using several rat strain combinations to select for mismatches in class I (RT1.A and C), class II (RT1.B and D), or only minor non-MHC antigens, demonstrated that CAV could be produced in a majority of combinations[50,51]. The severity of CAV was proportional to the duration of the allografting, suggesting the requirement of time (i.e. those allografts that rejected acutely showed little or no CAV). The severity of both the intimal proliferation and the intensity of lymphocytic infiltration could be enhanced by a single intraperitoneal injection of donor lymphocytes, and reduced by the administration of cyclosporin. The authors concluded justifiably that CAV in these models is not the result of an allogeneic response to a single specific vascular alloantigen, but may result from any number of different antigen mismatches. They also concluded that, based upon the ability to modify the lesions by immunization and T-cell-specific immunosuppression, CAV in these models is probably a chronic cell-mediated rejection response.

Using Lewis-to-F344 rat model, Cramer *et al.* studied the cellular composition of CAV serially from 7 to 90 days[52]. In these lesions the first cell line to appear was macrophages followed by T, natural killer and, to a lesser extent, B cells. The more bland lesions were made up primarily of smooth muscle cells.

Recently, several groups have begun using a rat heterotopic aorta allograft model. In this model a segment of descending thoracic aorta is looped and anastomosed end-to-end to the recipient abdominal aorta below the renal arteries and above the bifurcation[53–55]. Most recently, Shi *et al.* reported a new mouse model, in which the carotid arteries were transplanted between B.10A(2R) (H-2H2) donors and C57BL/6J (H-2b) recipients, and compared with arteries isografted between H-2b mice[56]. Both of these

models demonstrated similar histopathologic changes, which are basically seen in cardiac allograft models. The process starts with an inflammatory infiltrate containing activated T cells and macrophages followed by a progressive intimal thickening made up primarily of smooth muscle cells. The adventitia is infiltrated, with the external elastica lamina staying intact. The internal elastica lamina is also largely intact, but can show small areas of disruption. The advantages of these models are the large segment of vascular tissue that can be studied and the lack of the allograft being a vital organ. The difference between these models and the rat cardiac allograft model or the human disease is the extent of medial necrosis and complete replacement by fibrosis. It is unclear whether ischemia (the loss of the vasa vasorum with the transection of the vessel) plays a contributing role in this model. This important difference makes interpretation and the potential relevance of this model difficult to ascertain.

Evidence for cell-mediated immunity in human cardiac transplantation has been relatively rare. Although Uretsky *et al.* (1987) suggested that CAV is more common in patients with multiple episodes of cellular rejection[57], this has not been supported by most other series of cardiac transplant patients from individual centers. Multiple explant/autopsy series, although with small numbers of cases, supported the cell-mediated process with their histological studies. Liu and Butany[58] demonstrated cellular vascular lesions containing T cells and macrophages in both media and adventitia. Hruban *et al.*[59] showed marked lymphocytic endothelialitis in their cases with CAV. Salomon *et al.*[60] investigated seven freshly obtained allografts and demonstrated lymphocytes (both $CD4^+$ and $CD8^+$) and macrophages in coronary arteries in a ring distribution directly under the endothelial layer. They also noted an up-regulation of endothelial cell DR expression in these arteries.

We have investigated lymphocyte responses to donor-specific human aortic endothelial cells in 52 allograft recipients at three time-points following cardiac transplantation. First, as shown in Figures 2 and 3, despite a reduction in acute parenchymal rejection following transplantation, lymphocyte proliferation in response to donor-specific endothelial cells increases, as does the up-regulation of MHC class II antigen on the endothelium in response to the exposure to lymphocytes[61]. Furthermore, as shown in Figure 4, those patients who have developed CAV at 1 year post-transplantation have greater lymphocyte proliferation responses to their donor-specific endothelial cells at all time-points compared to those without CAV[62].

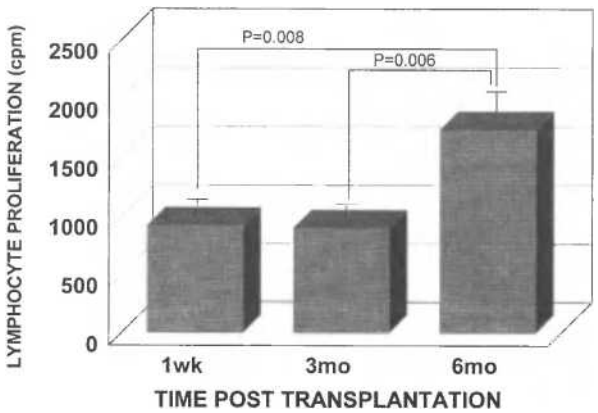

Figure 2 Lymphocyte proliferation to donor-specific aortic endothelial cells increases over time following cardiac transplantation (reprinted with permission, see ref. 61)

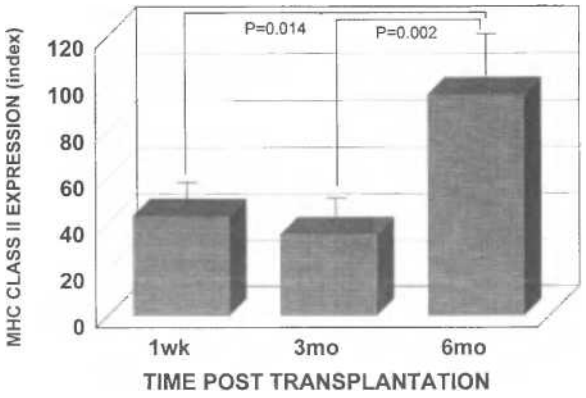

Figure 3 Endothelial cell expression of MHC class II antigen increases over time post-transplantation with exposure to recipient lymphocytes (reprinted with permission, see ref. 61)

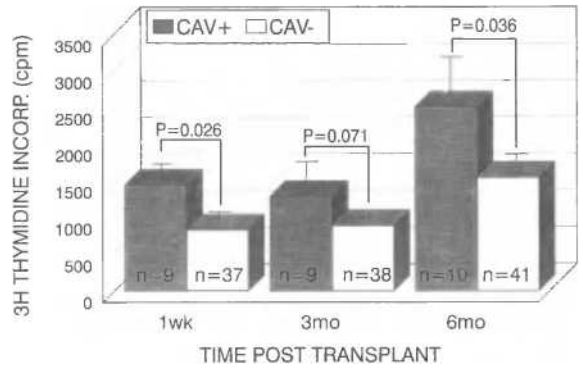

Figure 4 Lymphocytes obtained serially from patients who develop CAV 1 year following cardiac transplantation have a greater proliferative response to their donor-specific endothelium compared to those who have no coronary artery disease by angiography (reprinted with permission, see ref. 62)

The presence or development of antibodies to donor MHC antigens has long been associated with a reduction in graft survival, in the renal transplant literature[63]. In a recent study, Halloran *et al.*[64] reported on 13 patients who were prospectively identified as having antibody to donor class I antigens, and had higher frequency of acute graft rejection, endothelial abnormalities and ultimately a greater graft loss compared to 51 patients who did not have circulating anti-class-I antibody. Hammond *et al.*[65] demonstrated the association between antibody deposition in the cardiac allograft by immunofluorescence, acute rejection and reduced survival. They also presented data suggesting an increased incidence of CAV in those patients with positive immunofluorescence[66]. In a large retrospective study of 463 cardiac transplant recipients, Lavee *et al.*[67] demonstrated that the degree of panel-reactive antibody (PRA) positivity correlated both with acute cellular rejection within the first 3 months post-transplantation and with CAV. However, Smith *et al.*[68] demonstrated that although patients who

develop lymphocytotoxic antibodies directed against donor-specific HLA determinants had more cellular rejection, there was no increased incidence of CAV.

In the same study described above, we investigated the role of alloantibody to donor-specific endothelium using a flow cytometric assay for antibody binding. Of the 52 patients studied, two had positive antibody binding which was new, two additional patients had alloantibody detected which was known to be present prior to transplant (retrospective crossmatch), and four additional patients had borderline positive results. As shown in Figure 5, there was no relationship between the presence of alloantibody and the ultimate development of CAV on quantitative angiography[62]. Our negative findings have recently been confirmed by Mehra *et al.*[69] by comparing intravascular ultrasound to antibodies directed to umbilical vein endothelial cells and standard panel cytotoxicity assays.

A recent study by Rose and colleagues[70] showed that antibodies specific for the doublet of endothelial antigens (of polypeptides of approximately 60 and 62 kDa) are rarely produced by patients other than those with progressive CAV after transplantation. A follow-up of this study suggests that the target antigen is vimentin[71]. Given that vimentin is monomorphic, and does not vary within a species, it is unclear how an allogeneic response would develop to this protein. Alternatively, if this represents a sequestered (intracellular) antigen, its exposure by prior endothelial cell damage could elicit an autoimmune response.

Finally, Russell and colleagues[72] have demonstrated in a mouse model that, using the same degree of MHC mismatch, those strain combinations which result in alloantibody formation have a greater degree of intimal proliferation than those combinations where alloantibody is not produced. Furthermore, it appears that the intimal proliferative disease can be passively transferred in this model.

Based upon the available human evidence one must conclude that, although alloantibody may contribute to CAV, the data are insufficient to support a primary role. There are data, however, to support a complementary role for alloantibody if a cell-mediated response to vascular endothelium is important in the development of CAV. We have recently demonstrated that pooled serum containing high titers of alloantibody from patients awaiting renal transplantation increases the expression of ICAM-1 on vascular endothelial cells *in vitro*[73]. A typical experiment is shown in Figure 6. One could theorize that, once alloantibody develops, its presence could enhance T cell binding to the vascular endothelium. Alternatively, the development of alloantibody could solely

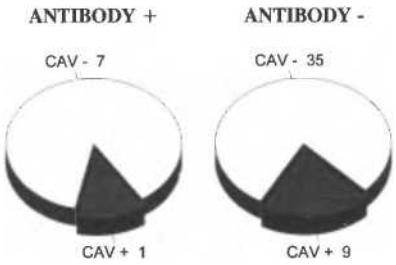

Figure 5 There is no correlation between antibodies in recipient serum directed to donor-specific endothelium and the development of CAV (reprinted with permission, see ref. 62)

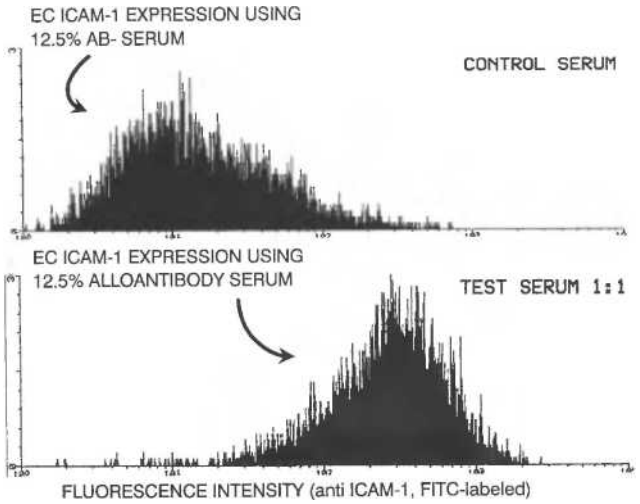

Figure 6 Serum containing high titers of anti-HLA antibodies stimulates endothelial cell up-regulation of ICAM-1: top panel, flow histogram using control serum; bottom panel, flow histogram using serum with anti-HLA antibodies (reprinted with permission, see ref. 73)

be an epiphenomenon of a more active cell-mediated response to vascular endothelium.

In preliminary studies[74] we have demonstrated that allogeneic lymphocytes can up-regulate endothelial IL-6, a cytokine which has, among other properties, the ability to recruit and expand B cell clones. The optimal production of endothelial IL-6 requires direct contact between the lymphocyte and endothelial cell. Although a variety of cytokines (IL-6, tumor necrosis factor-α (TNF-α)) are known to up-regulate endothelial cell IL-6, the regulation produced by allogeneic lymphocytes occurs extremely rapidly (peak mRNA response in 2 hours), suggesting that a second cytokine is not required.

Growth factors and cytokines

It has been well demonstrated that multiple polypeptide growth factors can act to modulate the proliferation rate of mesenchymal cells in either a promoting or a suppressing mode[75–77]. One family of growth factors that has been studied extensively is the heparin-binding growth factor/fibroblast growth factor (HBGF). Seven separate genes of the HBGF family have been identified: acidic and basic fibroblast growth factor (aFGF and bFGF), the int-2 locus, kFGF/hst, FGF-5, FGF-6, and keratinocyte growth factor (KGF). Platelet-derived growth factor (PDGF) is an another growth factor that is produced by a number of tissues, including endothelium, and is a potent smooth muscle cell mitogen as well as a chemoattractant. It is important to emphasize that smooth muscle cells likewise produce a number of growth factors and cytokines capable of amplifying smooth muscle cell proliferation (autocrine stimulation), including PDGF, bFGF, TGF-β, IL-1 and IL-6[78–81].

There is now emerging evidence that a variety of lymphokines and monokines can directly regulate the synthesis of growth factors, such as IL-1 stimulating the expression of PDGF-A gene in cultured fibroblasts, and TNF stimulating the endothelial cell release of PDGF[82–84]. Clausell *et al.* showed that, in the rabbit

heterotopic heart transplant model, *in vivo* blockade of TNF-α suppresses the acute development of neointimal formation by selectively reducing the vascular immunoinflammatory reaction and accumulation of fibronectin[85]. More recently, Russell *et al.*, in the Lewis-to-F344 rat transplantation model, have shown the allograft-specific up-regulation of IFN-α, IL-6, and monocyte chemoattractant protein-1 gene expression in cardiac allografts undergoing chronic rejection[86]. They also localized the gene products to infiltrating mononuclear cells in the interstitium and vasculature, supporting the cellular activation theory. Calderon *et al.* have demonstrated that IL-6 up-regulates PDGF B chain mRNA[87]. Ikeda *et al.* have shown that IL-6-dependent smooth muscle cell proliferation was blocked by monoclonal antibody directed against PDGF[88].

Recently, Oho *et al.*[89] reported a 10-fold increase in elastase activity associated with the development of post-cardiac transplant arteriopathy, and demonstrated a 5-fold increase in the breaks in the internal elastic lamina. They suggest that elastase may play a pathophysiological role in neointimal proliferation by potentially activating cytokines and growth factors, and by release of chemotactic peptides. Molossi *et al.*[90] demonstrated that in a piglet heterotopic cardiac transplant model there is increased fibronectin production by donor vascular endothelial cells, which is partly regulated by an autocrine mechanism involving IL-1β. They suggest that fibronectin may mediate lymphocyte trafficking and smooth-muscle-cell migration related to CAV. Recently, Zhao *et al.* have shown that the expression of aFGF and its receptor, along with PDGF A chain, is significantly increased in cardiac allografts during rejection, and that cardiac myocytes and vascular walls are the predominant sources for these factors[91,92].

We have previously reported that endothelial cells exposed to allogeneic lymphocytes up-regulate mRNA coding for a panel of mesenchymal growth factors, including bFGF, TGF-α, TGF-β, and PDGF A and B chains (Figure 7)[93]. We have now recently extended these findings to the cardiac transplant population. In those allograft recipients who ultimately develop CAV, their lymphocytes preferentially up-regulate mRNA coding for TGF-a, PDGF A chain and heparin-binding epidermal growth factor[94]. There is a direct link, therefore, between cell-mediated immunity to vascular endothelium, alterations in the levels of endothelial-cell-derived growth factors, and the ultimate development of CAV by angiography.

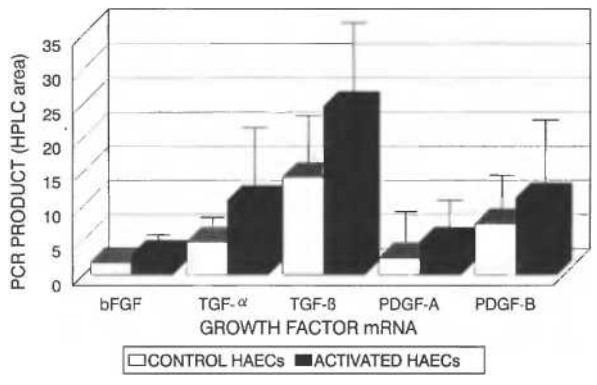

Figure 7 Endothelial cells exposed to allogeneic lymphocytes up-regulate mRNA levels coding for a panel of growth factors known to stimulate smooth muscle cell proliferation[93]

It is clear that the endothelial cell, and possibly the smooth muscle cell, can serve as targets for allogeneic immunity and be activated to produce a host of cytokines known to stimulate either paracrine or autocrine smooth muscle cell proliferation. In addition, several lymphokines and monokines directly stimulating these vascular cells can amplify this response.

NON-IMMUNOLOGIC PRECIPITATING FACTORS

Most transplant centers attempt to aggressively modify the usual risk factors for atherosclerosis, with the assumption that risk factors for native coronary artery disease may contribute to CAV. Although there are no controlled trials that have shown a decrease in the incidence of CAV with a decrease in serum lipids, several studies have documented the association between hyperlipidemia and CAV[95–101]. The development of hypercholesterolemia, an increase in low-density lipoprotein cholesterol, and hypertriglyceridemia have been uniformly shown to develop 3–18 months after heart transplantation in several studies[102–109].

It appears that multiple factors are in effect in causing post-transplantation hyperlipidemia, including (a) obesity that develops after transplantation[104]; (b) prednisone, by increasing hepatic apolipoprotein B production[103]; and (c) cyclosporin by inhibiting prednisolone clearance, either due to hepatotoxicity or interactions with the cytochrome P450 system[110]. Dietary changes frequently produce minimal lowering of cholesterol or triglyceride levels, leading to administration of lipid-lowering agents that may have troublesome side-effects, and that may interact with immunosuppressive agents. This makes their use difficult in the cardiac transplant population[108,111]. Of interest are the preliminary data from Kobashigawa *et al.*[112] suggesting that the early use of an HMG CoA reductase inhibitor (pravastatin) appears to reduce the development of severe CAV and the incidence of death in cardiac transplant patients on triple-drug immunosuppression.

Hypertension is common in post-transplant patients, especially in the cyclosporin era. However, studies have not found a relationship between hypertension and the development of CAV[95–99]. Likewise, smoking was not a factor in CAV development in these studies[95,100]. Recently, Munoz *et al.* confirmed previously published data on diabetic patients who underwent heart transplantation, showing that the long-term survival rate is similar to non-diabetic patients without an increased risk of CAV[113]. The role of gender was investigated by Sharples *et al.*[99] and compared with transplantations performed between donors and recipients of the same sex. Female recipients of a male donor heart had a relative risk of 1.56 of graft loss from CAV, and male recipients of a female donor heart had a relative risk of 3.33[99]. Other potential risk factors, such as ischemic time and donor age, have not been consistent with regard to the development of CAV, either in clinical or in experimental studies[114,115].

CYTOMEGALOVIRUS AND CARDIAC ALLOGRAFT VASCULOPATHY

The first suggestion that there was an association between cytomegalovirus (CMV) and CAV was from the Stanford group,

who reported their experience with 301 patients. Twenty-eight percent of CMV-infected patients developed 'severe' coronary obstructive lesions, whereas only 10% of patients not infected with CMV developed the same degree of CAV[116]. A similar association between CMV and CAV has been reported by others[117,118]. In contrast, Balk *et al.* failed to find a relation between CAV and the occurrence of CMV infection[119]. In their cohort of 100 patients who survived at least 1 year after cardiac transplantation, there was no significant difference in the incidence of CAV (any coronary disease) between CMV-seropositive and seronegative patients, between patients with and without CMV infection (culture positivity), or between patients with and without a clinical CMV syndrome.

Recently, Koskinen *et al.*[120] reported a cohort of 53 heart transplant patients, and carried out a correlation between their coronary angiograms, capillary and arteriolar changes in endomyocardial biopsy specimens and their CMV status. They documented that biopsy specimens showed significant change post-CMV infection (which was diagnosed on specific IgM, a positive viral culture from blood, urine or bronchoalveolar lavage fluid, together with a 4-fold IgG rise, or positive CMV antigenemia test). The significant changes in coronary angiograms followed 2 years post-transplantation[120].

In a study from Oregon (Table 2), using subset analysis, only those patients who had evidence of prolonged CMV infection (defined as persistently positive blood buffy coat cultures over a 4-month period) had a statistically significant increase in the incidence of CAV compared to the remainder of the study cohort[121]. Wu *et al.*[122] documented that allograft explants with CAV had a much higher incidence of positive *in-situ* hybridization for CMV nucleic acid in the vascular intima compared to explants without CAV. Finally, Lemstrom *et al.*[123], using the DA to WF (complete MHC mismatch) rat aorta transplant model, demonstrated that CMV infection enhanced the vascular inflammation and increased the degree of intimal proliferation by a factor of 2 compared to uninfected controls.

The mechanism by which CMV plays a role in the development of CAV is likely to be interaction between the virus and the allogeneic response, which to date has not been defined. The presumed initial response is an infection of one or more cell types within the vascular wall. Waldman *et al.*[124], using a strain of CMV propagated in endothelial cells, infected human umbilical vein endothelial cells and investigated lymphocyte proliferative responses using responder cells from CMV-seropositive individuals. They noted a substantial increase in proliferation of the $CD4^+$ lymphocyte population in response to CMV-infected human umbilical endothelial cells compared to uninfected controls. This increased $CD4^+$ lymphocyte proliferation occurred despite the lack of an increase in MHC class II antigen expression on the endothelial cells, suggesting a unique interaction between this strain of CMV, the endothelium and $CD4^+$ lymphocytes, as was shown in a previous study[125]. Van Dorp *et al.*[126] demonstrated that, in cultured endothelial cells, MHC class I antigen was induced by CMV infection, but likewise could not demonstrate a change in MHC class II antigen. This increase in endothelial cell MHC class I antigen has been confirmed by Tuder *et al.*[127].

In contrast, although we have demonstrated that human umbilical endothelial cells and human aortic endothelial cells are targets of CMV infection, only 5–10% of cells are infected, and we could document no alterations in MHC antigen expression. However, we have confirmed prior reports[128] that human aortic smooth muscle cells are readily infected by CMV. Furthermore, this infection of smooth muscle cells results in the increased expression of MHC class I antigen, hence potentially providing a mechanism for altering the allo-response[129].

PROGNOSIS

Keogh and colleagues demonstrated, in a cohort of over 350 patients, that those with proximal or midvessel discrete coronary stenoses had a 34% reduced survival compared to those without coronary stenosis[130]. Sharples *et al.*[131], using an analysis which factored in severity and progression, documented that if the initial angiogram was normal, progression to mild disease was low (12%/year) and progression to death was very low (3%/year). Once mild disease was detected, progression to severe disease was 47% per patient-year, and once severe disease occurred progression to death was 40% per patient-year[131].

Gao and colleagues analyzed their data specifically looking at the rate of development of CAV. Patients who had hemodynamically significant CAV by 1 year had a greater than 35% increased risk of an ischemic event at 1, 3 and 5 years post-initial detection of CAV, compared to those whose CAV developed later than 1 year post-transplantation[132]. Data from Oregon (Figure 8) also confirm the greater risk of mortality (in this case following their 1-year angiogram) for those with CAV, demonstrated or implied by the above studies from other centers.

MANAGEMENT

Although data from animal studies have suggested that several interventions, including antiplatelet agents[133], estrogens[134], androgens[135], somatostatin analogues[136], older[137] and newer[138] immunosuppressive agents, fish oil[139] and calcium antagonists[140], may be helpful in preventing or delaying the development of

Table 2 CMV infection subgroups and cardiac allograft vasculopathy (CAV)

Subgroup	*No. of patients*	*CAV incidence (%)*	*Probability*
CMVi+/–	89/40	20/23	n.s.
1°CMV+/–	20/109	25/20	n.s.
CMV4+/–	36/92	31/23	0.107
CMV6+/–	19/98	37/18	0.089
CMVv4+/–	17/111	47/18	0.012

CMVi = CMV infection, CMV4 = 4-month persistent CMV infection, CMV6 = 6-month persistent CMV infection, CMVv4 = 4-month persistent CMV viremia. From ref. 121.

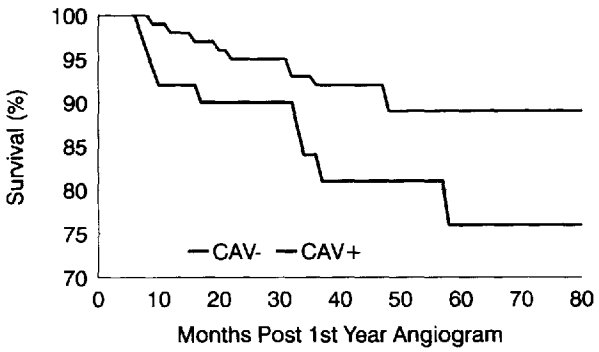

Figure 8 Patient survival following 1 year anniversary angiogram depending on presence or absence of CAV ($p = 0.044$)

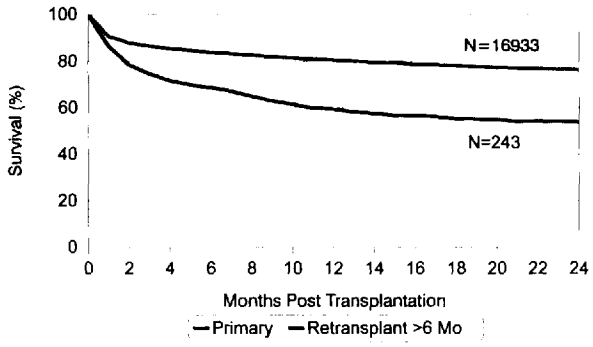

Figure 9 ISHLT/UNOS thoracic registry data comparing survival following first cardiac transplant to survival after retransplantation assuming retransplant occurred at least 6 months following first transplant operation

CAV, few data are confirmatory in humans. Most centers prescribe aspirin or other antiplatelet drugs, lower lipid levels and elevated blood pressures, and insist on no tobacco products, but there is little evidence to suggest that these measures have had any impact on CAV incidence or progression.

Only two studies have demonstrated any efficacy of medical therapy on the development or severity of CAV. Schroeder and colleagues from Stanford randomized patients to receive diltiazem or placebo[141]. They demonstrated a reduction in the severity of CAV and a lower incidence of ischemic events and mortality in the diltiazem group. As noted above, Kobashigawa *et al.*[112] in a preliminary presentation demonstrated a reduction in CAV and mortality in patients randomized to pravastatin.

The role of augmenting immunosuppression as a means of altering the progression of CAV would seem to be a promising strategy if, as assumed, CAV is a manifestation of chronic rejection. Addonizio *et al.*[142] compared double immunosuppression (cyclosporin and prednisone) with triple therapy (cyclosporin, prednisone and azathioprine) in 55 pediatric cardiac allograft recipients. The mean follow-up time was 36 months. They experienced a significant decrease in CAV with triple therapy, as diagnosed by coronary angiography. Also, most recently, Valantine *et al.*[143] documented that a lower dose of cyclosporin (defined as $\leq$ 3 mg/kg per day) is associated with an increased prevalence of death from CAV. Both of these studies suggest that inadequate immunosuppression represents a direct predisposition to CAV.

Revascularization procedures such as PTCA or directional atherectomy remain palliative measures. Although many centers report good initial success, ultimate outcome does not appear to be impacted; furthermore, most of the patients do not qualify for these procedures, due to the diffuseness of their disease[144–146]. Finally, retransplantation still remains the only clearly defined treatment for CAV, but with patient survival approximately 20% below first-time transplants (Figure 9)[1,147,148], along with a national shortage of acceptable organs for transplantation, this procedure is clearly not a long-term solution.

COMMENT

It is encouraging to see the proliferation of data on the basic mechanisms of CAV and trials of novel treatment modalities. However, CAV continues to be the major obstacle to the long-term survival of cardiac allograft recipients, and our knowledge base is far from complete. Solutions may come from better or more specific immunosuppression, or more probably from a more comprehensive understanding of the basic mechanisms resulting in the disease.

Diagnosis and Management of Cardiac Allograft Vasculopathy (Chronic Rejection)

L.W. MILLER, T. DONAHUE, T. WOLFORD AND J. DRURY

INTRODUCTION

The greatest impediment to long-term survival for adult and pediatric heart transplant recipients is the development of an accelerated form of coronary artery disease[1–4]. This is variously termed chronic allograft vasculopathy, chronic allograft coronary artery disease, or chronic rejection. This disease was reported in the original preclinical animal experiments[5], and subsequently in the early human heart transplant recipients at Stanford, USA[6,7] and Cape Town, South Africa[8]. The incidence of this disease has been estimated at 10% per year post-transplant[4,9–11]. Although cyclosporin has been associated with an improvement in 1- and 5-year graft survival, as well as a decrease in death due to rejection, it has not had an impact on reducing the incidence of allograft coronary artery disease (ACAD)[12–15] in adults, but increased immunosuppression may decrease the incidence in pediatric patients[15].

Progression of this disease is variable[16], with a percentage of patients having a very accelerated course, particularly in the epicardial vessels, which may be evident within 1–3 years of transplant, while other patients may have an isolated single vessel stenosis which remains unchanged for years. However, it has become apparent that, once patients develop at least a 70% stenosis by angiography, in even one coronary vessel, they have a very poor prognosis (Figure 1), with approximately a 70% mortality at 1 year, and an even higher mortality with an increasing number of vessels involved[17].

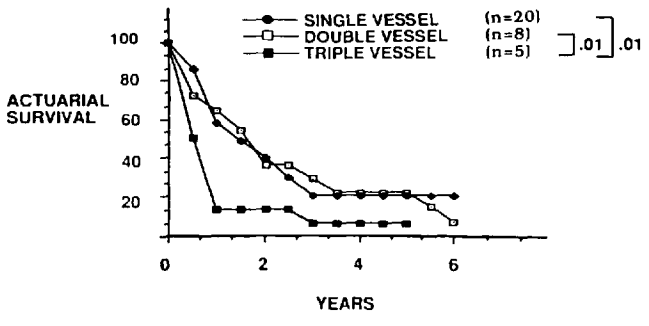

Figure 1 Survival over time post-heart-transplant once a 70% or greater stenosis is noted by angiography, by number of vessels diseased

Clinical presentation

The clinical presentation of ACAD may be acute, with new-onset heart failure, arrhythmia, or sudden death, often heralding an acute myocardial infarction[18,19] (which is typically not accompanied by anginal-like pain, due to the cardiac denervation that occurs at implantation). The inconsistent presence of chest pain with an acute MI often results in delay or misdiagnosis[19] (nearly 50% in the Stanford series) and, coupled with the paucity of collateral vessels, contributes to the reported mortality of >25%[19]. Recently, Wilson *et al.*[20–22] have shown that, with increasing time post-transplant, many heart transplant patients have detectable reinnervation, as confirmed by norepinephrine release in the coronary sinus in response to an intracoronary tyramine challenge. The extent of reinnervation is unpredictable but, if present, it would allow patients to have anginal symptoms. This makes it mandatory to investigate heart transplant patients, especially those more than 3–4 years post-transplant, who develop: (a) a change in functional status, or (b) EKG pattern, or (c) chest pain, which is consistent with angina pectoris.

Pathogenesis

The pathogenesis of ACAD has been the topic of extensive review[23–29] (Chapter 34). Most investigators describe the process as multifactorial, having both an immune and a non-immune basis.

Immune factors

Support for the primary role of an immune etiology includes: (a) concentric uniform involvement of the entire coronary vessel of the allograft (versus eccentric focal disease with typical atherosclerosis); (b) restriction of this rapidly proliferative disease to the allograft vascular bed; the development or occurrence in patients

of all ages, including neonates, or in patients with donor hearts under the age of 20 years; (c) the clear line of histologic demarcation between the donor and recipient aorta; and (d) reproducibility of the disease in numerous animal models of immune-mediated injury[30–33].

Debate continues on the relative contribution of the cellular versus humoral arms of the immune system to the pathogenesis of ACAD[34–37]. Although there are increasing data showing a high correlation between the occurrence of even one episode of acute rejection and the development of chronic rejection in kidney transplant recipients[38–40], there have been few data to support the correlation between the incidence, severity, or time to first cellular rejection and the development of allograft coronary disease in heart recipients[41–45] as measured by contrast angiography. This lack of supporting data, coupled with the reports of the high incidence of spontaneous resolution of diffuse mild or even focal moderate rejection[46–48], has caused most centers to become more and more conservative in initiating treatment of rejection.

Most recently, Kobashigawa[49] presented data from the CVIS investigators in which the ISHLT biopsy grading system was converted into a numeric scale. They noted that the average score of all biopsies during the first 3 months post-transplant, but not the incidence of treated rejections, correlated with the development of allograft coronary disease as defined by intimal thickening on intravascular ultrasound. These data raise the question of whether increased immunosuppression, or a lower threshold to treat rejection, will decrease the incidence or progression of ACAD, or, alternatively, result in significantly increased morbidity. This question remains to be answered.

The role of the humoral arm of the immune system in the pathogenesis of ACAD has been demonstrated. Hammond has described the association between vascular or antibody-mediated rejection and ACAD[50], and several centers have noted that the development of measurable circulating HLA antibodies post-transplant correlated with a poor prognosis and development of coronary disease[51–55]. The specificity of these antibodies has recently been shown to be directed against both HLA and non-HLA antigens on the surface of the endothelium[56–59].

HLA matching is not attempted in heart transplant recipients due to time constraints, but several series have shown an increase in rejection and decreased survival with increase in HLA mismatch[60–62], including a review by Costanzo[63]. There are increasing data demonstrating an inverse correlation between degree of match at the DR locus and the development of ACAD[63–65]. The presence of even one match at the DR locus reduces the likelihood of ACAD.

Non-immune factors

There are several non-immune factors which may correlate with or contribute to the pathogenesis or development of allograft coronary disease[66]. These include: (a) donor age, with a high direct correlation between risk and increasing donor age, particularly over the age of 50[67,68]. This is largely due to the presence of unsuspected coronary intimal irregularities and thickening in the general population by this age, a fact which may limit expansion of the donor pool; (b) ischemic heart disease pretransplant; (c) hyperlipidemia[69,70], in particular, both elevated triglycerides and total cholesterol. Recently, Valentine[71] reported that a low HDL was as important as an elevated LDL subfraction of total cholesterol. Hyperlipidemia plays an important, but secondary, role in the development of this disease. Animal data have shown that animals with immune-mediated intimal thickening have a marked potentiation of the development of this disease when fed a high-cholesterol diet, but a high-cholesterol diet alone could not alter the natural history of this disease[72,73];(d) cytomegalovirus (CMV) infection. The mechanisms of this correlation are at least two-fold, as CMV has been shown both to up-regulate expression of class 2 donor antigens on endothelium and to enhance lipid incorporation into the intima of the vessel[74–77]. Numerous clinical series have shown a correlation of CMV infection with the development of ACAD[78–82]; (e) obesity[69]. The mechanism by which obesity contributes to the pathogenesis is somewhat unclear, but may relate more to the associated finding of hyperlipidemia in these patients; (f) cryopreservation and reperfusion injury. Hypothermia can induce an injury to the coronary endothelium which may predispose the recipient to this disease[83]. In addition, cold preservation is a perfect model of reperfusion injury which may, by release of oxygen free radicals, result in early endothelial ischemic damage or dysfunction[84,85], that may play an important causal role in the subsequent development of ACAD. Blockade of free-radical-induced injury by superoxide dismutase significantly reduced the incidence of acute and chronic rejection in a prospective double-blind study in kidney transplant patients[86].

One new concept in the pathogenesis of allograft coronary disease is that not only is it a disease not limited to hearts or other vascularized allografts[87], but it may also represent an accelerated form of conventional atherosclerosis, with other examples being post-angioplasty restenosis and saphenous vein graft stenosis. The unifying theme of this paradigm of accelerated atherosclerosis is endothelial cell injury. Ip *et al.*[88] have described and graded endothelial injury from 1 to 4, with transplant coronary disease being a grade 3 and angioplasty restenosis representing grade 4 injury, not only involving the intima, but often extending into the media. The acute nature, deep extension, and severity of the PTCA lesion are perhaps the primary reasons for angioplasty restenosis being the most accelerated form, often evident within 2–6 months after angioplasty.

There has been a great deal of work in vascular biology[88–95] which has contributed greatly to our understanding of the factors involved at the molecular level in the pathogenesis of both ACAD and post-angioplasty restenosis. The most obvious pathologic feature of both allograft coronary disease and post-angioplasty restenosis is a significant smooth muscle cell (SMC) proliferation and subsequent migration across a relatively intact internal elastic membrane which results in a very expanded intima and progressive luminal compromise[96–98]. Central to the current understanding has been the identification of a number of cytokines, such as IL-2, IL-6, IL-10, and interferon-gamma[99,100], and growth factors[101], such as platelet-derived growth factor, insulin-like growth factor, and fibroblast growth factor, as well as other molecules that can induce or promote smooth muscle cell proliferation[102]. Equally important has been the demonstration of the capability of not only lymphocytes and macrophages, but endothelial cells to secrete or express a number of these molecules[99,103], largely in response to up-regulation of class II HLA antigens on the surface of endothelial cells. In addition, recent attention has been directed at the important role of matrix and

ground substance in plaque development[104]. This paradigm provides a unifying theory of host response to endothelial cell injury[88], whether immune-mediated, as with ACAD, or traumatic, as with post-PTCA restenosis[93,105], and provides new insights into the potential role of the immune system in conventional atherosclerosis[106].

Data supporting the concept of non-specific response to endothelial cell injury have been shown by Foegh *et al.*[107,108] in experiments with the somatostatin analogue, angiopeptin. This molecule, which inhibits insulin-like growth factor, has been shown to inhibit intimal proliferation in animal models of heterotopic heart transplantation as well as balloon-induced injury to a carotid artery. The importance of the understanding of these molecules and cofactors that inhibit smooth muscle cell proliferation[109,110] is that they also become potential targets for therapy to alter the natural history or prevent the development of this disease in the future (see discussion below on therapeutic agents).

DIAGNOSIS OF ALLOGRAFT CORONARY DISEASE

Non-invasive

Although non-invasive tests have become the mainstay of the diagnostic armamentarium for conventional atherosclerotic disease, these tests have unfortunately had far less sensitivity and specificity in heart transplant patients. Smart *et al.*[111] and others[112–114] have reviewed the diagnostic accuracy of these tests, using angiography as the gold standard. The original studies comparing nuclear thallium imaging involved very few patients, but suggested a sensitivity as low as 50%, which is below clinical applicability. Reasons for the lack of sensitivity with nuclear perfusion imaging have been thought to be due to the diffuse nature of the disease, particularly in small vessels. Use of SPECT, rather than conventional tomographic imaging, may improve the diagnostic accuracy, but use of newer agents, such as sestamibi, has not resulted in improved accuracy[114].

Recently, a good deal of interest has been focused on the use of dobutamine stress echocardiography to diagnose ACAD[115,116]. Unfortunately, despite its proven value with conventional atherosclerosis, this test also has been too insensitive to help manage transplant patients. However, Akosah *et al.*[117] recently found a high predictive accuracy between a positive test and the presence of angiographically significant stenosis. Other non-invasive tests being investigated include soluble IL-2 receptors as a marker of immune activation[118], as well as ultrafast CT and positron emission tomography[119], both of which are expensive and have limited availability.

Invasive

As a result of the poor sensitivity of non-invasive tests, the diagnosis of allograft coronary disease remains based on invasive techniques. Conventional contrast angiography remains the gold standard. Gao *et al.*[120] first described the angiographic appearance of this disease which includes epicardial stenoses very similar to conventional atherosclerosis, but the hallmark of ACAD is stellate tapering and/or abrupt cut-off of third- and fourth-order branch vessels (distal obliterative arteriopathy). Due to the very rapid development of this disease, collateral vessels are usually absent[121]. A number of investigators have used quantitative methods to caliper vessel diameter, quantitate percentage stenosis, and measure disease progression[122–125]. Although angiography is highly specific and predictive of a poor prognosis when significant narrowing or stenosis is evident[17,126–128], numerous patients have had an apparently normal angiogram only to die within months of the study, and have autopsy evidence of severe multivessel coronary disease[129].

The reasons for this disparity between pathology and angiography are numerous, and include use of neighboring vessels to judge luminal diameter of a vessel when, in fact, the vessel may be diseased from its origin and throughout the coronary vascular tree[130]. Perhaps even more important is the potential role of compensatory vessel dilatation in response to development of flow limitation as described by Glagov[131,132]. This phenomenon, which has been observed in carotid, cranial, and coronary vessels[133,134], as well as post-PTCA restenosis[135], allows a relatively normal luminogram and minimizes the flow limitations of progressive intimal thickening[136].

Historically, most centers performed the 'baseline' angiogram at the first-year anniversary of the transplant procedure. However, Gao *et al.*[137] have shown that, even using quantitative contrast angiography, there is a statistically significant decrease in luminal diameter between a study performed within the first 3–4 weeks post-transplant and a study at 1 year. The early study allows detection of disease transmitted in the donor that could be erroneously ascribed to a host response. As a result, many centers now perform the baseline angiogram within 1 month of transplant to detect unsuspected disease in the donor[138]. Nitroglycerin must be used to maximally dilate vessels, minimize spasm[139] which may occur, and maximize visualization of collateral or branch vessels.

There are several reports of making the diagnosis of ACAD by the finding of an obliterated intramural vessel on endomyocardial biopsy[140,141] or evidence of myocardial infarction or ischemic damage[84,142]. While these findings are very specific, they are extremely insensitive, especially for events involving the left coronary system and left ventricle, which is not sampled. The timing of catheterizations, and strategies to decide how often they should be repeated in the individual patient, are being evaluated by several groups[143,144].

Intravascular ultrasound (IVUS)

As a result of the lack of sensitivity of contrast angiography, a great deal of attention has been focused on the development of intravascular ultrasound (IVUS) to diagnose ACAD. This technique, which has recently been reviewed[145,146], employs the use of a catheter, with an ultrasound probe mounted on the tip, which can be advanced over a small guidewire down the coronary artery, providing a 360 degree real-time cross-sectional view of the vessel and the degree of intimal thickening. Research has resulted in miniaturization of the catheter to approximately a 3.0 French, or <1 mm diameter, thus allowing the catheter to be advanced nearly to the most distal portion of all three major coronary vessels. Recent reports have documented the safety of this procedure[147–149], as the operator can clearly detect prohibitive luminal narrowing on-line, particularly when unsuspected by an apparently normal angiogram.

One of the most important findings with IVUS is that it has been shown to be much more sensitive than angiography for the detection of ACAD[150–152]. A study from Stanford[152] demonstrated moderately severe intimal thickening with IVUS in over 50% of 42 patients with a normal coronary angiogram. Patients with abnormal angiograms also had moderate or severe intimal thickening, which was indistinguishable from the patients with normal angiograms. This significant increase in sensitivity with IVUS over angiography has also been reported in other series[145].

The appearance of a transplant coronary artery by IVUS has been reported by a number of investigators[151–154], and includes a line of demarcation for the intima, media, and surrounding tissue. The image can be planimetered to provide measurements of total area, luminal area and intimal area, and calculation of an intimal index, which is the percentage of luminal area occupied by plaque (Figure 2). The intima must be at least 150 μm, or 0.15 mm, before it is apparent on ultrasonography. Intimal thickness, as measured by ultrasound, has been validated by a number of autopsy studies and shown to be very accurate[145].

Intravascular ultrasound not only has provided a detailed look at the coronary intima and its composition, but has raised some fundamental questions about the pathogenesis of ACAD. Although the typical pathologic description of coronary arteries from heart transplant recipients with ACAD is of a uniform, concentric, doughnut-like appearance of the expanded intima, a

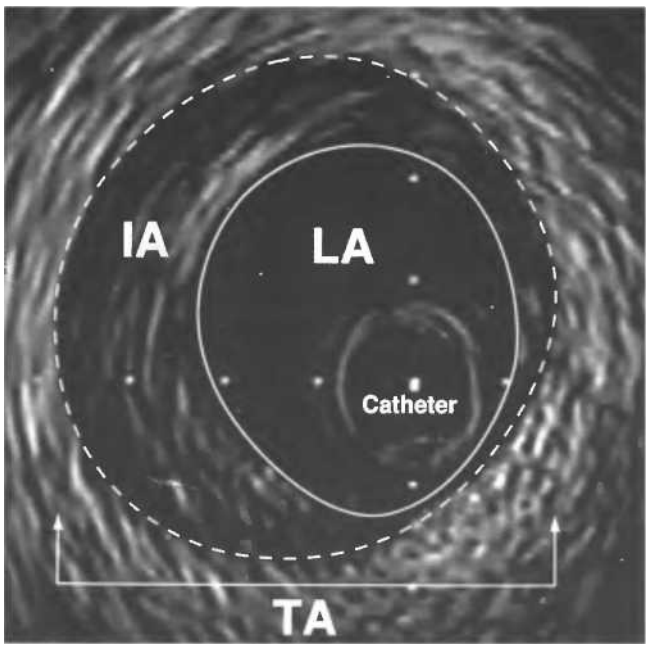

Figure 2 IVUS image of transplant coronary artery (dark area represents blood-filled lumen with small circle catheter; with planimetry of plaque showing TA = total area; LA = luminal area, IA = intimal area. Intimal index = TA–LA/TA

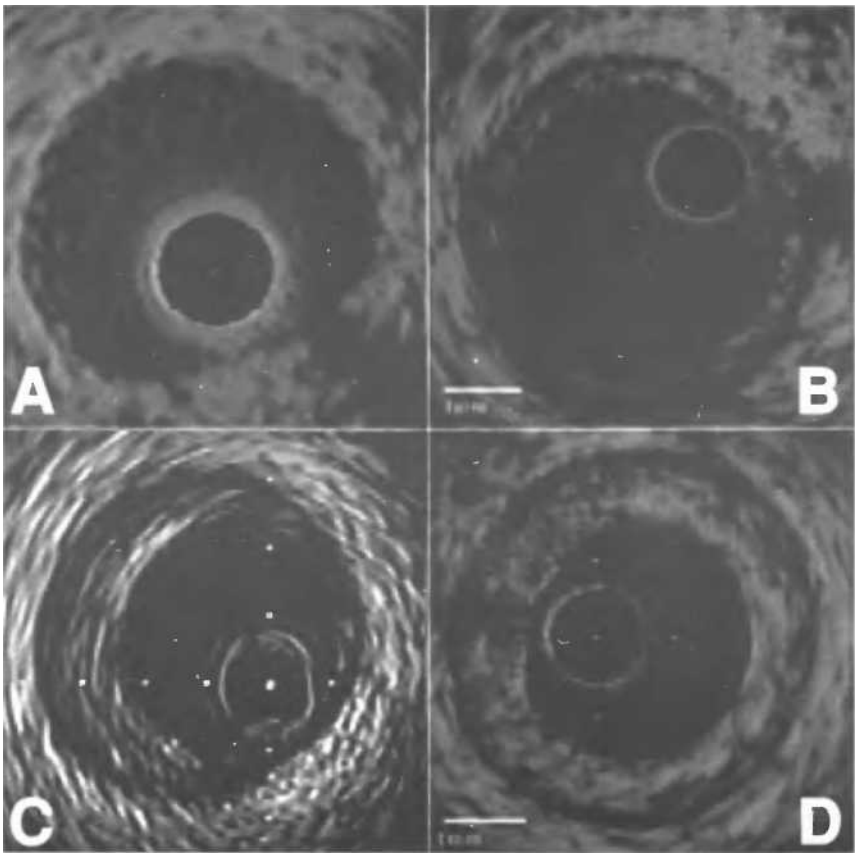

Figure 3 Patterns of intimal thickening by IVUS: **A:** no detectable intimal thickening; **B:** mild concentric intimal thickening; **C:** focal, eccentric plaque; **D:** severe concentric intimal thickening

variety of other patterns of involvement have been observed by IVUS (Figure 3). The most common finding by ultrasonography is a non-uniform eccentric lesion with the arc of involvement <180 degrees of the luminal circumference[151,155,156], although many patients have only the diffuse concentric pattern, or a combination of eccentric and concentric disease. Data from investigators at the Cleveland Clinic[155,156] have shown that the greatest percentage of eccentric intracoronary stenoses occur at vessel branch points, much like traditional atherosclerosis. These data suggest that non-immune factors, such as shear stress and flow dynamics[157], may be important in not only the pathogenesis, but also disease progression.

While the distal obliterative disease has been the hallmark of ACAD, the high proportion of focal epicardial stenoses has seemed inconsistent with the immune hypothesis. However, Botas[158] and investigators at Stanford have shown that most of the epicardial stenoses represent donor-transmitted disease which was evident at the early post-transplant study. Although these donor-transmitted lesions still represented the areas of maximal thickening at the 1-year follow-up, the greatest percentage change in intimal thickening occurred in *de-novo* sites rather than the pre-existing lesions. A multicenter observation study[159] has recently shown that the greatest percentage change in mean intimal thickness in 300 patients who underwent serial ultrasound studies from time of transplant occurred during the first year after transplant, but progression of mean intimal thickness occurred in each of the subsequent 2 years (group means). These studies[158,159], which examine patients serially to evaluate disease progression, will help to differentiate the risk factors that are directly related to host immune response from those related to pre-existing disease.

One of the commonly held beliefs about ACAD is that the development and progression of this disease is uniform throughout the coronary vessel[160]. Lin *et al.*[161] have recently reported a nearly uniform degree of intimal thickening in both proximal and distal vessels by careful autopsy analysis. However, this concept has not been supported by *in-vivo* ultrasound studies. Figure 4 shows a patient with all three forms of coronary disease, including focal eccentric epicardial disease in the most proximal segment, diffuse concentric disease in mid-vessel, and minimal if any disease in the distal vessel. In addition, there can be wide heterogeneity between vessels in the same patient (Figure 5). These findings are somewhat inconsistent with an immune-mediated injury, which should be uniform throughout the vessel.

Not only is the progression of this disease not uniform, but its development is also not inescapable. A significant number of patients have been studied with IVUS at nearly 10 years post-transplant[145], and were found to have minimal, if any, intimal thickening. There may be significant disparity between IVUS estimates of luminal compromise and that observed at autopsy, as can be seen in Figure 6 from a patient who died 2 weeks post-transplant. Pathologic specimens may potentially either *overestimate* the degree of luminal compromise by intimal thickening if they are not fixed under pressure, or *underestimate* the potential increase in total area (and secondarily luminal area) of the vessel

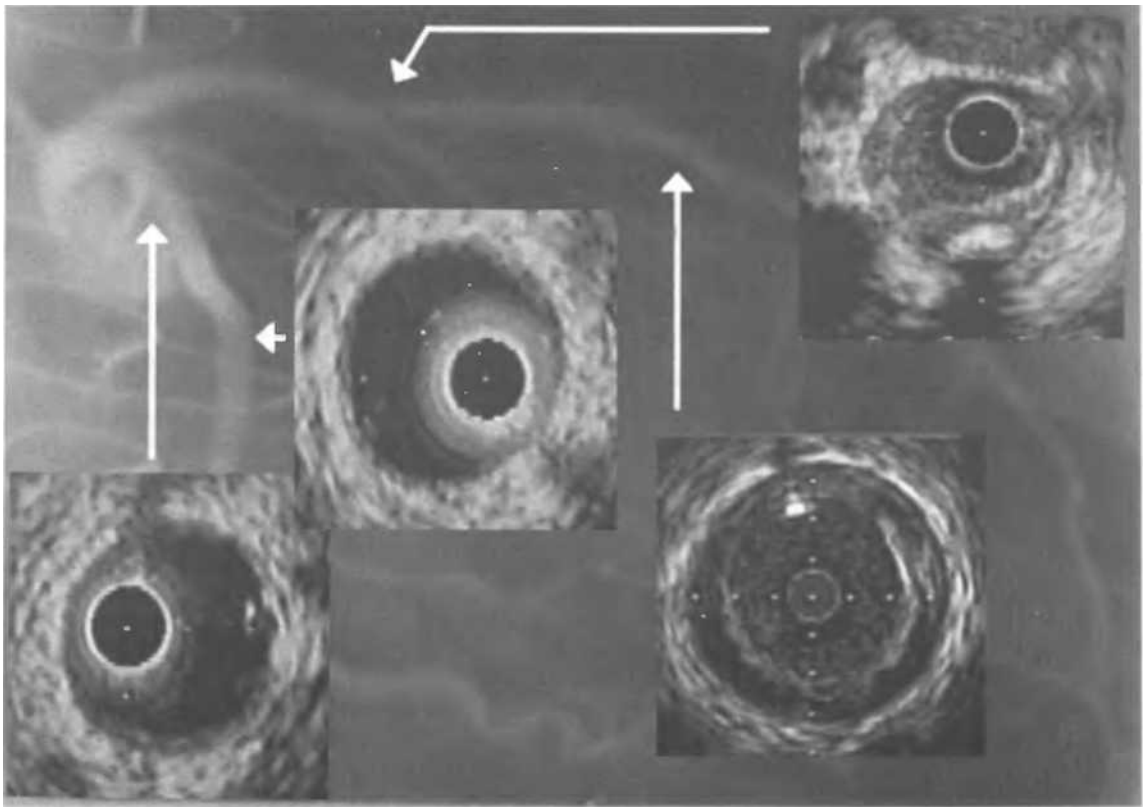

Figure 4 Heterogeneity of ACAD by angiography and IVUS between LAD and circumflex coronary arteries in the same patient

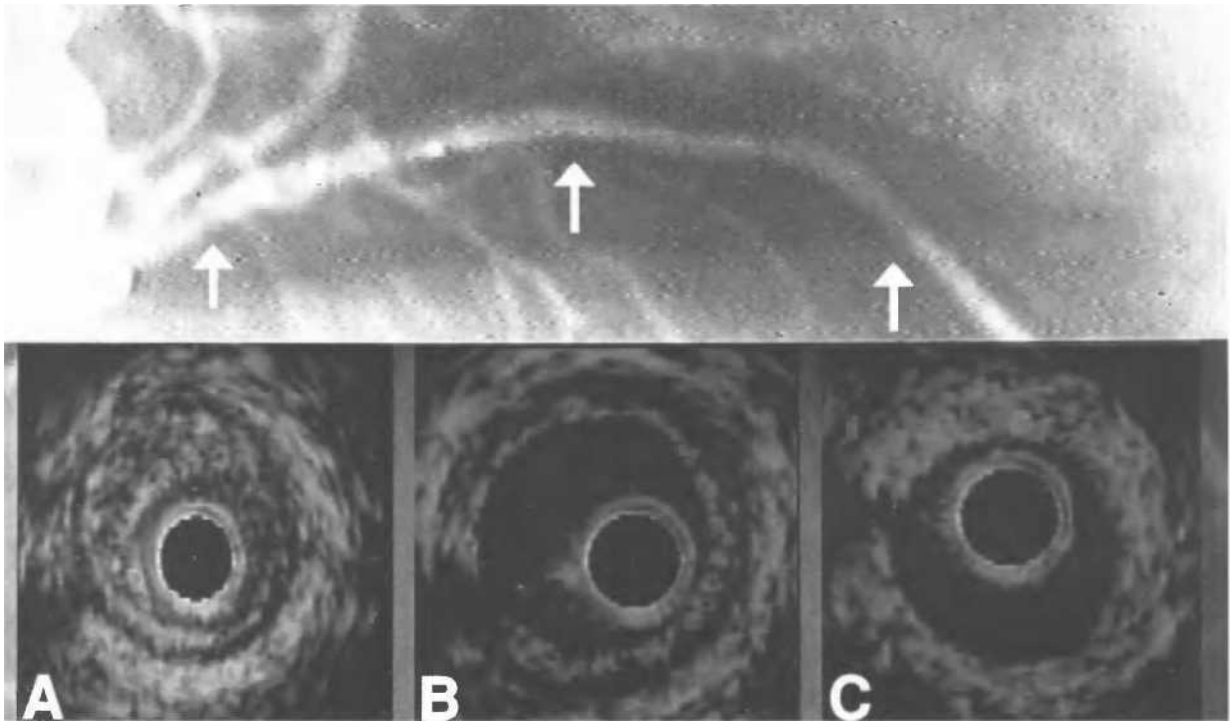

Figure 5 IVUS image showing non-uniform intimal thickening in a transplant coronary artery, **A:** proximal focal, eccentric plaque; **B:** mid-vessel concentric intimal thickening; **C:** distal vessel with minimal disease

Figure 6 **A:** Coronary angiogram and corresponding intravascular ultrasound image of donor heart pre-harvest; **B:** coronary artery autopsy specimen 2 weeks post-transplant

achieved *in vivo* by remodeling and compensatory dilatation as described by Glagov[137].

Perhaps one of the most important contributions of intravascular ultrasound is the ability to detect intimal disease at an earlier stage and with greater sensitivity than by conventional contrast angiography. Recent studies have also confirmed the prognostic importance of intimal thickening detected by IVUS. Intimal thickness >500 μm has been shown to be highly correlated with the subsequent occurrence of significant clinical events (e.g. myocardial infarction or death)[162,163].

Johnson and Kobashigawa[164] recently described the use of morphometry, a mathematical analysis of the number of sites in the coronary tree needed to minimize sampling error and potential bias, maximize reproducibility of IVUS measurements, and best describe disease progression. This approach employs a withdrawal of the catheter from the distal coronary at a fixed rate with periodic random sampling, as opposed to the current standard approach, which attempts to remeasure points of maximal intimal thickening by using injections of contrast to visualize branch vessels to guide site selection and measurement[159]. The comparative advantages or accuracy of the two techniques remain to be defined.

Ultrasound will play a key role in the future as the new gold standard[165] for the assessment of the efficacy of a number of therapeutic strategies designed to alter the natural history of this disease (see below in Future Treatment). This technology will allow a new description of the true incidence of this disease, and allow a refocus on the risk factors that contribute to its progression.

Coronary flow reserve (CFR)

The presence or extent of allograft coronary disease in the distal branch vessels has been very difficult to determine. The conventional approach has been to perform side-by-side visualization of the current and baseline angiograms to detect loss of third- or fourth-order branch vessels. The development of coronary flow reserve (CFR) measurement has dramatically advanced our ability to measure the *functional* impairment in flow in the coronary resistance bed, which is the major determinant of overall coronary flow[145,166,167].

A 0.018-inch wire can be inserted to the most distal portion of each epicardial coronary artery. Figure 7 is an example of the online signal obtained through that wire that demonstrates the predominant diastolic phasic nature of coronary flow. The status of the resistance bed can be assessed by the ability to augment flow in response to a hyperemic challenge which can be induced by a number of pharmacologic agents. Our laboratory utilizes an intracoronary bolus of adenosine at a dose of 12–24 μg. Coronary flow reserve can then be calculated as the ratio of a maximum hyperemic flow to basal. Normal flow reserve has been determined in our laboratory in over 800 non-transplant and transplant patients for age, gender, and time post-transplant with normal CFR>3.0[167].

Coronary flow reserve measurements performed early post-transplant document a mild impairment which is consistent with endothelial and arteriolar dysfunction, perhaps mediated by ischemia and cold preservation as well as by immune injury, which then normalizes by the first-year anniversary study. Flow reserve appears to remain normal until at least 3–4 years post-transplant,

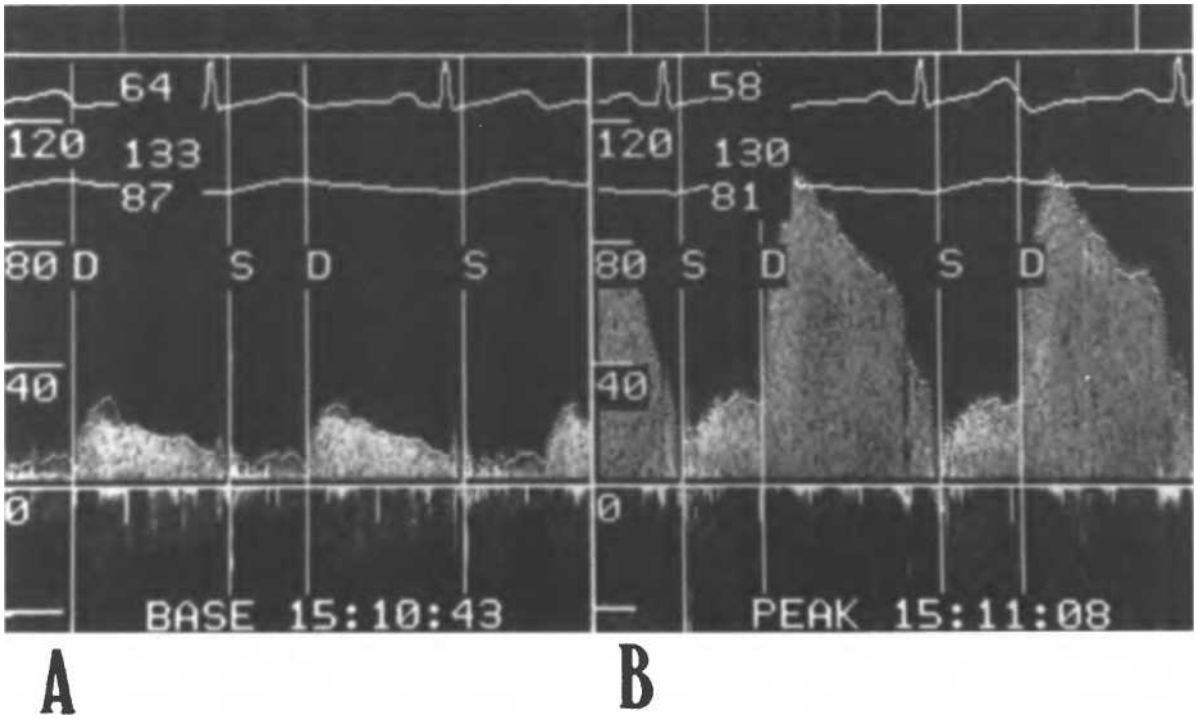

Figure 7 Real-time image from coronary Doppler flow probe in cardiac transplant patient: **A:** predominant diastolic flow, at rest; **B:** following hyperemic stimulus with adenosine. CFR = Hyperemic flow ÷ rest flow

when it begins to decline. Studies from our laboratory have demonstrated no correlation between CFR measurement with the extent of either focal or diffuse intimal thickening[168-170]. This again is in conflict with the concept of a uniform immune-mediated intimal injury and thickening.

One of the most important aspects of the measurement of CFR is the potential ability to utilize the documentation of relatively normal flow reserve in patients with severe epicardial stenoses to select ideal candidates for coronary bypass surgery as an alternative to retransplantation. Conventional bypass surgery has historically been considered not to be an option in transplant patients, because of the belief that the distal resistance 'run-off' vessels are always obliterated by the time epicardial disease is evident. Our preliminary data refute that premise. We have reported use of CFR to select a patient only 2.5 years post-transplant for coronary bypass surgery who had a normal CFR (3.2) and three-vessel epicardial ACAD. The revascularization surgery went uneventfully and resulted in an improved functional status and amelioration of nuclear scan evidence of ischemia.

Angioscopy

Ventura and colleagues[171] at the Ochsner Medical Foundation have reported use of intracoronary angioscopy to describe the topographic appearance of endothelial lesions in the coronary vessels of transplant patients. They are able to differentiate a white versus yellow plaque, with the yellow plaque consistent with the fatty streak of conventional atherosclerosis on pathologic examination, and the white plaque more consistent with immune-mediated diffuse thickening of the coronary vessel. Application of this technique is limited, but may potentially help elucidate the differential progression of pre-existing and *de-novo* disease.

Endothelial function

The endothelium represents the primary interface between the host and the allograft. As such, several investigators have examined measures of endothelial function, e.g. the response to endothelium-dependent vasodilators such as acetylcholine, as potentially the earliest manifestation of the development of ACAD[172-174]. Yeung *et al.*[175] originally reported a paradoxic vasoconstrictor response to high-dose acetylcholine in patients early post-transplant, that normalized by the 1-year anniversary study. Endothelial dysfunction has been shown to correlate with subsequent development of coronary artery disease, but there is growing controversy over the sensitivity and specificity of both endothelium-dependent and independent vasodilator responses in a given segment of a coronary artery. Other agents, such as Substance P, may be used to assess endothelial function, but their use remains a research application only.

TREATMENT OF ALLOGRAFT CORONARY DISEASE

The treatment of ACAD, once it is diagnosed, has been primarily preventive and based largely on extrapolation of the risk factor reduction approach used in patients with non-transplant atherosclerosis, specifically aspirin, exercise, lipid reduction, avoidance of smoking, and treatment of hypertension[176,177].

There is growing evidence to suggest that lipid reduction may also be one of the most important interventions in transplant recipients[178,179]. Kobashigawa[180] has shown that, if lipid therapy is not initiated until more than 1 year after transplant, it is unable to alter the subsequent progression of ACAD. These data suggest that lipid incorporation is an early post-transplant phenomenon, perhaps in association with the documented endothelial inflammation and injury that occur early in most patients. Kobashigawa *et al.*[181] have subsequently shown that use of pravachol from the time of transplant can, in fact, decrease the degree of intimal thickening, possibly due to an effect on natural killer cells as well as cholesterol levels. The specific lipid fractions to target also include serum triglycerides, which have correlated more strongly with the development of ACAD than have total, or subfractions of, cholesterol[182]. If the HMG-CoA reductase agent fails to normalize triglycerides effectively, specific therapy such as lopid or niacin may be warranted. Caution should be exercised with the combination of a 'statin' drug, most particularly mevacor, and lopid, due to the reported incidence of rhabdomyolysis with statin drugs alone, but particularly in combination with lopid.

Aspirin has been shown to reduce platelet aggregation and to be associated with a significant reduction in clinical events in non-transplant patients with coronary disease and unstable angina[183,184]. It has also become a mainstay for nearly all transplant patients, despite data indicating that it is of no benefit in transplant patients[185,186]. The dose of aspirin required remains controversial. French investigators[187] have shown that platelet aggregation is significantly abnormal in heart transplant patients, perhaps related to cyclosporin[188], and that the dose of aspirin required is at least twice that in non-transplant patients with atherosclerosis (500 mg vs 250 mg), a fact which may explain the negative results of previous studies of aspirin in heart transplant patients.

Recently, preliminary results of a trial at Stanford University have shown that the calcium-channel blocker, diltiazem, is associated with a significant decrease in intimal thickening compared to control patients[189]. Calcium-channel blockers have anti-atherosclerotic[190-192] and potentially immunosuppressive properties[193], and may be an ideal first-line therapy for the treatment of hypertension, as well as empiric preventive strategy for the development of coronary disease in high-risk patients. In addition, newer agents such as fish oil[194-196], antioxidants[197], ACE inhibitors[198,199] and, potentially, estrogen[200], which have been shown to reduce the development of atherosclerosis, may be future forms of preventive treatment for ACAD.

One of the most promising new strategies is the use of the drug angiopeptin[201], which has antiproliferative properties by virtue of its ability to inhibit insulin-like growth factor, a potent stimulant of smooth muscle cell growth. Preliminary results of a trial in Germany[202,203] have shown that it significantly inhibited intimal thickening in heart transplant patients as assessed by IVUS. Finally, almost all new immunosuppressive agents will have to demonstrate some ability to inhibit smooth muscle cell proliferation in addition to inhibiting rejection. Current examples of this combined ability included mycophenolate mofetil[204] and rapamycin[205,206].

Retransplantation

Traditionally, the only definitive form of therapy for allograft coronary disease has been retransplantation. However, the overall

results of retransplantation have been very discouraging due to poor overall survival and redevelopment of the disease in the second heart[207] (Chapter 43). Results, however, are apparently best for patients beyond 4 years post-transplant who undergo re-transplantation for ACAD[208]. In addition, the significant increase in the number of patients on active heart transplant waiting lists has further diminished the enthusiasm of most centers in offering retransplantation to many patients.

PTCA

Recently, a number of single[209] and multicenter[210,211] trials have been reported regarding the use of PTCA or arthrectomy in cardiac transplant patients with coronary disease. These studies suggest that the response rate in transplant patients is highly variable, but very similar to non-transplant patients with coronary disease, in which a restenosis rate of at least 30–35% can be anticipated for dilatation of a single lesion. However, in comparison to the Stanford data on patients with a luminal diameter stenosis of >70% without intervention[17], angioplasty would seem to potentially improve survival and outcome over the first year following angioplasty[212]. Clearly, a number of patients have had excellent long-term results from a single- or two-vessel dilatation, but the response is quite variable as the disease may be evident in another vessel on follow-up study, and all rates and types of progression have been described.

Coronary artery bypass surgery

Historically, conventional coronary artery bypass surgery has been considered to have no application in transplant patients because of the concept that patients had obliterative disease in the distal vessels once epicardial disease was evident[213–215]. This concept may no longer be valid and bypass surgery may become an alternative for patients, particularly with the very accelerated form of the disease. The use of coronary flow reserve (described above) may identify patients with a functionally intact distal vascular run-off bed who might do well with conventional bypass surgery. If so, coronary artery bypass would certainly be a better option for patients who are not amenable to angioplasty, either because of the high number of focal stenoses or where there is proximal severity (where bypass surgery would be a preferable option in non-transplant patients)[216].

Transmyocardial laser revascularization

The newest form of treatment for ACAD is the use of transmyocardial laser revascularization[217–219]. Although spurned by many skeptics, who do not support the basic premise of the possibility of the perfusion of the myocardium from the endocardium outward[218], this technique employs a limited anterior thoracotomy or median sternotomy to expose the heart without need for cardiopulmonary bypass support. A series of up to 40 holes is placed from the epicardium through into the left ventricular chamber by use of a CO_2 laser. This energy source can be controlled, and the blood in the chamber allows dispersion of the energy source, preventing injury on the contralateral side. The laser is able to achieve a burn that does not cause diffuse thermal injury to the myocardium, but allows enough scarring to keep the channels open.

Nuclear studies in animals, using separate isotopes to identify direct antegrade coronary perfusion from retrograde blood flow originating in the LV cavity, have, in fact, shown a greater degree of myocardial perfusion from endocardial to epicardial flow through these channels after laser revascularization. March[219] has recently reported on an experience in non-transplant patients (who were considered too ill for conventional revascularization) who have done well, with improved ventricular function and anginal control on follow-up. Clearly, this procedure, which causes limited morbidity, may be a superior option for a number of transplant patients with diffuse coronary disease, particularly if associated with ventricular dysfunction.

PROPHYLAXIS

Finally, strategies need to be evaluated for potential non-pharmacologic prophylaxis of ACAD. This may include such strategies as prospective HLA-DR matching, if preservation time can be extended, to allow better HLA-DR matching of donor and recipient, thereby potentially reducing the incidence of acute rejection. In addition, newer therapies, such as photochemotherapy[220,221], which has been shown in animal models to inhibit arterial smooth muscle proliferation as well as diminish development of donor-specific endothelial antibody formation in patients, may be particularly effective in high-risk patients, such as highly sensitized patients or those who develop vascular rejection following transplantation. Similarly, prospective matching by CMV serologies may potentially decrease the likelihood of infection with this agent, and acceleration of the development of this disease. The most futuristic approach is gene therapy[222], which is being explored as a means of deleting or inserting critical elements of the response to this disease.

COMMENT

There has been, and continues to be, a great deal of progress in the last several years, not only with our ability to diagnose ACAD and begin to understand its pathogenesis, but also to develop and begin trials of new therapies to alter the natural history of the disease, which remains the greatest obstacle to long-term survival following heart transplantation.

Cardiac Retransplantation – Indications and Results

S. TANIGUCHI AND D.K.C. COOPER

INTRODUCTION

When allograft failure or severe dysfunction of an orthotopically or heterotopically transplanted heart occurs, replacement of the heart may be indicated and can substantially extend patient survival. There are surprisingly few reported data on the indications for retransplantation, or on the complications and results of this procedure[1–4].

Cardiac retransplantation in a patient with a previous orthotopic heart transplantation was first performed at Stanford Medical Center as early as 1968[1]. The first such intervention after heterotopic heart transplantation took place in Cape Town in 1980[5] (Chapter 37). This present chapter is confined to a discussion of the indications and results of retransplantation after orthotopic heart transplantation. A similar discussion in regard to retransplantation after heterotopic heart transplantation is included in Chapter 37.

The introduction of cyclosporin (CsA), though undoubtedly reducing the incidence of severe acute rejection episodes, does not as yet appear to have prevented the development of graft arteriosclerosis, which today is the main indication for retransplantation. The demands made by the need for retransplantation may significantly reduce the number of donor hearts available to newly selected potential recipients, providing the medical team with an ethical dilemma.

As patient mortality is significantly higher after retransplantation when compared with primary transplants, retransplantation must be considered particularly carefully in each individual case. Each donor heart, a valuable and scarce commodity, must be utilized as effectively as possible. Retransplantation should therefore be performed only in carefully chosen recipients where the prospect of a successful outcome is high.

INDICATIONS FOR RETRANSPLANTATION

Retransplantation should be considered in any patient in whom the cardiac allograft undergoes failure or severe dysfunction from acute and/or chronic rejection. Retransplantation has also been performed on occasion for intractable arrhythmias of the donor heart, and for acute donor right ventricular failure due to an excessive pulmonary vascular resistance following orthotopic transplantation[1]; refinements of criteria for selection of both recipients and donors, and the use of such agents as prostaglandin E1 (PGE1) to reduce pulmonary vascular resistance, have made these indications for retransplantation rare. Early donor heart failure (primary allograft dysfunction) from causes other than acute rejection accounts for a significant proportion of the deaths of patients undergoing transplantation (Chapter 43); if a second donor heart can be obtained in time, or the patient can be maintained by prolonged pump–oxygenator support[6–8] or by an artificial heart or a mechanical assist device (Chapter 21), retransplantation may be lifesaving. Jurmann *et al.*[8] reported a patient who underwent retransplantation after 'bridging' with an intra-aortic balloon pump and right ventricular assist device for 14 hours after early primary graft failure. Morris *et al.*[7] described successful support by extracorporeal membrane oxygenation (ECMO) for 22 hours between immediate graft failure of a primary transplant and successful retransplantation.

Intractable acute rejection of an orthotopic graft, though relatively rare today, is clearly an urgent indication for retransplantation. These patients, however, do particularly poorly after retransplantation, almost certainly because they have frequently been very heavily immunosuppressed for the previous few days, or even weeks, in an attempt to retain the initial allograft. They are therefore at high risk for infection in the early post-retransplant period. Furthermore, as retransplantation is frequently required urgently, there is probably a tendency to accept a less-than-perfect donor heart in such circumstances. The risk of early graft dysfunction and failure is therefore increased.

There remains some controversy over the decision to perform retransplantation as an emergency for primary graft failure or intractable acute rejection. In view of the reduced success of heart transplantation under such circumstances, there are those who believe that acute cardiac retransplantation is not justified while there remains a critical shortage of donor organs[9].

The decision to retransplant a patient undergoing chronic rejection (graft arteriosclerosis) and, in particular, the timing of the procedure, may be difficult, as the patient's general condition may

remain good, despite evidence of increasing coronary arteriosclerotic changes. Both surgeon and patient may be reluctant to undertake retransplantation whilst the patient remains asymptomatic; delay, however, may result in sudden death from major myocardial infarction or dysrhythmia. Alternatively, the patient's general condition may have deteriorated from chronic infection or other complications of long-term immunosuppression, creating doubt as to his or her suitability for retransplantation.

Even with regard to primary graft failure for graft arteriosclerosis, some physicians and surgeons believe that retransplantation should not be allowed in view of concerns regarding: (a) the lower survival rate when compared with primary heart transplantation, (b) the less impressive cost–benefit ratio, and (c) the equitable allocation of scarce donor hearts[10,11]. Our own policy has been to offer retransplantation only to those patients in whom we believe the likelihood of successful short- and long-term outcomes is high, and is approximately equivalent to that in a patient undergoing a primary transplant. We have therefore excluded patients in whom primary graft failure, intractable rejection, or graft arteriosclerosis have already resulted in significant complications, such as failure of other essential organs or life-threatening infection. In the small group of carefully selected patients who have undergone retransplantation at our center, for whatever reason, the results have been comparable to those following primary transplantation (unpublished data).

SELECTION OF PATIENTS FOR RETRANSPLANTATION

All of the criteria for transplantation should be reassessed before retransplantation is performed (Chapters 5 and 19), since significant changes may have occurred since the patient was assessed initially. In particular, the increased immunosuppression that is necessary during acute rejection episodes, or the prolonged immunosuppression in patients who have survived long enough to develop graft arteriosclerosis, may have resulted in foci of infection. If possible these infections must be eradicated or suppressed before retransplantation is undertaken. If it is not possible to eradicate a significant focus of infection, then the patient may not be suitable for retransplantation.

Some degree of renal dysfunction may well have developed from prolonged CsA therapy and/or acute or chronic cardiac rejection (leading to impaired cardiac function) by the time retransplantation is considered. Careful assessment is required to ensure at least that the patient's renal function or reserve is sufficient to get him or her through the difficult early post-retransplant period when CsA dosage will of necessity have to be higher.

Such decisions are sometimes difficult, as the relative contributions to renal dysfunction of CsA and cardiac insufficiency may be difficult to distinguish.

The presence of such complications of immunosuppression as lymphoproliferative disease, even if currently controlled by a reduced immunosuppressive therapeutic regimen, remains a contraindication to retransplantation as the disease is likely to recur and spread when high-dose immunosuppressive therapy is administered after the second transplant.

The patient should also be carefully reassessed from a psychological standpoint to ascertain whether he or she can cope with the stresses and strains of a further transplant procedure. Particular attention should be paid to the patient's compliance with medical guidance, and his or her adherence to therapy during the course of the first transplant. Retransplantation may be inadvisable if non-compliance had contributed toward failure of the initial allograft.

Meticulous testing of the recipient for the presence of lymphocytotoxic antibodies must be carried out, and antibodies against any new potential donor excluded. Antibody formation occurs to a greater or lesser degree in many patients who have received cardiac allografts with or without blood transfusions, and may preclude the use of certain donors for retransplantation[12] (Chapter 6).

According to an investigation reported by Ensley *et al.*[13], based on data from 449 recipients of second allografts reported to the Registry of the International Society for Heart and Lung Transplantation, together with a further 125 repeat transplants at 13 transplant centers in the United States, the 'ideal candidate' for a second transplant is a patient with: (a) a long interval since the first transplant, (b) accelerated coronary artery disease as the cause of allograft loss, and (c) an absence of current mechanical assistance.

TIMING OF RETRANSPLANTATION

In primary allograft dysfunction or intractable acute rejection

Primary allograft dysfunction or failure unfortunately remains a significant complication in a small percentage of the heart transplants performed today. In contrast, with the immunosuppressive agents currently available, intractable acute rejection is a relatively rare occurrence. When graft failure from either of these causes develops in a patient with an orthotopic transplant, this, of course, constitutes a surgical emergency. Either retransplantation must be carried out as an emergency, or the patient must be assisted by some form of mechanical assist device. Without such mechanical assistance a second donor must be found within hours or a day or two, or death of the patient will occur.

In advanced chronic rejection

As with acute rejection, complete failure of an orthotopic allograft from chronic rejection results in the death of the patient; it is usually clear, however, that chronic rejection is occurring, and time is available to plan the retransplant procedure.

The timing of retransplantation may prove difficult, therefore, in patients with orthotopic grafts in whom chronic rejection is occurring. The decision to retransplant must not be delayed until graft function becomes totally inadequate; on the other hand, retransplantation should not be undertaken until absolutely essential. The exact timing is influenced by many factors, notably the ease or difficulty with which a suitable donor will be obtained; for example, if the patient has a high level of circulating lymphocytotoxic antibodies, some considerable delay may occur in obtaining a suitable donor, and the search should begin earlier rather than later.

The policy of the Stanford group has been to offer retransplantation to patients with evidence on coronary arteriography of life-

threatening occlusive lesions in the major coronary arteries, irrespective of the patient's exercise tolerance[2]. This policy evolved following the sudden death of three long-term survivors with such lesions. Our own policy has been possibly rather less aggressive, as we have rarely seen sudden death in an otherwise asymptomatic patient. We have generally waited until exercise tolerance has significantly deteriorated, and coronary arteriography and/or thallium scanning has confirmed advanced disease.

The rate of development and progression of graft arteriosclerosis is extremely variable. In the pre-CsA era we have seen advanced disease as early as 3 months, yet no disease as late as 13 years, after transplantation. The development of even moderately advanced disease may be compatible in many cases with an acceptable quality of life for several further months or even years. In one of our patients a 50% stenosis of the right coronary artery was demonstrated 6 years before death; this progressed to complete occlusion of this vessel at its origin and widespread disease of the left coronary system over the next 4 years. Some 2 years later the patient finally succumbed to the disease, retransplantation having been contraindicated on other grounds[14,15].

RETRANSPLANTATION – OPERATIVE CONSIDERATIONS

It is our present policy in all cases of retransplantation to prepare the femoral artery and vein. This allows initiation of pump–oxygenator support through this route if cardiac function deteriorates before median sternotomy is performed. In all cases inotropic agents should be available during induction of anesthesia. Very rarely, in a patient with particularly poor cardiac function who is hemodynamically very unstable, initiation of cardiopulmonary bypass by the femoral route (or at least preparation of the femoral vessels) under local anesthesia may be advisable before induction of general anesthesia.

Following encouraging reports of reduced blood loss following the use of aprotinin[16,17], more recently it has been our policy to utilize aprotinin in all patients undergoing retransplantation (or initial transplantation after previous open-heart surgery). Although our experience to date is small, our impression is that the use of aprotinin during the operative procedure has been associated with reduced blood loss, which is in agreement with others.

The operation of retransplantation in a patient with an existing orthotopic allograft presents the same technical problems and risks of reoperation as in any patient who has previously undergone cardiac surgery. Adhesions have invariably developed between pericardium and heart, frequently making the initial dissection time-consuming. As myocardial function in these patients is poor, particular care must be taken not to handle or disturb the heart more than is absolutely essential before pump–oxygenator support has been initiated; for this reason it may be necessary to resort at some stage during the dissection to the use of the femoral vessels to commence cardiopulmonary bypass.

After excision of the first donor heart, which can usually be achieved through or close to the old suture lines, the second heart is inserted as described in Chapter 24.

POSTOPERATIVE CARE AND IMMUNOSUPPRESSION

The immediate postoperative care of patients who have undergone retransplantation does not differ significantly from that following the initial procedure (Chapter 26). If retransplantation is performed during or immediately following an irreversible acute rejection episode, care must be taken not to over-immunosuppress the patient, as he or she will almost certainly already have received a considerable amount of immunosuppressive therapy; preoperative 'loading' doses of the various drugs will probably be unnecessary.

RESULTS OF RETRANSPLANTATION

The overall results of retransplantation as reported through the Registry of the International Society for Heart and Lung Transplantation (Chapter 43) and the Collaborative Heart Transplant Study (Chapter 44) are significantly inferior to those following primary heart transplantation. One- and 5-year survivals are approximately 50% and 30% following retransplantation compared with approximately 80% and 70% after primary transplantation. Most of this increased mortality, however, is during the early part of the first post-transplant year. If the retransplant patient survives 3 months, he or she has a comparable survival to the patient undergoing heart transplantation for the first time.

There are relatively few reports of series of patients undergoing retransplantation[4,13,18–20].

Between January 1968 and March 1980, 202 hearts were transplanted in 185 patients at Stanford University Medical Center. Sixteen patients with orthotopic allografts received second transplants, eight for accelerated arteriosclerotic coronary disease, six for unrelenting acute rejection, and two for dysrhythmia or right ventricular failure[4]. One patient required a third transplant because of donor left ventricular ischemia. All sequential transplants were managed similarly to the primary transplant.

Of the 16 initial transplant hearts at risk, 60% functioned for more than 1 year, and 57% for more than 2 years; these results were similar at that time to heart survival in patients not requiring retransplantation. Of the secondary transplant hearts at risk, however, only 31% survived for more than 1 year and 29% for more than 2 years, survival of approximately only 50% when compared with the primary group. The mortality was due largely to severe infection and the development of malignant tumors.

Infection of the secondary transplant (retransplant) patient appeared to play a more dominant role in fatality. The patients in this group were suspected to be initially free of infection in spite of primary allograft immunotherapy. The number and type of infections, however, were not substantially different from those in the group undergoing a primary transplant. Prolonged periods of immunosuppression during the perioperative period of the secondary transplant exposed these patients to this complication.

The Stanford group concluded that sequential orthotopic cardiac transplantation offers an acceptable alternative to patients with allograft failure, though survival was not as favorable because of the prolonged immunosuppression required.

Between December 1980, when immunosuppression with CsA was introduced, and May 1988, 288 patients underwent primary heart transplantation at Stanford University Medical Center[20].

During this period, 23 patients with orthotopic allografts received second transplants, 14 for accelerated graft atherosclerosis and nine for intractable allograft rejection. Four patients had received conventional immunosuppressive therapy (consisting of azathioprine, corticosteroids, and antilymphocyte globulin) after the primary allograft procedure. All other patients received CsA as part of the immunosuppressive regimen after transplantation of both the first and second allografts. Actuarial survival following primary transplantation (81 ± 2% at 1 year and 58% ± 4% at 5 years) was significantly better than that following retransplantation for intractable rejection (44% ± 17% at 1 year and 44% ± 0% at 5 years) ($p<0.05$). Cardiac retransplantation for acute rejection was associated with rejection and infection rates similar to those following the primary procedure. However, patients who underwent retransplantation for rejection survived these complications significantly less often than did patients who received primary transplants. Patients who underwent retransplantation for accelerated graft atherosclerosis experienced a lower rate of early rejection and similar rates of infection and survival compared with patients who received primary transplants.

Ensley *et al.*[13,19] analyzed data from 449 recipients of second allografts reported to the Registry of the International Society for Heart and Lung Transplantation and a matched group of 421 primary transplant recipients. Survival was markedly decreased in repeat transplantation patients with a 1-year actuarial survival of only 48% compared to 79% in the primary transplant group ($p<0.001$). Univariate analysis showed no impact on survival of recipient age or gender, ischemic time, or transplant center experience. Accelerated coronary artery disease as the cause of allograft failure, a longer interval between transplants, lack of preoperative mechanical assistance, and a second transplant performed after 1985 were predictive of increased survival following retransplantation. However, an 'ideal candidate', defined by these predictive variables, still had a 1-year survival rate of only 64%, which was not as good as in the matched primary transplant group.

Furthermore, a multicenter database was developed using data from 125 repeat transplant patients and 1325 primary transplants at 13 centers in the USA. In this group of retransplant patients the 1-year survival rate was greater than that reported in the International Society for Heart and Lung Transplantation Registry (60% vs 48%), and the impact of the predictive variables listed previously was decreased. The incidences of rejection, infection, and accelerated coronary artery disease were not different between the secondary and primary allograft recipients. Malignancies (other than skin cancer) occurred more frequently in repeat transplant patients (8% vs 4%; $p<0.05$). Recipients of second allografts were more likely to have major surgical complications, had a higher level of sensitization to HLA antigens, and were more likely to have a positive donor-specific lymphocytotoxic crossmatch (17% vs 2%). A trend towards improved survival was noted in patients with repetition in the second donor of mismatched HLA antigens present in the first donor (1-year survival rate of 68% vs 47%; $p=0.06$).

Michler *et al.*[16] reviewed 13 patients who had undergone retransplantation, including one patient who had received a third graft. Immunosuppression and follow-up protocols used in this cohort were similar to those in the primary transplant population at that center. No significant difference was observed in actuarial survival between primary transplant recipients (75.1% ± 2.2% at 1 year and 71.3% ± 2.4% at 2 years) and patients who underwent retransplantation (71.4% ± 12.1% at 1 year and 59.5% ± 14.8% at 2 years). Similarly, no differences were observed with regard to age, sex, race, cause of end-stage heart disease, or early (<30 days) mortality. The cause of primary graft failure did not correlate with survival outcome in the retransplantation cohort. Approximately 50% of patients in both groups experienced at least one rejection episode by 3 months. Within the limited time period of this study only one patient developed transplant coronary artery disease (approximately 27 months after retransplantation for acute rejection). The authors concluded that the prognosis for patients undergoing cardiac retransplantation was good if the indication for retransplantation was identified >30 days after the initial transplant procedure.

COMMENT

In summary, retransplantation should be reserved for very carefully selected patients, particularly those with graft arteriosclerosis in whom assessment of the patient and the retransplant procedure can be carried out electively without undue haste. Although it should be considered as a therapeutic option, it is probably least successful when performed as an emergency in patients with primary allograft failure from donor heart dysfunction or intractable acute rejection (humoral or cellular). The decision to offer retransplantation should always be made with due consideration for the needs of other patients awaiting primary heart transplants in light of the increasing shortage of donor organs.

Heterotopic Heart Transplantation – Indications, Surgical Techniques and Special Considerations

D.K.C. COOPER AND S. TANIGUCHI

INTRODUCTION

Heterotopic heart transplantation (HHT) has a long history in the experimental laboratory[1] (Chapter 18). Early experimental work was mainly by the Russian surgeon Demikhov[2], and subsequently by others[3–6], but it was Barnard and Losman's techniques of implanting an auxiliary heart in the chest in 1974[7–9] that led to the initiation of a clinical program. The surgical technique of biventricular assist (Figure 1) is described below. The technique of left ventricular assist alone (Figure 2) is now less commonly performed, but can be associated with excellent long-term survival[11].

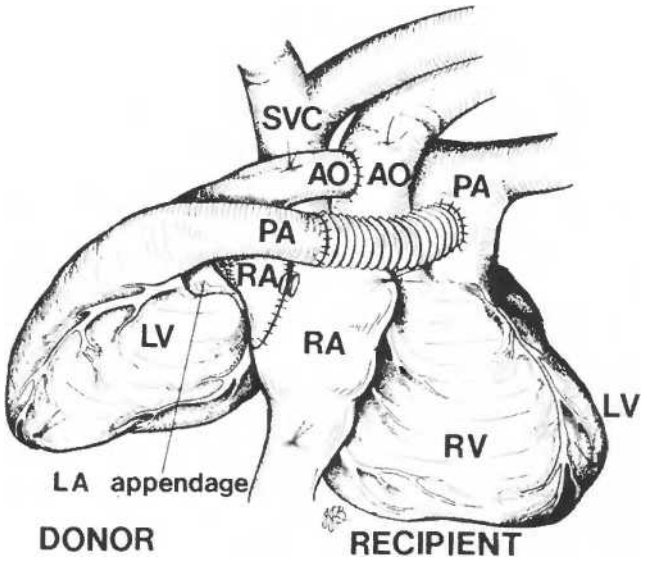

Figure 1 The completed operation of biventricular assist using a heterotopic heart transplant. (Arterial and venous cannulae have been removed.) (Abbreviations used in figures in this chapter are: LA = left atrium; RA = right atrium; SVC = superior vena cava; IVC = inferior vena cava; PV = pulmonary vein; RV = right ventricle; PA = pulmonary artery; AO = aorta; LV = left ventricle; CS = coronary sinus)

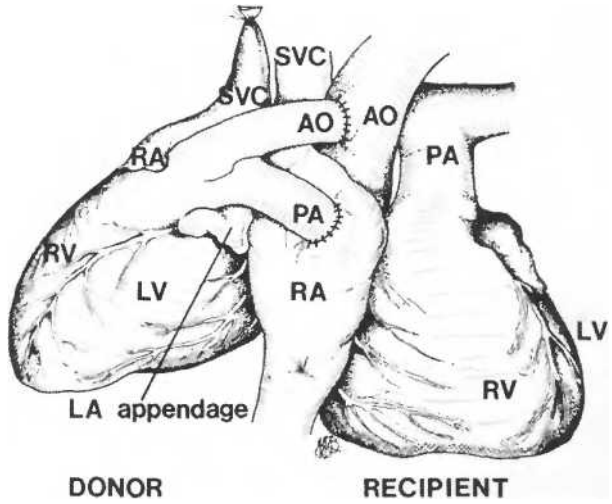

Figure 2 The completed operation of left ventricular assist using a heterotopic heart transplant. Anastomoses are performed between the donor and recipient left atria and aortae. Donor coronary venous return drains by the donor right atrium, right ventricle, and pulmonary artery into the recipient right atrium

Based on extensive experimental work by Losman and Barnard[8], a form of HHT was carried out in 1974 whereby the donor heart acted solely as a left ventricular assist device[7]. This operation (Figure 2) involved anastomoses between the donor and recipient left atria and aortae; donor coronary sinus venous return was drained via the donor right atrium and right ventricle into the recipient circulation by anastomosing the donor pulmonary artery to the recipient right atrium. Two such operations were performed. Both patients suffered recurrent attacks of native heart dysrhythmias, including ventricular fibrillation, during which

time the donor heart supported the circulation alone, though with significant loss of blood pressure[10]. Despite this, one patient survived for almost 10 years[11]. As a result of this experience, however, the technique was modified to allow bypass and support of both recipient ventricles[7,9]. Today HHT has relatively few specific indications, and is performed only under special circumstances[12].

The implantation of a natural auxiliary heart using the technique of HHT may be on a permanent basis, or may occasionally be temporary as a means of support while recovery of the patient's own heart is awaited, or a more definitive procedure is planned (as will be outlined later). Considerable clinical experience has now been amassed with auxiliary hearts implanted on a permanent basis; all such hearts have to date been allografts. Clinical experience of temporary support by an auxiliary heart has been small, and has largely been in the realm of xenotransplantation (Chapter 82). It is feasible that an animal heart may be utilized in the heterotopic position to provide a bridge for an infant or child in cardiac failure who is awaiting a suitable human heart, and for whom a suitable left ventricular assist device is not available.

(Techniques for utilizing the *left* ventricle of a heterotopically placed heart to support a failing *right* ventricle of the native heart (for example in certain complex congenital cardiac deformities[13] or in patients with pulmonary hypertension[14]) have been described but, to our knowledge, have not been utilized in clinical practice, and will not be discussed further here.)

HHT has both advantages and disadvantages when compared with orthotopic heart transplantation (OHT) (Table 1)[15,16], which have been documented fully previously[17–19]. In particular, the heterotopic procedure may allow recipient survival despite temporary or permanent loss of donor heart function following acute or chronic rejection (Figure 3); the circulation may be maintained by the recipient's own heart for at least a period of time. This advantage was of considerable practical importance in the precyclosporin era when irreversible rejection was not uncommon. In several patients the circulation was maintained by the recipient native heart until retransplantation could be performed. Indeed, this was one of the reasons that influenced Barnard to explore the technique. However, the efficiency of current immunosuppressive agents in preventing irreversible acute rejection has greatly diminished this advantage.

Nevertheless, HHT still has a role in certain specific conditions.

Indications

1. Whenever there is any possibility of recovery of the recipient's own myocardium, e.g. in acute myocarditis (of viral or rheumatic origin), then HHT should be considered. Unfortunately, the number of cases where recovery has been documented remains small[20,21].

2. When there is any possibility that initial donor heart function will be less than adequate to maintain the circulation alone, HHT may allow successful transplantation. This could be expected most commonly when there is a large discrepancy in body mass (>33%) between recipient and donor. Although a small donor heart will eventually hypertrophy to adapt to the demands made upon it, it might fail in the early post-transplant period unless the recipient heart remains *in situ* to lend some support. In this respect, however, it should be noted that a small child's heart may be technically impossible to insert heterotopically as a biventricular assist in an adult, as it may not be possible to join the two right atria; insertion of the heart solely as a left ventricular assist would, however, be possible.

The Baylor (Houston) group[22] utilized small donor hearts in HHT in a series of large patients (body surface area >1.95 m^2). Waiting times for large patients receiving a HHT (mean 67 days) were significantly shorter than those who received an OHT (mean 166 days). Waiting time mortality decreased from 24% to 9%. There was no difference between the two groups with regard to mid-term survival or early post-transplant functional status. This is one example of how HHT can increase the size of the donor pool for larger patients, who tend to wait much longer for a donor heart than do smaller patients.

Similarly, when a donor heart has undergone a particularly long ischemic period during transportation and transplantation, or for some other reason is deemed less than ideal (and yet the recipient's cardiovascular status is deteriorating so rapidly that survival (until the next donor becomes available) is not expected), then again HHT would seem to be advisable; the support given by the recipient heart in the early transplant period may allow time for recovery of the donor heart.

Table 1 Advantages and disadvantages of heterotopic over orthotopic heart transplantation

Advantages	*Disadvantages*
1. Recipient heart acts as a built-in cardiac assist device and may maintain circulation (a) During reversible loss of donor heart function during: (i) period of recovery of donor heart from ischemia sustained during transplantation; (ii) severe acute rejection episodes (b) Following irreversible loss of donor heart function from: (i) acute, or (ii) chronic rejection (while patient awaits retransplantation) (c) During adaptation of a very small donor heart to the demands of the circulation 2. Allows for possible recovery of recipient heart, e.g. after viral myocarditis 3. Can be performed even in the presence of a high pulmonary vascular resistance if the hypertrophied recipient right ventricle can continue to support the pulmonary circulation	1. Risk of systemic emboli from thrombus in poorly contracting recipient left ventricle 2. Requires long-term anticoagulation 3. Continuing angina related to ischemic recipient myocardium (rare) 4. Risk of infection and/or thrombus formation in relation to: (a) presence of valve prosthesis in recipient heart (this is a contraindication to HHT) (b) presence of Dacron graft between donor and recipient pulmonary arteries (c) compression of lower lobe of right lung due to presence of donor heart in right pleural cavity (rare) 5. Hemodynamically significant dysrhythmias of the recipient heart requiring high doses of antiarrhythmic agents

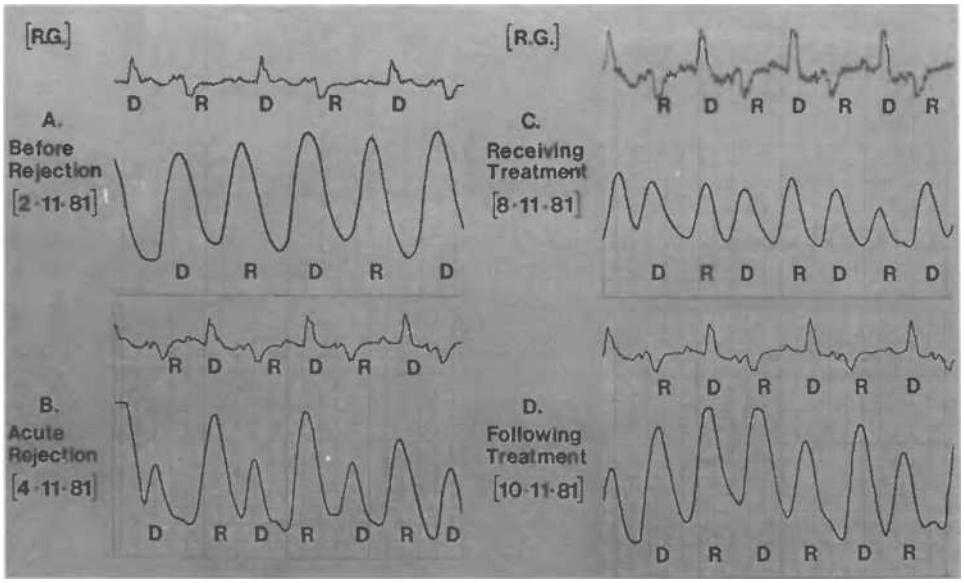

Figure 3 Diagram showing electrocardiogram (above) and femoral pulse trace (below) of donor (D) and recipient (R) hearts after heterotopic transplantation. Note the deterioration in the donor heart pulse in relation to the recipient heart pulse during an acute rejection episode, and the reversal of this trend following increased immunosuppressive therapy

Recovery of an ischemic donor heart was clearly demonstrated when two hearts in the Cape Town series were stored by hypothermic perfusion for periods of 7 and 13 h, respectively[23]. Diminished donor heart function was observed for 16–19 h until full recovery occurred; the recipient heart was invaluable in supporting the patient during this period.

3. When the patient is suffering severe anginal attacks unresponsive to full medical therapy and unrelieved (where possible) by myocardial revascularization procedures, and yet where left ventricular function continues to be good, it may on occasion be contraindicated to excise the recipient heart and perform OHT.

Disabling angina, although relatively rare today, might be considered by some to be a contraindication to HHT, as the risk of continuing angina post-transplant remains. Following HHT, however, a well-functioning transplant would greatly diminish the demands on the ischemic recipient heart, thus reducing the oxygen requirement (and the threshold of angina) and yet retaining the support given by the recipient left ventricle.

4. A fixed pulmonary vascular resistance (PVR) greater than approximately 5 Wood units (400 dyne/s per cm^{-5}) has long been considered by many a contraindication to OHT, as it was anticipated that early failure of the donor right ventricle would occur (Chapter 20). When the PVR is fixed >8 Wood units (640 dyne/s per cm^{-5}), it has generally been assumed that transplantation of the heart and both lungs should be carried out. When the PVR is fixed between 6 and 8 units, and where right ventricular failure is not severe, then HHT has been advocated. There have been few patients, however, in whom this theory has been put into practice and the results clearly documented. Furthermore, the extent of reversibility of the PVR may be difficult to ascertain absolutely before transplantation.

Reichenspurner *et al.* documented a fall in PVR from 4.9 to 2.4 Wood units in patients with HHT in Cape Town[24], and the La Pitié group in Paris confirmed a decreased PVR in the first post-transplant month in 42 patients undergoing HHT[25,26]. In the La Pitié series, however, although PVR fell significantly, post-transplant survival of patients with pretransplant pulmonary hypertension was poor, in part because of pulmonary complications and infection. A reduction in an elevated transpulmonary gradient has also been demonstrated in pediatric patients undergoing HHT using the left heart assist technique[27]. Even when a markedly elevated PVR does not reverse, the contribution of the heterotopic heart to left ventricular function can greatly improve the clinical status of the patient[28].

A statistical study by Kirklin and his colleagues from Alabama confirmed that elevated PVR is an incremental risk factor for premature death after heart transplantation[29]. The value of PVR used was that obtained closest to the time of transplantation, without specific attempts to modify it by vasodilator or inotropic agents. The rate of rise in risk of death corresponded with the progressive increase in PVR (particularly when expressed as Wood units × square meters = PVRI), rather than abruptly increasing at a certain point. Although this study indicated that there is no precise level of PVR beyond which OHT is contraindicated, there must come a point when the risk is so high that OHT is no longer advisable or, at least, an alternative surgical technique, e.g. HHT or heart–lung transplantation, is indicated. This topic is discussed fully in Chapter 20.

If significant right ventricular failure is present, secondary to irreversible pulmonary vascular disease (as opposed to being secondary to left ventricular failure alone), then right ventricular function will not improve after HHT. In doubtful cases we have found measurement of right ventricular ejection fraction by radionuclide scanning to be a valuable guide to the adequacy of right ventricular function. A right ventricular ejection fraction <20% (i.e. approximately 50% of normal) would discourage us from performing HHT in the presence of a fixed PVR >5 Wood

units and, instead, we would consider transplantation of the heart and both lungs.

The indication for HHT in relation to the PVR and/or transpulmonary gradient remains controversial, but it would seem reasonable to suggest that, in patients with left ventricular failure from ischemic or cardiomyopathic disease, HHT should be preferred whenever there is serious doubt that the right ventricle of the transplanted heart will be able to support the pulmonary circulation successfully. If the PVR were fixed >8 Wood units (or the transpulmonary gradient (TPG) fixed >15 mmHg) then heart–lung transplantation should be considered.

5. The temporary insertion of a human auxiliary heart as a 'bridge' to OHT would seem to have little place in modern cardiac transplantation. It has been clearly demonstrated that temporary support of a failing circulation can be satisfactorily provided by one of the several ventricular assist devices or artificial hearts which are currently available (Chapter 21). The use of an auxiliary (or orthotopic) non-human primate heart, however, as a bridge to transplantation would seem feasible, especially in infants and children for whom no mechanical device of suitable size is presently available. Current experimental data would suggest that a nonhuman primate heart would function satisfactorily in a human recipient for several days, and possibly weeks or months (Chapter 80). This would allow time for a suitable human heart to be located and inserted (with removal of both the non-human primate organ and the recipient's native heart, if it is still *in situ*).

Indeed, this was one possibility in two adult patients in whom auxiliary cardiac xenografts (one baboon and one chimpanzee) were implanted by Barnard and his colleagues in 1977[30]. The baboon heart proved of insufficient size to support the circulation, and, in this pre-CsA era, the chimpanzee heart was rejected on the fourth postoperative day before a suitable human donor could be found. No more recent attempts have been reported.

SURGICAL TECHNIQUES

Donor heart excision

Donor heart excision is very similar to that described previously for OHT (Chapter 24), but a greater length of superior vena cava (SVC) should be retained. The SVC is, therefore, mobilized along the whole of its length and two ligatures passed around it cranial to the azygos vein, which itself is doubly ligated and divided. Otherwise, excision is as described for OHT.

Preparation of donor heart

The heart is placed in a bowl containing saline or cardioplegic solution at 4°C, where it is prepared for implantation into the recipient (Figure 4).

The orifices of both right pulmonary veins and of the inferior vena cava (IVC) are closed with continuous, double-layered sutures of 5/0 polypropylene, care being taken to ensure that coronary sinus drainage is not obstructed during closure of the IVC.

The bridge of tissue between the left superior and inferior pulmonary veins is excised to make a single opening into the left atrium; this opening may need to be extended to achieve a diameter of approximately 3.5–4.0 cm or the equivalent of a normal mitral valve orifice. The midpoint of the posterior wall of this opening may be marked with a suture to act as a reference during subsequent implantation into the recipient.

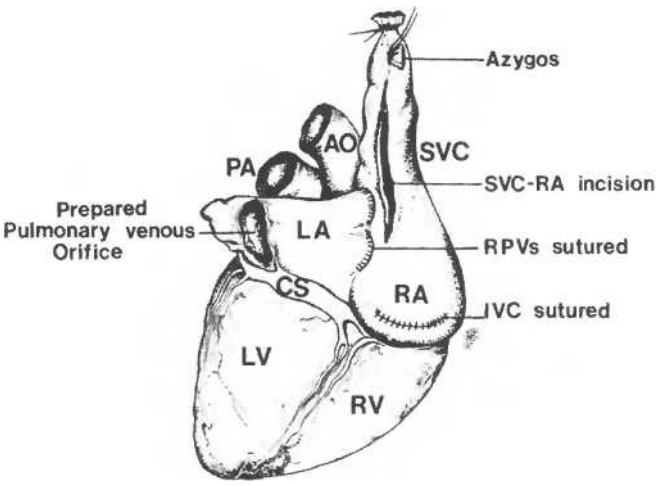

Figure 4 Donor heart (posterior view) prepared for implantation

A longitudinal incision is made in the posterior aspect of the SVC, beginning immediately caudal to the ligated azygos vein, and extended down just to the right of the interatrial septum into the right atrium. At least half the length of this 5 cm incision must involve the right atrial wall. It is essential to ensure that the incision is posteriorly sited in order to avoid injury to the sinoatrial node.

Approximately 10 min are required to prepare the heart in this way. The organ is then transferred to the recipient surgical team.

The recipient operation

With the patient supine, a midline sternotomy is performed and the pericardium opened longitudinally. A right-sided pleuropericardial flap is created (Figure 5), first by dividing the mediastinal

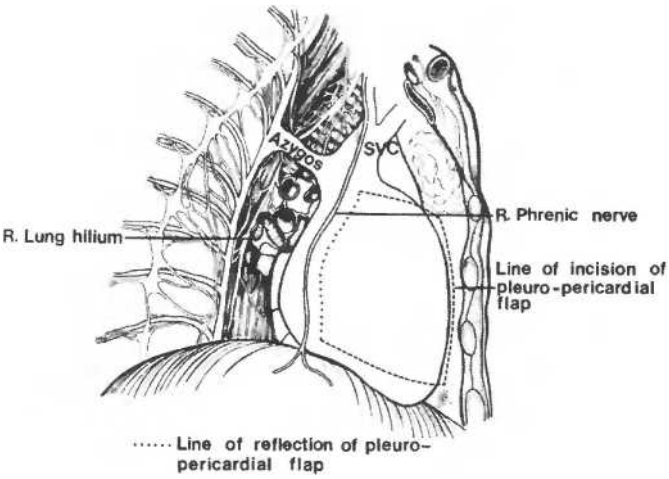

Figure 5 Recipient; right-sided view of mediastinum; the line of the pleuropericardial incision is indicated
