The marginal seas intercepted the flux of terrigenous sediments from continents and have the sedimentation rates one or two orders of magnitude higher than the sedimentation rates in open oceans. This is responsible for the development of wide continental shelves in marginal seas, such as in the marginal seas between Asia and western Pacific Ocean. Although South and East Asian continent and their

islands provide over 70 % of terrigenous suspended materials to the global ocean, these sediments were intercepted by marginal seas so that there are no large submarine deep-sea fans developed in the western Pacific comparable to Indian Ocean fans (Wang, 1999, 2004). The wide continental shelves of marginal seas are vulnerable to sea-level changes and thus might influence the climate. For example, because the South China Sea is a major source of

moisture for the summer monsoon rain in China, the reduction of shelf area in the last glacial maximum has enhanced the aridity in the China hinterland (Wang, 2004).

Primary productivity and biomass production

Marginal seas generally exhibit intermediate levels of primary production and biomass production, in comparison with the highest rates in coastal *upwelling* regions and

the lowest rates in open ocean regions. This is because variations in primary productivity in oceans and seas occur as a result of water column chemistry (e.g., nutrient and trace elements concentrations) and dominant physical processes. River runoff and water column mixing introduce dissolved nutrients, trace elements, and suspended particles into the photic (light) zones of nearshore regions and resulted in increased primary production; the addition

of suspended particles increases water turbidity, which results in reduced sunlight penetration and decreased primary productivity (Water Encyclopedia).

Importance of marginal seas

The marginal seas are often rich in oil and gas, fishery and biomass, and other resources. They also provide spaces for shipping and other human activities. These seas are the frontal areas of sea-land interactions with extensive mass, energy, and gene fluxes and have significant influences on global climate system. The thick sediments in the marginal seas contain detailed and often magnified records on the geological and environmental evolution of adjacent land masses (Clift et al., 2004; Wang, 1999).

The marginal seas in the geological context are a first-order tectonic feature in the Earth system. Along the boundaries between land masses and open oceans, marginal seas formed only in particular segment mainly in the western Pacific Ocean. The origin of marginal seas is a key to a deep understanding of the Earth's geodynamics. The formation of marginal seas had exerted significant impacts on the Earth system, such as on the geography, environment, and resources, on the ocean circulation and global climate, on the land-sea interactions and sedimentation, etc. These are the current research frontiers in geosciences.

Summary

It should be noticed that the definition of "marginal sea" is slightly different in disciplines of geology, geography and oceanography, and geopolitics. The most restrict definition is in geological context where a marginal sea must be underlain by oceanic crust, which is formed by lithosphere breakup and seafloor spreading. Marginal seas have many features different from those of open oceans. The formation of marginal seas created a space for extensive interactions between land mass and open oceans and has a significant impact on global geography, oceanography, geology, and climate system. The marginal seas also provide abundant natural resources and space for human being. The study of marginal seas is a frontier field in geosciences.

MARINE EVAPORITES

Walter E. Dean
U.S. Geological Survey, Denver, CO, USA

Definition

Marine evaporites form by extreme evaporation of seawater either directly in an open-water environment with restricted circulation or diagenetically from sediment pore waters.

Introduction

Geology hangs its interpretive powers on the principal of uniformitarianism, i.e., the present is the key to the past. Unfortunately for marine evaporates, there is no present example for the thick, aerially extensive ancient evaporite deposits ("saline giants"). That would require a large, deep basin with a marine connection but with restricted circulation, and a huge influx of seawater for a long time. The marine connection could be surface water or marine-fed groundwater. It would also require a warm climate with extreme net evaporation that existed for a long time. The Quaternary is not a good analog for the extent and distribution of climates that existed throughout most of the Phanerozoic because during the Quaternary the world was in an icehouse mode. However, during most of the Phanerozoic, the world was in a warm, greenhouse mode (Warren, 2010). In addition, the average salinity of the

world ocean during most of the Phanerozoic was 40–50‰ in contrast to 35‰ today (Hay et al., 2006).

Large evaporite basins occur on all continents, except Antarctica, and range in age from Late Precambrian to Late Miocene (Warren, 2006, 2010). The most recent saline giant occurred in the Latest Miocene (Messinian) in basins of the Mediterranean region (the so-called Messinian salinity crisis; Ryan et al., 1973; Hsü et al., 1973, 1978). Today, there are many environments with extreme net evaporation, but there are no connected large, deep basins with restricted marine connection. One candidate would be the Red Sea with a little more restriction and possibly a more arid climate. Leg 23 of the Deep Sea Drilling Project (DSDP) recovered bedded middle Miocene evaporates from the Red Sea when the basin was more restricted than today (Stoffers and Ross, 1974). Comprehensive reviews of evaporite deposits, marine and nonmarine, are given by Warren (2006, 2010).

Marine evaporite minerals

The first mineral to crystallize from evaporation of seawater is calcium carbonate ($CaCO_3$), usually as calcite, but at other times aragonite may form. Next is calcium sulfate either as gypsum ($CaSO_4 \cdot 2H_2O$) or anhydrite ($CaSO_4$). The next most abundant evaporite mineral is halite (NaCl), commonly known as rock salt. These two minerals, gypsum/anhydrite and halite, constitute more than 95 % by volume of the world's Phanerozoic evaporates (Warren, 2010). Under conditions of extreme, nearly complete evaporation potassium (K) and/or magnesium (Mg), minerals may form. These, often referred to as bittern or potash salts, are much less common. They include polyhalite ($K_2Ca_2Mg(SO_4)_4 \cdot 2H_2O$, sylvite (KCl), carnallite ($KCl_2 \cdot MgCl_2 \cdot 6H_2O$), langbeinite ($K_2SO_4 \cdot 2MgSO_4$), kainite ($MgSO_4 \cdot KCl \cdot 3H_2O$), glauberite ($Na_2SO_4 \cdot CaSO_4$), kieserite ($MgSO_4 \cdot H_2O$), bischofite ($MgCl_2 \cdot 6H_2O$), epsomite ($MgSO_4 \cdot 7 H_2O$), hexahydrite ($MgSO_4 \cdot 6 H_2O$), loeweite ($Na_4Mg_2 (SO_4)_4 \cdot 5H_2O$), and vanthoffite ($Na_6Mg(SO_4)_4$). Any one bed in an evaporite deposit commonly is monomineral, especially those composed of gypsum, anhydrite, or halite. Many more salts have been recorded from evaporite deposits but the above are by far the most common. Paragenetic mineral pairs with sylvite are common enough that they have been given mine-mineral names. Sylvite combined with halite is called "sylvanite," and sylvite combined with anhydrite and/or kieserite and/or polyhalite is called "hartsalz" by the Germans.

Permian Zechstein formation

The Upper Permian Zechstein Formation underlies most of Poland, Germany, the Netherlands, Denmark, east central England, and the North Sea. It is the most extensively studied evaporite sequence in the world. The Zechstein consists of four depositional cycles. The second oldest depositional cycle is the Stassfurt cycle or series named for its type section at Stassfurt, Germany. The Stassfurt

is the most studied and most economically important of the Zechstein series. At Stassfurt, the basal anhydrite is only 50 m thick, overlain by 500 m of halite, topped off by only 50 m of potash salts. Borings into the Zechstein throughout Germany in the early nineteenth century determined the locations of subsurface bedded rock salt and other evaporite minerals that formed a stratigraphic sequence more than 2,300 m thick at Stassfurt. At that time potassium and magnesium deposits (potash) associated with salt were considered contaminants and were discarded. However, it was soon recognized that potassium was necessary for plant growth, and for the rest of the nineteenth century, most of the potash of the world was supplied from mines near Stassfurt. Bischoff, in his book *Elements of Chemical and Physical Geology* (1864), was perhaps the first to recognize that halite and anhydrite (or gypsum) were precipitated from seawater but did not propose an exact method.

The following six zones represent a complete progressive evaporite cycle within the Stassfurt from youngest to oldest:

Hartsalz – sylvite plus anhydrite and/or kieserite, polyhalite, and halite
Carnallite – 55–60 % carnallite, 25 % halite, 17 % kieserite
Kieserite and carnallite – with approximately 65 % halite
Polyhalite – with approximately 93 % halite
Anhydrite plus halite – approximately 96 % anhydrite-laminated halite
Basal anhydrite – with dolomite laminae and some halite

Probably the most significant experiment in understanding the origin of evaporite minerals was the classic work of an Italian chemist named Usiglio (1849). He determined the sequence of precipitation of evaporite minerals from seawater by simply evaporating an aliquot of Mediterranean seawater and noting the sequence and quantities of precipitates with progressive evaporation.

The results of Usiglio's experimental evaporation of seawater (1849; reproduced in Clarke, 1924) show that calcium carbonate begins to precipitate inorganically when seawater has been evaporated to about half of its original volume. The most common carbonate mineral to form from seawater at normal-marine temperatures and pressures is low-Mg calcite, although aragonite, high-Mg calcite, and dolomite may also form if conditions are right, usually at higher salinities and/or in association with biogenic controls. Aragonite is unstable and with time and burial aragonite will recrystallize to form low-Mg calcite.

When the original water volume has been reduced to about 20 %, calcium sulfate begins to precipitate. Under salinity and temperature conditions of most evaporite deposits, anhydrite should theoretically be the most stable calcium sulfate mineral. However, in experimental and observed modern evaporite systems, gypsum is the almost universal calcium sulfate mineral to form. This may or may not have been true in the past. Primary anhydrite has been found in a few Holocene evaporite deposits such

as the sabkhas of the Persian Gulf, or associated with the heavy metal deposits in the deep, hot-brine basins of the Red Sea (Miller et al., 1966), and in Clayton Playa, Nevada (Moiola and Glover, 1965).

By the time the solution has been reduced to about 10 % of the original volume, most of the calcium sulfate has been deposited, and halite starts to separate along with gypsum (or anhydrite). When the volume of the solution is less than 5 % of the original, polyhalite takes the place of gypsum or anhydrite. Polyhalite separates together with halite until the solution is saturated with respect to Mg-bearing sulfates free from Ca and K. If the early-formed salts remain in contact with residual liquids at all stages and react freely with them, the final products of crystallization of the bittern salts are:

0° to 30 °C: epsomite + carnallite + bischofite + halite + anhydrite
13° to 17.5 °C: hexahydrite + carnallite + halite + anhydrite
17.5° to 110 °C: carnallite + bischofite + halite + anhydrite

Usiglio's experiment reproduced most of the evaporite mineral sequence found at Stassfurt.

To provide the theoretical or physical chemical explanation of the evaporite sequence at Stassfurt, the Dutch chemist Jacobus van't Hoff dedicated most of his career in the late 1890s and early 1900s to the study of the mineral equilibria of the Stassfurt salts. This was the beginning of experimental petrology. Van't Hoff's calculation produced a sequence of evaporites that was remarkably similar to the Stassfurt sequence. The main differences were with the potash salts. An informative historical summary of van't Hoff's work is provided by Eugster (1971), and an extensive description of the Zechstein is provided by Borchert and Muir (1964).

To explain the sedimentology of the sequence of minerals found at Stassfurt, Carl Ochsenius expanded the earlier model of Bischoff for the formation of evaporite minerals by evaporation of seawater and proposed the barred-basin model whereby a lagoon or seaway was separated from the open ocean by a bar. Ochsenius suggested that the Gulf of Kara Bogaz (Kara-Bogaz-Gol), which is separated from the Caspian Sea by a bar, might serve as an analog for a barred basin but on a smaller scale, both in terms of area and depth, than the large Phanerozoic evaporite basins.

Permian Castile and Salado formations

Another modification of the Bischoff–Ochsenius bar theory was proposed by R. H. King (1947) to explain the thick (1,300–2,000 ft; 400–600 m) anhydrite deposits, with minor halite, in the late Permian (Ochoan; 255 ka) Castile Formation in the Delaware Basin of west Texas and southeastern New Mexico. The Delaware Basin is an intercratonic basin with an area of 25,980 km^2 and was probably about 500 m deep before evaporite deposition (Kirkland, 2003). King proposed a "reflux model" whereby some brine was returned ("refluxed") to the open ocean but a continuous supply of seawater kept the salinity within the anhydrite stability field.

Adams (1944) showed that the "minor" halite in the Castile was not minor in the deeper, eastern part of the basin where it mostly occurs as thick beds of halite interlaminated with anhydrite. He produced the first comprehensive cross section of the basin based on borehole lithologies and defined the boundary between the Castile and the overlying Salado Formation. In the eastern part of the basin, halite makes up about one third of the thickness but represents only one fiftieth of the time of deposition (Anderson, 2011). In the shallower, uplifted western part of the basin, halite beds have been dissolved resulting in beds of dissolution breccias. During the late Permian when the Castile was deposited, the Delaware Basin was an embayment within a region of extreme aridity in the equatorial western margin of the supercontinent Pangaea surrounded by the well-known Permian reef complex (Guadalupian Capitan Formation) with saline groundwater seeping into the basin from the south and west from the giant Panthalassa ocean (Anderson and Dean, 1995; Anderson, 2011).

The Castile anhydrite consists mostly of seasonal laminae couplets of dark, organic-stained calcite and lighter-colored anhydrite, the typical "banded anhydrite" of most of the Castile (Figure 1) (Anderson et al., 1972). Each light–dark couplet is interpreted as an annual increment of sedimentation (a varve) (Anderson and Kirkland, 1966; Anderson et al., 1972). The Castile is divided into four anhydrite members, I–IV (from oldest to youngest), and three halite members, I–III (from oldest to youngest) (Anderson et al., 1972). Each halite member represents the culmination of a major salinity cycle. The halite units consist of cm-thick halite layers and thin anhydrite laminae. At the top of a salinity cycle, the typical calcite-banded anhydrite grades into nodular anhydrite (Figure 1). Dean et al. (1975) illustrate a progression from typical laminated anhydrite to nodular anhydrite but still with laminae of calcite that may be highly distorted to even resemble nodular "chicken wire" anhydrite that is common in supratidal evaporates (discussed below). The laminae are remarkably uniform in composition, thickness, and delicate detail over distances of at least 113 km (Anderson et al., 1972). The calcite–anhydrite varve couplets are repeated with remarkable regularity with more than 209,000 calcite–anhydrite and anhydrite–halite varve couplets in 450 m of stratigraphic section (Anderson, 2011). The evidence supports the deep-basin, deep-water interpretation especially for the typical "banded anhydrite" that represents the preponderance of time of deposition of the Castile.

The calcite–anhydrite varves of the Castile are very similar to the dolomite–anhydrite varves (jahresringe) of the Permian Zechstein Formation of Germany that were correlated for distances of as much as 390 km by Anderson and Kirkland (1966) using measurement by
Marine Evaporites, Figure 1 (*Top*) Correlation of typical laminated anhydrite (*light*) and organic-stained calcite (*dark*) varve couplets of the Castile Formation between the Cowden #4 and Phillips cores separated by 24 km in Culberson County, Texas. (*Bottom*) Nodular anhydrite in the Phillips core of the Castile Formation. The nodules started as displacive growth within the anhydrite laminae of normal varve couplets. Dark material is organic-stained calcite.

Richter-Bernburg (1957). The stratigraphic regularity and lateral continuity of laminated anhydrite, such as those found in the Castile and Zechstein Formations, are the main hallmarks of deep-basin, deep-water evaporates.

The anhydrite–halite laminations in the Castile halite members continue into the base of the overlying Salado Formation, which is dominated by halite and potash. The Salado is as much as 700 m thick and spills out over the Delaware Basin, as defined by the Capitan Reef and enclosed Castile Formation. Most of the Salado was deposited in shallow water over a longer time span than the Castile with much of the time represented by nondeposition. The Salado covers an area of about 150,000 km^2, although the area that includes the Carlsbad Potash District is only 70,000 km^2 (Lowenstein, 1988). The main potash-bearing unit is the McNutt Zone in the middle of the Salado that contains sylvite and langbeinite and minor carnallite, kieserite, and kainite (Barker and Austin, 1993). It is in the thick halite beds of the Salado that the Waste Isolation Pilot Plant (WIPP) site is located east of Carlsbad, New Mexico, for the disposal of low-level radioactive wastes.

Shallow-water evaporites

The deep-basin, deep-water model of evaporite deposition, represented by the Zechstein, Castile, and Salado Formations, prevailed during the first half of the twentieth century, but during the 1950s, examples of shallow-water evaporites began to emerge, interpreted as having been deposited in restricted estuaries or basins ("arms of the sea") (e.g., Scruton, 1953; Masson, 1955; Morris and Dickey, 1957).

Marginal-marine evaporite deposition was further stimulated with the documentation in the 1960s of supratidal ("sabkha") evaporite deposition along the Arabian (Abu Dhabi) margin of the Persian Gulf (e.g., Shearman, 1966; Kinsman, 1966, 1969; Butler, 1969). Here a whole spectrum of shelf carbonates and evaporites has been developed. A typical sediment sequence might include subtidal aragonite muds, pelleted muds, and oolites; intertidal laminated cyanobacterial (blue-green algal) mats with trapped and bound carbonate muds; and supratidal (sabkha) nodular anhydrite or gypsum in a carbonate matrix that may be dolomitized. With no modern analogs for the thick, extensive evaporite sequences of the Phanerozoic, the Holocene occurrences of marginal-marine evaporates have been used, and sometimes overused, to explain ancient evaporite deposits. For example, Shearman (1966) suggested that many ancient evaporite deposits, especially those dominated by anhydrite, but not excluding thick halite and potash deposits, had been formed by diagenesis in a sabkha-like environment. A review of Holocene carbonates and evaporites of the Arabian coast is presented by Alsharhan and Kendell (2003), and a discussion of supratidal mudflat evaporite deposition in general is presented in Kirkland and Evans (1973).

The application of the "sabkha model" was accelerated with the exciting recovery of upper Miocene (Messinian) anhydrite and halite from the floor of the Mediterranean Sea on Leg 13 of the Deep Sea Drilling Project (DSDP; Ryan et al., 1973; Hsü et al., 1973) and cored again in 1975 on DSDP Leg 42A (Garrison et al., 1978; Hsü et al., 1978; Kidd et al., 1978). The sediments that were cored with poor recovery on DSDP Legs 13 and 42A were from the upper ~70 m of the upper Messinian evaporite that may be up to 2 km thick based on seismic profiles and boreholes in the seafloor, outcrops on land, and up to 600 m of halite in the subsurface. The conclusion was that the evaporites from the upper part of the upper evaporite in eastern and western basins of the Mediterranean were deposited in shallow subaqueous to subaerial environments and that the Mediterranean must have dried up and refilled several times with a huge waterfall at the Strait of Gibraltar. This is called the deep-basin, desiccation hypothesis, and the event has been called the "Messinian Salinity Crisis" (MSC). It has been used to explain a wide
Marine Evaporites, Figure 2 (*Left*) Laminated anhydrite, Miocene, from the Mediterranean. Deep Sea Drilling Project, Site 124, Core 8, Section 1, interval 0–5 cm. variety of paleoceanographic and paleoclimatic events and has been the subject of numerous articles in both the scientific and popular literature, of books, and even of television shows.

The key features of the evaporites recovered on DSDP Legs 13 and 42A are laminated and nodular anhydrite (Figure 2), which are key fabrics for the interpretative application of the sabkha model. This has led to an uncritical use of the equations: laminated sediments = algal mats = tidal-flat environment and nodular anhydrite = sabkha = subaerial environment. Dean et al. (1975) presented sedimentological criteria to distinguish between deep-basin, deep-water, and shallow-water or sabkha evaporates. Schreiber et al. (1976) and Schreiber and El Tabakh (2000) described deep-water laminated gypsum in the Messinian of Sicily in which the laminae are continuous with carbonate interlaminations, for which the name "balatino" is often used. Ryan (2009) concluded that the finely laminated "balatino" anhydrite in the Mediterranean DSDP cores (e.g., Figure 2, left) when compared to the anhydrite varves of the German Zechstein appears to be "typical of relatively deep and calm waters." Hardie and Lowenstein (2004, 453), after careful examination of cores from both Legs 13 and 42A, concluded: "Several features of these [Miocene] evaporates used by the DSDP workers as evidence of shallow-water conditions are more comparable with deposition under deep-water (below wave base) conditions, and others can only be considered as of uncertain origin."

Since DSDP Leg 42A, there have been a number of symposia and workshops reassessing the Messinian Salinity Crisis. Most notably, 22 papers from a colloquium "The Messinian Salinity Crisis Revisited" held in

Palermo, Italy, occupy volumes 188 and 189 (2006) of "Sedimentary Geology" (Rouchy et al., 2006; Rouchy and Caruso, 2006). Most of those papers were based on borehole and outcrop data on land around the Mediterranean. In fact, supratidal evaporite deposition in general and the MSC in particular have dominated the evaporite literature in the decades since the 1960s.

A reassessment of the MSC was made by Ryan (2009). He concluded that a review of the current knowledge of the MSC requires the insertion of an early "deep-water," "deep-basin" stage that was not considered in the formulation of the original desiccation hypothesis in 1973. He states: "The revised model of evaporative concentration now has shallow-margin, shallow-water and deep-basin, deep-water precursors to desiccation."

Summary

Large marine evaporite basins occur on all continents, except possibly Antarctica, and range in age from Late Precambrian to Late Miocene. The progressive evaporation of seawater results in the precipitation of the following succession of evaporite minerals: a carbonate mineral (calcite or dolomite), a calcium sulfate mineral (gypsum or anhydrite), and sodium chloride (halite or rock salt). Anhydrite and halite constitute more than 95 % by volume of the world's Phanerozoic evaporates. Under conditions of extreme evaporation potassium (K) and/or magnesium (Mg), minerals called potash or bittern salts may form, which are much less common. There is no modern analog for the thick, aerially extensive, ancient evaporite deposits ("saline giants").

The most extensively studied "saline giant" in the world is the Upper Permian Zechstein Formation that underlies most of northern Europe. The Zechstein consists of four depositional cycles or series that culminate in halite and, in the extreme, potash. The second oldest depositional cycle of the Zechstein is the Stassfurt series and is the most studied and most economically important of the Zechstein series and comes closest to the experimental and theoretical sequences of evaporite minerals.

Another important "saline giant" consists of the late Permian Castile and Salado Formations of the Delaware Basin of west Texas and southeastern New Mexico. Halite beds occur at the culminations of four major salinity cycles that define four anhydrite and three halite members of the Castile. The anhydrite units consist of interlaminated anhydrite and thin calcite laminae. The halite units consist of cm-thick halite layers and thin anhydrite laminae. The anhydrite–halite laminations in the Castile halite members continue into the overlying Salado Formation, which is dominated by halite and potash. The Salado Formation is as much as 700 m thick and spills out over the Delaware Basin, as defined by the Capitan Reef and the enclosed Castile Formation.

The deep-basin, deep-water model of evaporite deposition, represented by the Zechstein, Castile, and Salado Formations, prevailed during the first half of the twentieth

century, but during the 1950s examples of shallow-water evaporites began to emerge, interpreted as having been deposited in restricted marginal-marine estuaries or basins. Marginal-marine evaporite deposition was further stimulated with the documentation in the 1960s of supratidal ("sabkha") evaporite deposition along the Arabian margin of the Persian Gulf. With no modern analogs for the thick, extensive evaporite sequences of the Phanerozoic, the Holocene occurrences of marginal-marine sabkha evaporates have been used to explain ancient evaporite deposits. The application of the "sabkha model" was accelerated with the recovery of upper Miocene (Messinian) anhydrite and halite from the floor of the Mediterranean Sea on Legs 13 and 42A of the Deep Sea Drilling Project (DSDP). The implication was that these evaporates were deposited in shallow subaqueous to subaerial environments and that the Mediterranean must have dried up and refilled several times with a huge waterfall at the Strait of Gibraltar. This has been called the deep-basin, desiccation hypothesis, and the event has been called the "Messinian Salinity Crisis." Supratidal evaporite deposition in general and the Messinian Salinity Crisis in particular have dominated the evaporite literature in the decades since the 1960s.

Definition

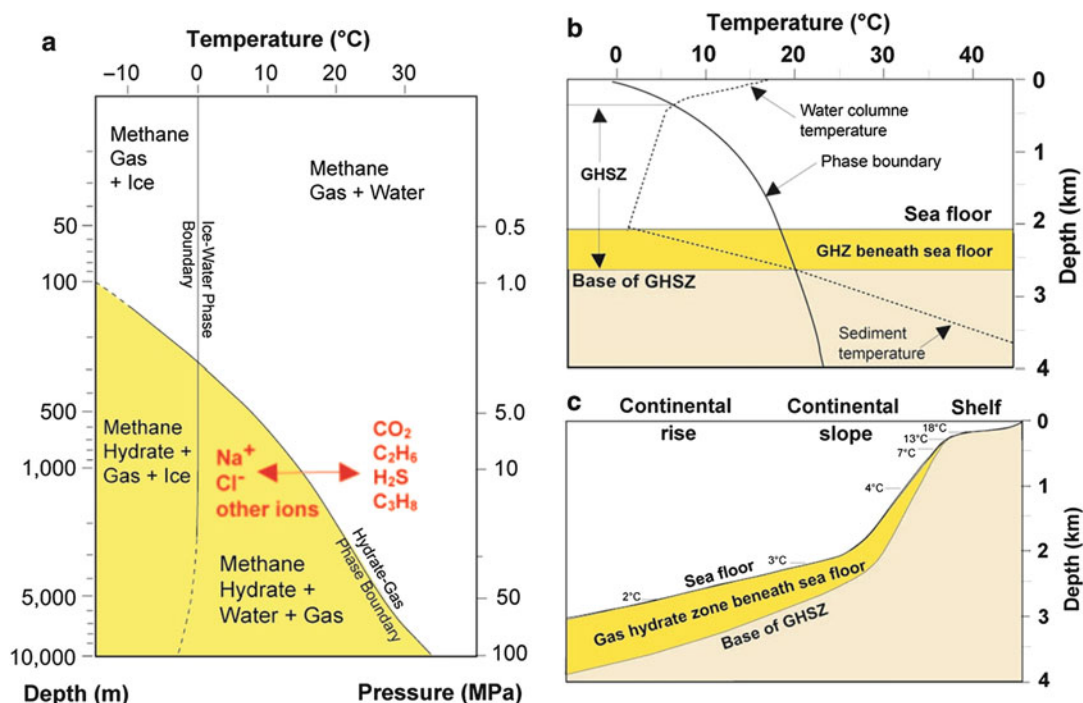
Gas hydrates are non-stoichiometric solid compounds in which low-molecular-weight gases are trapped (guests) within water cavities (hosts). The presence of gas hydrates is controlled by temperature, pressure, and the availability of appropriate gases and water.

Historic background

Gas hydrates were first described in the nineteenth century by Sir Humphry Davy, with his pioneering synthesis of chlorine hydrate. This type of compounds sparked industrial interest in the 1930s, when it became apparent that methane hydrates formed spontaneously within natural gas pipelines in permafrost regions. Research spearheaded by the oil and gas industry at that time created the foundation for our current understanding of the behavior of these compounds (Sloan and Koh, 2008). By the 1970s, Russian scientists had postulated that under certain temperature and pressure conditions, methane hydrates could form in natural systems and indeed observed these natural deposits in the Siberian permafrost. This discovery was soon followed by reports of methane hydrate presence in Canada's MacKenzie Delta and the Caspian and Black Seas. The next important advance in the study of these deposits came with the realization that sediments hosting gas hydrate could be imaged by seismic data (Stoll et al., 1971), thus providing a prospecting tool that fueled exploratory efforts along continental margins worldwide.

Gas hydrates were first cored by the Deep Sea Drilling Project (DSDP) in 1970 on the Blake Ridge (US continental margin), and the first deep-sea gas hydrate specimens were observed in sediments recovered from the Middle America Trench during DSDP Legs 66 and 67 in 1979. Since then, scientific ocean drilling has provided critical data toward the fundamental understanding of the nature, composition, and distribution of naturally occurring gas hydrates (Sloan and Koh, 2008). Large-scale new projects spearheaded by national-industry consortia are targeting gas hydrate deposits in search for new energy resources. Such projects are under way in the Indian Ocean, the South China Sea, the eastern sea off Korea, and both the eastern and western margins of Japan (Collett et al., 2009). In addition to scientific drilling efforts, near-surface gas hydrate deposits have been recovered from continental margins worldwide (Kvenvolden, 1988). These near-surface deposits are usually associated with locations of active cold seepage, where rapid transport of methane allows for massive deposits to form near the seafloor (Suess et al., 1999; Torres et al., 2011).

Gas hydrate stability in marine sediments

The stability of gas hydrate is fundamentally controlled by thermodynamic equilibria (Sloan and Koh, 2008). The pressure/temperature conditions required for pure methane hydrate stability are illustrated in Figure 1. The phase boundary is determined by the gas composition and by the ionic strength of the water (Figure 1a). The presence of CO_2, H_2S, ethane, and/or propane shifts the stability curve to the right, in effect increasing the gas hydrate stability. The presence of dissolved ions in the pore fluids, on the other hand, decreases the gas hydrate stability, so that an increase in salinity of the fluids from which the gas hydrate is forming shifts the phase boundary to the left (Figure 1a).


Marine Gas Hydrates, Figure 1 Phase diagram showing the boundary between methane hydrate (*yellow*) and free methane gas (*white*). Additions of ions and the presence of gases other than methane shift this phase boundary and hence gas hydrate stability (after Kvenvolden, 1988).

Temperature and pressure conditions consistent with methane hydrate stability are found at the seafloor nearly everywhere at water depths exceeding 300 m, but may be as deep as 800 m, depending on the regional seawater temperature (Figure 1c). For example, within the Black Sea where the bottom water temperature is 9 °C, the upper limit of hydrate stability is around 700 m water depth, whereas in the Mediterranean Sea, hydrates can be expected at depths >1,200 m with bottom water temperature of 14 °C and higher salinities (Pape et al., 2010). In contrast, in polar oceans, gas hydrate may be stable at depth <300 m (Kvenvolden, 1988).

Below the seafloor, temperatures increase with depth tracking the regional geothermal gradient (Figure 1b). As temperature in the sediments increases, it will eventually get high enough to cross the phase boundary, such that gas hydrate is no longer stable beneath this depth. Since the geothermal gradient is often quite uniform across broad regions beneath the seafloor, the thickness of the gas hydrate stability zone (GHSZ) is quite constant for a given water depth; hence, the thickness of the GHSZ may reach 800–1,000 m below seafloor in deep-water areas and shoals upward as water depth decreases (Figure 1c).

In addition to the P/T considerations described above, gas hydrates will only form if there is enough methane to stabilize the gas hydrate structure. In most of the deep ocean basins, however, methane concentrations in pore water are too low for gas hydrate formation (Claypool and Kaplan, 1974). Such that in general, gas hydrate formation is restricted to continental margins and enclosed seas, where organic matter accumulates rapidly enough to support in situ methane production by bacteria or where existing free or dissolved gas (sometimes from thermogenic sources and petroleum reservoirs) is transported into the gas hydrate stability zone (GHSZ).

Gas hydrate nucleation and growth also depend on sediment grain size, shape, and composition, as predicted by based on capillary pressure models and laboratory experiments using different host matrices (Clennell et al., 1999). These predictions were confirmed by field observations that document the preferential gas hydrate formation in coarse lithologies (Torres et al., 2008). In fine-grained sediments, gas hydrate tends to form discrete veins and lenses and occurs in massive blocks only in the near-sediment surface, where gas hydrate growth can overcome the overburden pressure, in effect displacing the sediment in a manner similar to the well-known ice heaving process (Torres et al., 2004).

Remote sensing techniques

Geophysical surveys are commonly used for detecting the presence of gas hydrate in marine sediments, through the
Marine Gas Hydrates, Figure 2 Seismic record from Blake Ridge showing a distinct reflection, known as the bottom-simulating reflection (Shipley et al., 1979). A seismic velocity model (*left*) shows the strong contrast of velocity across the BSR.

observation of a seismic reflection called "bottom-simulating seismic reflection" or BSR, because it approximately mimics the seafloor (Shipley et al., 1979). The negative polarity of this reflection indicates that it results from a decrease in acoustic impedance (defined as a product of density and seismic velocities) with depth (Figure 2). The BSR cuts across reflections of stratigraphic origin, making it readily apparent in marine seismic records. The BSR occurs approximately at the depth where the base of the gas hydrate stability zone is predicted based on thermodynamic equilibria (e.g., Shipley et al., 1979).

Although some details of the seismic reflection properties are not yet fully understood, it appears that the strength and the characteristics of the BSR are determined by the presence of free gas below the gas hydrate zone (Holbrook et al., 1996).

Imaging and quantification of natural gas hydrate

Gas hydrate rapidly dissociates during core recovery when using non-pressurized coring devices. Estimates of gas hydrate abundance and distribution rely by necessity on indirect estimates that include: total gas volumes from pressure-core samples and geochemical measurements of dissolved chloride (Cl^-) concentration and water isotopic composition. Like ice, gas hydrate incorporates water but excludes dissolved ions during formation. With time, excess dissolved ions will diffuse away from the location of gas hydrate formation, reestablishing a local background value. However, as gas hydrate dissociates during core retrieval, it adds fresh water to the pore space, thereby diluting dissolved ions. Since chloride in general behaves conservatively at depths in which gas hydrate accumulates, it is used as a good quantitative tracer of gas hydrate concentration (Torres et al., 2008). In addition, the water trapped within the hydrate cage is isotopically heavier than seawater, in both the oxygen and hydrogen atoms;

hence, the heavy-oxygen isotopes and the deuterium of the pore fluids sampled from sediments that originally hosted gas hydrate may be used to estimate gas hydrate concentration (Kim et al., 2012).

Geophysical logging records provide the only means of obtaining high-resolution data at in situ conditions from the entire borehole, including those intervals for which sediment is not recovered. The most robust logging indicators of in situ methane hydrate are elevated electrical resistivity, acoustic velocities, and NMR-log data. Estimates of the amount of gas hydrate derived from resistivity log data are perhaps the most commonly used. Resistivity data are used as input to the Archie relation to estimate the fraction of pore space in sediment occupied by gas hydrate, with special considerations for the nature of the reservoir (see Riedel et al., 2010).

Distribution and dynamics

The mode of gas hydrate occurrence can be broadly classified into end-member regimes, which are based on the mechanisms that control gas transport into the GHSZ (Tréhu et al., 2004). The most commonly occurring deposits have been denoted as distributed low-flux systems, where most of the available methane is generated in the vicinity of where gas hydrate is formed, and fluid flow is pervasive. Gas hydrate in the system occurs either as pore filling (commonly within coarse lithologies) or as vein filling in fine-grained sediments. In contrast, in the focused high-flux systems, methane from a large volume of sediment is concentrated within well-defined conduits that channel methane to the seafloor where it forms massive gas hydrate deposits. Torres et al. (2004) argued that to sustain the massive deposits found on Hydrate Ridge, methane must be supplied in the gas phase, since methane solubility is too low for aqueous transport to maintain the observed hydrate accumulations. These deposits are characterized by the presence of brines that result from rapid

incorporation of water into the growing gas hydrate structure, with salt remaining in solution and reaching concentrations as much as twice that of seawater (Torres et al., 2011). Massive gas hydrate and chloride brines in near-seafloor sediments along continental margins are not at all uncommon, and may represent a significant carbon reservoir that is susceptible to perturbations driven by changes in bottom water temperature.

Gas hydrates and energy

In several review articles, e.g., Boswell and Collett (2010), four gas hydrate reservoir types are evaluated in terms of their resource potential: sand-dominated reservoirs, clay-dominated fractured reservoirs, seafloor massive deposits, and clay-dominated disseminated reservoirs. Current exploration, production testing, and modeling target arctic and marine hydrate-bearing sand reservoirs in the North Slope of Alaska, Gulf of Mexico, and Japan, with additional research offshore China, Korea, and India. Proposed methods of gas recovery from gas hydrates were reviewed by Boswell and Collett (2010). Traditionally, these were based on: heating the reservoir above the gas hydrate stability, decreasing the reservoir pressure below gas hydrate equilibrium, and injecting a chemical inhibitor into the reservoir to decrease the gas hydrate stability. More recently, laboratory experiments have documented the feasibility of displacing methane molecules in the hydrate structure with carbon dioxide molecules, thus releasing methane and sequestering CO_2. In 2011 a multiyear project began to field-test the CO_2 for methane exchange concept on the Alaska Ignik Sikumi test well. This field test showed that CO_2 can be injected into a gas hydrate sandy reservoir, followed by methane production (Schoderbek et al., 2012).

Gas hydrates and climate

Methane is a powerful greenhouse gas with a greenhouse warming potential (GWP) 23 times that of CO_2 on a per-molecule basis. Sudden release of methane from gas hydrate therefore has the potential to affect global climate, and there are interesting although controversial hypotheses that attribute past climate variations to methane release from marine gas hydrates in response to ocean warming and/or sea-level change (Dickens, 2011). These hypotheses have yet to be confirmed and more research is needed to evaluate hydrate response to environmental change: the fate of methane from marine gas hydrate reservoirs to the seabed, ocean surface, and the atmosphere.

Gas hydrate observatories

Numerous laboratory and field studies at gas hydrate-bearing sites, including several drilling expeditions in the past decades, have provided critical background data on the conditions of gas hydrate stability and have given an overall view of the composition and distribution of gas hydrates in nature. Fundamental questions remain as to the residence time of gas hydrates near the seafloor and deeper within the sediment column, the nature and driving mechanisms for flow and biological interactions in environments where gas hydrates are present and fluid (aqueous and gas) migration occurs, and the role of the ocean in mitigating gas input to the atmosphere from the seafloor. The processes involved in modulating carbon transport within the seabed and in the water column are highly dynamic and can only be understood through monitoring of complementary parameters over decadal or longer timescales. Efforts are under way to collect time series data at several locations, e.g., at the Canadian cabled observatory, NEPTUNE (http://www.neptunecanada.ca/research/research-projects/project.dot?inode=30424), at Hydrate Ridge, offshore Oregon (http://www.oceanobservatories.org/infra-structure/ooi-station-map/regional-scale-nodes/hydrate-ridge/), and in the Gulf of Mexico (http://ieeexplore.ieee.org/xpls/abs_all.jsp?arnumber=4625508&tag=1).

Summary

Methane and other low-molecular-weight gases, such as ethane and carbon dioxide, can combine with water to form ice-like substances at high pressure or low temperature in what are known as gas hydrates. The stability of these compounds is controlled by several factors including pressure, temperature, salinity, and gas concentrations. Gas hydrates are commonly imaged by the presence of a bottom-simulating reflector in the seismic records, which is the most common tool for identifying hydrate-bearing sediments. Other geophysical tools and borehole logging strategies are used to characterize the presence, distribution, and abundance of these deposits. These techniques are calibrated against geochemical proxies that include pore fluid freshening by gas hydrate dissociation during conventional core recovery and controlled depressurization experiments from pressure cores. Interest in gas hydrate rises from their role in carbon cycling, potential climate effects, and energy considerations. They constitute a large carbon reservoir, and sand-hosted deposits are currently being explored for economic uses, with one of the most innovative approaches being the CO_2 for methane exchange.

Definition

Marine geosciences are covering all phenomena and processes related to the formations of shallow shelf seas and of the deep ocean. They draw on modern dynamics of seafloor and sediment formation, marine geophysics and tectonics, volcanology, geochemistry, microbiology, biology, and paleontology of marine organisms. They are of great economic importance because of the wealth of nonliving marine resources.

Introduction: why and how to study the global seafloors

In the past, there have been very different perspectives how scientists approached "marine geology" or as we say today "marine geosciences": There were those who studied oceans, shallow seas, and their sediments as products of specific geological processes out of their own right (often at US institutions and closely linked to oceanography), and there were those who came from investigating ancient marine deposits on land but then turned to the marine realm to find modern analogs and thus explanations for their fossil phenomena (as in many European

Eugen Seibold is deceased.

institutions). This entry leans heavily on the "Introduction" of Seibold and Berger (1993).

Another trade of the marine geosciences is the fact that technical new, sometimes dramatic developments, often driven by the military, have resulted in new discoveries. We will address some of these in due course. They include the developments of echo sounders, sensitive magnetometers, deep-diving research submarines, deep-sea drilling, ROVs and AUVs, and remote sensing, to name a few.

The history of the marine geosciences is also closely linked to the evolution of suitable and dedicated research vessels. Most of the vessels deployed during the early years of ocean exploration were former war or cargo ships, converted as good as possible into carriers of scientific instrumentation and/or laboratories; hence, they were a compromise between research needs and possibilities. The honor to have actually envisioned the first dedicated ocean research vessel falls on Fridtjof Nansen with the Fram, used for his famous crossing of the ice-infested Arctic Ocean (1893–1896) when he detected that it was a deep-sea basin (Nansen, 1904). It was the first of three ships (the other ones were the Norwegian Maud and the German Gauss) specially constructed and equipped to sail into ice-covered waters, and hence they represented the first generation of dedicated polar research vessels. Despite the great importance of the polar seas for ocean and atmosphere dynamics, strangely enough it should take another seven decades until the next generation of dedicated polar research vessels would be built (the Swedish Oden, the German Polarstern, and the USCG Cutter Healy).

Modern, dedicated research vessels suited for marine geosciences came essentially into service only after the middle of last century. Famous ocean research institutions such as Woods Hole, Lamont, or Scripps in the USA and similar institutions in other countries essentially started their work on the oceans with vessels which had been built for completely different purposes. Only when the needs for having access to modern and well-equipped laboratories at sea, for deploying heavy seismic gear, for sampling long stratigraphic sections of deep ocean crust and sediment cover, as well as for deploying scientific deep-diving submarines entered the marine geosciences, highly specialized vessels were constructed. The development probably culminated when the Deep Sea Drilling Project was founded in 1968 (with the GLOMAR Challenger as its drilling platform), which developed into the International Phase of Ocean Drilling in 1985 (which used the JOIDES Resolution as its main tool) and which in 2003 then widened its scope (IODP, "Integrated Ocean Drilling Program," since 2013 "International Ocean Discovery Program") by employing in addition to JOIDES Resolution the Japanese Chikyu with its capability for riser drilling (since 2005) as well as the MSPs (Mission Specific Platforms, since 2004) of ECORD (European Consortium for Ocean Research Drilling, cf. Kiyoshi, this volume for further details). No question, this development will continue into the future, because marine geosciences have

entered the stage of "big science" requiring state-of-the-art, very expensive instruments which then mostly have to be operated through international cooperation.

Pioneers of marine geosciences: identifying the basic questions and the phase of big national expeditions

Marine geology is a young offshoot of geology, a branch of science which begins with James Hutton (1726–1797) and his *Theory of the Earth* (Edinburgh, 1795). Among other things, Hutton studied marine rocks on land. Changes of sea-level ("encroachment of the ocean" and "the placing of materials accumulated at the bottom of the sea in the atmosphere above the surface of the sea") were a central tenet of his "Theory." Thus, the question of what happens at the bottom of the sea was raised at the beginning of systematic geologic investigations. This question had to be attacked if the marine deposits on land were to be understood. Hutton was not alone in these concerns. A few years before the *Theory of the Earth* appeared, the great chemist Antoine Laurent Lavoisier (1743–1794) distinguished two kinds of marine sedimentary layers: those that are formed in the open sea at great depth, which he called *pelagic* beds, and those formed along the coast, which he termed *littoral* beds. "Great depth" for Lavoisier was everything beyond wave base. Lavoisier supposed that sediment particles would settle quietly in deep water, and reworking would be much less in evidence here than near the shore.

Soon true expeditions to explore the oceans were mounted, with initiators from many nations. The first global scientific expedition (1803–1806) of the Russian Admiral A. J. Krusenstern discovered that the deep oceans were cold all over (Krusenstern, 1819). One of the most famous ones was the cruise of HMS Beagle (1831–1836) which transported Charles Darwin around the world (Darwin et al., 1839). Later followed the expedition of HMS Beacon into the Mediterranean and several others. Even though ocean exploration extends into the nineteenth century or even before, geoscientific information about the ocean floors was first limited to water depths (probed by sounding wires at specific locations), seafloor geomorphology, seafloor deposits, as well as rocks. Interest in the properties of the global seafloors arose in North America (Maury, 1855). These basically national efforts culminated in the British circumglobal expedition on HMS Challenger. The seafloor itself became the focus of attention, not for the sake of the clues it would yield for the purposes of land geology but for the clues it contained for its own evolution and its role in the history of Earth. The new emphasis is first evident in the works of the Scotsman, John Murray, naturalist on the HMS Challenger Expedition (1872–1876). This expedition, led by the biologist Charles Wyville Thomson (1830–1882), marked the beginning of modern oceanography. It established the general morphology of the deep-sea floor and the types of sediments covering it. Murray

and Renard (1891) laid a foundation for the sedimentology of the deep ocean floor. Murray's studies established a fundamental dichotomy of shallow water and shelf sediments on the one hand and of deep-sea deposits on the other. It became a commonplace textbook truism that not true deep-sea deposits are found on land anywhere (which we now know to be false). The basic morphology of the mid-ocean ridge started to emerge during the later part (Challenger Expedition 1872–1876) and the last years of the nineteenth century (German Valdivia Expedition, cf. Chun, 1903). Substantial work done by Norwegian scientists then allowed Murray and Hjort to write their famous book on the depths of the ocean (Murray and Hjorth, 1912).

Marine geology started in earnest with geologists going to sea and looking for the processes which helped produce the marine rocks with which they were familiar on land. Such work, obviously, began in the intertidal and in easily accessible shallow waters, and it was undertaken by a great many investigators. The German geologist Johannes Walther was very familiar with the observations resulting from this work and was himself a pioneer in these types of studies. Firmly rooted in classical geology, Walther (1894) set an outstanding example of applying *uniformitarianism*, that is, Hutton's doctrine that observable processes are sufficient to explain the geologic record and in 1893 gave an account of marine environments and the ecology of their inhabitants, with emphasis on shell-forming organisms and the deposits they produce.

The German expeditions on RV Meteor into the Atlantic Ocean resulted in substantial progress in marine geosciences. It carried a systematic survey of the morphology of the South Atlantic along traverses between Africa and South America. It was the first one to employ echo sounding devices which had been invented in Kiel, Germany, by Alexander Behm in 1912 and which now allowed to carry out systematic bathymetric surveys of the seafloor; its expeditions into the South Atlantic (1925–1927) defined location and shape of the mid-ocean ridge. This expedition also succeeded to systematically sample deep-sea floor deposits in the South Atlantic (Correns and Schott, 1935, 1937).

A satisfying explanation of the overall morphology of ocean basins and of the various types of continental margins could only come from geophysics, which deals with the motions and forces deep within the Earth (see further below). It is no coincidence that a geophysicist first formulated a global hypothesis for ocean margin morphology which proved to be viable: the meteorologist Alfred Wegener. He became intrigued with the parallelism of the coast lines bordering the Atlantic Ocean (a phenomenon noted already in 1801 by the famous naturalist-explorer Alexander von Humboldt). It seemed to Wegener that the continents looked like puzzle pieces which belong together. He then learned quite by accident that paleontologists had invoked former land bridges between the shores facing each other across the Atlantic to explain striking similarities between the fossil records of both sides of the ocean. After an extensive literature search, he became convinced that the continents had once been joined and had broken up after the Paleozoic. Replacing the concept of land bridges with his hypothesis of *continental drift*, he started the "debate of the century" in geology with a talk and article in 1912 and especially with his book on *The Origin of Continents and Oceans*, first published in 1915 (cf. Wegener, 1966, 2005). He envisioned granitic continents floating in basaltic mantle magma like icebergs in water and drifting about on the surface of Earth in response to unknown forces derived from the rotation of the planet. Wegener's hypothesis, in modified form, is now an integral part of *seafloor spreading and plate tectonics* (see further below), the ruling theories explaining the geomorphology and geophysics of the ocean floor and of the crust of the Earth in general.

Research on marine sedimentation in the following decades is summarized in Trask (1939). This symposium spanned the range of sedimentary environments, from the beach to deep sea, and many of the articles were written by pioneers in marine geology. As marine geologic studies progressed and moved further out to sea, there was a gradual change of emphasis in the set of problems to be solved. The doctrine of a quiet deep ocean (see also further below) was challenged when Ph. H. Kuenen demonstrated by experiment that clouds of sediment could be transported downslope on the seafloor at great speed and to great depth, due to the fact that muddy water is heavier than the clear water surrounding it. Sediment transported in suspension in this fashion settles out at its site of deposition, heavy and large grains first, fine grains last. The resulting layer is *graded*, and such layers are indeed common in the geologic record (e.g., Alpine *flysch* deposits). Kuenen made many other important contributions to marine geology, attacking a broad range of subjects in his book (Kuenen, 1950) and in numerous other publications.

The investigations of the seafloor proceeded parallel to that of marine sedimentation. Coastal landforms were the most accessible, and considerable information had been accumulated early in this century (Johnson, 1919). Much additional work on these topics was done by F. P. Shepard in the USA and also by J. Bourcart in France, who were able to test earlier concepts against field data collected in shallower water. These two pioneers of marine geology especially attacked the problems of the origin of continental margins and of submarine canyons, by studying their morphology and associated sedimentary processes.

F. P. Shepard's wide-flung field areas include the shelf off the US East Coast, shelf and slope off the US West Coast, and the floor of the Gulf of Mexico. Shepard (1948) summarizes the results of this work and presents global statistics on seafloor morphology. In the same year, M. B. Klenova's textbook *Geology of the Sea* was printed. Among other Russian pioneers, N. I. Andrusov (Black Sea) and N. M. Strachov (lithogenesis) should be

mentioned. Menard (1964) described the marine geology of the Pacific Ocean. Other representative works of Shepard cover the Northwest of Mexico (Shepard et al., 1960) and submarine canyons (Shepard and Dill, 1966). J. Bourcart carried out similar geomorphologic and sedimentologic studies off the shores of France, especially in the Mediterranean. His concept of continental margin "flexure," with uplift landward of a *hinge line* and downwarp seaward of it, proved useful in explaining the migrations of sea-level across the shelf and in studying the nature of sediment accumulation on the continental slope.

The marine geomorphologist par excellence was B. C. Heezen, whose *physiographic diagrams* of the seafloor (drawn with his collaborator, Marie Tharp) show great insight into the tectonic and sedimentologic processes of the seafloor (Heezen et al., 1959). His graphs now appear in virtually all textbooks of geology and geography. Of B. C. Heezen it has been said (somewhat facetiously, by E. C. Bullard) that he perfected the art of drawing maps of regions where no data are available. Much of his work is summarized in the beautifully illustrated book by Heezen and Hollister (1971). A brilliant summary of our knowledge about the geological properties of sea and ocean floors, seafloor spreading, and plate tectonics has been presented by Kennett (1982), later updated by Seibold and Berger (1993).

Modern marine geosciences in Russia, China, and other countries with similar "science histories" came about much later. Russia woke up after World War II when the cold war generated a fierce competition with western nations. Russian marine institutions acquired ocean-going research vessels and they were suddenly present on all major ocean basins; scientists from the Shirshov Institute of Oceanology and of the Vernadsky Institute of Geochemistry, both belonging to the Russian Academy of Sciences, made important contributions to global ocean atlases of all major ocean basins, and they appeared as authors of important textbooks. These important contributions to marine geosciences were only becoming familiar to western scientists after they had been translated into English (f. e. Lisitzin, 1972, 1996, 2002 or Emelyanov, 2005, see also Lobkovsky et al., 2013, 2014).

The fallacy of the quiet deep ocean

The earliest observers of deep-sea sediments were left with the idea that the deep ocean contained a tranquil depositional environment where fine-grained sediment comprised mainly clay and shell/skeleton remains of the plankton organisms living in the ocean water column. This soon proved to be wrong when Wüst (1936) based on the oceanographic data of the Meteor expedition discovered patterns of deep ocean water movements which transported cold and dense Antarctic bottom waters along their deepwater pathways to the North, in fact across the equator to the Northern Hemisphere. Today we also know

that a similar process transports cold and dense Arctic water from the Norwegian-Greenland Sea across the Greenland-Scotland Ridge into the deep basins of the North Ocean to form the North Atlantic Deep Water (for a general discussion, cf. Dietrich et al., 1975). Based on these earlier observations and on dating the times when ocean bottom waters were able to absorb the last time carbon dioxide from the atmosphere, Broecker (1991) developed the concept of the global ocean conveyor belt and its influence on climate change.

Strong circumstantial evidence that Kuenen's concept is important in deep-sea sedimentation was first presented by Heezen and Ewing (1952). In 1929 an important earthquake occurred off the Grand Banks, and at that time mysteriously a series of submarine telegraph cables failed, many in sequence downslope with increasing distance from the epicenter. There was much speculation about the causes, until Heezen and Ewing (1952) determined that turbidity currents, maybe also slumps triggered by the earthquake, had resulted in the cable breaks.

To assume that the deep ocean has a tranquil depositional environment has proven to be completely wrong, and many entries of this volume address phenomena and products of the highly dynamic sedimentary processes which influence (f. e. submarine slides) and in part shape (f. e. abyssal plains) large tracts of the deep-sea floors.

Stratigraphy, biostratigraphy, biochronology, and the dawn of paleoceanography

The first indications of stratigraphic changes in South Atlantic sediment cores were presented by Philippi et al., (1910) who had described the composition of sediment cores taken by the first German Antarctic Expedition. The next major step was achieved by Correns and Schott (1936) who deduced from changes in the composition of planktonic foraminiferal fauna in sediment cores taken by the German Meteor expeditions that one could develop a biostratigraphic correlations of the cores, that these changes were related to the transition of deposits from the last Ice Age to the Holocene, and that one could use these data to calculate oceanic sedimentation rates.

A major leap was achieved by the Swedish Deep-Sea Expedition on Albatross because the scientists from Gothenburg had developed the first piston corer, which provided for the possibility for collecting relatively undisturbed several meter long sediment cores. The Albatross traversed along a transglobal course the tropical-subtropical zones of all major ocean basins (see for a summary: Olausson, 1996). In all basins they detected patterns of a cyclical repetition of more or less calcareous, mainly biogenic deposits which were soon linked to glacial-interglacial changes. The Swedish Albatross cores can be considered to represent the dawn of paleoceanography and marine paleoclimatology which in later decades developed into a very important branch of

marine geosciences providing important input data for modeling the evolution of past climates.

The further development of absolute dating techniques by Urey and others, the approaches of Emiliani (cf. 1992, Shackleton and many others learned to use the variability of the fractionation of heavy and light O-isotopes between glacials and interglacials to determine sea surface and bottom temperatures. They also linked them to the transfer processes of large amounts of freshwater from the oceans through evaporation/precipitation to and from the large glacial ice sheets, resulting in isochronous isostatic sea-level changes on the order of 120–140 m. It was soon recognized that ocean sediment cores represented one of the best global archives of past climatic changes. CLIMAP, a large US-led paleoclimate project soon, used this fact to establish the global distribution of climatically important parameters, and they succeeded to publish a map of quantitative ocean surface temperature reconstructions for the time slice of the last glacial maximum (CLIMAP, 1976). At the same time they detected in the time series deduced from some Southern Ocean sediment cores a systematic and regular variability of a number of paleoceanographic parameters (Hays et al., 1976) which could be linked to the Milankovitch frequencies (for eccentricity, obliquity, and precession) which had been postulated in close collaboration with Milankovitch to regulate the regular Quaternary glacial-interglacial alterations already by Köppen and Wegener (1924). Imbrie and Imbrie (1979) thought – at that time – they had solved the mystery of the ice ages.

However, during recent decades, new discoveries in marine geology have provided a deeper insight into the last Glacial period. In particular, the dated and regionalized ice-rafted debris (IRD) in sediments of North Atlantic and the Arctic Sea as well as correlation with the oxygen isotope signature effected in Greenland ice cores have led to the event stratigraphy based on climate cycles (the Dansgaard-Oeschger cycles). These cycles are determined by alteration between warm (Greenland interstadials, GI) and cold (Greenland stadials, GS) events and describe the pacing of climate variation during the last 100,000 years (see Björck et al. 1998 and the "Dansgaard-Oeschger Cycles," "Encyclopedia of Paleoclimate and Ancient Environments"). Some of the cold events are called the "Heinrich Events" after the marine geologist who mapped the extension of sea ice-affected sediments which can be seen distributed basin-wide in North Atlantic (see Heinrich 1988, and "Ice Rafted Debris (IRD)," this volume). For the late Pleistocene to Holocene, Bond et al. (1997) discovered cold events (the "Bond Events"), based mainly on petrologic proxies of drift ice sediments in North Atlantic. Dating of the sediments led to identification of a climate cycle for the time span between the Marine Isotopic Stage 3 (MIS 3) and the Little Ice Age (the "Bond Cycle") with a pacing of $\approx 1{,}470 \pm 500$ years (Bond et al. 1997).

Although the driving mechanisms of this cyclicity is still intensely debated, identification of climatic cycles below the orbitally forced Milankovitch pacing has opened a new wide field for cooperation between geologists, oceanographers, climatologists, and modelers.

In the meantime, numerous paleoclimatic and oceanographic proxies have been developed (Fischer and Wefer, 1999), which allow to reconstruct quantitatively a vast array of ocean and climate properties. Some of them can be applied to the longtime series which are available through the acquisition of the cores obtained through the deep-sea drilling activities, in some areas actually reaching into Jurassic sediments.

Paleoceanography has developed into an important branch of the marine geosciences and by providing quantitative boundary conditions to climate modelers is reaching an ever-increasing importance for establishing possible scenarios for future climates.

Seafloor spreading and plate tectonics: the new paradigm

It was the work of seagoing geophysicists which eventually led to the acceptance of *plate tectonics*. The pioneering efforts of E. C. Bullard on earth magnetism, heat flow, and seismic surveying and of M. Ewing and his associates in all aspects of marine geophysics were of central importance in this development (although M. Ewing did not himself advocate seafloor spreading). These scientists also were instrumental in elucidating the structure of continental margins (Ewing et al., 1950; Bullard and Gaskell, 1941).

The turning point in the scientific revolution which shook the earth sciences and which culminated in *plate tectonics* is generally taken to be the seminal paper of Hess (1962). Hess started his distinguished career working with the Dutch geophysicist, F. A. Vening-Meinesz, on the gravity anomalies of deep-sea trenches. These investigations resulted in the hypothesis that trenches may be surface expressions of the downgoing limbs of mantle convection cells. As a naval officer, Hess discovered and mapped a great number of flat-topped seamounts, whose morphology suggested widespread sinking of the seafloor. Stimulated by subsequent discoveries on the mid-ocean ridge (rift morphology, heat flow, and others), he proposed his idea of the seafloor being generated at the center of the mid-ocean ridge, moving away and downward as it ages, finally to disappear into trenches. The term "seafloor spreading" was introduced by Dietz (in 1961, cf. Vine and Matthews, 1963; Le Pichon, 1968) for this postulated phenomenon. *Seafloor spreading* and its offspring *plate tectonics* have since become the basic framework within which the data of marine geology are interpreted.

As previously mentioned Russian marine geoscientists were slow to follow because their country was dominated by "fixists," and the new ideas about "seafloor spreading" and "plate tectonics" were only slowly accepted. It took

eminent scientists such as Khain and Khalilov (2008) and Lev Zoneshain (2013) to push for the acceptance of the new ideas.

Only some 35 years ago, it was still possible for geologists to think that the sediments on the deep-sea floor might contain the entire Phanerozoic record and lead us back even into the Precambrian. Today, there would be few indeed who would harbor such fond hopes. The most ancient sediments recovered from the seafloor are about 180 million years old, which is less than 5 % of the age accorded to fossil-bearing sedimentary deposits on land. Where, then, is the debris which must have washed into the deep sea, for the several billion years that continents have existed? According to the hypothesis of seafloor spreading, all sediments accumulating on the ocean bottom are swept toward the trenches, as on a tectonic conveyor belt. Here, some of the sediments are *subducted* into the Earth's crust; others are scraped off against the inner wall of the trench. Thus, the ocean floor is cleaned of sediments by constant renewal and destruction.

This remarkable idea did not exactly find a warm welcome when first proposed by Hess (1962) and Dietz (1961). Somewhat similar ideas had been advanced much earlier (f. e. by Alfred Wegener) and had likewise been discounted as premature speculations. Gradually, however, as more facts became available to test the hypothesis, opposition weakened, and by 1970 there were only a very few defenders of tradition who challenged the concept of a moving seafloor.

The opposition to large-scale horizontal movement on Earth's surface had a long history. It all began with *continental drift*, an idea that arose early in the present century and challenged the prevailing assumption of *fixism* with the new arguments of *mobilism.* The most serious challenge, as already mentioned, came from the German geophysicist A. Wegener, who proposed drastic changes in the distribution of continents and ocean basins within the last 200 million years. He also proposed that the continents actively plowed through the magma which carries them, an idea that proved to be wrong. In addition, he had a timetable for the drifting of certain land masses which was quite unrealistic. Skeptical geophysicists recognized these weaknesses in Wegener's proposal and argued forcibly for the rejection of the theory of continental drift. Thus, despite the support from geologists familiar with the incredible similarities of ancient rocks and fossils in South America and South Africa, Wegener's hypothesis did not find general acceptance before the 1960s.

In essence, evidence for continental drift was dismissed because the proposed mechanism was wrong. Only in the late 1950s, through the work on *geomagnetism* and *polar wandering* by E. Irving and S. K. Runcorn (Runcorn, 1967), did it become possible again to talk about continental drift without being thought ignorant of physical principles. The most compelling evidence, however, came from the magnetism of the seafloor itself (Vine and Matthews, 1963), and final proof came from deep-sea drilling, almost a decade later.

Toward the end of the 1960s, the new hypothesis of seafloor spreading had metamorphosed into the theory of *plate tectonics*. The theory is based on the mapping of magnetic anomalies and earthquakes, by which it is possible to define large regions of the Earth's surface that move as units (*plates*), with earthquakes occurring at the boundaries of these units. The mathematical tool allowing efficient description of the movement of the plates is a theorem of the Swiss mathematician Leonhard Euler (1707–1783), which states that uniform motion on a sphere is uniquely described by defining rotation about a *pole*. The path of migration of any point on a plate appears as a portion of a circle about that pole. Bullard and associates introduced Euler's theorem to global tectonics, in 1965, to produce a new *fit* of the continents bordering the Atlantic. In the same year, J. T. Wilson explained the nature of what he called *transform faults* as boundaries between "rigid plates," where there is lateral motion generated at a spreading center; in subduction zones they can end at a trench.

For the present, and at any time in the geologic past, plate motions on the surface of Earth are defined by giving the outlines of the dozen or so plates, the geographic location of the poles of rotation, and the associated angular velocities. The principles of this approach were presented by W. J. Morgan early in 1967 and by D. P. McKenzie and R. L. Parker also in 1967. Using this methodology, X. Le Pichon, in 1968, made a global map of the relative motions of the major plates. The same concepts and methods allowed the large-scale reconstruction of the past geographic configurations of continents and ocean basins, back into the Cretaceous period (cf. Le Pichon, 1968; Allégre, 1988; Lobkovsky et al., 2013, 2014).

Deep-sea drilling: discovering new dimensions of ocean history

The emergence of the new paradigm greatly stimulated the beginning of a major venture in marine geology: the systematic exploration of the deep-sea floor by drilling. Up to 1968, before the drilling vessel *GLOMAR Challenger* set out on her first cruise (from Galveston in Texas), knowledge of sediments older than 1 million years was entirely based on cores taken in regions of greatly reduced sedimentation and erosion, where younger sediments had been removed. Such a core would typically represent a short stretch of time somewhere within the long history of the ocean. Detailed comparison with other cores, from other regions, was hardly ever possible, because of the difficulty of exact age assignment. The task of reconstructing a global ocean history for the pre-Quaternary could only be seriously attempted when more or less continuous sequences of samples became available, through drilling, from many different regions. The earliest 23 legs of DSDP were actually dominated by marine geophysicists who spot cored the sites because they wanted mainly to date seismic reflectors. Only during Leg 24 in the NW Indian Ocean, the principle of continuous coring was adopted

by the chief scientists. The materials recovered by drilling resulted in a major jump in biostratigraphic resolution – soon it became possible to date samples within sequences with a temporal resolution of less than a million years relative to some standard. The first major result was full confirmation of the theory of seafloor spreading: Sediments overlying the "basement" basalt showed the exact age predicted by the geophysicists from counting magnetic anomalies. Occasionally, sediments were somewhat younger, which means that the basaltic rock was bare for a while, before it collected sediments. Other major results were more subtle but have had far-reaching implications for our understanding of the coevolution of life and climate and for the role of the ocean in climatic change over long periods of time.

In the early years of deep-sea drilling, present sedimentation patterns were assumed to be static, so that downcore changes would be interpreted mainly in terms of motions of the seafloor. It soon became clear, however, that the ocean's productivity changed markedly through geologic time, which produced large changes in sedimentation patterns. Also, it became evident that changes in ocean conditions (as reflected in sediments) were quite sudden at certain times and that such "steps" in climatic change were associated with reorganizations of the marine biosphere, including extinctions and subsequent radiations. The most intriguing period in the ocean's history, in this regard, proved to be the transition between the Cretaceous and the Tertiary, which witnessed large-scale extinction of tropical planktonic organisms (as well as many other terrestrial and oceanic organisms).

The importance of the deep-sea record for the reconstruction of Earth's history for the last 100 million years or so became obvious very quickly. The record on land is patchy and incomplete by nature – land is eroded and delivers sediment to the sea. This renders suspect all arguments about the pace of *evolution* that depend on a continuous record (Darwin pointed this out a long time ago). Only the record in the deep ocean can promise complete sequences, and even here gaps prove to be quite common in many settings. The gaps are not distributed randomly but occur preferentially just where conditions change. This illustrates a certain obstinacy of the ocean in yielding up the secrets of its history, something that many marine geologists have come to appreciate.

Deep-sea drilling has gone through important steps of evolution. While the technique to reenter a drill hole through a cone several times to exchanging the actual drilling tool has already been developed during DSDP and ODP times, the engaged international scientific community is nor striving for further progress. For the years 2003–2023, it has been decided to continue these efforts under the frame of IODP (Integrated Ocean Discovery Program, cf. Kiyoshi, this volume). Instead of using only one drilling platform with a limited scope of the scientific problems to be attacked, IODP is now trying to drill deeper and more dangerous areas than before by employing the Japanese Chikyu which can deploy a riser-protected drill string thus allowing into the seismically active zones of Japan, for example. JOIDES Resolution is still available to conduct drilling in all major ocean basins, with the cold subpolar deep-sea basins being much in the focus.

A system of Mission Specific Platforms has been equipped to drill in shallow shelf seas for determining, for example, timing and extent of global sea-level changes, the history of the Great Barrier Reef, or the central Arctic Ocean, putting the age of the first Northern Hemisphere ice covers back into the Eocene. In addition to drilling, technologies have been developed to install numerous measuring devices or observatories on a permanent or semipermanent basis in some of the drill holes.

One of the most notable aspects of deep ocean drilling – now improved through the deployment of the larger drilling vessels JOIDES Resolution and Chikyu – is the creation of an international community of marine geologists, hundreds of scientists from around the world who were shipmates at one time or another, eagerly listening for the driller's call "core-on-deck" and sharing the thrill of exploring where nobody had gone before.

The treasures of the seafloor

After the discovery of the principles in plate tectonics and mapping of the oceanic spreading centers, it was only a question of time to dive down to the production centers of new seafloor. Here, along the spreading axes, hot mantle material is upwelling and rises as magma and emerges as lava produced by cooling new oceanic crust. In 1977 scientists from the Scripps Institution of Oceanography used the deep submersible Alvin to dive to the East Pacific Rise. These scientists described the first time visually active hydrothermal venting and related processes. To their surprise they found a diverse inventory of venting phenomena such as hot water chimneys separated into black and white smokers along with chemosynthetic life forms which were completely unknown before (Londsdale, 1977). For the history of hydrothermal vent discovery, see "Hydrothermalism" (this encyclopedia). The discovery of chemosynthetic life initiated the development of new biological theory, such as the assumption of Gold (1992) who postulated a phylogenetic pathway of organisms from the "Deep Hot Biosphere" to the surface.

Predicted by economic geologists who had studied hydrothermal sulfides on land, in the course of exploring marine hydrothermal vents, significant polymetallic enrichment was found in the vicinity of the vents which was assigned to hydrothermal activities at or in the vicinity of the spreading centers. The identification of massive sulfide deposits leads to an intense international activity in exploration of marine ore reserves (Francheteau et al., 1979). Saline brines and metalliferous marine muds had been identified in the Red Sea already in the 1960s of the last century (Degens and Ross 1969), but the development of a general genetic concept of marine ores could not

be accomplished before the discoveries of the hydrothermal marine sulfides (Hannington et al., 2011). Together with the discovery of hydrothermal sulfides along spreading centers of the oceans, polymetallic (manganese) nodules covering wide areas of the oceanic basins have raised international interest during the last decades of the twentieth century ("Marine Mineral Resources," "Manganese Nodules," this encyclopedia). In a kind of "gold rush," the developed nations spared neither cost nor effort to explore marine ore deposits. National and international consortia (as Interoceanmetal) explored the ocean floor, whereby areas of the Pacific Ocean between Clarion and Clipperton Fracture Zones (CCZ) were – and are still – in the center of interest because of their economic favorability. Despite intense mapping and exploration, an industrial exploitation of polymetallic nodules has never started because of the drop in ore prices and unsolved environmental problems expected to be provoked by an industrial submarine ore mining. In contrast, commercial interests currently are focusing on seafloor massive sulfides (SMS) located on convergent plate boundaries (Rona, 2003), and in 2005 the first commercial SMS survey was launched at the Manus Basin, Papua New Guinea.

During the last third of the twentieth century, the international interest in seabed-bounded mineral resources exploded in the fear of a depletion of onshore deposits. So, extensive exploration programs were launched worldwide for sand and gravel, placer (heavy minerals, diamonds, gold), phosphorites, and carbonates on the continental margins, and most of the adjoining coastal states exploit mineral offshore resources ("Marine Mineral Resources," this encyclopedia) according to international and national laws. A historical pace forward in this respect was the establishment of an international legal regime for the world's oceans and seas by the United Nations Convention on the Law of the Sea in 1982 (United Nations, 1997). Within the frame of this law, the International Seabed Authority (ISA) based at Kingston, Jamaica, was founded, a UN body taking care of the organization, regulation, and control of all mineral-related activities in the international seabed area at the high sea, beyond the limits of national jurisdiction (for the program see United Nations, 2004). In addition to mineral deposits, another resource of the seafloor did raise enormous interest during the second half of the last century: hydrocarbons (oil and gas) and gas hydrates ("Energy Resources," this encyclopedia). After the first discoveries of offshore oil deposits at the US West Coast, during World War II, their systematic exploration and exploitation started in the Gulf of Mexico. After the war, worldwide discoveries followed in the Persian Gulf, Caspian Sea, Arabian Sea and the North Sea, and many other areas. The last and probably very big fossil hydrocarbon province is expected to be found under the Arctic shelf seas and continental margins. Very soon the areas of interest moved from the shelf to deepwater fields at water depths >1,500 m so that at the beginning of the twenty-first century already >50 % of new discoveries are located at deepwater environments.

Target areas for present future exploration and drilling activities are the so-called golden triangle of Brazil, the Gulf of Mexico, and West Africa and the oil and gas in deepwater environments at continental margins of the Arctic Ocean. Drilling in the deep ocean raises the risk of technical accidents and environmental disasters. The Deepwater Horizon oil spill in the Gulf of Mexico ("Oil Spill," this encyclopedia) in 2012 has shown the limits and threats of current exploitation of marine resources.

Another phenomenon of the world ocean related to energy sources has been discovered during the 1970s of the twentieth century: gas hydrates ("Marine Gas Hydrates," this encyclopedia). In 1970 the first time marine gas hydrates have been sampled at the Blake Ridge (Atlantic continental margin of North America). After these first discoveries (Kvenvolden and McMenamin 1980), drilling campaigns and international research programs have helped during the last decades to understand the theoretical background for genesis, structure, and appearance of marine (and continental) methane hydrates (cf. Suess et al., 1999). But, we are still far from the exploitation of gas hydrate reserves as energy source.

Oil and gas deposits and accumulation of gas hydrates are bounded to ocean margins with their sedimentary wedges hosting continental erosional products with relative high proportions of organic matter descending from the high productivity of the ocean margin waters. This organic matter forms the source for hydrocarbons or methane trapped in hydrate cages. For the exploration and balancing of reserves, a stratigraphic framework for the sedimentary successions is of extreme importance.

Deep biosphere

The discoveries of the "Deep Hot Biosphere" along with the investigation of hydrothermalism had raised special interest in the new "exotic" ecosystems. The ODP and later on the IODP drilling campaigns lead to a systematic search for evidences of microbial life in marine sediments and igneous rocks. These systematic discoveries did change completely the understanding of the limits of living organisms on our planet (Parkes et al., 2000; D'Hondt et al., 2004; Jørgensen et al., 2006). For an overview about discoveries and review articles, see "Deep Biosphere" (this encyclopedia). Despite the major progress in research, there are still important questions waiting to be answered. Among these, the balance of the microbial life, the energy source of microbial growth, the role of deep biosphere in the generation and destruction of hydrocarbons and gas hydrates, or in the remobilization of material from descending lithospheric plates is just a selection of important question. Origin and evolutionary history of the deep biosphere and the influence of the marine environments on their abundance is to be addressed for understanding the evolution of ancient life on Earth and will provide analogs for comparative cosmological studies. The crucial scientific problems and pathways to solution have been described as key topics in the science plans of

Integrated Ocean Drilling Program (Moore et al., 2001) and Integrated Ocean Discovery Program (Bickle et al. 2011) for the time span 2003–2023. Besides the scientific questions technological challenges were to be accepted. These challenges are sampling in order to avoid contamination of the microbiological samples during drilling and recovery of the cores.

Sequence stratigraphy

Based on Suess' (1906) fundamental theory of eustacy to link physical stratigraphy of different regions with the frame of global transgressions and regressions, Sloss (1964) and Vail et al. (1977) developed the concept of sequence stratigraphy as a worthwhile tool for a stratigraphic correlation of sedimentary units displayed by seismic images and correlated world-wise. The basic assumption is that at continental margins because of synchronous sea-level change during low-stand phases, wide areas are exposed to subaerial erosion so that the erosional surfaces displayed as reflectors in seismic imaging form spatial/temporal boundaries of "sedimentary sequences" which can be correlated basin wide. The original findings of Sloss (1964) and Vail et al. (1977) were based on data from marine Mesozoic to Cenozoic sequences in an onshore position in relative low resolution. With the beginning of the ocean drilling activities, it became obvious that this program can contribute to test the synchroneity and amplitudes of sea-level events, with the aim to explain the controlling mechanism on margin stratal architecture. In order to answer these questions, it was decided to drill for a global comparison transect offshore the tectonically stable New Jersey siliciclastic margin, on carbonate margins along Australia, at the Bahamas, and isolated northwest Pacific atolls. First results allowed comparisons of slope sequences with the eustatic curve of Haq et al. (1987), the Bahamas records, and benthic foraminiferal oxygen isotope data (Miller et al., 1998). Refinements after the first findings which promised correlation to the Cenozoic stratigraphic architecture on continental slopes and carbonate platforms to the orbital and even suborbital scales were achieved by the deployment of Mission Specific Platforms (MSPs) managed by ECORD to drill at the Jersey shallow shelf (IODP Expedition 313). To correlate marine isotopic stages (MIS) 5–1 of the continental shelf, reliable and high-resolution sea-level data for the last glacial cycle (LGC) are needed. Grant et al. (2012) have developed a probabilistic model of the LGC sea-level change based on a statistical analysis of oxygen isotopes of Red Sea and Mediterranean Sea Foraminifera. Lobo and Ridente (2013) studies give reason to hope that we will succeed to assign even the architecture of the MIS 5–1 shelf sediments to high-frequency Milankovitch cycles.

Sea-level and society

Sea-level and coastline shifts related to climate change and coastal hazards such as tsunamis are threatening increasingly the human society living along the edge of the world's oceans and seas. However, the influence of coastal change on mankind is not a recent phenomenon. Even in their early phases of cultural development, human populations reacted to marine regressions and transgressions and to climatic and environmental changes by migration and adjustment of their socioeconomic systems to the changing natural environment. Therefore, questions of postglacial sea-level change were put on the international research agenda at the end of the last century.

The phenomenon of sea-level change has been tackled in two ways: by empirical data interpretation and by modeling approaches. Pirazzoli (1991) compiled within the frame of an International Geological Correlation Program (IGCP) project postglacial sea-level data that lead the first time to a global overview about quantitative regional trends in coastline change mainly triggered by glacio-isostatic adjustment (GIA). Lambeck and Chappell (2001) used numerical models to describe the deformation of the Earth's crust to the loading and unloading by continental ice sheets and water masses in marine basins. But, besides the interest in historical reconstruction of the paleo-coastlines, increasing interest is paid to the generation of future scenarios. Future projections of sea-level processes are directly related to climate change and the interference of natural and anthropogenic driving forces so that at the beginning of the twenty-first century the door for cooperation between geoscientists, climatologists, and socioeconomists has been widely opened (Rahmsdorf, 2007).

Conclusions. Marine geosciences: quo vadis?

To answer the question of future development of targets and pathways in marine geosciences, it is helpful to go for the IODP Science Plan 2013–2023 (Moore et al., 2001; Bickle et al. 2011). This plan is characterized by a clear commitment to the "System Earth" – an interdisciplinary and integrated approach. The following research themes are on the agenda of the next 10 years:

- Climate and ocean change: reading the past, informing the future. Behaviors of climate, oceans, and ice caps under increasing greenhouse conditions and expansion of the database for climate modeling and prediction
- Biosphere frontiers: deep life, biodiversity, and environmental forcing of ecosystems. Exploration of life forms beneath the seafloor and in extreme environments where microbes live isolated from the photosynthetic worlds at the limits of natural habitats; relation between biodiversity and fast climate change; and the influence of large volcanic eruptions and the impacts extraterrestrial bodies on biodiversity
- Earth connections: deep processes and their impact on earth's surface environment. Geochemical exchange processes between the solid earth, oceans, and atmosphere; drilling into the Earth's mantle; understanding the properties and nature of changes of the Earth's magnetic field; and evolution of mineral deposits resulting

from exchange processes between ocean crust and seawater

- Earth in motion: short-term geodynamic processes of large and immediate relevance for mankind (earthquakes, tsunamis, landslides); understanding of fluid-flow processes in sediments and volcanic crust; formation and stability of gas hydrates; borehole observation laboratories and their networks; and setup of early warning systems for disasters

Despite the fact that drilling to the seafloor using advanced technologies will provide the scientific community with samples of rocks, fluids, and gasses from environments never sampled before, the deep understanding of Earth's systems, but also the societal service of marine geosciences, requires an embedding of new data into an array of monitoring and modeling approaches. Synchronous to the demands of the estimation of risk of hazards and projections of trends to the future, long-term instrumental data series gain increasingly importance. These data series have to be integrated into warning systems of disasters such as tsunamis. Besides the deep oceans, marginal seas and their coastal zones and river mouth systems will come into focus of national and international research projects. Studies of the modification of matter and energy on the pathway from the source at the continents to the sink in marine-receiving basins – including expressively anthropogenic effects – will help to manage processes at the interface between the terrestrial and the marine realm. In addition to this service of marine geosciences to management and planning of natural environments in order to find the balance between their exploitation and sustainable protection, another "classic" task will remain on the agenda: To explore the history of planet Earth, its structure and dynamics, as well as new potential sources for the supply of the society with raw materials and energy.

geological (and geomorphological) features of intrinsic scientific interest that allow us to understand the key stages in the evolution of the Earth (modified after Wimbledon and Smith-Meyer, 2012).

Marine geosites can be large or small, e.g., submarine canyons, seamounts, or submarine moraines. Geological and geomorphological features and their diversity (i.e., geodiversity) are of great importance for several reasons, both in terrestrial and marine environments. Values of geodiversity include intrinsic or existence value, cultural value, aesthetic value, economic value, functional value, and research/educational value (Gray, 2004). Geosites, as well as landscapes, shaped and defined by their geology, form the geological heritage, which is a part of the natural heritage of any country (Wimbledon and Smith-Meyer, 2012), on land and at the seafloor. Geomorphological features and rocks are just as much part of natural heritage as animals and plants. Thus conservation of geosites and geodiversity is justified and important also in marine environment.

The conservation of geological and geomorphological features, that is, geoconservation, has a long history. One of the first geoconservation, by legal action, has taken place already in 1819 in Scotland (McMillan et al., 1999). Geoconservation has been a well-established activity in the terrestrial environment, but it has been earlier largely absent in the marine environment. However, at present there are already several marine protected areas that are defined by geology. There are several national and international programs for site inventories and protection of important geological sites, like UNESCO's Global Geoparks and IUGS Geosites Programmes. In addition UNESCO keeps a World Heritage List of certain places on Earth that have outstanding universal value and should form part of the common heritage of humankind. That list includes unique places like the Great Barrier Reef in Australia and Kvarken Archipelago in Finland, among others, that make up the world's marine heritage. Conservation of both biological and geological components of nature forms a basis for the sustainable use of marine resources, sustaining biodiversity and ecosystem functioning in the world's oceans and seas, and is the responsibility of all countries and their governments.

Definition

Heat flow is a measure of the rate of thermal energy transferred (power) from one place to another normalized area, commonly denoted q. The units of q are equivalent to energy time^{-1} area^{-1}, which is W m^{-2} in the System International (SI) where a watt (W) is equivalent to a joule second^{-1} (J s^{-1}). Since the heat flow is typically small for most Earth processes, we often report heat flow in mW m^{-2}, where 1 mW = 10^{-3} W. Heat flow is physically defined by Fourier's law, given by the product of the thermal conductivity, k, with a thermal gradient between two points, $\Delta T/\Delta z$, i.e., $q = k (\Delta T/\Delta z)$. In marine geophysics steady-state conductive heat flow is the measurement typically made. Thermal gradients are estimated by driving a 3–10 m long, thin steel probe into the soft marine sediments. The probe contains several thermistors, to measure temperature (mK accuracy), distributed along the length at known distances. Such measurements over the short length of such a probe are possible because of the insulating effect of poorly mixed deep-sea water reservoirs. Thermal conductivity is more challenging to estimate but is typically done by (1) modeling the decay of heat due to insertion of the temperature probe or (2) performing measurements on retrieved sediment core. Very few heat flow measurements have been made through or around bare rock, and thus, inherently, the current measurements do not account for the advective heat loss due to the circulation of water at the Earth's surface (Louden and Wright, 1989).

Method of measurement

There are three principal methods of measuring seafloor heat flow. One pioneered by Bullard (1954) (Figure 1a) involves the use of a thin steel probe with the temperature measuring devices located within the steel probe. The second developed by Ewing (Gerard et al., 1962) (Figure 1c) uses a standard core tube and measures the temperature gradient using thermistors within outriggers mounted on the outside of the core tube. The third, the violin-bow probe (Figure 1b), designed by Lister in 1967 but described in Lister (1979), measures the temperature within a thin tube attached to a very strong 3–5 mm diameter steel rod. In this method, the thermal conductivity is determined in situ by pulsing heat into the tube and afterward examining the temperature decay with time from the pulse. The other two instruments rely on known relations between sediment properties and thermal conductivity from a nearby sediment core. In addition to the above methods, a number of measurements have been made using temperatures measured in a core pushed ahead of drill string in the Deep Sea Drilling and Ocean Drilling Programs (Pribnow et al., 2000). Agreement between the shallow measurements and the borehole observations is generally good (Hyndman et al., 1984) and confirm that bottom water temperature does not vary significantly in the eastern north Pacific and the central and eastern Atlantic. However, water temperature variations observed offshore western North America, South Atlantic, and eastern Pacific affect measurements with shallow, <5 m, penetration (Davis et al., 2003).

The above techniques require sediments so that the probe can penetrate below the surface. A thermal blanket (Johnson and Hutnak, 1997), made of a thin (5 cm) urethane foam sheet with known thermal conductivity and thermistors on either side, can be draped directly over a rock outcrop. Thermal blankets have seen very little use as they require placement by an ROV and must be left for approximately 12 h to equilibrate.

Introduction and early work

Measurement of the flow of heat through the Earth is crucial because it is heat and temperature differences that primarily drive motion within the Earth. Heat flow is difficult to measure because it involves measuring a gradient at or near the boundary between two different substances: sediment and water for the oceans and rock/sediment and air on land. Despite these difficulties heat flow measurements have contributed to many major advances in the Earth sciences. This contribution is especially true of the measurements from the ocean floor, and it is these measurements that are the subject of this review.

Essentially one man, Sir Edward Bullard, initiated marine heat flow as a subdiscipline of geophysics at the end of WWII. Given the controversy created by Lord Kelvin (1895) who used temperature gradients from mines on land to compute the age of the Earth, it is truly surprising that it took so long for heat flow measurements to be made
Marine Heat Flow, Figure 1 Mechanical configuration of the three most commonly used marine heat flow probes: (**a**) Bullard probe (see details in text); (**b**) Lister "violin-bow", developed to measure thermal conductivity and temperature gradient in situ at the same location; and (**c**) Ewing outrigger, developed to enable temperature gradient measurements to be taken during a standard Lamont-Doherty Geological Observatory coring station (After Louden and Wright (1989)).

in the oceans. Like almost all other geophysical measurements, the results from the first observations yielded the most startling results and helped change our view of the thermal properties of the Earth.

Bullard (1939) started in this field, before WWII, by measuring the heat flow on land in South Africa. His work there established the standards and techniques that are still currently in use in the global heat flow field. In 1945, he showed that the heat flow through the stable continents is remarkably uniform at ~60 mWm^{-2} (Bullard, 1945). He speculated that the heat was caused by the radioactivity of granite and, since that was missing on the ocean floor, it would be lower. He concluded "it would be of great interest to verify this by heat flow measurements under the oceans."

Hans Pettersson, a Swedish radiochemist, attempted the earliest marine temperature gradient measurements. He reported two measurements from the Pacific in his report on the 1947–1948 Swedish Deep-Sea Expedition (Pettersson, 1949). The temperature gradients were low and implied a heat flow (20–30 mWm^{-2}) much below that through the continents. As this was as expected, if radioactivity were the cause, the incentive to make more measurements evaporated, and little effort was made to continue them (Gustaf Arrhenius, Personal Communication, 2010).

Bullard had questions regarding both the method of measurement and the conclusions of Pettersson. In 1949, on an extended visit to Scripps Institution of Oceanography (SIO) together with colleagues, Revelle, graduate student Maxwell, and the SIO technical staff, he designed an instrument with a long probe to measure the temperature

gradient in the soft sediments of the ocean floor (Figure 1a). Multiplying this value by the conductivity measured on sediment recovered in nearby cores gave the heat flow.

After Bullard left SIO to become Director of the UK National Physical Laboratory (NPL), the group perfected the design of the original instrument and made six measurements in the deep North Pacific (Revelle and Maxwell, 1952). The values were close to the mean value for the continents (~60 mW m^{-2}). In his companion paper, Bullard (1952) pointed out that the values should have been much lower. He speculated that the extra heat necessary to elevate the heat flow values came from thermal convection cells in the upper mantle.

On returning to England, Bullard redesigned the probe and took six additional measurements in the North Atlantic from RRS *Discovery*. He combined all the additional measurements taken at NPL and SIO into one publication (Bullard et al., 1956). This paper was the first to point out the correlation, now known to be the feature of all mid-ocean ridges, between very high heat flow (i.e., >100 mWm^{-2}) and the crest of the mid-ocean ridges. This correlation was dramatically confirmed by further work in the Pacific by Von Herzen (1959) and Von Herzen and Uyeda (1963) and in the South Atlantic by Vacquier and Von Herzen (1964).

The theory of seafloor spreading implies the intrusion of hot molten magma at the crest of the mid-ocean ridges. The values reported by Bullard et al. (1956) and Von Herzen (1959) were critical to the development of this theory by Hess (1962). In his seminal paper, Hess wrote: "The Mid-Ocean Ridges are the largest topographic

features on the surface of the Earth. Menard has shown that their crests closely correspond to median lines in the oceans and suggests that they may be ephemeral features." Bullard et al. (1956) and Von Herzen (1959) show that they have unusually high heat flow along their crests.

Historical models of plate creation

The major question posed by the papers of Hess (1962) and Dietz (1961) (who expanded on the original idea of Hess) on seafloor spreading was "how did the zones of ocean floor creation relate to the places where the oceanic crust was being destroyed and how thick was the region that was moving?" Wilson (1965) argued that the simple concept that the Earth is made up of rigid plates of greater than 50 km thickness created at spreading centers and destroyed in trenches could explain the huge deep topographic offsets observed on the mid-ocean ridges. Importantly this showed that the region that was moving was much thicker than just the crust. Almost immediately, Ewing et al. (1966) and McKenzie (1967) used heat flow data to test the concept of a thick moving plate. This plate is now called the lithosphere. Ewing et al. (1966) argued that it did not, whereas McKenzie (1967) disagreed and constructed a simple model of plate creation (Figure 2a) that was compatible with the observations.

Sclater and Francheteau (1970) used this plate model to show that the global heat flow data and the subsidence of the ocean floor (Figure 2a), rather than being an argument against the plate theory, as Ewing et al. (1966) had suggested, strongly supported it. Because of the scatter in the heat flow (left-hand side of Figure 2b), it was realized that it was more useful to plot seafloor subsidence against crustal age. Sleep (1969) and Sclater et al. (1971) demonstrated that there was a simple relationship for the entire age of the ocean floor (Figure 2a) that was compatible with the creation of a plate about 100 km thick. Parker and Oldenburg (1973) showed that for the first 80 my in the North Pacific, there was a simple relation between subsidence and the square root of seafloor age (i.e., $z \propto \sqrt{t}$). This is to be expected if the creation of the ocean floor were to be represented by the cooling of a simple thermal boundary layer (Turcotte and Oxburgh, 1967). Davis and Lister (1974) showed that for crust <80 Ma, this relation held for all three oceans considered by Sclater et al. (1971).

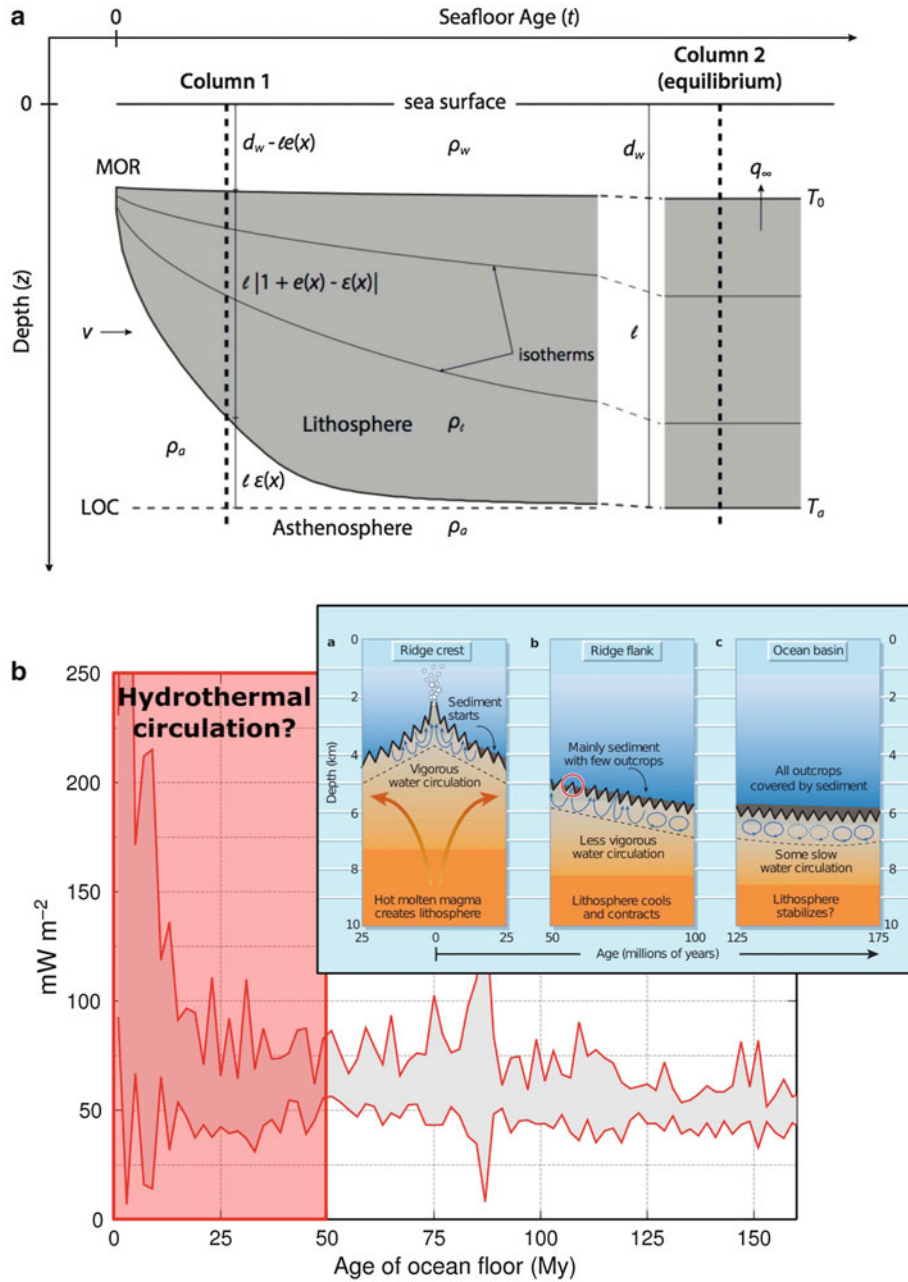
Hydrothermal circulation in the oceanic crust

Values from the initial measurements near the ridge axis in the oceans, according to Bullard et al. (1956), were highly scattered. This prevented use of these data for quantitative analysis (left-hand side of Figure 2b). In addition, the averaged heat flow values near the ridge crest were much lower than those predicted by the thermal model that best matched the subsidence of the older ocean floor (see Sclater and Francheteau, 1970). The problem was resolved by Lister (1972) who showed that the observed heat flow followed the values predicted by simple models

of fluid flow in a permeable crust where upward flow occurred in narrow vents with the downward flow being broad and diffuse. Immediately, it was realized that this hypothesis explained both the variability in the heat flow values and the low averaged values near the ridge crest. The hydrothermal hypothesis of Lister (1972) predicted the output of hot jets of water on the seafloor, and their discovery (Williams et al., 1974) spawned extensive interdisciplinary studies of seafloor hydrothermal circulation (see Davis and Elderfield, 2004 for a review). Sclater et al. (1976) showed that filtering heat flow data on young seafloor, only to include measurements made in well-sedimented areas with no nearby basement outcrops. This dramatically increased the heat flow to close to that predicted the models that matched the topography. Davis et al. (1999) and Davis and Becker (2004) documented clearly that, over variable but well-sedimented cover, the heat flow is directly related to the depth to basement (Figure 2b). This can only be possible if vigorous water circulation, occuring within the basaltic basement beneath the sediment, maintains a constant temperature at the sediment/crust interface.

Modern thermal models

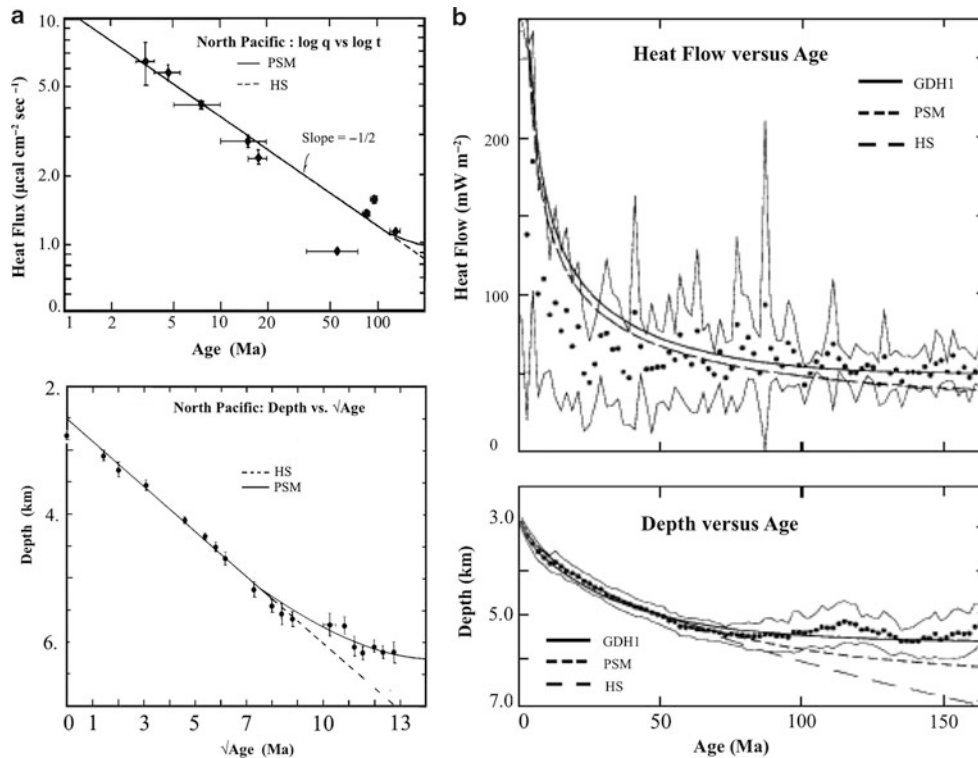
Using carefully filtered heat flow data (Sclater et al., 1976) and specially selected depth-age provinces, Parsons and Sclater (1977) showed (a) how extraordinarily well the plate model fits the observational data and (b) that various parameters of the plate could be obtained by constructing physical models that fit the data within measurement error (Figure 3a: top and bottom). Out of these analyses came a realization (Parsons and McKenzie, 1978) that the lithosphere, even when represented as a flat plate, was still simply the upper boundary layer of a cooling convection system (Turcotte and Oxburgh, 1967). Parsons and Sclater (1977) fit the data with a plate thickness of 125 km and a basal temperature of 1,330 °C. In an analysis using a much more complete data set, Hillier and Watts (2005) showed that the depth data for the North Pacific filtered to remove the effects of swells gave results very similar to that of Parsons and Sclater (1977). However, both papers matched the heat flow data by adding a 4 mW m^{-2} to account for the effect of radioactivity within the ocean crust. Such a large value is not supported by the overall measured radioactivity of the crust (Staudigal, 2003).

In an alternative observational approach, Stein and Stein (1992) ignored both filtering and the selection of special provinces and plotted all the depth and heat flow data in the Pacific and Northwest Atlantic against age of the ocean floor. They found a model (GDH1) that best fit both data sets that had a plate thickness of 95 km and a bottom temperature of 1,425 °C (Figure 3b). Though the basal temperature is too high to explain the rare Earth distribution in the melted rock found at the ridge axis (McKenzie et al., 2005), GDH1 was the first model that actually had the predicted heat flow high enough to fit the data over ocean floor >130 Ma without assuming the


Marine Heat Flow, Figure 2 (**a**) Simple model for the intrusion of the oceanic lithosphere under a mid-ocean ridge (Sclater et al., 1971, based on McKenzie, 1967) that accounts the subsidence with age by balancing the pressure at the base columns 1 and 2 assuming a fluid underlies them. (**b**) (*Left*). The envelope of unfiltered heat flow data versus age marked by *red lines* (from compilation of Francis Lucazeau (personal communication see Goutorbe et al., 2011)). (**b**) (*Inset*) Changes in ocean floor depth, sediment thickness, and hydrothermal circulation plotted against increasing age of the oceanic lithosphere. The ocean floor is depicted in *black*, sediment in *brown*, and hydrothermal circulation in *blue*. In (**b**) (*Inset*): *a*, heat flow is dominantly by advection; in *b*, by advection and conduction; and in *c*, dominantly by conduction. The *red circle* in *b* illustrates the flow pattern observed by Fisher et al. (2003) on the flank of the Juan de Fuca where hot fluid is emanating through a basement outcrop (Sclater 2003).

addition of an unreasonably high value for the crustal radioactivity.

Whether or not the depths increase as the square root of age on the oldest seafloor has proven controversial (e.g.,

Crough, 1975; Schroder, 1984; Marty and Cazenave, 1989; Stein and Stein, 1992; Carlson and Johnson, 1994; Hillier and Watts, 2005). The distinction is key: a direct continuation would favor the simplest cooling half-space


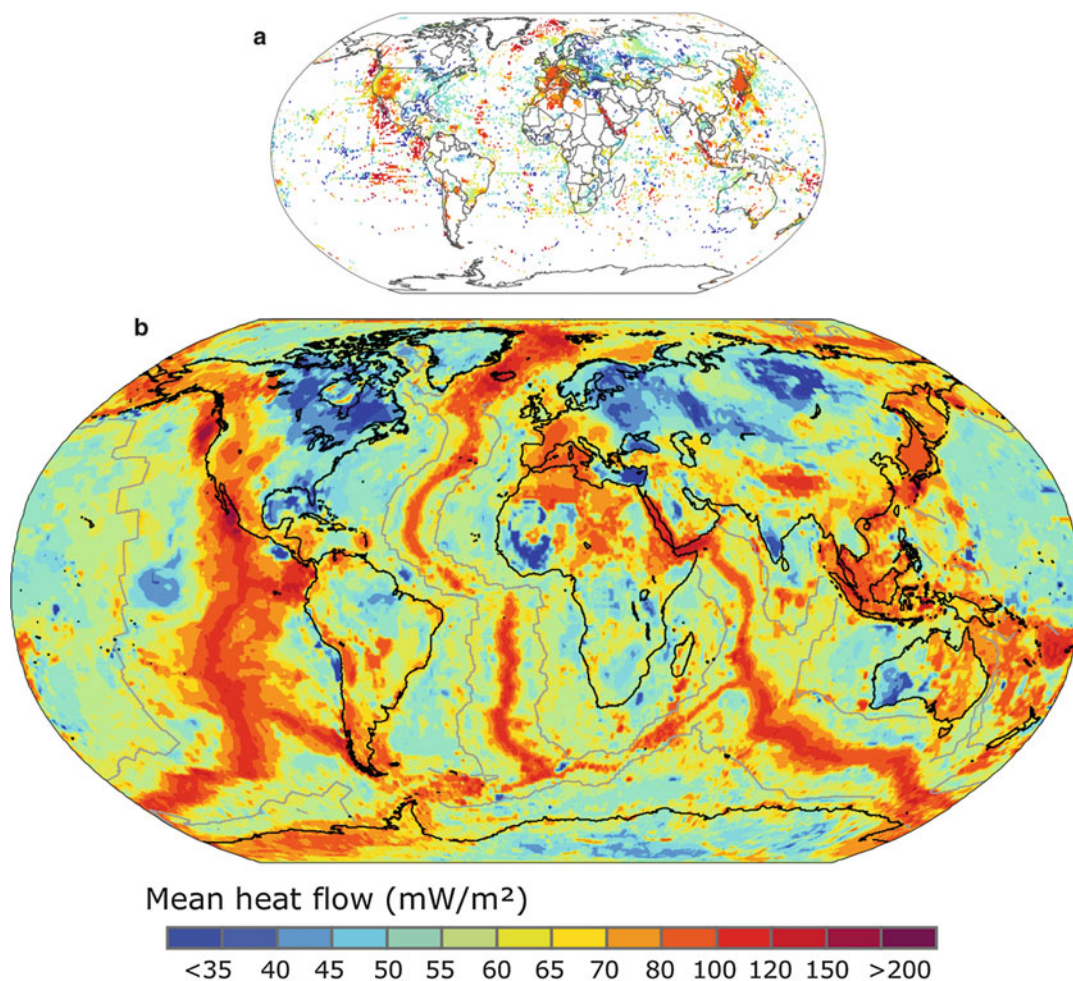
Marine Heat Flow, Figure 3 (**a**) (*Top*). Heat flow means calculated using data filtered for sediment thickness, plotted on a log/log scale versus age. The theoretical curve has a slope of −1/2 until an age of about 120 Ma. The small difference between the plate model and the cooling half-space model (*dashed line*: −t1/2 dependence) at older ages is just visible (Parsons and Sclater, 1977). (**a**) (*Bottom*). Mean depths and standard deviations plotted versus the square root of age for the North Pacific (Parsons and Sclater, 1977). (**b**) Data and models for heat flow (*top*) and ocean depth (*bottom*) as a function of age. Depths are an average of the North Pacific and Northwest Atlantic. Heat flow values are from sites in the same regions with data averaged in 2 Myr bins, and the envelope represents one standard deviation about the mean. GDH1, PSM, and HS are, respectively, the best fit model to the data, Parsons and Sclater (1977), and the half-space cooling model (from Stein and Stein (1992)).

model of the lithosphere, while shallower depths, a "flattening," favor a model of the lithosphere with basal heat input (plate, constant basal temperature, or, CHABLIS, constant basal heat flow (Doin and Fleitout, 1996)). Hillier (2010) has shown conclusively that the depths flatten with age on oldest ocean floor strongly favoring a model with basal heat input. This impacts upon expectations for seafloor heat flow.

Under continued scrutiny, how the depth and heat flow data are selected and the above controversy have brought to light two problems with the models. First, the plate thickness using the selected provinces was always thicker than that for the data taken as a whole. Second, Nagihara et al. (1996) summarized a series of carefully selected heat flow surveys on old ocean floor. They pointed out that neither the boundary layer nor GDH1 and the Parson and Sclater (1977) plate models could explain both the heat flow and age and depth and age relations on the oldest (>130 Ma) ocean floor without assuming the addition of an unreasonably high value for the crustal radioactivity. The data selection remains critical and a key to refining models.

Heat flow data

The global heat flow compilation published by the International Heat Flow Commission reported more than 22,000 stations. It incorporated the earlier work of Lee and Uyeda (1965), Simmons and Horai (1968), Jessop et al. (1975), Pollock et al. (1993), and Gosnold and Panda (2002) (http:www.geophysik.rwth.aachen.de/IHFC/heatflow.html). This database has been updated and extended by Laske and Masters (http://igppweb.ucsd.edu/~gabi/ rem.html). It was used in Davies and Davies (2010) and Davies (2013).

The latest papers reference compilations that now include >50,000 unique heat flow sites worldwide. The majority of the data are sparsely but relatively evenly distributed across the globe with a few isolated high-definition studies. For this review, we considered two recent compilations: Hasterok (2010) slightly updated in 2013 and Goutorbe et al. (2011). For the marine realm, both consist of about 14,000 + heat values, if the measurements on the shallow continental shelf are ignored. They differ mostly in the amount of confidential industry data that have been included. All


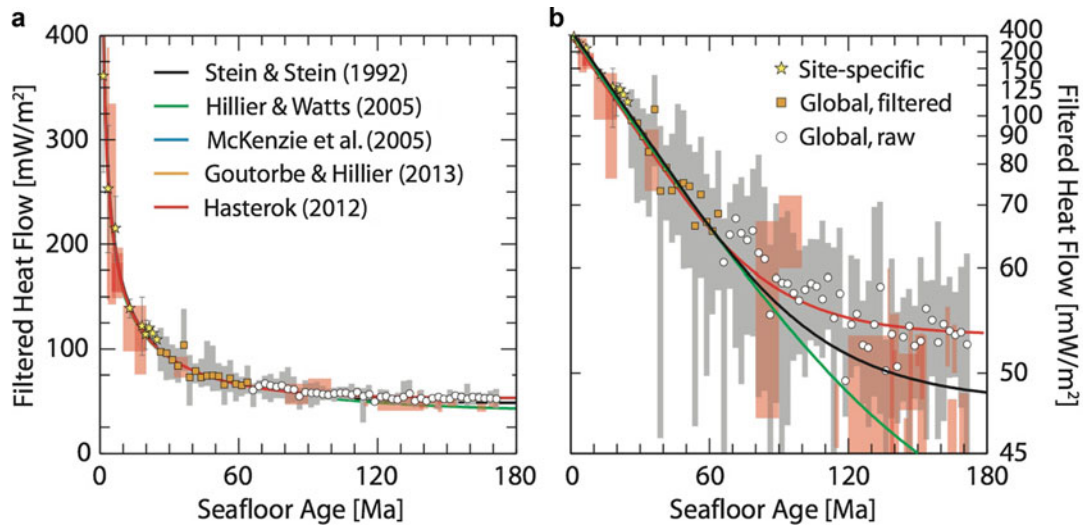
Marine Heat Flow, Figure 4 A 1° × 1° global heat flow grid used for this paper. (**a**) Gaussian filter with a 500 km radius was applied to smooth unexplained small-scale variations. Grid is available in the online supplementary material to Goutorbe et al. (2011). (**b**) A color contour chart of global heat flow that uses a "similarity method" to fill in gaps in coverage (From Goutorbe et al. (2011)).

start from the compilation of Francis Lucazeau (personal communication).

To illustrate the current state of the data, we constructed presentations based on Goutorbe et al. (2011). We present the raw data in 1° by 1° bins (Figure 4a) and a contour plot of the heat flow values based on a "similarity method" (see Goutorbe et al. (2011) for explanation) (Figure 4b). On a global scale, this analysis and a prior, less rigorous contour map, constructed using a similar approach by Shapiro and Rizwoller (2004), show a large area of strikingly high heat flow associated with the plate boundaries in the oceans. Davies (2013, Figure 7), using the theoretical heat flow versus age, presents an even more striking example of this effect. All of these charts illustrate how important the creation of oceanic plate is for the heat loss of the Earth (~60 % Sclater et al., 1981).

Heat flow versus age

The theory of plate tectonics predicts subsidence and decreasing heat flow as young buoyant lithosphere ages and cools. Because of the scatter in heat flow over young ocean floor, for most studies, models derived from the subsidence have dominated. Hasterok (2013) has recalibrated oceanic cooling models to include a filtered, hydrothermally free data set that simultaneously allows for a reasonable mantle temperature (~1,350 °C). He matched the observed heat flow data to a plate model and found that thinner plate cooling models with a thickness of 90 km gave the best fit (Figure 5a).

Hasterok (2013) considered five models (Figure 5a) when plotting heat flow against age of the ocean floor. All models appear to give the same degree of fit for younger ocean floor. However, as a result of the necessity to


Marine Heat Flow, Figure 5 (**a**) Worldwide observed heat flow data (*gray rectangles*: interquartile range) in 2.5 Ma bins from well-sedimented areas plotted against age compared with the five different thermal models that match the relation between depth and age (see text for explanation). *Open circles*: Raw global data. *Red rectangles*: detailed heat flow surveys over well-sedimented areas (Sclater et al., 1976, Nagihara et al., 1996) (after Hasterok (2013)). (**b**) Median heat flow versus age, vertical scale is scaled by heat flow^{-2} to emphasize flattening on older ages. The symbols and curves are the same as for (**a**) (after Hasterok (2013)).

include the data over the young ocean floor, the linear scale is too small to differentiate between the models at older ages. To enlarge the scale for the older ages, but still retain the young data, he plotted the data with the distance on the vertical axis scaled as 1/heat flow^2 (Figure 5b). In such a plot, only the models of Crosby and McKenzie (2009) and Goutorbe and Hillier (2013) give a good match to his statistical best fit to the filtered heat flow data. However, the model of Goutorbe and Hillier (2013) has a higher basal temperature of 1,390° and a greater plate thickness (106–110 km). Both models match the heat flow relation without adding the effect of crustal radioactivity.

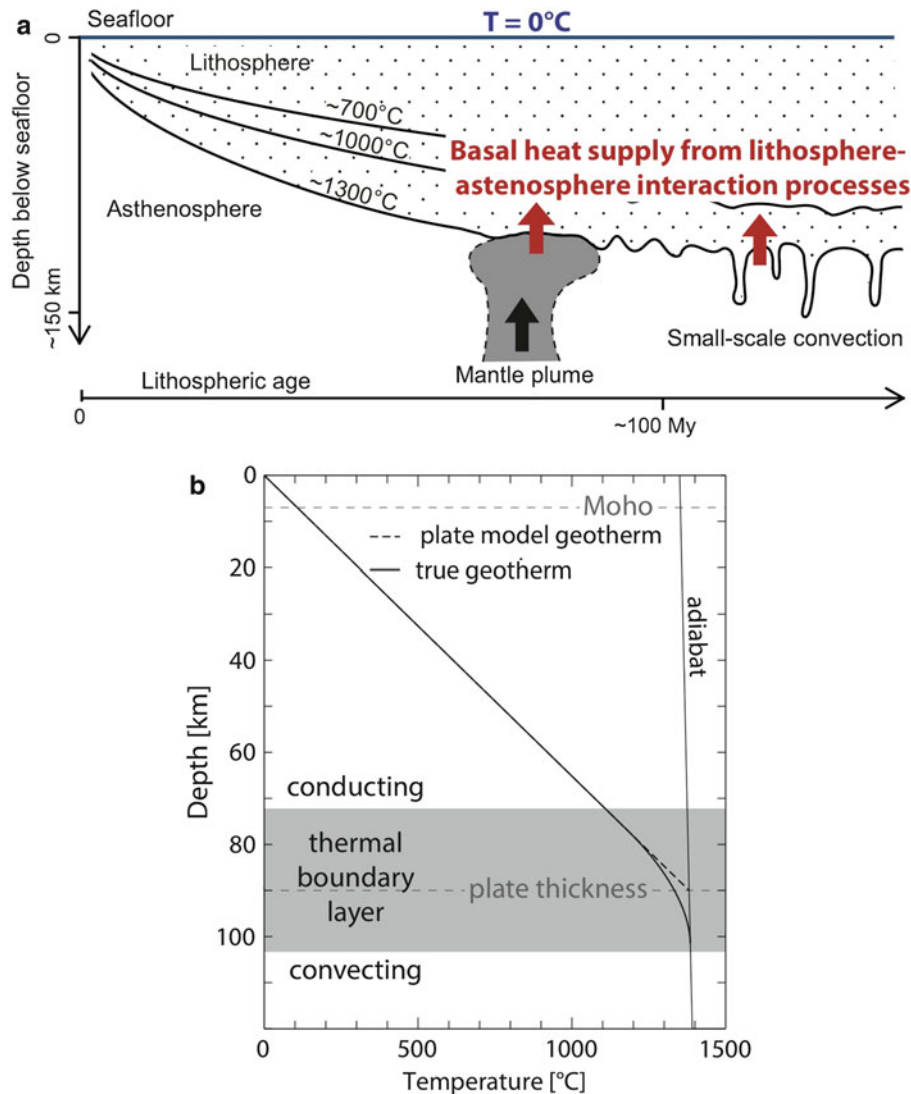
The best-fitting heat flow age model by Hasterok (2013), which fits the heat flow data, can be parameterized by the following simple relationship:

For $t \leq 17.4$ Ma, $q = 506.7 \, t^{-1/2}$.
For $t > 17.4$ Ma, $q = 53 + 106 \, e^{-0.034607t}$.

As a result of the reduction in the scatter in heat flow, it is necessary to reconsider the variation in the topography. It is created both by mantle plumes and their topographic expression (Goutorbe and Hiller, 2013) (Figure 6a). In addition, Crosby et al. (2006) have suggested that cells small-scale convection that give rise to dynamic topography also have an effect. To investigate the importance of this, they removed the effects of both mantle plumes and the dynamic topography, both positive and negative, by only considering depths in areas of low free-air gravity. Using these data Crosby and McKenzie (2009) found that the depth-age data in the North Pacific best fit a plate ~90 km thick and 1,315 °C bottom temperature.

This plate is much thinner than the thickness of 125 km given by Parsons and Sclater (1977). The thermal model of Crosby and McKenzie (2009) constructed to fit the depth-age relation also accounts for the heat flow relation for the old ocean floor, thus allowing a single thermal model to match both the heat flow and the depth without assuming significant radioactivity in the ocean crust.

Crosby et al. (2006), Crosby and McKenzie (2009), and Goutorbe and Hillier (2013) start with the assumptions of Parsons and McKenzie (1978) where the cooling oceanic lithosphere consists of a mechanical and thermal boundary layer. At older ages the thermal boundary layer becomes unstable and heat is added to the bottom of the plate (Figure 6a). McKenzie et al. (2005) have pointed out that the creation of a plate of constant thickness is a good approximation to this concept. The bottom of the plate lies within the thermal boundary layer (Figure 6b).

Both the models of Crosby and McKenzie (2009) and Goutorbe and Hillier (2013) consider the effect of dynamic topography within the mantle (Figure 6a). In the case of Goutorbe and Hillier (2013), they remove only the major plumes and their topographic expression. Crosby and McKenzie (2009) assume that all areas where the gravity anomaly is large are associated with small-scale dynamic topography and remove them from their analysis. The model of Crosby and McKenzie (2009) has the advantage of having the lower bottom temperature for the plate fixed at ~1,315 °C, and McKenzie et al. (2005) have argued that this is the required temperature for upwelling to make a crustal thickness of 7 km. However, it has the disadvantage that it is statistical in basis and


Marine Heat Flow, Figure 6 (**a**) Conceptual model of Goutorbe and Hillier (2013). The oceanic lithosphere consists of a mechanical and thermal boundary layer that is affected by thermal erosion due to overturn within the thermal boundary layer and by major mantle plumes. For the model of Crosby et al. (2006) and Crosby and McKenzie (2009), there is an additional effect due to small-scale convection in the upper mantle. (**b**) The base of the plate model lies within the thermal boundary layer. Note that the plate model geotherm lies close to that of a thermal boundary layer (after Crosby et al. (2006)).

the areas of low gravity have not yet been mapped in detail. Though the model of Goutorbe and Hillier (2013) has disadvantage of a high basal temperature, it has the advantages that with a thin plate (100+ km), it still fits the heat flow age relation and has clearly defined areas that have been removed when constructing the model to match the fit between depth and age.

Global heat loss/global heat flow estimates

Following the compilation by Lee and Uyeda (1965), a number of studies have estimated the global heat flow (Figure 7a). Estimates, prior to the widespread acknowledgement of advective heat transport through young

seafloor, gave ~30–31 TW (1 TW equals 10^{12} W) (Lee and Uyeda, 1965; Lee, 1970; and Chapman and Pollack, 1975). Approximately 20 TW came from the oceans and ~10 TW from the continents, giving a global heat flow of ~30–31 TW. However, these values are now known to be too low.

Vigorous hydrothermal circulation through young seafloor is now recognized as a major mechanism by which the Earth redistributes heat (Lister, 1972). Hydrothermal circulation near the ridge axis is so vigorous that conductive heat flow values can be reduced by nearly two orders of magnitude and expelled in highly concentrated regions that give rise to black smokers (Williams et al., 1974).
Marine Heat Flow, Figure 7 (**a**). Estimates of global heat flow of the Earth by date of publication (see references). *Blue circles* represent estimates derived from all heat flow observations, whereas the *red circles* substitute hydrothermally affected estimates with heat flow estimates derived from plate cooling models. Note the abrupt change when it was realized that the scatter in heat flow values was due to hydrothermal circulation. (**b**) Number of heat flow data within the global heat flow database (see list of references). *Upper bars* are the number of continental measurements, and *lower bars* are the number of oceanic measurements. The decrease in oceanic heat flow observations between Davies and Davies (2010) and Hasterok et al. (2011) is a result of reclassification of marine observations collected on the continental margins as continental in the latter study.

As the igneous crust becomes covered by sediment, direct flow between the oceans and lithosphere is cutoff. In extensively sedimented regions (Figure 2bc), heat flow may recover to near background values (Davis et al., 1999). However, flow may still occur between igneous outcrops, extracting heat beneath regions well covered by sediment for several tens of kilometers (Davis et al., 1999; Hutnak et al., 2008). The first global heat loss estimates adjusted to account for heat flow deficits on young seafloor now give global heat flow at ~41 TW with ~11 TW coming through the continents (Williams and Von Herzen, 1974; Langseth and Anderson, 1979; Davies, 1980; Sclater et al., 1980; Chapman and Pollock, 1980; Chapman (personal communication 1985 in Chapman and Pollack, 1987)) to ~44 TW (Pollack et al., 1993) (Figure 7a).

Even with an approximate doubling (Figure 7b) of the reported measurements, there has been little change in the value of global heat flow. The new data still show a significant observational deficit extending to oceanic crust of <60 Ma. Estimates of the magnitude of this deficit range from 9 to 11 TW (Sclater et al., 1980; Stein and Stein, 1992; Elderfield and Schultz, 1996; Mottl, 2003).

Hasterok (2013) provides the most recent estimate using a plate cooling model calibrated for heat flow at young ages. His estimated global heat flow deficit due to this ventilated flow is 8 (+2,−3) TW. This is ~20 % of the total heat loss of the Earth and >30 % of the heat flow through the deep oceans. Many of the differences in the estimates among older models result from the choice of cooling model parameters. However, adding a predicted heat loss estimate through hotspots rather than a change in the cooling model explains the increase from 44 TW (Pollack et al., 1993) to 46–47 TW (Jaupart et al., 2007; Davies and Davies, 2010). Ignoring hydrothermal circulation in crust <65 Ma and calculating the global heat loss of the Earth from observational data (Hofmeister and Criss, 2005) yields a value that is significantly low.

Jaupart et al. (2007) calculated the heat loss through the oceans by breaking the heat flow into two intervals: the first from 0 to 80 Ma where the simple boundary layer model gives a good match to the data and the second on older seafloor where the heat flow is approximately constant. They find that the heat loss due to plate creation is ~24.5 TW and that due to conductive flow on crust >80 Ma is 4.5 TW. Adding to the amount released by plate

creation, the extra heat loss at the swells of ~3 TW raises the nonconductive heat loss to 27.5 TW. This is approximately 85 % of the heat loss through the oceans. On the continents, they estimate that about half of the surface heat flow is due to radioactive decay in the upper continental lithosphere. This leaves a conductive flow from the upper mantle under the continents of ~6 TW, with much of this coming from sedimentary basins and shelves as a result of stretching of the continental crust (Jaupart et al., 2007). Thus, almost all the surface heat flow of the Earth, except that due to radioactivity on the continents, has as its origin convection in the upper mantle. The heat flow from the upper mantle through the cratons and platforms is very low, and these areas act like an isotherm (Jaupart et al., 2007). Thus, the heat loss from the upper mantle shows a huge difference between that occurring beneath the oldest continental lithosphere and that created by plate creation at the mid-ocean ridges. This must have a major effect on convection in the upper mantle.

Conclusions

Many fundamental advances in our understanding of the Earth have come from the study of marine heat flow:

1. The early heat flow values were the same as, if not higher than, the values on continents. Because of the low radioactivity, they implied an additional source of heat to that given by radioactivity to explain them.
2. High values observed at the crest of mid-ocean ridges were a key observation in the development of the theory of seafloor spreading by Hess (1962).
3. Attempts to understand the high scatter in heat flow measurements near the crest of the mid-ocean ridges led Lister (1972) to propose widespread hydrothermal circulation at the crest of mid-ocean ridges.
4. There is general agreement that thermal models requiring input of heat from below best match the relations between the heat flow and subsidence with age.
5. Removing the effect of dynamic topography in determining the relation between depth ages allows the construction of two self-consistent models that match both the heat flow and subsidence on old ocean floor without requiring significant radioactivity in the oceanic crust.
6. A remarkable discovery associated with plate tectonics is that one simple thermal model can explain the general dependence of both marine heat flow and bathymetry on age.
7. Creation of oceanic plate is the major way in which the Earth loses heat. From a global loss of 45–47 TW, three quarters comes through the oceans with one fifth occurring by the advection of seawater at the crest of the mid-ocean ridges. Creation of oceanic plate accounts for ~60 % of the heat loss of the Earth.

8. There is a large difference between the heat loss from plate creation and that occurring under the oldest continents.

MARINE IMPACTS AND THEIR CONSEQUENCES

Henning Dypvik
Department of Geosciences, University of Oslo, Oslo, Norway

Introduction

Asteroid and comet impacts (meteorite impacts) are important factors in shaping the surface of the terrestrial planets. The impacts release vast amounts of energy resulting in sudden increase in temperature and pressure, structural deformations, and redistribution of target and bolide (asteroid and comet) material. It is presently well accepted that impacts, especially into marine environments, have had a major influence on the development of the Earth. The Earth is covered by 71 % seawater (7 % shelf seas and 64 % deep oceans), and, consequently, impacts into marine targets should be the most common.

Asteroids and comets (both generally called bolides, projectiles, or impactors) impact regularly on the Earth and other planetary bodies in our solar system, forming impact craters, expelling ejecta material, and triggering earthquakes and tsunamis. The impact craters registered on the Earth range from a few meters to hundreds of kilometers in diameter (http://www.passc.net/EarthImpactDatabase/) mainly determined by bolide size, composition, and velocity as well as the composition of the target area and angle of impact (Figure 1). The most probable impact angle is 45° for asteroids and comets (Gilbert, 1893; Shoemaker, 1962).

The impacts on dry land form subaerial impact craters, while submarine or sublacustrine craters are the result of marine or lacustrine impacts (subaqueous impact craters), respectively (Dypvik and Jansa, 2003). The marine impacts/submarine craters can in general be classified into two broad classes: shallow marine, neritic, and deep marine, bathyal. The shallow marine cases represent impacts and related deposits on continental shelves with water depths down to about 300 m, while the deep marine impacts are found below 300 m, i.e., beyond the shelf edge and into the deep ocean. It should be noted that the critical depth depends on projectile size (D) and water depth (H). The shallow marine case is realized when H < D. Even 1,000 m is shallow water for a 10 km projectile.

Marine Impacts and Their Consequences, Figure 1 Impact craters on the Earth. Marine craters/impacts are marked by *red stars* (Figure modified from Dypvik and Jansa (2003)).

Impact cratering

According to NASA (2012), several thousand hazardous asteroids and comets exist, but detailed knowledge of their distribution is still lacking. Compositionally, the bolides can be recognized by comparable minerals to terrestrial rocks, often with the addition of enrichments in Pt-group metals (Ru, Rh, Pd, Os, Ir, Pt) and siderophile elements (e.g., Ni, Co, Au). High enrichment of Ir is of special interest and commonly used as an extraterrestrial indicator (French and Koeberl, 2010).

Generally, two main types of impact structure appear: simple and complex (Melosh, 1989; French, 1998). The simple craters are normally bowl shaped and less than 4 km in diameter, while the complex craters (>4 km) can have various shapes, often with a central peak and in some cases internal ring(s) (Figure 2).

Crater formation is completed within a few minutes, the actual time depending mainly on crater size which is controlled by bolide size, target composition, bolide velocity, and composition. The crater development can be subdivided into three main stages: contact/compression, excavation, and modification (French, 1998). In the contact and compression stage, kinetic energy is converted into shock waves that are transmitted into the target material; the duration of this stage is only a few seconds (Melosh, 1989). The result is a fractured and brecciated target area and a totally or partially evaporated projectile.

The succeeding excavation stage lasts longer than the contact/compression stage and is the result of the release waves (rarefaction) when the crater is opened up and a bowl-shaped depression is formed in the target site. Crushed and melted material is ejected, and a so-called transient crater is formed. The transient crater is a bowl-shaped depression with a structurally uplifted rim.

Ejecta deposits have been recognized in association with several impacts, i.e., with wide distributions of crushed target material as well as melted bolide and target material. In the marine impact cases, this phase is highly influenced and volatized by the vaporized water (Figure 2).

The excavation stage is followed by a modification stage dominated by processes remodeling the unstable transient craters, controlled by gravity and rock mechanics and crater sedimentation. The modification stage can last longer than the excavation stage, i.e., a few minutes for the largest impacts (French, 1998).

Marine target sites consist of three layers: from top down, the water column, thick sedimentary successions, and underlying crystalline basement. Their different thicknesses and rheological properties greatly influence cratering developments. First, a crater is generated in the water, then a crater is formed on the sea floor, and finally, in the crystalline basement if enough energy is still left after the bolide's penetration of the water and sedimentary
Marine Impacts and Their Consequences, Figure 2 Diagram of the main configuration of simple and complex craters (NASA website 2013; craters.gsfc.nasa.gov).

columns. The interaction of the impacting body and the water causes loss of the body's kinetic energy through oceanic drag prior to the ocean floor collision (Wünnemann and Lange, 2002).

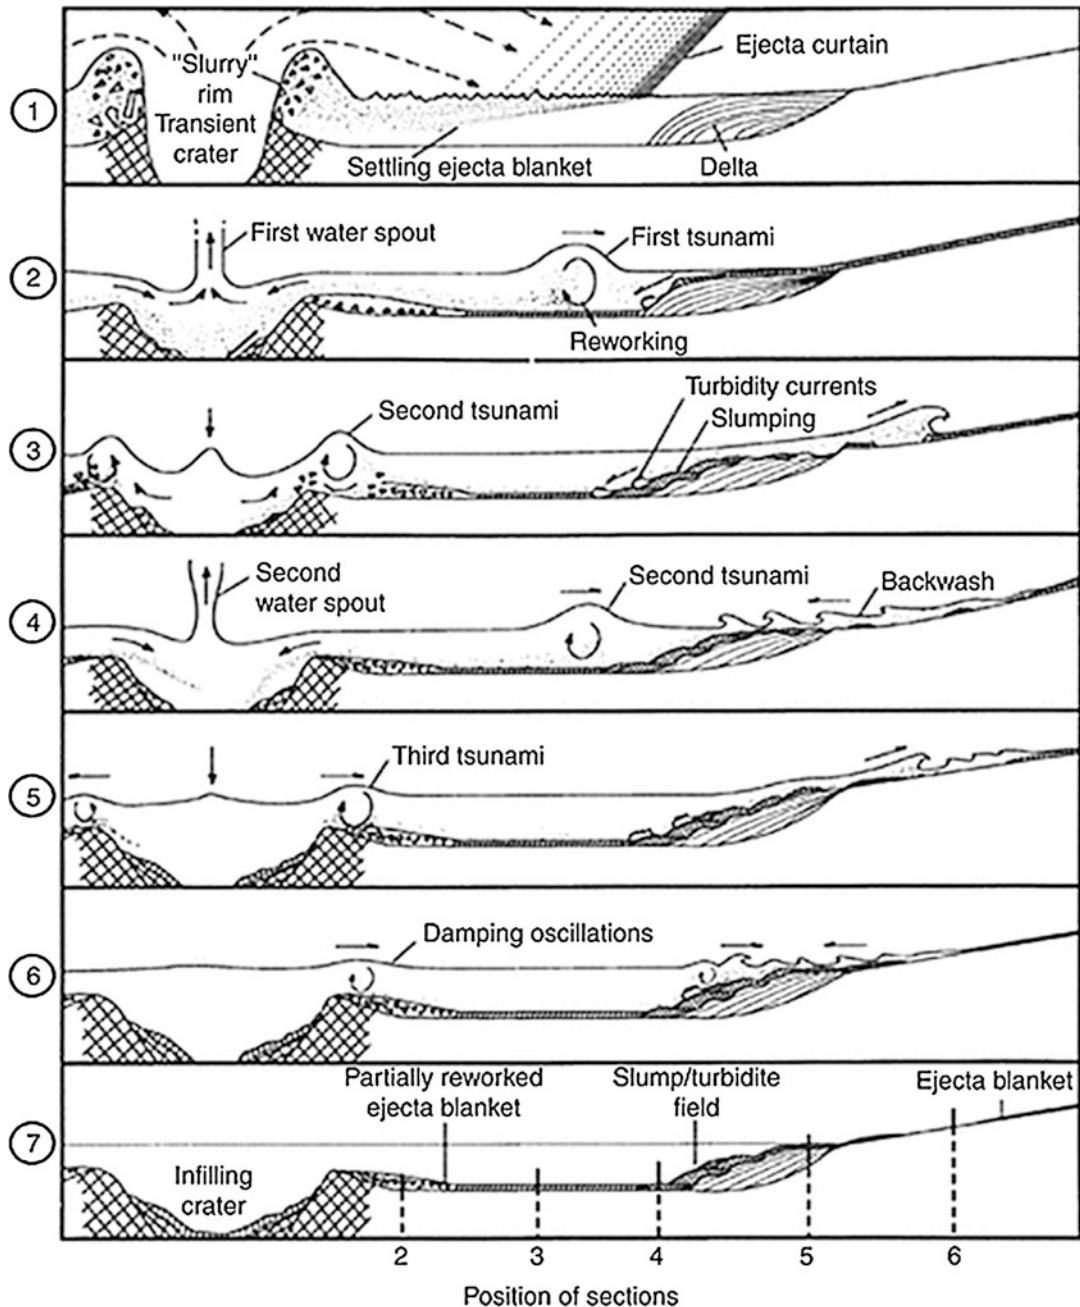
Oberbeck et al. (1993) presented one of the first detailed descriptions of marine impacts and submarine craters, discussing ejecta distribution, tsunami generation, crater formation, and current generation. Focusing on shallow seas, their Figure 6 (Figure 3 here) still gives a good illustration of the marine impacts, crater formation and violent ejecta distribution, tsunami generation, active crater modification, and later postimpact sedimentation filling of the craters.

Water depth will have little effect for the large bolides, but for small- and medium-sized ones, the ocean will function as an efficient filter, with marine impact craters only forming in relatively shallow water (H) compared to the size of the bolide (D) (Artemieva and Shuvalov, 2002); H < D.

Impact craters in marine sedimentary basins are filled by postimpact sediments rather quickly after impact. Consequently, submarine craters commonly are very well preserved compared to subaerial ones where erosion-dominated processes are more active. The well-preserved submarine craters of Mjølnir and Chesapeake Bay are good examples (Gohn et al., 2009; Dypvik et al., 2010).

The Earth Impact Database (December 2013) names 183 craters of which only 28 (may be three additional ones, totally 31) have been recognized as marine impacts (Figure 1). They all have been formed by impact into marine basins, but presently, most of them occur on land though a few are still located in a submarine setting. A closer look at the numbers, e.g., simple subtraction (183 − 28(31)), gives 155(152) structures which should represent the minimum number of subaerial impacts. 155(152) on land impacts should, taking the land/sea area ratio into consideration, indicate at least 379(372) marine impacts/submarine craters. Since 155(152) clearly is a minimum number, the 379(372) may also be regarded as a minimum total for marine impacts.

The fact that only 28 marine impact structures have been described so far is probably due to:

- The difficulties in searching for marine impact structures and too few engaged impact researchers.


Marine Impacts and Their Consequences, Figure 3 Hypothetical stages of events produced by a bolide impacting a shallow sea (The figure is from Oberbeck et al. (1993) who claims the seven stages will occur over a period of several hours. The vertical scale is exaggerated).

- All oceanic crust is younger than approximately 180 million years, due to plate consumption and generation in the plate tectonic cycle.
- Lack of knowledge of how to recognize deep oceanic impacts, since we know so little about these structures.
- The oceans and epicontinental seas globally cover huge areas of which only a tiny portion have been covered by geological and geophysical analyses.

- A large number of asteroids and comets never reach the sea floor; consequently fewer submarine craters should be expected compared to subaerial ones (Davison and Collins, 2007).

Through the years, crater and impact statistics have been compiled, and, e.g., in the Task Force UK report of 2000 (Table 1), the general impact frequency and crater sizes are listed.

Marine Impacts and Their Consequences, Table 1 Impact cratering bolide size (m and km), crater diameter (km), and impact frequency (year) (Modified from Task Force Group, 2000)

Bolide (m/km)	Crater diameter (km)	Average interval between impacts (year)
75 m	1.5 km	1,000 years
350 m	6 km	16,000 years
700 m	12 km	63,000 years
1.7 km	30 km	250,000 years
3 km	60 km	1 million years
7 km	125 km	10 million years
16 km	250 km	100 million years

Methods of studying marine impacts

Fossil marine impact structures may be found on land and can consequently be as accessible for detailed analyses as the subaerial ones. Modern and fresh submarine craters, present on and below the ocean floor, are more difficult and costly to study, being dependent on geophysical investigations. In particular, seismic, gravimetric, and magnetic surveys are needed to detect and describe these structures and their ejecta distributions, e.g., as done in the Chicxulub, Chesapeake Bay, and Mjølnir cases (Gohn et al., 2009; Dypvik et al., 2010; Schulte et al., 2010). Craters on the Earth traditionally need additional detailed information to be recognized and accepted as impact generated and not circular cavities with different origins. Cores and rock samples are necessary for structural, mineralogical, and geochemical analysis (French and Koeberl, 2010). Coring is normally expensive and rarely done, likely one important reason for our poor understanding of marine impacts.

Various core analyses are needed in order to differentiate crater depressions from other cavities on the seafloor, formed by, e.g., gas discharge, other structuring on the seafloor (faulting/fracturing), and volcanic eruptions. Rocks and sediments affected by impact can mineralogically and geochemically be characterized by the presence of, e.g., shocked altered minerals (shocked quartz), Ni-rich spinels, and geochemical enrichments (Ir in particular) (French and Koeberl, 2010).

Marine impacts

In a marine impact, water absorbs the energy very effectively; consequently, a very large bolide is needed to produce even a modest crater on the abyssal plain. The mobilization of sediment following an impact tends to obscure such a signature except in cases where the bolide diameter is comparable to the ocean depth (Gisler et al., 2010). It should be mentioned that so far very few coastal tsunami deposits related to impacts have been found and described (e.g., Chicxulub; Smit, 1999).

Marine impacts represent an intricate mixture of relatively poorly understood processes compared to subaerial cratering (Ormö and Lindström, 2000; Dypvik and Jansa, 2003; Dypvik and Kalleson, 2010). The relations between bolide size (D) and water depth (H) are crucial in constraining submarine crater formation, as also mentioned above. It has been shown that the ratio H/D is of great importance on the resulting cratering process. No subaqueous crater is formed at the seafloor if H/D > 10 (Gault and Sonett, 1982; Artemieva and Shuvalov, 2002), while if 10 < H/D < 1, the water column plays an important role during the cratering process to the size and morphology of the resulting structure (Shuvalov, 2002). When H < D, there is only a minor direct influence of the water column to the cratering process (Shuvalov, 2002).

In shallow water impacts, the crater rims are not normally leveled out (Ormö and Lindström, 2000; Dypvik and Jansa, 2003) and may even be taller than the returning water and consequently even hamper the resurge of water (e.g., the 2.7 km diameter rim of the Ritland structure; Riis et al., 2012; Shuvalov et al., 2012). Already in 1982, Gault and Sonett (1982) carried out experiments to model deep and shallow ocean impacts. They showed that water is remarkably effective in shielding the seafloor against significant excavation. In shallow water craters, their experiments demonstrated that central peaks in smaller craters could extend even above the water surface, as, e.g., in the Mjølnir case (Dypvik et al., 2010). In deep waters, the rims as well as the central peaks may be quickly leveled out by the generated current's reworking of soft sediments, explaining the typical marine crater characteristic of low or absent rims (Dypvik and Jansa, 2003). Resurge gullies may be formed during rather shallow marine impacts, cutting across the rim. Mass and debris deposits, turbidites, and other gravity deposits are produced as results of crater wall and central peak collapse, during and after crater excavation. Such gravity flow-related deposits are found both within and outside the marine impact craters (Dypvik and Kalleson, 2010).

Marine impacts or impact into wet targets can result in ejecta transportation as ground-hugging flows (Melosh, 1982; Masaitis, 2002). Such accretionary impact lapilli may occur both in proximal and distal environments relating to large- and middle-sized impact craters. The Alamo Breccia of Western USA and Albion Formation of Mexico and Belize are possible examples (Warme, 2004; Pope et al., 2005; Morrow et al., 2009).

In marine impacts, the sedimentation of the modification stage includes breccias, slumps, avalanches, mass/debris flows, and turbidity currents. Impact-generated earthquakes may trigger liquefaction reactions in the water-saturated seafloor sediments. The impact-related sediments rich in ejecta may consequently be widely distributed, like the ejecta and tsunamites from the Chicxulub impact (Smit, 1999; Clayes et al., 2002). The Baltic Narva Breccia was possibly formed from slumping, displacements, and wave

reworking after the middle Devonian Kaluga impact into an epicontinental, about 300 m deep sea (Masaitis, 2002).

The Chicxulub impact event at the boundary between Cretaceous and Paleogene (K/Pg) took place in shallow water, near the shelf edge at the Yucatan peninsula (Mexico) (Schulte et al., 2010). In that case, a 10 km bolide hit, generated earthquakes, and large parts of the outer shelf/shelf edge collapsed, triggering slumps and slides, avalanches, gravity flows, turbidity currents, and tsunamis.

The 142-million years old Mjølnir structure was found in the Barents Sea during geophysical exploration; later structural, mineralogical, and geochemical analysis proved its meteoritic origin (Dypvik et al., 2010). Mjølnir looks different to subaerial craters with its subdued and possibly gullied rim, chaotic marine succession, and marine fossils in the black shale formations above and below. On top of the folded, slumped, and fractured sediments forming the Mjølnir crater base, there is a sedimentary package about 20 m thick. It consists of breccias, partly from autobrecciation and mass-flow deposits including turbidites, forming the syn- and early postimpact succession. It is all topped by black shales, demonstrating a return of the black clay sedimentation in the basin, which prevailed before impact.

So far, no deep sea impact craters have been found, in spite of the large areas of the Earth which are and have been covered by deep seas. Davison and Collins (2007) claim there is still no definite relationship between impactor properties, water depth, and final crater diameter. Artemieva and Shuvalov (2002) and Gisler et al. (2010) presented similar relations between water, impactor size, and cratering as given by the ratio between bolide size and water depth and (H/D). For shallow craters with a ratio below 3–4, decreasing crater diameters are modeled with increasing water depth, but a ratio larger than 7–8 will result in no crater at all, though possibly some disturbance to the seafloor. Intermediate ratios may, according to Davison and Collins, result in relatively broad, complex craters. Artemieva and Shuvalov (2002) claim water depth/bolide diameter ratios larger than 25 will have no visual bottom effects.

The Eltanin impact (Bellingshausen Sea, SE Pacific) represents the only known large meteorite impact into a deep ocean. This Pliocene event (2.15 million years ago) (Figure 1) involved an approximately 1 km diameter bolide hitting the sea where it was about 4,000 m deep, and no crater was developed on the sea floor, but projectile ejecta and debris (reworked seafloor sediments) were spread in a diameter of at least 600 km across the ocean floor (Kyte, 1988; Kyte et al., 1988; Gersonde et al., 1997; Artemieva and Shuvalov, 2002; Wünnemann and Lange, 2002). The Eltanin-disturbed zone on the seafloor is characterized by a 20–40 m thick unit of chaotically mixed sediments that most probably originated from impact-induced turbulent currents (Gersonde et al., 1997; Gersonde et al., 2002).

Detailed observations of spherule beds in Australia, South Africa, and Greenland are possible remnants of Precambrian (Archean) oceanic impact activity, but without a recognized crater. These possible Precambrian craters may have been eroded or consumed during plate tectonic activity, and presently only the spherule layers have been found (Simonson et al., 2002; Simonson and Glass, 2004). It is speculated whether these spherules could reflect large oceanic impacts, maybe comparable or larger than Eltanin of the SE Pacific.

Consequences of impact

In addition to the impact itself and associated earthquakes, several other related processes can create hazardous situations in the oceans and along the coastlines (Figure 3); here, atmospheric effects, tsunamis, and currents must be mentioned.

Several authors (e.g., Ward and Asphaug, 2000; Artemieva and Shuvalov, 2002; Shuvalov, 2002; Ward and Asphaug, 2002; Gisler et al., 2010; Glimsdal et al., 2010) have stated that tsunamis will be generated, but according to Gisler et al. (2010), the real dangers from wet impacts are mainly atmospheric: blast wave from the explosion, winds, fallout, and high temperatures over small distances. Possible contamination effects of impact should also be mentioned as suggested partly causing the K/Pg extinction tied to the Chicxulub impact (Schulte et al., 2010). The K/Pg extinction was to a large extent controlled by bolide and target area composition, water depth, and impact velocity and direction (Schulte et al., 2010).

In the Chicxulub case, a bolide possibly 10 km in diameter hit a shallow to deep sea with significant lateral bathyal variations from 100 m to probably 2,000 m (Gulick et al., 2008; Schulte et al., 2010), creating an about 180 km diameter crater. The K/Pg extinction was triggered by the Chicxulub impact and its major pollution consequences such as soot and dust distribution partly shutting down photosynthesis, thermal radiation and different aerosols, acid rain, and possible change in the ocean circulation (Pope et al., 1997; Schulte et al., 2010). It should however be noted that several effects contributed to the large biological extinction which has to be evaluated from the background of ambient environmental conditions and the existing ecosystem (Kring, 2003).

The potential hazard of meteorite impact and tsunami generation in the ocean is controversial (Ward and Asphaug, 2000; Ward and Asphaug, 2002; Korycansky and Lynett, 2005; Korycansky and Lynett, 2007; Wünnemann et al., 2007; Gisler et al., 2010) with respect to the destructive power of the large waves (tsunamis) generated. It is important to mention that several types of tsunamis/waves are generated by impacts (Matsui et al., 2002; Glimsdal et al., 2010). Recent studies demonstrate that tsunamis generated by impacts are in general less destructive than the more common tsunamis generated by, e.g., plate tectonic movements. This reflects the nonlinear shoaling of the impact tsunamis (Korycansky and Lynett, 2007; Wünnemann et al., 2007; Glimsdal et al., 2010; Gisler et al., 2010). Impact tsunami may indeed undergo strong diminution of amplitude on continental slopes and

shelves (Melosh, 2003). This could be caused by wave breaking or bottom friction, reducing the amplitude of the shoreline run up, maybe to 30 % of the deepwater wave amplitude (Korycansky and Lynett, 2005).

Shuvalov (2002) carried out numerical modeling of tsunami formation, demonstrating, e.g., that the Mjølnir impact was responsible for a major disturbance of the water column. Following the impact-induced outward water surge, large amplitude tsunamis were formed, and the rapid resurge of seawater into the excavated crater transported large amounts of ejecta and crater wall material back into the crater. Glimsdal et al. (2010) modeled more specifically the tsunami generation and propagation from the Mjølnir event (Dypvik et al., 2010). Tsunamis started to develop as an undulatory bore, developing into a train of solitary waves. Waves with amplitudes exceeding 200 m were formed, but during shoaling, the waves broke rather far from the coastlines in relatively deep water. The tsunamis, however, induced strong bottom currents in the 30–90 km/h range, which caused strong reworking of bottom sediments with dramatic consequences for the marine environments.

Definition

Marine microfossils are fossils of small size (usually <1 mm) that need to be studied by microscopy to deduce the morphological characteristics of the organism or skeletal element concerned.

Introduction

Marine microfossils are produced by a variety of microorganisms that may be auto- or heterotrophic or planktic or benthic. Although most marine microfossils are body fossils of single-celled organisms (protists), some are small-sized elements of macrobiota, e.g., conodont elements or sponge spicules. The vast majority of marine microfossils possess permineralized skeletons that are composed of one of several common skeletal materials such as calcium carbonate (foraminifera (Figure 1), calcareous nannofossils), silica (radiolarians (Figure 2), diatoms (Figure 3), silicoflagellates, ebridians), organic compounds (acritarchs, chitinozoa, dinoflagellates (Figure 4), scolecodonts), or calcium phosphate (conodonts). Obviously, groups that lack mineralized or refractory skeletal elements have a considerably lower potential for fossilization.

History of study

The discipline of micropaleontology was founded by Christian Gottfried Ehrenberg (1795–1876), a German microscopist who was the first person to systematically describe microfossils (including diatoms, dinoflagellates,

foraminifera, radiolarians, and silicoflagellates) publishing nearly 400 scientific papers on fossil and recent microorganisms during his career (Tanimura et al., 2009). Other prominent early workers in the field of marine micropaleontology include Ernst Heinrich Haeckel (1834–1919), a pioneering radiolarian worker and creator of the famous illustrative work "Art Forms in Nature" (see Tanimura et al., 2009), and Georges Deflandre (1897–1973), whose remarkably rich publication record includes papers on nearly every known microfossil group (Evitt, 1975).

Early marine micropaleontologists tended to have a descriptive, taxonomic approach to their study. However, with the realization that fossils have great utility in constraining the relative age of sediments came an increased awareness of possible microfossil applications in biostratigraphy, paleoceanography, geochemistry, and even nanotechnology (e.g., Gebeshuber and Crawford, 2006).

The study of microfossils shifted from the occupation of a narrow group of scholars into one of the basic

disciplines of modern Earth science with the inception of the hugely successful international deep ocean drilling collaborations which began in the 1960s. The Deep Sea Drilling Project (DSDP, 1968–1983) and its successors, the Ocean Drilling Program (ODP, 1985–2003), Integrated Ocean Drilling Program (IODP, 2003–2013), and now the International Ocean Discovery Program (IODP, 2013–present), have collectively recovered thousands of kilometers of sediment cores from the world's oceans (("Ocean Drilling" by Kiyoshi, this volume) see

www.deepseadrilling.org, www.odplegacy.org, www.iodp.org). These sediments have provided a vital resource for geologists to understand the distribution of marine microfossils through geological time and to use the remains of marine microbiota to answer profound questions about Earth's past.

Summary of methods

The study of marine microfossils, termed marine micropaleontology, requires a well-equipped laboratory to safely handle the acids and bases used to dissolve large quantities of rock. Some means of particle concentration (microsieves, heavy liquids, centrifuges) are also desirable. Most of all, however, either a light microscope (LM) or a strong binocular scope is essential. Since the optical resolution of both these instruments is limited, marine microfossils are commonly examined by scanning electron microscope (SEM), transmission electron microscope (TEM), or other sophisticated microscopy techniques including computed tomography (CT) scanning and synchrotron analysis that permit 3D internal and external reconstruction of fossils (Cunningham et al., 2014; Schmidt et al., 2013).

Distribution patterns

The occurrence of marine microfossils in sediments is largely dependent on the distribution of living populations and taphonomic factors. The distribution of marine microbiota may be controlled by the availability of nutrients, sunlight, water temperature, oxygen, and other factors. Following the death of a microorganism, a complex series of processes is initiated that may eventually allow its incorporation into sediment. For instance, after the death of a planktic diatom cell (Figure 3), the skeleton (termed "frustule") settles through the water column toward the seabed. Since marine waters are commonly undersaturated with respect to silica (e.g., Tappan, 1980), diatom frustules often dissolve in transit through the water column, and thus only a fraction of those produced reach the deep ocean. Of those diatom frustules that avoid dissolution during settling, a large portion dissolves at the water-sediment interface (see summary in Witkowski et al., 2012). Thus, only a minor fraction of a planktic diatom assemblage is incorporated into marine sediments (e.g., Zielinski and Gersonde, 1997).

Calcareous microfossils (Figure 1) in particular can undergo dissolution at various depths in the ocean. The carbonate compensation depth (CCD) is an important threshold within the ocean where the arrival of carbonate particles such as calcareous microorganism is balanced by dissolution; in practical terms, calcium carbonate is not deposited and/or preserved in large abundances below the CCD, at ~4.6 km in modern oceans (Pälike et al., 2012). Thus, modern benthic calcareous microbiota such as foraminifers cannot dwell in the deep ocean below ~4.6 km, and planktic calcareous microorganisms that inhabit surface waters will not be incorporated into deep-sea sediments deposited below the CCD.

As organic-walled microfossils (Figure 4) are predominantly of clay-silt particle size range, their assemblages are subject to modification by winnowing during sinking and transport by bottom currents. While one of the benefits of organic-walled microfossils is that they are not prone to dissolution, they can be affected by oxidation. The composition of the skeletal wall of organic-walled microfossils is now known to differ markedly, even down to intra-generic level within such biological groups as the dinoflagellates (Bogus et al., 2012). This can have a significant effect on the resistance of the skeleton to oxidation, with most peridinioids being relatively more volatile and the gonyaulacoids more refractory (e.g., Bogus et al., 2014). Thus, exposure to oxygenated water masses during sinking, and/or long residence times at the sediment-water interface where sedimentation rates are low, will bias the composition of an organic-walled microfossil assemblage recovered from a sediment sample (e.g., Zonneveld et al., 1997, 2001).

The interplay between the factors described above controls the distribution of marine microbiota in sediments and the fate of microfossils that underlies the zonal distribution of pelagic sediments in the oceans ("Deep-sea Sediments" by Lyle, this volume). Generally speaking, wherever the terrigenous sediment input is low and nutrient supply high enough to sustain planktic microbiota in ocean surface waters, biogenic pelagic sediments will form on the seabed. At low latitudes, sediments are dominated by calcareous microfossils, predominantly foraminifera (forming the so-called Globigerina ooze that blankets much of the seafloor) and calcareous nannofossils, but potentially also the highly dissolution-susceptible pteropods (a group of tiny aragonitic mollusks) at shallow sites. Siliceous microfossils generally prevail in sediments deposited at high latitudes and elsewhere in regions of enhanced upwelling. This does not mean that diatoms or radiolarians do not occur in low-latitude pelagic sediments but rather that they are diluted by the more abundant calcareous taxa favored in warmer waters. Further, high alkalinity of carbonate-rich sediments ultimately boosts silica dissolution. On the other hand, cooler waters of high-latitude seas are more favorable for silica precipitation, which is why pelagic sediments in the Southern Ocean are impoverished in calcareous microfossils. In locations where the abundance and preservation of mineralized microfossils are depleted for these reasons, organic-walled forms such as acritarchs and dinoflagellates may well be the main groups of marine microfossils preserved in the sediment record and thus available for study in sediments deposited in high-latitude seas (e.g., Eldrett et al., 2004). These patterns are one of the main drivers of microfossil paleobiogeography through Earth history.

Marine microfossils through geological time

Earth's fossil microbiota spans some ~3.2 billion years (gyr) (Javaux et al., 2010) or longer – see the controversy

surrounding the purported "microfossils" in the ~3.5 gyr Apex Chert (e.g., Schopf, 1993; Marshall et al., 2011). The acritarchs, an important microfossil group of uncertain and perhaps polyphyletic systematic position, first occur in rocks from the Meso-/Neoproterozoic transition (Knoll et al., 2006) and are the earliest age-diagnostic microfossils, used for correlation in upper Proterozoic and lower Paleozoic sediments (Mendelson, 1993).

Radiolarians and foraminifera (Figures 1 and 2), both extant groups, are known from the Cambrian onward (Casey, 1993; Boersma, 1998) and are important biostratigraphic indicators. For instance, the fusulinid and schwagerinid benthic foraminifera commonly grew to large sizes and underwent a particularly rapid evolution during the Carboniferous and Permian, which makes them useful zonal markers for the younger Paleozoic (Davydov et al., 2012; Henderson et al., 2012). However, the toothlike conodonts, which range from Cambrian through Triassic and are believed by many to represent the feeding apparatus of early chordates (Donoghue et al., 2000), provide the primary means of global age correlation of Paleozoic strata. Simple vaselike chitinozoa, which are presumed to represent an ontogenic stage (i.e., eggs) in the life cycle of a cryptic animal group (Paris and Nolvak, 1999), first appeared in the Ordovician, with morphologically more complex forms evolving through the Paleozoic before the extinction of the group in the late Devonian (Grahn and Paris, 2010). Scolecodonts – fossil worm jaws – are a minor group which occur from the Paleozoic onward but are of little biostratigraphic use despite being found most commonly in lower Paleozoic rocks. Another biostratigraphically important microfossil lineage in Paleozoic and younger marine sediments is the ostracods, first identified in the Ordovician. Both the end-Permian and Triassic brought about major turnovers in oceanic microbiota which led to the development of three prominent phytoplankton groups during the Mesozoic, calcareous nannoplankton, dinoflagellates (Figure 4), and diatoms (Figure 3) (Falkowski et al., 2004), and the rise of the zooplankton – planktic foraminifera (Hart et al., 2003). Although not as significant in today's oceans, other microfossil groups that appeared later in the Mesozoic include silicoflagellates (McCartney et al., 2014) and ebridians (Hoppenrath and Leander, 2006).

Microfossils in biostratigraphy

Microfossils can occur in marine sediments in large abundances (yielding up to several billion individuals per gram of dry mass, e.g., Davies et al., 2009) and have widespread distributions and relatively rapid evolutionary rates making them ideal targets for dividing up geological time and correlating spatially disparate sediments. The advent of deep-sea drilling in recent decades allowed microfossils rather than macrofossils to form the basis for age determination in marine sedimentary sequences. However, since most chronostratigraphic units were defined based on onshore exposures where microfossils are absent or sparse (Bolli et al., 1985), one of the major challenges of modern

micropaleontology has been to tie emerging microfossil biostratigraphic zonations to the evolving chronostratigraphic framework (e.g., Cande and Kent, 1995; Gradstein et al., 2012). For planktic foraminifera and calcareous nannofossils, most bioevents are now tied directly to the geomagnetic polarity time scale (GPTS; Berggren et al., 1995; Wade et al., 2011), and many dinoflagellate bioevents are also so calibrated (e.g., Eldrett et al., 2004; Brinkhuis et al., 2003). However, in the longer term the aim is to fully calibrate microfossil-based data to the astronomical time scale, which provides the potential for much higher temporal resolution than that based on magnetics (e.g., Wade et al., 2011).

Here we focus on two examples from the Cenozoic to illustrate how calcareous and siliceous microfossils are used as zonal markers in low- and high-latitude sites.

Low-latitude Eocene zonation (56.0–33.9 million years ago)

Planktic foraminiferal and calcareous nannofossil biostratigraphy provide the basis for age control in most low-latitude Cenozoic marine sediments. There are currently 16 planktic foraminiferal biostratigraphic zones recognized in Eocene low-latitude deep-sea sediments, prefixed "E" by Berggren and Pearson (2005) (Figure 5). Magnetochronologic calibration is available for all of these zones, and the five uppermost zones are also astronomically calibrated (Wade et al., 2011). Low-latitude siliceous microfossil schemes are considerably less advanced than those based on calcareous and other microfossils largely due to a preservational bias acting against siliceous microfossils at low latitudes. However, the Eocene contains 13 radiolarian zones that are tied directly to the GPTS (Nigrini et al., 2005). In contrast, diatom biozones are typically only indirectly calibrated to the GPTS via correlation to planktic foraminifer, calcareous nannofossil, and/or radiolarian zones. Recently, Barron et al. (2015) have provided considerable amendments to the preexisting low-latitude diatom zonation scheme of Fenner (1984, 1985), and 13 zones are identified. But some diatom data remain uncertain, and no information is currently available to evaluate diachrony of key marker species, such as with foraminifera (e.g., Edgar et al., 2010) (Figure 5).

High-latitude zonation for the neogene

Siliceous microfossils offer better age control than their calcareous counterparts in high-latitude marine records, particularly in the Southern and equatorial Pacific Oceans which are characterized by widespread deposition of silica-rich sediments (Ragueneau et al., 2000) throughout the Cenozoic, enabling the development of detailed zonal schemes based on diatom bioevents (e.g., Harwood and Maruyama, 1992; Censarek and Gersonde, 2002; Kamikuri et al., 2012; Moore et al., 2015). Using data from 32 Neogene deep-sea sites in the Southern Ocean, Cody et al. (2008) compiled a computer-aided quantitative synthesis of 116 diatom first and last occurrences relative
Marine Microfossils, Figure 5 Comparison of Eocene foraminifer- and diatom-based biostratigraphic zonations presented versus the 2012 geological time scale (Gradstein et al., 2012, GTS 2012) and chronostratigraphic and magnetostratigraphic divisions (modified from Barron et al. (2015), using data from Wade et al. (2011) and Barron et al. (2015)).

to magnetostratigraphy and radiometrically dated volcanic ash horizons. The outcome is an improved temporal resolution of the Antarctic diatom biostratigraphy, on the order of ~100,000 years, a resolution inconceivable for the diatoms in the Paleogene low latitudes.

Paleoenvironmental utility of microfossils

Marine microfossils are one of the main tools used to reconstruct Earth's past climate and oceans. This can be achieved in various ways, ranging from simple observations of changes in taxonomic composition or the absolute abundance of microfossil assemblages to infer qualitative environmental changes to more quantitative transfer

function approaches or chemical analyses. Below are several notable examples from the recent literature.

Elemental composition and stable isotope records

Currently, one of the major applications of microfossils is to utilize the chemical composition of body fossils to reconstruct various paleoceanographic parameters, e.g., temperature, salinity, etc., and/or the paleoecology of the organisms themselves. $\delta^{13}C$ and $\delta^{18}O$ values are routinely measured in marine carbonates: either from foraminiferal tests (typically from selected specimens of a single species) or from bulk sediment. The $\delta^{13}C$ of carbonates is a function of the $\delta^{13}C$ of dissolved inorganic carbon in seawater and reflects changes in the carbon cycle, e.g., biological pump strength or removal of isotopically light carbon from the ocean-atmosphere system by enhanced organic carbon burial. $\delta^{18}O$ fluctuations can be interpreted in terms of changes in salinity, seawater temperature, or continental ice sheet volume. Long-term compilations of foraminiferal stable isotope records (e.g., Zachos et al., 2001, 2008; Cramer et al., 2009) are standard references for paleoceanographic studies of Cenozoic sedimentary successions. For instance, time series of Mg/Ca ratios can be used in paleothermometry; a recent example is a study by Bohaty et al. (2012), who generated Mg/Ca ratios in conjunction with $\delta^{18}O$ records to deconvolve the relative contribution of ocean cooling and ice growth across the Eocene-Oligocene transition and constrain the timing of the inception of Antarctic ice sheets.

Siliceous microfossils are typically less widely utilized in geochemical studies, but in recent years, a suite of new silica-based proxies have become available for reconstructing past paleoceanographic conditions. Two notable developments are diatom $\delta^{18}O$, typically generated from young, high-latitude sediments that are commonly characterized by pristine diatom preservation (e.g., Swann and Leng, 2009), and $\delta^{30}Si$, which can be generated from diatom valves, radiolarian tests, or sponge spicules (Egan et al., 2012) and provides insight on silicic acid utilization, and data from various levels in the water column, e.g., from sponges and diatoms, can be used to interpret productivity variations (Egan et al., 2013).

Paleoproductivity estimates

Photoautotrophic microfossil groups, e.g., dinoflagellates and diatoms, are well suited to reconstructing paleoproductivity provided that no significant diagenetic alteration of assemblages has taken place in sediments. Aside from being used as salinity and oxygenation indices and for determining onshore-offshore trends (e.g., Sluijs et al., 2005), organic-walled microfossils such as dinoflagellates can also provide a more useful productivity measure in neritic environments where a major portion of modern marine primary productivity originates. For instance, the peridinioid/gonyaulacoid ratio (P/G ratio, the proportion of cyst species produced by photoautotrophic versus heterotrophic dinoflagellates), has been used

to reconstruct relative nutrient availability fluctuations across past abrupt global climatic events (see Sluijs et al., 2005; Bijl et al., 2010). Principal component analysis of dinocyst distributions in the Oligocene has also been used to relate productivity changes to the structure of the water column (stratification), eutrophication, and oxygen depletion (e.g., Pross and Schmiedl, 2002). Fluctuations of biogenic silica content in sediment, usually measured spectrophotometrically (e.g., Iwasaki et al., 2014), are also used as a paleoproductivity proxy and comprise photoautotrophic diatoms and silicoflagellates and heterotrophic radiolarians and ebridians that feed on primary producers. Variations in diatom accumulation rates can be indicative of periods of elevated diatom production and flux (e.g., Witkowski et al., 2014). Owing to their unique life cycle characteristics, including resting spore formation in some planktic taxa, diatoms offer a number of ways to infer past variations in nutrient availability. For instance, Davies et al. (2009), based on laminated high-latitude late Cretaceous sediments including alternating resting spore and vegetative valve laminae, have successfully reconstructed seasonal fluctuations in diatom production and flux, thus testifying to ice-free summer conditions in the late Mesozoic Arctic.

Conclusions

Although the study of marine microfossils has so many facets, covering some two thirds of Earth's history and so many systematic groups, its main value is in the applied aspects, particularly in biostratigraphy and paleoceanography. The benefits of marine microfossils have been fully appreciated only recently, but scientific interest in them is certain to continue for many decades to come.

Synonyms

Seabed mineral resources

Definition

Marine mineral resources are accumulations of minerals that form at or below the seabed and from which metals, minerals, elements, or aggregate might be extracted as a resource. They are distinguished from energy resources such as oil, gas, or gas hydrates and living resources such as fish, although many of the metals potentially available are essential for green-energy applications.

Introduction

Earth provides natural resources including minerals and metals that are vital for human life. At present almost all of these resources are mined on land with large high-grade deposits becoming more and more difficult to find, driving industry to lower-grade sites where mining has greater environmental impacts or to greater depth. At the same time, the global demand for metals is suspected to rise further due to steady population growth, expected to reach 9 billion by the year 2050 (United Nations, 2014), and strong economic growth of countries such as China and India. The population growth may cause increasing land-use conflicts between the mining industry and the need to feed and house the growing population. In addition to the rising demand for metals, geopolitical issues can also limit the availability of metal resources. This was evident over the past years with China blocking export of "rare earth elements" from global markets awakening the media and policy. There is therefore a foreseeable risk of increasing resource supply shortages for metals that are important to the economy (DOE, 2011; European Commission, 2014). Hence, a number of countries are looking for ways to ensure secure supplies of these critical metals. In this rapidly changing global economic landscape, mining in the deep sea is one of the areas of interest not only for commercial entities but also for governments.

Legal aspects

Marine mineral resources fall under two different legal regimes depending on their location: they either occur within the legal boundaries of national jurisdiction or occur in areas beyond national jurisdictions. In terms of international law, the legal framework for deep-sea mining of mineral resources is set out in the United Nations Convention on the Law of the Sea (UNCLOS) as modified by the Part XI Implementation Agreement. UNCLOS distinguishes between "maritime zones" under the jurisdiction of coastal states (internal and archipelagic waters, territorial sea, exclusive economic zone, and continental shelf) and "areas beyond national jurisdiction," namely, international waters and the seabed beyond the continental shelves of coastal states (called *The Area* in Part XI of UNCLOS). Since it went into effect in 1994, this treaty has formed the basis for the use of marine raw materials from the seabed beyond the limits of national jurisdiction. As of March 2015, UNCLOS has been signed by 166 countries and the European Union.

With regards to marine mineral resources in areas under national jurisdiction, the coastal states have regulatory jurisdiction and can design and adopt their own legislation. The outer limit of the national jurisdiction is defined by the 200 nautical mile exclusive economic zone (EEZ), but individual states can apply to the Commission on the Limits of the Continental Shelf (CLCS) for an extension for up to 350 nautical miles or even beyond that if certain geological conditions are met (extended continental shelf as a juridical term not as a geological term).

All rights to prospect (search without exclusive rights), exploration (search with exclusive rights), and deep-sea mining of mineral resources in The Area are managed and promoted by the International Seabed Authority (ISA) that was established in Kingston (Jamaica) in 1994 based on UNCLOS. The regulatory regime for mineral resources of the deep sea is not complete. Regulations on prospecting and exploration in The Area have been adopted for manganese nodules, Co-rich ferromanganese crusts, and seafloor massive sulfides (SMS) (ISA, 2013a). The regulations for deep-sea mining

(exploitation) of manganese nodules are currently being developed (ISA, 2013b).

The seabed: a source of raw materials for humankind?

The seabed is already an important source of commodities for humankind. Sand and gravel as well as oil and gas have been mined from the sea for decades. Moreover, the so-called placer deposits of diamonds have been extracted off the coast of South Africa and Namibia for a long time in addition to deposits of tin, titanium, and gold along the coasts of Africa, Asia, and Australia (Cronan, 1992, 2000; Rona, 2003, 2008). These placer deposits are accumulations of minerals with a high density and chemical resistance to weathering that form along beaches by gravity settling due to wave or current movement.

Obtaining raw materials from the sea is therefore not a new practice. Interest is also growing with respect to *phosphorite* occurrences with projects being considered within the EEZ of New Zealand, Mexico, Namibia, and the USA. Marine phosphorites are sedimentary rocks that contain high concentrations of phosphate and form along continental margins with oceanic upwelling (Burnett and Riggs, 1990).

Raw materials are not confined to shallow water. Potential mineral resources from the deep sea currently investigated are *manganese nodules*, *cobalt-rich manganese crusts*, as well as *massive sulfides* (SPC, 2013; Hein et al., 2013; Fouquet and Lacroix, 2014). Details of the formation, characteristics, and resource potential of all these commodities can be found in the respective entries of this encyclopedia. The raw materials from the deep sea are commonly described as renewable resources. This is misleading since, for instance, the metals in manganese nodules and cobalt-rich ferromanganese crusts take millions of years to accumulate. Even the considerably faster growing SMS take thousands of years to accumulate to economically interesting amounts.

SMS, also known as black smoker deposits, are occurrences of metal-bearing minerals that form on and below the seabed as a consequence of the interaction of seawater with a heat source (magma) in the sub-seafloor region of volcanically active oceanic spreading centers and along volcanic arcs (Hannington et al., 2005). These occurrences are commonly associated with "oasis of life" harboring chemosynthetic faunal communities. By far the majority of SMS occurrences presently known are small, 3-dimensional bodies that can contain metals such as copper, zinc, gold, and silver. Other trace elements that are important for a variety of industry uses (Bi, Ga, Ge, In, Te) can be enriched at certain sites and are commonly considered as possible important by-products. Known SMS deposits at the seafloor rarely exceed a few million tonnes of metal (Hannington et al., 2011) with the exception of the metalliferous muds in the Atlantis II Deep of the Red Sea, which formed under different conditions and was estimated to contain 90+ million tonnes of ore (Nawab,

1984). New technologies to explore for inactive sites away from the ridge axis are being developed in order to investigate the full ocean potential for sulfides (Cathles, 2011; Hannington, 2011). As a result, there is considerable interest in exploration both within the EEZ of coastal states and The Area (see below, ECORYS, 2014). The technology for mining these deposits is currently being built, and first deep-sea tests were performed by the Japanese in their coastal waters (Masuda et al., 2014). The Canadian company *Nautilus Minerals* is constructing deep-sea SMS collectors for its Solwara 1 deposit in the territorial waters of Papua New Guinea. This site could become the first deep-sea mine site for SMS, as a mining license was issued by the PNG government in 2011. Current planning foresees the start of mining operations in 2018.

Manganese nodules occur widely on the vast, sediment-covered abyssal plains at depths of about 4,000–6,500 m. They are mineral concretions made up largely of manganese and iron that form around a hard nucleus and incorporate metals from the sediment and seawater. As manganese nodules form directly on the seafloor, these deposits can be regarded as a 2-dimensional resource. The greatest concentrations of metal-rich nodules occur in the Clarion-Clipperton Zone (CCZ; Hein and Koschinsky, 2014), which extends from Hawaii to Mexico. Nodules are also concentrated in the Peru Basin, near the Cook Islands, and at abyssal depths in the Indian and Atlantic Oceans. Manganese and iron are the principal metals in polymetallic nodules, but the metals of greatest economic interest are nickel, copper, and cobalt that combined can reach between 2.5 and 3 wt% (Hein and Koschinsky, 2014). In addition, there are enrichments of other valuable metals, such as molybdenum, vanadium, titanium, the rare earth elements (REE), and lithium, that have industrial importance in many high-tech and green-tech applications and can possibly be recovered as by-products once appropriate processing techniques are developed. The geochemistry of manganese nodules varies from ocean to ocean, and details are given in the respective entry of this encyclopedia.

Manganese nodules were explored intensely in the 1970s and 1980s mainly for their potential use as a copper resource. An estimate of the in situ value of these metals, published in 1962 by Mero, initiated a "gold rush" mentality that resulted in national exploration programs by numerous countries. At the same time, this "gold rush" was also responsible for setting the stage for international regulations culminating in the development of the United Nations Convention on the Law of the Sea (UNCLOS). During this first period of activities, several hundred tonnes of manganese nodules were collected from the seafloor during several hours of operation showing that mining is, in principle, possible and relatively easy. However, the step from a few hours of operation to reliable mining during 250–300 days a year is challenging.

Cobalt-rich ferromanganese crusts form on nearly all rock surfaces in the ocean that are free of sediment and are composed of manganese oxides and iron

oxyhydroxides that precipitate directly from seawater. Their thickness varies from less than 1 mm to about 20 cm. They form at water depths of 600–7,000 m on the flanks of volcanic seamounts, ridges, and plateaus with the thickest and most metal-rich crusts forming in depths between 800 and 2,500 m (Hein et al., 2010). Due to their slow growth rate of only 1–5 mm/million years (Hein and Koschinsky, 2014), economic occurrences are limited to old volcanic edifices. Many of these volcanic seamounts are located within the EEZs of Pacific Island states with fewer seamounts, and hence crusts, in the Atlantic and Indian Ocean. Crusts have, in general, lower copper and nickel concentrations than manganese nodules, and therefore, cobalt is the metal of greatest economic interest commonly exceeding values of 0.5 wt% cobalt. Other potential by-products are the rare earth elements (REE), platinum group elements, and tellurium (Te). Mining of crusts seems technologically more difficult as crusts are attached to a substrate rock, and dilution of the crusts by the substrate needs to be minimized. On the other hand, dispersion of sediments may not be a major issue of crust mining due to the lack of sediments (see below). Technology for crust mining is still in a conceptual state (Hein and Koschinsky, 2014).

Environmental concerns of deep-sea mining

To date no commercial mining activities have occurred anywhere in the deep sea limiting a full assessment of environmental impacts (Boschen et al., 2013). Nevertheless, some of the main impacts seem clear and are bound to the disaggregation of the ore at the mine site, the lifting to the surface vessel, and the dewatering of the ore slurry, which may lead to (1) loss of habitat (possibly with species extinction), (2) the formation of plumes and resedimentation, and (3) return water (discharge) and its effects on pelagic and/or benthic fauna depending on the depth of discharge (van Dover, 2010, 2011; Collins et al., 2013). Pollution from ships, noise from surface or seabed vehicles, and tailings disposal on land that accompanies the processing of all ores may also have negative impacts on the environment.

It is important to note that the impacts will be different for the various mineral types. While some ecosystems may recover quickly (SMS sites), those in the abyssal plains may take thousands of years or more to recover to the original species richness and distribution. The potential impacts of manganese nodule mining have been investigated on various scales by studies such as the DOMES, BIE, INDEX, DISCOL, and ATESEPP projects (see Hein and Koschinsky, 2014 and references therein). During the DISCOL study, an area of 11 km² was disturbed and monitored, the largest impacted area so far (Borowski and Thiel, 1998; Thiel et al., 2001). For SMS, the most comprehensive study of potential mining impacts is reported by the environmental impact assessment of Nautilus Minerals for its Solwara 1 deposit (see www.cares.nautilus-minerals.com). As deep-sea mining is not yet occurring,

the process of defining the regulations for mining by the ISA (Pandey, 2013; ISA, 2013b; Lodge et al., 2014) provides the opportunity for nongovernment organizations and scientists to contribute input that helps shape the regulations beyond the codes of conducts that have been issued by scientists in the past (Devey et al. 2007; IMMS, 2011). Comprehensive environmental impact assessment, mitigation strategies, baseline studies, and long-term monitoring need to be implemented into the regulations. Naturally, the duration of the impact and the size of the impacted area are of great influence. While mining for manganese nodules would cover several hundreds of square kilometers per year and for Co-rich ferromanganese crusts several tens of square kilometers per year for a single mine site, future mining in the Solwara 1 SMS project in Papua New Guinea would cover an area of only 0.112 km².

Ongoing exploration activities

For The Area, only exploration contracts have been issued by the ISA (Table 1; Figure 1). Up until March 2015, 26 applications have been approved out of which:

- Sixteen contracts for the exploration of polymetallic nodules, 14 are signed and 2 are pending signature (Table 1). Most of the contract areas (15) are located in the Clarion-Clipperton Zone covering 1.171 million km² and only one in the Central Indian Ocean (77,000 km²). Of the 16 contractors, 8 are government bodies, while the remaining 8 are private companies sponsored by states. It is interesting to note that until 2011 only government bodies applied for exploration contracts in The Area.
- Six exploration contracts, covering 10,000 km² each, have been approved for the investigation of SMS in The Area since 2011. All six contractors are government bodies and represent the states of China, Russia, South Korea, France, India, and Germany. Four of the contracts are for the Indian Ocean, the remaining two for the central Atlantic. The contract for India still needs to be signed.
- Four contracted areas for the exploration of cobalt-rich manganese crusts, covering 3,000 km² each, have been approved for government entities, signed by China, Japan, Russia and Brazil. The Brazilian application is in the Atlantic (Rio Grande Rise), while the other three contract areas are located in the far Western Pacific.

These 26 approved contracts in The Area cover an area of 1.24 million km². This is as big as France, Great Britain, and Germany combined. It should be noted that all contracts are exploration licenses, granted for a period of 15 years, and are subject to relinquishments over time. Regulations for deep-sea mining have not been released, despite the fact that the 6 earliest contracts for manganese nodules will expire in 2016. At this time, the contractors have to decide whether they want to start mining or extend the exploration contract for another 5 years if justifications warrant that extension.

Marine Mineral Resources, Table 1 Status of contracts with the International Seabed Authority

Contractor	Sponsoring state	Location	Size (km^2)	Date of entry into force	Expiry date

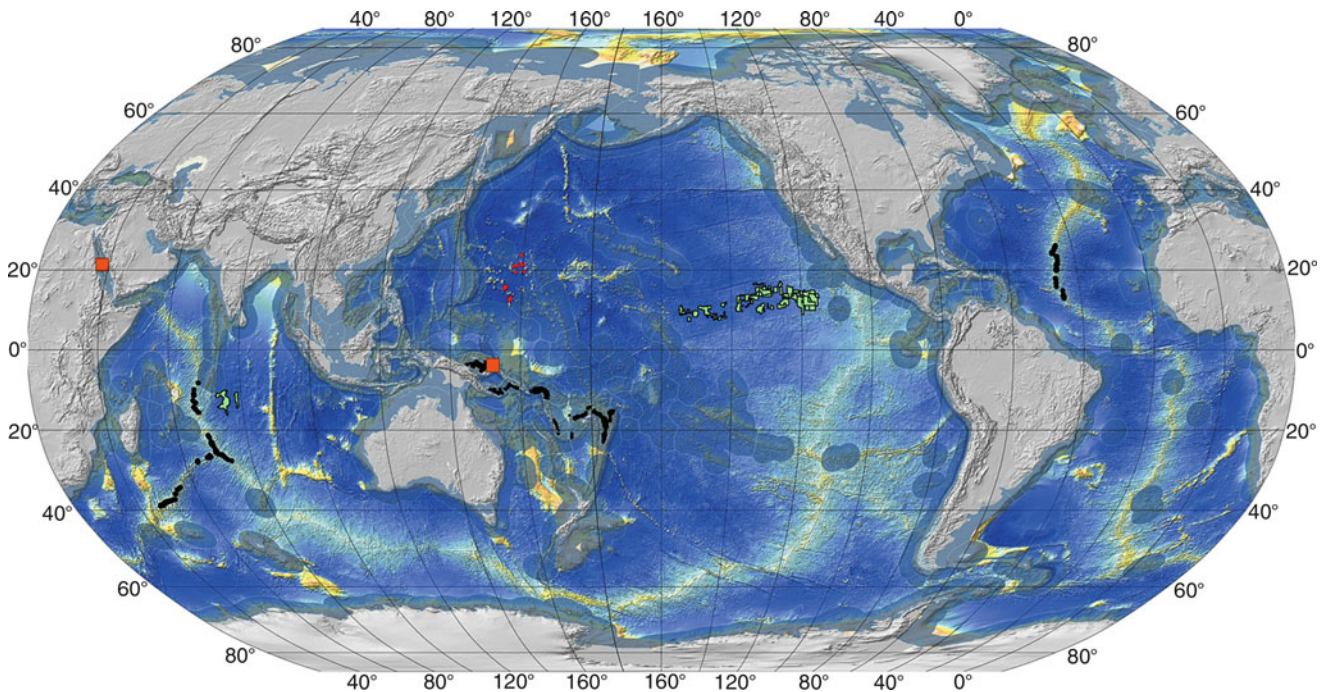
Another application for exploration work on manganese nodules in the Clarion-Clipperton Zone has been received by the ISA from China Minmetals Corporation (sponsored by China) in 2014 and will be handled during its annual session in July 2015.

Exploration activities in the EEZ of coastal states for mineral resources in shallow water are numerous (e.g., dredging operations for sand and gravel but also for placer deposits). Few large projects for phosphorites are under consideration (see entry "Phosphorites"). For the deep sea, the number of contracts can only be estimated since many countries do not make their contracts public. Nautilus Minerals and Neptune Minerals are the two companies for which some information can be


Marine Mineral Resources, Figure 1 Exploration and mining activities for deep-sea resources. Exploration contract areas for manganese nodules (*green*), Co-rich manganese crusts (*red*), and seafloor massive sulfides (*black* in The Area and *brown* within the EEZ of coastal states) are distinguished. Also shown by *orange squares* are the two mining licenses: the Solwara 1 project in Papua New Guinea and the Atlantis II Deep in the Red Sea.

retrieved. Both have extensive exploration contracts in several countries of the Western Pacific, and applications for Italy, New Zealand, Japan, and Portugal are pending. In a 2013 paper, Hein et al. estimated about 900,000 km^2 for exploration contracts in areas of national jurisdiction.

While there are only exploration licenses in The Area, two deep-sea *mining licenses* have been issued by national governments, both for SMS. The government of Papua New Guinea granted a license to Nautilus Minerals Inc. in 2011 (Solwara 1 project in the Bismarck Sea), and the governments of Saudi Arabia and Sudan granted a 30-year mining license to Diamond Fields International in 2010 for the Atlantis II project in the Red Sea. In both projects mining has not yet started.

There are also some strong national exploration programs, namely, by Korea, France, and Japan, within the EEZ of countries in the Western Pacific (Masuda et al., 2014; Fouquet and Lacroix, 2014). Most Pacific Island states regard deep-sea mining as a potential way to generate revenue and are therefore interested to establish regulations and governance structures (SPC, 2013).

Summary

Marine mineral resources such as sand, gravel, and placer deposits are currently being mined in shallow water (<500 m); however, economic, geopolitical, and strategic considerations make deep-sea mineral resources attractive to investors and governments. In contrast to land-based mining, there is only little or no overburden to remove to expose the mineral resource. Also, due to the higher grade of marine resources compared to land deposits, less ore is needed to provide the same amount of metal. Whether deep-sea mining will become viable in the future depends to a large extent on the ability to develop mining systems capable of efficient, reliable operation in deep-sea environments. Due to their abundance, manganese nodules and Co-rich ferromanganese crusts are clearly vast resources, and their mining would augment global metal supply. Since they are 2-dimensional deposits covering large areas of the seafloor, the environmental impact of mining may also be huge. SMS are likely to be the first mineral resource to be mined (within the EEZ of Papua New Guinea); however, most of these deposits are small, and the economic impact of mining them is likely to be small.

MARINE REGRESSION

Jan Harff
Institute of Marine and Coastal Sciences, University of Szczecin, Szczecin, Poland

Synonyms

Seaward shoreline shift

A marine regression occurs either due to relative sea-level fall (forced regression) or to increased sediment supply during a time when the relative sea-level is stable or even rising causing the shoreline to shift seaward (normal

regression) (Posamentier and Allen, 1999; Catuneanu, 2002). In case of forced regression former seafloor is emerged – converted into land. The relative sea-level change is an effect of eustatic change and/or tectonic/iso-static vertical movement of the Earth's crust (von Bubnoff, 1954; Seibold and Berger, 1993). The opposite of regression is "transgression," which occurs if the relative sea-level rises and former land is submerged. During regression, the emerged seafloor is exposed to erosional processes (truncation) and incision by fluvial systems. Only minor amounts of terrestrial sediments accumulate so that in the geological record, times of regression are marked by sedimentary hiatuses. A marine transgression following the period of sea-level low-stand hiatus leads to a new accumulation of marine sediments covering the erosional surface discontinuously and forming an unconformity. Because of the petrophysical contrast, the unconformities can be traced within seismic recordings as synchronous reflectors (sequence stratigraphy, seismic stratigraphy). Relative sea-level changes bound cycles in the Earth's history (Einsele, 1992) which can be hierarchically ordered on time spans from hundreds of millions years to millennia (Suess et al., 1906; von Bubnoff, 1954; Posamentier et al., 1988; Vail et al., 1991).

Definition

Marine sedimentary basins are any modern basin that is currently below sea-level and influenced by marine sedimentary processes and sedimentation. Many ancient marine sedimentary basins are now deformed and uplifted into modern, mountain chains as part of ongoing or ancient orogenic – or mountain-building – processes.

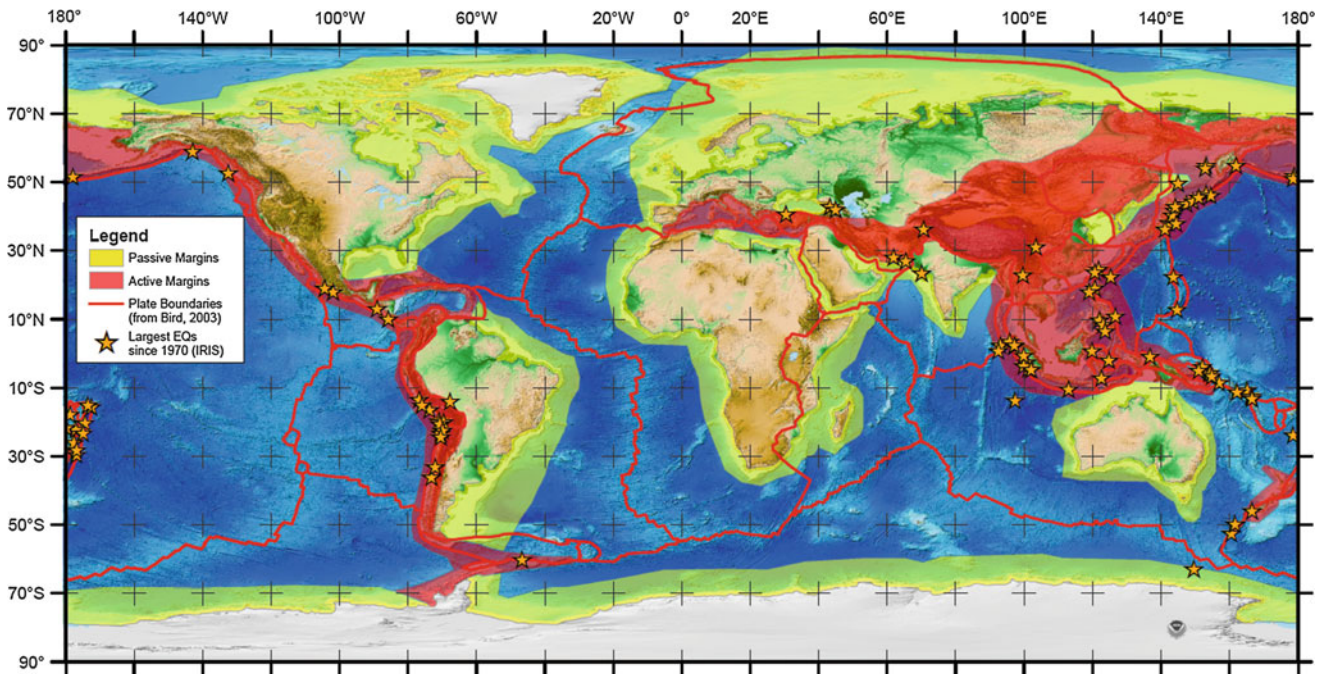
The modern marine sedimentary basins of the world's ocean basins can be subdivided into continental shelves, slopes, rises, abyssal plains, and oceanic trenches in passive margin settings (Figure 1). As these topics have been defined and discussed by other authors of the encyclopedia, I will focus on the origin of the main tectonic classes of marine sedimentary basins in active margin settings that include those produced in rift, collisional, subduction, and strike-slip environments, along with bolide impacts into marine environments (Figure 1).

Actively subsiding environments of modern marine sedimentary basins are commonly found near continent–ocean boundaries and land–sea interfaces, and for that reason, these basins can exhibit rapid alternations between marine and continental depositional systems.

A common sequence of events in the life stages of a basin is to move from initial subsidence with filling by continental sediments to marine incursion as the basin moves below sea-level – often as the consequence of accelerated tectonic subsidence – and back to continental sedimentation as the basin either moves above sea-level as the result of tectonic deformation or eventually fills to capacity as the rate of continental and marine sedimentation exceeds its rate of subsidence.

The examples below illustrate basins near continent–ocean boundaries and near land–sea interfaces that are in the process of sedimentary transitions from nonmarine to marine or vice versa (Figure 1).

Continental and marine rift basins: basins formed by stretching

The East African rift is the archetypal, continuous, and branching continental rift formed by stretching of continental crust extending 4000 km across East Africa (Figure 2a). Extension is linked to the rise of the mantle-derived African superplume that became active in mid-Cenozoic time. GPS results from Saria et al. (2014) show east–west opening of the rifts relative to the African


Marine Sedimentary Basins, Figure 1 Map of passive (*green*) and active (*red*) margins of the world modified from passive margin compilation by Bradley (2008). *Stars* show largest earthquakes since 1970 that are confined to the active plate margins shown with *red shading*.

plate to the west along a twin zone of rifting in East Africa (Figure 2b).

The northern terminus of the rift in the Afar area is locally 155 m below sea-level and influenced by periodic marine incursions that have led to evaporite deposits. As the rift progressively opens, marine incursions will progress further and further to the south along the rift axis and converting the rift from a nonmarine to a marine basin (Figure 2b).

The cross section in A and B from Saria et al. (2014) shows the typical structure of East Africa with either a half-graben structure or a full-graben structure. In inland areas of the African continent, the rift fills are removed from marine influence and remain continental.

Failed rift basins: basins formed by stretching

The West Siberian basin is a large failed rift system formed by rifting during the Permian–Triassic period as the result of a failed breakup of the northern Eurasia continent (Mann et al., 2003). As with many failed rifts, the West Siberian basin forms a multi-branched zone of rifting extending hundreds of kilometers into a continental area where fault-bounded rifts narrow and eventually terminate.

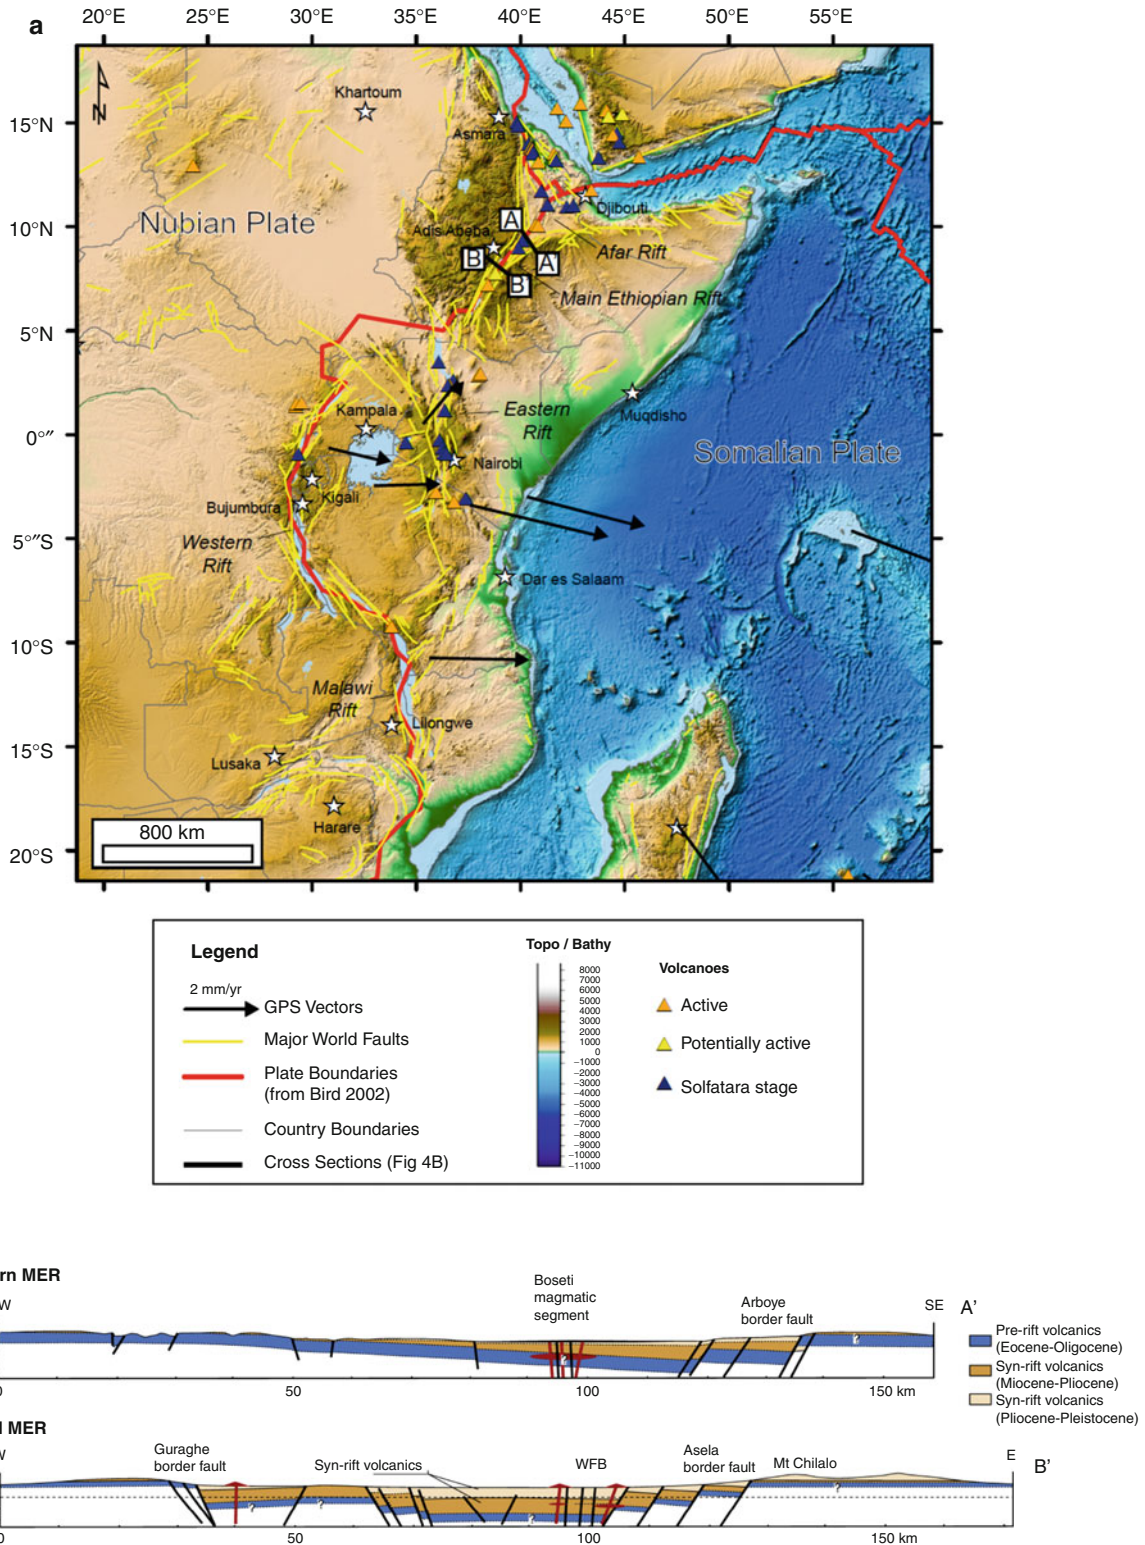
Much of the rifted areas are overlain by a thick and less faulted sag basin filled by marine sedimentary rocks. The thickness of the sag basin is controlled by thermal subsidence that produces a large, bowl-shaped marine sedimentary basin overlying the underlying and elongate, parallel

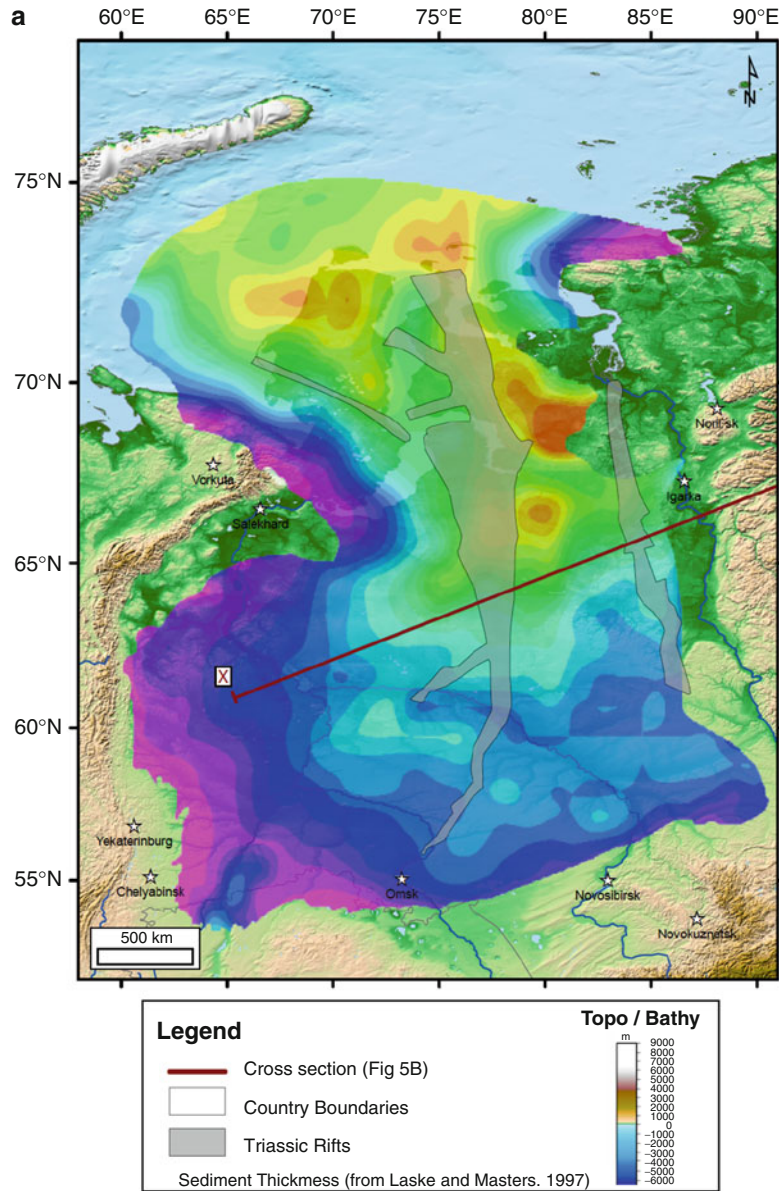
rifts (Figure 3a). The sag basin is relatively symmetrical with respect to the location of the underlying rifts that again reflects its origin by thermal subsidence (Figure 3a).

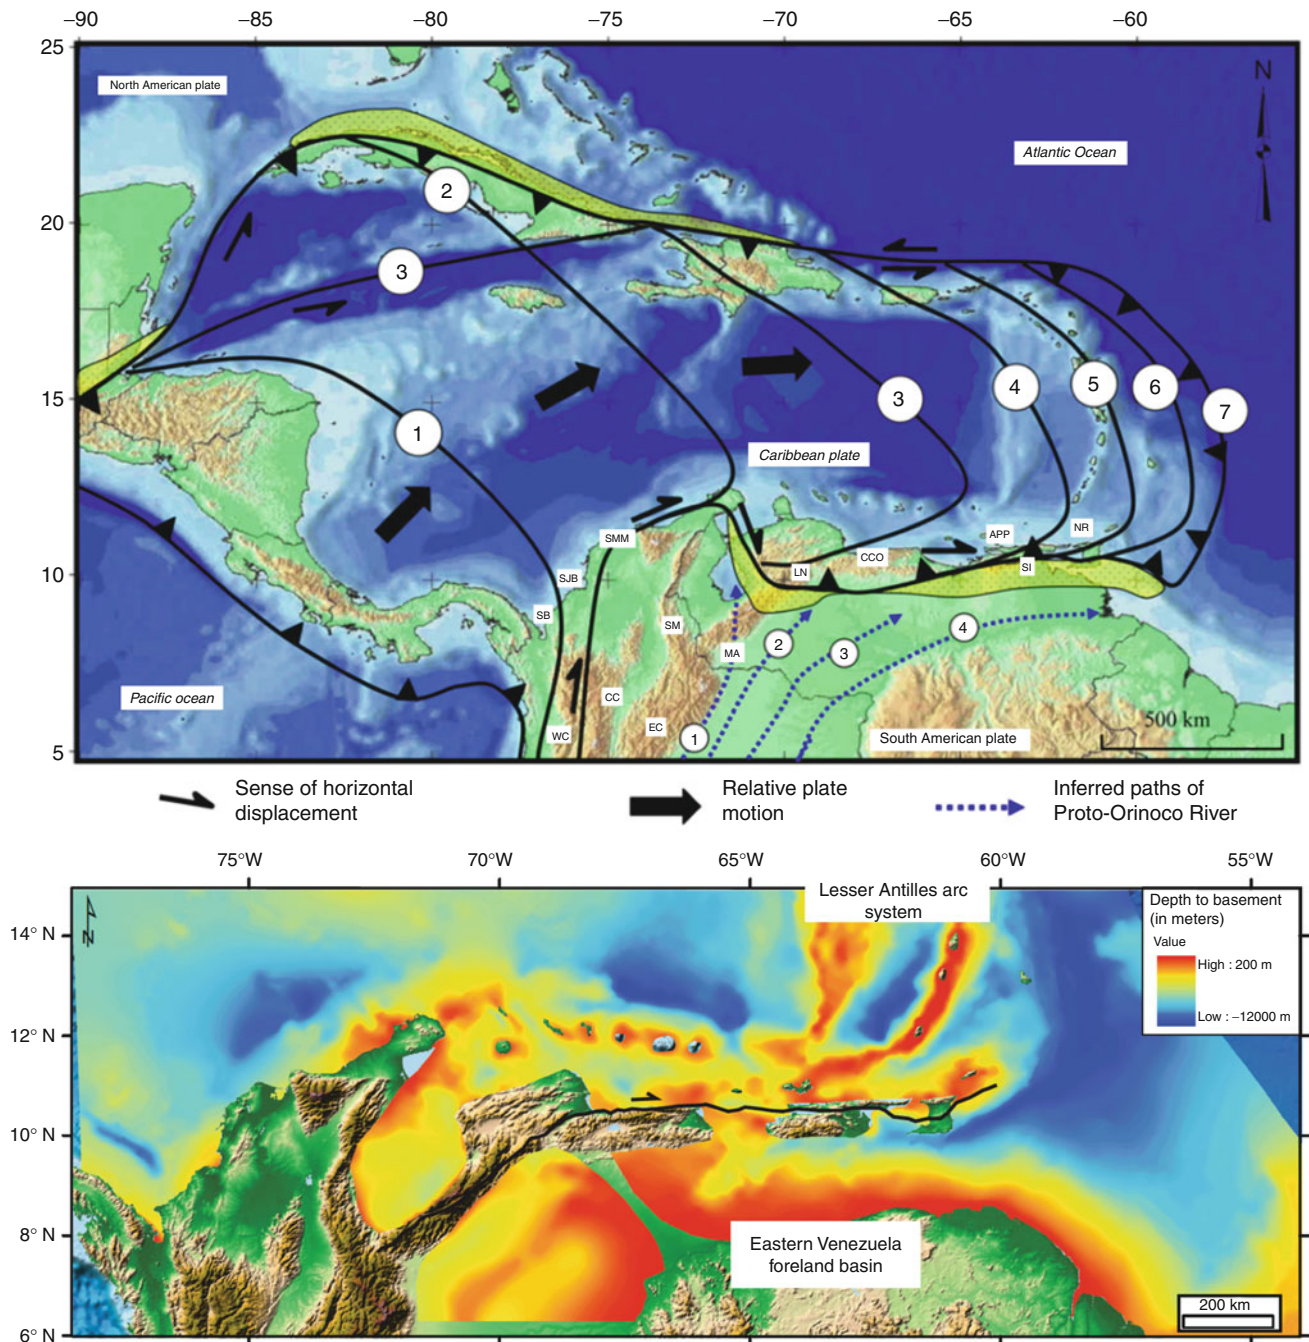
Widespread volcanic rocks related to the lithospheric thinning during the rifting event are present both on the eastern rift flank and underlying the sag basin as shown in the stippled pattern on the cross section in Figure 3b (Reichow et al., 2002).

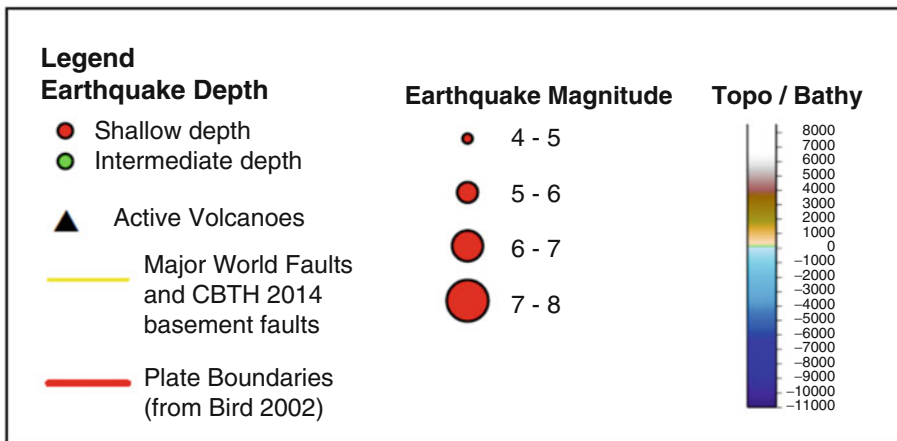
Collision-related basins: basins formed by flexure

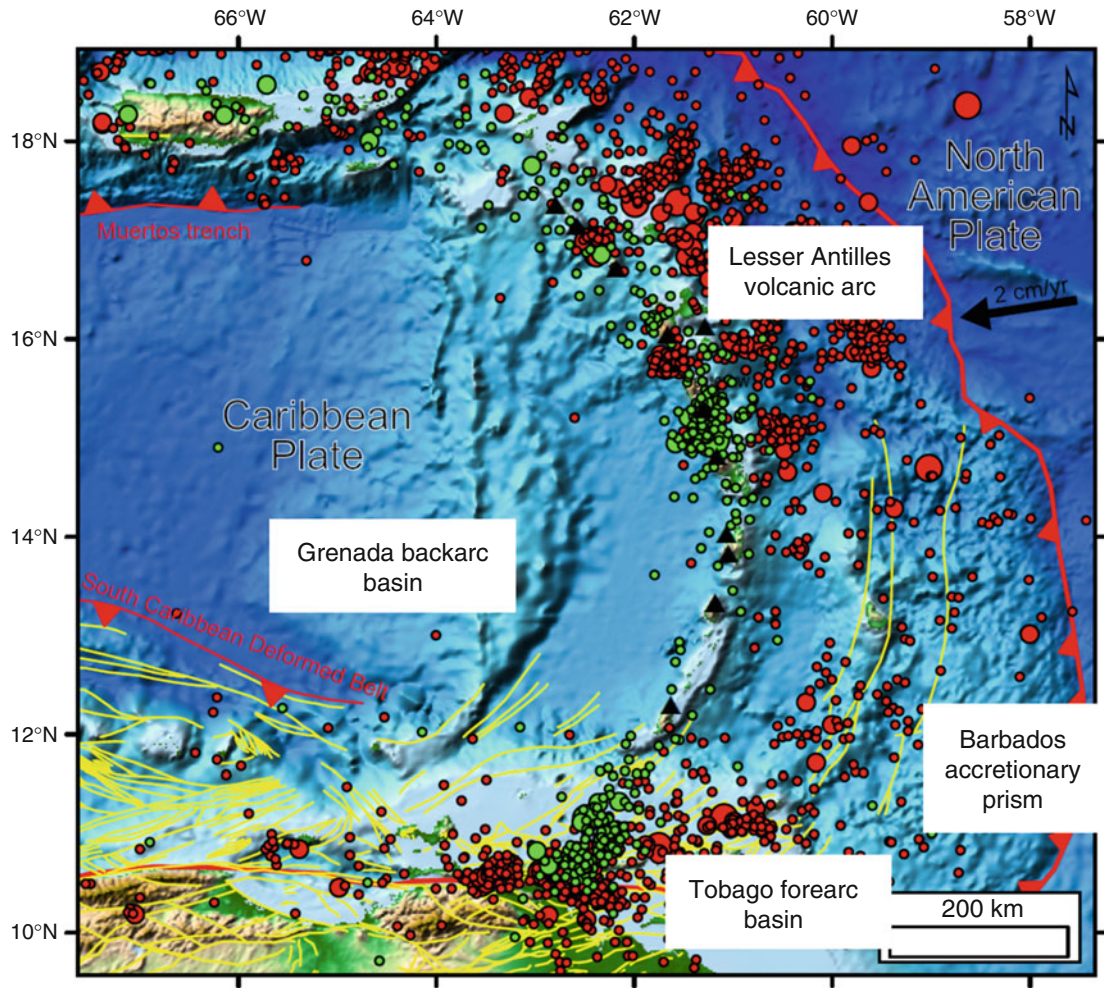
Some of the largest marine and nonmarine basins formed on continental crust are foreland basins produced by the downward flexing of the edge of a continent in response to the overthrusting and loading by a colliding continent, arc, or terrane. The northern margin of the South American continent in the countries of Colombia, Venezuela, and Trinidad provides an excellent regional example of the continental flexure of the continental crust of the South American plate beneath the diachronously colliding "Great Arc of the Caribbean" (Escalona and Mann 2011) (Figure 4). Foreland basins in this area are highly asymmetrical with the deeper edge of the foreland basin controlled by thrust faults of the colliding arc block in the north near the coast of the Caribbean Sea and the more gently sloping edge of the basin in the south controlled by the flexed area of continental crust.

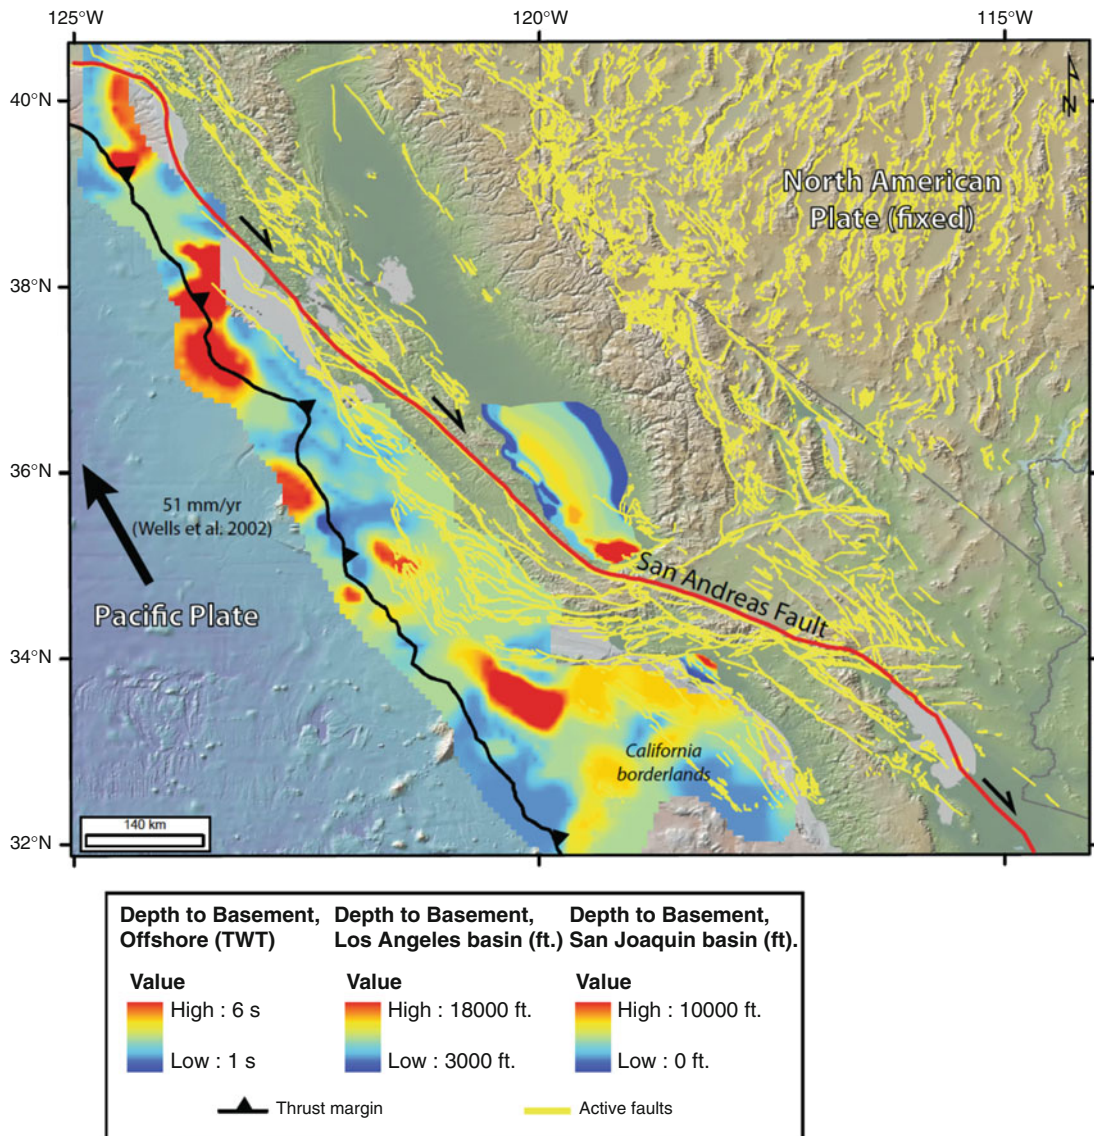
Marine rocks in foreland basins like the eastern Venezuelan basin were deposited during the underfilled stage of basin development when thrusting and depression of


Marine Sedimentary Basins, Figure 2 Tectonic map of the East African rift system modified from Saria et al. (2014). *Yellow lines* indicate active rift faults, and *black arrows* show GPS velocities relative to a fixed Africa plate. The Afar rift at the northern end of the East African rift system is locally 155 m below sea-level and subject to marine incursions. Marine influence will likely expand southward along the topographically depressed rift axis as the rift widens in an east–west direction.


Marine Sedimentary Basins, Figure 3 Tectonic map of the failed West Siberian rift basin modified from Laske and Masters (1997) and Mann et al. (2003) with colors illustrating the thickness variations in the thick sag basin overlying the three elongate rifts shown in *gray*. East–west cross section from Reichow et al. (2002) shows the underlying rifts, an overlying, marine sag basin, and the presence of widespread volcanic rocks in stipple pattern both on the eastern rift flank and beneath its central sag basin.


Marine Sedimentary Basins, Figure 4 Map showing the leading edge of the Great Arc of the Caribbean as it progressively and obliquely collided from west to east with the northern, continental margin of South America. Numbers represent the time that the intraoceanic Great Arc of the Caribbean occupied this location: 1, late Cretaceous; 2, Paleocene; 3, Eocene; 4, Oligocene; 5, Miocene; 6, Pliocene; and 7, present day. Depth to basement map for the top of crystalline continental crust of northern South America and the offshore area occupied by the Great Arc from Escalona and Mann (2011). The eastern Venezuelan basin is a large, foreland basin formed by the flexure of the continental edge of northern South America beneath the colliding Great Arc. Marine influence in the foreland basin is greatest during times of basin deepening that accompany periods of maximum thrusting and lithospheric flexure.


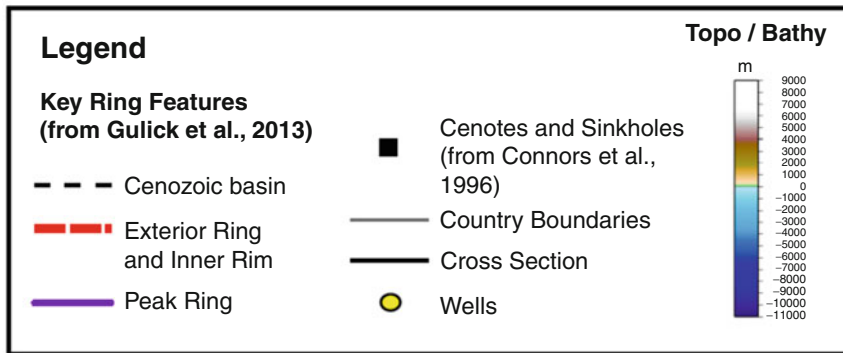


Marine Sedimentary Basins, Figure 5 Map of the Lesser Antilles island arc modified from Aitken et al. (2011) showing major basins formed mainly by the extensional process of "slab rollback" beneath the arc system. Arc-related basins are formed by stretching of the arc lithosphere as the subducting slabs rolls back in an eastward direction.


Marine Sedimentary Basins, Figure 6 Map of the active right-lateral, strike-slip San Andreas Fault system of California showing variations in depth to basement along the fault system modified from Mann (2013). Most strike-slip basins are small and formed as a consequence of either localized shortening or extension along strike-slip faults. The deepening of basins in the area of the southern San Andreas Fault is related to shortening-related flexure produced by the prominent restraining bend in that area.

continental crust beneath the basin reached a climax and outpaced the rate of sedimentation (Escalona and Mann 2011). As the zone of deformation between the northern South American continent and the obliquely colliding Great Arc of the Caribbean moved progressively eastward, the tectonically controlled subsidence rate waned, and the basin filled to sea-level with both marine and nonmarine sediments (Figure 4). Presently the central and eastern part of the foreland basin in Venezuela is filled to sea-level and forms a broad, alluvial plain with the Orinoco delta at its eastern end adjacent to the Atlantic Ocean (Figure 4).

Subduction-related basins: basins formed by stretching

Subduction-related basins generally form by processes of extension linked to the underlying, extensional process of "slab rollback" or steepening of the subducting slab that underlies the arc system. Extension produces back-arc basins like the Grenada basin and forearc basins like the Tobago basin that are fully marine in intraoceanic settings as the Lesser Antilles arc shown in Figure 5 and discussed by Aitken et al. (2011). Although occupying a much different tectonic setting, subduction-related basins form by the same processes of stretching that are observed in


Marine Sedimentary Basins, Figure 7 Map and cross section of Chicxulub impact crater of latest Cretaceous age in the offshore of the Yucatan Peninsula in the Gulf of Mexico modified from Gulick et al. (2013). Marine sedimentary basins produced by bolides are comparable in size to strike-slip basins but smaller than foreland basins.

continental rift basins like the East African rift (Figure 2) and West Siberian basin (Figure 3).

Strike-slip basins: basins formed by stretching and flexure

Strike-slip basins formed in marine and nonmarine basins may form by stretching as in the case of pull-apart basins or can form by flexure in restraining bend settings where thrust faulting and folding dominates. The California strike-slip margin includes examples of both nonmarine basin types in areas of elevated mountains along the controlling and central San Andreas strike-slip fault and deep marine basins of pull-apart origin in the California borderlands offshore of southern California and in the pull-apart basin province of the centerline of the Gulf of California (Mann, 2007) (Figure 6).

Restraining bend tectonics in the Big Bend area of southern California is dominated by thrusting and flexure of adjacent basins beneath uplifted mountain blocks. For this reason, the depth to basement is greater in the restraining bend areas than in the more extensional areas offshore (Figure 6). The line of deeper basins parallel to the coast of California in the Pacific Ocean reflects the trace of a relict subduction margin that preceded the current phase of strike-slip motion along the onland San Andreas strike-slip fault zone (Mann, 2013) (Figure 6).

Basins produced by submarine bolide impacts

Bolide impacts into marine areas can produce deep marine basins as illustrated in the 180–200 km-wide Chicxulub impact crater of latest Cretaceous age in the offshore of the Yucatan Peninsula in the Gulf of Mexico (Figure 7). Cross sections of the crater show a multi-ringed structure with a central structural uplift that is greater than 10 km and a Moho displaced by 1–2 km (Gulick et al., 2013). The outer rim produced during impact produced a belt of large slump blocks. Impact deposits along with normal marine sedimentation eventually filled the crater with marine sedimentary rocks up to 3 km in thickness (Figure 7).

Summary of marine sedimentary basins

Marine sedimentary basins form by a variety of tectonic processes including lithospheric stretching in rift (Figures 2 and 3), strike-slip (Figure 6), and subduction (Figure 5) settings and by lithospheric flexure in collisional (Figure 4) and strike-slip (Figure 6) settings.

The sizes of marine sedimentary basins in foreland or collisional settings are generally much larger than either rift, strike-slip, or bolide impacts in marine settings (Figure 7). The degree of marine fill of these basins is directly related to the proximity of the basin to marine waters. Marine waters can flow into the axis of a juvenile rift or foreland basin during its earlier underfilled stage. Non-marine fill can fill the basin to sea-level during its later, overfilled stage.

MARINE TRANSGRESSION

Jan Harff
Institute of Marine and Coastal Sciences, University of Szczecin, Szczecin, Poland

Synonyms

Landward shoreline shift

A marine transgression occurs if the rate of relative sea-level rise cannot be compensated by sediment supply and the coastline shifts landward (Posamentier et al., 1988; Posamentier and Allen, 1999; Catuneanu, 2002), so that former land is submerged and converted into seafloor. The relative sea-level change is an effect of eustacy modified by tectonic/isostatic vertical displacements of the Earth's crust. The opposite of transgression is "regression", which occurs if the relative sea-level drops, emerging former seafloor as land. During a transgression, the advancing highly dynamic coastal zone reworks the surface of the submerged land, resulting in the formation of coarse coastal sediments. These sediments can be used as "transgression horizons" in the geological record as an indicator of an advancing ancient sea and form ideal markers in stratigraphic correlation of well sections and seismic records (sequence stratigraphy, seismic stratigraphy). In the seismic record, reflectors marking transgressive strata are characterized by "onlapping" at their lower boundary. Relative sea-level changes bound cycles in the Earth's history which can be hierarchically ordered based on the time spans of millions of years to millennia (Suess et al., 1906; von Bubnoff, 1954; Vail et al., 1991; Seibold and Berger, 1993).

MASS WASTING

Jan Sverre Laberg, Tore O. Vorren and Matthias Forwick
Department of Geology, University of Tromsø, Tromsø, Norway

Synonyms

Mass movement; Slope failure

Driven by the pull of gravity, mass wasting comprises all the sedimentary processes related to remobilization of sediments deposited on slopes including creep, sliding, slumping, flow, and fall. The initial stage of remobilization is limited to a layer or zone of weakness, i.e., a stratigraphic interval with physical properties allowing liquefaction from an external trigger. This interval may be located from meters to >100 m below the sea floor. Following the initial liquefaction, the overlying succession is mobilized as blocks, slabs, or ridges and deformation mainly occurs in a basal shear zone. During further movement, disintegration into debris flows or mudflows with or without blocks of consolidated sediments may occur. The incorporation of ambient water during disintegration may lead to the development of turbidity currents due to erosion of the frontal part. If the velocity of the flow reaches a critical value, hydroplaning may occur (Mohrig et al., 1998).

The initial stage of mass wasting may be located anywhere on a slope and involve gradients <1°. Many slope failures have a retrogressive development, i.e., that shallower parts of the slope successively get affected due to the loss of support from below (Kvalstad et al., 2005). In such cases, weak layers or zones at different stratigraphic levels may be involved. Such a development may last from hours to days, and individual flows can vary in volume and run-out distance.

The shallowest part of the slide scar is delineated by a slope-parallel or amphitheater-shaped headwall or scarp that may be >100 m high. Sidewalls form by lateral shear in downslope direction. However, they sometimes also involve compressional features. Where weak layers at different stratigraphic depths are involved, prominent escarpments within the slide scar develop. Slide scars may be partly or completely evacuated.

Parts of the evacuated material are frequently deposited in areas with marked reductions in slope gradients, as, e.g., at the transition from the continental slope to the continental rise. Due to the reduction in slope gradient, the shear stress drops below the shear strength of the reworked sediments, leading, e.g., to freezing "en masse" of debris flows/mudflows. However, some debris flows/mudflows may proceed beyond the base of the continental rise and onto the abyssal plain. Run-out distances of debris flows

---

Tore O. Vorren is deceased.

can occasionally exceed 1,500 km from the point of failure and deposition occurs as a result from the transformation of a decelerating turbidity current (Talling et al., 2007).

On glaciated continental margins, fans or delta-like protrusions occur in front of many glacial troughs or channels crossing the continental shelves. Vorren et al. (1989) proposed naming these features "trough mouth fans" (TMF). Debris flows are the main building blocks of TMFs (Vorren et al., 1998). They originated on the upper slope, emplaced during periods when the grounding lines of ice streams were located near or at the shelf breaks at the trough mouths, probably resulting in very high sediment input. This situation caused oversteepened slopes and/or excess pore-fluid pressures in the accumulated sediments, creating instabilities and mass movement.

METAMORPHIC CORE COMPLEXES

Uwe Ring
Department of Geological Sciences, Stockholm University, Stockholm, Sweden

Definition

Metamorphic core complexes result from horizontal lithospheric extension and form in low-viscosity lower crust when extension occurs at high rates and deformation within the upper crust becomes localized in detachment faults. They are oval shaped usually updomed structures in which mid-crustal basement rocks of higher metamorphic grade have been tectonically juxtaposed against low-grade upper crustal rocks.

Introduction

Extension of Earth's lithosphere is one of the most fundamental processes that shape the face of our planet. Extension and breakup of continental lithosphere is key to understand the evolution of continents, the origin of sedimentary basins, and their hydrocarbon potential, as well as the thermohaline circulation in the oceans and thus global climate.

The most spectacular form of extension tectonics is the formation of metamorphic core complexes. Metamorphic core complexes mainly develop in continental crust, especially where it has been previously thickened by collisional processes. These processes heated up the thickened crust mainly by radioactive decay thereby weakening it and ultimately causing its failure. In oceans, metamorphic core complexes may form as well near mid-ocean ridges when magma supply is not efficient enough to accommodate extension (e.g., North Atlantic; Tucholke et al., 1998). This entry covers continental core complexes only.

What is a core complex?

Metamorphic core complexes are usually oval-shaped bodies in map view their long axis is typically some 20–50 km long. They result from localized extension, which drags out the middle or lower crust (metamorphic core) from beneath fracturing and extending upper crustal rocks and exposed beneath shallow-dipping extensional faults (detachments) of large areal extent (hundreds to more than one thousand square kilometers) (Lister and Davis, 1989) (Figure 1). As the size of a fault is linked to its displacement, the large areal extent of the detachments indicates considerable tectonic transport along those faults. Displacement along core complex detachments is typically of the order of 20–80 km but may exceed 100 km (Foster and John, 1999; Ring et al., 2001; Brichau et al., 2006) and ultimately juxtaposes rock types with radically different geological histories (Figure 2). The large displacements show that deformation during lithospheric extension is strongly localized during core complex formation.

The detachments separating the metamorphic core from the upper crustal rocks are usually underlain by broader brittle-ductile to ductile extensional shear zones. The deformation in both is kinematically coordinated. In general, the detachments (and shear zones as well) dip at low angles (<30°). There has been some debate in the past whether these low-dip angles represent original values or whether the faults have been rotated from a steep orientation (≈60°) into their present low-angle position. Although it has been demonstrated that some low-angle detachments have been rotated from a higher-angle position (Axen et al., 1995; Gessner et al., 2001), there is incontrovertible evidence that many low-angle faults
Metamorphic Core Complexes, Figure 1 Field photos of detachment faults. (**a**) Rawhide Buckskin detachment in the Basin and Range province of the western USA. Yellowish-gray rocks in the lower two thirds of the photo form the metamorphic core; the red-brown hill is a tilted block of sediments in the hanging wall directly above the detachment fault, the latter of which is dipping very modestly to the left in this photo. (**b**) Kuzey detachment in the Menderes Massif of west Turkey. The surface in the upper left represents the detachment plane dipping at about 30° to the right; the hill above this plane in the middle of the photo represents hanging wall sediments. (**c**) Naxos detachment in the Aegean Sea. The view is onto the detachment plane, which is characterized by a marked stretching lineation representing the tectonic transport direction during extensional deformation. Sedimentary rocks in the foreground are coarse-clastic breccias that make up the basal section of the hanging wall (Olivier Vanderhaeghe provided photos in (**a**) and (**c**), Klaus Gessner for the photo in (**b**)).

originated in a low-angle orientation (Wernicke, 1981; Lister and Davis, 1989; Cowan et al., 2003; Collettini and Holdsworth, 2004; Axen, 2007). A low-angle origin of the detachment faults readily explains the moderate variation in metamorphic grade along the crustal section exposed in the footwalls of core complexes (Lister and Davis, 1989).

The footwalls of core complexes are usually made up of middle/lower crustal metamorphic rocks that may be intruded by syn-extensional plutons (Figure 2). The deeper parts of these plutons are frequently not or very weakly deformed; toward the detachments, they are overprinted by extension-related mylonites. In a number of cases, it has been convincingly shown that high-grade metamorphism and pluton emplacement are a consequence of core complex formation (Ring et al., 2010; Schulte et al., 2014), whereas in some other cases, temporal relationships between metamorphism, magmatism, and core complex formation remain elusive (Reynolds, 1982).

In general, rocks in the footwalls of core complex detachments show a distinct sequence of ductile deformation fabrics that were successively overprinted by brittle structures toward the structurally higher part of the shear zone underlying the detachment (Figure 3). In the simplest case, high-temperature deformation structures may be preserved at the bottom of the shear zone. As the footwall is dragged up toward the surface, deformation becomes more localized, and lower-temperature deformation structures overprint earlier high-temperature structures in the upper portions of the evolving shear zone and are successively overprinted by cataclastic deformation once the footwall has reached the upper crust. The detachment faults at the top of the ductile shear zone are basically upper crustal manifestations of the shallow-dipping, normal-slip shear zones (Reynolds, 1982; Davis, 1983). This simple, idealized overprinting sequence is usually not fully met because deformation is commonly heterogeneously distributed in nature.

The footwalls of metamorphic core complexes cool very rapidly at rates exceeding $50–100\,°C\,Myr^{-1}$ as they are dragged up to the surface (Fitzgerald et al., 1993; Brichau et al., 2006; Thomson and Ring, 2006). Commonly thermochronologic ages that record true cooling through a certain closure temperature (e.g., fission-track and (U-Th)/He ages) are identical with error for minerals with different closure temperatures (Fitzgerald et al., 1993; Foster and John, 1999; Brichau et al., 2007). These cooling ages are also identical, or almost identical, to deformation ages from the extensional mylonites (Kumerics et al., 2005). Because most fault systems in metamorphic core complex are low angle, the amount of footwall exhumation is moderate (Deckert et al., 2002; Ring et al., 2003).

The upper crustal rocks above the detachments are often syn-extensional clastic sediments, which contain detritus of the metamorphic core. Therefore, the sediments provide evidence for syn-extensional exposure of the
Metamorphic Core Complexes, Figure 2 Idealized geometry of a continental core complex resulting from localized deformation as a response of horizontal lithospheric extension. Shallow-dipping ductile shear zone at depth grades into cataclastic shear zone and detachment fault in the upper crust. Note that in this model the crust-mantle boundary has been slightly exhumed as a result of extensional thinning of the crust. In cases where the lower crust has a lower viscosity, pronounced lower crustal flow may prevent thinning of the lower crust leaving the crust-mantle boundary flat.
Metamorphic Core Complexes, Figure 3 Idealized scheme for the evolution of ductile-to-brittle deformation in the uppermost footwall of core complexes. (**a**) Onset of core complex formation; extension is accommodated by detachment near surface, narrow cataclastic shear zone in deeper part of brittle crust, and greenschist- to amphibolite-facies shear zone in ductile lower crust below the brittle-ductile transition; note that shear zone is widening with depth (with increasing temperature). (**b**) As the amphibolite shear zone is dragged to the surface, it is overprinted by lower-temperature greenschist-facies deformation, which is in turn cataclastically overprinted as the shear zone moves into the upper crust.

exhuming and uplifting footwall and record the exhumation history of the evolving core complex.

Core complexes also offer an opportunity to look into the problem of absolute versus relative displacement along tectonic faults. Shear-sense indicators in ductile and brittle shear zones provide evidence for the relative displacement of faults; they do not per se provide constraints as to the absolute motion of either hanging- or footwall relative to the Earth surface. However, in a core complex the metamorphic core usually has been juxtaposed against non-metamorphosed sediments in the hanging wall. This provides evidence for the absolute upward motion of the footwall relative to the Earth surface. The sediments of the hanging wall remained more or less stationary with respect to the Earth surface.

Forms of continental extension and thermal stratification of continental crust

The metamorphic grade of high-grade rocks in the footwalls of exposed core complexes commonly shows that the rocks formed under a high thermal gradient exceeding $30\ ^{\circ}\text{C km}^{-1}$. The high thermal gradient leads to a relatively hot and soft crust with a shallow brittle-ductile transition (≤ 10 km depths) and a relatively high-strength contrast between the ductile lower crust and the brittle upper crust.

It has been shown that the thermal state of the continental lithosphere and its rheological structure control the variation between flow in the ductile middle and lower crust and localized deformation in the brittle upper crust and

explains the location and architecture of core complexes (Buck, 1991). Continental rifts (like the East African Rift) form in relatively cold and strong lower crust. In hot, weak, low-viscosity lower crust, core complexes develop (Gessner et al., 2007). It is a general observation that there is a lack of a topographic low above-core complexes and that the crust-mantle boundary is flat in a number of core complexes (Gans, 1987). Both observations suggest that the lower crust is extremely weak and fluid (Buck, 1988). It is assumed that the hot and weak lower crust enables viscous flow to accommodate horizontal pressure gradients laterally across detachments, and this lower crustal flow may be sufficient to accommodate crustal thickness contrasts, thus leaving the crust-mantle boundary flat across the extended lithosphere as observed, for example, in the Basin and Range province (Block and Royden, 1990). In other words, as extension thins the crust, the fluid lower crust is being drawn in from the surrounding areas keeping topographic and crustal thickness gradients small. Because of these processes a hot crust is not thinning significantly during core complex formation, which makes it hard to break it apart to form a new plate boundary.

Examples of regions of extended lithosphere

The classical example of a region that has undergone large-scale continental extension is the Basin and Range province in western North America (Anderson, 1971; Armstrong, 1972, 1982). The Basin and Range records >100 % of extension that has in part been accommodated by the formation of numerous individual core complexes (Coney, 1980). Another well-studied example of large-scale continental extension is the Aegean Sea extensional province in the eastern Mediterranean (Jolivet and Brun 2010; Ring et al., 2010). In both settings, extension by core complex formation was followed by rift-type extension along high-angle normal faulting. The rift-type extension records a stage of much more limited horizontal extension at a later stage of continental extension.

Radiometric dating of extension-related structures shows that there is a pause in tectonic activity between the core complex and the rift stage. It appears that this lull records the time for the hot, formerly overthickened crust to cool down. Core complex formation acts as a mechanism (valve) of how the overheated crust can get rid of its excess energy (heat). The pronounced lower crustal ductile flow causes advective transport of low-viscosity material toward the Earth surface and thereby cools the crust, preconditioning it for rift faulting and eventual continental breakup. This lull in tectonic activity leads to a "messy" split of hot continents. Examples from the Liguro-Provençal basin (Italy/France) and the West Coast of New Zealand show that it took about 25–30 Myr from initial core complex formation to sea floor spreading (Rosenbaum and Lister, 2004; Schulte et al., 2014).

Summary and conclusions

Metamorphic core complexes are spectacular examples of large-scale continental extension, usually juxtaposing metamorphic lower crust against upper crustal rocks. They are bounded by low-angle normal faults that accommodate 10's of kilometers of displacement. Metamorphic core complexes form when the strength contrast between ductile lower crust and brittle upper crust is high, which means when the thermal gradient is relatively high and therefore the brittle-ductile transition shallow (≤ 10 km depths). These hot conditions of the ductile crust make it hard for the lithosphere to fully break apart to form a passive continental margin. Therefore, the lower crust needs to cool down before continental breakup can occur.

Definition

Methane is the simplest hydrocarbon with the chemical formula CH_4. At room temperature and standard pressure, methane is a colorless, odorless gas. It is the main component of natural gas and thus important as an energy source. Due to its ability to absorb energy on the infrared band, methane plays a direct role in the Earth's greenhouse effect.

Methane distribution

Methane represents a key component of the carbon cycle in marine sediments. The amount of carbon that presently occurs as methane in marine sediments is thought to be ~500–10,000 Gt (Kvenvolden and Lorenson, 2001; Milkov, 2004; 1 Gt = 10^{15} g). The size of this reservoir is ultimately determined by a balance of organic carbon sources and sinks, which vary in time and space. The loci of large methane deposits are further controlled by thermal, lithological, and structural characteristics of the sediments. Methane production is fundamentally controlled by organic carbon rain to the sediments, which in turn depends on ocean productivity and water depths (Suess, 1980). Only a fraction of the organic carbon that reaches the seafloor is available for methane generation at greater depth, because a significant part of the organic carbon rain is already remineralized within the top meters

of the sediment column (review by Zonneveld et al., 2010). Early organic matter decomposition is partially controlled by the rate of sedimentation and is higher in regions of low sediment accumulation. Consequently, large methane concentrations are usually found in the rapidly accumulating sediments that underlie the high-productivity regions of most continental margins. The sediments beneath the low-productivity waters of the ocean gyres and those overlying recently formed oceanic crust do not harbor significant amounts of this simple hydrocarbon.

Sources

Our understanding of the origin and distribution of methane in marine sediments was pioneered by the work of Claypool and Kaplan (1974), who described microbial methane generation as the terminal catabolic product of organic matter degradation. As such, it follows an ecological succession of microbial ecosystems, driven mainly by the redox condition of the sediment. The remineralization of organic material proceeds in a continuous sequence of redox reactions that cascade from high to low free energy yield until the electron acceptor source is depleted. The sediment depths that harbor the various stages of this redox ladder depend on the nature and magnitude of the organic loading, sedimentation rate, seawater oxygenation, and sediment porosity. Methane production, commonly referred to as methanogenesis, is only significant in environments where burial of organic matter is rapid enough to survive remineralization by the more energy favorable electron acceptors (O_2, NO_3, Fe, Mn, and SO_4). Globally, microbial methanogenesis in marine and freshwater systems is thought to generate ~85 Tg CH_4/year (1 Tg = 10^{12} g; Reeburgh et al., 1993).

Microbial methanogenesis is a multistep process, performed exclusively by a diverse group of obligate anaerobic archaea, generally known as methanogens. These microorganisms can live in a wide range of temperature, salinity, and pH, but are limited in the substrates they can utilize for growth. A detailed description of the microbial methanogenic pathways in marine sediments is given by Wellsbury et al., (2000). The main pathway for microbial methane generation in organic-rich anoxic sediments is thought to proceed via autotrophic methanogenesis, whereby advantage of the energy released from the reduction of carbon dioxide by molecular hydrogen is taken. This is a multistep process, but the net reaction can be written as

$$CO_2 + 8\,H^+ + 8\,e^- \rightarrow CH_4 + 2\,H_2O \qquad (1)$$

Heterotrophic methanogens are known to utilize simple organic acids such as acetic acid to generate methane via acetoclastic fermentation, which releases both methane and CO_2:

$$CH_3COOH \rightarrow CH_4 + CO_2 \qquad (2)$$

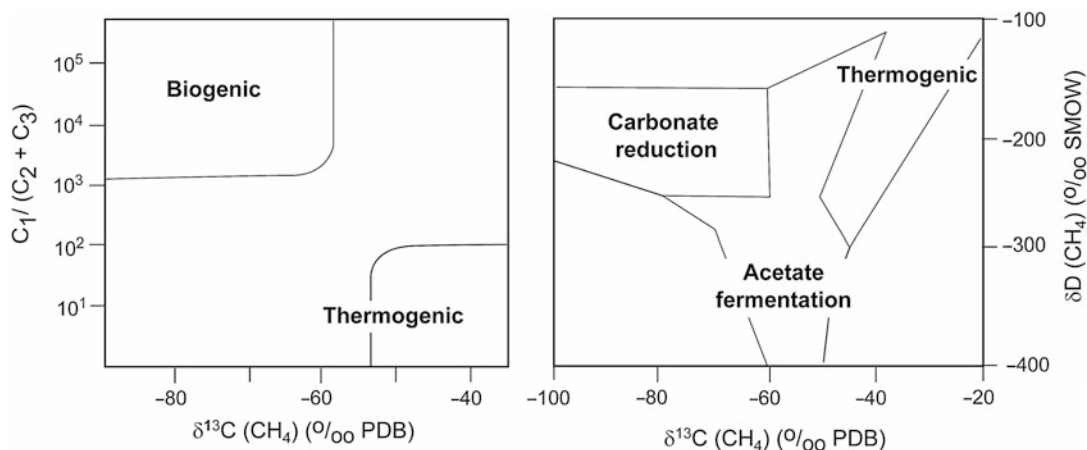
Temperature is a critical factor in sub-seafloor methane generation, as it may impact enzyme activity and

metabolic rates (Colwell et al., 2008). Usually deeper in the sediment, thermal alteration of organic matter generates methane and higher order hydrocarbons within the temperature range of 50–200 °C. At typical oceanic geothermal gradients of 20–50 °C/km, depending on the local geothermal gradient, sediment depths larger than 1 km are required to produce significant amounts of hydrocarbons by thermochemical reaction, with low molecular weight hydrocarbons (methane to butane) being produced at rates that are proportional to temperature.

Even though a few hyperthermophilic methanogens have been shown to produce methane at temperatures of ~122 °C (Takai et al., 2008), the upper limit for subsurface methanogenesis appears to be ~80 °C (Wilhems et al., 2001), which corresponds to depths of 1.500–3.000 m below seafloor, depending on the local geothermal gradient.

Several combinations of molecular and isotopic characteristics are commonly used to identify hydrocarbon sources (Figure 1), as well as their post-genetic alterations. Microbial methanogenesis generates mainly methane (C_1) and traces of ethane (C_2) and propane (C_3), resulting in relatively high $C_1/(C_2 + C_3)$ ratios (commonly > 1,000; Figure 1a). In contrast, thermogenic gases are commonly enriched in higher hydrocarbons, resulting in low $C_1/(C_2 + C_3)$ ratios (<100). The now classic differentiation scheme places microbial and thermogenic methane into distinct regions within the $\delta^{13}C_{CH4}$ and δD_{CH4} field (Figure 1b). In addition, carbon and hydrogen isotopes also aid in elucidating autotrophic vs heterotrophic microbial pathways. Differences in carbon isotopic fractionation arise from the large kinetic effects involved in breaking the C-O bond during CO_2 reduction (Eq. 1), which leads to a more ^{13}C-depleted methane than the methane generated by heterotrophic methanogenesis (Eq. 2), in which the methyl group remains intact. The hydrogen isotope signature may also provide information on the metabolic pathways, as acetate fermentation yields methane with a δD value lower than −250 ‰, whereas carbonate fermentation leads to δD values ranging from −150 ‰ to −250 ‰ (Whiticar et al., 1986).

Sediment reservoirs

Marine sediments contain an estimated 500–10,000 Gt (Kvenvolden and Lorenson, 2001; Milkov, 2004) of methane carbon. Because of its low solubility, methane dissolved in the pore fluids accounts for a negligible fraction of the total sedimentary reservoir. Another small fraction is adsorbed to solid phases (Reeburgh 2007). Traditional natural gas reservoirs are locations characterized by the presence of a source rock (high organic carbon needed for methane generation), a sedimentary trap (normally high-porosity layers where methane gas can accumulate), and a seal rock (which prevents methane leakage from the reservoir). Perhaps the larger methane component of the marine sediment pool occurs in the form of methane hydrates. These compounds are ice-like


Methane in Marine Sediments, Figure 1 Assignment of microbial and thermogenic methane sources based on (**a**) the ratio of methane (C_1) to higher hydrocarbons ($C_2 + C_3$) plotted against the stable carbon isotopic composition of methane (After Claypool and Kvenvolden, 1983) and (**b**) the stable hydrogen and carbon isotopes of methane (After Schoell, 1988). Stable isotope composition expressed in the δ-notation.

solids in which methane molecules are held within a hydrogen-bonded water lattice. These solids are stable at low temperatures and high pressures, as governed by their thermodynamic stability, and necessitate enough methane so to stabilize the hydrate structure (Bohrmann and Torres, 2006). Upon recovery from the seafloor, methane hydrates decompose, and at atmospheric conditions they release approximately 164 m^3 of methane per cubic meter of methane hydrate, thus explaining the large fraction of methane that is sequestered within methane hydrate deposits. This reservoir is, however, highly dynamic, and it has been described as a carbon storage capacitor, which stores and releases ^{13}C-depleted carbon at rates linked to external conditions such as deep ocean temperature (Dickens et al., 2011). Based on this concept, the massive negative carbon isotopic excursion recorded in marine and terrestrial sediments during the Paleocene-Eocene Thermal Maximum at ~ 55 Ma has been interpreted as a widespread release of isotopically light carbon from dissociating marine methane hydrates (Dickens, 2011).

Methane sinks

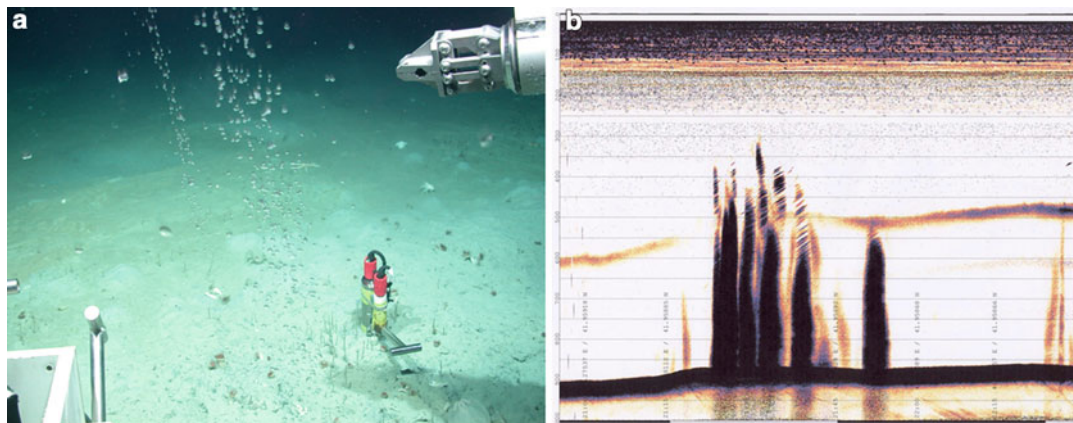
The fraction of the methane that is not trapped in conventional natural gas reservoirs or within methane hydrates migrates through the sediments via diffusion and/or advection, and in case of passing the seafloor, oxygen depletion in the overlying water column results as a consequence of methane oxidation (Boetius and Wenzhöfer, 2013).

In diffusion-dominated environments, methane is almost completely consumed by the microbially driven anaerobic oxidation of methane (AOM), which acts as a highly efficient methane filter, preventing dissolved methane release to the ocean and atmosphere. Reeburgh et al., (1993) estimated that this filter consumes nearly 90 % of the total methane produced in marine and

freshwater systems. Sulfate is the most likely electron acceptor for this reaction, given its high concentration in seawater, which supplies sulfate by diffusion into the sediments. In the sulfate-mediated AOM, several clades of anaerobic methanotrophic archaea (ANMEs) often form synergistic aggregates with sulfate-reducing Deltaproteobacteria (Boetius et al., 2000). Together, these microorganisms are thought to oxidize methane to carbon dioxide while reducing sulfate (SO_4^{2-}) to hydrogen sulfide (HS^-), splitting the energy supplied by this coupled process between them (Hoehler et al., 1994). This process can be summarized by the net reaction:

$$SO_4^{2-} + CH_4 \rightarrow HS^- + HCO_3^- + H_2O \qquad (3)$$

The hydrogen sulfate is feeding chemosynthetic fauna, whereas the hydrogen carbonate is often used for carbonate precipitation. Both processes are typical seafloor manifestations at cold seeps (Bohrmann and Torres, 2006). The sulfate-supported AOM consortia (Boetius et al., 2000) depend on sulfate and methane and thus typically occur at the sulfate-methane interface zone (SMI), a biogeochemical depth level where seawater sulfate and methane from the underlying anoxic sediments converge. The SMI depths in these environments are well defined and typically occur from a few centimeters to several meters below the surface, although deeper SMIs have been observed on the Indian margin (Briggs et al., 2012) and Demerara Rise (Arndt et al., 2009) sediment.

Alternative electron acceptors, which involve the coupling of methane oxidation to the reduction of nitrite, nitrate, and reactive metals, have been recently documented. An uncommon mechanism is mediated by an extremely unusual bacterium, *Methoxymirabilis oxyfera*, that makes its own oxygen to fuel AOM in anoxic environments (Joye 2012). In addition, Milucka et al., (2012) described an ANME-2 clade that uses


Methane in Marine Sediments, Figure 2 Gas bubble ebullition from seafloor to the water column documented (**a**) (*left*) by visual recording of ROV QUEST at 3,000 m water depth at the Makran continental margin and (**b**) (*right*) by hydroacoustic recording of a sediment echosounder (PARASOUND) at Batumi Seep at 800 m water depth, eastern Black Sea.

sulfate-reduction strategy to single-handedly mediate both AOM and sulfate reduction, and in so, eliminating the need for a microbial partner to shuttle electrons or metabolites. Other substrates of oxidizing power, which include halogenated organics and gradual dissolution of oxidant-bearing minerals, are thought to play a minor role in the overall AOM process and are detailed in a methane biogeochemistry review by Valentine (2011).

In advection-dominated systems, methane flux acts to shoal the SMI to depths of less than a few centimeters. In these environments, the high methane flux often overwhelms or even bypasses the AOM biofilter, leading to methane release to the bottom water in what are commonly known as gas seeps (Figure 2). For example, <40 % of methane is anaerobically consumed at the Håkon Mosby mud volcano (Niemann et al., 2006) leaving a large proportion of the methane to escape into the overlying water.

Methane released from the sediments at individual cold seeps by gas ebullition can be imaged as bubble plumes in the water column using acoustic survey techniques (Figure 2) and reaches values of $0.1–22 \times 10^6$ mol/year (Römer et al., 2012). Notwithstanding this massive release of methane gas, globally it accounts for just a few percent of the global atmospheric methane flux, highlighting the role of microbial activity in marine sediments and the water column in regulating methane concentrations in the atmosphere. As we have stated, most sedimentary methane is oxidized within the sediments by AOM, and the excess methane discharging at the seafloor is consumed aerobically near the sediment-water interface (Sommer et al., 2006) or within the overlying water column (Valentine et al., 2001). There are concerns, however, that methane currently trapped within the extensive Arctic shelves, as either gas hydrate or within "ice-bonded" sediments, can be discharged directly into the atmosphere as comparatively warmer Arctic Ocean waters flood the relatively cold permafrost areas of the shelf, driven by the continuing warming effects associated with the Holocene sea-level rise.

Summary

Methane forms primarily from the breakdown of organic matter, which can be mediated by microbial activity or occur through thermochemical processes. Thus highest methane contents occur in rapidly accumulating sediments that underlie regions of high primary productivity, such as those bordering most continental margins. Methane in marine sediments occurs in dissolved, gaseous, hydrated, or adsorbed states, as determined by thermodynamic constraints as well as by sediment structure and composition. In the presence of geologic traps, methane accumulates in the sediments as natural gas, and these deposits are commonly exploited commercially. However, the biggest methane reservoir in marine sediments is thought to exist in the form of methane hydrate, where methane molecules are trapped inside a water cage.

In the absence of geologic or gas hydrate traps, methane tends to migrate through the sediment via diffusion or advection. During this migration, methane can be effectively consumed by anaerobic microbial oxidation, a process which is thought to remove ~90 % of sedimentary methane, most likely via sulfate reduction mediated by Deltaproteobacteria in conjunction with anaerobic methanotrophic archaea (ANMEs). Methane oxidation in marine sediments is an area of active research, and various alternate electron acceptors and microbial pathways have been identified. At high advective rates, the large flux of methane overwhelms the microbial filter, and it is discharged at the seafloor in what is known as cold seeps, the most impressive of which are imaged as bubble plumes in the water column. Notwithstanding this massive discharge, the global methane input from marine sediments, including that from marine gas hydrate, accounts for a few percent of the global atmospheric methane flux.

Mg/Ca PALEOTHERMOMETRY

Dirk Nürnberg
GEOMAR Helmholtz Centre for Ocean Research, Kiel, Germany

Definition

Mg/Ca paleothermometry: Geochemical proxy used in paleoceanography to reconstruct past temperatures of the ocean surface.

Reliable sea surface temperature (SST) estimates are crucial to the reconstruction and modeling of past climate change. Reconstructions of the thermal state of the ocean, in turn, may help to assess the significance of

instrumentally observed climate variability and may validate global circulation models used to predict future climate change. Most promising in this respect is the Mg/Ca paleothermometry, which is based on the temperature dependence of the substitution of magnesium into biogenic calcite. It has long been known that tropical calcitic shells of marine organisms are generally more enriched in magnesium than subpolar shells (e.g., Savin and Douglas, 1973). But in particular for the important group of foraminifera (marine protozoa), a well-defined and species-specific calibration of the shell Mg/Ca ratio on ocean temperature was missing until the mid-1990s (Nürnberg, 1995; Nürnberg et al., 1996). Such species-specific Mg/Ca versus temperature relationships, however, are essential for all further quantitative paleotemperature reconstructions.

Meanwhile, the analytical protocol for Mg analyses has established (Greaves et al., 2008), and the Mg/Ca paleothermometry providing an SST accuracy of ~0.5–1 °C became one of the most important tools in paleoceanography. From cultivation experiments and core-top calibration studies, an exponential relationship between temperature and foraminiferal Mg/Ca was suggested for most planktonic species (e.g., Elderfield and Ganssen, 2000; Anand et al., 2003; Regenberg et al., 2009). Although temperature is the primary control on Mg/Ca, salinity and pH exert additional influence on Mg^{2+} uptake. Mg/Ca positively changes with salinity (Nürnberg et al., 1996; Kisakürek et al., 2008), which requires caution when expecting large-scale salinity variations through time. Seawater pH, instead, is negatively correlated to Mg^{2+} incorporation (Kisakürek et al., 2008). Both effects are assumed to cancel each other (Lea et al., 2000).

The method offers unique advantages compared with other SST proxies. Most importantly, Mg/Ca is measured on the same biotic carrier as stable oxygen isotopes ($\delta^{18}O$), thereby avoiding the seasonality and/or habitat effects that occur when proxy data from different faunal groups are used. Also, the magnitude and timing of SST and $\delta^{18}O$ changes can be separated, allowing to constrain the timing of surface ocean warming with respect to continental ice sheet melting and to approximate changes in ocean salinity (e.g., Nürnberg, 2000).

Most prejudicial to Mg/Ca paleothermometry is that calcite dissolution may cause the preferential removal of relatively soluble magnesium-enriched calcitic parts of the shells (Brown and Elderfield, 1996) and thus may limit the applicability of Mg/Ca as a tracer for SST. Regenberg et al. (2006) defined the oceanic 18–26 $\mu m\,kg^{-1}$ ΔCO_3^{2-} threshold of calcite saturation as critical for the removal. Various algorithms to correct for dissolution effects were proposed accordingly (Rosenthal et al., 2000; Dekens et al., 2002; Regenberg et al., 2006). Whether the long-term changes in seawater Mg/Ca (Tyrrell and Zeebe, 2004) need to be considered for the Mg/Ca paleothermometry, it is still deficiently studied.

MID-OCEAN RIDGE MAGMATISM AND VOLCANISM

Ken H. Rubin
Department of Geology & Geophysics, SOEST,
University of Hawaii, Honolulu, HI, USA

Definition

Mid-Ocean Ridge: A linear, narrow volcanic and tectonic region which marks the constructive boundary between two tectonic plates. It is divided into segments by transform faults and other offsets. The global ridge system cuts through every major ocean basin and comes ashore in a few places like Iceland. It forms an approximately 65,000 km long, globe-encircling, largely submarine mountain chain.

Magmatism: Magmatism is the production and migration of magma, which is molten rock produced from the partial or complete melting of solid materials within a planetary body. When magma erupts on the surface, it is known as lava.

Volcanism: Volcanism is the eruption of molten rock, hot gases, or solidified rock fragments from an opening ("vent") in the Earth's crust. Volcanism occurs on Earth and other planets and moons. Most of the volcanism on Earth occurs at mid-ocean ridges, almost always sight unseen.

Mid-Ocean Ridge Magmatism: By far, the dominant type of lava resulting from magmatic activity at mid-ocean ridges is basalt, also called mid-ocean ridge basalt (MORB). However, small amounts of other extrusive magma types (predominantly andesite, dacite, and picrite) also erupt there. Variations in the rate and style of magma production, volcanism, and faulting result from variations in upper mantle temperature, upper mantle composition, and seafloor spreading rate through the ridge system, causing differences in igneous ocean crustal thickness, structure, and composition.

Mid-Ocean Ridge Volcanism: Volcanic eruptions at ocean ridges vary in style, intensity, and duration around the globe as a function of parameters such as magma chamber depth, magma supply rate, and eruption depth beneath sea-level. Nevertheless, the dominant eruption styles either produce fissure-fed lava flows or point-source, single vent volcanic lava mounds. Nearly all volcanic products at ridges exhibit rapid quench textures, formed by the freezing of molten magma upon contact with cold seawater.

Introduction and history

Magmatism at mid-ocean ridges is one of our planet's most important geological processes, forming a dense, low-lying, igneous crust that floors the vast ocean basins, making up the solid rocks over nearly two-thirds of the Earth's surface. For most of geological history, the greatest number and volume of volcanic eruptions on Earth has occurred in the ocean, along mid-ocean ridges. Earth's globe-encircling volcanic system is a truly colossal geological structure (Figure 1). Yet it is one that many people are not aware of because the global mid-ocean ridge system mostly lies beneath the sea (except in rare occurrences, such as in Iceland, where the mid-ocean ridge is exposed on land due to an anomalously thickened crust from the effects of the colocated Iceland Hotspot). Viewed from space and with the world's oceans stripped away, the mid-ocean ridge system would stand out as one of our planet's most prominent surface geological features. The ridge system generally produces a layered crust, with volcanic rocks on top, coarse-grained intrusive rocks at depth, and an intervening layer of dikes. Together, these layers form the igneous basement of the oceanic crust.

Mid-ocean ridges are segmented at various length scales into volcano-scale units as well as longer coherent segments that are separated by major offsets and discontinuities (e.g., Macdonald, 1982). Although at their upper surface mid-ocean ridges are dominated by volcanic rocks, the number and frequency of volcanic eruptions that formed them is not well known (e.g., Rubin et al., 2012). Compared to eruptions on land, we know less about submarine eruptions and the magmas that drive them, especially those that occur in the deep sea (here defined as below 500 m depth) because eruptions in the deep ocean are much more difficult to detect and observe (Figure 1). Our first knowledge of submarine volcanic rocks from mid-ocean ridges probably comes from reports by deep-sea cable repair ships (Hall, 1876) and the Challenger Expedition (Murray and Renard, 1891), both of which recovered volcanic rocks from the seafloor in the 1870s. Thus, while geologists working on land have had thousands of years to develop an understanding of the magmatic processes that drive subaerial volcanism, marine geologists have had only a century or so. Still, concerted multinational efforts in the last 35–40 years have accelerated the pace of learning, with several marine expeditions to map, sample, and observe mid-ocean ridges occurring around the globe each year. Sampling campaigns over the past several decades have resulted in greatly increased, but highly uneven, sampling of the global ridge system. Some areas have few to no known rocks recovered from them, and at the other extreme, several locations have sampling density equivalent to the best-studied volcanoes on land (with 10–100 samples taken per km of ridge; Figure 1).

Historically active volcanoes in the past 500 years

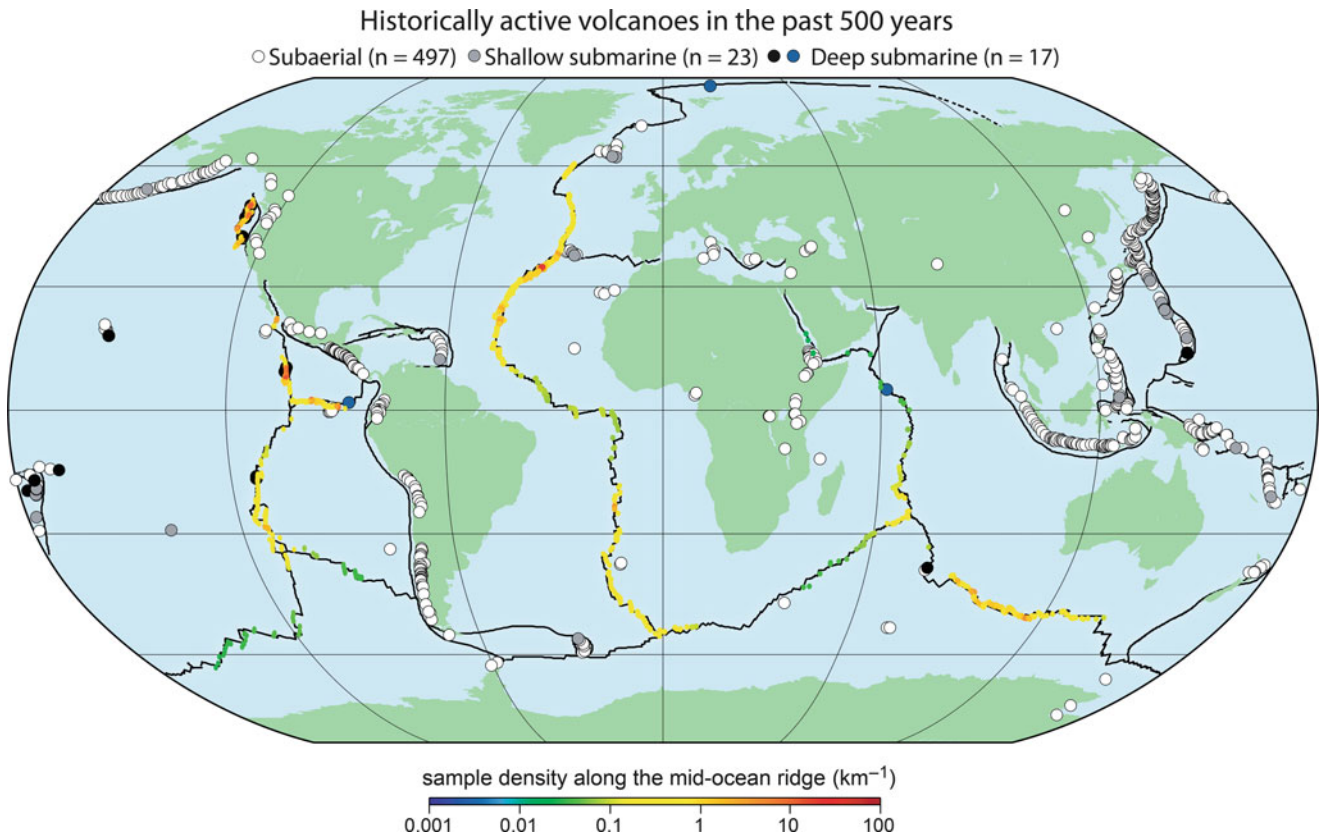
sample density along the mid-ocean ridge (km^{-1})

0.001   0.01   0.1   1   10   100


Mid-ocean Ridge Magmatism and Volcanism, Figure 1 Map of the world's continents (*green*) and oceans (*blue*) with major plate boundaries (*black lines*) and several types of volcano eruption and sampling data depicted. The *white*, *gray*, and *black circles* represent the locations of all documented volcanic eruptions on Earth over the past 500 years (as described in the caption of Rubin et al., 2012, Figure 1), and the colored dots represent sampling density of lavas from the world's mid-ocean ridge system (as described in the caption of Rubin et al., 2009, Figure 3; sample sites were compiled from the petrologic database, http://www.petdb.org). Notice that sample density along mid-ocean ridges varies by a wide range and that most of the ridge system is highly under-sampled (less than 1 sample per 10 km or not sampled at all). Notice also that there have been far more subaerial eruptions than submarine ones detected over the past 500 years globally, which is due to the much greater difficulty of identifying submarine eruptions, especially deep ones, and due to the relative youth of the field of submarine volcano studies. Shallow submarine eruptions leave a surface expression (as volcanic debris or ash/gas plumes) and are somewhat easier to detect and study than deep submarine eruptions. Most of the known deep submarine eruptions have occurred at mid-ocean ridges.

Mid-ocean ridge basalt (MORB) is one of Earth's most common and most intensely studied rock types. Murray and Renard (1891) published an early account of the composition of MORB, demonstrating that it was similar in major element composition to basalts erupted on land. Major progress in understanding the range of compositions of volcanic rocks erupted on mid-ocean ridges began roughly 75 years later, with the exploration and sampling of ridges during the early years of testing and acceptance of the theory of plate tectonics. Initially, samples were collected mostly by dredging, although by the 1970s, scientists had also begun to deploy both human-occupied submersibles, such as *Alvin*, to directly observe and sample the seafloor (e.g., Ballard and Van Andel, 1977), and to use drilling, via the Deep Sea Drilling Project (DSDP) and its successor programs to recover intrusive rocks from

beneath the seafloor. Evidence that these mid-ocean ridge volcanoes were underlain by active magmatic systems came via the discovery of warm springs on the Galápagos Spreading Center in 1977 (Corliss et al., 1979) and hot springs on the East Pacific Rise in 1979 (Spiess et al., 1980). Soon thereafter, ever-improving observational technologies paved the way for discoveries of specific eruptions (e.g., Embley et al., 1991; Haymon et al., 1993; see also reviews in Baker et al., 2012; Rubin et al., 2012). Exploration and monitoring of mid-ocean ridges continue to this day as we expand our understanding of magmatism and volcanism there. Current understanding of the recent volcanic history of several submarine mid-ocean ridge volcanoes now rivals that at volcanoes on land (Rubin et al., 2012; Clague et al., 2013).

Magma generation at mid-ocean ridges

Overview

Separation of tectonic plates causes compositionally heterogeneous mantle beneath mid-ocean ridges (e.g., Allègre et al., 1984) to rise and decompress, partially melting the upper mantle (e.g., Klein and Langmuir, 1987; Kelemen et al., 1997) and producing basaltic parent melts (e.g., Elthon, 1979). Magmatic compositions are modified by multiple processes during ascent and storage prior to eruption (e.g., Klein and Langmuir, 1987; Sinton and Detrick, 1992; Rubin and Sinton, 2007). Mid-ocean ridge magma compositions therefore reflect a combination of magmatic processes related to (a) the composition and temperature of mantle beneath the ridge, (b) the volcanic plumbing system within ridge volcanoes, and (c) cooling from the infiltration of overlying seawater along faults and fissures in the upper crust leading to magma differentiation (e.g., Macdonald, 1982; Phipps Morgan and Chen, 1994). Variations in the rate and style of magma production, volcanism, and faulting result from upper mantle temperature and composition variations (e.g., Dalton et al., 2014) and a change in seafloor spreading rate from <1 cm/year to 20 cm/year through the ridge system, causing differences in igneous ocean crustal thickness (e.g., Bown and White, 1994), structure and morphology (e.g., Small, 1998), and composition (e.g., Rubin and Sinton, 2007).

Away from hotspots, magma supply to ridges from mantle melting covaries positively with spreading rate, so that high spreading rate generally equates to high magma supply. Superimposed on this plate-spreading-driven magma supply, differences in mantle composition, melting, and melt transport further modulate melt supply to the ridge axis along its length (e.g., Langmuir et al., 1986; Sinton et al., 1991), in turn producing physical and chemical segmentation of the mid-ocean ridge at 10–100 km length scales. Upward migration of MORB melts through the mantle, followed by accumulation in crustal magma bodies called magma chambers, results in magma differentiation and crystallization (e.g., Klein and Langmuir, 1987; Grove et al., 1992; Herzberg, 2004) and perhaps to melt-rock reactions (e.g., Lissenberg and Dick, 2008; Lissenberg et al., 2013) prior to either eruption or emplacement as a pluton within the oceanic crust. Structural and thermal conditions within the mantle and crust produce magma supply and magmatic differentiation variations at even smaller spatial scales (i.e., 1–10 km along the ridge axis), producing spatial patterns in erupted magma compositions akin to those found within and between neighboring terrestrial volcanoes (e.g., Reynolds et al., 1992; Perfit et al., 1994; Perfit and Chadwick, 1998). Studies of individual eruption deposits (e.g., Rubin et al., 2001; Bergmanis et al., 2007; Goss et al., 2010; Colman et al., 2012) and dikes that feed eruptions (e.g., Pollock et al., 2009) reveal spatial geochemical patterns that record variations in the delivery of individual magma batches to, and magma mixing and differentiation

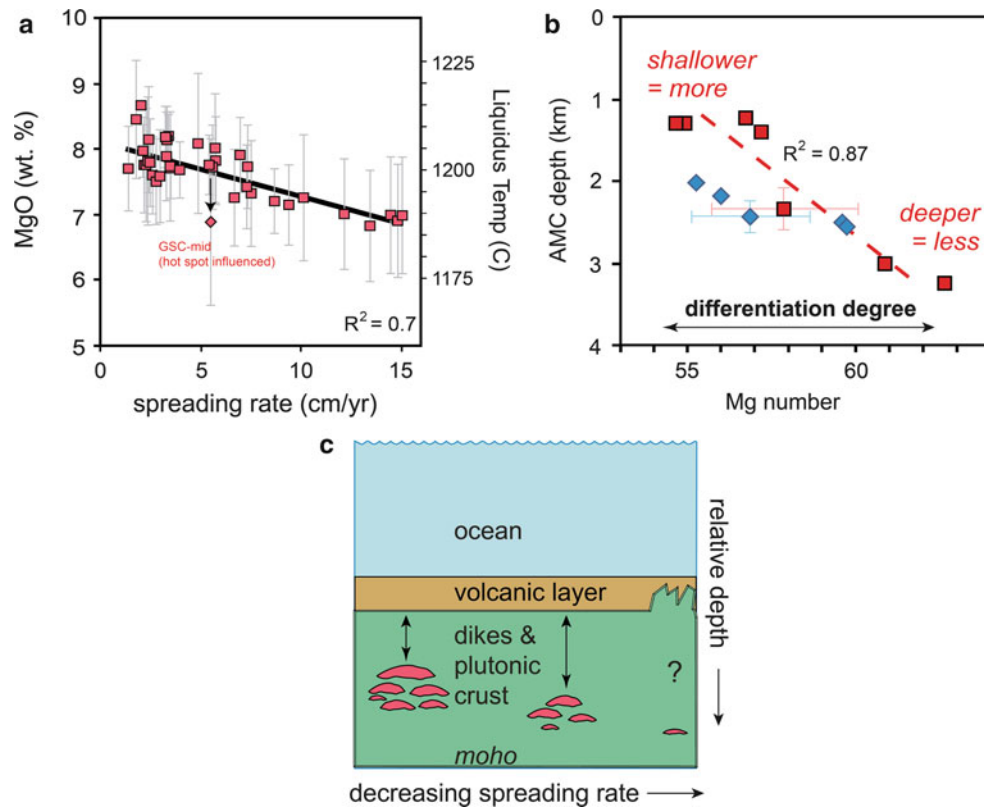
conditions within, subaxial magma reservoirs from which they erupt.

Magma and mantle source compositions

Like all mafic magma generation on Earth, the major element composition of MORB magmas is largely set by the composition of the parent rock in the mantle source, the melting depth, and the degree to which the source rock is partially melted. MORB major element compositions vary less than basalts erupted on land, in part because the aforementioned melting parameters and source compositions are comparatively homogeneous beneath ridges and in part because the thinner and compositionally more uniformly oceanic crust imparts significantly less chemical variation to MORB magmas during magma accumulation and differentiation before eruption. Still, MORB display geographical variations in major element, trace element, and radiogenic isotopic compositions that reflect regional differences in mantle composition and melting conditions around the globe (e.g., Dupre and Allègre, 1980; Hamelin and Allègre, 1985; Klein and Langmuir, 1987; Mahoney et al., 1989; Asimow et al., 2004; Hanan et al., 2004; Niu and O'Hara, 2008), as well as the influence of near-ridge hotspots (e.g., Schilling, 1991; Cushman et al., 2004).

Globally, the trace constituents in MORB (trace elements and radiogenic isotopes) vary more significantly than the major elements. Petrologists use these constituents to understand the mineralogy, chemical composition, and history of a magma's mantle source rock, as well as to help track preeruptive magma differentiation and magma-host rock reactions in the crust. MORB have been widely used to identify variations in upper mantle composition although such mantle signatures in MORB still need to be distinguished from variations imparted to the magmas by melting, magma transport, melt-rock reactions, mixing, and magma differentiation (e.g., see review by Rubin et al., 2009). Of particular importance are the degree to which different types of mantle rocks (i.e., lithologies), also known as "mantle heterogeneities," melt at different rates and proportions (e.g., Ito and Mahoney, 2005; Stracke et al., 2006; Russo et al, 2009) and the extent of subsequent magma mixing and homogenization (Rubin and Sinton, 2007). The latter works to partially or fully obscure inherent mantle source rock variability in aggregated melts of the mantle, becoming more pronounced as magma supply increases.

Magma chamber processes

Nearly all MORB erupt bearing the chemical and mineralogical signatures of magma differentiation (e.g., olivine and plagioclase crystallization) and partial loss of initial melt magmatic gas loads, essentially requiring that these magmas accumulated and partially crystallized in magma bodies at one or more locations in the crust before eruption. There is considerable debate as to the nature of these magma bodies, where they reside, and how they impart


Mid-ocean Ridge Magmatism and Volcanism, Figure 2 Three diagrams depicting compositional attributes of mid-ocean ridge basalts that can be used to infer conditions of magma differentiation, as discussed in the text. *Panel a*, which is modified from Figure 1 of Rubin and Sinton (2007) (see that paper for details of data analysis and spreading rate calculations), shows Mg variations and inferred eruption temperature in ridge section means from different geographic regions of the global mid-ocean ridge system using a >11,000 basalt glass database. Note the strong linear relationships with spreading rate (the *solid black line* is a linear regression to the data). *Gray bars* are 1 s deviations for each mean. Overall, erupted compositions are cooler and more differentiated at faster-spreading rate ridges and also more variable in differentiation-related parameters (see Rubin and Sinton, 2007 for a detailed discussion). The central Galapagos Spreading Center, which is an example of a hotspot-influenced ridge having anomalously high magma supply due to active upwelling, falls off the trend (*diamond symbol*). *Panel b*, axial magma chamber (AMC) depth versus Mg content of erupted MORB showing variations in both means of ridge sections (from *panel a*) also having AMC depth measurements (*red symbols*) and segments of the Juan de Fuca ridge having AMC depth (*blue symbols*). See the caption in Figure 8 in Rubin and Sinton (2007) for details of data sources and handing. This panel shows that magmas erupted from deeper magma chambers are generally less differentiated. Magma chambers are generally shallower at higher spreading rates and deeper at slower-spreading rates, where overall melt supply is high and low, respectively. The linear regression includes the *red* symbols. *Panel c*, A generalized depiction of the greater depth, smaller size, and lower connectivity of AMCs at low spreading rates, as discussed in Rubin et al., (2009). A wide range of geophysical and geochemical parameters were used to infer these variations, as discussed briefly in this article and in detail in Rubin et al. (2009).

structure to the oceanic crust (e.g., see discussion of the "gabbro-glacier" and "sheeted-sill" models in Coogan, 2007 and Keleman and Aharonov, 1998). An important characteristic of many mid-ocean ridges is the axial magma chamber (AMC), discovered in the 1980s by seismic reflection studies. The AMC represents the shallowest level of magma accumulation in the crust (Sinton and Detrick, 1992) and can be segmented at a variety of spatial and temporal scales (e.g., Carbotte et al., 2013). Far fewer AMC reflections have been detected at the ridges with very slow to slow-spreading rates (i.e., < 1–2 cm/year), despite most magmas erupted there showing the chemical and mineralogical signatures of differentiation at crustal pressures, which implies that the AMC bodies there are mostly too small and discontinuous to be seismically imaged. Where they can be detected, the size, continuity, and depth of the AMC vary substantially through the ridge system, but overall these parameters scale with spreading rate: the AMC generally becomes more continuous and shallower (as little as 1.5 or 2 km below the seafloor) at the fastest-spreading rates (Figure 2). This depth variation has been successfully modeled as an interplay between the rate of magma supply from below and the intensity of hydrothermal cooling of the shallowest crust from above (Phipps Morgan and Chen, 1994).

Global MORB magma compositions support the Phipps Morgan and Chen (1994) heat supply model: MORB major element compositions display a general relationship between petrologic indicators of fractionation depth and spreading rate, with evidence for generally higher magma crystallization pressures (Sinton and Detrick, 1992; Michael and Cornell, 1998) and magmatic gas equilibration pressures (Paonita and Martelli, 2007) being more common at slow-spreading ridges. A more recent study found very regular variations in MORB chemistry with spreading rate and AMC depth in a large, 11,000 sample group of MORB from around the globe (Figure 2). Here, the least differentiated MORB were found to occur at slow-spreading rates, becoming progressively more differentiated and erupting from a shallower AMC as spreading rate increases (Rubin and Sinton, 2007). This dichotomy, that cooler magmas generally erupt from ridges with the highest magma supply and hotter magmas from ridges with the lowest magma supply, demonstrates the importance of the AMC and its depth within the crust for modulating MORB composition.

At shorter temporal and spatial scales, chemical variations in MORB within and between successive historical eruptions at sites having an AMC show that magma chamber thermal conditions were relatively constant at these few sites over this time interval, with just 10–20 °C of magmatic heat loss over one to two decades (e.g., at 9° 50′N East Pacific Rise, Goss et al. 2010; 17° S East Pacific Rise, Bergmanis et al., 2007; CoAxial segment of the Juan de Fuca Rise, Embley et al., 2000). Many of these same eruption deposits also preserve magma temperature gradients along the eruptive fissures that indicate thermal variations within the AMC along axis that are not mixed out during eruptions (e.g., Rubin et al., 2001; Sinton et al., 2002; Bergmanis et al., 2007; Goss et al., 2010).

Evolved magma compositions

Small volumes of high-silica lavas (andesites and dacites) occur on mid-ocean ridges, often associated with ridge discontinuities such as propagating rift tips (e.g., Sinton et al., 1983), overlapping spreading centers (e.g., Wanless et al., 2010), and ridge-transform intersections (e.g., Schmitt et al., 2011); however, highly differentiated lavas can also occur in more "normal" ridge settings (e.g., Wanless et al., 2010) and at regions showing ridge-hotspot interaction (Haase et al., 2005; Colman et al., 2012). Many authors have suggested a tectonic control on the occurrence of highly differentiated lavas on mid-ocean ridges, primarily by allowing for extensive cooling of the AMC margins near places where magma supply might be lower. This promotes conditions that allow for extensive fractional crystallization of the magmas. Similar highly differentiated lavas also occur in Iceland, where strong shifts in oxygen isotopic composition relative to mantle values indicate a major role as well for the melting of altered crust (e.g., Martin and Sigmarsson, 2007). The bulk composition of many highly evolved mid-ocean ridge lavas is remarkably similar, and several different occurrences have been successfully modeled by a combination of extensive MORB fractional crystallization plus/minus partial melting and/or assimilation of seawater-altered oceanic crust (e.g., Haase et al., 2005; Wanless et al., 2010). Radiometric dating of zircons from dacite lava domes erupted near the intersection of the Juan de Fuca ridge and the Blanco transform (in the NE Pacific Ocean) indicates that this differentiation can occur rapidly (over just 10 millennia or so; Schmitt et al., 2011).

The plutonic crust

Beneath the volcanic carapace at mid-ocean ridges lies a thick plutonic crust. This intrusive material comprises roughly five times the volume of the extrusive (volcanic) section (White et al., 2006). Direct in situ observation of this crust is difficult, so that much of what we know about this relatively inaccessible material comes from drill hole studies. However, rare plutonic exposures on the seafloor occur in fracture zones and other faulting-exposed "tectonic windows," as well as in ophiolites (pieces of young oceanic crust obducted onto land, e.g., Cann, 1974; Pallister and Hopson,1981). Collectively, studies of these materials indicate a large range of lower crustal rock types, from mafic to evolved compositions, and a range of petrologic textures, some acquired during complex cooling and melt-reaction histories (e.g., Coogan, 2007; Coogan et al., 2007; Keleman and Aharonov, 1998; Lissenberg and Dick, 2008; Lissenberg et al., 2009; Suhr et al., 2008). The extent to which magmas erupted at the surface interact with and reflect this diversity of rocks in the lower crust is an area of active research.

Volcanic eruptions at mid-ocean ridges

Volcanic activity occurs predominantly on the axis of the mid-ocean ridge system with largely unknown frequency. Our understanding of how deep submarine volcanism has built structures on mid-ocean ridges has been greatly aided by sonar and visual mapping of submarine volcanic edifices and by sampling and compositional analysis of rocks there to learn the types and distributions of volcanic products that occur. There is a large literature on this subject, much of which is reviewed in Rubin et al. (2012). In summary, mid-ocean ridges produce low-lying elongate volcanoes from the combined effects of fissure eruptions of generally low viscosity magmas and the constant rafting away of eruption deposits due to plate separation. Bathymetric relief is lower at higher magma supply (e.g., faster-spreading) ridges because volcanic construction dominates over tectonic rifting processes (e.g., Buck et al., 1997; Macdonald, 1998). In fact, the boundaries of individual volcanoes and individual eruptions become more difficult to define at the fastest-spreading ridges because magma is erupted at relatively high frequency (e.g., Sinton et al., 2002; Bergmanis et al., 2007) from nearly continuous along ridge melt axial magma chambers (e.g., Singh et al., 1998) leading to axial high

and mound-like topography (e.g., White et al., 2002). At slower-spreading rates, tectonic forces (faulting and plate separation) dominate over volcanic construction, leading to the common axial valley morphology of the ridge, with volcanic accretion commonly localized along smaller ridges within this valley (e.g., Searle et al., 2010; Yeo et al., 2012) and fault block-dominated rift valley walls. At the very slowest-spreading rates, volcanic activity appears to be discontinuous along the highly tectonized ridge axis, leading to exposures of volcanic, plutonic, and even mantle rocks on the seafloor (e.g., Michael et al., 2003; Cannat et al., 2008).

Eruption products

The different styles of submarine volcanic eruptions and the deposits they produce are controlled by magma chemistry and physical properties, magma eruption rate, and physical conditions at the volcanic vent (e.g., Gregg and Fink, 1995; Perfit and Chadwick, 1998). The size, volume, thickness, and dispersal of both effusive and pyroclastic volcanic deposits provide key information about the conditions of the eruption(s) that produced them. Both effusive and explosive eruption styles are observed at mid-ocean ridges, although effusive lava flows are by far the dominant volcanic product of mid-ocean ridge eruptions. Lava flow thickness, run out, and surface morphology reflect variations in magma viscosity, effusion rate, local slope, topographic obstructions, and the sequence of emplacement events during individual eruptions (see discussion in Rubin et al., 2012 and references therein). Submarine lava flow morphologies are typically classified by the length scale of the quenched-crust units that collectively make up a lava flow, which themselves form as a function of flow rate and cooling rate. Common different types of lava deposits are known as pillow, lobate, and sheet lavas (see Figure 3). Common methods of detection and mapping of these flow types involve direct or remote visual observation from submersibles and towed camera systems (see Rubin et al., 2012), although a recent development employs high-resolution sonar data from autonomous underwater vehicles that have been automatically classified by surface geometry and texture to generate detailed lava flow morphology maps over relatively large areas of seabed (McClinton et al., 2013). Volumetrically minor deposits of lapilli- to ash-sized explosive fragments also occur throughout the depth range of observations in the deep sea (e.g., Clague et al., 2009; Helo et al., 2011).

Eruption frequency and duration

Just like volcanoes on land, the periodicity of volcanism at mid-ocean ridges reflects the rate of magma input to the volcano, the buildup of tectonic stress, and conditions within the crustal magma reservoir. Marine scientists currently lack the information to determine eruption frequency, size, and duration for all but a very small number of submarine mid-ocean ridge volcanoes (reviewed in Rubin et al., 2012). Individual eruptions can last just days to perhaps a year. In terms of eruption frequency, many mid-ocean ridge volcanoes likely operate at a quasi-steady state (e.g., Wadge, 1982) in which eruption volume and repose (the time between eruptions) correlate positively as the result of a relatively constant magma flux. Using such a steady-state assumption and calculating magma supply rate from the spreading rate and an assumption of constant crustal thickness, the smallest average eruption repose interval (~10 year) should occur at the fastest-spreading rates (for instance, on the Southern East Pacific Rise; Sinton et al., 2002 or at Axial Volcano, a ridge-centered hotspot on the Juan de Fuca ridge with anomalously high magma supply). An average repose interval of roughly 1,000 years should occur on slower-spreading ridges like the Mid-Atlantic Ridge (see Perfit and Chadwick, 1998; Sinton et al., 2002 and references therein). The small number of direct eruption observations (there are two submarine mid-ocean ridge sites that have been observed to have erupted twice) and studies utilizing volcano-scale geological mapping and deposit dating via high-precision radiometric or paleomagnetic chronological methods indicate that volcanic eruption frequency and repose are likely not steady state at the individual eruption scale, but that averaged over several eruptions, they do occur at roughly the predicted steady-state interval (e.g., Rubin et al., 2012; Bowles et al., 2014).

Eruption dynamics

Our understanding of the dynamics and mechanisms of submarine volcanic eruptions is informed by a relatively recent but growing body of direct and remote sensing observations. Intermediate- to fast-spreading mid-ocean ridges (i.e., the only places we have such observations) are dominated by short duration, high eruption rate events, or clusters of events (see Rubin et al., 2012 and references therein). Eruption rate variations produce a range of lava morphologies. Lava flows will advance for hours or days during each eruption pulse (e.g., Soule et al., 2012). Eruption pulses may continue if the pressure release was incomplete and/or pressure continues to build in the crustal melt lens by recharge. Widespread diffuse venting of hydrothermal fluids continues through the carapace of a new lava flow well after the eruption wanes. Focused flow hydrothermal activity (i.e., from chimneys) can persist at a site over multiple eruptions, although the character of fluids and chimneys at any given vent site is dominated by subterranean plumbing systems that are highly sensitive to changes that occur during eruptions (e.g., Von Damm, 2004).

Decadal-scale studies at several mid-ocean ridge sites with high melt supply reveal that magma chambers are persistent features over eruptive cycles (e.g., Carbotte et al., 2012). Magma chamber pressures increase over time (e.g., Chadwick et al., 2006), triggering increased seismicity rates along the ridge over several years (e.g., Tolstoy et al., 2006). When sufficient pressure has built in the
Mid-ocean Ridge Magmatism and Volcanism, Figure 3 Photographs of deep-sea eruption products roughly arranged by volcanic effusion rate (slowest at the *top* of the image) and/or eruption style (effusive or explosive). *Panels a*, *b*, and *c* depict pillow lavas which general extrude slowest and have the smallest cool units; the active pillow lava lobe inflating on a transverse and radial crack in *Panel a* is from West Mata volcano rather than a ridge setting, but the mode of emplacement is the same; *Panel b* shows a downward-looking view of 2005–2006 pillow lavas overlying older pillows at 9° 50′N EPR; *Panel c* shows a very young pillow lava at West Mata volcano colonized by an orange microbial mat. *Panels d*, *e*, and *f* depict lobate lavas, which have larger cooling units that often crust over and continue to flow underneath, leading to drainage of the interior and collapse of the surface crust; *Panel d* is of months old lobate lavas at 10° 45′N EPR covered by various microbial mats; *Panel e* is a downward-looking view of a remnant piece of lobate crust above the collapsed interior of lavas erupted in 2005–2006 at 9° 50′N on the East Pacific Rise; *Panel f* is a side-on view of 2–3 m tall lava pillars in the interior of the partially collapsed lobate lava flow erupted at Axial Seamount in 1998. *Panel g* shows a high-effusion-rate sheet flow from the NE Lau Spreading Center; *Panel h* shows young volcanic pyroclasts overlying pillow lavas from an eruption at Gakkel Ridge; *Panel i* shows a 1 m high section of consolidated pyroclastic deposit at one of the Vance Seamounts, near the JDFR. This figure is a modified subset of images of deep-sea eruptions in Rubin et al. (2012) [Photo sources: (**a**) Jason ROV dive J2-414, 2009; (**b**) WHOI TowCam, 2006; (**c**) Jason ROV dive J2-418, 2009; (**d**) Alvin HOV dive 3935, 2003; (**e**) WHOI TowCam, 2006; (**f**) ROPOS ROV dive R743, 2003 (**h**) Camper camera sled, 2007; (**i**) Tiburon ROV dive T1011, 2006].

magma body, diking initiates (e.g., Dziak et al., 2007) and may reach the surface given sufficient overpressure. Event plumes, which are thermally buoyant volumes of seawater carrying chemical signatures of volcanic and hydrothermal inputs, likely form at this time by advection of magmatic heat to the seafloor and/or discharge of hydrothermal fluids stored in the crust (e.g., Baker et al., 2011, 2012). The amount of magmatic gas within the system and the eruption depth will determine the extent of explosive activity that might accompany the effusive component of the eruption (e.g., Clague et al., 2009; Helo et al., 2011).

Eruption detection

This discipline of submarine eruption detection and study is quite a bit younger than complementary studies of eruptions on land. The first evidence for an eruption at a mid-ocean ridge came in the form of a hydrothermal event plume detected along the Cleft segment of the Juan de Fuca Ridge (JdFR) in 1986 (Baker et al., 1987) – a follow-up study of the seabed led to the discovery of a series of pillow mounds up to 75 m high in the same area, making them the first young deep-sea lava flows of known age (Chadwick et al., 1991; Embley et al., 1991). In 1991, the Alvin submersible happened upon the aftermath of a volcanic eruption at 9°50′N on the East Pacific Rise, finding dead and charred tube worms strewn among and under fresh lava and "snowblower" hydrothermal vents diffusely spewing white sulfur-rich microbial floc (Haymon et al., 1993). Radiometric dating subsequently demonstrated that this discovery occurred just 2–4 weeks after the eruption had stopped (Rubin et al., 1994). The first remotely detected mid-ocean ridge eruption was in 1993, when scientists at NOAA/PMEL detected an earthquake swarm on the CoAxial segment of the Juan de Fuca Ridge within the first month of real-time acoustic monitoring using the US Navy Sound Surveillance System (SOSUS) (Fox et al., 1994). Since then, multiple other eruptions have been detected and described by both remote and direct methods (see Rubin et al., 2012 for a full listing). For instance, the real-time hydroacoustic monitoring capability has led to multiple eruption discoveries and responses in the NE Pacific (e.g., Perfit and Chadwick, 1998; Dziak et al., 2007; Dziak et al., 2011; Baker et al., 2012).

Current investigations and controversies

The scientific community has learned a great deal about mid-ocean ridges over the half century, since the realization that they were centers of volcanism and seafloor spreading. Yet there is a great deal that is not well known about both volcanism and magmatism that occur in the Earth's most active and prolific volcanic province, so research continues on multiple fronts. These include the timescales of magmatic processes, magmatic processes leading to intrusions, and the architecture of the ridge at depth, eruption characteristics, and what are the spatial scales of mantle heterogeneity and how is this heterogeneity sampled and modified by magmatic activity. This section highlights some of these current topics of investigation.

Magmatic timescales

Researchers are actively developing and employing novel methods to unravel the timescales of magmatic processes at mid-ocean ridges, from the duration of melting to the rate of magma transport from mantle depths to the crust and the duration of magma residence in the crust before eruption. The nuclides of the naturally occurring U and Th decay series provide the best tracers for these applications because collectively they have a range of half-lives and chemical characteristics, hence varying recovery rates to secular equilibrium following chemical perturbations (where secular equilibrium is the condition of all isotopes in a chain decaying at the same activity, measured as decay constant multiplied by the number of atoms present). Recent U-series radioactive disequilibria studies have demonstrated that melting, melt extraction, and melt accumulation rates can range from millennial (Elliott and Spiegelman, 2007; Stracke et al., 2006; Sinton et al., 2002) to decadal timescales (Rubin et al., 2001; Bergmanis et al., 2007). For instance, covariation of short-lived ^{210}Pb–^{226}Ra disequilibria (half-life = 22 years.) and other compositional attributes of historically erupted MORB at intermediate to fast-spreading ridges indicate that magmatic conditions can fluctuate rapidly, even between successive eruptions separated by just a decade or two (Rubin et al, 2005; Bergmanis et al., 2007). And eruption of lavas with ^{226}Ra–^{230}Th disequilibria (half-life = 1,600 year.) far away from the axis of spreading implies eruption ages of one to eight thousand years even when located on crust of 75–100 kyr spreading age (i.e., assuming steady-state volcanism and post-eruption movement of lava flows by plate spreading; Waters et al., 2013 Standish and Sims, 2010). Despite these successes, it must be noted that the U-series constraints in the aforementioned studies and others like them are semi-quantitative and highly dependent upon model parameterizations of melting using imprecisely known melting rates, melt fractions, melt porosities, melt flow conditions, lithological diversity, and the spatial scales of mantle compositional and mineralogical variations, all of which are targets for future research.

At even finer temporal scales, the ^{210}Po–^{210}Pb dating method provides ultrahigh-resolution lava eruption ages (±1–3 weeks) by charting the post-eruption in-growth of initially degassed, volatile ^{210}Po from erupting magma. The method has been used on several submarine eruptions since its first use on the East Pacific Rise in 1994 (Rubin et al., 1994) to provide temporal constraint on post-eruption recovery of hydrothermal systems and biological colonization and ecological succession on newly emplaced seafloor (summarized in Rubin et al, 2012). Recent applications using large sample numbers along

with detailed lava flow mapping by manned submersible and remotely operated vehicle (e.g., Soule et al, 2007) provided data to reconstruct eruption dynamics and the temporal and spatial evolution of a lava flow field. For example, detailed study of a lava flow erupted at 9° 50′N EPR showed that this long fissure eruption began in summer 2005, with subsequent smaller eruptive pulses from ever-shortening fissures, culminating in a small eruption in mid-late January 2006 (Rubin et al., 2015), with eruption pulses being correlated in time with hydrothermal fluid exit temperatures recorded in situ. Paleomagnetic intensity dating of lavas (e.g., Carlut et al., 2004; Bowles et al., 2006) and radiocarbon dating of planktonic and benthic foraminifera collected from lava flow tops (Clague et al., 2013) are two other methods that both show promise for developing site-specific century to millennial eruption histories.

Mantle compositions and the spatial scales of mantle heterogeneities

Many researchers over the past several decades have been motivated to use MORB magmas to probe upper mantle compositional variations because of several factors that should simplify the connection of erupted magmas to their mantle source, including the common occurrence of relatively undifferentiated magmas, the thin and compositionally less variable oceanic crust (compared to the continents), and the broad spatial coverage of the upper mantle by mid-ocean ridges, which span much of the globe. Such studies have revealed many first-order variations in mantle compositions, as discussed above. More recently, studies addressing the physical nature and distribution of heterogeneities have shown that a few percent of highly fusible mantle pyroxenite veins can dominate aggregate melt composition but not melt flux (e.g., Russo et al, 2009) and that isotopic compositional domains along parts of the ridge system reflect stretching, thinning, and folding of compositionally distinct domains by mantle convection (Graham et al., 2006). Spectral analysis of MORB chemistry along the Mid-Atlantic Ridge has revealed mantle heterogeneity arising from modern hotspots as well as ancient heterogeneities preserved by incomplete mantle mixing during convection (Agranier et al., 2005) and perhaps different mantle-upwelling patterns beneath Indian and Atlantic mid-ocean ridges compared to those in the Pacific (Meyzen et al., 2007). New, high-quality trace element data sets from relatively large numbers of MORB have revealed variations in the degree of depletion of the MORB source mantle around the world (Arevalo and McDonough, 2010; O'Neill and Jenner, 2012) and a more refined definition of and characterization of "normal" MORB (aka N-MORB), as well as depleted and enriched MORB variants in a geographic framework (Gale et al., 2013).

Such studies will help researchers with their goal of understanding the spatial scale of mantle composition and lithology variations and how they are expressed in erupted MORB compositions. However, over the past decade, researchers have also come to realize that magmatic process produces significant overprinting of mantle compositional variations in MORB (e.g., Rubin and Sinton, 2007; Rubin et al., 2009; O'Neill and Jenner, 2012). For instance, the magnitude and temporal variability of melt supply largely affects the degree to which mantle heterogeneity is expressed in MORB magmas (Rubin and Sinton, 2007), which among other things produces reduced variance of mantle parameters in intermediate to high magma supply Pacific ridges compared to other ocean basins, an effect incorrectly assumed to reflect mantle heterogeneity or upwelling patterns in several of the aforementioned studies. The coupling of apparent mantle compositional homogenization with increased magma differentiation, which can be observed over a number of length scales (Rubin et al, 2009), implies that much of this mixing happens at shallow crustal levels, where magmas pool and differentiate in melt-rich lenses prior to eruption. O'Neill and Jenner (2012) argue that disruption of trace element variations in MORB occurs in frequently replenished, open-system magma chambers, although other authors have also argued that magma-rock reactions during intergranular porous flow deeper in the crust also modify the signatures of mantle source characteristics in the erupted MORB (Lissenberg et al., 2013). New advances in this area will likely require more eruption and volcano-scale studies using geological mapping, sampling, and chemical analysis to sort out the full range of processes that operate and under which conditions they occur.

Another way to get at the spatial scale of mantle composition and lithology variations is to look at mantle rocks themselves where they are exposed on the seafloor or in ophiolites. The mantle beneath mid-ocean ridges is thought to be largely depleted by melt prior extraction and magmatism, leading to, for instance, continental growth. But within this depleted matrix likely also lie veins and domains of enriched material injected into the mantle at subduction zones and slowly mixed and spread around by mantle convection. Studies of mantle rocks at ridges have shown that (a) they range in composition, from very melt depleted on ridges near hotspots to less so at locations away from hotspots (e.g., Dick et al., 1984), (b) a large proportion of the upwelling mantle beneath some ridges contributes little magma to the ridge axis because of extreme prior melt extraction (e.g., Liu et al., 2008), and (c) the average mantle beneath ridges may be far more isotopically depleted and compositionally more variable than inferred from erupted oceanic basalts (e.g., Stracke et al., 2011).

Eruption detection and response

Multidisciplinary studies at several focus sites around the world illustrate the important interplays between magmatism, hydrothermal activity, and biological processes at active and dormant mid-ocean ridge volcanoes

(e.g., Kelley et al., 2002; Fornari et al., 2012). Mid-ocean ridge eruptions provide windows into rapidly changing magmatic, hydrothermal, and deep-sea biological processes (e.g., Delaney et al., 1998), so there has been great interest in detecting eruptions or intrusions, followed by rapidly organized seagoing response efforts to study these interplays (see reviews in Baker et al., 2012; Rubin et al., 2012). Such field studies, which began in the early 1990s, have largely been in response to remotely detected seismicity or serendipitous discovery. Despite the logistical difficulty of getting research vessels, equipment, and crew together on short notice, thirty-five recognized events have been responded to on submarine volcanoes over the world (i.e., at mid-ocean ridges and arc and intraplate seamounts; Baker et al., 2012). This list includes eleven historical eruptions at mid-ocean ridges (Rubin et al., 2012). As of this writing, the most recent of these eruptions, which occurred at Axial Seamount in 2011 (on the Juan de Fuca), was a triumph of prior planning and deployment of modern instrumentation, so that the geophysical, geodetic, and geological characteristics of the event were captured in exquisite detail (Caress et al., 2012; Chadwick et al., 2012; Dziak et al., 2012). The newest approaches in submarine eruption studies include autonomous detection stations, autonomous vehicle development for response efforts, and the establishment of permanent seafloor observatories. These will provide extraordinary research opportunities at a handful of sites, but active monitoring of most of the global ridge system will take a concerted effort by the international scientific community, as well as many more interested scientists and infrastructure to conduct these rapid response research efforts.

Summary

The global mid-ocean ridge system is a vast, complicated array of volcanoes, the great majority of which remain unvisited and sparsely sampled. Detailed studies at a few dozen sites reveal patterns of volcanic style, magmatic processes, and erupted compositions that generally reflect variations in spreading rate, magma supply, mantle composition, and proximity to ridge discontinuities and hotspots. Such studies also reveal the range of site-specific geological conditions that affect MORB composition and mid-ocean ridge volcanism. These effects are being studied in ever more locales at ever higher resolution to understand the spatial and temporal scales of ocean ridge magmatic processes, revealing how mid-ocean ridge volcanoes operate and how they sample the underlying mantle. Combined petrological, geochemical, geophysical, and geological data about mid-ocean ridges indicate that inferred mantle compositions are significantly modified in range, magnitude, and length scale at mid-ocean ridges by preeruptive magmatic processes such as magma residence and transport through the upper mantle and lower crust. Submarine eruptions construct new ocean crust and are a primary agent for the transfer of heat, chemicals, and microbes from the Earth's mantle or crust into the overlying ocean. Studying these eruptions is therefore important as well for a complete understanding of the chemistry and biology of the deep sea.

MODELLING PAST OCEANS

Jürgen Sündermann
Institute of Oceanography (IFM), University of Hamburg,
Hamburg, Germany

Understanding the formation of the Earth's surface and the evolution of the Earth–Moon system requires knowledge of the ocean's circulation and tides through geological history. The most important tools to get this information are numerical models simulating the physical and biogeochemical state of the sea. These models are widely tested for the present Earth system. Research on climate, global fluxes of matter, marine ecosystems, as well as operational services like weather forecast are based on them. The models are founded on the laws of nature (e.g., Newton's conservation of momentum) which are formulated as mathematical equations and transformed into complex program codes on major electronic computers. For model validation, measured field data as sea-level elevations, surface temperatures, or ice coverage are used. Past ocean models were based on paleontological data of topography, sediments, and marine organisms which were available for times more than two billion years ago. The models are driven by astronomical reconstructions of the Earth's, the Moon's, and the Sun's ancient orbital motions and scenario-like assumptions on early volcanism, greenhouse gases, sun spots, etc. Coupled ocean–atmosphere–cryosphere–biosphere models simulating ancient circulations and climates, warm and cold periods, extend some 10–100 million years back (Heinemann et al., 2009). They are most reliable for the Holocene with increasing accuracy toward the present (Fischer and Jungclaus, 2010). Tidal models explaining geological sediment patterns or the increases of the length of day and the Moon distance cover the Earth's history back to the Proterozoic (Kagan and Sündermann, 1996). Examples are model calculations of ocean currents and tides for the Gondwana period, for the Tethys ocean, for the early Atlantic, for the world ocean during last glacials and interglacials, and for the recent millennium. From model results, we know today that there exist multiple equilibrium states of the atmospheric and oceanic circulation, e.g., with and without the Gulf stream. We also know that the rate of deceleration of the Earth's rotation by tidal friction through geological history was not uniform due to continental drift and changing ocean resonance.

MODERN ANALOG TECHNIQUES

Michal Kucera
MARUM-Center for Marine Environmental Sciences,
University of Bremen, Bremen, Germany

Modern analog technique, often abbreviated as MAT, is a popular type of transfer function used in paleoceanography to reconstruct past ocean properties from the composition of fossil assemblages extracted from deep-sea sediments. In the vast majority of cases, MAT is applied to reconstruct past sea-surface temperature from remains of marine unicellular microplankton such as planktonic foraminifera, radiolaria, diatoms, and dinoflagellates.

The method has been introduced to paleoceanography by Hutson (1980). Mathematically, it is akin to k-nearest neighbor regression. Its procedure is computationally and conceptually very simple. First, a similarity coefficient is calculated between the composition of a fossil assemblage in a geological sample and the compositions of corresponding assemblages in a "calibration dataset" of surface-sediment samples. Then, the surface-sediment samples are sorted by their similarity coefficient, and a subset of those with most similar assemblages, termed the "nearest" or "best modern analogs," is used in the second step to calculate an estimate of the desired ocean property. The estimate represents a mean of the present-day values of the ocean property at the site of the deposition of the best modern analogs, typically weighted by the respective similarity coefficient of each sample. Like all paleoceanographic transfer functions, MAT relies on the assumption that the reconstructed ocean property is a statistically important determinant of the assemblage composition of the studied organisms. It also assumes that the fossil assemblage and its covariance with the ocean property are represented in the calibration dataset. If this is not the case, the fossil assemblage is said to represent a no-analog condition, which may render the reconstruction of past ocean properties invalid.

MAT is a strict interpolator; it does not attempt to extract a general relationship between assemblage composition and environmental factors. Its applicability is therefore contingent on appropriate coverage of the environmental gradient and of the associated assemblage compositions. Because of no-analog conditions due to evolution of niche requirements of the constituent species, assemblage-based transfer functions are typically limited in their applicability to late Quaternary sediments. Sea-surface temperature reconstructions via MAT can be obtained to a precision of 1 °C, and the variance among the SST values of the best analogs can be used to assess the uncertainty of a fossil estimate.

MOHOROVIČIĆ DISCONTINUITY (MOHO)

Carolina Lithgow-Bertelloni
Department of Earth Sciences, University College London, London, UK

Synonyms

Crust-mantle transition; Moho

Definition

Moho: The rapid increase in seismic velocity with which we often identify the boundary between Earth's crust and mantle. More specifically, the Moho is the depth at which the P-wave velocity first increases rapidly or discontinuously to 7.6–8.6 km/s, or if steep velocity gradients are not present, then it is the depth at which the P-velocity exceeds 7.6 km/s (Steinhart, 1967).

Introduction

The Mohorovičić discontinuity, also known as the Moho, is a discrete jump in seismic wave velocities – a seismic discontinuity – that has come to define the boundary between the crust and the mantle. Its significance stems from its clear demarcation of the first boundary of the chemically differentiated solid Earth. This seminal discovery (Mohorovicic, 1910) complemented that of Earth's other major chemical boundaries with the nearly contemporaneous discovery of the outer core (Oldham, 1906) and the inner core (Lehman, 1936) a few decades later.

The seismic discontinuity at the Moho is explained generally as a chemical (compositionally distinct) boundary separating crust (both oceanic and continental) from the mantle, although in detail the Moho is a much more complex boundary. This is in contrast with most other seismic discontinuities in the mantle, which are explained by changes in the structure of minerals with homogeneous composition as a function of pressure. The petrologic Moho is defined as the change from more felsic crust to more mafic mantle, but it does not always coincide with the Mohorovičić discontinuity as determined by refraction velocity studies or reflection studies. The velocity discontinuity may in places occur within the crust as the basalt to eclogite metamorphic transition (O'Reilly and Griffin, 2013) or within the mantle at the base of a serpentinized layer. Depending on tectonic setting its thickness may vary.

Today, mapping of the Moho at global and regional scales with a variety of geophysical probes, from active-source seismic reflection and refraction studies to teleseismic studies to gravity inversions, is a crucial aspect of geological and geophysical research. Drilling through the Mohorovičić discontinuity remains an elusive goal.

In honor of the centenary of its discovery, an excellent and comprehensive review of historical progress and state-of-the-art research was published in December 2013 (*Moho: 100 years after Andrija Mohorovičić, Tectonophysics, 609, 2013*).

Historical overview

Andrija Mohorovičić saw a peculiar signal in seismograms from a shallow earthquake 40 km southeast of Zagreb, Croatia, in the Kupa Valley on 8 October 1909. Mohorovičić obtained records from seismic stations within 800 km of the epicenter for both earthquake and aftershocks. He observed additional primary (P) wave arrivals with different apparent velocities, at distances between 400 and 720 km, which he called $\overline{P}$. The "normal" arrival was the direct travel path of the P-wave from hypocenter to receiver. The other was from a wave traveling along the interface between two media and refracted towards the receiver at the critical angle (Figure 1). The latter headwave (P_n) arrived earlier and its apparent velocity, ~7.8 km/s, was much faster than the direct wave. Mohorovičić surmised that $\overline{P}$ could be from no deeper than ~50 km and it must represent ". . . a sudden change of the material which makes up the interior of the earth, because there a step in the velocity of the seismic wave must exist" (Mohorovičić, 1910, p. 34). The P_n headwave identifies the seismic discontinuity that marks the compositionally distinct boundary between crust and mantle. Over the following two decades, contributions from Sir Harold Jeffreys, Victor Conrad, and others showed that the Mohorovičić discontinuity was ubiquitous.

However, even by the late 1950s, mapping of the Moho was limited. But from the late 1960s onwards, regional maps were published for Europe (Morelli et al., 1967), the Soviet Union (Belyaevsky et al., 1973), and the USA (Warren and Healy, 1973). Remarkably, these are very similar to today's compilations (Thybo et al., 2013).

Drilling to and through the Moho to understand the nature of the discontinuity and its relation to changes in other physical properties is difficult. The only direct attempt is Project Mohole, which ended in 1967
Mohorovičić Discontinuity (Moho), Figure 1 A seismogram from a M 4.3 earthquake in Central California recorded at station PFO, 280 km away, shows the early arrival of P_n. Inset: Cartoon showing the direct P and the headwave, P_n, along the interface.

(Greenberg, 1974). Though unsuccessful it developed critical technology and led directly to the Deep Sea Drilling Project.

Observational techniques

Studies of the Mohorovičić discontinuity have largely focused on seismic techniques. The analysis of seismograms for the P_n and other arrivals was used to map the Moho and the presence of other intracrustal discontinuities (Prodehl et al., 2013), particularly on continents. In the oceans, studies of seismic refraction were pioneered by Ewing and Ewing (1959) with the use of controlled-source seismology (active sources). Following these first studies (e.g., Shor, 1963; Sutton et al., 1971), marine multichannel reflection studies helped define the oceanic Moho (e.g., Hasselgreen and Clowes, 1995). Active-source seismology has proved very effective in continental regions through the use of both deep seismic reflection and refraction experiments. Reflection studies provide the highest resolution images of the Moho, whereas seismic refraction studies provide the best velocity control, and hence relation to the standard Moho definition. More recently the use of earthquake receiver functions has revealed the richness of intracrustal structure such as double and inverted Mohos in subduction zones (Bostock et al., 2002). Receiver functions allow for the removal of earthquake source complexity and image local structure. Stacking and migration produce depth sections and illuminate the variability of the Moho, though generally with lower resolution than active-source studies, except across dense networks. Novel techniques like inversions of ambient noise (Shapiro and Campillo,

2004) and surface waves (Lebedev et al., 2013) further illustrate Moho complexity. Surface wave waveforms and dispersion are strongly influenced by Moho depth, but combined with a priori knowledge of seismic velocities; receiver functions and gravity can be jointly inverted to create regional maps of the Moho.

It is possible to use gravity data to study crustal structure and detect the Moho as the density increases across the interface (e.g., Oldenburg, 1974). However, gravitational inversions are nonunique and require additional information. It is possible to overcome the nonuniqueness by a joint inversion of gravity data with point information on crustal structure from seismology. High-resolution global gravity data from satellite missions (GRACE and GOCE) has led to global and regional Moho models (Reguzzoni et al., 2013; van der Meijde et al., 2013).

Current knowledge

The Mohorovičić discontinuity is not fully mapped in the oceanic basins, and the distribution of observations is irregular (Mutter and Carton, 2013). Often we refer instead to the reflection Moho, the deepest, high-amplitude, laterally extensive reflection or group of reflections present at depths commensurate with other estimates of crustal thickness (Cook et al., 2010). However, current knowledge puts its average depth below the seafloor at 6–7 km reaching thicknesses >25 km at oceanic plateaus like Ontong Java (Gladczenko et al., 1997). Initial observations implied a sharp interface and little change towards the ridge crest. Recent work has shown that the Moho ranges from a sharp interface to a gradual transition (Mutter and Carton, 2013). Moho variability in the oceans
Mohorovičić Discontinuity (Moho), Figure 2 Global crustal thickness model derived from GOCE gravity data (reproduced from Reguzzoni et al., 2013).

does not correlate with spreading rate or age. The Moho appears to form very close to zero age and change little so that it is fully formed 50,000 years from the ridge crest.

On continents the Moho averages ~35 km depth. It is as deep as 65–70 km in the Andes and Himalayas and shallower than 10 km in Afar. Variations in Moho depth and therefore crustal thickness are strongly correlated with tectonic regime. Cratons and platforms average ~40 km thick crust, while mountain belts are above ~45–50 km. Global crustal thicknesses from new inversion of the gravity field measured by GOCE are shown in Figure 2.

The oceanic Moho is exposed on continents where oceanic sections (ophiolites) have been abducted onto the continent as in Oman. In regions of continental collision, the crust-mantle boundary is exposed such as in the Ivrea zone in the Alps. In the oceans, the mantle outcrops at ultra-slow spreading centers like the Gakell ridge in the Arctic.

The Mohorovičić discontinuity is not always indicative of the boundary between crust and mantle. In the oceans, this is known as the difference between the petrologic and seismic Moho. We expect the lower crust to be more mafic and to be derived from partial melting of the mantle below. The velocity of mafic lower crust can be very similar to that of the mantle, complicating observations of the Moho. The Moho may occur within the crust in continental regions where the lower crust has transformed to eclogite, or within the mantle, in oceanic regions at the base of the serpentinized layer (O'Reilly and Griffin, 2013).

Controversies and gaps in current knowledge

The last 105 years since Andrija Mohorovičić's discovery have brought enormous progress, but gaps and controversies remain. A complete mapping of the oceanic Moho

from ridge to subduction zone remains elusive, not least because of the sparse coverage of ocean bottom seismometers (Mutter and Carton, 2013). Current outstanding efforts of global compilations of Moho depths include those from active-source experiments (Prodehl and Mooney, 2012), receiver functions, and published information like CRUST1.0 (Laske et al., 2013) and those combining gravity and prior crustal models such as GEMMA2012C (Reguzzoni et al., 2013).

The fact that the seismic Moho and the base of the crust do not always coincide makes the interpretation of the origin of the Moho challenging. In the oceans, the Moho may be relatively simple as a transition from the crust to the mantle. However, on continents, the Moho is generally much more complex, partly due to tectonics (Cook et al., 2010; Carbonell et al., 2013). Possibly the crust-mantle boundary is not sharp but transitional and changing with time (O'Reilly and Griffin, 2013). These complications are particularly evident at subduction zones, where both the Moho of subducted oceanic crust and the overriding plate are visible. The flat slab segment of Argentina provides a beautiful illustration (Gans et al., 2011). The double Moho in subduction zones is often associated with a low velocity region, which may represent a hydrated oceanic layer (Bostock, 2013).

The presence of fluids should have a strong effect on physical properties including electrical conductivity. Measuring the electrical Moho (eMoho) is often complicated by past tectonism and metamorphism though still visible with high-quality data (Jones, 2013). We expect seismic properties such as anisotropy and attenuation to change across the Moho as well as rheological properties, but our knowledge of these changes is limited to a few regional examples (Thybo et al., 2013).

Summary

The Mohorovičić seismic discontinuity, known today as the Moho, was discovered in 1909 by Andrija Mohorovičić. It is defined by a jump in seismic velocities from 5.6 to ~7.8 km/s. It represents the boundary between the more felsic crust and the mafic mantle. Combining seismic, gravity, and other data to map the Moho has led to global compilations (CRUST1.0 and GEMMA2012C) that have achieved impressive resolution and coverage. The petrologic and seismic Moho do not always coincide because of complications due to eclogitisation and serpentinization. Modern seismic techniques have revealed richness in structure including double and inverted Mohos at subduction zones (Bostock, 2013) and great complexity in continental regions (Cook et al., 2010; Carbonell et al., 2013). It is now clear that the Mohorovičić discontinuity is a dynamic feature. Ongoing efforts include detecting and understanding other changes in physical properties across it, such as electrical conductivity, scale changes in heterogeneities across it, and viscosity.

Technology, Trondheim, Norway

Synonyms

Glacial landform; glacial sediment; till

Definition

"Moraine" is a genetic term for a landform deposited in a glacial environment (Benn and Evans, 2010; Schomacker, 2011). Commonly, "moraine" refers to a ridge-shaped glacial landform such as an end moraine. It also describes large-scale terrestrial glacial landscapes, i.e., hummocky moraines formed by the melt-out of debris-charged dead-ice or ground moraines (till plains) formed in subglacial environments. In marine settings, "moraine" almost entirely refers to ridge- or wedge-shaped landforms deposited at the margin of tidewater glaciers and oriented transverse to the ice-flow direction. Moraines consist of sediments directly deposited by a glacier and/or deformed by a glacier.

Introduction

"Moraine" spans over an extremely wide range of glacial landforms deposited in many different environments. End moraines and other marginal moraines form at the margins of glaciers and both in terrestrial and aquatic environments (e.g., Boulton et al., 1999; Bennett, 2001; Benediktsson et al., 2008, 2009, 2010; Evans et al., 2012). Till plains or ground moraines form in the subglacial environment of terrestrial glaciers (e.g., Dyke and Prest, 1987; Ross et al., 2009; Schomacker et al., 2010). Its analogue in aquatic environments is subglacially streamlined terrains, typically formed by (paleo-) ice streams (Figure 1a; Dowdeswell et al., 2008; Winsborrow et al., 2010; Jakobsson et al., 2011; Howe et al., 2012; Livingstone et al., 2012; Nitsche et al., 2013). On land, hummocky moraines form in dead-ice environments by the melt-out of stagnant, debris-covered glacier ice (e.g., Boulton, 1972; Clayton et al., 2008; Schomacker, 2008). Numerous other types of moraines are known to form in these glacial environments or in a combination of them. They comprise landforms such as ribbed moraines (Figure 1b), controlled moraines, morainal banks, and many more (e.g., Möller, 2006, 2010; Evans, 2009; Benn and Evans, 2010; Goff et al., 2012).

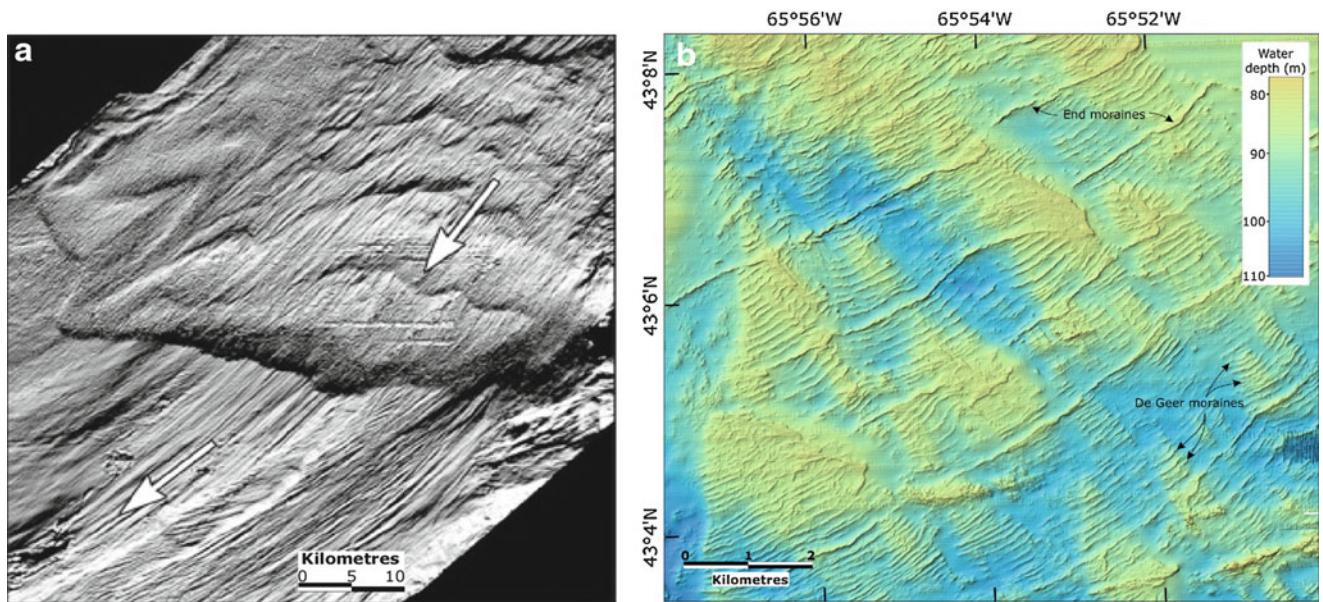
The interior of moraines consists of a variety of sediments. Overall, they can be divided into sediments deposited at the same time as the moraine (e.g., basal till plain, ground moraine, ice-marginal dump moraine) and glacially deformed sediments that were originally deposited prior to the moraine formation (e.g., glaciotectonic end

moraines, Figure 2). Sedimentologic and geomorphologic features of moraines formed in glaciomarine environments are mainly described from studies of Pleistocene moraines that have been isostatically uplifted and are now accessible on land (e.g., Nemec et al., 1999; Lindén and Möller, 2005; Evans et al., 2012). Numerous studies have described the processes of terrestrial ice-marginal moraine formation, whereas much less is known of the processes forming moraines at ice margins terminating in the sea due to the inaccessible environment. The morphology and internal architecture of submarine moraine ridges have also been deciphered by geophysical methods such as multibeam and seismic reflection surveys (e.g., Dowdeswell et al., 2008; Shaw et al., 2009; Jakobsson et al., 2011; Goff et al., 2012).

This entry aims to briefly review the most important moraine types formed in marine glacial environments. Focus is on the geomorphology and sedimentology of ice-marginal moraines as well as their implication for glaciation history.

Ice-marginal moraines formed at tidewater glaciers

Moraine ridges formed at the margins of tidewater glaciers reflect deposition in complex environments where the action of meltwater, gravity, and subglacial processes control the morphology and sedimentary facies. The range of "moraines" formed in this environment spans from subaqueous fans, mainly of glaciofluvial sediments, to transverse moraine ridges built up by both subglacial till and glaciofluvial sediments, e.g., so-called De Geer moraines. In paleoglaciological reconstructions, such moraine ridges are interpreted as formed at a quasi-stationary ice margin. During longer glacier stillstands, large subaqueous fans might accumulate and merge or even build up to the water surface of the basin as an ice-contact delta (Fyfe, 1990; Nemec et al., 1999). It may be confusing that these landforms are often referred to as "moraines" although they should be regarded as marginal ice-contact deltas (Fyfe, 1990; Nemec et al., 1999). The use of the term "moraine" to describe these landforms is probably because they are broadly ridge shaped and delineate a former ice margin. Their paleoglaciological significance is therefore similar to terrestrially formed end moraines that mark the extent of a glacier advance or the position of a stationary ice margin (e.g., Bakker, 2005).

Excellent geological sections in gravel pits in the Kregnes "moraine" in Gauldalen in mid-Norway allowed Nemec et al. (1999) to study the sedimentology and architecture of this ice-marginal deposit. The Kregnes moraine was formed during the Younger Dryas cold period along the western margin of the last Scandinavian ice sheet. The majority of the "moraine" is a Gilbert-type delta with 150 m thick gravelly foreset beds and 2–3 m topset beds with beach deposits reaching the local marine limit of 175 m a.s.l. However, the study by Nemec et al. (1999)


Moraines, Figure 1 Examples of seafloor geomorphology of paleo-ice streams. suggests that the Kregnes moraine was initially a submarine ice-contact fan that experienced glaciotectonic deformation. As sedimentation in the fjord basin progressed, the deposit evolved into an ice-contact delta and a large glaciofluvial delta. Similar architecture is known from numerous other "marine moraines" (e.g., Lønne, 1995, 2001).

Lindén and Möller (2005) and Lindén et al. (2008) described the geomorphology and sedimentology of transverse moraine ridges (ribbed moraines and De Geer moraines) in north Sweden formed at calving tidewater glacier margins during the retreat of the last Scandinavian ice sheet. They showed that these moraines generally consist of a lower, proximal part of basal till or glacially
Moraines, Figure 3 Conceptual model for the formation of De Geer moraines at the grounding line of a glacier terminating in deeper water. The model is based on glacial geological investigations in northern Sweden. (**a**). Deposition of subglacial deformation till proximal to the grounding line. This till is the "base" for the subsequently deposited De Geer moraines. A subglacial channel network transports meltwater and sorted sediments toward the grounding line. (**b**). Glaciotectonic deformation at the grounding line and thickening of the subglacial bed initiates the De Geer moraine. Subglacial till accumulation on the proximal side of the ridge and sediment gravity flows on the distal side. (**c**). The ridge buildup and deformation continues until the grounding line moves up-glacier due to a calving event. Subsequently, glacioaquatic fine-grained sediments accumulate in an on-lapping style to the ridge (modified after Lindén and Möller, 2005).

deformed sediments proximal to the grounding line. The distal part of the ridges is characterized by lee-side cavity-deposited sediments or sediment gravity flows distal to the grounding line (Figure 3). The larger ribbed moraines were interpreted to have formed further up-glacier than the smaller De Geer moraines that formed at the grounding line. Transverse moraine ridges, very similar in size and geomorphology to the Swedish De Geer moraines, have been described from Wisconsinan glacial landforms at the seafloor off Nova Scotia (Figure 1b; Shaw et al., 2009). Ottesen et al. (2008) suggest that minor transverse moraine ridges on the sea floor in front of a modern surge-type tidewater glacier on Svalbard might be a modern analogue to the De Geer moraines described by Lindén and Möller (2005).

Conclusions

The term "moraine" describes a glacial landform directly deposited by a glacier and/or deformed by a glacier. Many

marine moraines are ridge shaped, transverse to the ice-flow direction, and indicate the extent of a glacier advance or the position of a stationary glacier margin. Moraines formed at the margins of glaciers grounded in marine or large lacustrine basins comprise ridges of mainly till, diamict, and outwash sediments. The term "moraine" is also used for ice-marginal landforms anywhere in the continuum of grounding-line moraines to ice-contact or even glaciofluvial deltas.

MORPHOLOGY ACROSS CONVERGENT PLATE BOUNDARIES

Wolfgang Frisch
Department of Geosciences, University of Tübingen, Tübingen, Germany

Definition

Convergent plate boundaries are plate boundaries where one plate subducts beneath the other due to convergent plate movement. Due to its higher density, mostly oceanic lithosphere is the subducting part.

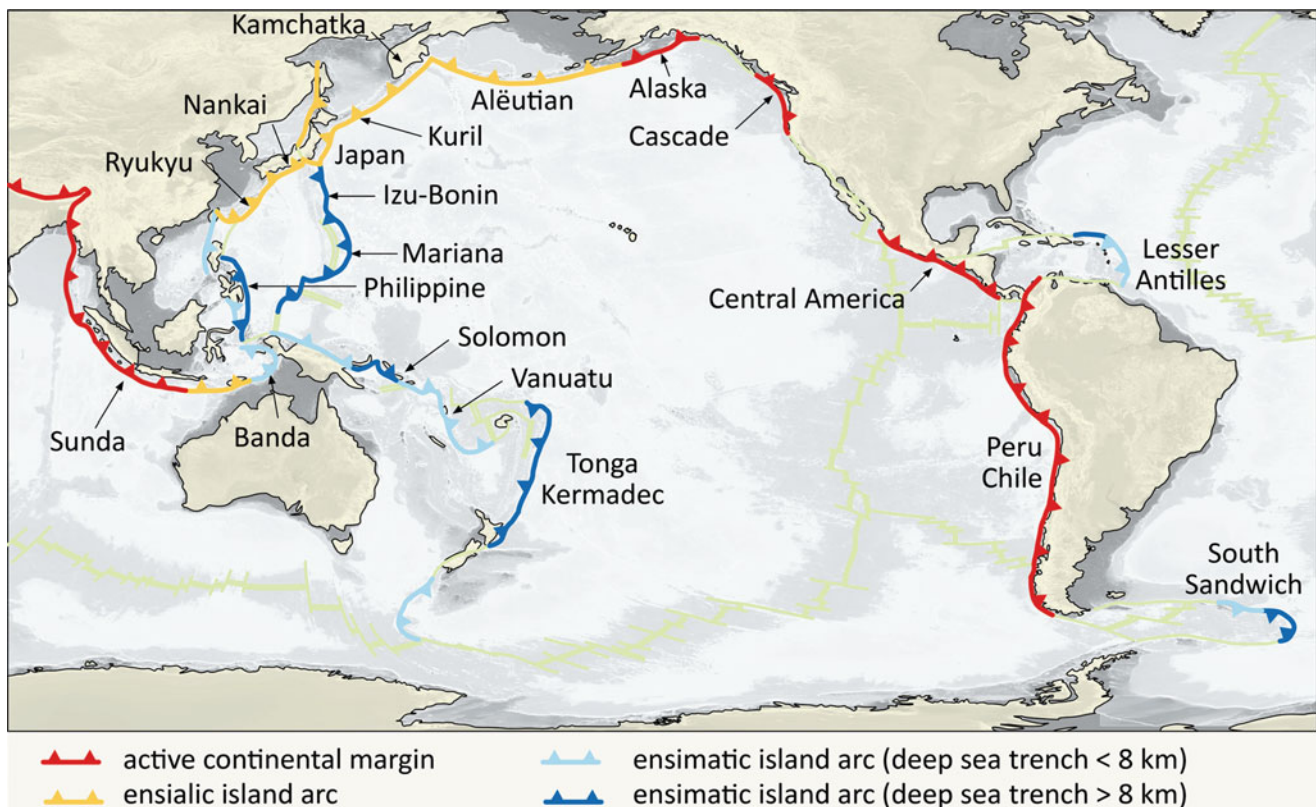
Four types of convergent plate boundaries

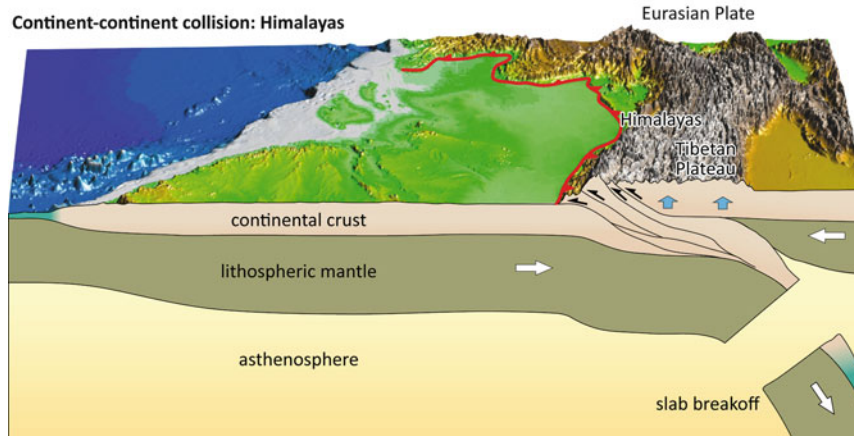
Four types of convergent plate boundaries are recognized (Figures 1 and 2):

The first type occurs when oceanic lithosphere is subducted below another oceanic lithosphere ("Intraoceanic Subduction Zone") to create a volcanic island arc system built on oceanic crust ("ensimatic island arc"; *sima* – artificial word first used by Wegener made from silicon and magnesium to characterize ocean floor and Earth's mantle). Examples for intraoceanic, ensimatic island arc systems include the Mariana Islands in the Pacific and the Lesser Antilles in the Atlantic.

The second type occurs where oceanic lithosphere is subducted beneath continental lithosphere and an island arc underlain by continental crust forms ("ensialic island arc"; *sial* – silicon and aluminum for continental crust). The island arc of this system is separated from the continent by a marine basin underlain by oceanic crust. Examples for island arc systems underlain by continental crust are the Japanese Islands and the eastern Sunda Arc.

The third type of convergent plate boundary represents the active continental margins where oceanic lithosphere is subducted beneath continental lithosphere without a marine basin behind the volcanic arc; rather, the arc is built directly on the adjacent continent. The continental margin is connected directly to the hinterland, although a shallow marine basin may exist behind the volcanic arc. Examples for active continental margins are the Andes, SE Alaska, and the western and central Sunda Arc that includes Sumatra and Java.

The fourth type of convergent margin occurs along zones of continent-continent collision. If two continental


Morphology Across Convergent Plate Boundaries, Figure 1 Convergent plate margins of the Earth characterized by ensimatic island arcs (underlain by oceanic crust), ensialic island arcs (underlain by continental crust), and active continental margins.


Morphology Across Convergent Plate Boundaries, Figure 2 Examples of different types of plate margins with subduction zones. The island arc of the Marianas developed on oceanic crust, that of Japan on continental crust. The volcanic zone of the Andes is built on the South American continent (active continental margin). The collision of two continents produces a mountain range like the Himalayas – subduction wanes, leading to slab breakoff.
Morphology Across Convergent Plate Boundaries, Figure 3 Structure and morphology of a plate margin system with subduction zone and ensialic island arc.

masses collide during continuous subduction, they eventually merge. Telescoping of the two plates and the buoyancy of the subducting continent eventually leads to a standstill of subduction within the collision zone. The oceanic part of the subducting plate tears off and continues to drop down, a process referred to as "slab breakoff." Continent-continent collisions ultimately result in the formation of mountain ranges like the Himalayas or the Alps.

Structure and topography of plate margin systems with subduction zones

Systems of convergent plate boundaries are characterized by a distinct topographic and geologic subdivision. Although the plate boundary itself is only represented by a line at the surface, commonly within a deep-sea trench, a zone several hundreds of kilometers wide is formed by processes which are related to subduction. The volcanic zone above the subduction zone, in many cases expressed as an island arc, is the dominating element of this plate boundary system. We use arc as shorthand for the terms volcanic arc or magmatic zone. The arc is the point of reference for the convergent boundary that is usually divided into three parallel zones: from the trench to the arc is the forearc zone, the arc zone comprises the magmatic belt, and the region behind the arc is the backarc zone (Figure 3). This generally agreed upon subdivision of three parts turned out to be practical in order to describe the complex structures of convergent plate boundary systems.

Deep-sea trenches form the major topographic expression at convergent plate boundaries. These deep, narrow furrows surround most of the Pacific Rim and small portions of the rims that surround the Indian and Atlantic oceans. Oceanic lithosphere is bent downward under the

margin of the "upper plate" and dives into the asthenosphere. The result is an elongated deep trench that is located between the abyssal plains and the border of the upper plate. The deepest trenches, with water depths of about 11,000 m, are known from the Challenger and the Vitiaz Deep (named after a British research vessel and a Russian researcher, respectively) in the southern Mariana trench. Water depths of more than 10,000 m are also known from the Kurile, Izu-Bonin, Philippine, and Tonga-Kermadec trenches (Figure 1).

Convergent plate boundaries are responsible for the greatest differences of relief on the Earth's surface. Differences in altitude of 10 km between the deep-sea trench and volcanoes of the magmatic arc are not unusual. A relief of 14,300 m across a distance of less than 300 km can be observed between Richards Deep (−7,636 m) and Llullaillaca (+6,723 m) in the Chilean Andes, the highest active volcano on Earth.

In a transect from the trench onto the upper plate, the following morphological features generally occur (Figure 3). The landward side of the deep-sea trench is part of the upper plate and consists of a slope with an average steepness of several degrees. In front of the Philippine Islands, the angle exceeds 8° where a rise from −10,500 m to −200 m occurs over a distance of 70 km. The so-called outer ridge follows behind the slope. In most cases, the ridge remains substantially below sea-level; however, in several cases, islands emerge above sea-level (Sunda Arc: Mentawai; Lesser Antilles: Barbados). The outer ridge is not always distinctive. It is prominent in those places where large amounts of sediment are scraped off from the subducting plate along the plate boundary and accreted onto the base of the upper plate. Next in the transect, directly in front of the volcanic arc, lies the forearc basin, another prominent morphological element.

Collectively, the deep-sea trench, outer ridge, and forearc basin comprise the forearc region. The distance between the plate boundary and magmatic zone has a width of between 100 and 250 km. This region is also called the arc-trench gap, a magmatic gap that with very few exceptions is void of magmatic activity. Low temperatures in the crust are caused by the coolness of the subducting plate underneath; the low temperature gradient prevents the formation of magma by melting or the rise of magma from deeper sources.

The volcanic arc, with an average width of 100 km, is the central part of the island arc or the active continental margin system and is characterized by significant magmatic activity. Approximately 90 % of all active volcanoes above the sea-level, most of which are in or around the Pacific Ocean, are subduction-related volcanoes. The zone of volcanism has a sharp boundary on the forearc margin and a gradual one on the backarc margin (Figure 3).

Island arcs are separated from adjacent continents by a marine basin underlain by ocean crust, the backarc basin (Figures 2 and 3). Active continental margins have a backarc region that may have thinned continental crust and/or a zone of compressional structures.

In principle the arcuate shape of island arcs is easy to explain. Before a plate enters a subduction zone, it possesses a curvature according to the curvature of the Earth. When it dives into the subduction zone, this curvature inverts and convex becomes concave. Adjacent arcs commonly display a catenary-like pattern as observed in the Western Pacific where one island arc drapes next to the other. The radius of an arc is a function of the radius of the Earth and the inclination angle of the subduction zone, but is also influenced by structural features of the upper plate. This becomes evident along continental margins where the shape of the continent substantially controls the shape of the plate boundary, e.g., along the continental margin on the western edge of South America.

Morphological differences caused by Mariana- and chile-type subduction

The western rim of the Pacific Plate is characterized by lithosphere with ages greater than 100 Ma. Therefore, spontaneous subduction driven by the density of the cool oceanic lithosphere dominates (Mariana-type subduction). However, younger lithosphere typical of the eastern margin of the Pacific, mostly less than 50 Ma old, as well as that of the Philippine Sea Plate and the western Sunda Arc is too buoyant to subduct spontaneously, but rather is forced underneath the upper plate by compressional forces (Chile-type subduction). Such conditions promote shallow subduction and a strong coupling to the upper plate. In other words, the horizontal compressional force is transferred from the subducting plate to the upper plate and compressional structures such as folding and stacking of crustal units evolve far into the upper plate (Figure 4, lower). In contrast, spontaneous subduction with steeply
Morphology Across Convergent Plate Boundaries, Figure 4 Mariana-type (*above*) and Chile-type (*below*) subduction zones. At the Marianas, subduction occurs easily and the subduction zone rolls back to the east (insert). At Chile, young and specifically light lithosphere pushes upwards; subduction is forced. The two types of subduction cause highly different morphological features.

dipping subduction zones generates extensive decoupling along the plate boundary so less deformation of the upper plate occurs and extensional structures form (Figure 4, upper). Forced subduction may evolve from spontaneous subduction as increasingly younger portions of the downgoing plate are subducted thus changing the vertical component at a plate boundary to a more strongly coupled horizontal force.

Steeply dipping subduction zones such as the ***Mariana-type subduction*** produce significant consequences. A strong slab pull of the subducting lithosphere forces the subduction zone to roll back oceanward – i.e., towards the subducting plate or easterly into the edge of the Pacific Plate in the case of the Marianas (Figure 4). The locus of the hinge zone, where the ocean floor is bent down into the subduction zone and which marks the plate boundary, migrates backwards, away from the locus of the arc. This process is termed subduction or slab rollback (Figure 4, insert). The rollback causes extensional forces to develop at the plate boundary, and the edge of the upper plate is

extended. The rollback causes the island arc to migrate towards the outside of the arc system which in turn results in a strong extension of the backarc region. If the arc was originally built on a continent, this process leads to the separation of the island arc from the upper plate continent. The resulting separation behind the island arc generates a backarc basin and with sufficient extension, new oceanic crust may form (e.g., Sea of Japan). The western Pacific is characterized by numerous island arc–backarc systems (Figure 1). The garland- or drape-like alignment of the island arcs results from their separation from the continent. Typically, the garlands have lengths from 2,000 to 2,500 km. Because the Mariana Arc comprises an intraoceanic subduction zone, the formation of the backarc basin occurred solely within oceanic crust (Figure 2).

Subduction rollback that forms during Mariana-type subduction has an effect on the topography of the plate boundary system. The mean topographic elevation on the edge of the upper plate is low because of the effect of suction and extension. Like in the Marianas, the magmatic arc may only form a chain of small islands representing the peaks of the volcanoes. Also, the deep-sea trenches are significantly deeper on average because the subducting plate bends downward very steeply and the island arcs do not deliver enough sedimentary material to even partially fill the trench. The world's deepest trenches, all with depths greater than 8,000 m, occur along westward-directed subduction zones (including those of the Atlantic Ocean) that involve old oceanic lithosphere (Figure 1). The rollback of the westward-directed subduction zones may be enhanced by an eastward-directed asthenospheric current as calculated from global plate drift compared to flow of the sublithospheric mantle.

A curious situation at subduction zones with backarc basins (Mariana-type subduction) is the juxtaposition of strong convergence and divergence. Although relative plate movement velocities at convergent plate boundaries in the western Pacific approach 9 cm/year, a wide area at the edge of the upper plate is under extension. Compressive structures are restricted essentially to the tip of the upper plate.

The subduction zones and convergent plate boundaries of *Chile-type subduction* are fundamentally different in many ways. The subducting plate is intermittently coupled to the upper plate because of the buoyancy of the former; this causes compression and thickening of the upper plate (Figure 4). Thickening of continental crust leads to the generation of a mountain range. Deep-sea trenches are shallower and volcanic zones are characterized by significantly higher elevations than volcanoes associated with Mariana-type subduction. The highly elevated hinterland is more likely to deliver sedimentary material into the trenches, and the sediment supply is generally not hampered by intervening ridges. Even more consequential than the topographic height is the structural height, the total amount of uplift within the volcanic zone, which may exceed 20 km. Crustal structures originally formed at depth are subsequently uncovered by erosion. In fact,

metamorphic and intrusive magmatic rocks at the surface in the Andes can be used to estimate the amount of uplift and subsequent amount of erosion.

Along Chile-type subduction zones, the compressional forces are transferred far into the upper plate. Therefore, earthquakes in this area are particularly strong and frequent. Regionally, compressional structures with overthrusts evolve that are oceanward-directed in the forearc and continentward-directed in the backarc region (Figure 4). Consequently, the backarc area is also under compressional stress. Crustal shortening occurs across the entire magmatic zone, which in turn has an effect on the magmatism itself. Melts rising from the asthenospheric wedge above the subduction zone typically become trapped in the crust and crystallize as intrusions or melt adjacent crustal rocks and feed highly explosive acidic volcanoes. The collective processes of tectonic stacking and magmatic accretion have formed a crustal thickness of 70 km in the Andes, one of the areas of thickest continental crust on Earth.

MUD VOLCANO

Achim Kopf
MARUM-Center for Marine Environmental Sciences, University of Bremen, Bremen, Germany

Synonyms

Diatreme; Mud diapir; Pockmark

Definition

A type of sedimentary volcano (Kopf, 2002; van Loon, 2010) composed of fine-grained mud, in both subaqueous and subaerial settings.

Landforms proposed to be mud volcanoes: Pitted cone, Mound, Mud diapir, Diatreme.

Origin of term

The Greek "diapeirein" means "to pierce," and the first mention of diapiric structures dates back to Leymerie (1881), who suggested the word "tiphon." This nomenclature was adapted by Choffat (1882) when describing sedimentary diapiric manifestations in Portugal, calling these small domes "tiphonique." Mrazec's (1927) definition of diapirism as the process of forceful movement of a more or less plastic body from areas of greater pressure to areas of less pressure has since then widely been accepted. It has often been restricted to salt structures instead of having been applied on mechanical grounds, although some workers used it for effusive or intrusive magmatic processes (e.g., Wegmann, 1930). The term "sedimentary volcanism" supposedly (Saunders, personal communication, 2000) goes back to Kugler (1933).

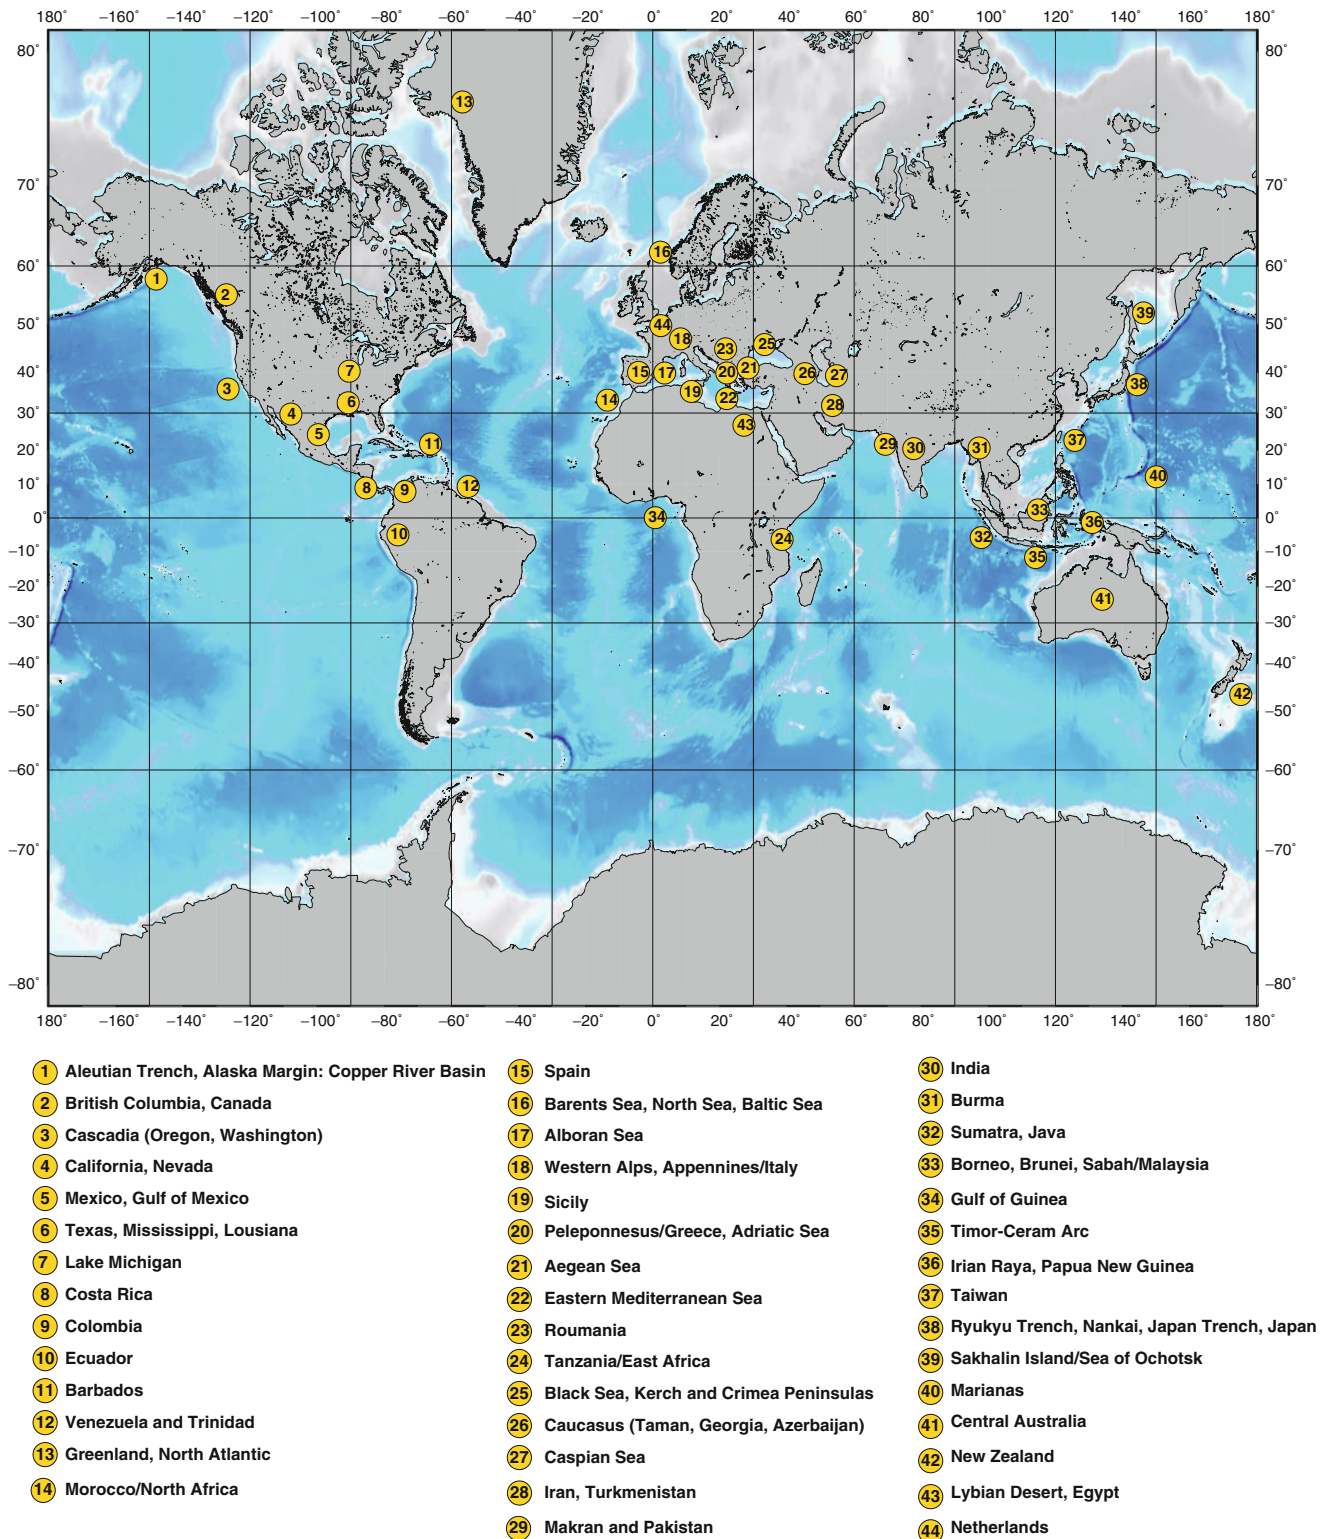
Introduction and historical background

Mud volcanoes on Earth extrude relatively low temperature slurries of gas, liquid, and rock to the surface from depths of meters to kilometers (Kopf, 2002). Slurries build circular to subcircular deposits of mud and rock breccia that range in diameter from a few meters up to tens of kilometers. They can produce a variety of morphologies, domes, cones, caldera-like forms, or relatively flat structures, reflecting physical properties of the rising material. The depth of origin of the different phases may be variable within the same mud volcano and ranges from a few meters to several kilometers sub-bottom.

Mud intrusion and extrusion are well-known phenomena whereby fluid-rich, fine-grained sediments ascend within a lithologic succession due to their buoyancy. These processes have long been recognized as related to the occurrence of petroleum, regional volcanic and earthquake activity, and orogenic belts (see the enlightening presentation by Ansted (1866)). The abundance of mud volcanoes was first examined systematically on a broad scale by Higgins and Saunders (1974). These authors mostly focused on mud volcanoes on land and used industry drillhole data to establish relationships between mud volcanism, hydrocarbons, and regional tectonics. The onshore mud volcanoes and their important role in predicting petroleum reservoirs have been summarized by Rhakmanov (1987) and were heavily used at times when drilling the subsurface had not been invented yet. Recent improvements in seafloor imagery and seismic exploration led to the discovery of countless mud extrusive provinces all over the world (Figure 1). In fact, compared to the compilation by Higgins and Saunders (1974), more than twice as many occurrences are presently known, with the number gradually increasing through time. Most importantly, mud volcanoes occur along convergent plate margins where fluid-rich sediment is accumulated in deep-sea trenches at high rates. Such deposits then enter the subduction factory, where liquids and volatiles are released due to incipient compactional stress and temperature. Studies of geophysical data and samples of mud volcanoes have considerably improved the understanding of the mechanics, driving forces, and evolution of the features through the most recent Earth history (e.g., Barber et al., 1986; Brown, 1990). In addition, deep ocean drilling and submersible studies shed crucial light on eruptivity, emission of volatiles, and potential hazard originating from violent mud extrusion (e.g., Bagirov et al., 1996; Robertson et al., 1996; Kopf, 1999). The wealth of results attests that mud extrusion predominantly occurs in collisional settings (i.e., zones of convergent plate motion), with mostly pore fluids during early (often marine) stages and hydrocarbons at later stages (often on land; e.g., Jakubov et al., 1971; Tamrazyan, 1972; Speed and Larue, 1992). Although quantification of fluid and mud discharge in mud volcanoes is not easy due to their short-lived nature and inaccessibility on the seafloor, first-order estimates regarding flux rates have recently been attempted for various features and regions (e.g., Henry et al., 1996; Kopf and Behrmann, 2000). When put into a broader context, such estimates indicate that mud extrusion contributes significantly to fluid backflux from the lithosphere to the hydrosphere. Along wide parts of large accretionary prisms (like the Barbados or Mediterranean Ridges), hundreds of features can cause fluid expulsion at rates exceeding those at the frontal part of the prism (see discussion in Kopf et al., 2001). Provided that the process of mud volcanism has been equally common in the past, these features have been major players in fluid and gas budgets and geochemical cycling in collision zones.

Formation, occurrence, and habitus

Mud volcanoes (MVs) are the surface expressions of deeply rooted vertical structures, and they are composed of coarse, poorly sorted "mud breccia" made up of materials which migrated upward from zones of overpressure. Sediment extrusion is driven by a mobile fluid phase, most often a mixture of aqueous and gaseous fluids (on Earth, water, hydrocarbons, and CO_2; on Mars: it is proposed to be partly methane). Mud volcanoe (MV) occurrences have the following aspects in common: (1) an origin from thick, rapidly deposited sequences of marine clays, (2) a tertiary age, (3) a structural association due to tectonic shortening and/or earthquake activity, (4) sediment overpressuring and accompanied fluid emission (free gas, brines, gas hydrate water, rarely oil), and (5) polymictic assemblages of the surrounding rock present in the ejected argillaceous matrix (e.g., Ansted, 1866; Higgins and Saunders, 1974; Fertl, 1976; Yassir, 1989; Kopf, 2002). Less commonly, volcanic and geothermal activity, often associated with ascent of hydrothermal fluids, may form mud domes and mud pools (e.g., at the basal flanks of the Costa Rica volcanic arc onshore). See Figure 2.

The possible causes of undercompaction are numerous, and sediment loading is one mechanism which may apply in any setting. It can be enhanced by rapid plate motion in


Mud Volcano, Figure 1 Map of global mud volcano occurrence based on compilation by Kopf (2002) and recent publications on individual regions (after Kopf, 2002).

fluid sources for overpressuring and mud extrusion:

(1) pore fluid expulsion from compaction
(2) biogenic methane from degradation of organic matter
(3) lateral fluid flux through stratigraphic horizons or fault zones
(4) fluid migration along deep seated thrusts
(5) thermogenic methane and higher hydrocarbons
(6) fluids from mineral dehydration (opal, smectite)
(7) hydrothermal fluids, alteration of crustal rock
(8) fluid expulsion from internal deformation within the diapiric intrusion

Mud Volcano, Figure 2 Schematic diagram of a mud diapir, MV extrusions (= mud volcanoes) and diatremes, including possible fluid sources (numbered 1–8); geochemically mature fluids may be found among categories *3*, *4*, and *7*; while categories *1*, *6*, *8*, water from dissociated gas hydrates may provide "freshened" fluids (after Kopf, 2002).

a subduction zone setting, because dewatering may not keep pace with the rate the undercompacted material is underthrust beneath the overriding plate. However, among the numerous other possibilities causing undercompaction, the most prominent are gas hydrate dissociation, tectonic loading, diagenesis and mineral dehydration reactions, hydrocarbon generation, aquathermal pressuring, or osmosis (e.g., Yassir, 1989). Several of these processes may act simultaneously in MV areas at depth, so that distinction between them is difficult. A summary of various origins for elevated pore pressures is given in Table 1.

On Earth, MVs are particularly abundant in Azerbaijan, the Caspian Sea, and the Eastern Mediterranean Sea, where their contributions to global budgets and fluid transfer from the geosphere to the hydrosphere/atmosphere are significant (Kopf et al., 2001). Smaller features are typically tens of centimeters of cm to a few meters high and

wide, while larger edifices may be up to hundreds of m high and several km wide (Kopf, 2002). In general, the largest features have been described for the Mediterranean Ridge accretionary complex, where seismic reflection data reveal pie-shaped (i.e., tabular), deeply rooting MVs of a few tens of kilometers across (Huguen et al., 2001; Huguen et al., 2004). Evidence for a deep origin of the ejecta is manifold, and mud and embedded clasts may originate from different (often shallower) levels than the aqueous or gaseous fluids (e.g., Robertson and Kopf, 1998; Kopf, 2002; Kopf and Deyhle, 2002; Dupré et al., 2014).

In terms of their morphology, the clast content usually defines the height, while viscosity and flux rate define the overall shape. Little information exists concerning the geometry of the conduit (or feeder channel) for ancient and modern examples. Surface observations indicate small diameters of 15 cm (Taiwan MVs; Yassir

Mud Volcano, Table 1 Causes for overpressuring, distinguished by their origin, mechanism, and corresponding geological setting. A selection of references is provided (Modified from Clennell, 1992)

Origin	Mechanism	Environment	Significance	Selected references
Burial	Sedimentary loading, compaction/settling	Any sedimentary setting, i.e., deltas, active and passive margins	Major in such settings	Braunstein and O'Brien, 1968 Morgan et al., 1968 Moon and Hurst, 1984

(1989) and 30 cm (Greece; Stamatakis et al. (1987) to 1.5 m (Burma; Pascoe (1912) and 2 m (Sakhalin; Gorkun and Siryk (1968). The first values agree well with cemented chimneys in the ancient "Verrua" MVs in Italy (Cavagna et al., 1998). Also, theoretical considerations and calculations based on Stokes' law indicate similar diameters of 2–3 m for the Mediterranean Ridge MVs (Kopf and Behrmann, 2000). However, some controversial data are reported for the feeder geometry at depth. From seismic data, conduits of 1.5–3.5 km width have been proposed for the Black Sea area (Limonov et al., 1997). Similarly, a width of 2 km has been proposed for the bigger of the Barbados Ridge features (Griboulard et al., 1998) and the Alboran Sea mud domes (Perez-Belzuz et al., 1997).

The relationship between the width of the conduit, the associated ascent velocity, and the resulting surface topography is simplistically illustrated in Figure 3 (assuming identical material properties in each case). Given the variable degree of fluid saturation and difference in overlying medium (seawater vs. air), differences in longevity/resistance to erosion and morphology exist between onshore and offshore features, not to mention extraterrestrial mud volcanoes (see next paragraph).

Natural examples of pockmark fields associated with mud volcanoes as well as onshore and offshore examples are presented in Figure 4 and are particularly abundant in thickly sedimented delta fans such as the Mississippi, Nile, or Niger deltas (e.g., Loncke and Mascle, 2004; Judd and Hovland, 2007; Sultan et al., 2014).

Mud volcanoes are commonly associated with neotectonic regions or natural gas fields, but exceptions to this rule are known. Extraterrestrial analogs are, e.g., Martian pitted cones (McGill, 2005). Undersea examples include Haakon Mosby, Napoli and Milano, El Arraiche (Morocco), Gulf of Cadiz, Barbados and Mediterranean Ridges; and Conical Seamount (Marianas Arc), while subaerial examples are Lusi, Dashgil, or Lokhbatan (Kopf, 2002; van Loon, 2010). Mud volcanoes serve as "valves" in many compressional belts, so that their episodic activity and associated transient changes in physical and chemical properties make them suitable indicators for, e.g., seismicity and other deep-seated processes (e.g., Hedberg, 1974; Manga et al., 2009). Next to active margins, MVs are also frequently associated with large deep sea fans such as that of the Nile (Loncke and Mascle, 2004), Niger, or Gulf of Guinea (Sultan et al., 2014). Here, the depth of origin of the ejecta is shallower, and clasts, a prerequisite of tectonic

Mud Volcano, Figure 3 Variable feeder geometries and associated surface topography of mud extrusive phenomena, assuming otherwise identical physical properties and buoyancy forces. Note the "negative" topography (i.e., depression) in case of high discharge rates, which often are associated with a depleted (or drained) reservoir at depth. Such mud domes or diatremes are difficult to distinguish from pockmarks and may actually be identical except that pockmarks do not involve upward transport of a solid phase. Figures illustrating the various features onshore are from (*left* to *right*): Appenines/Italy (A. Kopf/Univ. Bremen) 2 x; Georgia (V. Lavrushin/RAS Moscow).

forcing in collisional belts/subduction zones, are scarce or absent; naturally, the height of these features is low and depressions from degassing (formerly organic-rich sediment) are commonly observed.

Landforms derived from the same processes

Onshore examples versus offshore examples, difference in rate of erosion/ longevity between the two; sand volcanoes (Burne, 1970) in delta settings, restricted to rapid sediment accumulation and/or excess overburden stress as a trigger.

Similar landforms derived from different processes

The term "sedimentary volcanism" refers to the similar geometry of many mud extrusions and igneous volcanoes, and only very rarely are MVs connected with igneous

activity (e.g., von Gumbel, 1879; White, 1955; Chiodini et al., 1996). Magmatic volcanoes show fairly similar shapes (shield vs. cone), but comprise totally different material. Often the two are associated, e.g., hydrothermal fluids of arc volcanoes feed mud pools/volcanoes in Costa Rica.

Essential concepts and significance

The process of mud volcanism provides possible models for the origin of pitted cones and domes with various morphology on Earth (Kopf, 2002) as well as those on Mars, Venus, and several icy moons (Bradak and Kereszturi, 2003).

Mud volcanoes contribute significantly to the global fluid reflux from the geosphere to the hydrosphere,
Mud Volcano, Figure 4 Examples of pockmark and MV features: (**a**) active pockmarks 2 days after an EQ in the Hellenic subduction zone, off Greece (Courtesy of George Ferentinos); (**b**) aerial photograph of a large MV in Pakistan (Courtesy of Peter Clift); (**c**) crater lake of Dashgil MV, Azerbaijan, with the Caspian Sea in the background. Note heavy CH_4 bubbling (A. Kopf); (**d**) Fluid-bearing fault feeding a small MV on the Mediterranean Ridge accretionary complex (Modified after Kopf et al., 2011).

namely, in subduction zones (Kopf et al., 2001), while the amount of solid mass is usually not as prominent (Kopf, 1999).

Several studies have attempted to estimate the contribution of MVs to global methane emissions and effectively climate change (Dimitrov, 2002; Kopf, 2003; Milkov et al., 2003; Judd, 2005); however, and despite considerable variations in the database used and methane volumes estimated, it has been accepted that methane release is significant and probably has been over significant periods during Earth's history. The fate of some of the submarine methane remains controversial; however, even if a fraction is fixated as carbonates or oxidized to CO and CO_2 in the water column, there may be a contribution to global warming.

Mud volcanoes provide possible microhabitats in the subsurface, providing pathways for fluid migration and fracturing sediments through which MVs move sediments from depth to surface. This process is significant for deep biosphere research on Earth and may be important for astrobiological studies elsewhere (Oehler and Allen, 2010, 2011).

The first marine drilling campaign into MVs, Ocean Drilling Program Leg 160, attested that the initial deposits in MV formation were clast-supported, coarse sediments, whereas later stages of eruptive activity showed fewer clasts, no clasts, or even mousy (i.e., gas-rich) mud comprising almost pure clay (Robertson and Kopf, 1998). The resulting concept assumes that in fault-bound MVs, the initial deposit represents the fault breccia, and once that is removed, the underlying mud reservoir is depleted.

Current investigations

Microbial turnover rates at active MVs are fuelled by seepage at enhanced rates (e.g., Niemann et al., 2006), and a growing body of work is clustering around the best investigated features such as the Haakon Mosby MV off Norway or features in the Mediterranean, Gulf of Cadiz, or Gulf of Mexico. Given that the flux has been shown to be highly episodic (e.g., MacDonald et al., 2003), current research often involves long-term monitoring of key parameters, e.g., methane bubbling, aqueous fluid seepage, or temperature transients, as has recently been shown for Haakon Mosby MV (de Beer et al., 2006). Similarly, long-term probes were deployed in the Nile deep sea fan MVs, on the Mediterranean Ridge, or the Nankai prism in Japan. These studies build on long-term flux quantification by osmotic samplers, piezometers, or borehole instruments (Kopf et al., 2015) and unravel transient changes in

physical parameters that foster MV activity. Other work focuses on onshore settings such as the prominent Lusi mud volcano (Mazzini et al., 2007; Mazzini et al., 2009; Davies et al., 2008), whose triggering mechanism is controversially debated as being somewhere between anthropogenic and seismic. Similarly, other ongoing researches similarly address the seismic triggering of MVs and how groundwater flux in onshore settings (Rojstaczer et al., 1995; Chigira and Tanaka, 1997) as well as methane release in offshore settings (Tsunogai et al., 2012) may be associated with it.

Future prospects/research avenues: gaps in current knowledge

When taking the aforementioned aspect a step further, certain geophysical or geochemical transients can be utilized to identify earthquake precursory phenomena related to MV activity. Recent investigations of active domes in the Kumano Basin, Japan revealed that both methane plumes in the water column (Tsunogai et al., 2012) and/or pore pressure and temperature transients in the formation can be related to seismicity. Historical records further attest that the chemistry of both aqueous and gaseous fluids changes a few hours up to a few days prior to large earthquakes, most likely as a result of stress changes at depth (Kopf et al., 2005). This finding may represent a versatile way to use MVs as stress indicators because of their fluid-rich nature and hydraulic connection to depth. They function similar to a valve; stress changes from deformation before, during, and after EQs may be discernable as transients in pore pressure, fluid chemistry, and mud or gas discharge rates if affordable instruments with standardized data protocols were widely used.

Summary and conclusions

Mud volcanoes represent a global phenomenon where significant amounts of solids and fluids interact between the geosphere and hydrosphere, thereby providing a window to depth otherwise hardly accessible by, e.g., drilling. Ascent is driven by buoyancy and aided by faults and other pathways, with the MVs being hydraulically connected to depth and hence may be capable of recording stress variations and precursors to geohazards. Hydrocarbon emissions from MVs are suspected to not only contribute to greenhouse climate but also to serve as indicators for reservoirs at depth.

NANNOFOSSILS COCCOLITHS

Hans R. Thierstein
Department of Earth Sciences, Swiss Technical
University, Zürich, Switzerland

Definition
Nannofossils/coccoliths: Minute (ca. 10^{-6} m) calcite skeletons, produced by marine phytoplankton and found in deep-sea sediments

General significance
Coccolithophorids are a major group of primary producers in the photic zone of the world's oceans today. Their single cells (coccospheres) are covered by coccoliths, which are structured aggregates of calcite crystallites (Figure 1).

The calcite platelets (coccoliths) covering these cells sink to the ocean floor and form the dominant part of the calcareous oozes that are found on most ocean floors at water depths of less than 4–5 km (i.e., above the CCD). Vast amounts of nannofossil chalks have accumulated on the world's ocean floors since the late Jurassic. Nannofossils include coccoliths and a few other biogenic remains of similar size, such as calcitic cysts of dinoflagellates (*Thoracosphaera* sp.), or of unknown taxonomic affinity, such as star-shaped *Discoaster* sp. in Tertiary sediments or rock-forming *Nannoconus* sp. in Cretaceous deposits.

Coccoliths and nannofossils have been used in the dating of sediments (biostratigraphy), in the reconstruction of the history of the world's oceans (paleoceanography), and in the analyses of evolutionary processes (Figure 2).

Biostratigraphy
Nannofossils have become very important in the determination of the geologic age of fine-grained, marine sediments (Perch-Nielsen, 1989; Bown, 1999) both in academic research and in oil exploration. Nannofossils are a major constituent of many marine sediments (up to 90 % in calcareous oozes), they are a highly diverse group (up to 150 known species in the late Cretaceous), and they can be quickly prepared on smear slides and examined in a polarizing light microscope. A quantum step in our knowledge of the taxonomy and biostratigraphy of nannofossils – and of many other marine microfossil groups – was taken with the initiation of systematic drilling of the world's ocean floors by the Deep-Sea Drilling Project in 1967.

Paleoceanography
This field was initiated with the publication of *Studies in Paleo-Oceanography* (Hay, 1974) containing the first integrated attempts to reconstruct aspects of the history of the world's oceans. Since then, various paleoceanographic proxies – prominently among them are nannofossils – were used to reconstruct the history of surface currents, long-term changes in water temperature, carbonate saturation of oceanic water masses, primary productivity, etc. (e.g., Stoll and Ziveri, 2004). Correlations between coccolith sizes of certain taxa and calcification and pCO_2 changes in laboratory experiments and a sediment core may hold potential for a new paleoproxy
Nannofossils Coccoliths, Figure 1 Coccospheres of *Emiliania huxleyi* (left) and *Calcidiscus leptoporus* (right) as revealed in a scanning electron microscope. The coccospheres sit on a filter through which a water sample was rinsed from 25 m water depth off Bermuda (North Atlantic) on 1 May 1991.
Nannofossils Coccoliths, Figure 2 Scanning electron micrograph of a Cretaceous nannofossil chalk showing a still intact coccosphere of *Watznaueria barnesae* embedded in rock particles which are mostly coccoliths and fragments of them. This sample is from 200 m below seafloor at DSDP Site 258, which was drilled on Exmouth Plateau (off SE Australia) at a water depth of 3 km.

for past global climate changes (e.g., Iglesias-Rodriguez et al., 2008).

Evolution

About 250 coccolithophore species are known to live in today's ocean waters (Young et al., 2003), but coccoliths of only about 50 of them are found in recent deep-sea sediments (Bown et al., 2004). The long-term species diversity history shows a rather gradual increase from 230 Ma (mid-Triassic) to an all-time high of about 140 species at 70 Ma (late Cretaceous), followed by a drastic reduction at the K/T boundary (65 Ma) and numerous fluctuations throughout the Cenozoic (Bown et al., 2004). The causes

for these species richness changes or of other macroevolutionary parameters, such as coccolith size of individual species or entire assemblages, however, remain enigmatic (Langer et al., 2006; Herrmann and Thierstein, 2012).

Summary and conclusions

Nannofossils and coccoliths are the microscopic remains of single-celled planktonic algae that have lived in the world's oceans for about 230 Ma. Nannofossils are found in many calcareous rocks and help geologists to tell the age of these deposits and the environmental conditions at that time.

NITROGEN ISOTOPES IN THE SEA

Thomas Pedersen
School of Earth and Ocean Sciences, University of Victoria, Victoria, BC, Canada

Definition

Nitrogen has two stable isotopes, ^{14}N and ^{15}N, comprising, respectively, 99.64 % and 0.36 % of the nitrogen atoms on earth. The isotopes are fractionated one from the other in a wide variety of biochemical processes in the sea (see Sigman et al., 2009, for a comprehensive review). Measurements are reported in the delta notation, relative to nitrogen in air (N_2):

$$\delta^{15}N\ (‰) = \left[\frac{\left(^{15}N/^{14}N\right)_{sample} - \left(^{15}N/^{14}N\right)_{air}}{\left(^{15}N/^{14}N\right)_{air}} \right] \times 1{,}000$$

Understanding of fractionation phenomena has accelerated rapidly in recent decades and has shed important new light on, for example, nutrient cycling in the modern and past ocean (see Galbraith et al., 2008, for a review).

Dissolved nitrogen occurs in the sea in a wide variety of molecules and ions, including N_2 (gas), nitrate (NO_3^-), nitrite (NO_2^-), ammonia (NH_3), ammonium (NH_4^+), and urea. Fractionation occurs primarily during the transformation of one such nitrogen-bearing species to another:

- Nitrogen fixation, or diazotrophy, is the conversion of triply bonded N_2 (gas) to reduced N species (like NH_4^+) by nitrogen-fixing cyanobacteria in the surface ocean, with only modest kinetic discrimination against the heavy isotope (0 to -2 ‰). Such fixation is the principal pathway by which dissolved nitrogen species are introduced to the ocean.

- Denitrification occurs in oxygen-minimum zones in the subsurface below roughly 100–300 m and ~1 km water depth off NW Mexico, Peru, Namibia, and Western India, for example, and refers to the stepwise bacterially mediated conversion of NO_3^- to N_2 (gas). This has a large fractionation factor (~25 ‰; Brandes et al., 1998), producing isotopically light end product N_2 and enriched residual nitrate with $\delta^{15}N$ values as high as +20 ‰ in waters several 100 m below the surface.

- Denitrification also occurs in the pore waters of almost all continental margin sediments, but because NO_3^- is typically completely consumed in such deposits, there is normally no net (overall) isotope fractionation between the N_2 gas product and the nitrate precursor.

- Anaerobic ammonium oxidation (anammox) is a relatively recently discovered process in the sea, first reported in 2002. Nitrite (produced either by nitrate reduction or oxidation of ammonium) serves as an electron acceptor (thus, an oxidant) in the bacterially mediated anaerobic oxidation of NH_4^+. The effect of anammox on nitrogen isotope distributions in the sea is as yet poorly known.

NORTH ATLANTIC OSCILLATION (NAO)

Erik Kjellström
Swedish Meteorological and Hydrological Institute, Norrköping, Sweden

The large-scale atmospheric circulation in the North Atlantic sector is characterized by westerly winds that result from the meridional pressure gradient between the Azores High in the south and the Icelandic Low in the north. As the strength of this pressure gradient varies over time, also the strength of the westerlies varies. In periods of strong north-south gradient, the westerlies are more pronounced and vice versa when the gradient is weak. Fluctuations between these different states are known as the North Atlantic Oscillation (NAO).

The strength and phase of the NAO can be summarized by an index (NAOI). There exist a few different NAOI definitions. The most commonly used is likely the one comparing normalized mean sea-level pressure (MSLP) in Iceland and in Portugal (Hurrell, 1995). One of its main strengths is that this type of NAO index can be derived also for historical times as surface pressure readings exist at some locations dating back to the nineteenth century. Other definitions, such as those based on principal component analysis (PCA), are also commonly used (e.g., Barnston and Livezey, 1987). A benefit of the latter type of methods is that they can better depict variability/changes in the center of action of the NAO.

The NAO has a profound impact on the climate in the North Atlantic region. During winter the positive phase is associated with temperatures below average in western Greenland and southern Europe and above average in large parts of the eastern USA and northern Europe. At the same time, the precipitation is above average in northern Europe and in the eastern USA and below average in southern Europe and western Greenland. In the negative phase of the NAO, opposite anomalies are found in temperature and precipitation in these areas. Also in summer, there are impacts on the climate with distinct differences between northern and southern Europe in the respective phases of the NAO (Folland et al., 2009).

As the large-scale pressure pattern varies on different time scales, fluctuations in the NAOI are seen starting already at daily time scales ranging over weeks and months to seasons or years or even decadal time scales. Studies of the temporal behavior of the NAOI show some weakly significant and intermittent oscillations on quasi-biennial and quasi-decadal time scales (see review of Wanner et al., 2001). This shows that the NAO is not a pure random process indicating that there may be predictive potential associated with it.

O

OCEAN ACIDIFICATION

Ulf Riebesell
GEOMAR Helmholtz Centre for Ocean Research Kiel, Kiel, Germany

Ocean acidification refers to the process of increasing seawater acidity by dissolving additional carbon dioxide (CO_2) from the atmosphere.

As CO_2 dissolves in seawater, it forms carbonic acid (H_2CO_3), which readily dissociates into bicarbonate (HCO_3^-) and hydrogen (H^+) ions. The hydrogen ion concentration determines the acidity of seawater, expressed by the pH scale. Part of the hydrogen ions released in this process is buffered by the seawater carbonate system by consuming carbonate ions (CO_3^{2-}) and forming additional bicarbonate. As pH is defined as the negative logarithm of the hydrogen ion concentration, pH decreases as the acidity increases (Figure 1).

The increase in atmospheric CO_2 concentration since preindustrial times from 280 ppm (parts per million) to ca. 400 ppm has caused a decline in surface ocean pH by 0.12 units. This corresponds to an increase in seawater acidity (hydrogen ion concentration) of 30 %. If atmospheric CO_2 concentrations continue to increase at present rates, surface ocean pH values will decline by an additional 0.35 units by the year 2100 (Wolf-Gladrow et al., 1999). This corresponds to more than a doubling in seawater acidity and a decline in carbonate ion concentrations by 45 % relative to preindustrial levels. These changes in seawater chemistry are expected to widely affect marine organisms and ecosystems (Raven et al., 2005). Most prominently, calcifying organisms such as corals, bivalves, sea urchins, coralline algae, and a variety of calcareous plankton species have shown to be sensitive to ocean acidification (Gattuso and Hansson, 2011). Equally important as the magnitude of ocean acidification is its rate of change, as this determines to what extent species have the ability to adapt. The current speed of CO_2 increase in the atmosphere and the corresponding rate of ocean acidification are unprecedented in Earth's history for at least 300 million years (Hönisch et al., 2012).
Ocean Acidification, Figure 1 The process of ocean acidification: (*1*) atmospheric carbon dioxide (CO_2) dissolving in seawater; (*2*) dissolved CO_2 reacting with water to form carbonic acid (H_2CO_3); (*3*) carbonic acid dissociating to bicarbonate (HCO_3^-) and hydrogen ion (H^+); and (*4*) hydrogen ion reacting with carbonate (CO_3^{2-}) to form bicarbonate. As a result of ocean acidification, the concentrations of CO_2, HCO_3^-, and H^+ increase, whereas the pH and CO_3^{2-} concentrations decrease.

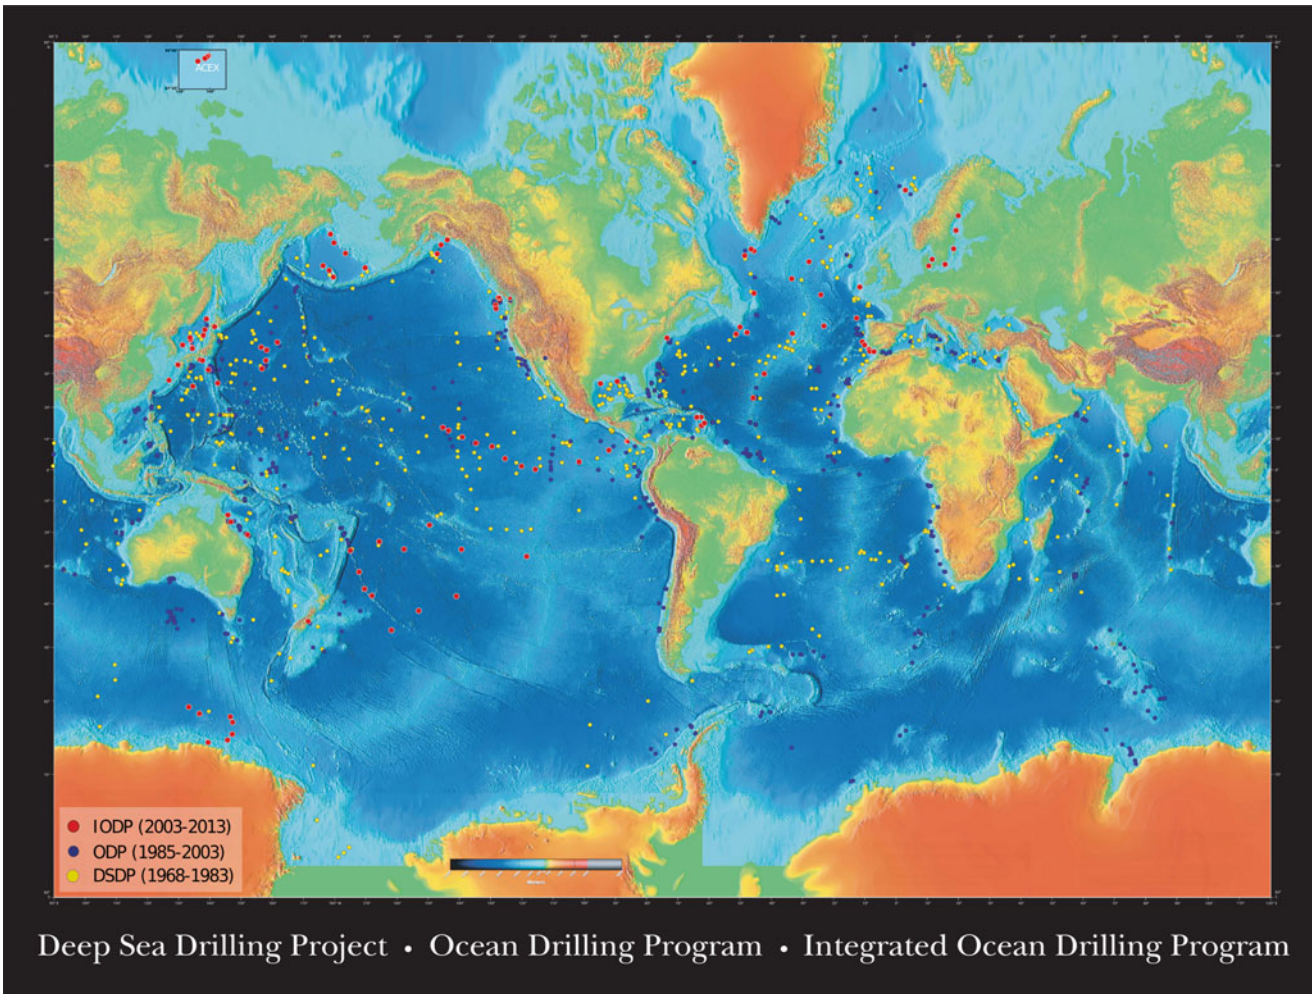
OCEAN DRILLING

Kiyoshi Suyehiro
Integrated Ocean Drilling Program, Management International, Tokyo, Japan

Definition

Ocean drilling broadly refers to science conducted by utilizing ocean drilling platforms (vessels) to retrieve material samples and measurements from boreholes drilled beneath the seafloor in deep seawater not achieved by other shallow sampling methods such as dredging, gravity coring, or shallow piston coring (Figure 1).


Ocean Drilling, Figure 1 World map view of ocean drilling sites drilled through DSDP (1968–1983, 624 sites), ODP (1984–2003, 669 sites), and IODP (2004–2013, 127 (up to U1427) + 58 (up to M58) + 22 (up to C22) = *207* sites) era (1968–2013). IODP sites are shown with abbreviated expedition names. ACEX sites (Exp. 302, Lomonosov Ridge, M2-4) in small box are at 87°51–56′N latitudes. Southernmost sites (270–272) are at latitudes 77°07–43′S (DSDP Leg 28, Ross Sea). (Seafloor bathymetry deepens with oceanic plate age. High anomalies depict ocean ridges, island arcs, hot spots, large igneous provinces, and continental margins, and lows indicate ocean trenches. These and the configuration of oceans including gateways control the ocean circulation driven by atmospheric motion. The drill sites are not as geographically uniform or dense as compared, e.g., to the Argo float monitoring network (www.argo.ucsd.edu)).

Scientific analyses are applied to the samples (cores with interstitial waters) obtained by wire line coring and downhole measurements made by logging tools. Long-term borehole observatories are established in some cases to obtain time series records. These data and samples are used to describe and understand the Earth's history, structure, and processes that shaped the present-day Earth system and to predict its future from a wide spectrum of disciplines of marine geo-biosciences.

The framework for conducting scientific ocean drilling was established in 1968 and in 1975 became an international scientific program with participating member countries and consortia from the Americas, Asia, Europe, and Oceania to support the operations of drilling vessels and science to be conducted on board. Scientists interested in obtaining samples and data from boreholes in world oceans submit proposals for eventual drilling expeditions or request samples from archives to be evaluated by peer

review. Scientists compete to make their cases why drilling in a particular geographical locality can help in solving problems of fundamental or global importance that cannot be achieved otherwise.

The progress of scientific ocean drilling can be described in terms of technological advancements in core sampling and downhole measurements, program management, and scientific achievements.

Ocean drilling history

The history of scientific ocean drilling starts from the Mohole Project Phase 1 (1958–1966), which eventually aimed to penetrate the Mohorovičić discontinuity, which is the seismic velocity discontinuity that separates the crust and the mantle (Bascom, 1961). The Mohole Project started from engineering developments, as scientific ocean drilling from a vessel without anchoring in deep water had not existed. On April 2, 1961, *CUSS I* with a dynamic positioning system to keep its station made its historic achievement of sampling basalt beneath 183 m of sediments in 3,658 m of water depth offshore Guadalupe Island. Although this Phase 1 was a success, technical difficulties and financial constraints prevented the project to advance to the next phase.

The success of Phase 1 opened the era of scientific ocean drilling more focused on sediments and shallow crustal drilling at many geographical locations rather than aiming for a few deep crustal penetrations. Exploration of the sediments builds on the success of Kullenberg piston corers (e.g., Swedish deep-sea expedition Albatross 1947–1948). These led to successful years of scientific programs: Deep Sea Drilling Project (1968–1983), International Phase of Ocean Drilling (1975–1983), Ocean Drilling Program (1985–2003), Integrated Ocean Drilling Program (2003–2013), and International Ocean Discovery Program (2013–2023) (Table 1).

After the retirement of the drilling vessel, *Glomar Challenger* for DSDP (Legs 1–96), *JOIDES Resolution* (*JR*) was introduced from ODP (Legs 100–210; a Leg is typically about 8 weeks long with about 25 scientists on board) and 32 *JR* expeditions for IODP (similar to ODP mode). IODP has been a major upgrade for scientific ocean drilling as the participating countries had agreed to operate three uniquely capable drilling platforms to expand the potential drilling targets to ice-covered, very shallow (a few tens of meters water depth), or very deep water drilling (>~5 km) (Figure 2).

The European Consortium for Ocean Research Drilling (ECORD) introduced chartered drilling vessels for IODP in 2004. This type of platform is called Mission-Specific Platform and is aimed to drill in waters where *JR* is not the optimal platform. The first MSP was a fleet of vessels to drill in ice-covered Arctic Sea (Exp. 302). In 2007, a riser-equipped drilling vessel *Chikyu* joined the program as planned for IODP. *Chikyu* is capable of drilling deeper because the riser pipes that allow mud circulation to prevent hole collapse are normally used by the oil industry.

Ocean Drilling, Table 1 Ocean drilling platforms

Glomar challenger (DSDP, retired 1983)
Built 1968: 123 m length, 20 m breadth, 10,500 t displacement (LT)
Maximum drilling/coring depth: 8,375 m (reentry depth 7,960 m)
Drilling water depth: >6,000 m
JOIDES Resolution (ODP and IODP (overhauls in 1984 and 2009, scientists 25))
Built 1978: 143 m length, 21.3 m breadth, 10,282 gross tonnage
Maximum drilling/coring depth: 8,375 m (reentry depth 7,960 m)
Drilling water depth: 75 m to >6,000 m
Wire line coring retrieval rate: ~200 m/min
Chikyu (IODP, scientists and lab staff 50)
Built 2005: 210 m length, 38 m breadth, 56,752 gross tonnage
Maximum drilling/coring depth: 10,000 m
Drilling water depth: 500–2,500 m (riser drilling mode)
Wire line coring retrieval rate: ~150 m/min
Mission-Specific Platforms (IODP; various chartered platforms outfitted with drill rigs)
Vidar Viking, Oden, and Sovetskiy Soyuz were utilized for drilling through the Arctic ice (Exp. 302). Other expeditions by *DP* (dynamically positioned) *Hunter* (Exp. 310), *L/B Kayd* (liftboat, 313), *Greatship Maya* (325), and *Greatship Manisha* (347)

Currently, *Chikyu* can drill in riser mode to 2,500 m water depth with 10,000 m drill pipes. During IODP, five MSP expeditions were conducted (Exps. 302, 310, 313, 325, 347, Arctic Sea and shallow waters). *Chikyu* was mostly engaged in a multiple-expedition project to drill and study the plate subduction fault off central Japan capable of generating M8-class earthquakes (ten expeditions). *JR* holds the record of penetrating deep in oceanic crust (2,111 m below seafloor (mbsf) as of 2013) at Hole 504B, and *Chikyu* holds the record of deep drilling in thick sedimentary sequence of continental margin (2,466 mbsf as of 2013) at Hole C0020.

The *Glomar Challenger* (*GC*) visited 624 sites during DSDP and cored 97 km total length at 57 % recovery rate. *JR* visited 669 sites during ODP and cored 222 km at 69 % recovery rate.

In a few occasions, *JR* has drilled in shallow water depths at <500 m (38 m water depth test (Leg 143) and other legs such as Leg 194 in 304 m, Exp. 307 in 420 m, Exp. 317 in 84 m, and Exp. 334 in 137 m). Deepwater depth drillings have been successfully made in depths well exceeding the normal ocean basin depths (e.g., Leg 129 in 5,980 m (*JR*), Exp. 343 in 6,898 m (*Chikyu*)).

Scientific ocean drilling owes much to the technology of dynamic positioning and wire line coring. The former allows the drillship to sail almost anywhere in the world oceans in deep waters and drill at the desired location keeping the position. The latter allows continuous coring without retrieving the drill string. The precision of absolute position on Earth and relative location in a particular seafloor locale has improved over the years by GPS positioning and seafloor swath bathymetry. The ability to recover as much as possible from beneath the seafloor owes much to the drilling technology, i.e., cutting into

Ocean Drilling, Figure 2 Drilling platforms utilized in the current IODP program (see Table 1). *JOIDES Resolution* has been operating since the start of ODP. *Chikyu* operated by Japan Agency for Marine-Earth Science and Technology is a new addition with long-awaited riser drilling capability suitable for deep drilling. Mission-Specific Platform charters are an operationally optimal platform for drilling not suitable for *JR* or *Chikyu*, such as ice-covered or shallow waters.

the sediments and rocks by drill bits. The wire line corer (typically each core trip brings on board a cylindrical sample (9.5 m length with 6.2 cm diameter)) runs up and down inside the drill string as the drilling advances the corer length. The actual drilling is made by various designs of corers determined by the physical properties of the cores to be taken. This is why a detailed site survey before drilling is essential to anticipate the samples. In soft sediments, hydraulic piston coring can be employed with minimum disturbance to the obtained cores as it involves a vertical downward thrust motion to penetrate deeper without drill bit rotation (Figure 3).

Once a hard rock stratum is reached or the sediments get too consolidated and hard for piston coring, rotary core barrel (RCB) with a core bit at the bottom is used (Figure 3). This system has been used throughout the history of scientific ocean drilling. See literature for other variations and details (e.g., Huey, 2009). Coring challenges are met at hard rocks, chert layers, alternating soft and hard materials such as sills into sediments, or high-temperature environments such as proximities of hydrothermal vents.

Ocean drilling logistics and technology

Scientific ocean drilling is a basic research and has been open to any scientists to submit drilling proposals with clear targets and objectives. A successful drilling proposal will demonstrate that drilling is a unique method to advance the state of scientific understanding in a significant way. Overall decadal-scale scientific goals are defined through open international debate (ref. in Table 3), by which each proposal is evaluated for merits. Such goals have evolved from understanding the history and structure of the Earth to physical and chemical processes that shaped the present state of the Earth with increasing interest in the role of the sub-seafloor biosphere and relating to the future of the habitable planet Earth.

Drilling is the most expensive part of the scientific quest for new discoveries and verifications (e.g., IODP budgets and expenditures are given in IODP Annual Reports). International participation by national science funding agencies and institutions has supported the ocean drilling since 1975 (Table 2). As of 2013, there are 26 countries participating as 6 countries and 2 consortia (the USA, Japan, PRC, Brazil, India, South Korea), ECORD (Austria, Belgium, Canada, Denmark, Finland, France, Germany, Iceland, Ireland, Israel, Italy, the Netherlands, Norway, Poland, Portugal, Spain, Sweden, Switzerland, the UK), and ANZIC (Australia, New Zealand). The international cost sharing is dedicated to providing the common infrastructure to be enjoyed by all the scientists supported by the participating member countries through international governmental agreements. Each of the drilling expeditions is conducted as an ocean drilling community project with chief scientists (most often cochiefs) nominated to oversee the science. Normally, scientific analyses take place at each scientist's home
Ocean Drilling, Figure 3 Coring tools. Improvements are continuously made to increase core recovery rates in difficult formations such as hard-soft alternating layers, high temperature, very hard rocks, or chert layers. They allow the core barrel to hydraulic piston coring to be used for *APC* (advanced piston corer for *JR*) and *HPCS* (hydraulic piston coring system for *Chikyu*) to recover undisturbed samples in soft sediments. Beyond the depths of piston coring, *RCB* (rotary core barrel) is utilized, where the drill bit rotates downward to recover core sample into the core liner. Core disturbance is inevitable. Another often-utilized tool is XCB (extended core barrel for *JR*) and *ESCS* (extended shoe coring system for *Chikyu*) (not shown). Its principle is to allow the core barrel to capture the core a few inches ahead of the main bit roller cones (e.g., Huey, 2009).

institution for eventual scientific publications. Each country funds this part. In essence, drilling and sampling are the common infrastructure supported internationally, and all the rest is left to normal scientific competition.

The data and findings are made openly and freely available (www.iodp.org). All obtained core samples are archived at core repositories (core repositories in North America, Europe, and Asia store cores from global oceans according to geographical location; Table 3) ready to be utilized for new hypotheses to be verified or to be scrutinized by advanced analyses. Scientific drilling attempts not to directly seek natural resources for commercial purposes but to look into their scientific significance.

The drill site needs to be characterized by geological and geophysical methods such as the seafloor geomorphology and seismic reflection data to warrant the discovery to be made with good chance in a safe manner. A special international proposal evaluation scheme has been established to allow for international experts in scientific disciplines and drilling technology to advise the proponents and plan for an optimal drilling schedule. This voluntary science advisory system is the core of selecting proposals for scheduling based on scientific merits and technical feasibilities.

Once a drilling proposal is adopted for scheduling, an international science team is assembled to define a scientific project to achieve the proposal objectives considering all the technical aspects of drilling offshore including weather and ocean conditions. The team covers all aspects of required expertise: sedimentology, paleontology, paleomagnetism, petrology, organic and inorganic geochemistry, microbiology, physical properties, etc. Chief

Ocean Drilling, Table 2 A brief history of scientific ocean drilling

1961	US Project Mohole Phase 1: *CUSS I* keeping its position at 3,558 m water depth (dynamic positioning) off Baja California proves deep-ocean core drilling and samples basalt beneath fossil-rich sediments
1963	US Project LOCO: *Submarex* cores tertiary sediments on the Nicaragua Rise in the Caribbean Sea
1964	JOIDES (Joint Oceanographic Institutions for Deep Earth Sampling) is formed: Lamont Geological Observatory (now Lamont-Doherty Earth Observatory), Inst. of Marine Science (now Rosenstiel School of Marine and Atmospheric Science), Scripps Institution of Oceanography, and Woods Hole Institution of Oceanography
1965	US Project CALDRILL: JOIDES conducts a transect drilling on the Blake Plateau off Florida
1968	US Project DSDP (Deep Sea Drilling Project) starts with *Glomar Challenger* as the drillship. DSDP Leg 1 is conducted in the Gulf of Mexico to find a salt dome and traces of petroleum
1969	DSDP Leg 3 in the Atlantic Ocean verifies the seafloor spreading hypothesis
1975	DSDP enters an international phase (International Program for Ocean Drilling, IPOD) with the participation of the Federal Republic of Germany, Japan, the UK, USSR, and France
1979	Hydraulic piston coring becomes available in DSDP. Sediment cores are sampled with little disturbance
1979–1983	A series of experiments of borehole seismometer installations conducted. Ocean sub-bottom seismometer (Sites 482, 494, 543, 581) and marine seismic system (Sites 395, 595)
1981	The first international Conference on Scientific Ocean Drilling (COSOD) held at the University of Texas
1985	Ocean Drilling Program (ODP) is started with *JOIDES Resolution* as the drillship
1987	Second COSOD held in Strasbourg, France, to redefine the future of ocean drilling science
1989	Digital ocean bottom downhole seismometer experiment (Leg 128)
	Oldest Pacific Ocean crust dated at 170 Ma (Leg 129)
1991	Sub-seafloor hydrogeology observatory experiment (CORK) started (Site 858 and subsequently many others)
1993	ODP Leg 148 reaches 2,111 m below seafloor (deepest ocean basin borehole)
1998	Ocean Seismic Network first installation (OSN-1, Site 843, ION prototype)
1999	Conference on Multiple Platform Exploration (COMPLEX) of the Ocean held in Vancouver, Canada
1999–2001	Borehole seismo-geodetic observatories installation in western Pacific (ION Sites, 1150, 1151, 1179, 1201)
2004	Integrated Ocean Drilling Program (IODP) is started utilizing three drilling platforms. The *JOIDES Resolution* embarks on the first cruise (Expedition 301)
	The first Mission-Specific Platform expedition of ECORD (European Consortium for Ocean Research Drilling) utilizes the *Vidar Viking* to core at the Lomonosov Ridge in the Arctic Ocean through the ice

Ocean Drilling, Table 2 (*Continued*)

2007	The first riser-equipped drillship *Chikyu* of JAMSTEC (Japan Agency for Marine-Earth Science and Technology) sails on IODP Expedition 314
2009	IODP New Ventures in Exploring Scientific Targets (INVEST) Conference in Bremen, Germany, to set the course of ocean drilling science in 2013 and beyond
2012	*Chikyu* sets the deepest scientific coring depth at 2,466 m below seafloor (Exp. 337)
	Chikyu installs thermistor string across the fault zone of the 2011 Tohoku earthquake (M9.0). Recovered with data in 2013
2013	The International Ocean Discovery Program succeeds IODP

Core repositories

Bremen Core Repository in Bremen, Germany, hosts DSDP, ODP, and IODP cores from the Atlantic Ocean, Mediterranean and Black Seas and Arctic Ocean (http://www.marum.de/en/IODP_Bremen_Core_Repository.html)

Gulf Coast Repository in Texas, USA, stores DSDP, ODP, and IODP cores from the Pacific Ocean, the Caribbean Sea and Gulf of Mexico, and the Southern Ocean (http://iodp.tamu.edu/curation/gcr/)

Kochi Core Center (joint with Japan Agency for Marine Science and Technology and Kochi University) in Kochi, Japan hosts DSDP, ODP, and IODP cores from the Indian Ocean and seas of Asia and Oceania (http://www.kochi-core.jp/en/)

Ocean Drilling, Figure 4 Core sample photographs. A few examples from a vast collection of legacy cores since DSDP openly available to scientists from core repositories. **a** Exp. 302 M0004-11× (297.30–301.35 m; ~49 Ma): there is an extremely dense concentration of remains of the hydropterid (freshwater) fern *Azolla* – unprecedented in other Eocene sections yielding *Azolla*. The event testifies to an extreme change in environmental conditions at the base of the *lower* middle Eocene (Lutetian) (from Proc. IODP 302, 2006). **b** Exp. 312 1256D-223R (1450.78–1452.28 mbsf): gabbro (*lower* crustal rock) section first recovered from the Pacific Ocean after ODP Leg 206 and IODP Exp. 309 at Hole 1256D. **c** Exp. 343 C0019-17R (821.5–822.5 mbsf): strongly deformed clays inferred to be the slip zone (decollement) of the 2011 Tohoku earthquake fault (Proc. IODP 343, 2013) (This photo was taken before cutting into halves (from CDEX, JAMSTEC)).

scientists are required to synthesize the results from different disciplines in order to prove, alter, or disprove the hypotheses they conceived. This characteristic norm of an ocean drilling expedition, in which an international team of scientists works around the clock for about 2 months isolated from land, offers a unique experience to each scientist. The drillships (Chikyu and JOIDES Resolution) are equipped with laboratory equipments for shipboard scientists to conduct core sample analyses to complete a preliminary report before returning ashore. It is a collective, concerted, and concentrated effort for the team on board often having to deal with contingencies on the spot under the pressure of time.

As a drill core (typically 9.5 m long) is recovered from depth on deck, it is cut into 1.5 m sections (Figure 4). The sample from the core catcher at the bottom provides microfossil data (micropaleontology) for dating. An X-ray CT (computed tomography) scanner is a tool on *Chikyu* that offers a 3-D look (X-ray attenuation in response to irregularities inside the core) of the core before dissection. Interstitial water and whole-round core section may be taken for geochemical and microbiological studies. Nondestructive standard measurements of P-wave velocity, gamma-ray attenuation (GRA) density, magnetic susceptibility, electrical resistivity, and natural gamma-ray radiation are made to estimate density, porosity, permeability, or magnetic signatures after the core temperature is stabilized. It is then customary to split the core into archive half and working half. Visual core description is made on the archive half together with other nondestructive measurements (photo, magnetism, etc.) that is subsequently stored in containers. Working halves are to be dissected by scientists as discrete samples for analyses on board and onshore. Geological age determination of obtained samples is an important process and is estimated from paleontological and geomagnetic observations before radiometric age determination is made onshore. Physical properties, X-ray diffraction, and organic and inorganic geochemical parameters are also obtained on

board. Microscopes of various resolutions (optical, digital, and scanning electron microscopes) are powerful tools to identify microfossils and determine petrology to elemental composition level. All the initial results from these observations and measurements are described in a single publication for each cruise. Parameters of interest are also searchable across all cruises from the IODP database system (sedis.iodp.org).

Another important source of information of the borehole is to use downhole logging tools to measure physical, chemical, and structural properties through the borehole wall. These tools provide continuous records of in situ data such as sonic velocities, density, or electrical resistivity that complement the core measurements which may be limited by the recovery rate or biased by drilling disturbances.

Ocean drilling science

The human habitable zone, which is the land surface of the Earth, is at the juncture of the fluid sphere (atmosphere and hydrosphere) and the solid sphere. Energy and material movements from above and below (ocean and air circulations and internal mantle/core convections) define the state of the Earth at the surface including the ecosystem. Ocean drilling science contributes in describing these processes from the records of the past in the sediments and igneous rocks below and from in situ borehole measurements. Paleoceanography is a field of science borne out of ocean drilling.

Climate history

For any data of geological past scattered around the globe, time marking is essential in marking precise dates and obtaining time derivatives for the specimens of interest and tying them to plate tectonics, climate, paleoceanography, and life evolution. Biological time markers (planktonic microfossils) are established for the last 150 Ma. These are linked to magnetic polarity reversals and to radiometric absolute age of rocks. The resolution

is as fine as 0.1 Ma level and can be further refined by tuning in to the Earth's orbital change (Milankovitch cycles (20–100 kyr)) detectable in sediment cores. Drilling in corals and high-sedimentation-rate sites allows for even higher temporal resolution. Since the ocean floors are destroyed by subduction, the oldest core sample is ~170 myrs old (ice cores <~800 kyr) covering ages since Jurassic. Drilling data contributed in defining the average temperature change over this time period, mostly warmer than the present Earth but covering the period without continental ice ("greenhouse Earth") and the period with ice sheets present ("icehouse Earth").

While the basic geological inferences come from lithostratigraphy, core specimen also provides information on past environments from oxygen isotope ratios and planktonic or benthic microfossils to infer the surface and bottom temperatures, which in turn infer continental ice volumes. The balancing depth of the carbonate supply and its dissolution rates called CCD (calcite compensation depth) was found to have abruptly deepened at about the time of the Antarctic glaciation (Pälike et al., 2012). Recent finding dates the Antarctic glaciation onset to 33 Ma and to be influenced by the atmospheric carbon dioxide; it also coincides with the separation of Australia and South America from Antarctica. Such findings form and advance the field of paleoceanography. It is now possible to infer atmospheric carbon dioxide concentrations to link to past warm climates. These past time series in a short time scale (decadal to millennial) indicate abrupt climate changes likely to be associated with the "flip-flop" of deep-ocean circulation in the North Atlantic. In the longer time scale is the shift from warm climates to the current era with cryosphere. Organic carbon-rich layers from the mid-Cretaceous suggested prevailing anoxic conditions during warm ocean time ("greenhouse"). Drilling in high latitudes elucidated continental glaciation timings as well as developments of ocean current pathways (e.g., Antarctic bottom water or North Atlantic bottom water or isolation of Pacific and Atlantic Oceans at Isthmus of Panama). A significant recent IODP discovery was obtained by drilling in the Arctic Ocean for the first time to go back 55 myrs and to find freshwater fern in 49 Ma when there was no ice (IODP Exp. 302; Moran et al., 2006). The cooling in the Arctic started about 46 Ma much earlier than previously conceived.

There are numerous other key findings that are relevant to shaping the Earth's environment. Drilling across the Cretaceous-Tertiary border time (65 Ma) clearly substantiated the bolide impact causing mass extinction and recovery. The Mediterranean Sea was dried near the end of the Miocene creating salt deposition influenced by the restriction of the water flow into the sea (DSDP Leg 13).

Microbiology

The investigation of the deep biosphere has brought surprising results of finding microbes in excess of 500 m depths into the sediments (Parkes et al., 1994).

The sub-seafloor microbes do not depend on photosynthesis. So far, the deepest record is finding active microbes 1,626 mbsf in 111-Ma-old sediments (Leg 210; Roussel et al., 2008). Microbes are found to prevail in organic-rich or hydrate-bearing sediments. Traces of microbes in volcanic rocks are also found (Mason et al., 2010; Exps. 304, 305); thus, the limit is not the sediments, but more likely to be the thermal condition and energy supply (e.g., Bach and Edwards, 2003). Studies of life sub-seafloor have expanded recently with growing interests in defining the habitat, ecosystem, link to fluids, limiting environmental conditions, and the role of these life forms in the Earth-life coevolution and geochemical cycles. Drilling contaminates the core samples, and therefore, technological scrutiny to study only the uncontaminated portion is required.

Solid earth processes

Oceanic bathymetric highs range from scattered seamounts to seamount chains to oceanic plateaus, not directly linked to volcanisms at mid-ocean ridges. One of the major discoveries about the genesis of these features is that it is proven by ocean drilling that the bend between the Emperor seamount chain and the Hawaiian chain is produced not by the plate motion change but by the change in the mantle upwelling motion (e.g., Tarduno et al., 2009). This is an example that working hypotheses will be modified by new findings.

Large igneous provinces (LIPs) are continental flood basalts and oceanic plateaus created by a large supply of mantle-derived magma in a relatively short period (1–10 myrs) (Legs 130, 192, Ontong Java Plateau; Legs 119,120, 183, Kerguelen Plateau; Leg 198, Exp. 324, Shatsky Rise). Mantle plumes are considered the likely source, and their impact on climate (greenhouse Earth) and ocean anoxia (oxygen-depleted ocean) is not well understood, partly because of the difficult core sampling strategy.

Plate subduction occurs both in accretionary tectonics and subduction erosion tectonics around the Pacific Rim. Recent deep drilling in the Nankai subduction zone has revealed the tsunami genesis history in geological perspective (IODP NanTroSEIZE Exps.).

The database can be utilized for objectives that can be achieved through global sampling not possible for a single cruise such as compiling for rare-earth element distribution (Kato et al., 2011).

Ocean igneous crust

Ocean crustal rocks beneath the sediments have not been recovered with significant continuous coring except for recovering the topmost section for obtaining the date of the seafloor formation. The basic structure of an oceanic crust is estimated from geophysical (remote sensing) or geological evidence offshore (exposures of rocks formed at high pressure and temperature) and onshore (ophiolite considered to be obducted oceanic crusts) to be about

6–7 km plus or minus a few kilometers and composed of basalt (pillow basalt, sheeted feeder dikes), gabbro (lower crust), and the mantle rock (variations of peridotite). The Moho discontinuity is seismologically detectable almost ubiquitously in oceans, but its petrologic characteristics dependent on the spreading rate and postulated to be the gabbro to peridotite boundary or an alteration front of serpentinized peridotite remain to be verified.

Since the seafloor spreading hypothesis was verified on Leg 3 of DSDP, the physics and chemistry of how the oceanic crusts are formed at ocean ridges and age and cool away from the ridge axes forming the uppermost layer of the lithosphere have been an important focus of ocean drilling. The difference in the seafloor spreading rate is currently considered a major factor in determining the petrologic structure of oceanic crusts. Where magma supply is sufficient to balance the spreading rate, the crustal layering is expected to be vertically stratified. Crusts formed at fast spreading rate ($>\sim100$ mm/year) are in this category. Crusts formed at slow spreading rate ($<\sim50$ mm/year) accompany tectonic adjustments such as exhumation of deeper crustal or mantle rocks, as the magma supply seems insufficient to accommodate the spreading rate and to cause larger lateral heterogeneity than crusts from fast spreading ridges.

Deep penetration coring has been made since DSDP at Sites 332 (Leg 37, mid-Atlantic), 395 and 920–922 (Legs 45, 153, mid-Atlantic), 418 (Legs 52–53, Bermuda Rise), 504 (Legs 69, 70, 83, 111, 137, 140, 148, E. Pacific, Nazca Plate), 735 (Legs 118, 176, SW Indian Ridge), 801 (Legs 129, 185, W. Pacific), 1256 (Leg 206, Exps. 309, 312, 335, E. Pacific, Cocos Plate), and 1309 (Exps. 304, 305, mid-Atlantic, Atlantis Massif). Hole 332B was the first multiple reentry hole to deepen the hole with new bits. Holes 735B and 1309D recovered gabbroic rocks representing the lower crust. Hole 1256D, although not the deepest, reached gabbros at 1,407 m below seafloor (Wilson et al., 2006). These with drilling attempts to shallower penetrations into the igneous crusts contributed in observing the lateral change away from and in parallel to the ridge segmentation (e.g., Leg 209, mid-Atlantic Ridge) or test hypotheses of finding exhumed lower crust or mantle rocks (Leg 147, Exp. 345, Hess Deep). Other attempts include drilling into continental rifted margins (Leg 103, Galicia; Legs 149, 173, Iberia; Leg 210, Newfoundland; Leg 104, Norway; Leg 152, Greenland) to investigate the continental breakup process from continent-ocean transition structure and their relation to magma feed at the time of rifting.

Through ocean drilling combined with surface geophysical surveys, the understanding of petrologic evolution of oceanic crust has progressed to infer its relation to spreading rates, seismic models (e.g., Layer 2/Layer 3 transition; Detrick et al., 1994; Swift et al., 2009), interactions with fluids, and inclusions of microbes (Mason et al., 2010). To further the understanding of oceanic crusts in relation to mantle convection and plate tectonics, the current state of sampling is insufficient depth-wise and also plate age-wise. The feasibility of deep penetration into the lower crust and reaching the mantle across the Moho boundary is being seriously studied with the advent of the riser drillship *Chikyu*.

Fluids

The notion of the dark and motionless world of the seafloor and below is completely revised by numerous seafloor investigations and drilling expeditions. Fluids are seeping up and down not only at hydrothermal vents but also at plate subduction zones and possibly elsewhere providing energy for microbes to thrive and massive sulfide minerals to deposit or serpentinizing mantle peridotites. The physical behavior of the fluid fluxes is being studied at and around ridges by borehole observatories including chemical and biological parameters (Davis et al., 2000, Davis et al., 2000; IODP Exps. 336, 337).

Marine gas hydrates have become important scientific targets in order to understand their formation, distribution, and role in affecting the environment from the viewpoints of natural resource potential, methane storage, and control in relation to sub-seafloor ecosystem and geohazard risk.

Observatories

Ocean-drilled boreholes have long been perceived to provide a stable environment for global seismic observatories (e.g., Byrne et al., 1987; Stephen et al., 2003). The global seismic network has progressively advanced the understanding of earthquakes and the entire internal structure of the Earth as the frequency bandwidth and dynamic range widened. 3-D tomography of the Earth and complex fault motion description are direct products of the network data. The weakness of the global network has been the inhomogeneous distribution of the seismic stations because of the lack of stations in the oceans (71 % of Earth's surface). There have been several attempts to overcome this (Suyehiro et al., 2006) utilizing ocean drilling holes. Technically, a broadband digital seismic observatory with equal fidelity as on-land observatories can be established in the boreholes on solid basement rock that provide more quiet observational environment than on seafloor or in soft sediments. Feeding power for long term and getting data back in real time are the remaining challenges.

While complementing the global resolution of the network, ocean sites uniquely contribute in obtaining new data at upper mantle depths where on-land stations do not have the resolving power. For example, a new implication is made on the thickness of the ocean lithosphere suggesting that the lithosphere-asthenosphere boundary is not a simple rheological change produced by the cooling of the lithosphere (Kawakatsu et al., 2009) or a detailed anisotropic structure of the ocean upper mantle (Shinohara et al., 2008). Regional-scale seafloor cable networks are being established to cover tectonically active areas such as off Japan or off North America to obtain

seismic and geodetic data continuously real time from boreholes (e.g., DONET (www.jamstec.go.jp/donet/e/), NEPTUNE Canada (www.neptunecanada.com)).

The main objectives of developing CORK (Circulation Obviation Retrofit Kit) technologies for enabling time series observations have been to identify and quantify sub-seafloor fluid flows and associated processes where physically focused flows may be expected such as in the vicinities of ocean ridges (thermally driven flows) and plate subduction zones (tectonic compaction).

In order to observe in situ fluid flow and estimate flow rates and permeability with minimum disruption, CORK design is intended to seal holes and control perturbation originally at the seafloor and subsequently evolved to enable multilevel isolated zones inside the borehole. The observation parameters expanded from original pressure and temperature to chemical and biological sampling.

It has been proven that these borehole observations not only provide permeability to be estimated from tidal responses but also function as volumetric strainmeters at a microstrain level (Davis et al., 2001). Transients such as associated with seismic events can be registered (Sites 1173, 1255). Furthermore, the temperature and pressure series from multiple CORK observatories where observations can be correlated, combined with the subsurface heterogeneous structure, can provide 4-D flow pattern (Holes 1026B, 1027C).

Conclusions

The ocean floor constitutes the top of the oceanic plates created by seafloor spreading and destroyed by plate subduction as part of the mantle convection. At the same time, the ocean floor is the bottom of the water column that hosts the thermohaline "conveyor belt" ocean circulation system and ocean currents. The chronological records of these processes are kept in the sediments and crust to be explored by ocean drilling. Ocean drilling provides ways to retrieve such information from sub-seafloor core samples and data to better understand how these systems operate and interact with each other.

Ocean drilling has evolved from the early days of exploratory stage to the more recent idea-testing stage over half a century backed with technological advancements for better core recovery and deeper penetration and higher-resolution downhole measurements. Paleoceanography is an Earth science field borne from ocean drilling. Recent new field is the biosphere beneath the oceans.

Ocean drilling boreholes can also be utilized as monitoring observatories for active processes in situ or for remote sensing for hydrology, geophysics, and biology. The framework of conducting ocean drilling has evolved over the last 50 years, but currently the sampling density in space is quite undersampled particularly in high latitudes, deeper crusts, or high-temperature environments.

Operating drilling platforms year-round requires international coordination of funding agencies, scientists, engineers, and platform operators. It has grown from a single

non-riser drilling vessel era (DSDP-ODP) to a multiple platform era (IODP) that enables very deep penetrations or drilling in very shallow waters or ice-covered seas. The history of ocean drilling has been to advance for recovery of high-resolution and high-quality samples with long history in all oceans as well as deeper penetrations into igneous rocks and developing capabilities to monitor ongoing geophysical, geochemical, and biological processes. It should be recognized that much of the ocean floor remains undersampled considering the heterogeneous nature of the processes in the oceans and beneath. Ocean drilling is emphasizing its utility to predictions of climate, geohazards, and ecosystem through new discoveries in basic science.

Ocean drilling complements continental scientific drilling and ice core drilling.

OCEAN MARGIN SYSTEMS

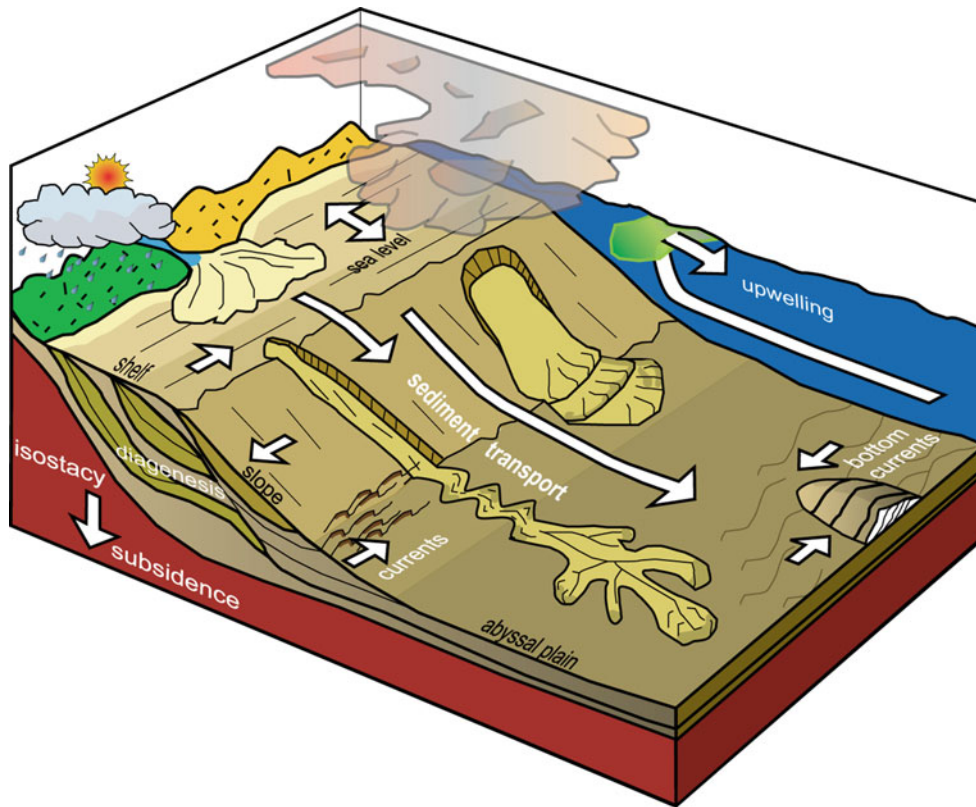
Gerold Wefer
MARUM-Center for Marine Environmental Sciences,
University of Bremen, Bremen, Germany

Definition

Transitional zones between the oceans and continents, representing dynamic systems in which numerous processes shape the environment.

Introduction

Ocean margins are the transitional zones between the oceans and continents where most of the sediments derived from the land are deposited. The effective processes here are influenced by a variety of steering mechanisms, from mountain building and climate on the land to tectonics and sea-level fluctuations at the margins of the seas. These areas are also of great importance for the global biogeochemical cycles. Although these areas make up only about 20 % of the ocean's surface, 50 % of the global marine production takes place here. Compared to the open ocean, the ocean margins represent more dynamic systems (see Wefer et al., 2002).

The region of the ocean margins extends from the coastal zone across the shelf and the continental slope to the continental rise (Figure 1). About 60 % of all people live in the adjacent coastal land areas, and they have intensively used the coastal waters for the extraction of raw materials and food over a long period. In recent times,


Ocean Margin Systems, Figure 1 Sedimentation processes at ocean margins (MARUM).

human activity has spread farther out into the oceans as the margins receive increasing attention as potential centers for hydrocarbon exploration and industrial fisheries. The great commercial potential of these regions, however, is countered by the presence of high potential hazards, for example, in the form of earthquakes and possible tsunamis triggered by slope instability, which can have a direct impact on the densely populated coastal regions.

The basis for the wealth of natural resources at the ocean margins lies in their high biological productivity. This can lead to the development of large fish populations on the one hand and to the deposition of immense amounts of organic materials on the other, which, through diagenetic processes, can be transformed into energy sources. It is often the case, however, that prerequisite conditions for the formation of resources are first created by large-scale sediment transport processes, i.e., from the shelf into the deep sea. The ocean margins are a dynamic system in which many processes shape the environment and impact the utilization and hazard potentials for humans.

Margin types

The terms Atlantic margin and Pacific margin were first introduced in the nineteenth century (see Seibold and Berger, 1996). Atlantic-type margins are steadily subsiding areas with thick sequences of deposited sediments.

In contrast, Pacific-type margins are uplifted, associated with volcanism, faulting, and other mountain-building processes. Atlantic-type margins are also called "passive margins" and Pacific-type margins "active margins." These characterizations are due to tectonics, particularly the occurrence of earthquakes and active volcanism (Figure 2).

Atlantic-type (passive) margins

The Atlantic-type margins originate through the breakup of plates or parts of plates, a process that is still taking place today in the Atlantic at a speed of 2–4 cm per year, in connection with subsidence and deposition of sediments on the ocean margins. A recent model is the Red Sea. Also the upper Rhine valley is an example of the initial stage of uplift and breakup of lithospheric plates. In an early phase of rifting, the deposition of salt is common, e.g., in the South Atlantic. In special areas, e.g., seaward of large deltas, up to 15 km of sediments can be deposited. Atlantic-type margins are also common in East Africa, Australia, off India, and around the Antarctic continent.

Pacific-type (active) margins

On Pacific-type margins three collision types can be distinguished: continent-continent collision, e.g., in the Himalayan region; continent-ocean collision, e.g.,
Ocean Margin Systems, Figure 2 Features of a passive ocean margin (*top*) and active margin (*bottom*) (modified after Tarbuck and Lutgens (2009)).

between the Pacific and South America; and subductions in the area of island arcs, e.g., in the Mariana Trench. Faulting, shearing of sediments, volcanism, and melting of the submerging lithosphere are characteristics of colliding margins. Special rocks called ophiolites, a mixture of pelagic sediments and basaltic rocks, are characteristically formed at subduction zones.

In contrast to passive margins, steep slopes are formed on active margins by plate collision, favoring mass transport into the deep-sea trenches. As result of the higher pressures, sediments are subject to dewatering, which is documented by the release of gases and fluid at sites called cold seeps. A special phenomenon of subduction at island arcs is back-arc spreading, the breakup of lithosphere behind the island arc, which is common in the western Pacific.

Morphology

The composition and structure of ocean margins are governed by a wide variety of sedimentation processes along the sedimentary pathway.

Shelf

Shelf regions are characterized by high sedimentation rates because of the input of terrigenous materials from the land and high biological productivity. Massive sediment transport is widespread in these areas due to the high energy levels caused by tides, waves, and the dissipation of energy from internal ocean waves at the shelf edges.

Continental margin

Continental margins are also characterized by high sedimentation rates. Short-term mass transport of sediments is common, depending on the steepness of the slope. These episodic transport events occur at various intensities, ranging from slow-moving slope slides of intact layered packages to stirred-up, disorderly debris flows and further to turbidites that can extend for distances up to 1,000 km. Sedimentation patterns can thus be modified by sediment redistribution.

Through exploration for gas and oil on continental margins, large infrastructures have been installed in recent years, leading to increased concern regarding stability of the margins. In history, large submarine landslides are known to have occurred with a volume of more than $20,000 \text{ km}^3$ of material transported, within an area of more than $100,000 \text{ km}^2$. These events can be triggered, for example, by increased sediment overload, by expulsion of gas hydrates, or through an external trigger such as an earthquake. In addition to the few known very large events

that have influenced areas of up to 100,000 km^2, there have probably been a large number of smaller slides.

Climate coupling

Climate plays a prominent role in driving the processes that shape the environment, and it also interacts closely with ocean circulation and productivity. The climate-induced fluctuations of sea-level alone, with swings of over 100 m during the Late Quaternary glacial cycles causing broad shelf regions to alternately be dry and part of the land and then flooded and covered by the sea, highlight the sensitivity of the ocean margins to climate. In addition to the fact that these areas represent extremely active transitional areas between the oceans and continents, the presence of high sedimentation rates due to the input of terrigenous sediments is a very important characteristic.

Direct climatological measurements, which are critical for a basic understanding of such processes, only go back to the year 1850. Records extending farther back in time are documented primarily in the ocean margin sediments. The ocean margin sediments clearly provide an impressive archive of past climatic, productivity, current, and sedimentation conditions.

The past thousand years represent a particularly interesting time interval. In addition to historical records, there are also numerous high-resolution climate archives available from this period (e.g., coral skeletons, tree rings, continental slope sediments) that make it possible to compare the effects of relatively small-scale natural climate anomalies (e.g., the Middle Ages warm period and the "Little Ice Age") to recent variations caused by humans under somewhat similar boundary conditions.

Another time scale of interest includes the past 30,000 years, which incorporate the transition from the last ice age to the present warm period, the Holocene, which began about 10,000 years ago. Another important time interval encompasses the past 500,000 years (the last glacial-interglacial cycles). During this period, processes leading to variability of the global ocean in the Late Quaternary can be identified. These processes, in turn, are closely coupled to the drastic climate fluctuations over the course of the glacial-interglacial cycles. The ocean is a central component of the global carbon and hydrological cycles, and it also has a critical influence on the other two major components of the climate system, the atmosphere and continental ice.

Productivity

Organic matter deposition

The deposition of large amounts of organic material resulting from high-productivity conditions along the ocean margins leads to very high turnover rates at the seafloor, so these areas can also be characterized as efficient biogeochemical reactors. These high turnover rates of organic carbon, along with associated elements such as nitrogen, phosphorus, sulfur, and iron, play a critical role in the global mass cycles, but above all in the global carbon cycle.

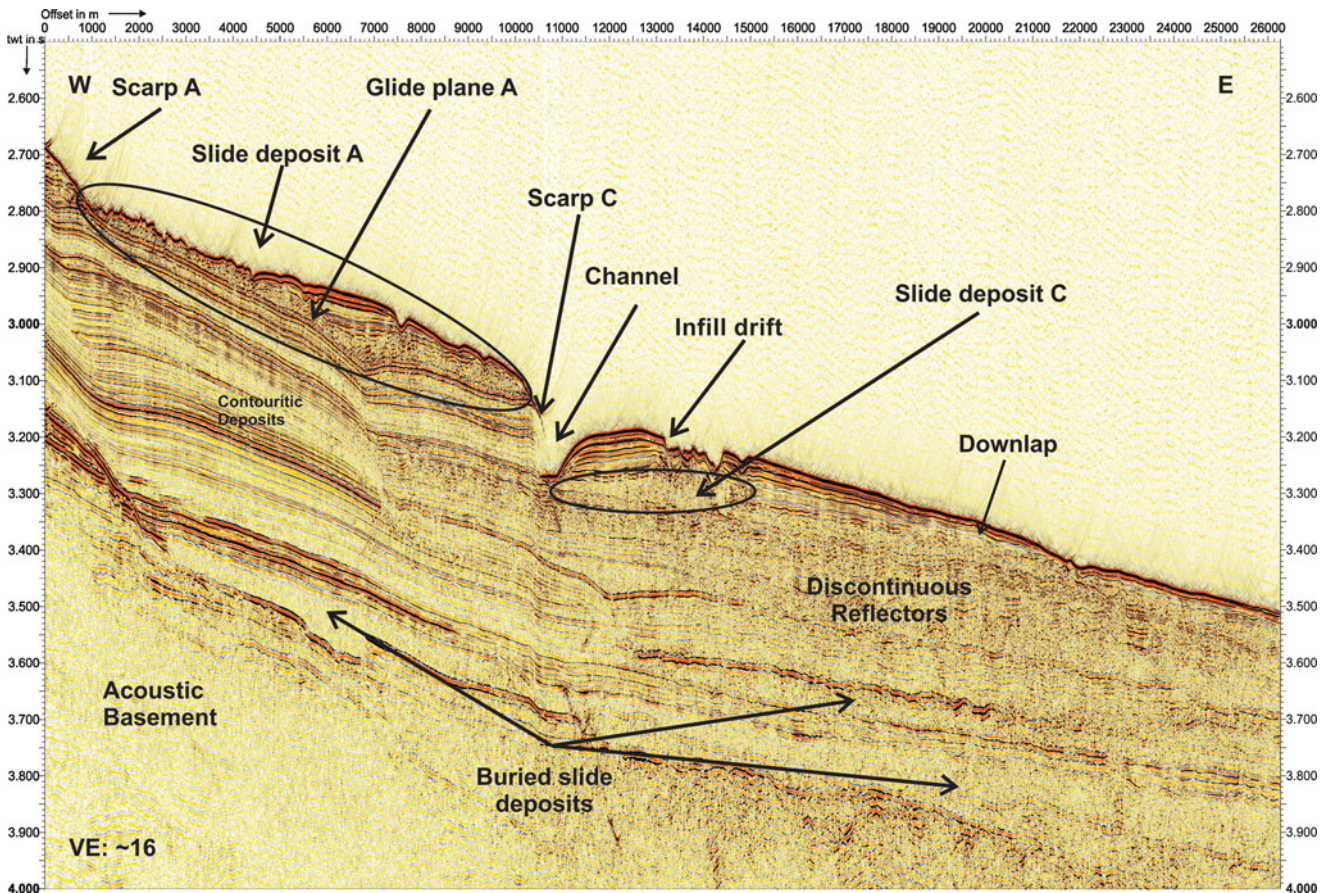
In high-productivity regions, elevated flux rates of organic substance often lead to the formation of an oxygen-minimum zone. In the highly productive ocean margins, these oxygen-minimum zones are in direct contact with the seafloor, strongly affecting the organism communities and the biogeochemical processes. The oxygen deficit varies with the dynamic balance between the flux of degradable organic detritus, stratification stability, and exchange time of the water masses. Interactions between the seafloor and the oxygen-depleted water column are much more intense than in the deep sea, leading to a close coupling between the bottom-water processes and those in the sediment. Oxygen concentration is one of the most important biological-chemical steering parameters for these processes.

Sediments at the seafloor are the habitat for countless, so far only partly known, microorganisms that drive these cycles and contribute significantly to the conversion of both organic and inorganic materials. Along with the normal flux of materials from the water column into the sediments, these microorganisms contribute to an intense return of nutrients from the sediments back into the water column.

Gas hydrates

Gas hydrates are firm, icelike associations of gas molecules and water, present in water depths between 300 and 700 m (see "Marine Gas Hydrates"). Besides methane, other hydrocarbons and other gases like carbon dioxide and nitrogen can also form gas hydrates at higher pressures and lower temperatures. Besides specific pressure and temperature conditions, an additional requisite is a sufficient amount of gas. In ocean margin sediments, the gas can be the product of microbial decomposition of organic material. Gas can also be produced by "thermocatalytic" processes in deep sediment columns. Because abundant organic material is commonly available on ocean margins, gas hydrates are common there. High plankton production and high sedimentation rates are favorable for the deposition of large amounts of organic material on the seafloor (see "Sapropels").

There are concerns regarding the instability of gas hydrates concentrated at the ocean margins as it relates to the warming of the oceans, which is in part caused by humans. The temperature increase could, on the one hand, lead to a wide-scale destabilization of the continental slopes resulting in large slides (see "Submarine Slides") with possible tsunamis and, on the other hand, release immense amounts of methane, which would contribute to a significant strengthening of the greenhouse effect.

Methane hydrates are also often discussed as a potential source of energy for the future. Although estimates are highly variable, the resources might be comparable to today's known fossil fuel (see "Energy Resources"). If they are eventually exploited, the exploration for methane hydrates will probably start in permafrost areas.


Ocean Margin Systems, Figure 3 High-resolution multichannel seismic profiles off Argentine (Krastel et al., 2014).

Sedimentological features

Benthic boundary layer

An important transition area between water and sediment is called the benthic boundary layer (BBL), where the exchange of material takes place. Processes at the BBL determine the deposition of terrigenous material and organic substances, as well as the release of nutrients into the water column. Furthermore, the BBL is important for the lateral transport of particles at ocean margins, which is controlled by hydrodynamics within the BBL (see "Bottom-Boundary Layer"). Within the BBL, but also deep in the sediments, intensive early diagenetic processes take place, which are significant for the carbon, nitrogen, and oxygen cycles in the ocean.

Turbidites

Turbidites often reach the deep ocean regions through various types of submarine canyons. Some canyons are formed initially in connection with slope slides and then gradually cut their way upslope, over time, into the shelf region (see "Turbidites"). Another type originates near the mouths of glacial rivers (i.e., during low sea-level

stands, especially at the shelf edge) or during high stand has cut its way back to the inner shelf.

These sedimentation processes, oriented toward the open ocean, are overprinted by transport processes parallel to the slope that are driven by bottom currents and can be either erosive or accumulative, forming contourites or drift sediment bodies. Because ocean margins include the active interfaces in such balances, these regions are critical for understanding of the global mass transport and transformation of material in the land-atmosphere-ocean system.

Contourites

Contourites are deepwater sedimentary deposits influenced by bottom currents, seafloor morphology, and sediment supply (Figure 3) (see "Contourites"). Bottom currents are driven by thermohaline circulation flowing parallel to the continental margin or along the deep-sea floor. These currents may also be influenced by wind or tidal forces. Sediment for contourite deposits is supplied by erosion processes at the seafloor. Transport to deeper water occurs mostly through by turbidites.

Cold seeps

Besides the transport of dissolved substances by rivers and through the atmosphere, an important transport of dissolved components and gases takes place on vents and seeps, as well as diffusive transport between the sea-floor and water column. This also includes submarine releases of groundwater. Seeps are characterized by a special community of benthic organisms, the formation of massive authigenic carbonates, gas releases, and occurrence of gas hydrates. Chemosynthetic communities are common, dominated by giant tube worms and large bacterial mats (see "Cold Seeps").

The return of materials from the sediments into the water is not limited to the microbiological and diagenetic processes in the uppermost sediment layers. Similar to the hydrothermal ("hot") vents at the mid-oceanic ridges, recent discoveries of cold seeps along the ocean margins have revealed ascending fluids flowing into the seawater, in part originating at great depths in the sediments. These fluids, often enriched in methane, sporadically maintain self-sufficient ecosystems based on chemosynthesis such as those known from the hydrothermal vents.

Recently discovered numerous large carbonate mounds (see "Carbonate Factories") located on the continental slope are associated with the discharge openings of such fluids. These carbonate deposits are often occupied by a fascinating ecosystem.

Biology

At ocean margins a large variety of habitats and biological communities are present, e.g., coral mounds, sediment slopes and gravel banks, canyons, and mud volcanoes. With new technology, especially using remotely operated vehicles (ROVs), new habitats have been discovered in recent decades. One example is illustrated by deepwater corals providing a habitat for a great number of other organisms. These communities are in danger as a result of increased commercial use of living and nonliving deepwater resources on the ocean margins, particularly deep-sea fishing and oil and gas production. Recently discussions have begun regarding the exploration of metals from the deep sea. This planned exploration must be combined with careful monitoring of the deep-sea environment.

Cold-water corals

Over the past several decades, reef-forming cold-water corals have been intensively studied (see "Reefs (Biogenic)"). They are comparable in extent and diversity to tropical coral reefs. Together with the two dominant species, *Lophelia pertusa* and *Madrepora oculata*, more than 1,000 other species were identified living in the cold-water coral environments (Freiwald and Roberts, 2005). Ocean margins contain a large number of different habitats and biological environments. Because ocean margins are increasingly being used for fisheries, as a biological resource, and for the exploitation of oil, gas, and minerals, management of the environment and establishment of conservation areas are under discussion (e.g., coral reefs off Norway).

Deep biosphere

In addition to these previously unknown ecosystems, significantly more important systems, quantitatively, have been discovered within the depths of the sediments (see "Deep Biosphere"). The presence of a rich bacterial life below the seafloor has been identified, reaching a sediment depth of more than 1,000 m and penetrating even into the volcanic rocks below the sediment cover. It is estimated that this newly discovered ecosystem accounts for up to 10 % of the active global biomass.

Human usage

The most obvious impacts of human usage on the oceans are naturally seen in the coastal regions. As the transition area between land and sea, the coastal zones are becoming more and more threatened by increasing intensive use as residential or industrial areas and as agri- and aquacultural areas. Added to this are the pressures of harbor sites and tourism. Already today, 60 % of the world's population lives in this zone, and 75 % of all cities with populations over 2.5 million are located in estuarine regions (see "Integrated Coastal Zone Management").

In addition to the input of pollutants and nutrients to the coastal waters, they are increasingly being directly used for human activities in which clear traces of the use remain. The shore, banks and shallow-water areas are being altered by construction (e.g., dikes, harbors, and pipelines, as well as river-bottom deepening and river correction and gravel and sand removal), which has a lasting effect on the current conditions, sea-level change (absolute level and storm-flood frequency), and rates of erosion and deposition (see "Coastal Engineering" and "Engineered Coasts").

On the seaside of the coastal zone, the wide continental shelf is exploited by fisheries and marine mining (see "Marine Mineral Resources"). The shelf regions represent high-productivity regions for fisheries, with 95 % of the total global catch coming from this zone. They are also easily accessible for marine mining, especially for the production of oil and gas, as well as gravel and other building materials. Oil exploration and especially the fisheries have also begun to advance out onto the continental slope. Fishery activity particularly contributes to large-scale changes on the seafloor through intensive bottom trawling. This leads, e.g., to the endangerment of unique ecosystems such as the cold-water coral reefs that occur on the continental slopes in water depths up to 1,000 m.

Conclusions

Ocean margins are extremely important for mankind due to their great commercial potential for hydrocarbon exploration and fisheries. On the other hand, these areas possess a high risk of hazards in the form of earthquakes and tsunamis. Increasing human activities, including

construction, oil and gas exploration, fisheries, and possible deep-sea mining for metals, can have a great impact on sediment mobilization and transport and on the ecosystems in general. Our present understanding of the complex sedimentation processes and ecosystems on continental margins is not sufficient, and integrated studies using modern technologies for observation and modeling are needed.

OCEANIC PLATEAUS

Andrew C. Kerr
School of Earth and Ocean Sciences, Cardiff University, Cardiff, Wales, UK

Definition

Oceanic plateaus are large areas of elevated, over-thickened basaltic ocean floor ($>5 \times 10^5$ km^3) which have formed throughout most of Earth's history, and, unlike most oceanic crust, they are not primarily the result of seafloor spreading processes and melting of ambient upper mantle but rather are widely regarded to have been formed by decompression melting of hot mantle plumes (Kerr, 2014).

Introduction

The vast erupted and intruded volume of oceanic plateaus means that they are classed as large igneous provinces (LIPs), along with continental flood basalts and volcanic rifted margins. The term large igneous provinces was originally proposed by Coffin and Eldholm (1992) as a generic term for igneous provinces with a volume exceeding 0.1×10^6 km^2 (see also Coffin and Eldholm 2005). More recently, this definition has been revised by Bryan and Ernst (2008), who proposed a classification scheme that includes giant radiating dike swarms and silicic LIPs. Bryan and Ernst's formal definition is as follows

> LIPs are magmatic provinces with areal extents $>0.1 \times 10^6$ km^2, igneous volumes $>0.1 \times 10^6$ km^3 and maximum lifespans of ~50 m.y. that have intraplate tectonic settings or geochemical affinities, and are characterised by igneous pulse(s) of short duration (~1–5 m.y.), during which a large proportion (>75 %) of the total igneous volume has been emplaced.

In the early 1970s, new evidence from seismic surveys revealed that several large portions of the ocean floor were much thicker than "normal" oceanic crust (6–7 km) (see Layering of Oceanic Crust). One of the first areas of such over-thickened crust to be identified was the Caribbean Plate which Donnelly (1973) proposed to be an "oceanic flood basalt province." The term "oceanic plateau" was first used by Kroenke (1974) to describe the large area of thickened crust (>30 km) and then recently discovered in the Western Pacific and now known as the Ontong Java Plateau.

The thick crustal sections and elevated topography of oceanic plateaus (generally 2–3 km above the surrounding ocean floor) result in them being more buoyant than normal oceanic crust. Thick oceanic plateaus and those that are relatively young when they interact with subduction zones are therefore difficult to subduct (e.g., Cloos, 1993; Tetreault and Buiter, 2012). The resultant collision of thick, buoyant oceanic crust with subduction zones results in extensive oceanic plateau fragments being preserved in accreted terrains (see below). These accreted oceanic plateaus are more likely to be preserved in the geological record than continental flood basalts that are more easily eroded by subaerial processes, and so oceanic plateaus could have been major contributors to the growth of continental crust throughout Earth's history (Kerr and Mahoney, 2007).

As our knowledge of the ocean basins and accreted terrains has improved over the last 30 years, many more oceanic plateaus have been identified, both relatively recent "in situ" plateaus (Figure 1) and older accreted examples.

Characteristics of oceanic plateaus

The three best-known extant (i.e., still predominantly in the oceanic realm and not accreted) oceanic plateaus are the Ontong Java, Kerguelen, and Caribbean–Colombian plateaus (Figure 1). The following sections will mostly

Oceanic Plateaus, Figure 1 Map showing all major oceanic plateaus formed within the last 150 Ma (Modified from Kerr, 2014).

draw on these examples to illustrate the salient features of oceanic plateaus and their formation.

Duration of formation

Both the Ontong Java and Caribbean plateaus have been formed during more than one phase of eruption, but geochronological data suggest that the vast bulk of the volcanism occurred in one short (<3 m.y.) main initial episode (like many similarly derived continental flood basalts), with subsequent magmatism in both plateaus being volumetrically minor. The main phase of Ontong Java eruption occurred within a few million years around 120 Ma, whereas the bulk of the Caribbean Plateau was formed around 93–89 Ma (see reviews in Kerr et al., 2003 and Fitton and Godard, 2004). Although recent ^{40}Ar–^{39}Ar dates have widened the age span of magmatism on the Kerguelen Plateau, very large volumes of magma were nevertheless generated in several pulses, 120–110 Ma and 105–100 Ma, over geologically short timescales (Duncan, 2002).

Structure

The crustal structure of oceanic plateaus can be deciphered from accreted plateau fragments (e.g., Kerr et al., 1997) and from seismic and gravity surveys on

extant plateaus (e.g., Miura et al., 2004). In general, oceanic plateaus comprise a lowermost layer of predominantly olivine cumulates, overlain by isotropic gabbros. The base of the extrusive sequence is dominated by geochemically heterogeneous high-MgO lavas that are in turn succeeded upward by relatively homogeneous basaltic lavas (a similar structure has been proposed for continental flood basalt provinces).

Accreted oceanic plateau sections generally do not possess a sheeted feeder-dike complex, unlike many ocean ridge-type and supra-subduction zone ophiolites. Instead, the lava succession of oceanic plateaus is intruded by a significant number of thick sills or sheets (e.g., Kerr et al., 1997). In the accreted exposures of Ontong Java Plateau crust in the Solomon Islands, the lack of dikes has been interpreted either as evidence that most lavas have traveled a considerable distance or that the volume of magma being emplaced was too great to be accommodated by extension alone and that most magma was emplaced laterally in sills (Kerr and Mahoney, 2007).

Temperature of the source

The high rate and large volume of magma production in these plateaus and in many large continental flood basalt

provinces imply relatively deep asthenospheric melting. For example if, as seems likely, the Ontong Java Plateau was the result of ~25 % peridotite partial melting, then the spherical mantle volume required to form this amount of melt would be more than 700 km across (i.e., deeper than the 660 km discontinuity) (Kerr and Mahoney, 2007).

The generation of such large volumes of magma as are observed in oceanic plateaus means that the source region must either be hotter, more fertile, or have a higher volatile content than ambient upper mantle, or undergo a large amount of decompression, or some combination of the above. However, the most common explanation for these high melt production rates is the mantle source temperatures significantly higher than the ambient upper mantle (see review in Campbell, 2007). Most geoscientists regard the source of this hot material to be mantle plumes that have risen from a thermo-geochemical boundary layer such as the core mantle boundary (see Hot Spots and Mantle Plumes). The evidence for elevated mantle source temperatures for oceanic plateaus is extensive:

Firstly, as reviewed by Kerr and Mahoney (2007), the eruption of high-MgO (>15 wt%) magmas (picrites and komatiites) in some oceanic plateaus, particularly in the Caribbean Plateau and in Precambrian accreted plateaus, provides evidence of mantle source temperatures well in excess of the pressure-corrected temperature of the normal upper asthenosphere (1,300–1,400 °C). Herzberg and Gazel (2009) calculated that high-MgO magmas from the Caribbean Plateau were derived from mantle sources with temperatures (corrected for pressure) up to 1,620 °C.

Secondly, Herzberg (2004) has used mantle melting phase relations to calculate that the Ontong Java primary magmas contained 17–19 wt% MgO and were derived from a mantle source with a temperature range of 1,500–1,560 °C. These figures are confirmed by trace element-based estimates of the mean degree of melting in the source region of the Ontong Java Plateau that range from 25 % to 30 %, and these are consistent with derivation from a mantle source with a temperature greater than >1,465 °C (Fitton and Godard, 2004).

Thirdly, numerical modeling of the petrological characteristics of large igneous provinces (e.g., Farnetani and Richards, 1994) indicates that mantle source temperatures well in excess of ambient upper mantle are required in order to generate the large melt volumes of these oceanic plateaus from peridotite.

Furthermore, in addition to these petrological constraints, several Cretaceous oceanic plateaus display significant evidence for subaerial or shallow marine eruption, resulting from seafloor uplift. This uplift is due to the thermal buoyancy of the plume and is consistent with sources hotter than the ambient upper mantle. In the Caribbean Plateau, these include shallow water sedimentary sequences with carbonized tree trunks, overlying accreted Caribbean Plateau basalts in Colombia (Kerr

and Mahoney, 2007). In addition to this, volcaniclastic deposits near the top of the accreted Caribbean Plateau sequence on Aruba, in the southern Caribbean, comprise tuffs and ignimbrites that are consistent with eruption in a shallow marine or subaerial environment (Kerr and Mahoney, 2007).

Many of the drill holes into the Cretaceous Kerguelen Plateau show evidence of subaerial eruption, including oxidized flow tops, aa and pahoehoe flows, pyroclastic flows, and fluvial conglomerates. Furthermore, the presence of terrestrial and shallow marine sediments containing terrestrial plant remains, overlying the igneous basement at ODP Leg 183, Site 1138, provides substantial evidence for a prolonged period of subaerial exposure of the Kerguelen Plateau (Frey et al., 2003).

Drilling on the Ontong Java Plateau at Site 1184 during ODP Leg 192 discovered extensive basaltic phreatomagmatic deposits that, in conjunction with oxidized horizons and wood fragments, indicate a substantial phase of subaerial eruption on the eastern lobe of the plateau (Fitton and Godard, 2004), although evidence of significant uplift is lacking for other parts of the plateau (e.g., Tejada et al., 2002).

This evidence of subaerial exposure of oceanic plateaus is entirely consistent with upwelling from the deep mantle of hot buoyant material and associated dynamic uplift of the lithosphere above the ascending plume. This, in combination with the evidence from petrology and geochemistry, provides significant support for mantle plume models for the formation of oceanic plateaus (see Kerr, 2003).

Geochemical features of oceanic plateaus

Geochemically, most oceanic plateau rocks can be subdivided into three main groups:

1. Basalts and dolerites with a narrow compositional range and flat to slightly light rare earth element-enriched chondrite-normalized patterns. Most igneous rocks from Cretaceous oceanic plateaus have MgO contents ranging from ~6 to 11 wt%, with most lavas possessing a relatively restricted MgO range of 6.5–8.5 wt%. Concentrations of incompatible elements are similar to those in mid-ocean-ridge basalts, whereas radiogenic isotope ratios are broadly ocean-island-like (see reviews in Kerr and Mahoney, 2007; Kerr, 2014). Virtually all sampled Ontong Java Plateau lavas are of this type, as are many of the lavas of the Caribbean and Kerguelen plateaus.
2. Basalts with high La/Nb ratios and high initial $^{87}Sr/^{86}Sr$ (>0.705), along with low $^{143}Nd/^{144}Nd$ (<0.5127). Many early Kerguelen Plateau lavas possess this signature that is consistent with contamination by continental crust (see review in Kerr, 2014).
3. Picrites and komatiites with high-MgO contents (>12 wt%), which have a wider range of isotope ratios and incompatible trace element concentrations and

ratios than group 1. Such rocks are widespread in the Caribbean Plateau (e.g., Kerr et al., 2003).

Explaining compositional differences between the groups

High-MgO rocks have been found in accreted sections of the Caribbean Plateau but not (thus far) in the Ontong Java Plateau. Furthermore, the incompatible-element and isotopic compositions of high-MgO Caribbean Plateau lavas are more heterogeneous than those of lower-MgO basalts from both the Caribbean and Ontong Java plateaus.

It has been proposed that oceanic plateau source regions are heterogeneous and that the homogeneity of many plateau lavas and intrusions is a result of magma mixing, either in the melting column or in magma chambers (Kerr et al., 1997). The source region of the Caribbean Plateau was clearly markedly heterogeneous over much of its area and on a relatively small scale (Kerr et al., 2003). Such widespread and small-scale heterogeneity is also consistent with evidence from present-day lavas found at mid-ocean ridges and oceanic islands (e.g., some oceanic islands display greater isotopic and elemental heterogeneity than observed in the entire Ontong Java Plateau).

Why compositionally heterogeneous, high-MgO lavas have not been found on the Ontong Java Plateau but are relatively common in the Caribbean Plateau may well be related to differences in the thickness of the plateaus and in the depth to which the crust has been exhumed during accretion (Kerr and Mahoney, 2007). High-MgO, heterogeneous lavas are most likely to be erupted where there are few magma chambers and the magmatic plumbing system is poorly developed; in such areas, individual magma batches are more liable to ascend quickly from the source to the surface with little mixing in magma chambers. Therefore, in large igneous provinces, high-MgO lavas are most commonly found at the base of the succession. Later magmas are more likely to become trapped in magma chambers and so mix and fractionate (e.g., Kerr et al., 2003).

Accreted crustal sections provide the best way of studying the internal structure of oceanic plateaus, because they can expose deeper levels of the crust than those reachable by drilling,. However, due to the thicker lithosphere and the length of time between formation and accretion (Kerr and Mahoney, 2007), only the topmost 3–4 km of the Ontong Java Plateau basement crop out in large accreted thrust slices in the Solomon Islands (Petterson et al., 1997). Therefore, the deeper plateau sections that, according to the model of Kerr (2003), will be markedly heterogeneous, and the more Mg-rich lavas are not exposed on the Ontong Java Plateau.

Tejada et al. (2004) has proposed an alternative model to explain the homogeneity of the basalts of the Ontong Java Plateau, which suggests that the mantle source of the Ontong Java Plateau was essentially homogeneous at the very large scale and extent of melting. Tejada et al. (2004) argued that although mixing of more heterogeneous magmas in large open-system magma chambers could partly explain this geochemical homogeneity, mixing would always have to result in essentially the same composition and so reasoned that this was unlikely given that there is little evidence for magma mixing in the isotope and trace element data.

Given the great volume of melting and the large fractions of partial melting involved, it is probable that the melting process played a key role in averaging out smaller-scale source heterogeneity to produce the remarkable isotopic and incompatible-element homogeneity of basalts from the Ontong Java Plateau. Perhaps significantly, the estimated extents of melting for most of the Caribbean Plateau are lower than for the Ontong Java, a feature that would have resulted in less homogenization of melts in the mantle (Kerr and Mahoney, 2007). A similar conclusion was also reached by Heydolph et al. (2014) to explain the geochemical homogeneity of initial volcanism at the Shatsky Rise LIP.

As noted above, some of the oldest lavas drilled on the Kerguelen Plateau possess geochemical features consistent with contamination by continentally derived material. These continental fragments are likely to have been incorporated within the Indian Ocean lithosphere during the breakup of Gondwana prior to plateau formation. During formation of the Kerguelen Plateau, partial melts from these fragments would have contaminated the plateau magmas. This model has been confirmed by the discovery at ODP Site 1137 of a conglomerate containing Precambrian garnet–biotite gneiss cobbles (see review in Frey et al., 2002). Furthermore, seismological evidence also indicates the presence of continental crust in parts of the plateau, although the overall amount is not well established (e.g., Borissova et al., 2003).

Buoyancy and accretion of oceanic plateaus

The main reason for the elevated nature of oceanic plateaus (~2–3 km above the abyssal ocean floor) is the thickness of their basaltic crustal sections, which is generally much greater than the 6–7 km of normal oceanic crust generated at spreading centers. For instance, the Ontong Java Plateau has an average crustal thickness of ~33 km (e.g., Richardson et al., 2000), whereas the Caribbean Plateau crust varies from 8 to 15 km thick (see review in Kerr et al., 2003).

This thicker basaltic crust results in oceanic plateaus being more buoyant than the surrounding ocean floor and is the key reason why plateaus often resist subduction and so are often accreted to continental margins, thereby increasing their likelihood of preservation in the geological record. The extent of the buoyancy depends on both crustal thickness and plateau age. Plateaus that collide with a subduction zone only a few million years after they form will be more likely to resist subduction than a plateau

of similar thickness that encounters a subduction zone many millions of years later (e.g., Cloos, 1993). This is related to the fact that oceanic crust becomes less buoyant as it cools.

The Caribbean Plateau largely resisted subduction because it collided with an arc at the entrance to the proto-Caribbean seaway only a few million years after the plateau formed at ~93–89 Ma (Kerr et al., 2003). In contrast, the Ontong Java Plateau, most of which formed at ~120 Ma, collided with the Solomon Islands subduction zone ~100 m.y. after its formation (e.g., Petterson et al., 1997). In this case, the plateau has resisted subduction because of a combination of very thick crust (Cloos, 1993), an anomalously small amount of post-emplacement subsidence, and a >300 km-thick mantle "root" that has helped to choke subduction (Wessel and Kroenke, 2000). Thus, only the topmost 3–4 km of the Ontong Java Plateau are uplifted and exposed on the Solomon Islands (Petterson et al., 1997), whereas the much deeper crustal regions of the more buoyant Caribbean Plateau are exposed in accreted sections around its margins and in Colombia (Kerr et al., 2003).

When an oceanic plateau collides with a subduction zone, various things can happen (Figure 2):

1. At an ocean–ocean convergent margin, the subduction direction (polarity) can reverse (the so-called subduction flip; Figure 2a). This happened in the Solomon Islands subduction zone, following the collision with the Ontong Java Plateau (e.g., Petterson et al., 1997).
2. In addition to subduction polarity reversal at its leading edge, the collision of a plateau with an island arc can result in a "back-stepping of subduction" behind the accreting plateau where a new subduction zone is initiated (Figure 2a). This occurred as the Caribbean Plateau was tectonically emplaced between North and South America and has resulted in the present-day Central American arc and the formation of the Caribbean Plate (Kerr et al., 2003).
3. Collision of an oceanic plateau with an active continental margin also results in subduction back-stepping, but without subduction polarity reversal (Figure 2b). This happened in the Late Cretaceous when part of the Caribbean Plateau collided with the northwestern margin of South America, leading to the preservation of oceanic plateau crust in accreted blocks (Kerr et al., 2003). Indeed, it is clear that oceanic plateau accretion has occurred several times along this margin; portions of at least two or three plateaus appear to comprise accreted terrains that are commonly grouped with the Caribbean Plateau (see Kerr and Tarney, 2005).

Plateaus that collide with intra-oceanic island arcs can also eventually be accreted onto and incorporated into continental crust. Consequently, it has been suggested that the accretion of oceanic plateaus may have contributed to continental crustal growth throughout much of geological time (e.g., Abbott and Mooney, 1995; Tetreault and Buiter, 2012). Sequences interpreted to be of oceanic
Oceanic Plateaus, Figure 2 Idealized cross sections illustrating the likely effects of the collision of an oceanic plateau with (**a**) an island arc and (**b**) an active continental margin (Modified from Kerr and Mahoney, 2007).

plateau origin have been argued to represent an important component both in the upper and lower crust of Precambrian greenstone belts (see review in Kerr, 2003)

Identifying oceanic plateaus in the geological record

Oceanic plateaus are therefore likely to have been accreted to the continents throughout much of geological time.

The diagnostic geochemical and geological features of Cretaceous oceanic plateaus can be used to help distinguish plateau sequences in the geological record from those originating in other tectonic settings. These diagnostic features are reviewed below and more fully discussed in Kerr et al. (2000).

Igneous rocks formed in any subduction zone setting are relatively easily distinguished from oceanic plateau sequences because arcs possess generally more evolved lavas, with high La/Nb ratios, and only occasionally high-MgO lavas. Additionally, oceanic plateaus do not possess the abundant volcanic ash layers present in volcanic arc sequences. However, a La/Nb ratio ~1 is not an entirely robust discriminant of an oceanic plateau sequence, given that the Kerguelen oceanic plateau often possesses low La/Nb values, due to magma interaction with the continental lithosphere beneath the plateau. This illustrates the point that geochemical discriminants of tectonic setting should not be used in isolation and that other geological evidence should also be considered. In the case of Kerguelen, the lack of volcaniclastic horizons and the thickened oceanic crust help confirm its oceanic plateau affinity.

Most mid-ocean ridge basalts possess light rare earth element-depleted chondrite-normalized patterns in contrast to the generally flat patterns of oceanic plateau lavas. Furthermore, high-MgO lavas are much more common in oceanic plateaus than at mid-ocean ridges.

The geochemistry of igneous rocks is only of limited use in distinguishing between volcanic successions formed in back-arc basins from those formed in oceanic plateaus. However, the mantle temperature below a back-arc basin (i.e., ambient mantle) is lower than a mantle plume (200–300 °C hotter than ambient mantle), and this results in the eruption of relatively few high-MgO lavas. Furthermore, because of their proximity to active subduction zones, back-arc basin sequences will also be more likely to contain abundant volcaniclastic horizons than oceanic plateaus.

Examples of accreted oceanic plateaus
On the basis of many of the criteria outlined above, a significant number of accreted oceanic plateaus have been identified in the geological record (Kerr, 2014). Examples of some of the more significant plateaus are briefly reviewed below:

Wrangellia oceanic plateau
The accreted Wrangellia plateau, comprising basalts, with minor picrites, is discontinuously exposed along the continental margin of Alaska and Canada over a distance of ~2,300 km. The plateau formed in the Panthalassa Ocean ca. 230–225 Ma, in a progressively shallowing marine environment, which eventually became subaerial (see reviews in Greene et al., 2008; Greene et al., 2009a; Greene et al., 2009b). The plateau accreted to western North America in the Late Jurassic–Early Cretaceous.

Most of the Wrangellia plateau basalts contain 5–9 wt% MgO and are light rare earth element enriched, unlike the Ontong Java Plateau and most of the Caribbean Plateau. In contrast, many of the lower basalts are light rare earth element depleted with MgO contents that extend to more magnesian (6–12 wt% MgO) compositions (Greene et al., 2008; Greene et al., 2009a; Greene et al., 2009b). Modeling suggests that the magmas were derived by 23–27 % partial melting of a mantle source ~200 °C hotter than ambient mantle, thus supporting a hot mantle plume origin for the Wrangellia plateau (Greene et al., 2009b).

Carboniferous to Cretaceous oceanic plateaus accreted in Japan
Japan comprises a series of terrains that have been accreted to the Eurasian plate over the past 400 Ma. The Chugoku and Chichibu belts in southwest Japan contain up to 30 % basaltic material. Geochemical data suggests that these basaltic assemblages are remnants of a Carboniferous plume-derived oceanic plateau that formed in the Panthalassa Ocean (Tatsumi et al., 2000).

Permian greenstones of the Mino–Tamba accretionary complex found in southwest Japan comprise pillowed and massive basalt flows with minor picrites, with similar isotopic and trace element compositions (Ichiyama et al., 2008) to the Ontong Java and Caribbean plateaus. Ichiyama et al. (2008) proposed that these basalts were formed by partial melting of a shallow mantle plume head below the thick oceanic lithosphere in the Early Permian.

In contrast to the other accretionary belts in Japan, the Sorachi–Yezo terrain is dominated by oceanic crust and lithosphere (Kimura et al., 1994; Ichiyama et al., 2012). It comprises pillowed basalts with occasional picrites and dolerite sills of Tithonian age (150–145 Ma), which have been interpreted to represent an accreted oceanic plateau. This Jurassic–Early Cretaceous plateau (named the Sorachi Plateau; Kimura et al., 1994) is the same age as the Shatsky Rise (Figure 1), suggesting that the Sorachi Plateau and the Shatsky Rise were originally a single plateau that formed near the Kula–Pacific–Farallon triple junction at ~150 Ma (Kimura et al., 1994; Ichiyama et al., 2014). The Sorachi part of the plateau was carried northwestward on the Kula Plate and collided with the Eurasian continental margin in the mid-Cretaceous.

Precambrian oceanic plateaus
As already noted, the accreted oceanic plateau material has been a significant contributor to crustal growth. Some of the oldest oceanic plateau sequences comprise pillow basalts and komatiites found in the ~3.5 Ga greenstone belts of the Kaapvaal Craton of Southern Africa. The geochemical signatures of these rocks suggest an oceanic plateau origin (Chavagnac, 2004) and, along with mafic rocks found in the Pilbara Craton of Australia, they represent some of the oldest oceanic plateau material on Earth (see review in Kerr, 2003).

Greenstone belts of the Canadian Superior province and the Baltic Shield (3.0–2.7 Ga) consist of many lava formations that have been interpreted to be remnants of accreted oceanic plateaus. The evidence for an oceanic plateau origin is based on the occurrence of pillow basalts and komatiites with no terrestrial sedimentary intercalations or sheeted dike swarms, possessing broadly chondritic La/Nb ratios and low positive ε_{Nd} (see reviews in Ernst and Buchan, 2001; Kerr, 2003).

Proterozoic oceanic plateau terrains have also been identified in the Birimian Province of Western Africa, the Arabian–Nubian Shield, the Flin Flon Belt in Canada, and the Iron King Volcanics in Arizona. More detailed summaries of these accreted terrains and other Precambrian oceanic plateaus are given in Ernst and Buchan (2001) and Kerr (2014).

Environmental impact of oceanic plateau formation

Many periods of oceanic environmental crisis in Earth's history are marked by significant black shale deposits, which indicate oxygen-poor conditions in the deep ocean, i.e., oceanic anoxic events (OAEs). In the Cretaceous, these events are associated with periods of mass extinction and oceanic plateau formation particularly around the Cenomanian–Turonian boundary (93.5 Ma) and in the Aptian (124–112 Ma).

Cenomanian–Turonian Boundary (CTB) event

As reviewed in detail by Kerr (1998, 2005), the CTB event is characterized by the worldwide deposition of organic-rich black shales, indicating widespread anoxia in the oceans at this time. The CTB is also marked by a rise in sea-level and significantly higher average global surface temperatures than the present day. These higher temperatures are most likely due to an increase in global atmospheric CO_2 to 3–5 times higher than preindustrial levels (Fletcher et al., 2008). These phenomena were accompanied by an extinction event that resulted in the demise of 26 % of all known genera (Raup and Sepkoski, 1986).

The CTB event has been linked to the formation of oceanic plateaus (Kerr, 1998, 2005; Kuroda et al., 2007). An oceanic plateau trace element signature in black shales was first noted by Kerr (1998) and was subsequently reported by Snow et al. (2005). More recent isotopic studies (Kuroda et al., 2007) on CTB black shales from Italy showed that their Pb isotope signatures are significantly shifted toward the geochemical composition of the Caribbean plateau, thus implying a substantial input from the plateau.

Links between CTB oceanic plateau volcanism and environmental perturbation

Most plume-related volcanism around the CTB occurred in the oceans, with the formation of significant portions of the Caribbean, Ontong Java, and Kerguelen plateaus. The probable worldwide environmental effects of such volcanism are reviewed below and summarized in Figure 3.

The net result of the emplacement of millions of cubic kilometers of magma both into and onto the preexisting ocean crust in combination with the uplift associated with buoyant plume head impingement on the base of the oceanic lithosphere will be to raise the sea-level, due to the displacement of seawater. The progressive rise in global sea-level throughout the mid-Cretaceous (Haq et al., 1987) may signal the gradual impingement of the Caribbean, Ontong Java, and Kerguelen plume heads below the oceanic lithosphere. This uplift of oceanic lithosphere and subsequent magma emplacement are also likely to have resulted in the disruption of oceanic circulation systems such that cool, polar (oxygenated) water was not circulated to lower latitudes, leading to increased anoxia in the oceans (Kerr, 1998). In addition to the CO_2-induced, elevated, global oceanic temperatures, hydrothermal fluids from oceanic plateau volcanism may also have contributed to warmer oceans and, thus, to anoxia, since oxygen is significantly less soluble in warmer water (see review in Kerr, 2005).

Calculations suggest that increased volcanic activity around the CTB is likely to have added ~10^{17} kg of CO_2 to the atmosphere (Kerr, 1998). This volcanic activity probably also released substantial amounts of SO_2, chlorine, fluorine, and H_2S into the seawater, resulting in the CTB oceans being more acidic. This could have resulted in the dissolution of oceanic carbonate and may help to explain the lack of carbonate at the CTB (Kerr, 1998, 2005), which would also release more CO_2 to the atmosphere. Higher atmospheric CO_2 levels and nutrient upwelling from the deep ocean is likely to have resulted in increased productivity in ocean surface waters (Figure 3), leading to the widespread deposition of black shales and, so, ultimately a reduction in CO_2 levels (Jarvis et al., 2011).

Other links between oceanic plateau formation and black shale formation

Black shales are relatively common in the geological record and are generally associated with, sometimes severe, environmental disruption (Wignall, 1994; Bond and Wignall, 2014). It is highly significant that these black shale events also correlate with the formation of oceanic plateaus or plume-related volcanic rifted margins (Kerr, 2014).

During the Aptian–Albian (125–100 Ma), three distinct oceanic anoxia events (with associated black shales) occurred, indicating a prolonged period of global environmental disturbance (Wignall, 1994). The Aptian–Albian was also a major period of oceanic plateau formation in the Pacific and Indian Oceans (Coffin and Eldholm, 2005). Although many of the geochemical features of the Aptian–Albian OAE are very similar to those of the CTB, one of the black shale horizons in the mid-Aptian shows sharp decrease in $\delta^{13}C$. This decrease is consistent
Oceanic Plateaus, Figure 3 Diagram summarizing the possible physical and chemical environmental effects of the formation of large igneous provinces around the Cenomanian–Turonian boundary (Modified from Kerr, 2005).

with the catastrophic release of methane hydrates from ocean floor sediments and would have substantially contributed to global warming and oceanic anoxia in the mid-Aptian (Jahren et al., 2005).

Significant black shale formations are found throughout the Mesozoic and these usually correlate with oceanic plateau (or rifted margin) volcanism, e.g., Kimmeridgian to Tithonian (155–146 Ma) black shales formed at the same time as the Sorachi Plateau in the Western Pacific. Furthermore, Toarcian (187–178 Ma) black shales are coeval with the eruption of the Karoo, Ferrar, and Weddell Sea large igneous province during the breakup of Gondwana (Kerr, 2003). Furthermore, Condie et al. (2001) have proposed that the correlation between black shales, paleoclimatic disturbance, and mantle superplume events extends into the Precambrian and have noted that there is a particularly good correspondence between these events at 1.9 and 2.7 Ga.

The recognition that oceanic anoxia and black shale deposition may have been a result of oceanic plateau formation has important implications for the location of potential oil source rocks in the geological record. It is probable that many of the world's Cretaceous oil source rocks owe their existence to the emplacement of oceanic plateaus that caused widespread global anoxia (Kerr et al., 2003).

Thus, the formation of oceanic plateaus can have far-reaching environmental effects and can set in motion a chain of events that often leads to global warming, oceanic anoxia, black shale deposition, and, ultimately, mass extinction.

Summary

Oceanic plateaus are large areas of over-thickened oceanic crust that are generally regarded to have formed by decompression melting of hot mantle plumes. Oceanic plateaus are found throughout the geological record. The thick crustal sections of oceanic plateaus are difficult to subduct. As a result the upper crustal portions of oceanic plateaus are frequently accreted to continental margins and so have been an important contributor to crustal growth throughout Earth's history.

Much of our knowledge of the composition, origin, and structure of oceanic plateaus has come from our study of Cretaceous oceanic plateaus such as the Ontong Java, Caribbean, and Kerguelen plateaus. The homogeneous basalts of the Ontong Java Plateau either indicate a homogeneous mantle source region or, more likely, homogenization of heterogeneous magmas during mantle melting. In contrast, the mantle source region of the Caribbean Plateau is markedly heterogeneous, and high-MgO lavas are abundant. Initial magmatism on the Kerguelen Plateau is associated with the breakup of Gondwana in the Early Cretaceous, and as a result the early plateau, lavas are contaminated with continental crust.

Throughout much of Earth's history, oceanic plateau formation correlates with periods of environmental catastrophic events characterized by oceanic anoxia, leading to black shale formation and mass extinction.

OCEANIC RIFTS

Adolphe Nicolas
Geosciences Montpellier, University of Montpellier 2, Montpellier, France

Definition and historical review

Rifts share comparable morphologies whether they start as continental rifts, evolve to oceanic rifts, or, successfully, open to become a mid-oceanic ridge. They are elongated with an axial valley a few tens of kilometers wide, below symmetrical shoulders some 2,000 m higher than the regional elevation. This relief is thermally supported by the upwelling of the asthenospheric mantle through the thinning lithosphere. However, it is now realized that due to evolution of tectonically hyperextended systems, such architectures may be absent even in extensive continental rifts such as the North Sea. The rift upwelling triggers partial melting in the upper mantle and, in turn, volcanism in the rift. The rift itself results from collapsing of the shoulders' vault, along normal faults implying some tectonic extension.

These attributes are common to two modes of mantle behavior during rifting, being "passive" or "active," respectively. "Passive" rifting is induced by stretching and rupturing of the continental lithosphere that triggers the upwelling of the underlying asthenosphere (Mckenzie, 1978) (Figure 1a). Passive rifting has been successfully modeled both numerically (Huismans and Beaumont, 2007; Sachau and Koehn, 2010) and by analogic experiments (Brun and Beslier, 1996). It has received the support of field

observations such as in the Rio Grande Rift where stretching preceded volcanic activity in the rift, in contrast with the East African Rift where asthenosphere upwelling preceded stretching (Allen and Allen, 2005). However, in a "normal," homogeneous, continental lithosphere, with a temperature at Moho depth of only ~500 °C, it is not expected that mantle peridotites would yield to the horizontal far-field tensile stress applied to the lithosphere (Nicolas et al., 1994). "Active" rifting is initiated with a local upwelling of an underlying, hot mantle plume (Figure 1b). Another attribute of active rifting should be a copious magmatic activity in the rift because twice more melt is generated by a 100 °C overheated mantle plume compared to normal rising asthenosphere (White and McKenzie, 1989). Provided that this upwelling occurred in an area of tensile stress, rifting can occur (otherwise, the plume builds a major volcanic edifice, such as the Hoggar). Rift initiation may postdate an episode of thermal erosion of the lithosphere by the mantle plume. Spohn and Schubert (1982) predict that a plume can reduce the lithosphere by a factor of two in 30 Myr. Rupture in this thinned and heated lithosphere is now possible and a wedge of asthenospheric mantle can rise, resulting in rift opening (McMullen and McMorhaz, 1989; Nicolas et al., 1994).

If the affected lithosphere is homogeneous, the rifting should be symmetrical, although symmetry versus asymmetry depends also on other factors such as the rates of extension. If the lithosphere was heterogeneous, for instance, guided in continental lithosphere by mechanical

or thermal weakness lines, rifting should be asymmetrical (Wernicke, 1981) (Figure 1c). In marine environments, such as the slow-spreading Atlantic Ocean, the analogues are the oceanic core complexes (Tucholke et al., 2008). Rifting may be more complex, combining pure and simple shear (Figure 1d).

We describe briefly below the Northern Red Sea, illustrating the situation of an active and symmetrical rifting, and next, the situation of a passive and asymmetrical rifting with the Galicia Bank where the Atlantic Ocean first opened. The western margins of the Atlantic Ocean in Newfoundland have been classically considered as illustrating a magma-rich system, contrasting with the magma-poor eastern margin of the Galicia Bank, rifting by a major tectonic extension and thinning. Recently, it has been recognized that such relatively simple models evolve in time, with hyperextension affecting the ocean-continent margins. Finally, the views developed here by the author may be biased because of a better knowledge of the deep mantle and lower crust structures of rifts.

The Northern Red Sea: an active rift

The Red Sea oceanic rift opens and propagates northward between thinned continental crusts, since ~11 Ma (Hempton, 1987; Izzeldin, 1987). In its northern part considered here, at its initial stage, rifting was symmetrical (Buck et al., 1988). The rift is narrow with small oceanic basins filled by hot metalliferous brines, between
Oceanic Rifts, Figure 2 Early lithospheric thermal erosion above a mantle plume. At that time, the plume was located below Egypt. Lithospheric fracturing opened conduits for rising basaltic melt from the melting asthenospheric intrusion (*red*), beneath the lithosphere (*brown*) and continental crust (*blue*), stretched and invaded by basaltic dikes. This intrusion penetrated the crust and opened a failed rift, the Zabargad Miocene marine basin (sediments in *yellow*, basalt sills in *deep blue*). Opening of the Red Sea occurred 10 to 15 My later, with stretching and fracturing of the preheated continental crust (Nicolas et al., 1994).

attenuated continental crust shoulders. Nowadays, this Red Sea rift expands northwards in a continental lithosphere, being fed by a hot spot located in the Southern Red Sea, at the triple junction with Aden Gulf and the Afar continental rift. The hot spot volcanic activity is 30 Ma old (Jones, 1976). In the Southern Red Sea, rifting is more complex with asymmetrical features (Buck et al., 1988; Coleman and McGuire, 1988; Dixon et al., 1989).

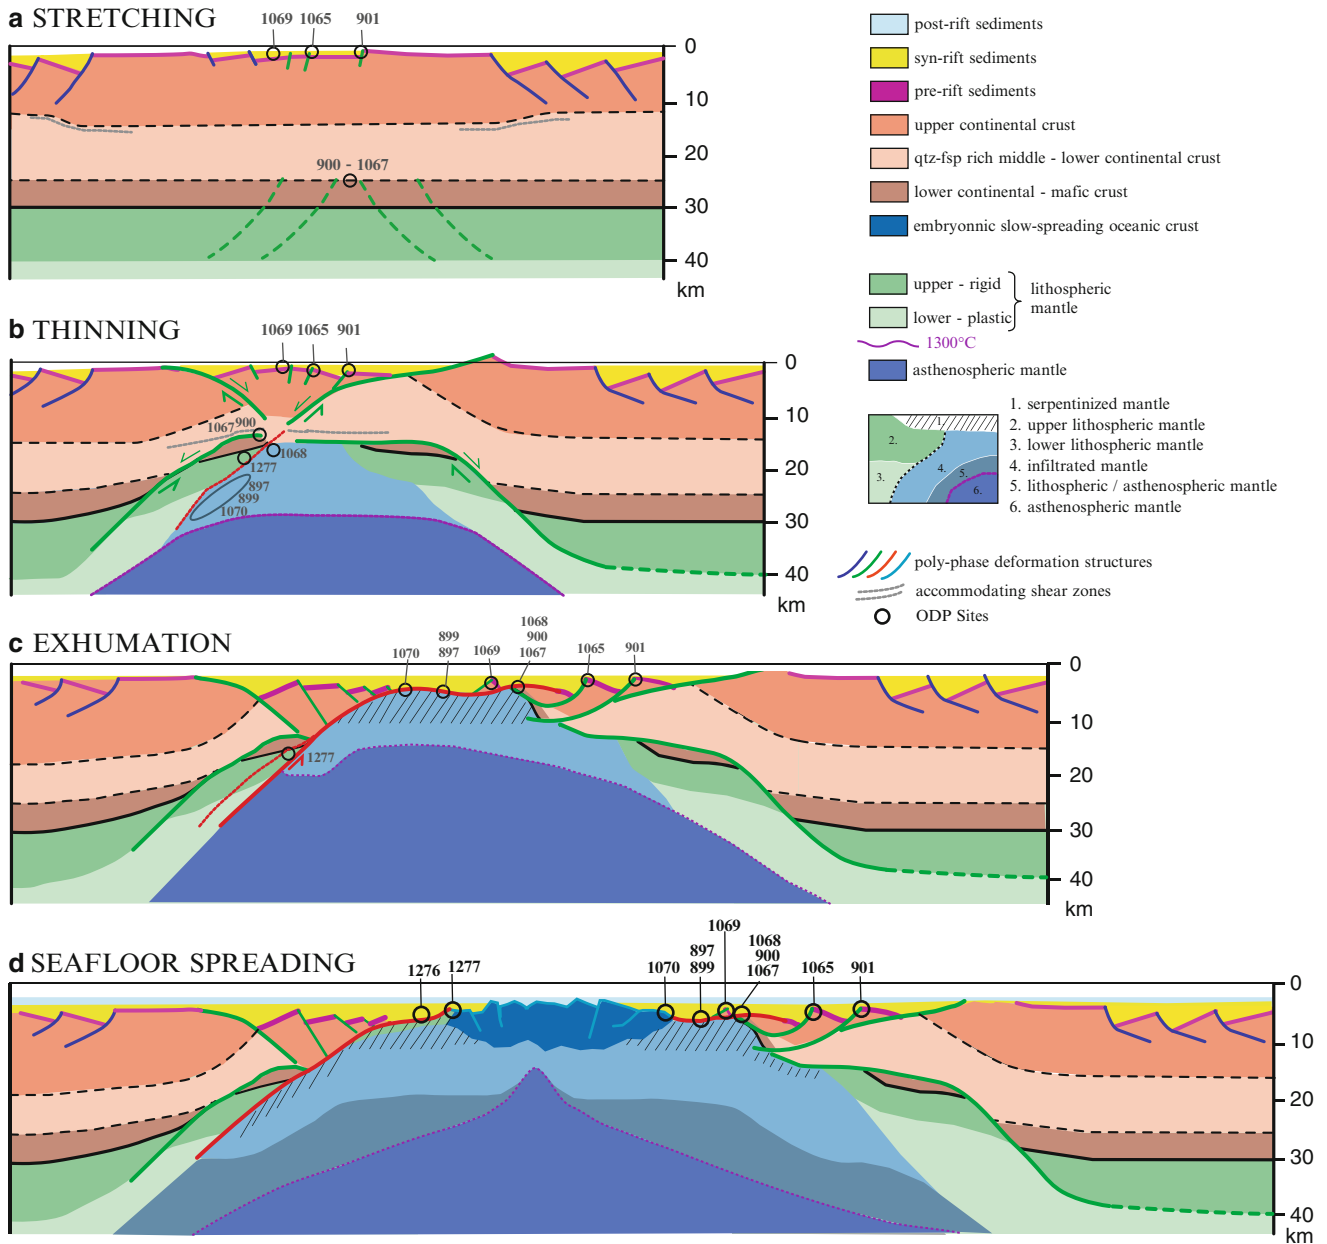
In the Northern Red Sea, a first episode of failed rifting opened small, elongated basins during Miocene, 23 Myr ago (Cochran and Martinez, 1984). Such an early episode of rifting is also recorded in powerful injections of N-S diabase dikes and intrusions (Coleman and McGuire, 1988; Baldridge et al., 1991). Narrow basins, locally opening within the attenuated continental margin of the Red Sea, anticipate the subsequent and successful Red Sea northwards rifting. One of those basins opened in the western margin of the Red Sea is now the Zabargad Island standing over a large gravity high. It displays a peridotite massif, a piece of former and melting asthenosphere that intruded and heated the lower continental crust. It was accompanied by copious diabase diking, parallel to dikes in the Northern Red Sea, with an early age (Sebai et al., 1991). The peridotite massif is a pristine and fertile plagioclase lherzolite, hardly molten during its ascent (Styles and Gerdes, 1983; Bonatti and Seyler, 1987; Nicolas et al., 1994).

Figure 2 proposes a scenario where the lithosphere needs to be thermally eroded before rifting occurs because the tensile stress of the normal continental lithosphere is too strong to yield mechanically. The Miocene event prepares the following event dated early Pliocene, 10–15 My later, with major stretching of the continental crust to its rupture, generating the first oceanic lithosphere. Heating by a mantle plume should be accompanied by a regional doming in the kilometer range of the Northern Red Sea. However, thermal relaxation during 10–15 My and necking of the weakened upper lithosphere have limited the uplift.

Passive rifting

Traditionally, opening of the Atlantic has been presented as showing a striking contrast between the American continental margin, mainly along Newfoundland, that is intruded and covered by thick basalts and the European side of this ocean, a tectonically denuded margin exposing the underlying mantle that is best observed in Galicia (Figure 3b). These contrasted features have been studied along the Iberia-Newfoundland transect (location in Figure 3 of ODP Legs 149, 173 and 210). These features have been explained by an initial asymmetry with a detachment occurring along the European margin (Boillot et al., 1988) and, along the American margin, upwelling of mantle associated with a massive basaltic activity. This simple model is now disputed on the basis of intense field research introducing the concept of hyperextension. Oil companies also conducted research on both margins of the Atlantic, with scientific drilling and many seismic reflection and refraction surveys. The discovery of hydrocarbons in deep margins in the South Atlantic has promoted a new interest in rifted margins. One result has been a major change in the way of thinking about evolution of rift systems with new questions such as how hyperextension relates to magmatism or thermal and isostatic behaviors. The earlier contrast between the opposed margins is now attenuated with complex detachment tectonics being active on both margins. This is illustrated in Figure 3 by the schemes of successive ocean-continent transitions (OCT). In some way, the present day model (Figure 3d) becomes symmetrical. This points out that symmetry depends on the scale: rift systems may be symmetric on the scale of the lithosphere but not necessarily on the scale of the crust.

Conclusions

Historically in the 1970s, two views were prevailing on the origin of rifts. In the model of passive rifting, extension forces applied to a continental lithosphere would stretch and thin this lithosphere with, consequently, uprise of the underlying asthenosphere (Figure 1a). This uprise is responsible for two main attributes of rifts: volcanism and thermally supported reliefs. In the active model, rifting is primarily triggered and localized by a mantle plume (Figure 1b). The asthenosphere rises, either by thermal erosion or fracturing of the lithosphere (Figure 2). In this active model, crustal extension may be limited.


Oceanic Rifts, Figure 3 A new model for the mid-ocean rifting of the Atlantic Ocean, (**a**) and (**b**) from continental rifting, with development of conjugate detachments and mantle uprise, (**c**) OCT between European margin in Galicia and American margin in Newfoundland, with a new major detachment from the western margin and exhumation of lithospheric mantle, and (**d**) seafloor spreading of the Atlantic Ocean (Péron-Pinvidic and Manatschal 2009).

Thermal erosion alone would only create a volcanic dome, such as Hoggar. We conclude that active rifting requires also tensional forces in the lithosphere. Passive or active rifting reflects some of the observed variety of rifts. Another major factor is whether the lithosphere subjected to rifting was homogeneous or already bearing scars, namely, major shear bands, either thermal or geological, for instance, the trace of a former subduction zone. With respect to symmetrical rifting (Figure 1a, b), this would favor asymmetrical rifting (Figure 1c). In this simple model, the strength of a normal, homogeneous continental lithosphere would be too high to yield, unless a flat-lying weak zone is present. This would generate a cold detachment fault (Figure 1c). However, these models remain very simple. There is also an evolution in time. As illustrated by the Red Sea evolution, the initiation of an oceanic rift in the North tends to be symmetrical, whereas in the Southern Red Sea that is in a further stage of oceanic

rifting, heterogeneous structures appear such as detachment faults that increase the asymmetry. Despite 40 years of active research, there is still much to learn about rifting as illustrated by recent developments.

Definition

Seafloor spreading is a process on the earth's surface where oceanic lithosphere is created.

Full spreading rate is the rate (mm/year) at which two plates diverge from each other.

Ridge axis and plane define the position of the spreading center.

Neovolcanic zone lies on the ridge axis where melt is delivered to the surface and lavas erupt.

Hydrothermal circulation is a process where seawater is circulated and heated in the crust.

Hydrothermal vent field (also known as black smokers) is the site on the seafloor where mineral-laden hot water exits the seafloor.

Axial melt lens (AML) is a thin body of magma seismically imaged beneath oceanic spreading centers.

Magma chamber is a domain beneath ridge crests between melt lens and Moho comprised mixtures of melt and crystals.

Layer 2A is the seismically defined top layer of oceanic basaltic crust made of lava flows.

Layer 2B is the seismically defined layer between layer 2A and layer 3, the gabbroic layer, consisting of a diabase dike sequence.

Lid comprises the basaltic layers 2A and 2B above the axial melt lens.

Layer 3 is the seismically defined layer comprised of gabbro unit between the lid and upper mantle.

Moho is the seismically defined boundary between the crust and mantle.

Lithosphere is the upper layer of the earth comprised of the uppermost mantle and crust that moves as a rigid layer over the asthenosphere.

Asthenosphere is the deformable part of the earth mantle over which the lithosphere may move independently.

Seismic reflection is a geophysical technique to image to sharp physical boundary in the crust.

Seismic refraction (also referred as tomography) is a geophysical technique to image large-scale velocity structure of the earth.

Introduction

Plate tectonic theory defines the movement of the upper part of the earth's surface where plates (lithosphere) move over the asthenosphere. Different plates interact with one another along boundaries that are classified as (1) divergent plate boundaries (spreading centers), (2) convergent plate boundaries (subduction and collision zones), and (3) transform plate boundaries along which two plates slip in opposite directions (Figure 1). At oceanic spreading centers, two plates move apart due to the upwelling of the asthenosphere near the surface and due to the pull of plates as they are subducted at convergent boundaries. As the hot asthenospheric mantle rises beneath ridges,

the pressure decreases leading to partial melting of the mantle, yielding basaltic melt rising towards the surface of the earth to form the oceanic crust. Part of the melt erupts on the seafloor forming extrusive lava flows at the ridge axis where it solidifies. Laboratory measurements of seismic velocities of these lava flows correspond to the seismically defined layer 2A (Figure 2). Lavas are fed by intrusive dikes whose velocities correspond to the seismically defined layer 2B. Below the dikes that feed the overlying lava flows is a small melt lens (AML), molten at ~1,200 °C. Crystals forming in this magma body feed a gabbroic mush subsiding in a magma chamber below. Away from the ridge axis, these melt lenses and the magma chambers cool and crystallize to form the gabbroic lower crust, whose velocities correspond to the seismically defined layer 3. The cooling and crystallization is achieved by efficient hydrothermal circulation of the seawater throughout the crust. The heated seawater returns to the seafloor axis as hydrothermal vents, the black smokers. Below the crust, the mantle consists of high-density peridotites. The boundary between the crust and mantle is called Mohorovičić seismic discontinuity or

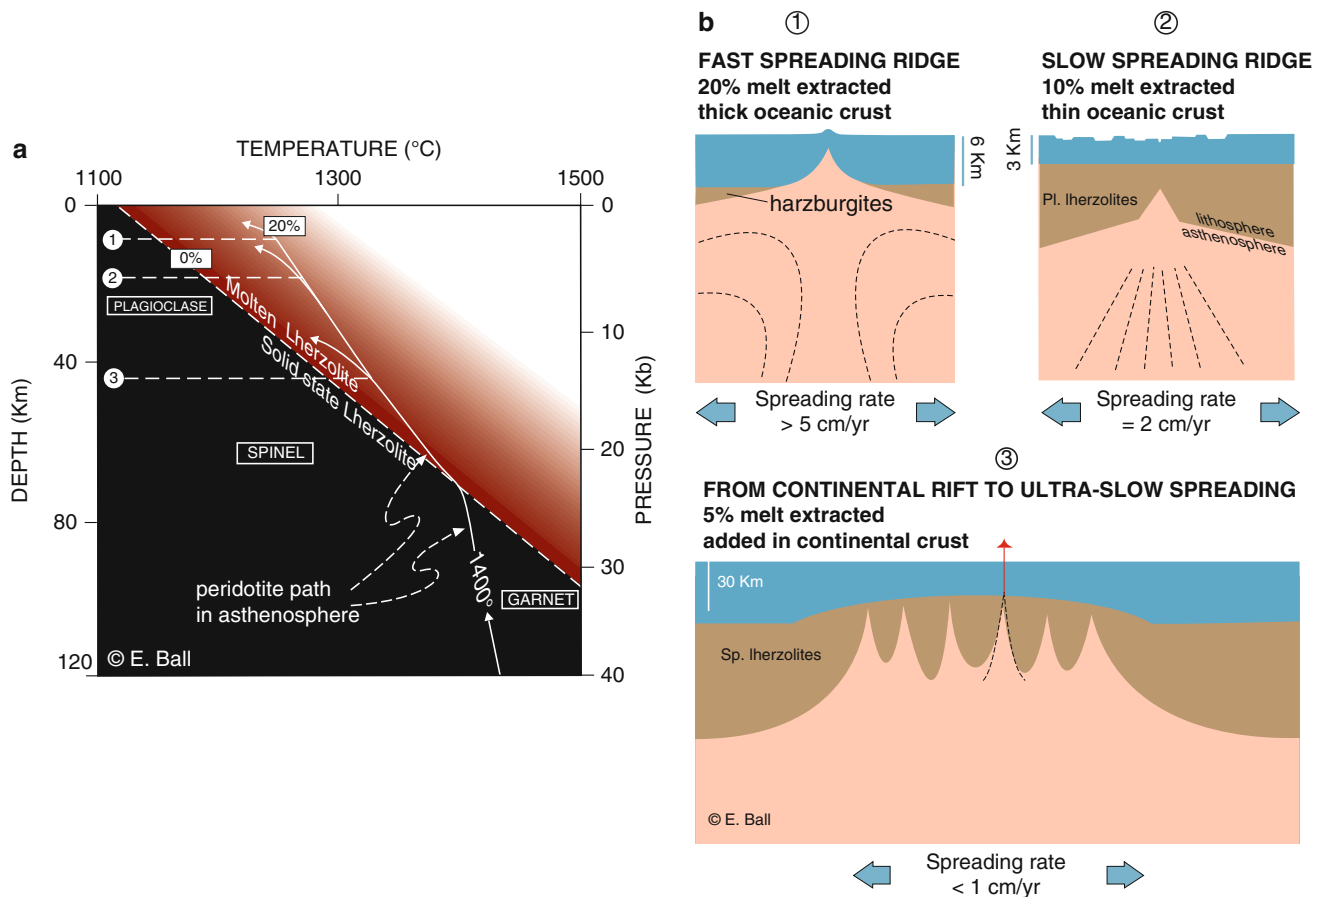
Moho for short. Thus, based on a combination of seismic velocities and the petrological descriptions, the oceanic crust can be divided into three layers (Figure 2a): (1) layer 2A consisting mainly of lava flows, (2) layer 2B consisting mainly of dike sequences, and (3) layer 3 containing mainly gabbroic rocks. However, as we shall discuss later, there are significant deviation from this simple model of the oceanic crust (e.g., Figure 2b).

Diverging plates at spreading centers exert horizontal stresses leading to fracturing of the cold and brittle part of the crust and upper mantle (lithosphere) causing earthquakes and faulting. With increasing spreading rate, the amount of melting in the mantle increases leading to increased crustal thicknesses. As presented below, the various physical features and differences in crustal structure can be correlated with spreading rate, rates of cooling, and faulting of the crust. However, other parameters, the nature of the rising mantle and the extent that it melts, may play a more important role. The mantle is unlikely to be homogeneous and could be more or less fertile, warmer or colder, and dry or hydrated. This is known from inferences made from the chemistry of basalts derived from the mantle and the study of ophiolites where different types of mantle have been sampled (Nicolas, 1989). However, a "standard" mantle may be defined. The various physical attributes of spreading centers are therefore largely controlled by the mantle upwelling beneath them. Consequently, the ocean spreading ridges can be classified on the basis of their spreading rates and this in turn can provide a clearer understanding of seafloor spreading processes.

There are four main types of spreading centers based on spreading rates: (1) fast spreading center with a spreading rate greater than 70 mm/year and superfast ones, say more than ~120 mm/year; (2) intermediate spreading center with spreading rate between 40 and 69 mm/year; and (3) slow spreading center with spreading rate between 20 and 39 mm/year and (4) ultraslow spreading center with spreading less than 20 mm/year. Figure 1 shows the location of the main spreading centers on earth. The East Pacific Rise is a fast spreading ridge, Juan du Fuca and Lau Spreading Centers are intermediate spreading ridges, Mid-Atlantic and Central Indian Ridges are slow spreading ridges, and Southwest Indian ridge is an ultraslow spreading ridge.

A simple conceptual model for oceanic ridges

In order to address how rates of seafloor spreading are related to most of the features of fast, intermediate, slow, and ultraslow spreading ridges, as well as oceanic rifts (see entries "Oceanic Rifts" and "Ophiolites" in this volume), a good approach is to address the basic question of how melting operates in the rising mantle below these different spreading systems and how it generates distinct oceanic spreading centers (Figure 3).

Figure 3a illustrates a pressure-temperature diagram showing a trajectory of rising mantle within an


Oceanic Spreading Centers, Figure 3 (**a**) Simplified sketch of melting in a rising mantle along a steep pressure-temperature adiabatic path (in *black* field), before it reaches the lithosphere and follows shallower paths due to conductive cooling. Partial melting occurs in the *red* domain, above the dry mantle solidus, where the adiabatic curve flattens due to the enthalpy of melting. Above the solidus, the three main trajectories depend on the depth of first melting (here 80 km), the melting fraction per Gp), and the meeting point of each trajectory with the lithosphere: Case (1) corresponds to the trajectory for a thin lithosphere, (2) for a thicker lithosphere, and (3) for a very thick lithosphere. (**b**) The corresponding transverse structures of ridges and rifts: case (1) for a fast spreading rate with a thin lithosphere and large melt delivery, (2) for a slow spreading ridge with a thicker lithosphere and less melt delivery, and (3) for a ultraslow spreading ridge with a very thick lithosphere and associated little or no melting (Nicolas, 1989, 1992).

asthenospheric upper mantle where the thermal regime is convective (adiabatic gradient ~0.3 °C/km). At a depth of ~80 km, this mantle trajectory crosses the steeper fertile lherzolite mantle melting curve above which the melt fraction increases linearly with a slope largely smaller than that in the dry adiabatic domain below. Due to enthalpy of melting, a shallower slope results from the heat used for further melting. Melting ceases depending on the depth where the uprising mantle meets the solid lithosphere. However, magmas keep rising, following the conductive gradient in the static lithosphere. This new gradient has a flatter trajectory up to the earth's surface. In this simple model, the nature of any spreading center is controlled only by the lithospheric thickness that is itself dependent on the spreading rate. In a fast spreading situation (Figure 3b1) at the ridge axis, the asthenosphere rises up to ~2 km beneath the lithospheric lid, and ~20 % melt is

generated. Lithosphere would be thicker (<10 km) at a slow spreading ridge (Figure 3b2); the melting column is shorter near the central rift valley, thus generating ~10 % basaltic melt. Finally, a ~60 km-thick lithosphere would create a continental rifting opening at ~0.5 cm/y as in the French Massif Central (Figure 3b3). In an oceanic rift such as Red Sea, or in an ultraslow oceanic ridge, lithosphere would remain thicker than that beneath slow spreading ridges. Below we discuss the general features of the two main spreading systems, fast and slow with brief comments on ultraslow ridges and with some comments on back-arc spreading centers.

Fast spreading center

The East Pacific Rise (EPR) is the simplest and most stable geological system in space and time and, thus, the best adapted to understand the process of seafloor accretion.

Morphology

The morphology of fast spreading centers is characterized by an axial high, which can be up to 15–20 km wide and ~500 m high relative to nearby abyssal plain with the shallowest points around neovolcanic zone where volcanism and hydrothermal venting are concentrated and often have a region of volcanic collapse at the center (Figure 4). The presence of axial highs is due to the upwelling of hot mantle beneath the spreading centers. The lithosphere exactly beneath the ridge axis is limited to the lid itself, and therefore, very few faults are observed, but as the lithosphere drifts and thickens, some faults develop away from the ridge that are expressed as abyssal hills. On the larger scale of several hundreds of kilometers, fast spreading ridges are segmented by large transform faults and overlapping spreading centers that offset the spreading center axis. In a few places rotating microplates ranging from ~500 km across at the Easter microplate to ~50 km at the Wilkes nanoplate also offset the spreading center. The scale of individual segments could be from 50 to 150 km. Two segments along a ridge may overlap, developing basins between overlapping spreading centers or duelling, one propagating forward against the other that is receding (MacDonald et al., 1988) (Figure 4). Within a larger ridge segment, a smaller change in the linear nature of the axis is known as a DEViation in Axial Linearity (DEVAL). Because the lithosphere remains thin even off axis, segmentation reflects some independence between lithospheric and asthenospheric tectonic activity (Toomey et al., 2007).

Structure

The layer 2A, the extrusive volcanic unit, is either defined by a change in P-wave velocity gradient around 4.5 km/s contour or by seismic image (Harding et al., 1993) (Figure 2). The thickness of layer 2A varies from 150 to 200 m on the ridge axis to 300–700 m away from the ridge axis due to accumulation of lava (Kent et al., 1993). The low velocity of layer 2A relative to the velocity measured in basaltic lava is generally due to the presence of pores (fluids), where the porosity decreases with depth from 30 % near the surface to 5–6 % at the base of layer 2A (Collier and Singh, 1998).

Layer 2B, the sheeted dike layer, is defined by a low-velocity gradient layer, where the P-wave velocity ranges from 4.5 to 6 km/s (Figure 2). The presence of high velocity suggests a further decrease of porosity down to ~1 %, but a low-velocity hydrothermal-rich layer has also been imaged at the base of layer 2B (Singh et al., 1999). The thickness of layer 2B varies from 1.5 to 2 km thick, depending upon the depth of the axial melt lens (AML) that defines the base of dike layer above and gabbro below.

The P-wave velocity in the AML has been measured to be between 2.5 and 4 km/s (Murase and McBirney, 1973). The large decrease in velocity leads to a strong seismic
Oceanic Spreading Centers, Figure 4 The seafloor morphology of the 9° N EPR, showing the 9° N overlapping spreading center (OSC in *white box*) and the Clipperton and Siqueiros transforms and associated fracture zones.
Oceanic Spreading Centers, Figure 5 3D view of AML beneath 9° N overlapping spreading center (Kent et al., 2000).

reflection, generally with a negative polarity as compared to the seafloor (Detrick et al., 1987; Kent et al., 1993). The velocity within the AML could be estimated using seismic full waveform inversion (Singh et al., 1998). The AMLs could be 200–4,500 m wide and 50–100 m thick, although thicker melt lenses (300 m) have been observed beneath the 9°N overlapping spreading center (Kent et al., 2000) (Figure 5). AMLs are present along a significant part (70 %) of the ridge axis beneath fast spreading centers. AMLs are not only present at the center of the ridge axes but also at segment ends (Kent et al., 2000) (Figure 5). Melt lenses have also been observed off axis as well (Canales et al., 2011). Along the ridge axis AMLs can be segmented into areas of pure-melt and crystal-melt mush zones that can be distinguished from zero and non-zero S-wave velocity (Singh et al., 1998). Areas of pure melt seem to be responsible for vigorous hydrothermal circulation and the presence of hydrothermal vent fields observed on the seafloor (Singh et al., 1999). The cooling and crystallization of melt from the AMLs are responsible for the formation of the upper part of layer 3 (upper gabbro).

On the ridge axis, a low-velocity layer is observed beneath the AML, where the P-wave velocity varies from 3.5 to 6.0 km/s, suggesting the presence of partial melt (5–30 %) (Dunn et al., 2000). This region is known as the axial magma chamber (AMC) and is thought to consist of thin melt sills or melt pockets rather than large regions of magma (Figure 6). The width of the AMC is generally 5–8 km, which could up to ~10 km wide at the Moho depths as noted in ophiolites such as in Oman where the internal nature and structure of the AMC has been studied (see Figure 8). The cooling and crystallization of melt in the AMC and AML forms the gabbroic layer 3. Layer

3 is characterized by a low-velocity gradient where the P-wave velocity varies from 6.5 to 7 km/s over a depth range of ~3 km (Harding et al., 1989).

The P-wave velocity in the mantle beneath the ridge axis is about 7.6–7.8 km/s, which increases to 8.0–8.1 km/s away from the ridge axis (Dunn et al., 2000). The P-wave velocity in the mantle is determined by seismic refraction methods. The strong velocity contrast at the crust-mantle boundary could produce Moho reflections. The Moho is observed beneath the ridge axis at zero age, suggesting that the crust at fast spreading centers is formed at zero age (Singh et al., 2006a) (Figure 7a). The Moho reflection can have different characters: sharp, shingled, or diffuse (Kent et al., 1994) (Figures 7b–d). A reflection from the crust and mantle would not be observed if the boundary is thick (~1 km) where the velocity gradually increases with depth. In both cases, wide-angle reflections are observed on seismic data, allowing crustal thickness estimation. However, from wide-angle reflection data alone, it is uncertain if the crust-mantle boundary is sharp or has a velocity gradient (Moho Transition Zone, MTZ).

The mantle beneath the spreading center is characterized by a low-velocity anomaly that extends down to 70 km in depth over a 50 km-wide zone (Toomey et al., 1998), suggesting the presence of partial melt. Some of these melts could get trapped below the Moho in a form of a sill, similar to those interpreted to exist as the MTZ in ophiolites (Crawford and Webb, 2002; Nedimovic et al., 2005).

The lithosphere-asthenosphere boundary lies at the top of the magma chamber and the level of the axial melt lens, rapidly deepening away from the ridge axis. The precise nature of this boundary away from the ridge axis remains
Oceanic Spreading Centers, Figure 6 2D P-wave velocity anomaly beneath 9° 30′ N East Pacific Rise (Dunn et al., 2000). AML stands for axial melt lens where seismic velocities are remarkably low because of large melt fractions, and AMC is axial magma chamber where melt fraction would be in the range of 20 % (Nicolas and Ildefonse, 1996). *Black dashed line* marks the Moho boundary, which is underlain by a broad low velocity in the mantle underneath.

a matter of debate in the oceans (Kawakatsu et al., 2009; Karato, 2012).

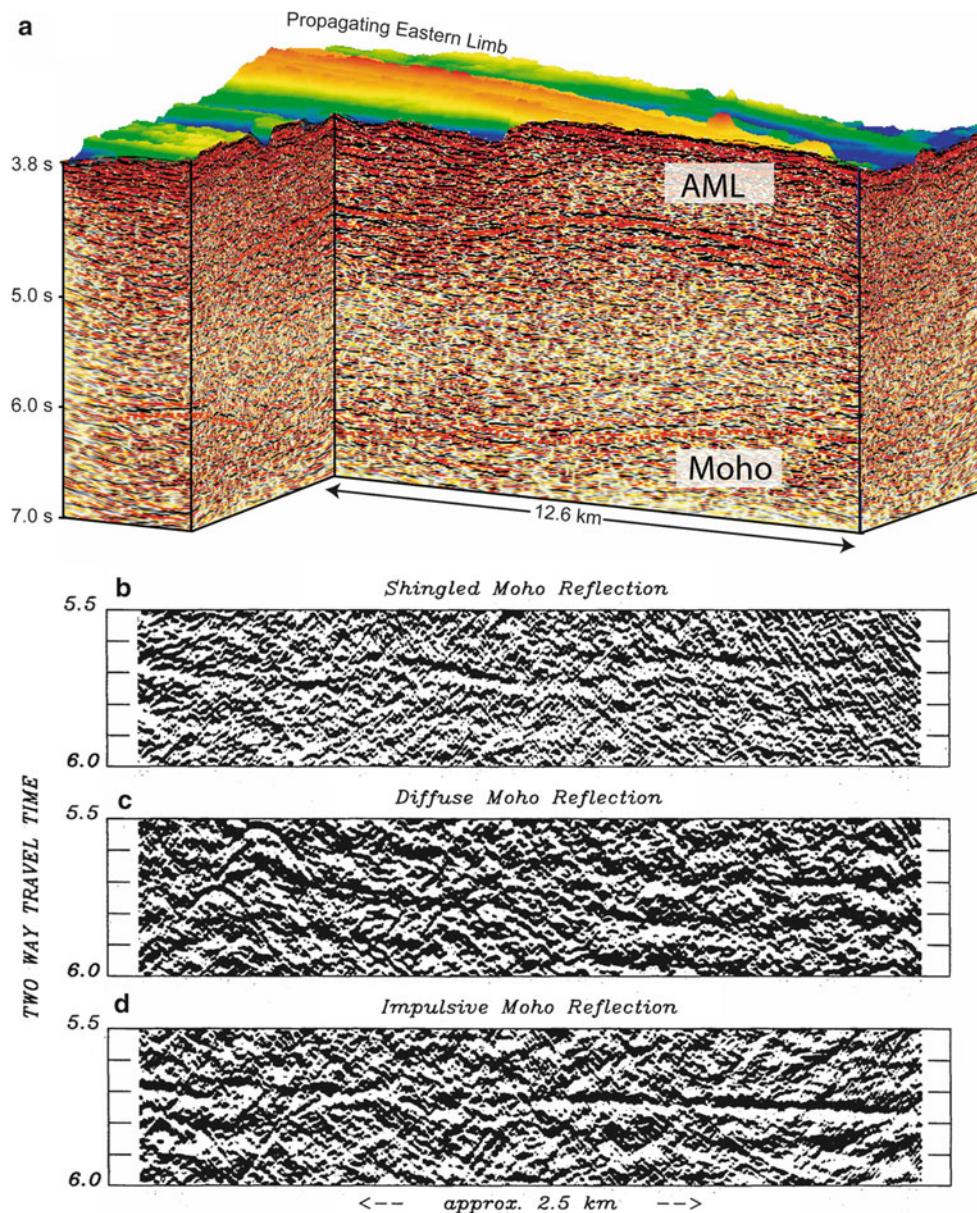
Hydrothermal circulation

The temperature of the melt in the AML and AMC is ~1,200 °C, which is cooled by hydrothermal process as cold seawater enters the crust (thermal sink near the ridge axis), then rises back to the seafloor where it exists as hydrothermal vents (black smokers) with a water temperature up to 400 °C. Just below the ridge axis, the water circulates down to the AML, whereas it could potentially circulate down to Moho depths around the AMC (MacLennan et al., 2004). At one time it was believed that hydrothermal circulation mainly occurred across axis, but recent studies have shown that a significant amount of hydrothermal circulation takes place along the ridge axis (Fontaine and Wilcock, 2007; Tolstoy et al., 2008).

Comparing internal structures of the EPR and Oman ophiolite

With the exception of the seafloor itself, little of the internal geology of fast spreading ridges can be directly studied, in contrast to slow spreading ridges where kilometers of relief are exposed along deep transform faults and oceanic core complexes. Few exceptions are Hess Deep where the westward-propagating Galapagos Spreading Center cuts through young the EPR crust, exposing its crustal section. It has been drilled during the IODP program (Legs 147 in 1993 and 345 in 2012–2013). Another site is the Pito Deep, the tip of a propagator on the Easter microplate. So far only gabbros (in situ) have been recovered in these sites. This is why

we briefly present some of the prominent geological features exposed in the field in the Oman ophiolite and show how they compare with the wealth of geophysical data discussed above (see also "Ophiolites" and "Oceanic Rifts" in this encyclopedia).

The Oman ophiolite is a piece of oceanic lithosphere formed 95 Ma ago that got detached and thrust on to the passive margin of Oman about 10 Ma later. It is best suited for a comparison with the EPR as it was formed at fast spreading to superfast (20 cm/year) spreading centers (Rioux et al., 2012). It is very large (500 km long and 60–80 km wide), compared with the well-studied 200 km by 50 km 8–10°N segment of the EPR (Figure 4). The Oman ophiolite has excellent exposures, is flat-lying, and has not been structurally dismembered. Its structural and petrologic study is remarkably complementary to that obtained by the detailed studies conducted around 9°N on the EPR. Two examples illustrate this complementarity. AMLs are well imaged at the EPR using seismic reflection techniques (see above) whereas in Oman, the existence of such a melt lens could not be imagined because AMLs are transient features of an active ridge, vanishing at a kilometer distance from the ridge axis. However, looking between the lid and the gabbro unit for evidences of their presence in Oman, it has been possible to identify their former existence along the ridge and to describe their past magmatic history, such as episodic filling by new melt or internal convection, obviously out of reach in active ridges. AMLs generate most of the gabbro unit by deposition of gabbroic mushes on their floor (Boudier and Nicolas, 2011). This is followed by subsidence of this mush from the floor to deeper in the crust (Nicolas et al., 2009). The typical layering of


Oceanic Spreading Centers, Figure 7 (**a**) 3D seismic reflection image of Moho beneath the AML along the eastern limb of the overlapping spreading center at 9° N East Pacific Rise (Singh et al., 2006a), (**b**) seismic reflection image of shingled Moho, (**c**) diffuse Moho, and (**d**) impulsive Moho (Kent et al., 1994).

gabbros is dominantly inherited from the episodic filling and internal convection in AML, together with intrusion of gabbro and wehrlite sills. Layering is reinforced by large magmatic flowage (e.g., Figure 8).

Contrasting with the AML concept at the EPR, mantle diapirs were early discovered and mapped in the Oman ophiolite. The mantle diapirs are derived from hot, partially molten mantle rising beneath the ridge axis. They are ~10 km wide at the Moho level where the vertical mantle flow pattern is broken and diverges horizontally (Rabinowicz et al., 1984) (Figure 8c). Similar mantle

upwellings have been interpreted to occur at the 9°N EPR from seismic refraction studies (Dunn and Toomey, 1997; Toomey et al., 2007). Beneath the Moho in the Oman ophiolite, there is a ~400 m thick Moho transition zone (MTZ) typically composed of a residual dunite impregnated by gabbroic melt. The MTZ at an active ridge should be largely molten with a viscosity accounting for the mantle flow rotation (Jousselin and Nicolas, 2000) (Figure 8c). It is this MTZ that seems to have been imaged by seafloor compliance studies at the EPR (Crawford and Webb, 2002). Based on field studies in Oman, at the ridge
Oceanic Spreading Centers, Figure 8 Typical images in the Oman ophiolite. (**a**) Lower gabbros with a flat-lying layering foliation. (**b**) Dynamic, magmatic foliation gabbro with black sills of wehrlites (bar = 10 cm). (**c**) The horizontal Moho. Below the light-colored layered gabbros, the geologists stand on the *brown*-colored mantle.

axis above the Moho, wehrlites, a mobile mixture of the melt-impregnated dunites derived from the MTZ, are injected mainly into the lower crust. When injected within the AMC, they form sills that get stretched by magmatic flow (Figure 8b). When they are injected outside the AMC, they constitute intrusions, commonly kilometers long (Figure 9). Interestingly, the tent shape of the magma chamber observed at the EPR by wide-angle seismic refraction (Detrick et al., 1987) and in Oman by geologists was discovered simultaneously (Nicolas et al., 1988). Later on, magma chamber models were further refined by Oman geologists (Mainprice, 1997) and marine

geophysicists (Dunn and Toomey, 1997) with a good agreement on the overall shape and nature of the gabbroic mush that fills it.

There is also an agreement between the results from Oman and EPR regarding the hydrothermal alteration of the juvenile crust by seawater. The black smokers at the EPR are the surface manifestation of hydrothermal circulation at spreading ridges, whereas at depth the hydrothermal plumbing is known from drilling through the basalts and sheeted dikes in the upper crust to near the top of the melt lens (IODP leg 147, Hess Deep and leg 1256, EPR), showing seawater alteration at ~400 °C (Lowell et al., 2012). In the gabbro cores recovered from Hess Deep, evidence of a high temperature (~700 °C) alteration has been discovered (Manning et al., 1996). In Oman, where the 3D hydrothermal structure down to the Moho is fully exposed, this high temperature alteration (Manning et al., 2000) and a very high temperature (~1,000 °C) (Nicolas et al., 2003) metamorphism are related to a thermal boundary layer (TBL) plated along the walls of the magma chamber (Cathles, 1993) (Figure 9).

The transition between fast and slow spreading ridges

The transition from fast to slow spreading ridge occurs when the magmatic input controlling the spreading activity is no longer continuous and becomes time dependent. Typically, this is observed in slow spreading ridges with successive episodes of ridge accretion by new magmatic addition and by tectonic stretching of the lithosphere, in particular, creating spectacular oceanic core complexes (OCC). The distinction between fast and slow spreading ridges is around 4–5 cm/year (Phipps Morgan and Chen, 1993), a rate above which coincides with the appearance of a stable melt lens on top of the low-velocity zone. As noted above, this limit depends on the nature of the rising mantle. For instance, the Reykjanes ridge, which is fed by the nearby Iceland hot spot, has many attributes of a fast spreading ridge, such as a permanent crustal magma chamber, even though the spreading rate is ~2 cm/year (Sinha et al., 1997).

Slow spreading centers
Morphology
The morphology of slow spreading centers is characterized by an axial valley (median valley), which could be up to 15–25 km wide and ~500–1,000 m deep (Figure 10). The shallowest part of the ridge is generally at the center of the segment, possibly with a central volcano, and it is deepest at the segment ends (Figure 10). The lithosphere at slow ridge axes is quite variable but typically ~6 km thick (Figure 3b2). The median valley is bounded by active ridge-ward dipping faults. Commonly, there are many other smaller faults within the median valley. In contrast with fast spreading ridges, kilometers-deep transform faults, the extensions of which are called
Oceanic Spreading Centers, Figure 9 A general structural model of accretion at a young ridge segment in Oman. The melt (*red*) rising through a mantle diapir accumulates in the MTZ, just beneath the Moho. In this mushy horizon of melt-impregnated dunites; the steep mantle flow rotates and diverges. Also in the MTZ, the melt chemically reacts and re-equilibrates with dunite to become MORB magma. Physically, it can be stored in the dunitic mush before an extrusion towards the AML, shorter than a few years (Boudier and Nicolas, 2011). It may also rise through the gabbro magma chamber, either by percolation or by wehrlite intrusions derived from the MTZ mush. On the *left* side of the figure, hydrothermal alteration is sketched (*green*). It refers to a nonconventional model (Cathles, 1993). In contrast with the conventional model based on progressive heating of the descending seawater flow, here low-temperature seawater reaches the Moho through fissures and fractures from a distance of ~5 km from the ridge axis: the approximate width limit of the magma chamber at the Moho level. Seawater upflow is heated by the return flow from a thin TBL that is plated against the magma chamber walls and its associated melt lens roof. The return seawater flow at 400 °C or above ascends through a low porosity channel at the edge of the TBL.

fracture zones, can expose sections of the entire crust. Between these dominant faults, segments can also be separated by non-transform offsets. Commonly located at the internal corner between ridge and fracture zones, long-lived detachment faults tend to generate oceanic core complexes (OCC), described below (Figure 13), although OCC have also been observed within segments (Escartin et al., 2008).

Structure

Because of faulting and rotation of blocks in OCC, the seafloor morphology of the crust formed at slow spreading ridges is very irregular and rugged. For this reason, only limited combined seismic reflection and refraction studies have been successful; the best results were obtained at the Lucky Strike segment of the Mid-Atlantic Ridge (Crawford et al., 2010). Layer 2A in this area is thicker (400–800 m) than that at fast spreading centers, which could be due to the accumulation of lava flow over a long time and slow spreading. The thick layer 2A could also result from a complex interaction of lava flow, faulting, and hydrothermal circulation. At the Lucky Strike segment, layer 2A does not seem to vary along the ridge axis, indicating that the thickness of layer 2A remains constant along the whole 70 km long segment, suggesting that volcanism plays an important role along the whole segment. The thickness of layer 2A decreases around the bounding

faults, suggesting that the tectonic processes could decrease the thickness of volcanically constructed crust.

The imaging of layer 2B is rather difficult beneath slow spreading ridges because of the absence of AML in the crust and complex accretion process. However, a 3–4 km wide and 7 km long AML was recently imaged at the center of the Lucky Strike segment at ~3 km depth (Singh et al., 2006b) for the first time, suggesting that layer 2B there could be 2–2.5 km thick (Figure 11). There is a low velocity beneath the AML, which could be due to the partial melt in the lower crust, but the percentage of melt is much less than that observed at fast spreading centers (Dunn et al., 2000). The presence of AML also allows to characterize the lower crust, layer 3, which in the Lucky Strike area is about 3–4 km thick, leading to a crustal thickness of 7 km at the center of the segment (Seher et al., 2010). The crustal thickness at the segment ends smoothly decreases to 5 km, suggesting the crust at slow spreading centers are boudin shaped, i.e., thick in the center of segment and thin at segments end.

Seismic reflection images at the Lucky Strike segment also show faults that penetrate down to AML, which include not just the median valley bounding faults but many other faults within the axis (Figure 11). As expected, these faults are ridge-ward dipping. These faults could be responsible for hydrothermal circulation and may influence the positions of hydrothermal vent fields.
Oceanic Spreading Centers, Figure 10 Seafloor morphology of 35° N Mid-Atlantic Ridge, showing transform fault, non-transform offset, rift valley, and faults scarps (Data source: GeoMap App).

The crustal seismic structure at non-transform faults show some low velocities in the lower crust, which could be due to the serpentinization of ultramafic oceanic rocks that likely include parts of the mantle (Cannat, 1996; Canales et al., 2000). The crust beneath fracture zones is generally thin, 3–4.5 km, and shows absence of the layer 2A, indicating the absence of volcanism (Detrick et al., 1993).

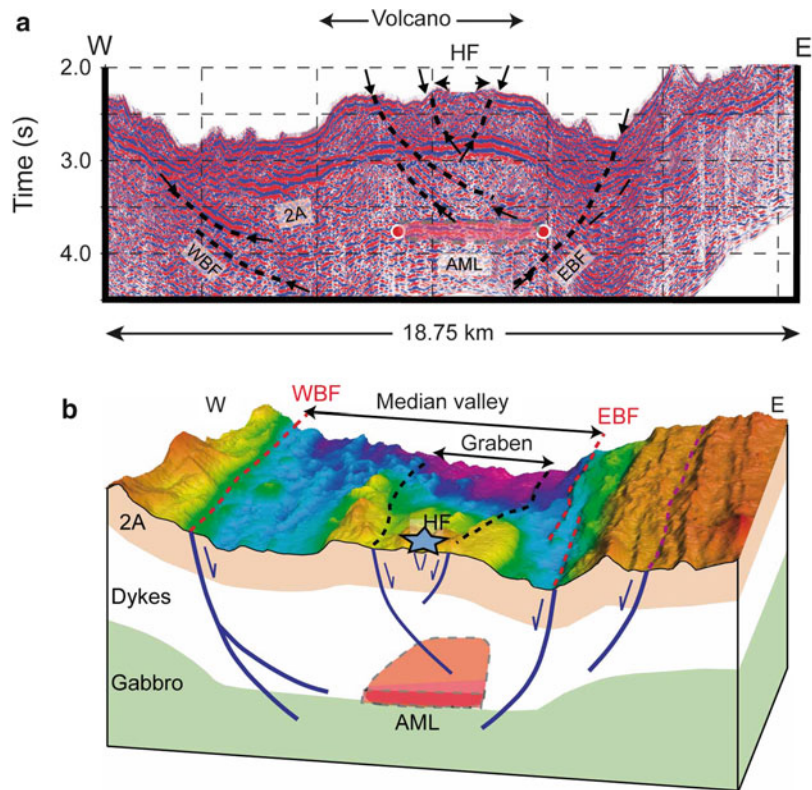
Oceanic core complexes

The distinctive features of slow spreading ridges are due to their lower thermal budget as compared to fast spreading ridges. Because melt delivery is believed to be discontinuous in time and space, the continuous spreading imposed by plate tectonics leads to alternate episodes of magmatic and tectonic accretion. Magmatic accretion allows the temporary formation of a magma chamber, such as at Lucky Strike, with the presence of an AML. Tectonic accretion proceeds by the normal faulting responsible for the axial rifting and by the detachment faulting creating the spectacular OCCs (Tucholke et al., 1998). Mantle lithosphere dips about 30° away from the ridge axial plane (Figure 3b) and studies of ophiolites (Nicolas, 1989; Jousselin and Nicolas, 2000) suggest that these lithospheric slopes channel mantle flow parallel to the ridge axis between major transform faults. As a consequence,

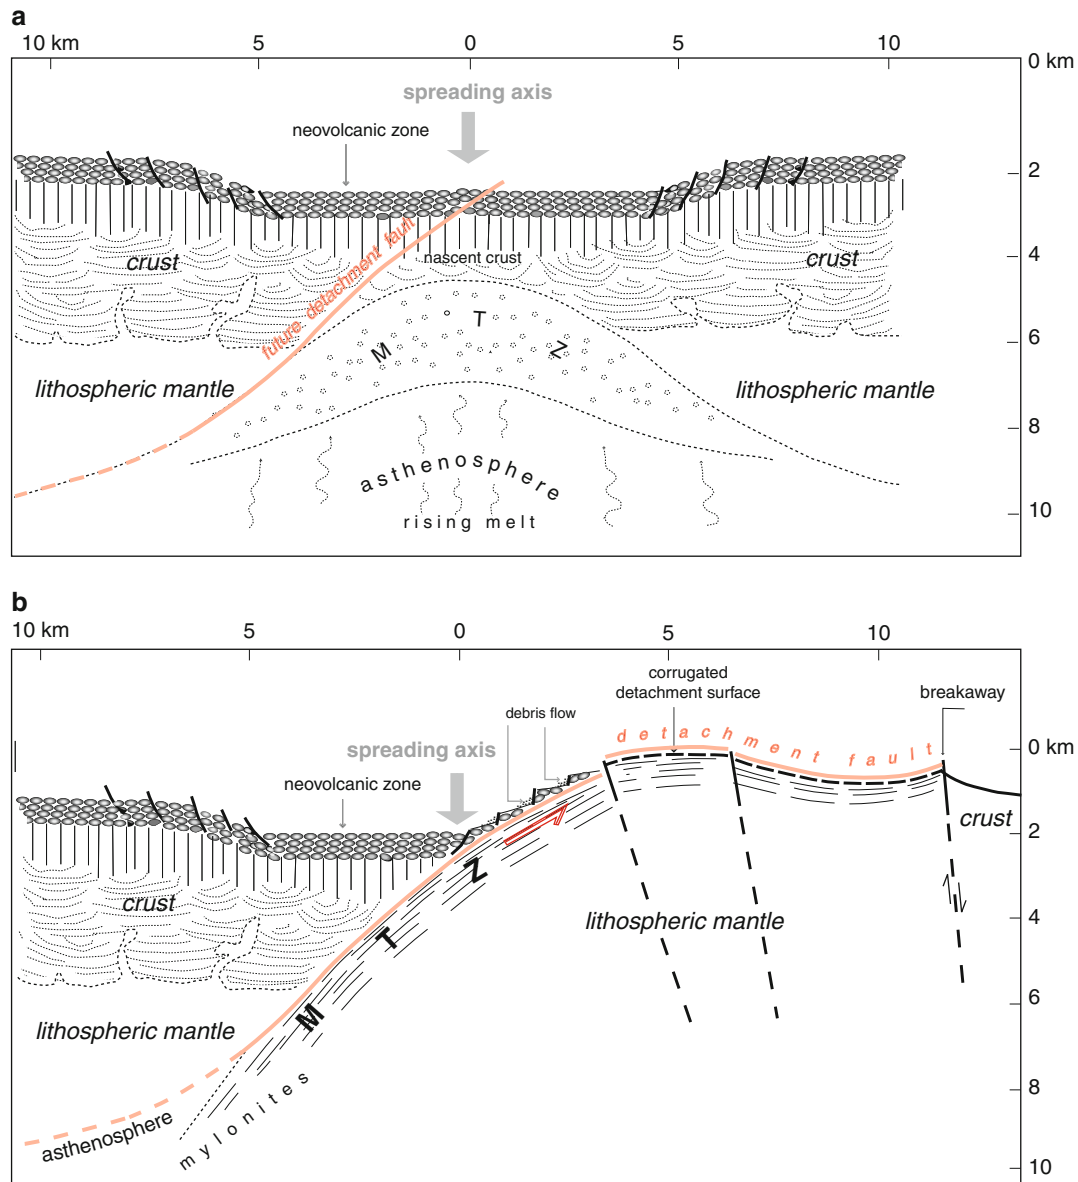
the MTZ would become a few kilometers thick below the ridge axis, compared to a few hundred meters at fast spreading ridges. However, it thins out at a short distance on each side of the ridge (Figure 13).

We briefly present the characteristic morphology of OCC from the Atlantic seafloor (Figure 12) and, tentatively, introduce (Figure 13) a model derived from the Mirdita ophiolite in Albania. It may complement the marine studies on OCCs that are mostly limited to seafloor observations. Introducing field observations on the deep structure of OCCs in this slow spreading ophiolite, we take into account the geophysical data obtained in OCCS from MAR (Nooner et al., 2003; Schroeder and John, 2004; DeMartin et al., 2007; Henig et al., 2012; Hansen et al., 2013).

Ultraslow spreading centers

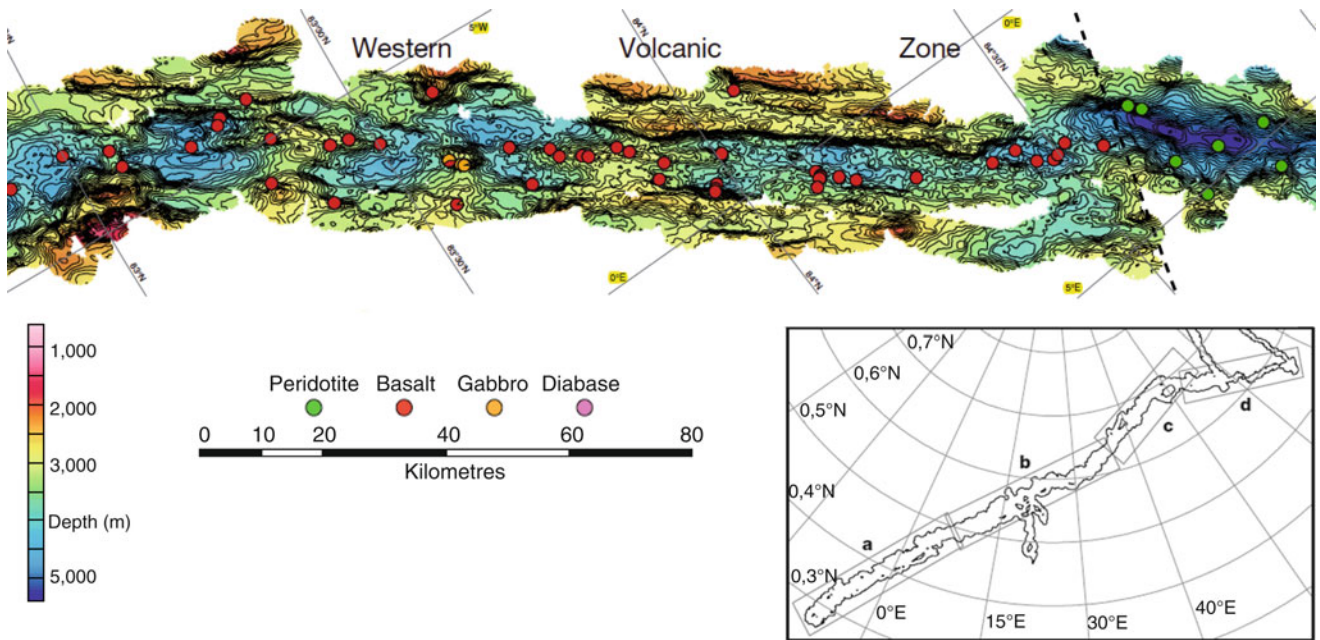
Ultraslow spreading centers correspond to spreading rates of 1–2 cm/year, rates between those that characterize slow spreading ridges described above and those of oceanic rifts (see Oceanic Rifts). The Southwest Indian Ridge (SWIR) and the Gakkel Ridge in the Arctic have both been recently studied, and a few general features can be anticipated based on the mantle melting models presented in Figure 3. The fertile mantle rocks collected on seafloor of these two ridges are in the field of spinel lherzolites,


Oceanic Spreading Centers, Figure 11 (**a**) Seismic reflection image at the Lucky Strike volcano, Mid-Atlantic Ridge, and (**b**) schematic diagram showing the interpreted crustal structure (Singh et al., 2006b). *EBF* eastern bounding fault, *WBF* western bounding fault, *HF* hydrothermal field. 2A: Layer 2A. *AML* axial melt lens.
Oceanic Spreading Centers, Figure 12 Core complex at MAR, 23.5°N. The setting with the OCC at the internal corner between the ridge, looking southwest along the Kane fracture zone. The breakaway occurred along the former ridge site, where the detachment emerged and moved SW parallel to surface grooves (the megamullions). There are two successive detachments within the back of the breakaway normal fault, limiting the tectonic extension generated by these detachments and, in the front, the high-angle, outward-facing normal faults (*dots*) that are interrupted as detachments (Tucholke et al., 2008).

corresponding to a depth of ~30 km (Figure 3b3). Thus, the lithosphere thickness may attain this depth as a consequence of a much reduced melting as compared to faster ridges. These two ultraslow ridges share many similar features. The average seafloor depth is over 3 km and down to 6 km inside deepest rifts (Figure 14). Over a thin "crust," the seafloor is covered with basalts and mantle serpentinized peridotites, locally fresh in Gakkel Ridge. The SWIR rough topography seems to result from imbrication of detachment faults, lubricated by serpentinites, an expected consequence of spreading being dominantly tectonic rather than magmatic (Sauter et al., 2013). Along the western part of SWIR, the oblique spreading direction with respect to the rift alignment creates oblique and small-scale segmentation within the rift (Dick et al., 2003; Cannat et al., 2008). There are, however, sharp variations along axis, defining a large-scale segmentation (over 200 km) controlled by melting in the underlying mantle. In western parts of the SWIR, the rift rises to a depth of some 3 km and develop a thin, continuous mafic crust; the drilling has revealed a gabbro layer of ~2 km thick (Dick et al., 2003). In this region of the SWIR, the spreading may be influenced by the South African hot spot. Although spreading rate likely remained ultraslow over time, the excess heat and magmatism from the hot spot may explain both the topography and the accretion


Oceanic Spreading Centers, Figure 13 Deep detachment model at ~10 km within the thick MTZ suggested by studies in the slow spreading Mirdita ophiolites (Nicolas et al., 1999) and that incorporates geophysical data from MAR. The lithosphere/asthenosphere shape has been modeled accordingly from Sleep and Rosendahl (1979) data.

of a mafic crust (Cannat et al., 2008). In the SWIR, the NS diverging plate motions are responsible for the EW trend of the rift shifts to SW-NE, presumably due to oblique asthenospheric channeling. It is only within the thinner and weaker rift floor that EW traces relating to the NS extension are observed, reflecting the lithosphere tectonic print (Cannat et al., 2008). Interestingly, below slow spreading ridges where the lithospheric walls penetrate deeper than 10 km, these walls seem to control somewhat the longitudinal upper asthenospheric flow.

In comparison to the SWIR, the Gakkel Ridge is more linear with few tectonic discontinuities, with spreading rates decreasing eastwards that are lower than those at the SWIR. From west to east, the topography deepens and magmatism progressively decreases, but it is controlled neither by lower spreading rates nor by lithospheric tectonics. Again, the source of these discrepancies lies in primary heterogeneities of the melting mantle, either due to temperatures and/or chemistry (variable levels of depletion/enrichment, as recently documented by Wanless


Oceanic Spreading Centers, Figure 14 The western segment of Gakkel Ridge (segment "a"), mainly in the volcanic zone (volcanoes, *red dots*), and to the right (segment "d"), the border of the central zone with rift floor at 6,000 m largely exposing the peridotite (Michael et al., 2003).

et al., 2014). Hydrothermal activity in Gakkel Ridge is unexpectedly abundant and may be a result of focusing of mantle melts feeding large volcanic centers, coupled with deep penetration of faults through the cold lithosphere (Michael et al., 2003).

Back-arc spreading centers

Apart from spreading at mid-ocean ridges, spreading can also occur in back-arc settings where the spreading is initiated due to the rollback of the subducted lithospheric slab beneath the active volcanic arc. Examples of such situations include the Lau Spreading Center in the Lau Basin behind the Tonga-Kermadec island arc and subduction zone (Turner et al., 1999; Jacobs et al., 2007), the East Scotia Sea spreading center behind the Scotia arc (Livermore et al., 1997), and the Andaman Sea spreading center (Kamesh Raju et al., 2004) behind Andaman-Nicobar subduction. Since they are related to the subduction systems, they are generally younger spreading centers, showing strong variability in terms of ridge morphology, petrology, and crustal structure, both in time and space. The Lau Basin spreading center is the most completely studied back-arc spreading center. It is intermediate in terms of spreading rate, ranging from 95 mm/year in the north to 40 mm/year in the south and is located 185–45 km from the Tonga-Kermadec volcanic arc. It is about 550 km long and is segmented by overlapping spreading centers, instead of transform faults. Because of this strong variation in spreading rate and the

distance from the arc, crustal structure also varies rapidly along the ridge axis. The layer 2A thickness varies from 400 m in the north to 1 km in the south. AMLs are present in the north and south and lie at 1.5 km depth in the north to 2.8 km in the south. Similar to the 9°N OSC, a wide AML was imaged beneath, the Lau OSC (Collier and Sinha, 1990). The average layer 2A velocity varies from 3.2 to 2.5 km/s, whereas the average layer 2B velocity varies from 5 to 3 km/s; this large velocity variation is attributed to petrological changes from more mid-ocean ridge basalt-type to more silica-rich arc-type melt beneath the ridge axis (Taylor et al., 1996; Turner et al., 1999).

Summary

From fast or superfast to slow and ultraslow spreading rates, the respective roles of asthenosphere and lithosphere in the features of ocean ridges deserve some concluding comments. The faster the spreading rate, the thinner the lithosphere remains over wide areas and the more this thin lithosphere appears autonomous with respect to the underlying asthenosphere. This is illustrated by Toomey et al. (2007) who describe at an oblique alignment of the mantle individual diapirs compared to the ridge alignment along the 9°–10° N EPR and the associated orthogonal transform faults (Figure 4). It appears that this thin lithosphere is decoupled from the soft, underlying asthenosphere and responds by brittle fracturing to the large-scale plate tectonics. In contrast, the progressive thickening of lithospheres from slow to ultraslow

spreading ridges is increasingly controlled by the uprising asthenosphere. This is visible in their morphology and their large-scale tectonics. There is some evidence from ophiolites (Nicolas et al., 1999) and slow spreading ridges, based on seismic anisotropy (Li and Detrick, 2003; Nowacki et al., 2012), suggesting that mantle flow is ridge parallel and not more ridge perpendicular. As discussed above, ultraslow ridge morphology and crustal composition respond to variations in mantle upwelling and associated melt delivery.

The combined study of ophiolites and geophysical data at oceanic ridges has allowed to comprehend the inner working of ocean spreading processes. The ophiolites allowed us to image deep accreted lithosphere and, indirectly, to investigate accretion processes, whereas the geophysics provide direct images of the accreting ridge systems. These observations showed that these accreting systems are different depending firstly on spreading rates and sometimes displaying significant variations along the same segment of a ridge axis. For example, along the most studied 9° N segment of the EPR, the width of the AML changes significantly and so does the melt-mush distribution along the ridge axis. Along slow spreading ridges, the crust is normally thickest at the center of a segment and thinnest at segment ends. The crustal accretion process at slow spreading centers is further complicated by the presence of ocean core complexes, which are not just present at segment ends, but could be present along a significant part of a segment (Escartin et al., 2008). The ultraslow spreading ridges, a special class of ridges, show extreme variations in seafloor morphology, crustal thickness, and geochemistry; more geophysical studies of ultraslow spreading ridges are required to fully appreciate the diversity of ridge processes on earth.

OIL SPILL

Erich Gundlach
E-Tech International Inc., Boulder, CO, USA

Definition

An oil spill is the accidental release of liquid hydrocarbons to the environment as crude oil or a petroleum product.

Introduction

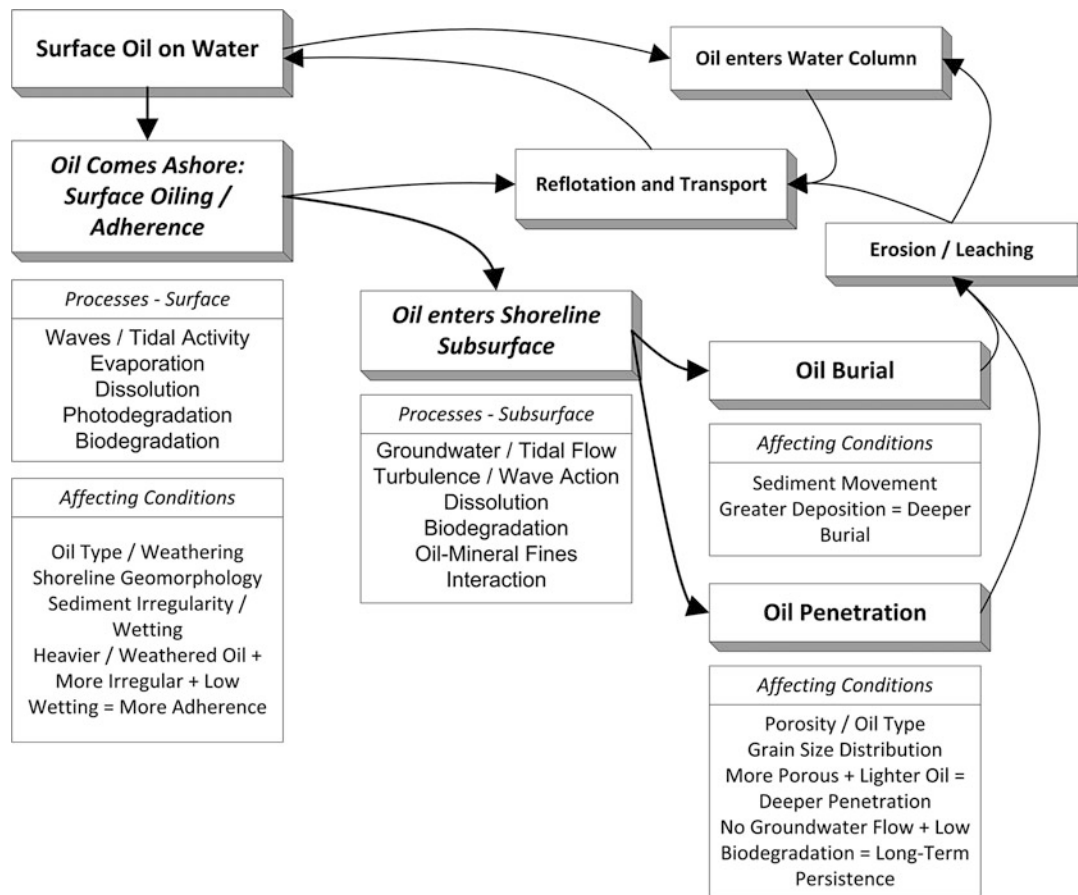
Experts in coastal geosciences play a key role in understanding the processes affecting a spill, measures appropriate to remove spilled oil, and, importantly, when to end cleanup activities and let nature continue the cleansing process. The major processes affecting oil on sedimentary shorelines are illustrated in Figure 1.

Oil composition and weathering

The spilled oil's composition and subsequent changes over time (weathering) greatly influence the interaction of oil in coastal environments. Oil is composed of a complex mixture of straight-chained and ringed/cyclic hydrocarbon compounds, with small amounts of N, S, O, and trace metals, depending on the source reservoir and petroleum processing (cracking). Spilled oil is commonly categorized into broad categories. Light oils have a low specific gravity (SG < 0.8) and low viscosity (0.5–2.0 cSt) and include gasoline/petrol, naphtha, and kerosene. Medium-grade oils are mostly crude oils and medium fuel oils (SG 0.80–0.95, 8–275 cSt), while heavy fuel oils comprise the heavy oil category (SG > 0.95 and viscosity >1,500 cSt).

Weathering refers to the biochemical processes affecting oil when released to the open environment and includes spreading, advection, evaporation, emulsification, dissolution, dispersion, photooxidation, sedimentation, and biodegradation (Reed et al., 1999). Of these, evaporation and emulsification are the primary affecting processes. Evaporation potentially reduces the quantity of remaining oil up to 40 % for light oils, whereas the generation of emulsified oil (a water-in-oil mixture commonly called "mousse") potentially doubles the amount of oily material. As oil weathers, viscosity, density, and adhesion (stickiness) to sediments and rock surfaces all increase. Biodegradation is a long-term process slowly reducing the amount of remaining oil. These major processes have been summarized for the Amoco Cadiz (Gundlach et al., 1983), *Exxon Valdez* (Wolfe et al., 1994), and Deepwater Horizon (FISG, 2010) oil spills.

Applying geosciences to oil spills

The impetus to understand the dynamic processes of spilled oil in coastal environments began in the 1970s as a result of an increasingly strong environmental movement, several major oil spills (e.g., Torrey Canyon, 1967; Santa Barbara, 1969), and offshore oil and gas


Oil Spill, Figure 1 Processes and conditions affecting spilled oil on sedimentary shorelines (modified from Page et al. 2013).

development. Field investigations in 1970 (*Arrow*), 1975 (*Metula*), 1976 (*Urquiola*, *Argo Merchant*), and 1978 (*Amoco Cadiz*, Ixtoc I) enabled geoscientists to begin understanding the complex interactions between spilled oil, shorelines, sediments, and coastal processes. Table 1 lists the major studies of oil/shoreline interactions and serves as references to the observations described in the following sections. *Exxon Valdez* studies have continued for more than 20 years and provide the longest detailed record of any oil spill to date (Wiens, 2013).

Spill interaction: sediment-dominated shorelines

On sedimentary shorelines, the extent of oil impact and persistence is determined by oil characteristics, changes in the beach profile in response to wave and tidal action, and grain size characteristics. Both depths of oil burial and penetration generally increase with grain size, with wide variability dependent on local conditions. Silt or fine-grained beaches show less burial/penetration and cobble/boulder shorelines the greatest. Sediments where pore spaces are filled with water, as on tidal flats or along lower portions of sedimentary shorelines, inhibit oil entry and generally remain unoiled.

As the spill progresses, sediment movement, wave action, and weathering tend to distribute the spill into ever smaller particles (tar balls), which are then exposed to further degradation by microorganisms. Stranded oil may also be reduced by adherence to very fine-grained material (mineral fines) (Bragg and Owens, 1995; Owens and Lee, 2003). Small quantities of weathered oil may become deeply incorporated into beach sediments, requiring several years for natural removal. Spilled oil may also interact with shoreline sediments and sink in the nearshore zone. Changes in wave energy or direction can cause a movement of this oil and sediments onto the beach and cause reoiling.

The *Exxon Valdez* is an ongoing case study where oil has deeply penetrated into coarse-grained environments and is still present at least 23 years later in well-known localities. The remaining oiled sediments reside in an area of restricted interstitial water flow and below the zone of active sediment movement. Therefore, physical as well as microbial processes are greatly reduced but not totally stopped.

Spill interaction: rock-dominated shorelines

Spilled oil tends to be held offshore by wave reflection on uniform vertical cliffs exposed to high wave action.

Oil Spill, Table 1 Major field and experimental studies of oil interaction with shoreline environments. Shoreline types: *C* coarse grained, *R* rocky, *S* sandy, *T* tidal flat, *M* marsh

[a]Persistence >6 years as of last publication

However, oil may settle in thick pools as the irregularity of the shoreline increases and in areas with lower wave energy. Light oils are rapidly removed by wave action. Heavy oils are the most persistent and commonly require extensive pressure washing to remove.

Spill interaction: vegetated shorelines

The generally quiescent nature of marsh and mangrove shorelines enables spilled oil to settle onto the silt-clay surfaces of the habitat. Oil may mix into soft sediment and/or penetrate by the infilling of animal burrows (Howard and Little, 1987). The loss of plants potentially causes shoreline erosion and habitat loss. Oil incorporated into these sediments, in the absence of wave action and reduced microbial degradation, has been shown to persist at least 35 years. The large-scale destruction of mangroves in the Ogoni area of Nigeria (UNEP, 2011) potentially shows the greatest loss of mangroves due to oil spillage to date.

Coastal geomorphology and oil spill sensitivity

Early studies identified the influence of shoreline characteristics in predicting spill persistence, difficulty of cleanup, and, because biota also vary by shoreline type,

its potential biological effects. To enable use by nonscientists, a vulnerability index classification, later changed to environmental sensitivity index (ESI), was developed, which categorizes and ranks shoreline geomorphology according to sensitivity to spilled oil (Gundlach and Hayes, 1978). With the inclusion of ecological and social data (NOAA, 2002, 2012), ESI maps are now an international standard to provide summary information to governments and industry involved with spill response planning.

Geoscience advise during response operations

During major oil spills, geoscientists play a key advisory role in directing SCAT (Shoreline Cleanup Assessment Technique) teams. These teams provide site-specific data concerning the quantity of oil present (surface and subsurface), biological and social characteristics, and cleanup options and restrictions (Owens and Sergy, 2003). Importantly, SCAT teams include the representatives of the spiller, government, and landowner. First deployed during the *Exxon Valdez* spill, SCAT information enabled the long-term tracking of remaining oil on the shoreline (Taylor and Reimer, 2008; Wiens, 2013). SCAT presently has widespread international support by governments and

industry and was used extensively during *Deepwater Horizon* (Santner et al., 2011).

Oil spill modeling

Advances in oil spill modeling occurred with the inclusion of oil-holding capacities (Gundlach, 1987) based on the sedimentary characteristics, the oil type, the depositional width of the shoreline, the tidal range, and the application of a removal rate parameter dependent on shoreline type (Reed et al., 1989; Howlett and Jayko, 1998; Etkin et al., 2007). The integration of coastal characteristics into oil spill models enables a more realistic representation of what happens when spilled oil reaches the shoreline. Some spill models simplify the entire process into a simple reflotation parameter (i.e., high reflotation from exposed rock surfaces, low reflotation from sheltered marshes and mangroves). The testing of various reflotation parameters for the same section of shoreline indicates their importance for spill modeling (Danchuk and Wilson, 2010).

Shore zone coastal mapping

Shore zone mapping uses low-altitude high-resolution photography and video surveying to classify the shoreline into standardized geomorphic and biological categories. It is used to characterize large sections of coastline (e.g., Alaska) with the benefit that images and data are able to be retrieved from any web-linked computer (Hamey et al., 2008; NOAA Fisheries, 2012). The access to these images is a valuable tool for both spill planning and response.

Summary and conclusions

The scientific understanding of oil spill interactions in the coastal and marine environments has progressed substantially from its initial beginnings in the mid-1970s. Because of their unique background in understanding these interactions and affecting processes, marine geoscientists play a key role in providing technical and scientific support during most major oil spills occurring today.

OPHIOLITES

Adolphe Nicolas
Geosciences Montpellier, University of Montpellier 2, Montpellier, France

Definition

Ophiolites represent fragments of oceanic lithosphere that have been detached from their ocean of origin and transported by plate tectonic processes onto a continent.

Historical development of the ophiolite concept

Ophiolite, the "snake stone" in Greek for its serpentine component appears for the first time with Brongniard in 1813. At the turn of the same century, Italian alpine geologists had fully recognized its deep marine origin and its main components: with, from sea bottom, radiolarian cherts and basaltic pillow lavas, over and associated to gabbros and serpentinites. The surge of plate tectonics in the 1960s, that was a direct result of oceanic floor mapping, fostered studies on ophiolites. Ten years earlier, De Roever (1957) and Brunn (1959) had equated with the so-called alpine ophiolites to the Atlantic oceanic ridge, and by that time, most European geologists knew that ophiolites derived from oceanic spreading centers. Interestingly, marine geophysicists remained for a long time reluctant to this connection. In the 1960s with only a few exceptions, American colleagues were not convinced by the comprehensive concept of "ophiolite." They had correctly identified "peridotite-gabbro" complexes as the basement of seafloor but were doubting any connection to the upper crust of ophiolites. Outstanding among American dissidents was Harry Hess, a geologist who was promoted admiral in the US Navy during the Second World War, launching the mapping of the oceans' seafloor that has been critical when he anticipated the seafloor spreading theory. During a famous field trip meeting in Oregon, European and American communities adopted the following manifesto on ophiolites, a modern concept that we revisit here.

> *Ophiolites* refers to a distinctive assemblage of mafic to ultramafic rocks. It should not be used as a rock name or a lithologic unit in mapping. In a completely developed ophiolite, the rock types occur in the following sequence, starting from the bottom and working up:
>
> – *Ultramafic complex*, consisting of variable proportions of harzburgite, lherzolite, and dunite, usually with a metamorphic and tectonic fabric (more or less serpentinized)
> – *Gabbroic complex*, ordinarily with cumulus textures, commonly containing cumulus peridotites and pyroxenites and usually less deformed than the ultramafic complex
> – *Mafic sheeted dike complex*
> – *Mafic volcanic complex*, commonly pillowed
> – Associated rock types include (1) an overlying sedimentary section typically including ribbon cherts, thin shelled interbeds, and minor limestones; (2) podiform bodies of chromite, generally associated with dunites; and (3) sodic felsic intrusive and extrusive rocks.

Faulted contacts between mappable units are common. Whole sections may be missing. An ophiolite may be incomplete, dismembered, or metamorphosed. Although ophiolite generally is interpreted to be oceanic crust and upper mantle, the use of the term should be independent of its supposed origin.

Importance of studies in ophiolites

Beyond the interest for mineral resources historically extracted from ophiolites (copper, chrome, PGE, dunites, . . .), two scientific aspects should be mentioned. The structural, petrological, and geochemical features of ophiolites that have been implied in collision belts can be used to constrain their marine environment of origin, for instance, a mid-ocean ridge (MOR), a supra-subduction zone (SSZ), or any other marine environment. This concern appears in a vast number of studies on ophiolites using geochemical data, considered as discriminant for the different environments of origin. Initiated by Miyashiro in Cyprus (1973), this concept has been applied to the Oman ophiolite the conclusion that it was generated within a SSZ environment. Developed in the entry "Sea floor spreading," another aim in studying ophiolites deals with seafloor accretion processes operating at oceanic ridges where the 3D information obtained in ophiolites is important, complementing and interacting with the geophysical observations: for instance, on shape and dynamics of mantle diapirs and overlying magma chambers at fast-spreading ridges and on deep rooting of oceanic core complexes and kinematics of their emplacement at slow-spreading ridges.

Typology of ophiolites

The first attempt to classify ophiolites has been presented in 1985, independently by Ishiwatari and by Boudier and Nicolas. Both started from the idea to classify ophiolites on the degree of partial melting in the mantle of origin.

Ophiolites, Table 1 The three main ophiolite types reflecting decreasing mantle partial melting related to decreasing spreading rates. Specific references to the massifs of origin (their number in first line) are presented in Nicolas and Boudier, where a comparable typology based on information from oceanic environments is also presented

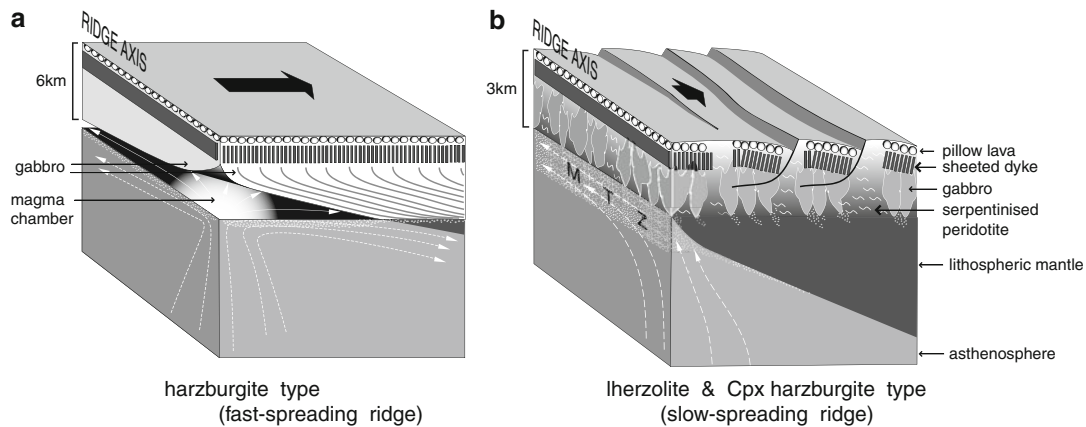
	Harzburgite ophiolite type (HOT)	Harzburgite lherzolite ophiolite type (LHOT)	Lherzolite ophiolite type (LOT)
Number of Massifs considered	3	12	4
Crustal section	Thickness: 4–6 km	Thickness: 2–3 km	Thickness : 0–1 km
Volcanics overlying sheeted dikes	Low-alumina tholeiite	High-alumina tholeiite	Alkali basalt
Sheeted dikes	Well expressed and steep	Steep to horizontal, poorly organized	Absent or poorly organized
Gabbros Exposure	Thick, continuous	Thin, continuous, or nestled	Absent, small bodies
Lithology	Foliated ol-gabbros locally gabbronorites	Dominant gabbronorites, ol-gabbros, ferrogabbros	Ol-gabbros
Structure	Lower, layered gabbros Upper, foliated gabbros Top, isotropic	Well to poorly layered-foliated gabbros, isotropic gabbros	Isotropic to foliated gabbros
Penetrative deformation	Very large, magmatic	Magmatic to plastic (flasergabbro)	
Seawater alteration	Variable, up to high-T	Variable	Variable, metamorphic
Wehrlite intrusions	Abundant	Present	Absent
Mantle section Moho transition zone (MTZ)	Dunite-gabbro, websterites 50–400 m	Locally thick (up to 2 km) dunite, interlayered with wehrlite, websterite	Dunite lenses
Shear zones	Uncommon, HT, vertical horizontal lineation	Common, mid-T to low-T, steep, steep lineation, oceanic core complex horizontal detachments	Very common, mid-T to low-T steep
Diabase occurrence	Uncommon	Common	Common dikes-sills
Chromite pods	Uncommon	Common to very large	Uncommon, absent
Serpentinization	Lizardite	Lizardite and antigorite	Antigorite

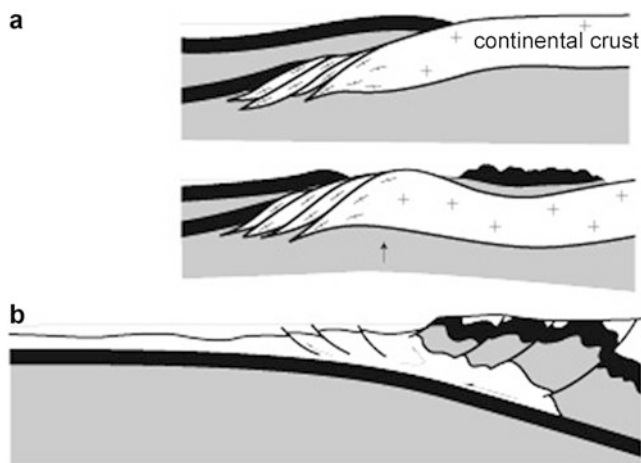
Ishiwatari mainly considered petrological and geochemical criteria in gabbros and basalts, whereas Boudier and Nicolas applied a structural and petrological approach, largely based on the mantle component of ophiolites. This mantle contribution to the fate of any ophiolite and its structural approach being essential, we wish to incorporate these wider criteria in Table 1.

In a rising mantle with an average mantle composition, mantle depletion increases with spreading rate of the ridge of origin. This approach does not account for ophiolites that depart much from the average norm. For instance, the present day Reykjanes Ridge is significantly hotter than other ridges because it is located close south to the Iceland hot spot.

Figure 1 emphasizes the contrast between fast-spreading (HOT) and slow-spreading (LHOT-LOT) ridges. The copious thermal budget in HOT supports the continuous activity at ~1,200 °C of a crustal magma chamber beneath the ridge axis (see "Oceanic Spreading Centers"). The asthenosphere/lithosphere upper limit (~1,100 °C) is the wall of this permanent magma chamber. At the Moho level, this limit flattens. As a consequence, the fast rising and melting mantle diapir rising below the ridge axis can diverge in nearly all directions. In contrast in LHOT, the thermal budget does not sustain a permanent magma chamber. The steepened limit between lithosphere and asthenosphere along the ridge axis channels mantle flow parallel to the ridge and generates just beneath Moho and only locally, a thickened MTZ compared to HOT. The LOT ophiolites ascribed to conditions of continental to oceanic rifts are structurally akin to LHOT with, as a consequence of a lower thermal budget, a steep limit between lithosphere and asthenosphere channeling mantle flow parallel to the ridge axis (see "Oceanic Rifts").

Modes of emplacement of ophiolites

Within the frame of plate tectonics, Moores (1982) and Coleman (1984) divided ophiolites into two groups. The *Tethyan ophiolites* are giant thrust sheets resting upon passive margins of continental and adjacent oceanic crust, as along the Oman margin of Arabia (Figure 2a). In contrast, the *Cordilleran ophiolites* are incorporated, often dismembered or incorporated in mélanges, into accretion terranes. This is typically achieved in California Cordillera where ophiolites are in a situation of forearc (Figure 2b). Clearly, the Western Pacific and its complex back-arc


Ophiolites, Figure 1 Compared ridge structure and dynamics between (**a**) HOT and (**b**) LHOT-LOT deduced from studies in ophiolites. The scales are different. The fast-spreading ridge permanent magma chamber is transversally ~ 10 km wide, as wide as the underlying mantle diapir that it is covering. In slow-spreading ridges, upper mantle flow is channeled parallel to the ridge plane. Magma chamber are discontinuous with serpentinites screens. MTZ stands for mantle transition zone, a dunitic transition to the crust.


Ophiolites, Figure 2 The two main modes of ophiolites emplacement onto (**a**) passive and (**b**) active continent margins (oceanic crust, *black* and mantle *gray*). (**a**) Tethyan-type, oceanic thin lithospheric thrust. Following their detachment at the ridge of origin, ophiolites have been thrust on a passive continental margin before a crustal rebound, as recorded in Oman ophiolite (Boudier et al., 1988, Ishiwatari et al., 2005). (**b**) Cordilleran-type, accretion, and upheaval of oceanic sediments and of forearc oceanic crust in a subduction-related accretionary prism (Platt, 1986).

spreading over subduction zones has been a nursery for a number of ophiolites. These supra-subduction zone (SSZ) ophiolites are opposed to mid-oceanic ridge (MOR) ophiolites.

Tethyan ophiolites. This mode of emplacement, conceived as an MOR ophiolite being thrust onto a continental margin, could alternatively be detached from an SSZ back-arc ridge and thrust either on the arc itself or in the opposite direction. A compilation on 63 ophiolites from various environments throughout the world, with

a fair knowledge on a number of them, has shown that over half of them have been emplaced as *Tethyan ophiolites* (Nicolas, 1989, p. 298). Some are still resting as giant thrust sheets, with a high-temperature metamorphic sole, upon passive margins, as in Oman (Glennie et al., 1974) or in Papua New Guinea (Finlayson et al., 1977) (Figure 3b). Some have been implied in collision belts and are identified thanks to their typical metamorphic sole.

Cordilleran ophiolites deriving from a forearc. These ophiolites are associated to margins that are still active or have been implied in collision belts with partial destruction during their emplacement. Before upheaval, forearc ophiolites (that have no a priori reason to be SSZ related) may have been entrained in the shallow subduction zone or, at the least, underthrust within the accretion prism to over 1 GPa (Ernst, 1981). Ophiolites may also derive from fragments scrapped off the subducting lithosphere. Whatever their origin, a number of cordilleran ophiolites have reached high-pressure metamorphic conditions before being incorporated into more superficial formations as in the Franciscan Mélange of California.

Thrusts with a high-temperature sole in Tethyan ophiolites

Few Tethyan ophiolites that still rest upon a passive margin have been saved from the destructive effects of collision. They are most favorable to retrieve the conditions of accretion at oceanic ridges. The flat structures of asthenospheric mantle flow (~1,200 °C) grade, within ~1 km of increasingly deformed peridotites, into a high-T metamorphic sole at the expense of the underlying oceanic crust and its sedimentary cover (Figure 3). At this contact, peridotites are mylonitic deforming at ~1,000 °C with, in the underlying crust, development of high-grade metamorphism. Overthrust basalts are transformed to amphibolites and radiolarian sediments to quartzites.
Ophiolites, Figure 3 Model of oceanic detachments and thrust of the rigid lithosphere slab. (**a**) Oman. The late volcanism (V2) has been contaminated with water released by the ironing effect of the hot thrust (Boudier et al., 1988; Ernewein et al., 1988; Ishiwatari et al., 2005). (**b**) Comparison with the geophysical modeling of oceanic thrusting of Papua New Guinea ophiolite (Finlayson et al., 1977).

With time and decreasing temperature, greenschist facies metamorphism migrates downward. This inverse metamorphism develops over a vertical distance of some 200 m. While moving away from the ridge, the ophiolite nappe shovels at its front and drags below its sole, marine sediments forming ophiolite mélanges. Commonly, this nappe rides over high-pressure mélanges, relating to some former active margin (review in Nicolas 1989).

This is best illustrated by the Oman ophiolite, where the oceanic thrust was ~15 km thick (Figure 3). The basal thrust plane remains parallel to the overlying Moho and was nearly horizontal. This leads to the model of an initially thin and flat lithospheric slab being detached and thrust over a sole of wet and heated oceanic crust. A nearly flat lithosphere points to Oman being derived from a fast to super-fast ridge, as confirmed by precise U-Pb dating (Rioux et al., 2012).

The "ironing effect" of the ophiolite nappe is only possible if the detachment occurred at very high temperatures near the ridge axis (Figure 3). This thermal constraint is confirmed by U-Pb geochronology on age difference between the last magmatic events related to ridge activity and melt products related to the metamorphic sole. In Oman, the age span is only ~300,000 years between accretion and early thrusting (Warren et al., 2005; Rioux et al., 2012). Such precise geochronological data open a new era in ophiolite studies.

MOR versus SSZ origin

For a long time, Oman has been dominantly considered, as most other ophiolites, as being originated in a back-arc environment. This conclusion is based on the geochemical discriminant diagrams. SSZ origin relies on hydrous fluids being implied in the ophiolite generation. The question is whether SSZ environment is compulsory for ophiolites? Recent contributions point to the importance of seawater contamination in the late products of the Oman ophiolite pile. Let us consider hydrous fluids at 1,000 °C reaching the magma chamber wall, or the secondary magmatism (wehrlites and plagiogranites) in the gabbro section (Koepke et al., 2009) or V2 (Ernewein et al., 1988) and boninitic lavas (Ishiwatari et al., 2005) related to fluids from the metamorphic sole (Figure 3). Large mantle shear zones, deep into the mantle section, have also been the path for the hydrous fluids that have generated high-Cr chromites (Boudier, 2014). This large data set suggests that MOR ridges exchange with seawater at all temperatures and renders the deeper SSZ implication, not compulsory.

Arc or back-arc setting is hardly compatible with regional geology in Oman as arc-related volcanics have never been described in the Hawasina basin that has been overridden by the ophiolite nappe. In terms of modeling, the recent reduction to a few hundreds thousand years the age span between accretion and thrusting of the ophiolite nappe from the ridge vicinity seems difficult to reconcile with the SSZ origin of the ridge. The thrust of Figure 3 has been assimilated to a "shallow subduction of hot oceanic lithosphere" by a few authors (Ishiwatari et al., 2005; Koepke et al., 2009). Here, we may be facing a semantic problem. If so, it would be sane to come back to original definitions (Coleman, 1971, 1977) who forged the term "obduction" to describe the thrusting of a hot Tethyan ophiolite nappe onto a continent margin, in contrast to a cold subduction, the one-way trip to the deep mantle.

Summary

The large variety of ophiolites is issued from most types of ocean spreading centers. Ophiolites are scattered onto continents, either on their passive margins or implied into collision belts. The latter are generally more deformed and

the former less and more suited to study the processes that lead to the oceanic accretion. Because ophiolites display deep sections into lithosphere, they complement marine data mainly obtained from the seafloor. When implied into mountain belts, they are keys to reconstitute regional paleogeography.

[2]National Research Tomsk Polytechnic University, Thomsk, Russia

Definition

The organic matter is presented in the ocean as a basis of living organisms and their decomposition products in the

particulate, dissolved, and colloid forms. Sequence of these forms in the synthesis–destruction system constitutes the biogeochemical cycling of matter in the ocean and the biosphere as a whole.

Forms of organic matter

Organic matter (OM) occurs in marine and oceanic water as dissolved compounds (DOM), colloids, and particulate OM. The colloidal and dissolved fractions can be separated from each other with methods such as ultrafiltration and ion exchange, but in practice, they are usually treated together. Hence, DOM includes the truly dissolved compounds (particles <1 nm) and colloids, including 1–10 nm and 10–450 nm structures. Large particles (>0.1–1.0 µm), which can be collected by filtration through a variety of filters, such as glass fiber Whatman GF/F (~0.6–0.7 µm pores), separators, and sediment traps, refer to particulate matter. OM of living beings producing and degrading the bulk of OM in the ocean represents only a small part of the total amount of OM. The three forms of OM in the World Ocean, i.e., living, particulate, and dissolved OM, make up the pyramid of mass 1: 13: 250 ($4 \cdot 10^{15}$, $50 \cdot 10^{15}$, and $1,000 \cdot 10^{15}$ g C_{org}), which reflects the dynamic equilibrium existing in the biogeochemical cycle. These forms are combined into an interconnected heterogeneous system that includes organic nitrogen, phosphorus, sulfur, and organometallic compounds of natural and anthropogenic origin. Since most of OM in the ocean is produced during photosynthesis, N- and P-containing compounds of OM are predominantly of natural origin, while among S-containing compounds, the fraction of anthropogenous substances increases.

Sedimentation of particulate matter leads to the fact that all sediments include OM: the maximum concentration is typical for muds of near-continental areas, especially for upwelling and high productive waters, and the minimum one is observed in coarse-grained deposits and red clay, common in areas where OM supply is scarce. Annually, 160–$250 \cdot 10^{12}$ g C_{org} are buried in sediments of the World Ocean, including about 95 % of near-continental and 5 % of pelagic oceanic sediments (Hedges and Keil, 1995; Eglinton and Repeta, 2003; Romankevich and Vetrov, 2013).

Sources of organic matter

The main primary source of OM in the ocean is phytoplankton (Figure 1). Its average net production, including lifetime excretions, is ~$60 \cdot 10^{15}$ g C_{org} year^{-1}. Another source of OM is the production of ice algae (0.2 10^{15} g C_{org} annually) and phytobenthos (3 10^{15} g C_{org}) created by macrophytes and diatoms living in sediments, as well as a part of OM produced by chemolithotrophs in the rift zones of the ocean and cold seeps, widely developed in seas and on the periphery of all oceans. Assessment of the extent of bacterial chemosynthesis that proceeds through the oxidation of reduced compounds coming from the Earth's interior suggests its small contribution (<0.6 % of photosynthesis products) to OM balance (Romankevich, 1984).

To the autochthonous (marine) sources of OM more resistant to degradation, allochthonous (terrigenous) OM coming from the land is added (~$0.7 \cdot 10^{15}$ g C_{org} year^{-1}). The most important terrigenous source of OM in the ocean is the river runoff, which supplies ~$0.6 \cdot 10^{15}$ g C_{org} year^{-1} in the dissolved and particulate forms (~30 % and 70 %, respectively). There are also unevenly distributed organic compounds in the troposphere; its contribution to the ocean is estimated as $<0.1 \cdot 10^{15}$ g C_{org} year^{-1}. Finally, we should mention such minor, sometimes underestimated, sources of OM such as coastal erosion, thermoabrasion, and underground runoff giving in total ~$0.4 \cdot 10^{12}$ g C_{org} year^{-1}.

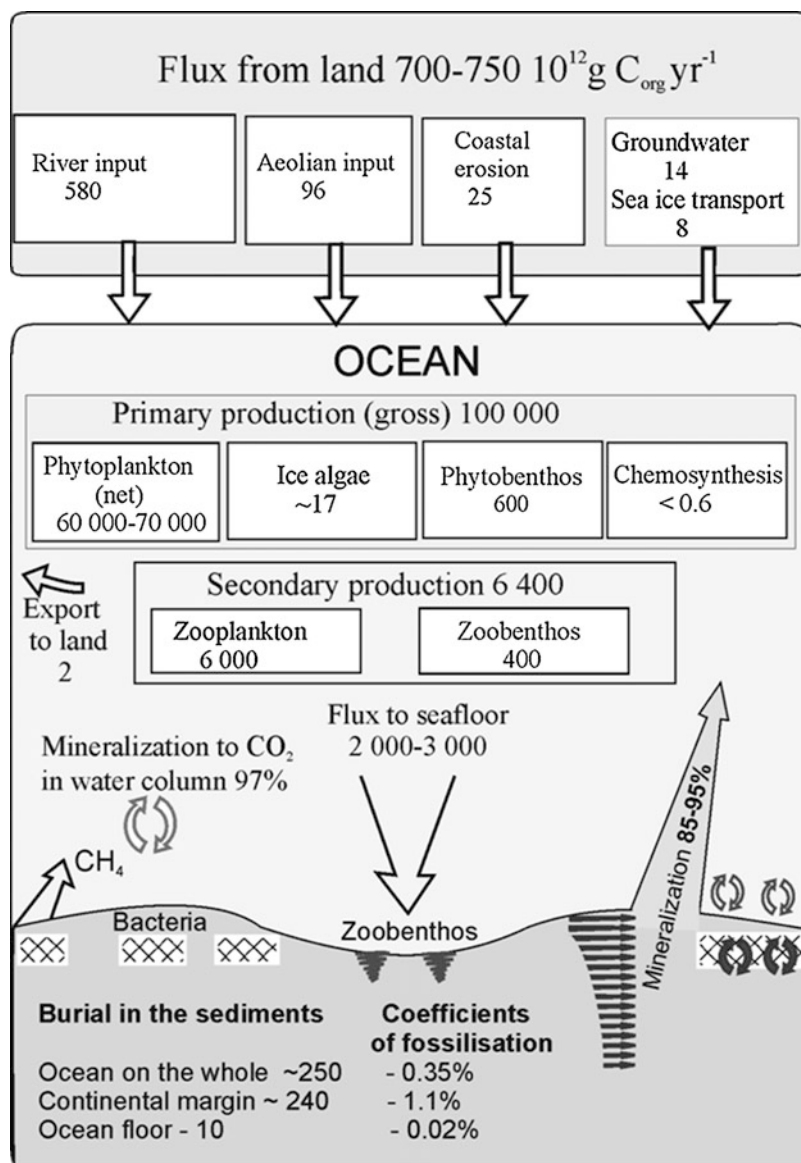
Living OM produced on land and in the ocean differs in ash contents (5 % and 44 %, respectively), proteins (5 and 62 %), carbohydrates (62 % and 25 %), lipids (6 and 13 %), and lignin (27 % and traces). Marine OM contains about five times more nitrogen and sulfur, more trace elements, and less oxygen. The $\delta^{13}C$ value varies from -19 to -24 ‰ in the ocean and differs from the same parameter for land plants of C_3 type (from -27 to -28 ‰) and C_4 type (~ -12 ‰) of carbon fixation.

Dissolved organic matter

In the World Ocean, dissolved OM represents ~94 % of the total OM and its mass is estimated as 750–$1,000 \cdot 10^{15}$ g C. This is roughly equal to the carbon amount in the atmosphere.

With the exception of viruses and small non-aggregated bacteria, DOM is mainly represented by nonliving OM, which is extremely small and cannot sink in water at appreciable rates. Seawater DOM affects light transmission in the ocean. Approximately 25–35 % of marine DOM occurs in molecules with masses of 1 kDa that correspond to nominal molecular sizes of 1 nm or more. Seawater DOM has numerous sources and sinks and a range of different reactions.

In the active surface layer, DOM concentrations vary over space and time within two orders of magnitude from 5–10 to 1,000 µM C (1 µM C = 0.012 mg Cl^{-1}). The main DOM pool is found in the deep ocean where concentrations vary little (mostly within 35–45 µM, Figure 2). General patterns of DOM distribution are expressed in reducing concentration from coastal areas with high productivity of plankton, including the areas of allochthonous supply from rivers to oligotrophic regions of the ocean, as well as decreasing concentration with depth in the pelagic areas. A typical depth profile of DOM concentration in the ocean shows that the presence of labile DOM is associated with only the upper part of the water column.

About 30 % of the DOM (sometimes up to 80 %) is represented by colloids scattering light (size >1 nm) and containing bioactive and bioavailable organic compounds. Submicron DOM components include liquid excretions of phytoplankton, phytobenthos, protozoa,


Organic Matter, Figure 1 Fluxes of organic carbon in the World Ocean, 10^{12} g year^{-1}.

and other animals, the products of bacterial decay of seston and fecal pellets, viral particles, and organic compounds that come with river runoff and from sediments. A small part of DOM is currently linked to the activities of people creating more and more xenobiotics. The loss of DOM is associated with photodegradation, sorption on sinking particles, and microbial utilization. Fungi, protozoa, and different mixotrophic organisms play a significant role in mineralization and transformation of OM, but these processes are not well understood and underestimated so far.

UV radiation leads to the mineralization of some DOM, its transformation, and formation of new organo-mineral compounds in the thin ocean surface and subsurface layers; this, in turn, affects the physicochemical,

biological, and biochemical characteristics of the surface layer and gas exchange in the air–water system.

Humic substances play an important role in the transition of DOM in particulate OM (POM). Labile colloidal substance is a significant part of DOM in coastal waters. The conservative nature of terrigenous DOC and its direct correlation with salinity are violated in coastal conditions, which affects the behavior and transport distance of DOM offshore.

Marine DOM differs from river one by the lower content of unsaturated aromatic hydrocarbons, lignin phenols, a heavier isotope composition of carbon and nitrogen, lower C/N ratio, and much greater age according to Δ^{14}C. The age of water at 2,000–3,000 m and 5,000–6,000 m depths is estimated as 2–3 and 5–6
Organic Matter, Figure 2 Vertical profiles of concentration (*circles*) and Δ^{14}C (*squares*) versus water column depth for dissolved organic carbon in the temperate Pacific Ocean (after Druffel et al., 1989).

1,000 years, respectively. Although marine DOM contains many organic molecules found in marine biota, the composition of the most part of DOM (up to 80–95 %) is not well studied due to hard selection and identification of trace quantity compounds. The high-molecular-weight (HMW) fraction of DOM (>1 kDa), which can be accounted for as chromatographically measured amino acids and sugars, is only 15 % in surface water and 6 % in the deep ocean, which is several times lower than in marine plankton (~80 %) and particulate OM (~30 %). Low-molecular-weight (LMW) fraction of DOM contains even less organic polymers and is more refractory.

Extremely low biochemical content of HMW DOM points toward a highly altered chemical structure. ^{15}N NMR analyses indicate that all the nitrogen is in amide structures that are almost certainly of biochemical origin. ^{13}C NMR spectra indicate large concentration of carbohydrates that decrease with depth and thus are relatively labile. These spectra indicate very little aromatic compounds, as is generally associated with humic acids. The mechanism of formation of the carbon-rich aliphatic

fractions, which increases in relative abundance with depth, is unknown (Hedges et al., 1997; Benner, 2002; Emerson et al., 2008).

Among amino acids, alanine, serine, and aspartic and glutamic acids are enriched in D-enantiomers (>10 mol%), as is typical of bacterial cell walls. As for the sugars, galactose dominates glucose in the DOM as opposed to living organisms. LMW compounds and some humic acids have the highest refractory in DOM composition (Hedges et al., 1997; Benner, 2002; Emerson et al., 2008).

The flux of DOM from sediment that is much richer than seawater DOM in the shelf and continental slope areas has not been studied yet and is a challenge for the future.

Particulate organic matter

Particulate OM is the second most common form $(50 \cdot 10^{15}$ g $C_{org})$ after dissolved OM and plays an important role in biogeochemical cycling of matter in the ocean. It has a great influence on the CO_2 content in the atmosphere binding CO_2 during photosynthesis and transporting organic compounds from the euphotic layer to the sediments. Regional, seasonal, and interannual variations of quantity and composition of the bulk of POM in the seas and oceans are mainly determined by the primary production of phytoplankton. This relationship may be corrupt or even absent in the near-shore zone, especially in the regions of a large supply of suspensions (rivers, technogenic waste release), due to high turbidity, light deficit, or unfavorable conditions for photosynthesis and living biota.

OM produced by phytoplankton is transformed by heterotrophs and reducers and precipitate relatively quickly (days, weeks, depending on their size, density, and depth of the ocean) in the form of aggregated particles, pellets, and residues of zooplankton. Dependence of POM mineralization on the depth is close to hyperbolic function, so only a few percent of POM reach the seabed in pelagic zone (Figure 3). OM of both phytoplankton and small zooplankton would have almost completely decayed and could not reach seabed but for the mechanism of pellet transport.

The most active POM destruction takes place in two zones of the ocean, namely, in the surface water (0–200 m) and on the seabed (benthic water, nepheloid layer, and bioturbated sediments). Changes in the elemental composition of POM in the water column reveal that the destruction of N- and P-containing organic compounds are, respectively, 40 and 70 % faster than mineralization of total OM. These processes continue in the sediments. The river/sea mixing zone plays an important role in sorption of microelements, sedimentation of various forms of OM, and its extent offshore. In this zone, a small part (5–15 %) of DOM can transfer into POM. Up to 40–>90 % of POM may precipitate in the estuarine zones and adjacent shelf (Lisitzin, 2004). However, over time,
Organic Matter, Figure 3 Organic carbon fluxes with depth in the water column normalized to mean annual primary production rates at the sites of sediment trap deployment. The undulating line indicates the base of the euphotic zone (by Suess, 1980).

a part of settled particulate material and some part of surface sediments enriched by OM are transferred to the shelf depressions, lower part of the continental slope, and continental rise by currents, gravity, and tectonic movements. During mineralization, the balance between autochthonous and allochthonous matter changes considerably in favor of the latter as the more resistant one.

POM, which is mostly pellet material, is very different from phytoplankton and zooplankton as it has less protein, N, and P, more polysaccharides, aliphatic hydrocarbons, aromatic structures, and the presence of trace quantities of geopolymers (humic substances), which have different molecular and isotopic compositions. In the arctic seas, seasonal ice contains many of POM due to the sea algae (mainly diatoms and coccolitophorids) bloom. This substance contains a characteristic molecular and isotopic indicators of origin, namely, high content of the stable isotope ^{13}C up to $\delta^{13}C = -8\,‰$ compared with POM in open water (from -20 to $-28\,‰$). Increased level of ^{13}C is apparently caused by the low concentration of CO_2 in the pores of the sea ice (Thomas et al., 2010).

Organic matter of sediments

The particulate matter reaching the seabed and a thin surface layer of sediment (<1 cm) are enriched by OM. Resuspension, bioturbation, and microbial utilization deplete the OM content. At high accumulation rate, the zone of active OM degradation extends down to 2 m or more. Deeper enzymatic OM decay slows down. It depends a lot on the OM content and composition, sedimentation rate, and burial conditions. Most of the OM degrades in oxygen conditions. In anoxic conditions, the main degradation processes are sulfate reduction and methanogenesis, and rate of enzymatic OM degradation slows dramatically.

OM buried in sediments (Figure 4) contains a wide range of transformed compounds of marine and terrigenous genesis, gas hydrates of methane and other gases, as well as OM of interstitial water. Annually, approximately 0.35 % C_{org} of the primary production and OM supplied from land is buried in sediments of the World Ocean. During diagenesis and catagenesis, this OM forms kerogen, liquid and gaseous hydrocarbons, and other organic and nonvolatile compounds – prospective oil and gas resources.

OM of sediment contains different classes of organic compounds such as hydrocarbons, alcohols, amines, aldehydes, ketones, carbonic acids and their esters, amino acids, carbohydrates, amino sugars, peptides, and vitamins.

The basic change of OM at the stage of early diagenesis is confined in its humification, which represents a mixture of enzymatic depolymerization of biological molecules and the formation of new geopolymers, stable out of living
Organic Matter, Figure 4 Distribution map of total organic carbon in surface sediments, % of dry sediment.

being. A part of autochthonous humic acids (HA) is formed in melanoidin reaction and differs from allochthonous HA in increased content of nitrogen (2–7 %) and heavy metals. Autochthonous insoluble OM is genetically related to the HA, but has more C and a smaller content of N and P. HA and kerogen form the vast majority of OM of the ocean sediments (up to 95 %).

Conversion of lipids in both oxidative and reductive environments leads to the selective preservation of low-polar compounds, including hydrocarbons, fatty acids, and sometimes sterols. Alteration of the carbon isotopic composition of lipids is a good indicator of the degree of biogenic OM transformation. Hydrocarbon content in OM of recent marine sediments ranges from <0.02 % to 4 %. They contain cyclanes >50 %, alkanes <30 %, and arenes 10–15 %.

Among n-alkanes (or n-paraffins) the most abundant hydrocarbons are C_{15}–C_{36}; among polysubstituded alkanes – isoprene, phytane and pristane; the isoparaffinic hydrocarbons are less common in marine sediments. Distribution of n-alkanes is a good indicator of changes in facies depositional environment, contribution of terrigenous components, and transformation of OM. Along with hydrocarbons, phenols of lignin are also undoubted indicators of the contribution of terrigenous material in sedimentation (Stein and Macdonald, 2004).

Aromatic hydrocarbons of oceanic sediments include monocyclic, uncondensed and condensed bicyclic, tricyclic, or polycyclic (PAH) structures. Benzene and its derivatives constitute 50–80 % of aromatic hydrocarbons, PAH – usually up to 1 %. Geochemical PAH background is formed in the sediments under the control of lithological, climatic, pyrogenic, and anthropogenic factors. The individual composition of PAH, along with n-alkanes and lignin phenols, is an informative indicator of OM transformation in the stage of sedimento-, dia-, and catagenesis.

Summary

The organic matter (OM) in the ocean is continuously created in the form of primary production of micro- and macroalgae and chemoautotrophic bacteria, simultaneously with processes of consumption, dying, and decay. The remains of dead organisms found in the form of a particulate matter are a source of dissolved OM. In addition, dissolved and suspended OM come to the ocean from the land as part of the river and groundwater flows, wave abrasion products, and aerosols. Dissolved OM contains proteins, amino acids, carbohydrates, pectin, fatty acids, and humus. Products of OM mineralization are involved in the next biogeochemical cycles. A small part of the OM, however, is buried in the sediments and forms the oil and gas fields during diagenesis and catagenesis. For the accumulation of OM, down-slope transport by turbidity currents/slumps and rapid burial are important processes for the preservation of OM in the sediments.

Synonyms

Orogens: orogenic belts, mountain belts; Orogeny: mountain building, formation of orogens

Definition

Orogeny, from the Greek ὄρος (*óros*) "mountain" and γένεσις (*génesis*) "creation," refers to the geodynamic processes leading to deformation of the Earth lithosphere resulting in crustal thickening, surface uplift, and the formation of large-scale topography rising more or less abruptly from the surrounding level.

Introduction

Orogenic belts are large mountain belts forming usually at destructive plate boundaries, as part of an orogenic cycle. They record a number of complex geodynamic processes, often associated with subduction of an oceanic plate beneath another tectonic plate, which is eventually followed by collision between two continents or between a continent and an island arc. Contrary to the continental crust, which is thick (generally >30 km) and buoyant (density ~2,700 kg m^{-3}), the oceanic crust is thin (generally <10 km) and dense (density ~2,900 kg m^{-3}). It can be easily recycled into the mantle during subduction, due to its transformation to very dense eclogite (density >3,300 kg m^{-3}). Since subduction has been consuming oceanic lithosphere through the Earth history, almost no oceanic crust older than ~180 Ma (lower Jurassic) exists. Orogenic belts represent thus important archives for more than 95 % of the Earth history (Figure 1).

The formation of mountain belts has induced major environmental and climatic global changes during the Earth history, through modifying the atmospheric and oceanic circulations, the location of elevated terrains suitable for inland ice, the radiation balance, and the geochemical cycles. The present-day orogenic belts are associated with active tectonics and volcanism which manifest them by potentially deadly geological hazards (earthquakes, landslides, and volcanic eruptions). Understanding the formation and the destruction of orogens at both short and long term is, therefore, essential.

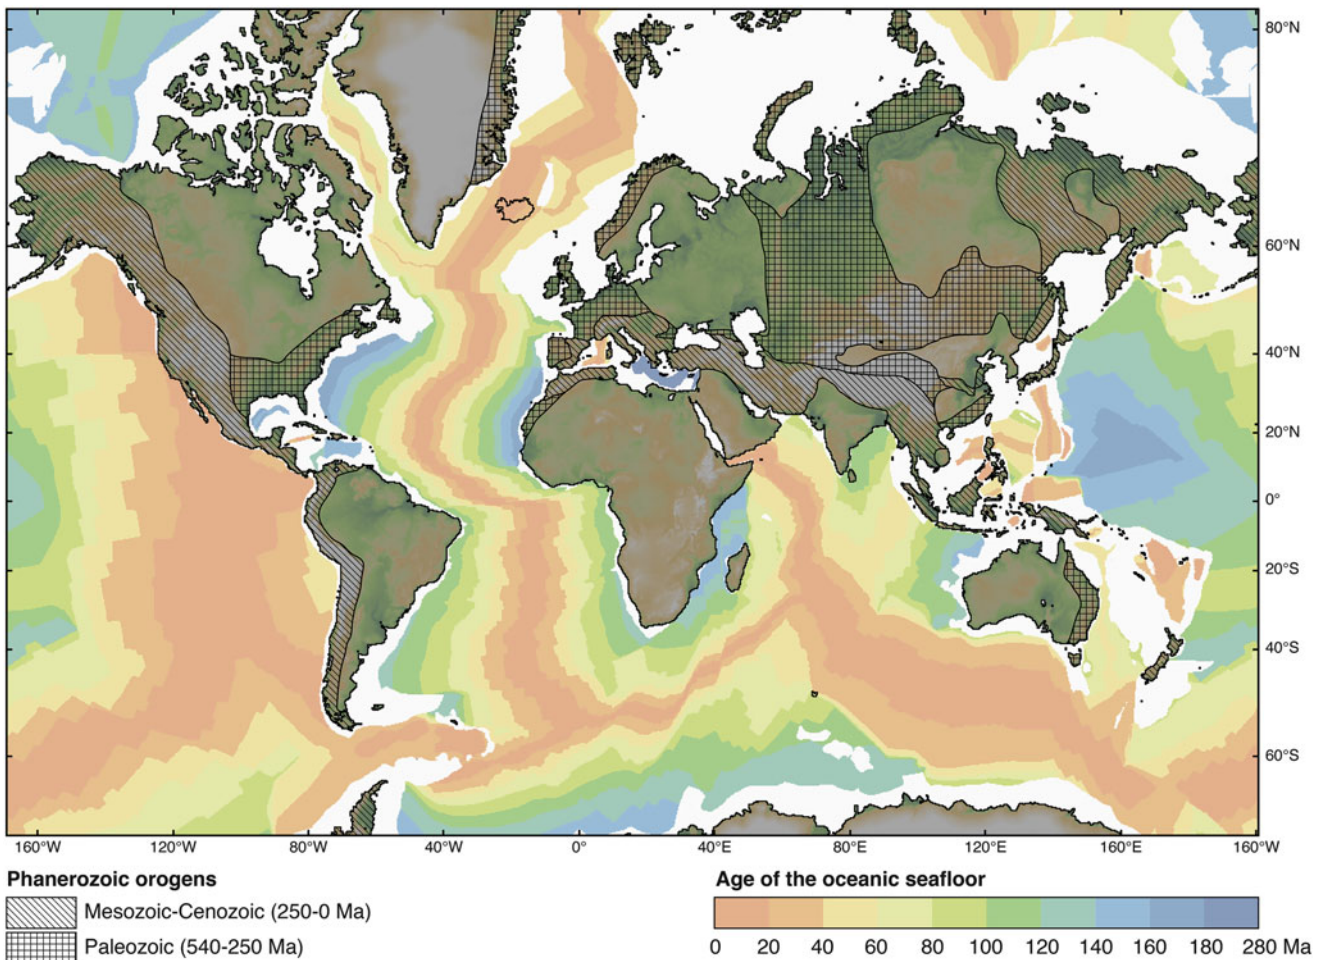
Although orogens are generally considered to form at destructive plate boundaries, it is important to note that deformation of the lithosphere and its resulting topography may develop in other geodynamic environments: along constructive plate boundaries (e.g., East African Rift), extensional orogens (e.g., Canadian Cordillera), along conservative plate boundaries (e.g., Dead Sea Transform fault system), and above hot spots (e.g., Hawaiian–Emperor Seamount Chain).

The orogenic cycle

The Canadian geologist John Tuzo Wilson (1908–1993) described the periodic opening and closing of oceans giving rise to the formation of orogens as the orogenic cycle (sometimes called *"Wilson Cycle"* or *"supercontinent cycle"*). Each stage of such a cycle combines a number of different geodynamic processes (Moores and Twiss, 1995). For example, deep tectonic processes controlling the formation and the destruction of an orogen are always associated with erosion and sedimentation, which act at the surface (England and Molnar, 1990; Avouac and Burov, 1996).

There are four characteristic stages in an orogenic cycle:

(i) *Continental rifting and opening of a new oceanic basin*. Thick shallow-water sediments accumulate along the margin of an oceanic basin. In the more central parts of the basin, deep-water sediments are deposited on top of basaltic flows and gabbroic intrusions forming at the mid-ocean ridge.

(ii) *Subduction of the oceanic lithosphere* initiates along a ridge-parallel fault, an oceanic fracture zone, a transform fault, or an ocean–continent transition. It may be associated with the obduction of oceanic


Orogeny, Figure 1 Global map of the Phanerozoic orogens. The Paleozoic and Mesozoic–Cenozoic orogens are distinguished by different hatches. Continental areas without pattern correspond to Precambrian domains (cratons and Pan-African orogen). The topography of the continents (SRTM30_PLUS, Becker et al., 2009) and the age of the oceanic seafloor (Müller et al., 2008) are also presented.

lithosphere onto the continental margin. Dehydration of the downgoing oceanic plate leads to melting of its overlying mantle wedge and induces the formation of a volcanic arc in the overriding plate.

(iii) *Continental subduction and collision of two continents* eventually occurs, as the continental margin at the other side of the previous oceanic basin arrives in the subduction zone. Ongoing shortening induces deformation, metamorphism, magmatism, and thickening of the crust. Surface uplift together with erosion of the rising orogenic belt results in deposition of synorogenic sediments. Convergence may be accommodated by lateral escape of crustal blocks along continent-scale strike-slip faults.

(iv) *Destruction of the orogen* is accompanied by lithospheric extension, crustal thinning, development of fault-bounded sedimentary basins, and intrusions of large magmatic bodies. Once the crust has reached a normal thickness, a new orogenic cycle can begin.

Although similar stages can be found in all Phanerozoic orogenic belts, such a cycle is a very broad simplification, which probably does not apply to all orogens in detail. In fact, it is very unlikely that rifted continental margins reassemble at the same location since in most continental collisions the two colliding continents were never previously close together. It must also be noted that orogeny and the orogenic cycle are here described in the framework of plate tectonics, the onset of which is debated (sometimes in the Precambrian, Eriksson et al., 2004). Other geodynamic processes than those described here have probably controlled formation of mountain ranges early in the Earth's history.

Types of orogens

Based on the different tectonic, metamorphic, and magmatic evolutions of orogenic belts, two main different types of orogens, which are in fact two different stages
Orogeny, Figure 2 Section across a model composite orogenic belt.

of an orogenic cycle, have been proposed (Zwart, 1967; Pitcher 1979; Ernst, 2005; Frisch et al., 2011):

(i) *Cordilleran-type* or *arc-type* orogens are dominated by I-type (derived from the melting of a igneous protolith) andesitic volcanism and granodioritic batholiths. These orogens are not formed by continent–continent collision but rather developed during a geologically long period of oceanic subduction beneath a continental margin. Although these orogens may experience a protracted history including collisions (with seamounts, oceanic plateaus, or microcontinents), abyssal sedimentary rocks, a suture zone, and basement nappes are generally missing. Above the downgoing oceanic plate, huge sedimentary sequences form thrust sheets of an accretionary wedge. The distribution of metamorphic rocks in such orogens can be described as paired metamorphic belts parallels to the chain. Low pressure–high temperature metamorphism occurs along the magmatic arc, while high pressure–low temperature rocks are present as part of a mélange incorporated to the accretionary wedge.

(ii) *Alpine-type* orogens result from the collision of two continents after subduction of an oceanic plate. Such orogens form relatively narrow belts, which are dominated by thick nappe stacks involving basement of different metamorphic pressure–temperature evolution. The nappes experience considerable deformation and large-scale overthrusting in the order of 100 km or more. Ophiolitic material marks the suture zone between the initially separated continents, where the separating oceanic plate has been consumed. Typically, one or more tectonic units record high-pressure (blueschist and/or eclogite facies) or even ultrahigh-pressure metamorphism (>2.7 GPa). They are extruded up to the surface above a major thrust and below an apparent normal fault. Syn- and post-tectonic plutons are dominated by S-type granites (derived from the melting of a sedimentary protolith).

Anatomy of orogens: the critical parts

Although the processes involved in the formation of orogenic belts may vary significantly, there are several major elements which are common to many of these belts (Hatcher and Williams, 1986). The formation of these typical elements has been successfully modeled by analogue and numerical experiments, through their ability to simulate shallow and deep processes occurring at different space and time scales. Here we describe a composite orogenic belt, at the collision stage (Figure 2).

(i) *A foreland basin* forms parallel to the mountain front because the mass created by crustal thickening causes the lithosphere to bend (i.e., lithospheric flexure). The cross-sectional shape of the lithosphere can be described as an asymmetrical low close to the mountain front and a broad convex upwards deflection along the forebulge (Catuneau, 2004). The facies of the sediments deposited in foreland basins generally evolves during the life of the orogen, from flysch in the early stages to molasse in the late stages. The width and depth of the foreland basin is mainly controlled by the flexural rigidity of the underlying lithosphere and the size and thickness of the mountain belt. Basin fillings can reach up to 10 km thick sediment succession derived from the eroding mountains, thinning away from the mountain belt (Allen and Allen, 2005). Pro-foreland basins occur at the surface of the downgoing lithosphere (e.g., the Ganges Basin, south of the Himalaya). Retro-foreland basins occur on top of the overriding plate (e.g., Andean basins, east of the Andes). Foreland basin systems have an orogeny-parallel, structured internal geometry and comprise several distinct depozones that result from the flexural response to topographic loading of the overlying continent and subduction processes of the downgoing plate (DeCelles and Gilles, 1996).

Since the geometry of foreland basins is mainly influenced by fold-and-thrust belt migration, flexural

subsidence, and sedimentation derived from the rising mountain belt, geodynamics models have been used to derive important parameters like the rheology of the lithosphere, thrusting rates, or erosion rates (DeCelles and DeCelles, 2001; Jordan and Watts, 2005; Pelletier, 2007). Numerical models of foreland basin successfully combined the effects of fold-and-thrust belt migration, flexural subsidence, and sedimentation including three-dimensional geometries and nonlinear crustal rheology (Garcia-Castellanos et al., 1997, Clevis et al., 2004).

(ii) *A fold-and-thrust belt* consists in intensely thrusted and folded unmetamorphosed or low-grade sediments, derived from the passive margins of the downgoing continent. In cross section, the fold-and-thrust belt has a wedge-shaped geometry with a sole fault (décollement) at its base. The deformation generally propagates outwards in a sequence so that the deformation near the core of the orogen and at high structural levels is older than the deformation near the foreland at the structural base of the thrust stack. The décollement characteristically contains weak rocks like shales or salt along which the deformation of the overlying wedge is decoupled from the underlying rocks, which frequently consists of crystalline basement rocks. This style of deformation where strongly shortened sedimentary rocks are detached from a basement is called thin-skinned tectonics. At the contrary, thick-skin tectonics describes a fold-and-thrust belt in which the basement is also deformed (typically by reactivation of normal faults as thrusts).

The shape of the wedge has been explained by the mechanics of a deformable sequence above a basal décollement, generally known as the critical Coulomb wedge theory (Davis et al., 1983). Critical parameters, which influence the deformation within the wedge, are the dip angle of the décollement, the basal traction along the décollement, the friction angle of the décollement, and the pore fluid pressure, which counteracts the overburden. Numerous physical and numerical models have tested the influence of various parameters on the development and geometry of fold-and-thrust belts like the décollement layer thickness, intermediate décollements within the sedimentary sequence and syn-shortening erosion (Costa and Vendeville, 2002; Ellis et al., 2004; Sherkati et al., 2006, Cruz et al., 2010, Fillon et al., 2013).

Since fold-and-thrust belts are estimated to contain 15 % of the undiscovered global recoverable hydrocarbons, numerous studies focused on the development of balanced cross-section techniques, which aimed to geometrically constrain the style of folding and thrusting and to kinematically model palinspastic reconstructions by unfolding and retro-deforming the stratigraphic sequence (Dahlstrom, 1969; Elliot, 1983; Groshong, 1994; Homza and

Wallace, 1995). However, recent studies have demonstrated that the characteristics and the wavelength of folding in fold-and-thrust belts are strongly influenced by rheological parameters and mechanical isotropies of the stratigraphic pile (Yamato et al., 2011; Ruh et al., 2012). Therefore, future research will focus on mechanical reconstructions of fold-and-thrust belts (Simpson, 2009; Frehner et al., 2012; Vidal-Royo et al., 2012) including three-dimensional mechanical interaction of fold and fault growth (Schmid et al., 2008a; Grasemann and Schmalholz, 2012).

(iii) *A crystalline core zone* forms the central and highest part of a mountain belt, usually above the orogenic root, where the crust is the thickest. It mainly consists of metamorphic and magmatic rocks derived from the upper crust of the lower plate. Lower crustal rocks are rare (Jolivet et al., 2003). Units of oceanic material involved earlier in the subduction zone can also be found, overthrusting the continental units. The crystalline zone is mainly deformed by ductile flow, resulting in large shear zones and folded nappes recording complex multiple deformation events. Metamorphism reaching the amphibolite and eclogite facies is widespread. The metamorphic evolution is, however, very heterogeneous in time and space. Frequently the high-grade metamorphic nappes preserve an inverted metamorphic field gradient, showing an increase of the metamorphic pressure and temperature conditions towards structural higher levels. The presence of eclogites, some of which experienced ultrahigh-pressure metamorphism, suggests that at least parts of the core zone of mountain belts have been involved in continental subduction at mantle depth and later exhumed back to the surface (Chopin, 1984; Hacker and Peacock, 1995; Hacker and Liou, 1998; Jolivet et al., 2003).

Structural field observations demonstrate that the high-grade rocks are exhumed above high-strain shear zones with thrusting kinematic at the base and below normal shear zones at the top. Physical and numerical models together with geological data resulted in several extrusion wedge models accounting for more or less complex internal nappe stack structures (Grujic et al., 1996; Grasemann et al., 1999; Beaumont et al., 2001; Grujic et al., 2002; Gerya et al., 2008; Yamato et al., 2008), which have been applied to most Phanerozoic orogens (Himalayas, Alps, Hellenides, Dabie Shan, Ural, Hindu Kush, or Caledonides; Ernst, 2001; Law et al., 2006). Most of these models have in common that the extrusion of the high-grade rocks has to be at least partly balanced by surface erosion (Froitzheim et al., 2003; Beaumont et al., 2004; Schulmann et al., 2008) requiring huge sediment accumulations in the foreland of the orogen (White et al., 2002).

Synorogenic S-type granites result from partial melting of metasedimentary source rocks from the lower part of the continental crust that has been

thickened by formation of a mountain root during collision. These plutons record a strong interaction and mechanical feedback with deformation in major shear zones (e.g., Schneider et al., 1999; Rosenberg, 2004).

(iv) *A suture zone belt* marks the original contact between two plates that have collided or accreted and is therefore of central interest in order to determine the timing and the nature of collision processes (Haynes and McQuillan, 1974; Klootwijk et al., 1984; Colchen et al., 1986; Agard et al., 2005; Anders et al., 2005; Schmid et al., 2008b; Jolivet and Brun, 2010). In orogen perpendicular cross sections, suture zones are generally steeply dipping zones, which are characterized by an asymmetry inherited from subduction separating block with a marked different geological history. A collisional suture marks the site of a subducted oceanic plate, which separated the collided continents. Therefore, the suture zone consists of various strongly deformed lithologies derived from the oceanic plate, exotic terrane, or accretionary wedges of the continents (tectonic mélange). The existence of ophiolitic remnants between continental blocks is the most direct evidence for the location of the suture zone.

Geodynamic models suggest that during the initial stage of collision, the suture zone forms a large shear band where most of the deformation is localized (Toussaint et al., 2004). This stage is followed by back thrusting around the suture zone and displacement of the initial crustal suture zone towards the overriding plate (Willet, 1994; Beaumont et al., 1996; Ellis, 1996). A zone of high topography, erosion, and exhumation grows above the area of active deformation. After further shortening the suture zone is no longer the major locus of deformation, but crustal scale thrusts dominate the surface deformation leading to the formation of another zone of surface uplift (Toussaint et al., 2004).

(v) *A volcanic arc* forms in the hanging wall of an oceanic subduction and is the result of melting of the mantle wedge induced by volatiles released from the downgoing plate (mainly water), which drastically lower the melting point of the mantle. Therefore, magma ascends above the subducting slab and forms an arc of volcanoes parallel to the subduction zone. This arc can form at the rim of a continental plate (continental arc, e.g., the Andes) or at the rim of an oceanic plate (island arc, e.g., the Lesser Antilles), depending if the oceanic crust subducts beneath a continent or another oceanic crust, respectively. The arcuate shape of volcanic arcs is the result of the curvature of the Earth's surface forcing the subducting plate to deform into a concave shape.

About a quarter of the magmatic rocks on Earth are produced above subduction zones to form volcanic arcs (Schminke, 2004). Water-bearing fluids from the subducted slab, which are mainly derived from destabilization of chlorite at approximately 50 km depth, rise into the overriding mantle wedge induces partial melting of and generates low-density, calc-alkaline magma (Stern, 2002). The magma buoyantly rises through the overlying crust because of its lower density. If the crust above the subduction zone is oceanic, the basaltic to andesitic magma is not significantly altered. Magmas, which intrude into the continental crust are altered by assimilation of crustal material and is enriched in SiO_2 and K_2O.

Recently, the geodynamic processes associated with subduction and volcanic arc growth have been studied by various numerical models including the subduction dynamics influenced by volatile release (Gerya et al., 2002; Rüpke et al., 2004), melting processes associated with the downgoing slab (Gerya and Yuen, 2003; Gerya et al., 2004), growth and mixing dynamics of magmas in mantle wedges (Gorczyk et al., 2007a; Gorczyk et al., 2007b), and the crustal growth of volcanic arcs (Nikolaeva et al., 2008). Some of these models include the physics of various geochemical–petrological–thermomechanical processes investigating slab retreat and bending, crust dehydration, fluid transport, mantle wedge melting, and melt extraction. The results of these numerical experiments show that the rate of plate retreat significantly influences the rate of crustal growth of the volcanic arc and the composition of newly formed crust because of the major contribution of a crustal component by hydrated partially molten upwellings rising from downgoing slabs (Gerya and Yuen, 2003; Nikolaeva et al., 2008).

Destruction of orogens

Continental collision leads to crustal thickening and building of high topography supported by a thick crustal root. The transition from the cold oceanic subduction regime to the warm collision regime weakens the orogenic root, inducing the formation of a continental plateau. The lower crust below the plateau can melt and flow out horizontally in response to crustal thickness variations (Royden, 1996; Rey et al., 2001). During ongoing convergence, lateral extrusion of crustal blocks can become the dominant mechanism accommodating crustal shortening, instead of crustal thickening (Tapponnier and Molnar, 1976; Ratschbacher et al., 1991). Depending on free or extensional boundary condition, crustal blocks can accommodate tens to hundreds of kilometers of lateral displacement along major strike-slip faults (Seyferth and Henk, 2004). When convergence between the two plates involved in the orogen stops, gravitational collapse occurs, inducing thinning of the crust and destruction of the orogenic belt (Vanderhaeghe, 2009). It may be associated, at depth, with slab rollback, slab detachment, delamination, or convective thinning of the lithospheric mantle (Houseman et al., 1981; Wortel and Spakman, 1992; Davis and von Blanckenburg, 1995) and reflected by generalized post-orogenic I- and S-type magmatic activity.

During gravitational collapse, the root of the orogen can be exhumed at the surface in metamorphic core complexes. These crustal scale structures are domes of high-grade rocks located in the hanging wall of low-angle normal fault systems or detachments (Whitney et al., 2013). The erosion products of the exhuming hanging wall are deposited in supradetachment basins. The formation of metamorphic core complexes is controlled by the rheological layering of the lithosphere at the onset of collapse (Buck, 1991). However, the exhumation of these dome-shaped structures below low-angle normal faults has long been considered as mechanically paradoxical. Thermomechanical modeling and field observations have shown that warm geotherms, intrusions (Tirel et al., 2008), partial melting (Rey et al., 2009), complex crustal layering inherited from the collision (Huet et al., 2011), and metamorphic reactions (Collettini and Holdsworth, 2004; Hürzeler and Abart, 2008; Grasemann and Tschegg, 2012) create the conditions for strain localization in low-angle normal faults and mechanically interacting high-angle normal faults which rotate to lower angles during ongoing extension. After gravitational collapse, continental crust of normal thickness and thermal regime is produced. Further extension then leads to continental rifting and the onset of a new orogenic cycle.

Outlook and conclusions

Much advance has been made in recent years in the understanding of the dynamics of orogenic belts in response to the large-scale motion of the lithospheric plates and numerous ideas, many of which developed from studies on the collision between India and Asia have led to a better understanding of the thermomechanical evolution of orogens (for a comprehensive overview see Stüwe, 2007; Turcotte and Schubert, 2014). Large, global geophysical datasets, including topography, gravity, geoid, and magnetic anomaly, together with new high-resolution geological datasets constraining the rheology of the lithosphere and the rates of geodynamic processes, increased our knowledge about the evolution and structure of orogens (Magni et al., 2013). Numerical thermomechanical models have demonstrated that the dynamics of orogens is strongly controlled by the temperature-dependent strength distribution within the lithosphere and the efficiency of erosion. Indeed, the recognition of a significant linkage of deep Earth dynamic processes with surface and/or near-surface geological processes is one of the important developments in Earth sciences over the past decade (Braun, 2010, Cloetingh and Willet, 2013).

Recently, it has been suggested that mantle dynamics has a major influence on building mountains. Two orogenic end-members have been distinguished, depending on the forces controlling the formation of the orogen (Faccenna et al., 2013). Slab pull dynamics is associated with slabs subducting in convective upper mantle, trench rollback, and the formation of mountains with moderate crustal thickness (e.g., the Mediterranean). Slab suction is associated with slabs penetrating through the phase transitions around 660 km, leading to the formation of mountains with thick crustal columns (e.g., the Himalayas).

In spite of this rapid increase of our knowledge level about orogeny, the effects of three-dimensionality in orogenic systems and their forming processes are still poorly understood. Recent three-dimensional mechanical models of folding (Schmalholz, 2008; Schmid et al., 2008a), faulting (Walsh et al., 2001; Imber et al., 2004; Seyferth and Henk, 2004; Soliva et al, 2008; Le Pourhiet et al., in review), rifting (Allken et al., 2012), crustal wedges (Braun and Yamato, 2010), metamorphic core complexes (Le Pourhiet et al., 2012), and mid-ocean ridges (Gerya, 2012) demonstrated the urgent need to use high-resolution three-dimensional numerical models in order to further develop our understanding of geodynamic processes in orogens.

OXYGEN ISOTOPES

Mark Maslin[1] and Alexander J. Dickson[2]
[1]Department of Geography, University College London, London, UK
[2]Department of Earth Sciences, University of Oxford, Oxford, UK

Definition

Marine sediments provide long continuous records of past climate changes at intraannual, annual to centennial scale resolutions enabling insights into past changes within both oceanic and continental environments. Stable oxygen isotopes are a fundamental tool for paleoceanographers providing the means to reconstruct a range of variables including sea surface and bottom water temperature, sea surface salinity, sea-level, river discharge, and iceberg activity. Comprehensive introductions on oxygen isotopes and their physicochemical behavior/systematics are given in Craig and Gordon (1965), Garlick (1974), Hoefs (1997), Criss (1999), Rohling and Cooke (1999), Zeebe and Wolf-Gladrow (2001) and Pearson (2012).

Oxygen isotopes in marine archives

Oxygen isotope compositions can be measured in many forms of mineral, including calcite, aragonite, opal, and barite. The shells of carbonate producing organisms have most commonly been used for $\delta^{18}O$ analysis, and have underpinned many of the advances in stratigraphy and paleoceanographic reconstruction that have been made in recent decades. However, $\delta^{18}O$ in the other minerals has also been extremely important in allowing $\delta^{18}O$-based paleoclimate reconstructions to be extended into carbonate-poor regions of the global oceans and in complementing carbonate-derived data in regions where the different minerals coexist.

There are several major influences on the $\delta^{18}O$ compositions in marine minerals (Eq. 1). First is the $\delta^{18}O$ of the seawater in which minerals precipitate ($\Delta\delta^{18}O_w$). This is

controlled by the globally significant impact of the storage and release of ^{16}O-enriched freshwater in continental ice sheets ($\Delta\delta_{GIV}$), and the local balance of evaporation verses freshwater inputs from precipitation, river, or iceberg discharge ($\Delta\delta_{local}$). Second is the water temperature at which the precipitate forms ($\Delta\delta_T$). A greater proportion of ^{16}O is incorporated into marine minerals at higher temperatures. The oxygen isotope composition of marine carbonates is also controlled by the carbonate ion concentration of the seawater from which they precipitate and by the impact of postdepositional dissolution under conditions of carbonate ion undersaturation. In the sections below, these influences are examined and examples given of how they can be used to reconstruct past climate on a range of timescales.

$$\Delta\delta^{18}O_M = \Delta\delta^{18}O_w + \Delta\delta_T$$
$$= \Delta\delta_{GIV} + \Delta\delta_{local} + \Delta\delta_T + \text{vital effects} \quad (1)$$

where:

$\Delta\delta^{18}O_M$ = oxygen isotopes of the mineral precipitated (e.g., calcite or opal)

$\Delta\delta^{18}O_w$ = oxygen isotope composition of the water which is a combined affect of variations in global ice volume ($\Delta\delta_{GIV}$) and local influences ($\Delta\delta_{local}$)

$\Delta\delta_T$ = water temperature

Vital effects = deviations from equilibrium due to the incorporation of oxygen into biogenetically produced calcite or opal. These effects include ontogeny, symbiont photosynthesis, respiration and life history (see Rohling and Cooke, 1999; Marchitto et al., 2014).

Global ice volume ($\Delta\delta_{GIV}$)

During particularly cold intervals of Earth history, ^{18}O-depleted precipitation is transferred from the oceans to continental ice sheets, where it is stored over timescales of 10^3–10^4 years. This transfer registers as a whole ocean shift in the oxygen isotope composition of seawater, given that the magnitude of the isotope perturbation is considerably longer than the ocean mixing time of ~2000 years. The oxygen isotope composition of marine minerals thus allow stratigraphic records from around the world to be correlated with a precision of a few thousand years (Figure 1).

Changes in seawater δ^{18}O have been calibrated to known variations in global sea-level (e.g., Chappell and Shackleton, 1986; Shackleton, 1987; Fairbanks, 1989; Bard et al., 1996; Schrag et al., 1996; Burns and Maslin, 1999; Shackleton, 2000). Using the best current estimate for the magnitude of shifts in both parameters over the past ~20,000 years (1‰ and 130 m) produces a relationship of 0.0077 ‰/m. However, it is known that the relationship between RSL and benthic foraminifera δ^{18}O is non-linear and is also different for both deglaciation and glaciation (see Figure 2). This is firstly because there is clear evidence that there were large differences between

the average isotopic composition of each of the major ice sheets that existed during Quaternary glacial periods (Duplessy et al., 2002) with compositions ranging from −16‰ to −60‰ for Northern Hemisphere and Antarctic ice. The timing of the growth and melting of each ice sheet will consequently influence the temporal evolution of the RSL-$\Delta\delta_{GIV}$ relationship as illustrated in Figure 2. Secondly, the extent of isotopic fractionation during snowfall changes as ice sheets grow, typically increasing as the ice sheet matures through a combination of continentality and altitude effects.

Carbonate ion concentrations

pH can affect seawater δ^{18}O. In seawater, dissolved inorganic carbon (DIC) is comprised of the sum of several species:

$$DIC = CO_{2[aq]} + H_2CO_3 + HCO_3^- + CO_3^{2-}$$
At present day seawater pH, the relative abundance of these species is dominated by bicarbonate (HCO_3^-). At times of higher seawater pH, when the relative abundance of carbonate ions (CO_3^{2-}) is higher, the δ^{18}O of seawater decreases due to a lower equilibrium δ^{18}O composition in CO_3^{2-} compared to HCO_3^-. The magnitude of this effect has been quantified in culture experiments of the planktonic foraminifera in the range −0.0015 to −0.005‰/μmol/kg (Spero et al., 1997), which agrees closely with a gradient of −0.0024‰/μmol/kg calculated from inorganic precipitation theory (Zeebe, 1999). Quantifying the magnitude of the carbonate ion effect on long-term stratigraphic record of seawater δ^{18}O is, however, difficult due to problems reconstructing carbonate ion concentrations using proxy data.

Paleotemperature ($\Delta\delta_T$)

Temperature causes a change in the δ^{18}O of marine minerals due to inorganic kinetic fractionations during mineral formation. This effect has been quantified in several inorganic precipitation experiments (e.g., McCrea, 1950; Craig, 1965; O'Neil et al., 1969; Kim and O'Neil, 1997), examples of which include:

Epstein et al. (1953)

$$T = 16.5 - 4.3(\delta_c - \delta_w) + 0.14(\delta_c - \delta_w)^2 \quad (2)$$

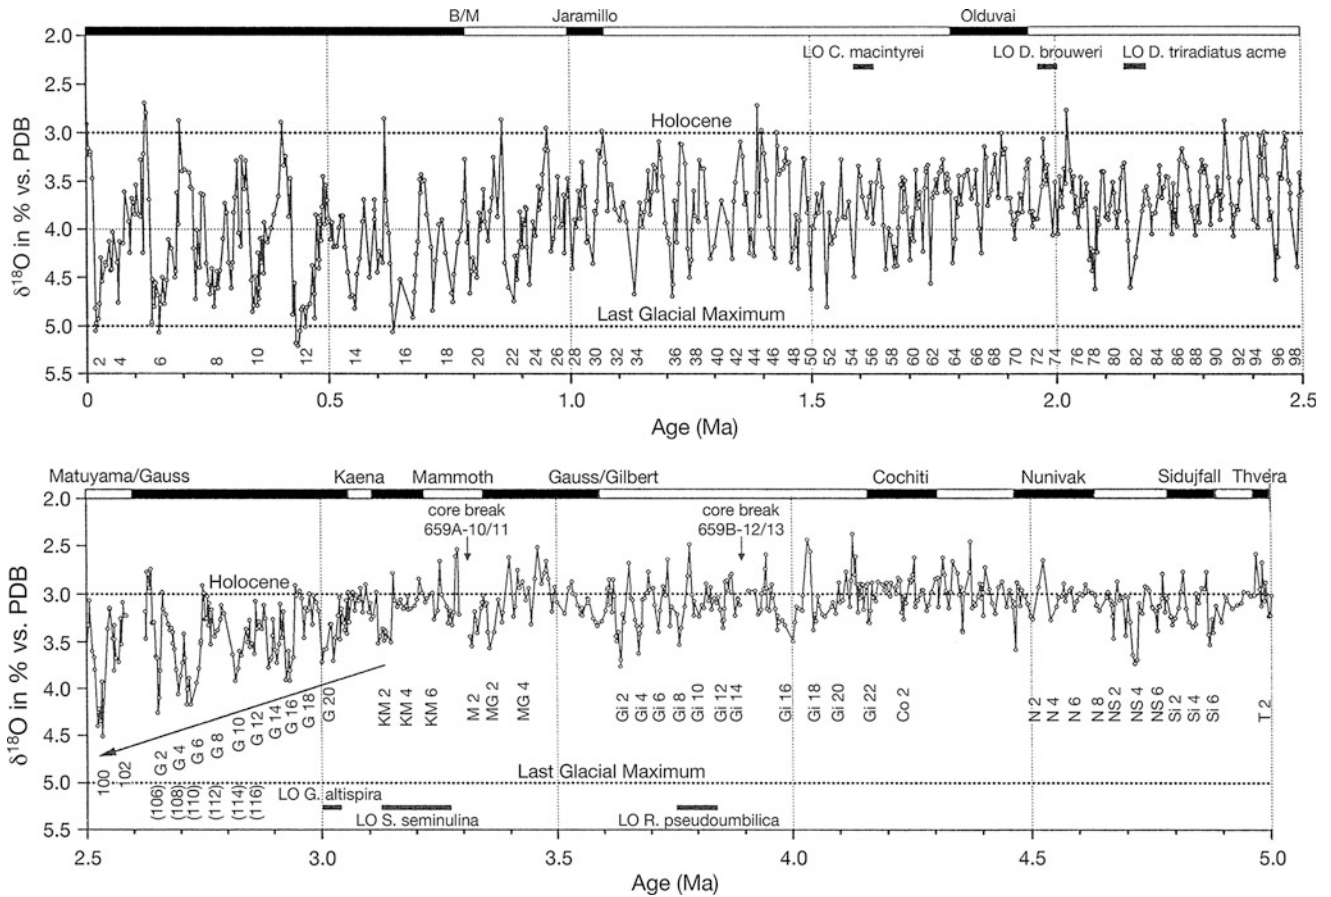
Shackleton (1974) based on O'Neil et al. (1969)

$$T = 16.9 - 4.38(\delta_c - \delta_w) + 0.1(\delta_c - \delta_w)^2 \quad (3)$$

Hays and Grossman (1991) based on O'Neil et al. (1969)

$$T = 15.7 - 4.36(\delta_c - \delta_w) + 0.12(\delta_c - \delta_w)^2 \quad (4)$$

Shemesh et al. (2002)

$$T = 11.03 - 2.03\left(\delta^{18}O_{(diatom)} - \delta^{18}O_{(water)} - 40\right) \quad (5)$$


Oxygen Isotopes, Figure 1 Benthic foraminifera oxygen isotope record from ODP 659 in the tropical North East Atlantic with paleomagnetic reversal boundaries and marine oxygen isotope stages (*MIOS*) defined (adapted from Tiedemann et al., 1994).

When;

T = isotopic temperature estimate
$\delta_c = \delta^{18}O$ of the foraminifera calcite test
$\delta_w = \delta^{18}O$ of the surface waters,

Alternative equations have been proposed by Bemis et al. (1998), which take the form of linear relationships between (foraminifera) calcite $\delta^{18}O$ and temperature, e.g.,:

$$\Delta\delta_c = \Delta\delta_w - 0.23\Delta T \qquad (6)$$

Moreover different calibration equation have been developed for different species of planktonic and benthic foraminifera (Marchitto et al., 2014). Although these equations differ in their predictions of absolute temperature, they consistently predict a gradient of ~ -0.2 to $-0.3\permille/^oC$. An important pre-requisite to reconstructing absolute past temperatures from $\delta^{18}O$ is a knowledge of the seawater $\delta^{18}O$ (δ_w). Since δ_w has varied in the past, temperature reconstructions require that there should be little or no change in global ice volume and/or local

conditions during the period of reconstruction or there should be independent estimates of both these influences.

Paleosalinity ($\Delta\delta_{local}$)

Calculation of surface water salinity or sea surface salinity (SSS) is possible in locations where the $\Delta\delta_{local}$ is primarily controlled either by the balance of evaporation verses precipitation (E-P) or the input of ^{18}O-depleted freshwater such as from melting icebergs or rivers. The local influence on the marine oxygen isotope record is calculated by subtracting the temperature influence and the global ice volume variations from the precipitate record:

$$\Delta\delta_{local} = \Delta\delta^{18}O_M - \Delta\delta_T - \Delta\delta_{GIV} \qquad (7)$$

Sea surface temperatures can be independently reconstructed in five ways; planktonic foraminifera assemblage data (e.g., Imbrie and Kipp, 1971; Pflaumann et al., 2003), ratios of n-alkenones with differing number of unsaturated bonds (U^K_{37}) (Prahl and Wakeham, 1987), the number of cyclic inclusions in archaea-derived
Oxygen Isotopes, Figure 2 Relationship between relative sea-level (*RSL*) and oceanic oxygen isotopes assuming the four major past ice sheets (Antarctic, Greenland, Eurasia, and North America) melted or grow in different successive orders. Note the different amount of fractionation that occurs within each ice sheet alters the RSL-δ^{18}O relationship and could create an error of up to 30 m RSL. *Insert* – The relationship between individual continental ice sheet size and oceanic oxygen isotopes may also not be linear.

biomarkers (TEX$_{86}$) (Schouten et al., 2002), clumped oxygen isotopes (Eiler, J.M., 2007, EPSL 3–4, p 309–327) and Mg/Ca ratios in planktonic foraminifera tests (Elderfield and Ganssen, 2000). These estimates of temperature can be converted to $\Delta\delta_T$ using Eqs 2, 3, 4, 5, and 6. The isotopic effect of changing global ice volume can be estimated by converting RSL or ESL to oxygen isotopic variation using a simple linear relationship of ~0.008–0.01 ‰ m^{-1}. Once $\Delta\delta_{local}$ has been calculated then the relationship between it and sea surface salinity can be estimated. This relationship depends on the oxygen isotope value of the end-member inputs i.e., freshwater (δ_{fresh}) and mean marine sea water (δ_{ocean}). These values vary with locality due to the input of meltwater or precipitation or river runoff compared with the influence of evaporation and ocean circulation. The oxygen isotope-salinity relationship can be defined as:

$$\Delta\delta_{local} = (\delta_{ocean} - \delta_{fresh}/S_{ocean} - S_{fresh})S_{local} + \delta_{fresh} \quad (8)$$

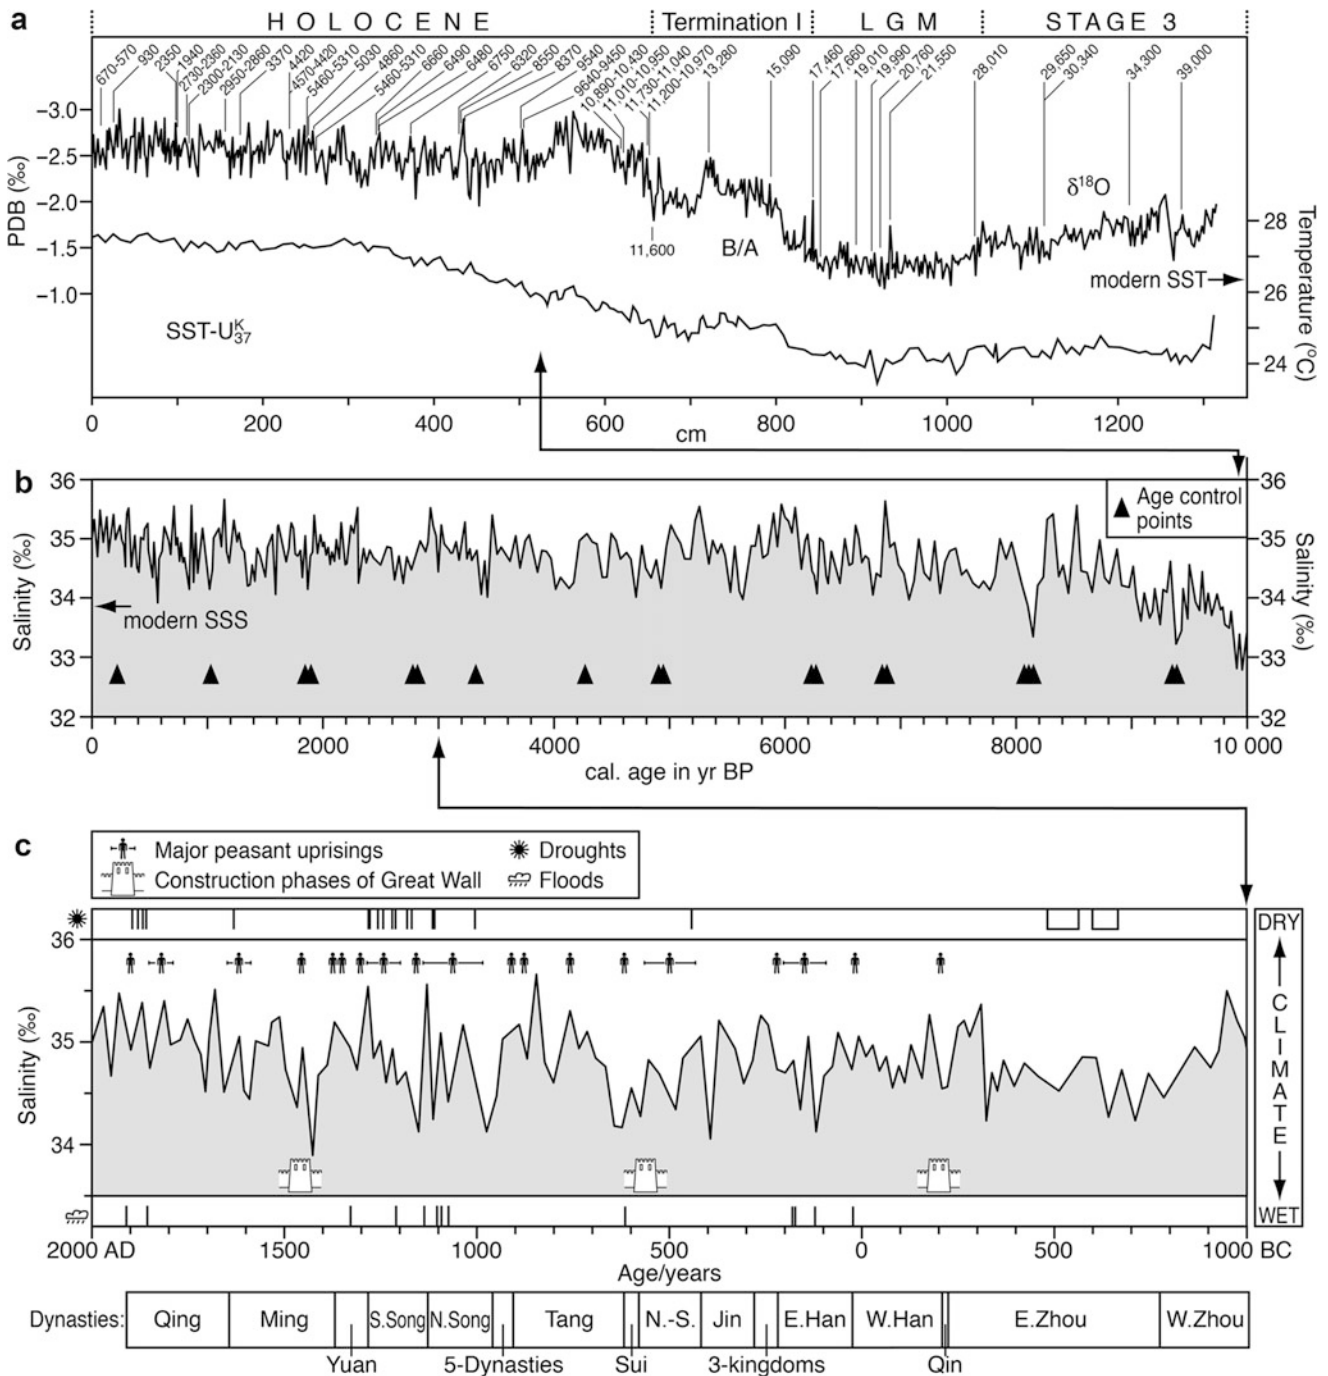
where salinity of freshwater (S_{fresh}) is equal to zero and can therefore be omitted and the equation solved for local Salinity:

$$S_{local} = (\delta_{fresh} - \Delta\delta_{local})(S_{ocean}/\delta_{fresh} - \delta_{ocean}) \quad (9)$$

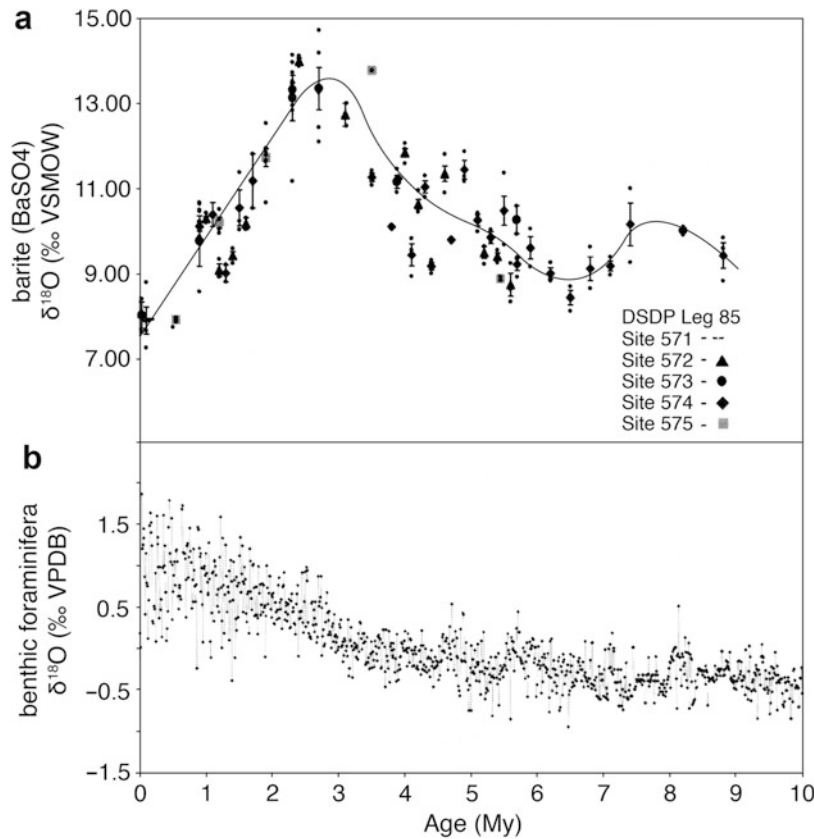
Calculation of surface water salinity, however, is fraught with difficulties due to the propagation of the uncertainties associated with estimating each unknown parameter in Eq. 6 (Schmidt, 1999; Rohling, 2000). These include (i) uncertainties in the paleo-SST estimates, which are ± 1–$1.5\,°C$ for mid- to high-latitude sites and over at least $\pm 2\,°C$ in the tropics (see Elderfield and Ganssen, 2000; Pflaumann et al., 2003; Kucera et al., 2005), (ii) Estimation of the $\Delta\delta_{GIV}$ has been shown above to contain uncertainties, which are usually quoted as ± 0.001 ‰ $°C^{-1}$, (iii) accurate determination of the mean ocean salinity (S_{ocean}) due to the concentration effect of changing global ice-volume effect. This can be calculated using Eq. 9, but suffers from the uncertainties in estimating past sea-levels, which can be on the order of centimeters to meters.

$$S_{ocean} = 34.74 \times RSL/(3900 - RSL) \quad (10)$$

(iv) The estimation of the oxygen isotope freshwater endmember (δ_{fresh}) also has inherent uncertainties. Selection of freshwater endmember compositions of ~ -20‰ or -40‰ can produce significantly different mixing gradients resulting in salinity estimates that vary greatly.

Not only are there large errors associated with each of the above assumptions but these errors are cumulative in the calculations (Rohling, 2000). Salinity reconstructions have been used to infer a large number of climatic parameters including: iceberg discharge (Maslin et al., 1995;


Oxygen Isotopes, Figure 3 South China Sea: Comparison of the planktonic foraminifera oxygen isotopes, sea surface temperature estimates and reconstructed sea surface salinity for the last 3000 years with documentary evidence from China of periods of droughts, floods, peasant uprisings, construction phases of the Great Wall and changes in the ruling Dynasties (redrawn from Wang et al., 1999).

Chapman and Maslin, 1999) river runoff (Maslin and Burns, 2000; Maslin et al., 2011), iceberg rafting (Maslin et al., 1995), surface ocean circulation and upwelling (Swann et al., 2006; Dickson et al., 2010; Martinez-Mendez et al., 2010), and monsoonal strength (Wang et al., 1999). An example is shown in Figure 3, where $\Delta\delta_{local}$ was isolated from planktonic foraminifera $\delta^{18}O$ data from the South China Sea to infer changes in the SE Asian monsoon over the last 3000 years (Wang et al., 1999).


Oxygen Isotopes, Figure 4 Comparison of benthic foraminifera oxygen isotopes with barite oxygen isotopes for the last 8 Ma (adapted from Turchyn and Schrag, 2004).

Influence of diagenesis

Oxygen isotopes in marine minerals can become altered from their primary compositions following sediment burial. This effect arises due to the higher $\delta^{18}O$ composition of cold deep ocean water compared to warmer surface waters, where many planktonic (surface dwelling) organisms live. Following sedimentation on the seafloor, such planktonic organisms may partially dissolve due to carbonate or silicic acid undersaturation, or barite reduction (Schrag, 1999; Broecker, 2003), before recrystallizing in pore waters with a higher saturation state (Schrag et al., 2013). Diagenesis may in principal have a large effect on Paleoceanographic reconstructions, principally through biasing temperature reconstructions towards lower values.

Several studies had previously argued for relatively cool tropical surface ocean waters during the Mesozoic, a period of prolonged greenhouse warming (e.g., Shackleton and Boersma, 1981; Bralower et al., 1995). However, subsequent studies have utilized well-preserved planktonic foraminifera recovered from clay-rich lithologies that limit the impact of pore water recrystallization to demonstrate that cool temperatures were likely to have been the result of diagenesis (e.g., Wilson and Norris, 2001; Pearson et al., 2007; Pearson, 2012).

Sulfur cycle

Oxygen isotopes can also be used to examine the sulfur cycle (Turchyn and Schrag, 2004; Turchyn et al., 2009). The amount of sulfate in the ocean is controlled by three major processes: input from rivers, sulfate reduction and sulfide reoxidation on continental shelves and slopes, and burial of anhydrite and pyrite in ocean crusts. These controls on the biogeochemistry of the sulfur cycle can be monitored using oxygen isotopes as each source has a distinct isotopic signature. Natural riverine input has a $\delta^{18}O_{SO4}$ of −2 to +7‰ VSMOW which is a mixture of weathered evaporate deposits (11−13‰) and oxidiative pyrite (−4 to +2‰). While sulfur reduction leaves the sulfate pool enriched by 8−10‰ (up to 25‰ enriched in sulfate-limited environments) and sulfide reoxidation on continental shelves ^{18}O-enriches sulfate by 8−17‰ compared with the $\delta^{18}O$ of seawater, depending on what metals are present. The final effect on $\delta^{18}O_{SO4}$ is direct sulfide oxidation in hydrothermal and some shallow sediment environments which produces sulfate with the same $\delta^{18}O$ as the seawater it was oxidized in. Turchyn and Schrag (2004) have modeled these various inputs to the $\delta^{18}O_{SO4}$ and suggest that the oxygen isotope shifts over the past 10 million years can be linked to sea-level

Oxygen Isotopes, Table 1 Environmental influences on marine oxygen isotopes

Environmental Factor	Higher	Lower
Temperature	$\delta^{18}O$ decrease	$\delta^{18}O$ increase
Global Ice Volume	$\delta^{18}O$ increase	$\delta^{18}O$ decrease
Salinity[a]	$\delta^{18}O$ increase	$\delta^{18}O$ decrease
Density[a]	$\delta^{18}O$ increase	$\delta^{18}O$ decrease

[a]an exception is sea ice formation which increases surface water salinity and density but lowers the surface water $\delta^{18}O$ (O'Neil 1968) as $\delta^{18}O$ always increases in the formation of ice from water. This affect though is minimal and is not believed to influence past climatic records

fluctuations during the Plio-Pleistocene glacial cycles, which influencing the burial and oxidation of pyrite on continental shelves (Figure 4).

Conclusions

Table 1 summarizes the relationship between marine oxygen isotopes and their main environmental controls, namely water temperature, ice volume, and salinity. This provides a guide to the causes of ^{18}O-depletion or ^{18}O-enrichment in ocean water, which form the basis of all Paleoreconstructions. In this article, we have demonstrated how oxygen isotopes records can provide stratigraphy as well as enabling the reconstruction of a range of environmental parameters such as global ice volume, ocean temperatures, sea-level, and the sulfur cycle. The advances in our understanding of past climates due to oxygen isotopes are fundamental, the most important of which are: confirmation of the theory of orbital forcing, variability of deep ocean circulation of a range of timescales from millions of years to century, variability of atmospheric weather systems such the El Nino Southern Oscillation, monsoonal and riverine systems, and discovery of large amplitude millennial variations in relative sea-level (Maslin and Swann, 2005).

PAIRED METAMORPHIC BELTS

Wolfgang Frisch
Department of Geosciences, University of Tübingen,
Tübingen, Germany

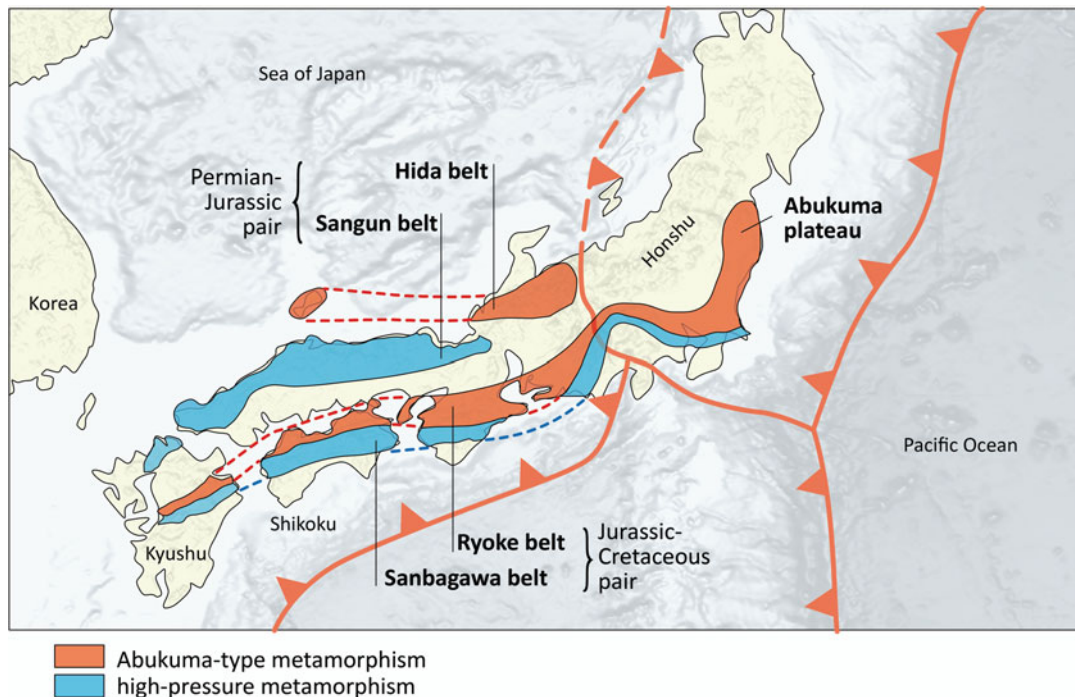
Definition

As first identified in Japan, pairs of elongate, parallel belts with significantly different metamorphic rocks are indicative of former subduction activity. One metamorphic belt consists of rocks formed by high-pressure metamorphism and the other consists of rocks of the Abukuma facies high-temperature metamorphic rocks. These two belts of metamorphic rocks, which were formed under extremely different pressure/temperature relations, occur in direct association and are called "paired metamorphic belts."

Orogenic processes involve uplift that raises portions of the metamorphic rocks toward the surface and into the zone of erosion. From the spatial arrangement of the two contrasting belts at the surface, it is possible to detect not only former subduction activity but also the polarity of the subduction zone (Figure 1). The high-pressure belt (subduction metamorphism) marks the area of the subduction zone, and the high-temperature belt (Abukuma-type metamorphism) marks the location of the magmatic arc. In Japan, the paired metamorphic belts indicate subduction beneath the Asian continent since the Permian epoch. Since that period, the subduction zone has shifted twice toward the present Pacific Ocean. The presently formed metamorphic rocks are still hidden at depth.

High-pressure or subduction metamorphism

Rocks in subduction zones are metamorphosed under conditions of high pressure at relatively low temperature, hence the terms high-pressure (properly high-pressure/low-temperature) metamorphism or subduction metamorphism (Figure 2). Such metamorphism results because cool rock material is rapidly subducted to great depths. Normally, at a depth of 50 km that corresponds to a pressure of 1.5 gigapascal, the temperature is approximately 800–900 °C. In contrast, oceanic crust that reaches the same depth in a subduction zone reaches temperatures between 200 to more than 500 °C. The lower value is valid for old, cool, rapidly subducting lithosphere, and the higher value is for young and warm, more slowly subducting lithosphere (Stern, 2002). The isotherms in the subduction zone are strongly declined downward because rocks are poor heat conductors and they need millions of years to adjust to the higher temperatures normally seen at depth (Figure 3).

Rocks that have been buried within subduction zones (to even more than 100 km) and subsequently exhumed during orogenic processes can be observed directly on outcrop. Metamorphic conditions in a subduction zone transform basalts, dolerites, and gabbros of the oceanic crust into glaucophane schists (blueschists) and eclogites (Figure 2). In addition, sedimentary rocks and splinters


Paired Metamorphic Belts, Figure 1 Paired metamorphic belts in Japan. The different ages of the belts indicate that subduction lasted for more than 250 million years, each with subduction directed toward N or NW. The subduction zone shifted stepwise outward (southeastward) and is today offshore the Japanese coast in the Pacific (after Frisch et al., 2011).

of continental crust carried with the subducted material experience high-pressure metamorphism. Basalts and sediments contribute significantly to the dewatering in a subduction zone. Water released in the subduction zone causes intense changes in the mantle above and, from a certain depth, interacts with hot asthenospheric material and triggers melting processes which are responsible for magmatism above the subduction zone (Figure 3). The rising magmas cause increasing temperatures in the magmatic belt above a subduction zone, where Abukuma-type metamorphism occurs.

Abukuma-type metamorphism

The magmatic zones of island arcs and active continental margins are characterized by high geothermal gradients generated by the rising magmas. Whereas the temperature increases downward in the subduction zone and in the forearc area by less than 10 °C per kilometer, the geothermal gradient in the upper crust at the magmatic front jumps to 35–50 °C/km. Consequently, rocks of the crust below the volcanic belt experience completely different metamorphism than rocks in the subduction zone.

Metamorphism in the magmatic zone is characterized as low pressure/high temperature. This temperature-dominated metamorphism is named Abukuma-type metamorphism after the Abukuma Plateau in Japan (Figures 1 and 2) and produces characteristic mineral assemblages. Because of the high temperatures, the rocks are easily deformed. Due to the high geothermal gradient, the temperature increases to generate the highest grades of metamorphism, 650–900 °C, present at crustal depths. Rocks experience partial melting (anatexis) under these conditions, when water is present. Dry magmatic rocks and sedimentary rocks, which have already expelled their water, are not melted under these conditions; instead, granulites develop in the deep continental crust.

Abukuma-type metamorphism occurs below 7–10 km depth and reflects regional metamorphism. In contrast, intrusions that rise into shallow depths of only a few kilometers create a zone of contact along their margins, the metamorphic aureole. During this contact metamorphism (Figure 3), heat of the intrusive body reacts with the cold country rock and mobilizes aqueous fluids that trigger numerous mineral changes.
Paired Metamorphic Belts, Figure 2 Pressure-temperature (P-T) diagram showing different types of metamorphism and metamorphic facies. High-pressure metamorphism is typical for subduction zones, and Barrovian-type regional metamorphism typifies continent-continent collisions. Abukuma-type regional metamorphism and contact metamorphism occur in the magmatic belts above subduction zones (after Frisch et al., 2011).
Paired Metamorphic Belts, Figure 3 Cross section through an active continental margin showing the location of subduction and Abukuma-type metamorphism. *Dashed lines* are isograds; numbers indicate temperatures in °C (Schubert et al., 1975).

PALEOCEANOGRAPHIC PROXIES

Gerold Wefer
MARUM-Center for Marine Environmental Sciences, University of Bremen, Bremen, Germany

Definition

Proxies stand in for direct measurements of past environmental conditions such as temperature, salinity, etc.

Introduction

Measured climate information such as temperature is only available back to the late nineteenth century. To extend the record further back in history, proxies have to be used. Proxies are physical and chemical parameters that can be transformed through a calibration process to real measured variables such as temperature. From the ratios of stable oxygen isotopes in the carbonate shells of marine organisms, e.g., past temperatures can be reconstructed if the isotopic composition of the seawater is known. The information is stored in sediments of the shelf areas, continental margins and abyssal plains, and in the skeletons of tropical or cold-water corals. Environmental information can be obtained from the quantity and composition of organic matter, carbonate, and opal shells and from the species compositions of plants and animals. An overview of the use of proxies in paleoceanography is given by Fischer and Wefer (1999).

New results on proxy research are presented at many conferences, particularly at the triennial International Conference on Paleoceanography (ICP). The 11th ICP took place in Barcelona (Spain) in 2013; the next will be held in Utrecht (Netherlands) in 2016.

What is a proxy

The definition of a proxy, according to Wefer et al. (1999):

Proxy, as used here and elsewhere, is short for proxy variable. The word "proxy" is commonly used to describe a stand-in, as in "proxy vote" or "fighting by proxy." By analogy, "proxy variables" in the parlance of paleoenvironmental reconstruction are measurable descriptors which stand in for desired (but unobservable) variables such as temperature, salinity, nutrient content, oxygen content, carbon dioxide concentration, wind speed, and productivity. These are the *target parameters*. The concept of a proxy, then, presumes the existence (in principle) of a target, that is, the proxied parameter of the system being reconstructed. Consequently, each proxy is associated with a rule or rules denoting how the transform from proxy to target is to be accomplished. Usually, this means that a transforming algorithm has to be established by calibration.

Source of proxies

Proxies are preserved in different types of sediments and corals. Depending on productivity and sediment transport by rivers and the atmosphere, the temporal resolution can vary from millennia in offshore and low-productive areas to centuries or decades on continental margins or in coastal areas. In oxygen-depleted areas, sediments can be deposited in annual layers, varves, caused by seasonal sedimentation patterns. Varves are only common in oxygen-free areas due to the lack of bioturbation, e.g., are formed in high-production areas or in anoxic basins on the continental slope. A particularly high temporal resolution is provided by skeletons of tropical corals, which even allow the reconstruction of annual cycles. Paleoclimate reconstructions are not restricted to the oceans. Often, they also include land-based phenomena such as tree rings, which permit global temperature reconstructions over the past 1500 years (Mann et al., 2009). Important information is also provided by loess deposits, especially in China (Guo et al., 2002).

What can be reconstructed?

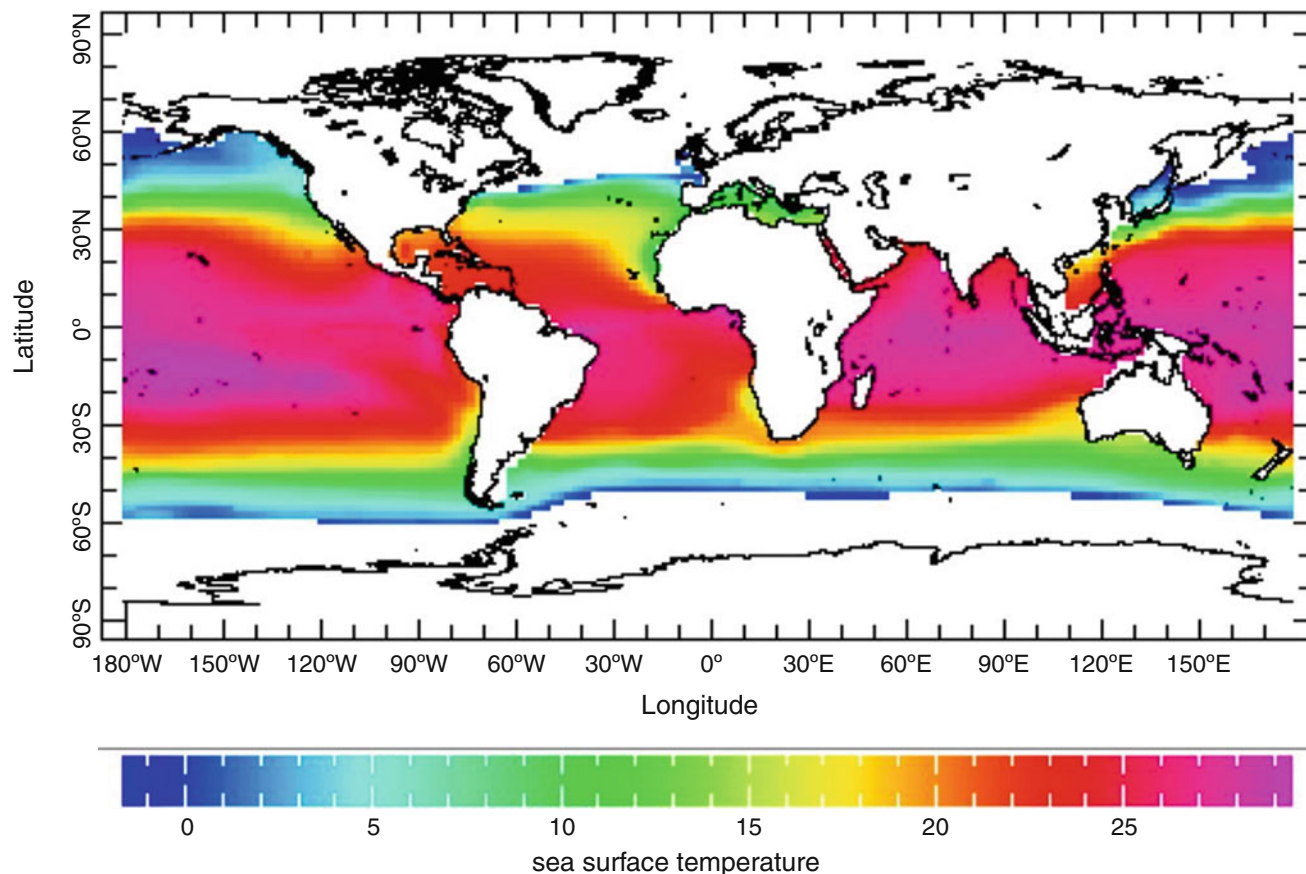
Temperatures

Most often, temperature is reconstructed, because it is an important parameter and because temperatures can be determined quite easily in comparison to salinity or productivity and with relatively high accuracy. A few decades ago transfer functions were developed (Imbrie and Kipp, 1971). Planktonic foraminiferal communities were employed to calculate a temperature or temperature range (Figure 1). This method was the basis for the reconstruction of sea-surface temperatures during the Last Glacial Maximum (CLIMAP, Climate: Long range Investigation, Mapping, and Prediction, CLIMAP, 1981) (Figure 2).

Another proxy applies the ratios of stable oxygen isotopes ^{16}O and ^{18}O incorporated in the calcite shells, which are temperature dependent. If the isotopic composition of the surrounding water is known, it is possible to determine temperature or changes in temperature because the absolute temperatures are distorted by vital effects. In general, the oxygen-isotope ratios are used for stratigraphy, and other proxies, such as Mg/Ca ratios or alkenones, are used for temperatures.
Paleoceanographic Proxies, Figure 1 Scatter diagram showing measured winter sea-surface temperatures versus those estimated from faunal assemblages in core-top samples using factor analysis and transfer function methods (From Imbrie and Kipp 1971).

Mg/Ca ratios in benthic and planktonic foraminifera and corals are frequently used for temperature reconstructions. At higher temperatures the amount of Mg replacing Ca in calcareous skeletons is greater. A number of equations have been specially developed for individual foraminiferal or coral species. Several effects must be considered in this method including impurities, vital effects, partial solution, or postmortem mineral formation.

Another proxy for temperatures employs Sr/Ca ratios. Corals incorporate Sr in a complicated way in their aragonite skeletons, but in relation to water temperature (Cohen et al., 2002). If the skeletons are well preserved, temperatures can be reconstructed with high temporal resolution, even up to seasonal cycles. One example is the reconstruction of tropical Atlantic temperature seasonality at the end of the last interglacial, about 117 kyr ago (Felis et al., 2015).

For temperature reconstructions, lipid biomarkers such as alkenones (UK_{37}) or isoprenoid glycerol dialkyl glycerol tetraethers (GDGTs or TEX_{86}) are also frequently used. Alkenones are long-chain organic molecules, which are produced by coccolithophores in surface waters. These chains are formed depending on the ambient temperature, and different calibration curves are used. GDGTs are membrane lipids of marine planktonic Thaumarchaeota. Not only is it important to understand the calibration relationship between the contents of these lipids and temperatures but also how these lipids are transported to the deep


Paleoceanographic Proxies, Figure 2 Sea-surface temperatures during the Last Glacial Maximum (February) from Data Library CLIMAP LGM (http://iridl.ldeo.columbia.edu/SOURCES/.CLIMAP/.LGM/.feb/.sst/figviewer.html?map.url=X+Y+fig−+colors+coasts +lakes+−fig).

sea and how they can be changed, both on their way and at the seabed (see, e.g., Mollenhauer et al., 2015).

Salinity

Salinity is much more difficult to determine than temperatures. One possibility is to use stable oxygen isotopes, when temperatures are determined by other methods, e.g., Mg/Ca ratios or alkenones.

Productivity

In the reconstruction of productivity, it is necessary to distinguish between flux proxies (export of biogenic material formed in the surface water) and nutrient proxies (containing information on nutrients such as phosphate and nitrogen).

General information on the productivity of surface waters is provided by the accumulation of organic carbon. However, this information is qualitative, since the settling of organic matter to the seafloor does not exactly correspond to primary production. The fraction of the primary production depends on the production system or on the water depth. Also, laterally introduced organic matter influences the results. Another method was developed by

Herguera and Berger (1994). They used the abundance of benthic foraminifera in the sediment as a measure of productivity, because their frequency is related to the food supply, the amount of organic matter deposited on the seafloor.

The ratios of stable carbon and nitrogen isotopes are nutrient proxies, expressed as deviations from a standard $\delta^{13}C$ or $\delta^{15}N$. A measure for fertility is the difference in $\delta^{13}C$ between foraminifera living in different areas in the ocean, e.g., shallow-living versus deep-living planktonic foraminifera or planktonic versus benthic foraminifera. Reconstructions depend on a variety of background information, e.g., on exchange with the atmosphere or calcification depth of planktonic foraminifera, or whether benthic foraminifera live on the surface or in the sediment.

Nitrogen isotopes, the ratio of $^{14}N/^{15}N$, are another tool. During the uptake of nitrogen by phytoplankton, isotope fractionation takes place with a preferential uptake of ^{14}N, so ^{15}N becomes enriched in the seawater. The organic matter that is exported from the photic zone is enriched in ^{14}N, which will subsequently be set free in the deep ocean or on the seafloor by oxidation of the organic matter. For a review of the marine nitrogen cycle, see Altabet (2006).

Circulation of the ocean

Several proxies are available to decipher the history of ocean circulation. The ratio of the stable carbon isotopes ($^{12}C/^{13}C$) in benthic foraminifera is a measure of the age of the bottom water. During descent of oxygenated surface water to the deep sea, organic matter enriched with the stable isotope ^{12}C is degraded. Through this process, water in the deep ocean becomes more enriched in ^{12}C, which is recorded in the shells of benthic foraminifera. The more organic matter that was decomposed using oxygen, the more ^{12}C is present in the shells, and the isotopic ratio is lighter. A similar mechanism operates for the cadmium/calcium isotope ratios. The Cd/Ca isotope ratios and the phosphate content of the water show a linear relationship. With the decomposition of organic matter, cadmium and phosphate are released, and therefore, the Cd/Ca ratios in the shells of benthic foraminifera provide information on the phosphate content, which is related to the age of the bottom water and ventilation of the ocean in the past.

A relatively new proxy is the isotopic ratio of protactinium ^{231}Pa to thorium ^{230}Th. Both isotopes are formed by the radioactive decay of uranium dissolved in the water column, and ^{231}Pa has a longer residence time in the water column due to its greater half-life. Changes in the $^{231}Pa/^{230}Th$ ratio are related to the intensity of the thermohaline circulation. Another proxy is the ratio of the neodymium isotopes ^{143}Nd and ^{144}Nd. This ratio characterizes specific bodies of water. The neodymium isotopes are incorporated into manganese crusts and nodules, and, because of the low growth rates of the nodules, the temporal resolution is low, but the records can go far back into the Earth's history. There are also a number of sedimentological proxies, e.g., the proportion of sortable silt (10–63 μ) of deep-sea sediments, which provides information about bottom currents.

Not only currents or water masses are reconstructed; diatoms and biomarkers also allow the reconstruction of past sea-ice boundaries (Gersonde et al., 2014). Promising new biomarkers include sea-ice diatom-specific highly branched isoprenoids with 25 carbon isotopes. A review is given by Stein et al. (2012) describing efficient kinds of proxies that can be used to reconstruct sea-ice cover and temperatures in polar environments.

Sea-level

One specific issue is the past sea-level stand in relation to climate. There are many regional sea-level reconstructions that need to be related to the eustatic sea-level. The problem is the dynamics of ice sheets. During the melting of ice shelves and the associated rise of the land, the ice body is stabilized. For the correction of sea-level reconstructions, it is important to know where the ice was deposited or melted. For an example of a sea-level reconstruction that takes into account the melting of the Greenland Ice Sheet and West Antarctic Ice Sheet, see Raymo and Mitrovica (2012). While for the present sea-level rise of between 1.5 and 2 mm/year thermal expansion plays a major role, ice dynamics are dominant over longer periods.

CO_2 content of the atmosphere

Boron isotope ratios ($^{11}B/^{10}B$) can be used to reconstruct the past CO_2 content of the atmosphere. The boron isotope ratio depends on the acidity, pH, and alkalinity of the water, which are determined by the CO_2 concentration of the atmosphere and the concentration of bicarbonate ions in the ocean. The boron isotope ratios are incorporated into the shells of planktonic foraminifera and are a proxy for CO_2 levels during earlier times. The theory is understood (e.g., Hönisch and Hemming, 2004), but the measurements are complicated, and hence the data contain large uncertainties.

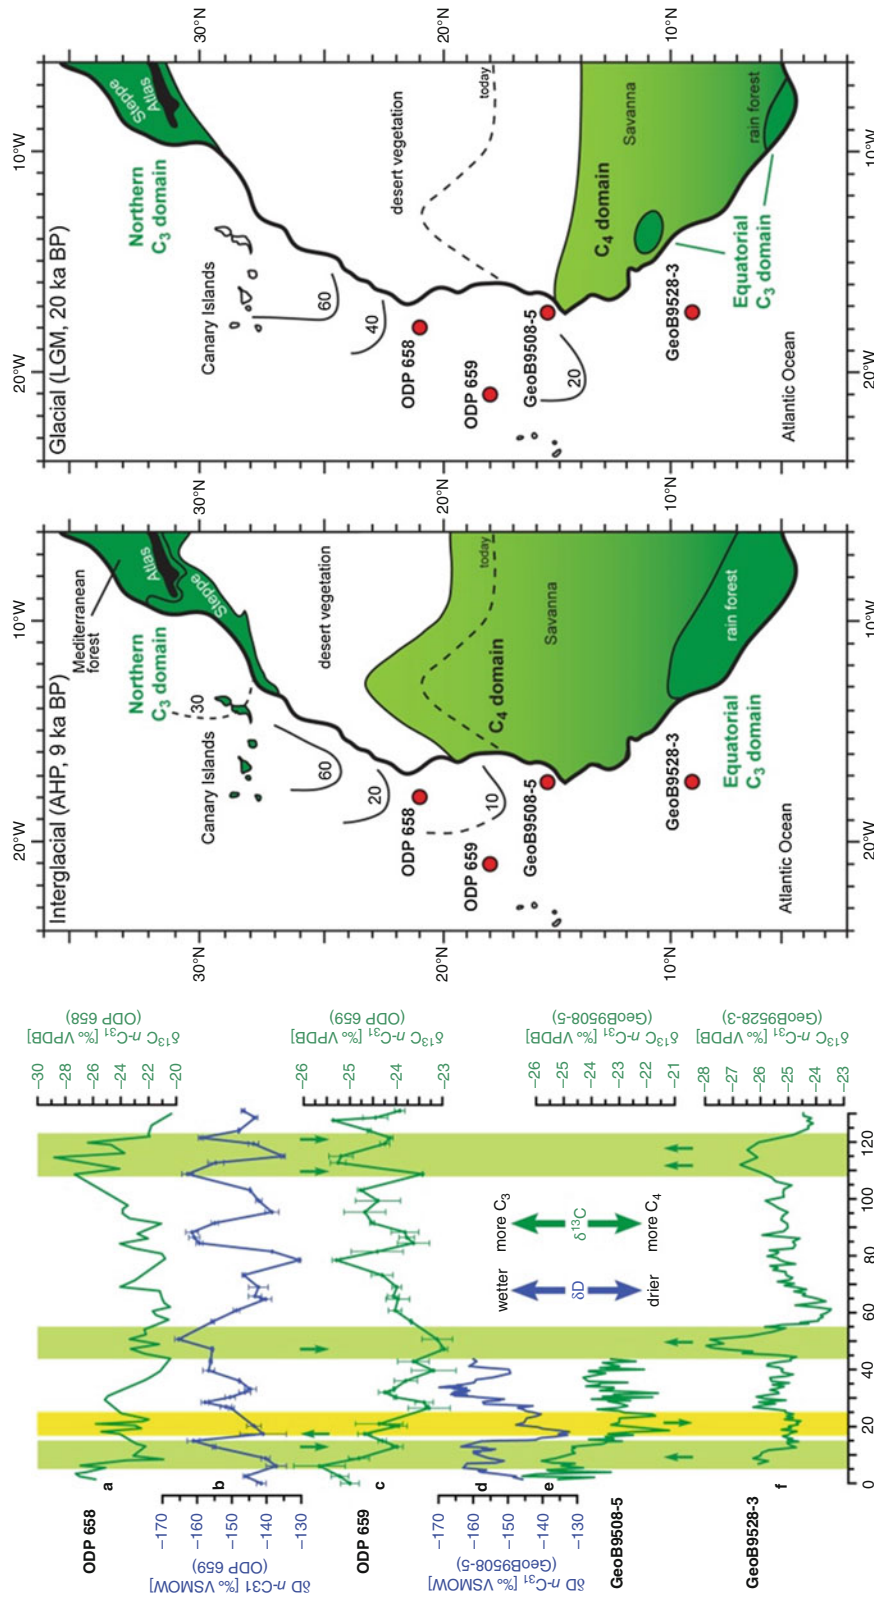
What role the ocean plays in the CO_2 content of the atmosphere depends on the physical and biological pumps. An important location for studying the effectiveness of the biological pump is the Southern Ocean, as there are unused nutrients available. Therefore, many investigations of the effectiveness of the biological pump during past times are carried out with respect to the position of fronts, sea ice, and dust flux (e.g., Ziegler et al., 2013).

Land vegetation and rainfall

The pollen of land plants is very resistant to degradation. It is transported by rivers or through the atmosphere into the ocean, settles to the seafloor, and is embedded in the sediment. With pollen communities, the history of vegetation and precipitation patterns of land masses can be reconstructed when the transport routes are known. Recently, pollen distributions have been combined with organic proxies to reconstruct vegetation history and precipitation patterns using the signatures of plant-wax-specific hydrogen (δD) and carbon isotopes (δ^{13}C) (Kuechler et al., 2013) (Figure 3).

Stratigraphy

A prerequisite for climate reconstructions is a sound chronological classification of the sedimentary record. Depending on the time period, different methods are available. Approximately the last 60,000 years can be dated with the radioactive isotope ^{14}C, which has a half-life of 5730 years. New possibilities of dating were created by the development of accelerator mass spectrometry (AMS) because significantly smaller sample sizes were sufficient for the measurements. In contrast to 14C, which has a relatively long half-life of 5730 years and thus does not allow high temporal resolution, 210Pb produced in the atmosphere and deposited in sediments over the past 100–150 years can be dated. This dating method is used in marine and lacustrine sediments, peat and ice deposits.

Since the ^{14}C content of the atmosphere is subject to fluctuations caused by the cycles of sunspots and fluctuations of the Earth's magnetic field, calibration curves are needed based on dendrochronology and other


Paleoceanographic Proxies, Figure 3 Distribution of C3 and C4 plants in North Africa during the interglacial (African Humid period, AHP, ca. 9 ky BP) and glacial (Last Glacial Maximum, LGM, ca. 20 ky) (from Kuechler et al., 2013).

LRO4 Benthic Stack
Paleoceanographic Proxies, Figure 4 LR04 stack of Lisiecki and Raymo (2005), using 57 published benthic $\delta^{18}O$ records and orbital tuning to develop an age model for the last 5.3 my.

information. The knowledge of the age of the water at the time of the incorporation of ^{14}C into the carbonate shells of planktonic and benthic organisms is important (reservoir effect). In the analysis of organic matter, a possible admixture of older material (without ^{14}C) must be considered. When dating young sediments, the influence of industrialization and the atomic bomb effect has to be taken into account. The combustion of fossil fuels releases ^{14}C-free carbon into the atmosphere (Suess effect), and with the atomic bomb tests (1945–1993), additional ^{14}C was released.

For older deposits, different methods of stratigraphy are used, e.g., biostratigraphy. The first appearances and extinctions of fossils provide time markers. Also widely used is magnetostratigraphy, which can divide the younger geological history on the basis of magnetic field reversals.

The backbone of paleoceanography is oxygen-isotope stratigraphy. The ratio of the stable oxygen isotopes ^{16}O and ^{18}O, which is incorporated into the calcite shells, depends on the isotope ratio of the water and the temperature, documenting climate development, and in particular the growth and dismantling of ice sheets. Since they are related to the Earth's orbital parameters, time intervals can be defined based on these cycles. A frequently used time scale based on $\delta^{18}O$ values of benthic foraminifera was published by Lisiecki und Raymo (2005) (Figure 4). Lisiecki und Raymo used 57 globally distributed records, recording global ice volume and deep-sea temperatures. Orbital tuning was used to establish a time frame of 5.3 my (LR04 stack).

Conclusions

The development of proxies is an ongoing process and always closely linked to the reconstruction of past environmental conditions. In recent decades, great progress has been made in the accuracy of the reconstructions, for instance in reconstructing temperatures with multiple proxies. A great potential lies in the field of biomarkers. They offer, for example, information about the CO_2

system of the ocean and precipitation patterns on the continent.

The further you go back in Earth's history, the less accurate are the reconstructions. Often, however, it is not the proxy, but the time frame of the deposits. Through the use of orbital forcing during the Neogene, supported by a biostratigraphic framework, the chronological time frame has improved substantially (e.g., Röhl et al., 2000). The use of nondestructive measurements of sediment characteristics such as sediment color or magnetic susceptibility has been very beneficial for the production of high-resolution records.

Definition

Paleoceanography is the science of the history of the world ocean and its subbasins, of their physiography, benthic and planktonic biota, water masses and their properties, circulation patterns of surface, intermediate, and bottom water masses. Quantitative paleoceanography can in essence only be done from pelagic and hemipelagic sediments of the Mesozoic and Cenozoic ocean, basically from the age of the oldest undisturbed ocean crust to modern times. It is closely linked to the time of collecting ocean-wide geophysical data (marine seismics, magnetics), of deep-sea drilling and our increasing ability to collect long sediment cores, providing a global coverage and long, undisturbed time series of paleoceanographic data. It is henceforth a young subdiscipline of the marine geosciences.

Paleoceanography from infancy to maturity

When Schopf (1980, see also Kennett, 1982) wrote the first textbook about "paleoceanography," important steps toward development of this new subdiscipline of marine geosciences had already been taken, and the term had been introduced in earlier publications (Van Andel et al., 1975). During the late 1950s and early 1960s one had learned the techniques to take long and undisturbed sediment cores and to drill through/sample ocean sediment sequences, to date these with great precision, to interpret their contents of microfossils and their chemical (isotopic) composition (Emiliani, 1992) for establishing the properties of past ocean surface and bottom water masses. However, with his devotion to time spans older than Mesozoic Schopf (1980) missed one important aspect of modern paleoceanography, namely its importance of climatic and paleoclimatic modeling efforts for our attempts to deduce possible future climate scenarios from past analogies.

Now, some 40 years later, "Paleoceanography" has developed into a mature discipline of the marine geosciences, which is pursued at many universities and research institutions with great sophistication, as can be demonstrated by many entries in this Springer Encyclopedia as well as in Gornitz (2009). The examples selected for this entry concern the Late Mesozoic and Cenozoic Oceans whose physiographic evolution can be deduced from the through-time-increasing areas of undisturbed and undestroyed ocean crust (cf. Müller, this volume). The salinity of the marine water masses also demonstrates that we are dealing with a compartment of the environment, like the atmosphere of truly global dimensions (and contrary to terrestrial, limnic, or ice core data which record regional or local phenomena). After decades of sediment coring and drilling in most of the ocean basins, the modern development of powerful research ice breakers capable to enter the central ice-covered Arctic Ocean (Fütterer and Shipboard Scientific Party, 1992; Moran et al., 2006) has opened up the last virtually unexplored deep-sea basin for paleoceanography. Here an ecclectic

and subjecive overview of some of the *most important discoveries* of the past decades will be presented.

Paleophysiography: When Alfred Wegener hypothesized about the "origin of continents and ocean" between 1912 and 1929 he had to do so without sufficient information about the nature of the ocean floor; despite this deficiency he succeeded to interpret correctly many of the paleogeographic changes of the distribution of land and sea through time. In modern times (cf. Müller et al., this volume) the information deduced from the age distribution of sea-floor spreading magnetic anomalies and of our understanding of the subsidence of ocean crust after its formation due to its thermal history (Sclater et al., this volume) allows us to draw a detailed picture of the paleophysiography of the location, shape including depths, size, and volume of the ocean basins and their evolution through time, at least since mid-Mesozoic times (cf. Müller et al., this volume). Basically it is the evolution of planet Earth from a geography with one large continental land mass versus one contiguous ocean basin at the end of the Paleozoic to the modern one with numerous "small" continents and an ocean basin fragmented into many subbasins.

Plate tectonics and climate: The major changes of the physiography of ocean basins, in particular tectonically driven changes of the seaways between ocean basins, were clear since Wegener's (1912–2005) publications. A modern example is described in Haug and Tiedemann (1998), who reasoned that the closure of the Isthmus of Panama led to environmental changes resulting in the deteriorating livelihood of the late Holocene Central American populations. However, more recently, a much closer (and hitherto) poorly understood correlation between volcanic/tectonic processes at the mid-ocean ridges and the evolution of climate seems to emerge. Van der Meer et al., 2014 have determined plate tectonic controls on atmospheric carbon dioxide levels in the atmosphere since the Triassic and speculate about an intricate interrelationship between subduction rates and carbon dioxide levels in the atmosphere, controlled by processes over time scales of 10 to 100 million years. However, recent comparisons of volcanic activity on Iceland and the observations of the similarity of the fine grain of the morphology of volcanic structures of the mid-ocean ridge regions with Late Cenozoic climate variability seem to suggest that plate tectonic and climate variability are much more closely linked and over much shorter time scales than presumed hitherto.

Plate stratigraphy: The mode of the general subsidence of the ocean floor and the mechanisms of pelagic sediment formation generate a characteristic stratigraphic pattern of sediments on top of the ocean crust, as demonstrated in many cores of the various deep-sea drilling projects (cf. Suyehiro, this volume, and discussed by Kennett, 1982 and Van Andel et al., 1975). The global patterns of pelagic sediment formation (cf. Lyle, this volume) and in particular the water depth-dependent aragonite and calcite differential dissolution as well as the existence of the calcite lysocline and Calcite Compensation Depth (CCD, cf. Berger, this volume) result in the preservation of the ubiquitous calcareous deep-sea deposits only in well-defined regions and depth intervals (Van Andel et al., 1977; Ehrmann and Thiede, 1985). Young ocean crust lies usually above the CCD giving place to the formation of calcareous oozes if not biogenic siliceous oozes are formed under highly productive ocean surface waters. In high latitudes the input of terrigeneous fines dominates ocean sediment formation. Old ocean crust which had sunk below the CCD in temperate to tropical regions is mostly covered by red deep-sea clays.

Marine microfossils and their environmental record: Marine microfossils have been producing the first proxies for paleoceanographic and paleoclimatic records deduced from ocean sediment cores. This was first realized by Schott (1935, in Correns and Schott, 1935/37), who mapped out planktonic foraminiferal distributions in sediment cores from the South Atlantic and who was able to argue that these cores covered the transition from the last glacial to the much warmer Holocene. In the meantime it has been recognized that all planktonic microfossils reveal distribution patterns according to temperature zonations in the ocean and that they are superb indicators which can be exploited by using modern analog techniques (Hale and Pflaumann, 1999), a technique which has been developed by Imbrie and Kipp (1971) during the early stages of the CLIMAP project (Cline and Hays, 1976). In the meantime this method has been applied to many other examples, cf. Pflaumann et al. (2003).

Paleotemperature, paleosalinity, ice in the ocean: When reconstructing the hydrography of former oceans, one needs to quantify its basic hydrographic properties. This is relatively easy but sometimes ambiguous (Stärz et al., 2012) for ice in the oceans, because it leaves traces in the distribution of ice-rafted sediment components and of biotic remains of organisms (diatoms) adapted to the life in and under the sea ice (Thiede et al., 2011; Stickley et al., 2009). The relatively recent drilling on Lomosow Ridge close to the North Pole (Moran et al., 2006) suggests that the central Arctic Ocean at least was seasonally sea-ice covered in the middle Eocene, milions of years before the assumed initial glaciation of the northern hemisphere. Paleotemperatures and –salinities can be quantitatively established by a wide variety of biotic and geochemical methods as summarized by Fischer and Wefer, 1999.

Fractionation of Oxygen isotopes in relation to global ice volume: When Emiliani studied the O-Isotpe ratios in forminiferal shells from Upper Quaternary deep sea sediments (Emiliani, 1955), he considered the O-isotopic variations to be mainly due to temperature changes between Glacials and Interglacials. However, even though benthic foraminifers showed similar variations with a clear offset, it would not have been possible to invoke the same temperature variations as their cause. And it was Shackleton (1987) who linked the O-isotope fractionation observed in the foraminiferal records to the late Quaternary climate variability (ice volume, sea-level) assuming that the major

effects of the isotope fractionation were mainly caused by the evaporation of large quantities of water from the ocean to be bound in the glacial ice sheets during Glacials, both on the northern and the southern hemisphere, respectively released during Interglacials.

Paleoceanographic proxies (or proxy variables): There are numerous proxies which have been developed over the past decades which allow describing paleoceanographic properties of past oceans (Fischer and Wefer, 1999). Beside biotic proxies such as pelagic microfossils there are numerous geochemical and oganochemical tools to address variations of the surface water and bottom properties and circulation (including temperature and salinity) and water mass stratification. Biogenic Barium can be used to describe paleoproductivity and nutrient distributions. A variety of radiogenic isotopes can be used as tracers for bioproductivity and particle fluxes in the oceans. The carbon isotope ratios of alkenones help to assess past carbon dioxide distributions (Paleoceanographic Proxies).

Grain size and current strength: McCave et al. (1995) used sophisticated grain size analyses of relatively fine-grained terrigenous sediments, in their attempts to reconstruct the vigor of bottom water currents in the North Atlantic during the transition from the Last Glacial Maximum (LGM) to the Holocene. They used well-dated sediment cores from the Rockall area and were able to prove the stratification and strength of the bottom currents during a time of an intense reorganization of the North Atlantic current systems. This is but one example of numerous in the world ocean. Similar attempts have been made to describe the flow of the Antarctic Bottom Water in the Southern Ocean.

Global Conveyor Belt: Ocean surface waters are warm in the tropics but cold close to the poles. But it was known since the Russian explorer Krusenstern's circumglobal expedition almost 200 years ago that the deep oceans were cold all over. With the first systematic hydrographic investigations such as carried out during the German "Meteor" expedition to the South Atlantic Ocean (Wüst, 1936) it was recognized that cold waters which had gotten their most important hydrologic properties in the polar regions filled many deep-sea basins. They were dense enough to sink as part of the thermohaline circulation into the oceanic deep-sea basins where their flow was controlled by the morphology of the gateways. Minor differences in their densities controlled the mode of their layering in the Atlantic Ocean with water of Arctic in many areas below those of Antarctic origin. Broecker (1991), after having determined by means of radiocarbon dating and thus the last time when these waters were able to exchange carbon dioxide with the atmosphere, established the young "ages" of bottom waters in the deep Atlantic Ocean, contrasting the old ones in the deep North Pacific Ocean. Based on this pattern and combining it with the large-scale circulation system of ocean surface waters he coined the term "great ocean conveyor belt." How this ocean circulation system has been changing going back in time has been subject of controversial debates ever since, because there is no question that ocean deep-water masses were much warmer during the earliest than during the late Cenozoic (Zachos et al., 1993).

Atmospheric circulation: The atmospheric circulation and its past variations leave many traces in deep-sea sediments. Dust plumes originating from desert systems like the Sahara in North Africa are exported across the African coast. They document through increased accumulation rates (Thiede et al., 1982) and grain sizes (Sarnthein and Koopmann, 1980) during glacial intervals an intensification of the glacial atmospheric circulation. Similar messages can be deduced from the dust records in ice cores (Svensson et al., 2000) or South Pacific dust records (Thiede, 1979). It can be concluded that the glacial atmospheric circulation not only changed its patterns but also increased in intensity due to the steeper temperature gradients between low and high latitudes. Conclusions about former atmospheric circulation patterns can also be reached by looking at the distributions of pollen, spores, and other biotic remains of terrestrial origin preserved in deep-sea sediments as well as the distribution of organic matter of terrestrial origin (Fischer and Wefer, 1999).

Time slices versus time series: The progress in dating techniques of pelagic sediments was a prerequisite for establishing reconstructions of the paleoceanographic properties of certain regions both in terms of a well-defined time slice as well as time series. One of the best examples for the former is the reconstruction of the surface properties of planet Earth during the Last Glacial Maximum produced by CLIMAP (CLIMAP Project Members, 1976). The first time series which allowed proving Milankovitch frequency controlled time series from the ocean was published by Hays et al. (1976), but since then numerous time series of paleoceanographic data sets have been documented in the results of the deep-sea drilling projects.

Milankovitch Frequencies: When Köppen and Wegener (1924) published their monograph "The Climate of the Geological Past," the time scales of the late Cenozoic alterations between Glacials and Interglacials were only vaguely known. However, they had established a close cooperation with Milutin Milankovitch. They were convinced that the geometry of the Earth´s orbit around the sun with its regular changes of eccentricity, obliquity, and precession are controlling the insolation (amount of incoming solar radiation) and hence are important climate boundary conditions. Milankovitch published (Milankovitch, 1941) the detailed data of the Milankovitch frequencies only decades later. But it was one of the major successes of the CLIMAP project (Hays et al., 1976) that it found two sediment cores from the southernmost Indian Ocean which could be dated precisely enough and which reflected the paleoceanographic responses to the Late Quaternary glacial-interglacial changes. Thus Köppen and Wegener`s (1924) claim could be substantiated by well-dated time series derived from the very best global climate archive. In the meantime the

Milankovitch frequencies have been documented also in numerous other historic records, such as those derived from ice cores in Antarctica and long lake sediment cores. Milankovitch frequencies can be extrapolated into the future, which raised the possibility of the predictability of future climate change (Thiede and Tiedemann, 1998). The paper of Berger (2012) represents a modern perspective of the Milankovitch frequencies (cf. also Berger, this volume).

Climate Modeling: Paleoceanograhic studies provide indispensable data for paleoceanographic and paleoclimatological modeling (cf. Sündermann, this volume), both as boundary conditions to run the models as well as for their validation. The first true global data set which could be used as input parameters for modeling glacial climates (Herterich et al., 1999) has been produced by CLIMAP (Climate: Long-range Investigation and Prediction), a large paleoclimatic research project in the USA (CLIMAP Project Members, 1976). Since that time available models (GCMs) developed by various institutions (NCAR, Boulder/US; MPI Meterology in Hamburg; Hadley Center – Met Office/UK, to name a few) have all delivered their own modeling approaches aiming to model various compartments of the global environment (e.g., like the ECHAM model series in Hamburg). For a more detailed discussion see Paleoclimte Modelling Intercomparison Project (http://pmip.lsce.ipsl.fr/). Many of these efforts of generating past oceanographic and climatic scenarios are trying to understand through the reconstruction of the past, how the future oceans might behave, e.g., with a seasonally ice-free Arctic Ocean which would affect the entire northern hemisphere.

Summary

Paleoceanography is fed by data sets from the only truly global climate archive, namely ocean sediments. It has developed from modest beginnings during the early 1960s (prior to the onset of deep-sea drilling) to a highly sophisticated discipline of the marine geosciences. And it provides quantitative reconstructions of former global climates as boundary conditions for modeling climates with no modern analogue.

PALEOMAGNETISM AND JURASSIC PALEOGEOGRAPHY

María Paula Iglesia Llanos
IGEBA, National Scientific and Research Council,
University of Buenos Aires, Buenos Aires, Argentina

Introduction

From the Late Carboniferous until the Middle Jurassic, continents were assembled in a quasi-rigid supercontinent called Pangaea, which occupied most of a hemisphere, while the rest of the Earth's was part of a large ocean called Panthalassa. For decades, authors interpreted that South America remained stationary in similar present-day latitudes during most of the Mesozoic and the end of the Paleozoic, because paleomagnetic poles (PP) clustered close to the geographical pole (e.g., Valencio et al., 1983; Oviedo and Vilas, 1984; Beck, 1999). More recent data obtained in Patagonia, Argentina, show that Early Jurassic PP actually fall far away from the geographic pole (Iglesia Llanos et al., 2006).

Using these and other selected poles from South America, a substantially different and more refined Jurassic apparent polar wander (APW) path was constructed (Iglesia Llanos et al., 2006; Iglesia Llanos and Prezzi, 2013). APW paths depict the past positions of the Earth's spin axis (= averaged paleomagnetic pole) with respect to a certain lithospheric plate, hence the name "apparent" (Creer et al., 1954). The path is constructed as a sequence of paleomagnetic poles tracking away from the geographic pole with increasing age. Tracks represent rotations about Euler poles, whereas cusps symbolize times of reorganization of the lithospheric plate boundaries and resulting driving forces (Cox and Hart, 1986).

In this study, Jurassic APW paths of Eurasia, North America, and Africa were built and compared to those obtained in South America. PP were selected mostly from the Global Paleomagnetic Database v.4.6 2005 (http://www.tsrc.uwa.edu.au/data_bases) and from other recent studies. Such PP are considered to be representative of stable cratons (Torsvik et al., 2008; Kent and Irving, 2010).

APW paths from Eurasia, North America, and Africa were rotated to South American present-day coordinates, using classical paleoreconstructions available in the literature for Jurassic Pangaea. Among all kinematic models, those which provided the best clustering of paleopoles were taken into account for this study. Thus, Africa was rotated to South American coordinates using the paleoreconstructions proposed by Lawver and Scotese (1987). Eurasia was translated first to North America using the paleoreconstruction of Frei and Cox (1987), then to Africa, and subsequently to South America using Lawver and Scotese (1987). North America, on the other hand, was first moved to Africa with the paleoreconstruction of Klitgord and Schouten (1986) and then to South America using the parameters of Lawver and Scotese (1987). The resultant paths proved to be almost

identical in terms of shape and chronology. Subsequently, by averaging nonoverlapping poles with 5–10 Myr windows, a master path was derived for Pangaea that could be used in any continent in the Jurassic (Figure 1). The resultant curve shows, when observed from South America, a W-E track between 215 and 197 Ma (Late Triassic-Earliest Jurassic), followed by a SE-NW track between 197 and 185 Ma (Early Jurassic). The intersection of these two tracks defines a cusp at ∼197 Ma. After 185 Ma until 170 Ma, a smaller track and consecutive standstill that might have lasted until the Late Jurassic are observed. The 197–185 Ma (Early Jurassic) track reveals a c. 50° shift in the pole positions and a minimum angular change of poles of approximately 4° Myr^{-1}.

Discussion

There are a few phenomena that could have caused such shift in the pole positions: either the geomagnetic field was not dipolar at that time or some geodynamic event took place. With regard to the first, it is well accepted that the Earth's magnetic field behaved essentially as a geocentric dipole (e.g., McElhinny and Brock, 1975; Evans, 1976; Livermore et al., 1983, 1984). This means that the c. 40° polar shift in the APW path cannot be attributed to nondipole components. The cause of the polar shift is rather related to some kind of geodynamic event, such as lithospheric motion or true polar wander (TPW). In order to appraise lithospheric motion, the South American plate constitutes an illustrative case. Paleomagnetic data indicate that, during the Late Triassic and lowermost Jurassic, the continent rotated 50° CW (Figure 1). Had such rotation resulted from sole lithospheric motion, South America would have been forced to override the trench as well as the Pacific plate, thus causing major compression in the overriding plate. Yet, the formation of the Andes comprised two main deformation stages, the first (∼ 200 to 90 Ma) characterized by comprehensive extension in the overriding plate, during which major rift systems like in Peru, northern Chile (e.g., Cobbing et al., 1981; Åberg et al., 1984; Mpodozis and Allmendinger, 1993), and Argentina (e.g., Giambiagi et al., 2008) are formed. The last stage on the other hand occurred in the mid-Cretaceous and characterized a major compressional regime (Somoza and Zaffarana, 2008).

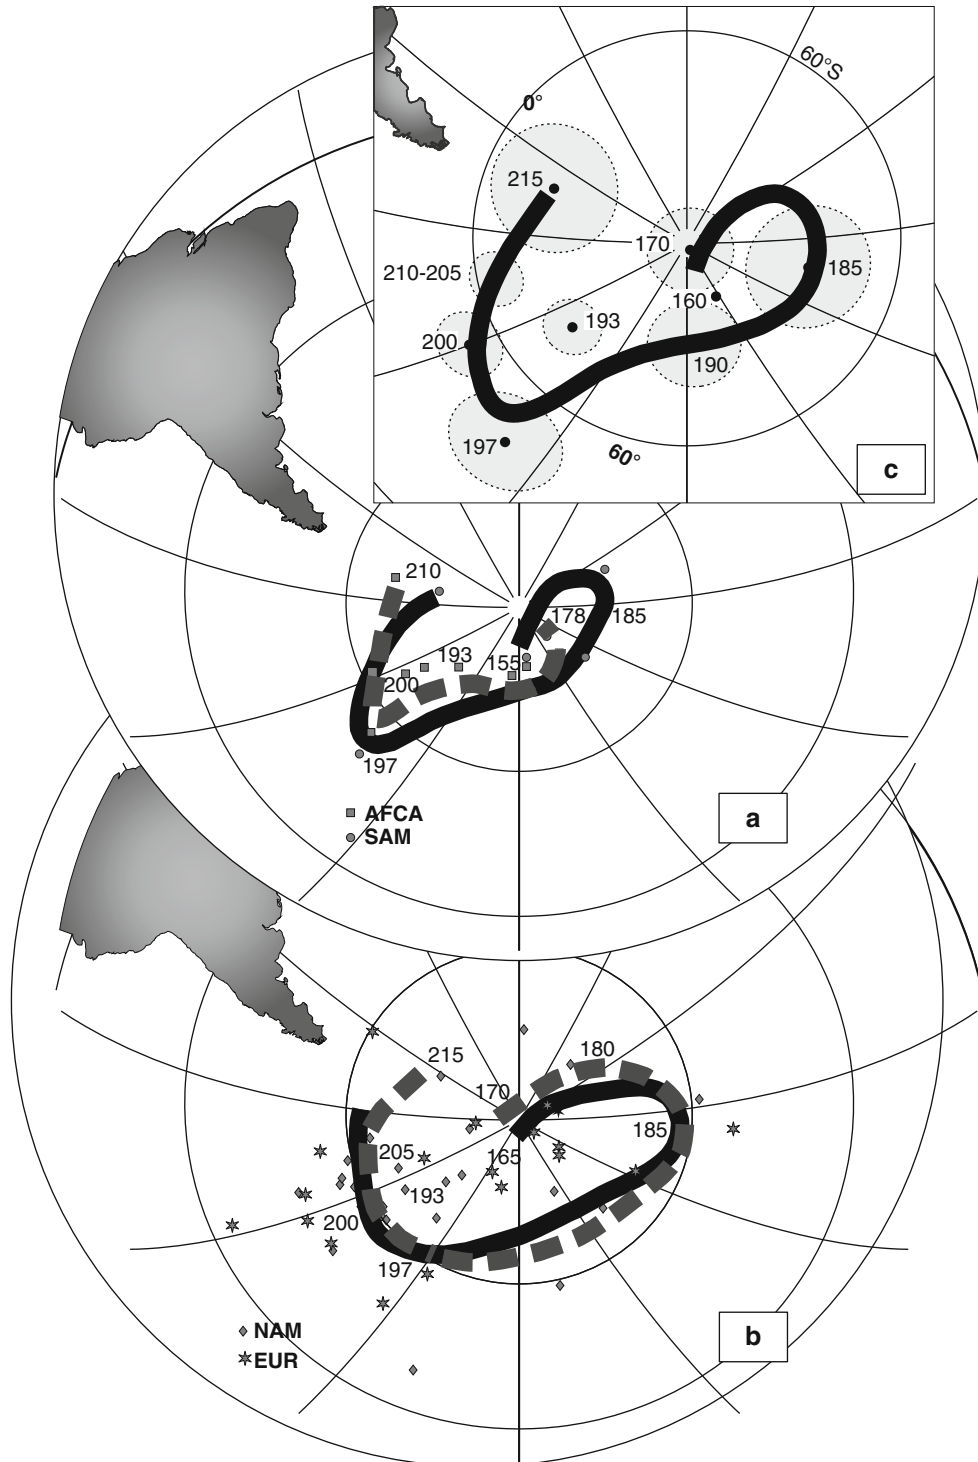
Therefore, the polar shift might have been resulted from the other geodynamical event which is TPW, defined as the drift of the spin axis in relation with the solid Earth over geological time. TPW is determined from hot spots, which are assumed to form an array of fixed points in the mantle-mantle reference frame. Defined as it is, TPW makes all continents and mantle plumes rotate around an Euler pole located at the Equator (Goldreich and Toomre, 1969; Jurdy and van der Voo, 1975). TPW is a global type of event; therefore, it should be recognizable in all APW paths from that time. The similarity in all four curves (Figure 1) is hence the first hint of TPW. Despite that fixity of hot spots is still hot matter of debate, many authors such as Besse and Courtillot (2002) use this uniquely available tool to determine TPW in the Jurassic.

To assess the occurrence of TPW, the most straightforward way is paleolatitudes plots. For this study, two South American localities were analyzed (Figure 2). To do this, continents were first rotated to South American present-day coordinates and rotated once again to position them with respect to the mantle using Morgan's (1983) grid of hot spots. Two sets of paleolatitudes were thus calculated for each locality, one derived from the master APW path and the other from the array of hot spots (Figure 2). Had no TPW existed, both paleolatitudinal sets should coincide. But data show a significant divergence of the curves after 200 Ma, which could be interpreted as caused by TPW. The curves show that whereas no evident latitudinal change occurred from the hotspots reference frame, the South American continent was actually moving northward. This is solid evidence of the occurrence of a clear TPW event in the Early Jurassic.

In addition, the TPW path constructed after removing plate motions in the APW path reveals that at ∼197 Ma, poles displaced approximately 45° over a 12-Myr period or a minimum angular change of 4° Myr^{-1} (0.4 Myr^{-1}). This magnitude is consistent with the values predicted by Prévot et al. (2000) of 1–5° Myr^{-1}, or the 3°–10° Myr^{-1} proposed by Sager and Koppers (2000) for the Pacific plate. Subsequently by the end of the Early Jurassic, the path turned back on itself.

Paleomagnetism can provide paleolatitudes and orientations of the continents, but because the time-averaged geomagnetic field is symmetric about the rotation axis, the paleomagnetic method alone cannot assess paleolongitudes. There are other methods to calculate paleolongitudes such as hot spots. Thus, if the motion of, e.g., South America, can be established in relation with the grid of hot spots, all other plates can be put together within this frame after applying the corresponding kinematic model. Therefore, by combining relative motions of the plates, their motions relative to the hot spots, and paleomagnetic data which indicate the ancient position of the geomagnetic pole (paleopole) for a specific locality and time, "absolute" paleoreconstructions can be achieved.

Paleogeographic reconstructions thus obtained reveal (Figure 3) that during the Late Triassic-Sinemurian (∼210 to 200 Ma), Pangaea would have been located at its southernmost position with continents rotated CCW with respect to present-day orientation. Subsequently, the supercontinent moved northward while rotated approximately 50° CW at higher speeds (c. 4° Myr^{-1}). By the Pliensbachian (∼185 Ma), the supercontinent achieved its northernmost latitudes. In the end of the Early Jurassic, Pangaea moved to the south again until the Middle Jurassic when it positioned similar present-day latitudes.

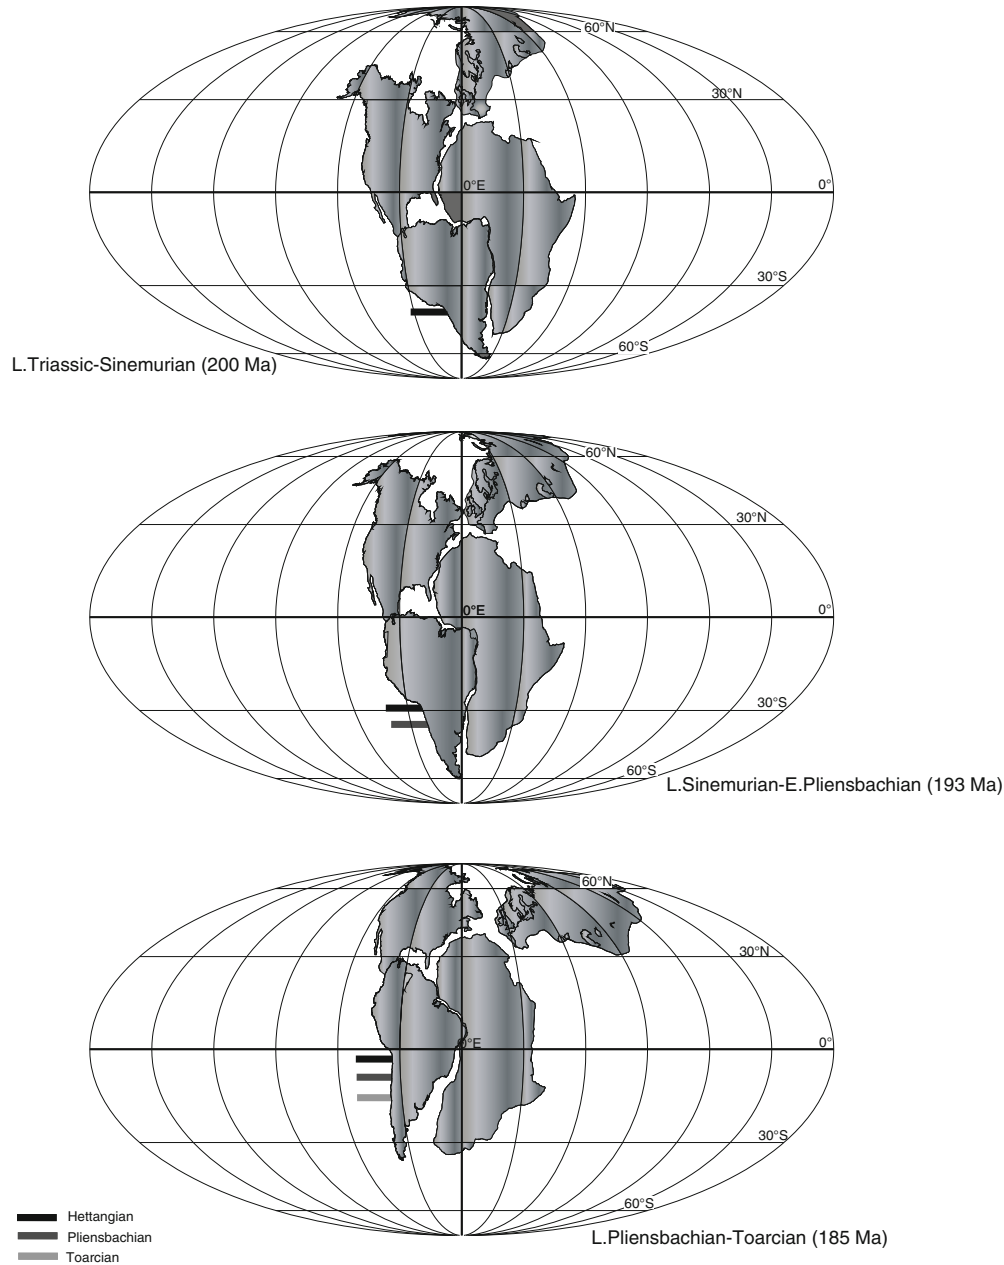
Since latitude affects climate, it is possible to correlate paleolatitudes derived from the paleomagnetic method with paleoclimatic data derived from fossils having a


Paleomagnetism and Jurassic Paleogeography, Figure 1 Jurassic APW paths with mean ages for (**a**) Africa and South America, (**b**) North America and Eurasia. Africa, North America, and Eurasia have been rotated to South American present-day coordinates (**c**) Master APW path for Pangaea with 95 % confidence interval.
Paleomagnetism and Jurassic Paleogeography, Figure 2 Paleolatitudes plot support the occurrence of TPW after 200 Ma. Two paleolatitude sets are shown for two South American localities, one from Brazil and the other from Argentina, the *first* representing paleolatitudes calculated from the master APW path paleomagnetic reference frame and the *second* set from Morgan's (1983) grid of HS (mantle reference frame). If no TPW occurred, both *curves* should be coincident.

geographic distribution limited to certain climatic regions. In this study, paleobiogeographic data were analyzed in order to confront paleolatitudes with paleoclimatic proxies (Iglesia Llanos and Prezzi, 2013).

When taking into account marine invertebrates, it is known that bivalves are very sensitive to water temperatures. In the Southern Hemisphere (Figure 3) during the Hettangian-Sinemurian (∼200 Ma), the boundary between the South Pacific high latitudes and Tethyan low latitudes realms was located in northern Chile (Damborenea, 2001, 2002). This coincides with the time that the supercontinent was located at its southernmost position (Iglesia Llanos and Prezzi, 2013). By the end of the Sinemurian and throughout the Early Jurassic, the same boundary shifted to the south until the Toarcian, high-latitude bivalves became restricted to southernmost South America. At this time, the continent was located far off to the north (Figure 3). The Pliensbachian marked the first expansion of colonial corals (warm water temperatures) in west-central Argentina. Meanwhile in the Northern Hemisphere, average water temperatures indicated a major drop – from 18 °C to 14 °C – during the Pliensbachian–Toarcian boundary (Rosales et al., 2004). This drop was also recorded in the Arctic and was the

likely cause of the significant turnover registered in Boreal marine invertebrates during this time. Moreover, the sub-Tethyan and Low Boreal bivalves that dwelt northward of 68° N present-day coordinates in the terminal Pliensbachian migrated southward to the latitude 55°N at the beginning of the Toarcian and returned to North Siberia in the Late Toarcian (Zakharov et al., 2006). Likewise, ostracods experienced an extinction episode during the Late Pliensbachian and Early Toarcian (Arias, 2009). On the other hand, ammonites of the Tethyan Realm kept moving to the north until the Late Pliensbachian, when the Boreal Realm commenced to shift southward replacing the Mediterranean fauna. Subsequently throughout the Late Pliensbachian and Earliest Toarcian, ammonites were affected by a major extinction which caused particularly the Tethyan species to disappear and be replaced in the Early Toarcian (Macchioni and Cecca, 2002), when the continent was located at its northernmost position (Figure 3).

The paleoflora, vertebrates, and geological records from both the Southern and Northern Hemispheres also are consistent with the paleolatitudes determined from the paleomagnetic record (Iglesia Llanos and Prezzi, 2013).


Paleomagnetism and Jurassic Paleogeography, Figure 3 "Absolute" paleogeographical reconstructions of Pangaea for the Early Jurassic. During the Late Triassic-Early Sinemurian, Pangaea was placed at its southernmost position. At this time, the boundary –solid thick line between the South Pacific (high latitudes) and Tethyan (low latitudes) realms of bivalves – was located in northern Chile (Damborenea, 2001, 2002). Subsequently and throughout the Early Jurassic, Pangaea moved northward and rotated CW, until the Late Pliensbachian-Early Toarcian when it reached the northernmost position. During this time, the boundary kept shifting toward the south until in the Early Toarcian; high-latitude bivalves became restricted to the southern extreme of the continent.

Conclusions

A master APW path for the Jurassic Pangaea was constructed using selected Eurasian, North American, African, and South American high-quality poles. The resultant path reveals a distinctive cusp at ~197 Ma and a subsequent standstill which seemed to persist until the Late Jurassic. The 197–185 Ma Early Jurassic track reveals a c. 50° shift in the pole positions during this time and a minimum angular change of poles of approximately $4° \; \text{Myr}^{-1}$. This path clearly shows that Pangaea would have been subjected to a 50° CW rotation between the Sinemurian (~197 Ma) and Pliensbachian (~185 Ma),

while it moved to the north. The motion of the supercontinent is interpreted to be primarily caused by TPW defined as the drift of the spin axis with respect to entire solid Earth, rather than other types of phenomenon such as lithospheric motion or an artifact produced by nondipole components. The c. 50° rotation is interpreted to result from the motion of the lithosphere AND the mantle. Estimated paleolatitudes are in good agreement with paleoclimatic proxies derived from fossil and geological records having a geographic distribution limited to certain climatic regions.

Paleogeography of Ocean Basins

Definition

Plate motions and the history of plate boundary geometries through time are the primary drivers for the large-scale paleophysiography of the ocean basins. These in turn determine the history of seafloor spreading and subduction, driving the time dependence of the age-area distribution of ocean floor. The depth of the ocean floor and volume of the ocean basins are primarily dependent on its age. Reconstructions of the age and depth distribution of the ocean floor combined with estimates of sediment thickness through time and the reconstruction of oceanic plateaus yield broad-scale paleophysiographic maps of the ocean basins.

Introduction

The paleophysiography of the ocean basins relies on an understanding of the current physiography of the oceans and the processes governing its development through geological time. The most fundamental parameter driving the depth distribution of ocean basins is the age of the oceanic lithosphere. The recognition that age and depth are linked via the cooling of oceanic lithosphere as newly formed crust moves away from mid-ocean ridges provides a framework for mapping ocean basin depth through time. Constructing a present-day physiographic map of the oceans is relatively straightforward due to the preservation of oceanic lithosphere. However, to generate complete oceanic physiographic maps in the past involves recreating ocean crust that has since been subducted. This becomes progressively more difficult back through time.

History

Turcotte and Oxburgh (1967) were the first to suggest that the subsidence of the seafloor away from mid-ocean ridges can be explained by the cooling of the lithosphere as a thermal boundary layer. Ten years later, a major analysis of the relationship between depth and age of the ocean floor (Parsons and Sclater, 1977) showed that the cooling of a simple rigid boundary layer can explain the depth–age relationship of crust younger than 80 Ma of age. For older ocean floor, the depth was shown to increase asymptotically to a constant value, i.e., to "flatten." The flattening of the depth implied the addition of extra heat under the older ocean floor. Parsons and Sclater (1977) showed that a plate of constant thickness gave a good approximation to this concept and gave birth to so-called plate models describing oceanic depth–age relationships. The

severe computational restrictions during the 1970s compared to today's standards meant that the observational parameter space could not be efficiently explored for the best-fit solution. A formal best-fit solution was first found by Stein and Stein (1992) via their widely used GDH1 model (global depth and heat flow #1). More recently, Crosby and McKenzie (2009) suggested a revised age-depth curve by adding a damped sinusoidal perturbation to the flattening of seafloor older than 80 Ma. This approach is based on the observed sinusoidal shallowing of the reference depth–age curve for the North Pacific and to a lesser extent the North Atlantic between the ages of 80 and 130 Ma. They argued that this sinusoidal shallowing resembles the results of early numerical models where a surface boundary layer cools by conduction and then becomes unstable once its local Rayleigh number exceeds a critical value. The growing instability then suddenly increases as the base of the lithospheric boundary layer falls off and is replaced by hotter asthenosphere from below. The new material then cools again by conduction, until it in turn becomes unstable, resulting in a series of decaying oscillations about an asymptotic steady-state value. As well as these "thermal" models, there exist other age-depth models, which are categorized as either "dynamic" or "chemical" models. In dynamic models, increasing pressure in the asthenosphere prevents the seafloor from subsiding (Phipps Morgan and Smith, 1992). Chemical models take into account the compositional and rheological stratification on small-scale convection (Afonso et al., 2008) or consider the lateral flow and spreading of depleted, buoyant mantle residuum left over from the melt extraction process at mid-ocean ridges (Phipps Morgan et al., 1995). Despite the ongoing debate about the details of the depth–age relationship of relatively old ocean floor, models such as GDH1 are a good approximation to construct paleophysiographic ocean basin models. Other uncertainties such as the effect of large-scale mantle convection on oceanic depth (Spasojevic and Gurnis, 2012) and uncertainties in the elevation of oceanic plateaus and sediment thickness through time (Müller et al., 2008b) potentially play a large role in reconstructing the paleo-depth of ocean basins.

Reconstructing mid-ocean ridges and flanks

The reconstruction of the ocean basins relies on a global plate motion model to establish the location and geometry of mid-ocean ridges through time. This is achieved through marine magnetic anomaly identifications, geological information such as paleomagnetic data from terranes and microcontinents (especially in the Tethys Ocean), mid-ocean ridge subduction events, and the rules of plate tectonics (Cox and Hart, 1986). Uncertainties in reconstructing mid-ocean ridges and flanks grow progressively as you travel back through time as more and more mid-ocean ridge flanks are subducted and, hence, need to be recreated. Even though the details of now subducted mid-ocean ridge geometries cannot be known, reasonable

and conservative estimates can be made for their geometry, orientation, and location based on available geophysical and geological data while adhering to the rules of plate tectonics. Pre-Jurassic ocean basin physiographies have never been explicitly reconstructed to date.

Preserved magnetic lineations in the Pacific Ocean provide unequivocal evidence that a vast mid-ocean ridge system existed in the Pacific Ocean in the mid/late Cretaceous, significantly longer than today's ridge system, and much of which is now subducted – this was first recognized by Larson and Chase (1972). Subsequent detailed mapping and compilation of magnetic M-sequence anomalies in the northwestern Pacific Ocean (Nakanishi et al., 1992a) revealed the complete Mesozoic magnetic anomaly lineation pattern in this area and the origin of the Pacific plate as a triangularly shaped microplate at a triple junction between the Izanagi, Farallon, and Phoenix plates in the Panthalassa Ocean basin, the predecessor of the Pacific Ocean. This work forms the basis of Pacific Ocean reconstructions. In the southwest Pacific, the reconstructions from Seton et al. (2012) implement the opening of ocean basins between fragments of the Ontong Java–Manihiki–Hikurangi large igneous provinces (LIPs) (Viso et al., 2005; Taylor, 2006), a major tectonic event that was missing from previous reconstructions of the Cretaceous Pacific Ocean (Müller et al., 2008b). The Tethys Ocean, separating Laurasia from Gondwanaland, is reconstructed by accounting for the migration history of a series of Gondwanaland ribbon continents that were rifted off the northern margin of Gondwanaland and accreted to southern Eurasia in several stages. By using combined evidence from preserved magnetic lineations in the present-day Indian Ocean and geological data from the terranes that accreted to southern Eurasia and the rules of plate tectonics (Cox and Hart, 1986), it is possible to constrain the overall geometries of the Tethyan mid-ocean ridge system. The closure of the Mongol–Okhotsk Ocean between 200 and 150 Ma is modeled after van der Voo et al. (1999).

The overall physiography of the global oceans since the Mesozoic follows an alternating pattern mid-ocean ridge length increase and decrease as well as changes in the average age of the oceanic lithosphere. A number of old mid-ocean ridge flanks in Panthalassa and the Tethys oceans were gradually being destroyed between 200 and 150 Ma, while new mid-ocean ridge systems were initiated in a stepwise fashion between the late Jurassic and early Cretaceous, leading to a substantial younging and shallowing of the ocean basins from the Jurassic to the Cretaceous period. After the Cretaceous, the length of the mid-ocean ridge system decreased and was accompanied by an aging and deepening of the ocean basins toward the present day.

To produce a model of the age-area distribution of the ocean basins since the Mesozoic, we take the global set of plate rotations, reconstructed plate boundaries and seafloor magnetic anomalies, and fracture zones imbedded in the global plate model of Seton et al. (2012) and construct a set of seafloor spreading isochrons, equivalent to paleo-mid-ocean ridge geometries and locations. Seafloor isochrons are then gridded (Müller et al., 2008a) to produce smooth, continuous models for the age-area distribution of ocean floor through time (see "Plate Motion"). The resultant age grid becomes the primary input to producing models of the depth of the ocean basins through time, based on a selected depth–age relationship. To convert age to depth, we use the GDH1 model (Stein and Stein, 1992). Other recent depth–age models, e.g., Crosby and McKenzie (2009), result in an extremely similar mapping of age to depth (see Müller et al. (2008a) for details) and would make little difference for the reconstruction of ocean basin depths.

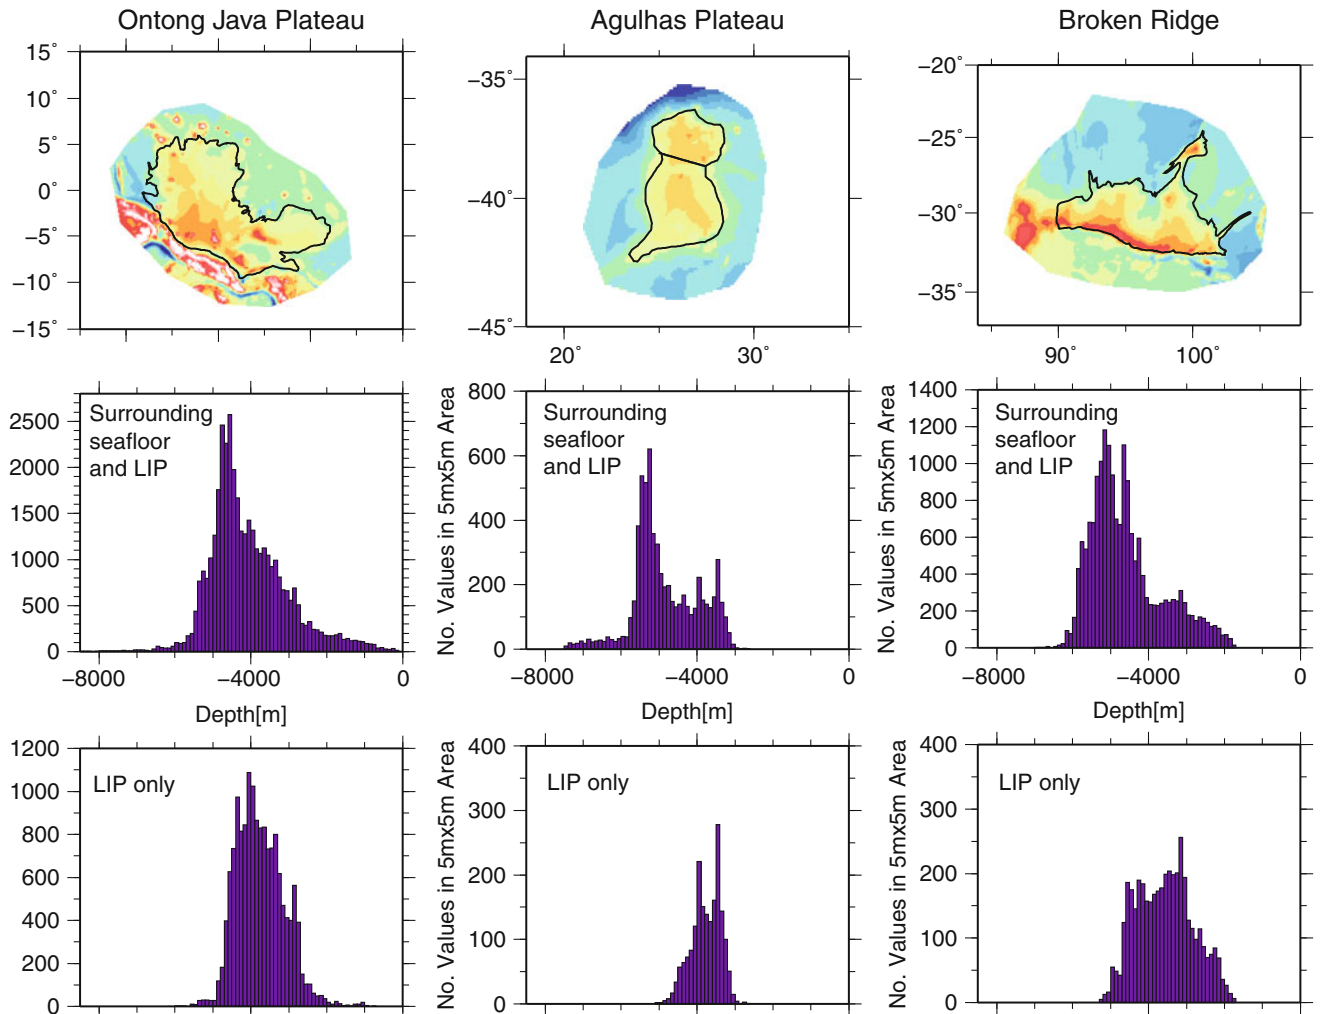
Oceanic plateaus and sediment cover

Two additional factors play a significant role in controlling ocean basin depth through time, namely, the generation of oceanic large igneous provinces (LIPs) and oceanic sedimentation. To account for the effect of LIPs on oceanic depth, we take a subset of the Coffin et al. (2006) dataset to include LIPs that were generated by a transient plume head as we are most interested in capturing the voluminous volcanism rather than the small scale. We use Schubert and Sandwell's (1989) method to determine the average elevation of major oceanic plateaus relative to the surrounding seafloor, based on the difference between the modal depths within two polygons, one outlining the perimeter of a given oceanic plateau and another larger polygon including surrounding ocean floor (Figure 1). Individual plateaus are included in basement depth grids at their emplacement time based on a compilation of eruption ages (Müller et al., 2008b). Where available, the paleo-depth estimates of LIPs were cross-referenced with published data (e.g., back-stripping from well data or from seismic data).

As the ocean floor ages, the thickness of its sediment cover increases, but abyssal sediment thickness is also latitude dependent, as illustrated in a polynomial surface fit of global sediment thickness as a function of oceanic crustal age and latitude (Figure 2). The observed latitudinal sediment thickness variation primarily reflects differences in productivity between zones of tropical upwelling and an increase in sediment thickness toward high latitudes, reflecting terrigenous runoff. The simple relationship provides a good first approximation for reconstructing an estimate for regional oceanic sediment thickness through time. We isostatically correct for sediment loading based on Sykes (1996).

Paleophysiography of Mesozoic and Cenozoic ocean basins

Overview

Broad-scale paleo-bathymetries of the ocean basins can be constructed by combining oceanic basement depths derived from a depth–age relationship with oceanic plateaus and sediment thickness estimates (Figure 3). The


Paleophysiography of Ocean Basins, Figure 1 Accounting for the eruption and subsidence of LIPs through time is an important aspect of paleo-depth models of the ocean floor. We show three examples of LIPs (Ontong Java and Agulhas Plateaus and Broken ridge) and the method applied to predict LIP depth. *Top panel* shows present-day bathymetry from ETOPO with *black outline* indicating the outline of the LIP. *Middle panel* shows the depths of the seafloor surrounding the LIP as well as the LIP itself per 5 × 5 m area. *Bottom panel* shows depths for the LIP only.

paleo-bathymetries presented here, spanning the period from the early Jurassic (200 Ma) to present day, focus on the physiogeography of the main ocean basins, i.e., mid-ocean ridges, their flanks, and abyssal plains, but exclude detailed depth estimates of passive continental margins and submerged continental plateaus and microcontinents. These depths in these regions are difficult to derive as they require a global compilation of well and seismic data to reconstruct the regional tectonic subsidence and sedimentary history, in areas where data coverage is generally sparse.

200 Ma

At 200 Ma, the supercontinent Pangaea is still intact and is surrounded by the Panthalassa "super-ocean" and the Tethys ocean basin (Figure 3a). Panthalassa primarily

consists of ocean floor that formed by seafloor spreading between the Izanagi, Farallon, and Phoenix plates. The Cache Creek Ocean exists along the northeastern margin of Panthalassa, adjacent to the North American continent. This smaller ocean basin owes its name to the Cache Creek Terrane, a mid-Paleozoic to mid-Jurassic oceanic terrane with exotic Permian Tethyan faunas in limestone blocks and long-lived island edifices (Nelson and Mihalynuk, 1993; Mihalynuk et al., 1994). At this time, the Tethys Ocean is divided into the northern paleo-Tethys, a narrow abyssal seaway, which is a remnant of a once vast ocean basin whose mid-ocean ridge was previously subducted, and the southern meso-Tethys, which formed by means of a number of continental blocks and slivers rifting off northern Gondwanaland, separating the paleo- from the meso-Tethys by a continental barrier
Paleophysiography of Ocean Basins, Figure 2 Sediment thickness as function of latitude and crustal age. The observed latitudinal sediment thickness variation primarily reflects differences in productivity between zones of tropical upwelling and an increase in sediment thickness toward high latitudes, reflecting terrigenous runoff. Regional marine sediment thickness also depends on many other factors, including depth of carbonate compensation depth and regional changes in terrigenous flux. The above relationship provides a good approximation for our aim to reconstruct an estimate for mean oceanic sediment thickness through time.

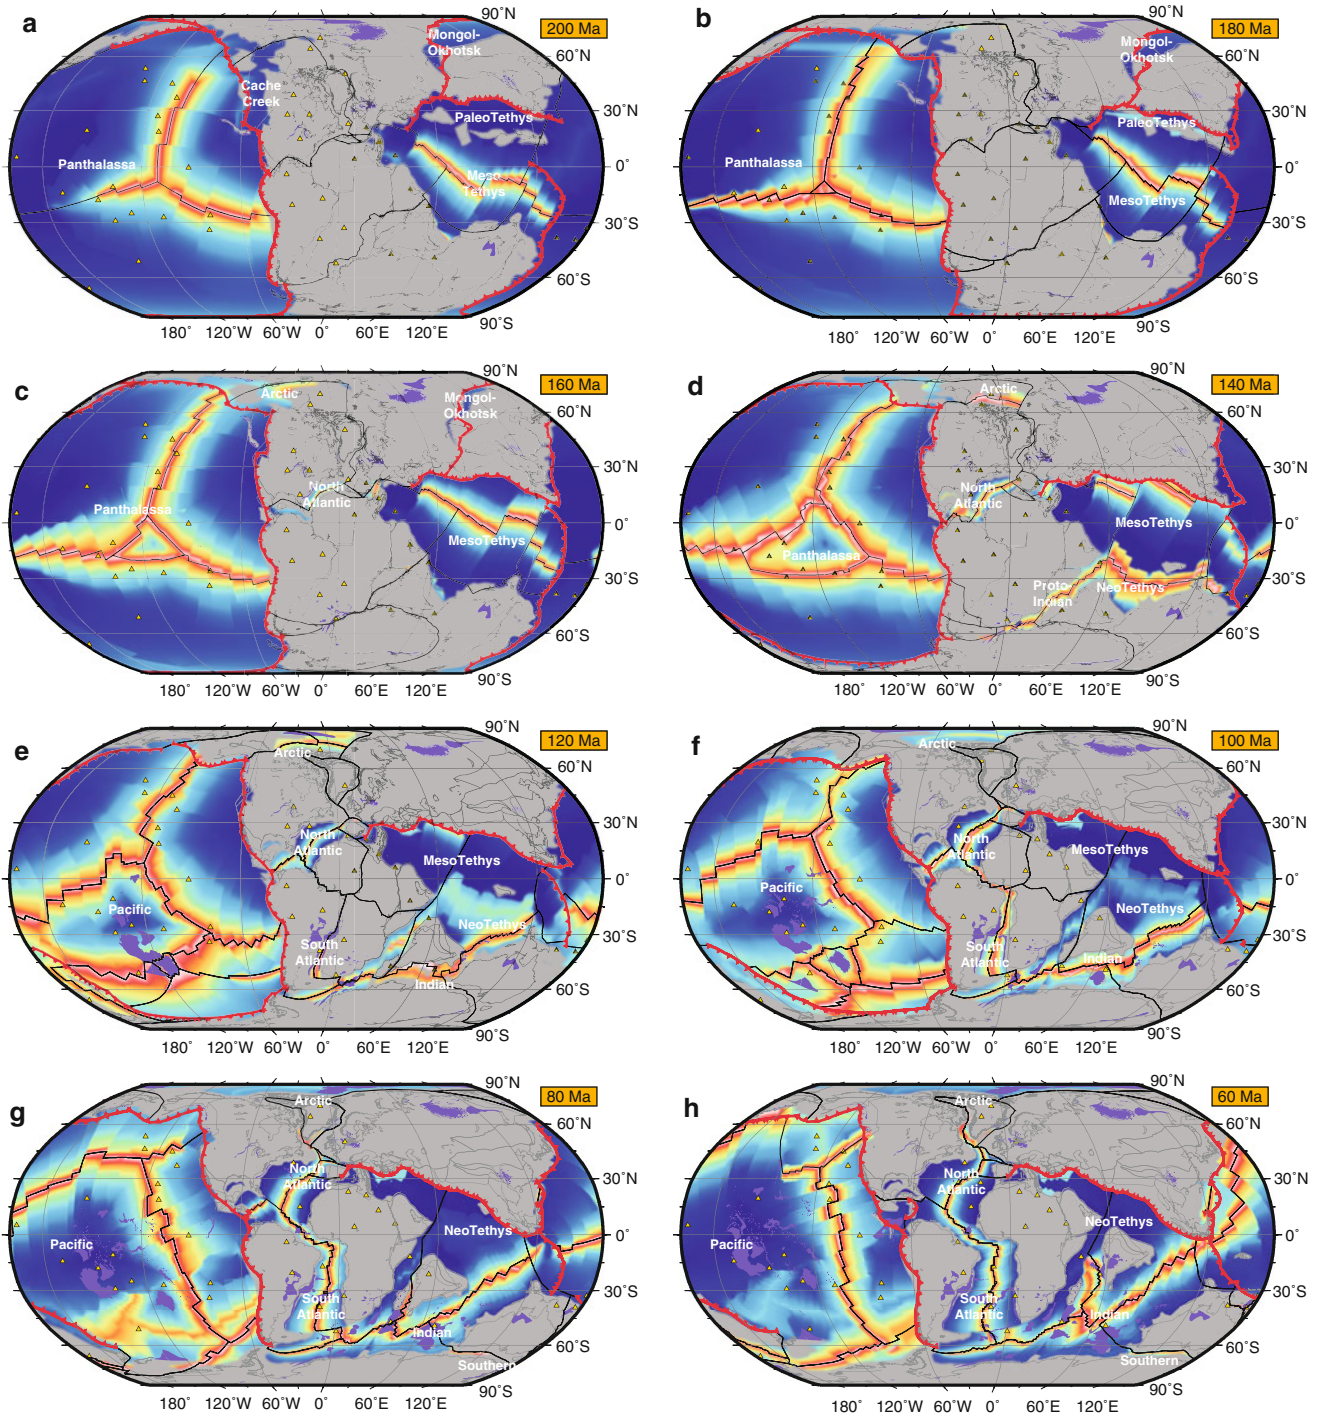
referred to as the Cimmerian terrane. The detailed configuration of the Cimmerian terrane is unknown. In addition, there is evidence for the existence of the Mongol–Okhotsk Basin in central Asia (Figure 3a) from a series of remnant island arc volcanics and ophiolites adjacent to the suture zone as well as a large volume of seismically fast material in the lower mantle underlying Siberia, imaged in seismic tomography, and representing subducted Mongol–Okhotsk Ocean slabs (Van der Voo et al., 1999). The initiation of breakup of Pangaea is focused in the central North Atlantic, where seafloor spreading may have initiated as early as 200 Ma (Labails et al., 2010).

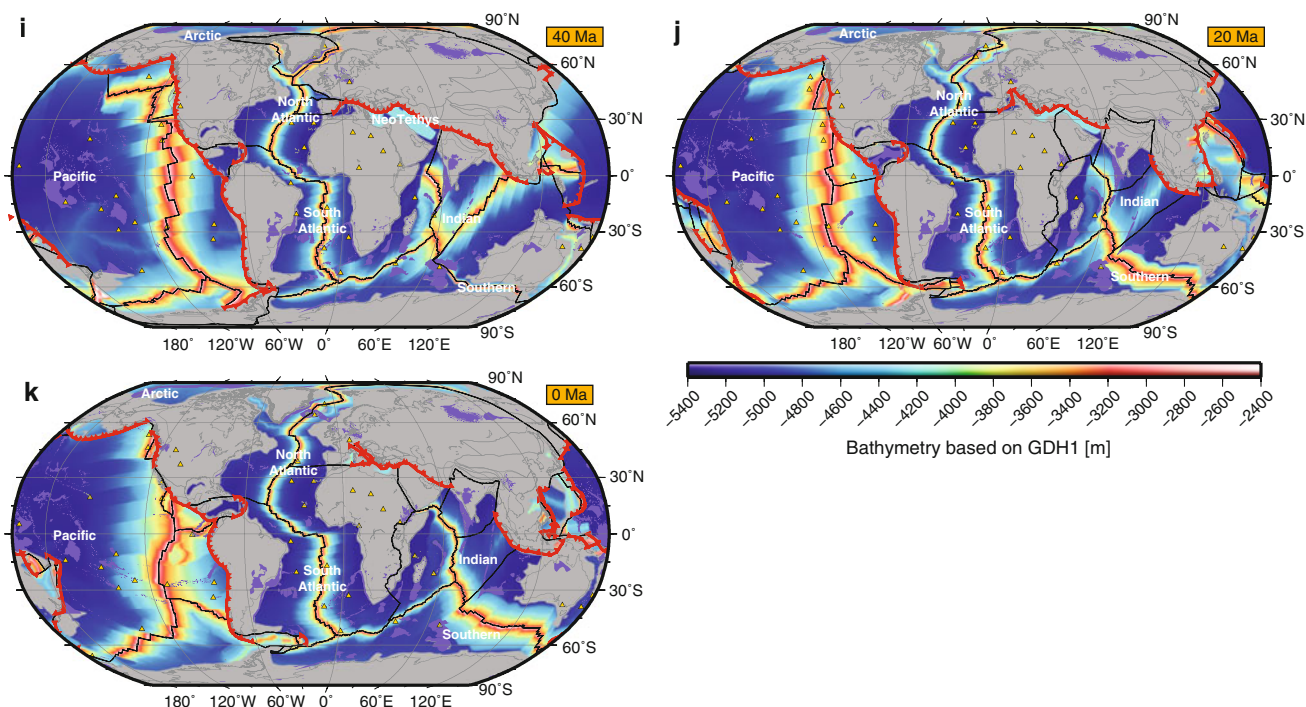
180 Ma

At 180 Ma the configuration of the global oceans becomes simplified as they are nearly entirely dominated by Panthalassa and the meso-Tethys, with all smaller ocean basins reduced to narrow remnant strips of deep ocean crust. The closure of the Cache Creek Ocean is tightly constrained to around 172–174 Ma (Colpron et al., 2007) and references therein. The closure of the paleo-Tethys and accretion of the Cimmerian terrane occurred along the southern Laurasian margin at 170 Ma in this model (Figure 3b, c). This time also sees the birth of the Pacific plate, visible as a triangular area in Figure 3b in the center of Panthalassa. The "Pacific triangle" is an area of the western Pacific where three Mesozoic magnetic

lineation sets (Japanese, Hawaiian, and Phoenix lineations) intersect, recording the birth of the Pacific plate at a triple junction from three parent plates: the Farallon, Izanagi, and Phoenix plates. The northwestern (Japanese) lineations represent spreading between the Pacific and Izanagi plates and young toward the west–northwest, the easternmost (Hawaiian) lineations represent spreading between the Pacific and Farallon plates and young toward the east, and the southernmost (Phoenix) lineations represent spreading between the Pacific and Phoenix plates and young toward the south (Atwater, 1970; Nakanishi et al., 1992b). These three plates existed prior to the establishment of the Pacific plate in a simple ridge–ridge–ridge configuration (Figure 3a).

160 Ma

Rapid growth of the Pacific plate is recorded during this time with a gradual increase in the spreading rate. Seafloor spreading is well underway in the central North Atlantic, signifying the breakup of Pangaea into Laurasia and Gondwanaland (Figure 3c). The earliest onset of breakup between North America and Africa has recently been redated at around 200 Ma (Labails et al., 2010) coincident with ultraslow seafloor spreading but with an increase in spreading rate from 170 Ma. Further south, the deformation within South America associated with the breakup of the South Atlantic is believed to have initiated at around


Paleophysiography of Ocean Basins, Figure 3 (continued)


Paleophysiography of Ocean Basins, Figure 3 Physiogeography of ocean basins through time from 200 Ma to present in 20 Ma intervals. Basemap shows predicted oceanic depth, *gray* denote non-oceanic areas. *Blue* (i.e., *deep*) areas mark the abyssal plains. *Red* (*shallow*) areas mark the mid-ocean ridge system. *Black lines* show plate boundaries and *yellow triangles* are present-day hotspot locations.

150 Ma (Torsvik et al., 2009). The Mongol–Okhotsk Ocean is almost entirely closed, with complete closure dated at around 150 Ma based on the cessation of compression in the suture zone region (Zorin, 1999).

140 Ma

This reconstruction illustrates the initial formation of the proto-Caribbean between North and South America as a consequence of the divergence between Laurasia and Gondwanaland. In the Arctic Ocean, the Canada Basin started forming via counterclockwise rotation of the North Slope of Alaska away from the northern Canadian margin (Halgedahl and Jarrard, 1987), with seafloor spreading starting at 142 Ma (Alvey et al., 2008). The Canada Basin spreading ridge is connected with the North Atlantic rift zone, which in turn connects to the northern Tethyan subduction zone and the central North Atlantic spreading ridge (Figure 3d). The neo-Tethys started forming prior to 140 Ma, best documented by the separation of Argoland from the northwest shelf of Australia around 155 Ma (Gibbons et al., 2012). The neo-Tethyan mid-ocean ridge likely wrapped around northern India and is assumed to have connected with seafloor spreading in the Somali Basin (Figure 3d). This incipient spreading system continued south into the Mozambique Basin, the Riser-Larson, and the Weddell seas, marking the fragmentation of Gondwanaland. The southwest Panthalassic margin, along

eastern Australia, involved the opening of the South Loyalty Basin, due to rollback of the southwest Panthalassic subduction zone from 140 Ma.

120 Ma

This time marks a significant increase in seafloor spreading rates in Panthalassa corresponding to the mid-Cretaceous seafloor spreading pulse, with spreading between the Pacific, Farallon, Izanagi, and Phoenix plates. The breakup of the Phoenix plate occurred due to the eruption of a suite of LIPs, most notably the Ontong Java, Manihiki, and Hikurangi Plateaus, which originally formed one giant oceanic plateau (Taylor, 2006) (Figure 3e). The eruption of this mega-LIP led directly to the formation of the Hikurangi, Manihiki, Chasca, and Catequil plates (Figure 3e). Additional two triple junctions were active in the region leading to the breakup of the eastern Manihiki Plateau and the development of the Tongareva triple junction. The South Loyalty Basin off northeast Australia was actively opening until 120 Ma, when it was halted by a major change in the plate configurations in the SW Panthalassic Ocean. After a landward ridge jump of the neo-Tethys ridge at 135 Ma, the mid-ocean ridge propagated southward to open the Gascoyne, Cuvier, and Perth Abyssal Plains between India and Australia (Gibbons et al., 2012). The West Australian spreading ridge system joined with the Enderby

Basin spreading ridge, separating Antarctica from the Elan Bank/India, to the west and to the rift between Australia and Antarctica to the east. Spreading extended southward along the South Atlantic ridge with a northward propagation leading to seafloor spreading in the "central" segment by 120 Ma and in the "equatorial" segment by 110 Ma. Breakup between Iberia and North America occurred around 110 Ma. The North Atlantic rift zones connected with the spreading center in the Canada Basin until about 118 Ma, marking the cessation of seafloor spreading in the Canada Basin. Spreading terminated when the rotation of North Slope Alaska ceased, coincident with a change in the southern North Slope margin from largely strike-slip to convergence due to a change in spreading direction in Panthalassa.

100 Ma

The mid and South Atlantic ridges were well established from 100 Ma and spread along the central North Atlantic ridge and continued into the proto-Caribbean Sea until this time (Figure 3f). Evidence from the seafloor fabric for a global plate motion change is abundant between 105 and 100 Ma, with either fracture zone bends or terminations preserved in all ocean basins (Matthews et al., 2012). For example, a change in spreading direction is recorded in the Mendocino, Molokai, and Clarion fracture zones (associated with Pacific–Farallon spreading), which is dated to 103–100 Ma (Seton et al., 2012) coincident with an observed bend in the hotspot trails on the Pacific plate, suggesting a plate reorganization at this time. A major change in spreading direction is also recorded in fracture zone trends in the Indian Ocean around 100 Ma (Gibbons et al., 2012). Spreading between India and Australia subsequently became dominantly N–S directed, establishing the Wharton Basin. The West Australian mid-ocean ridge system formed a triple junction with the Australian–Antarctic ridge around 100 Ma (initiation of ultraslow seafloor spreading) and spreading between India and Antarctica north of the Elan Bank microcontinent (Figure 3f). The Indian–Antarctic ridge (or southeast Indian ridge) connected with the African–Antarctic ridge (or southwest Indian ridge) from 100 Ma.

80 Ma

The Pacific was dominated by the breakup of the Farallon plate into the Kula plate with seafloor spreading initiating at 79 Ma along the E–W trending Kula–Pacific ridge and the NE–SW trending Kula–Farallon ridge (Figure 3g). The Kula–Farallon ridge follows the location of the Yellowstone hotspot and intersects the North American margin in Washington/British Columbia before migrating northward along the margin. At 86 Ma, the Hikurangi Plateau docked with the Chatham Rise triggering a cessation in spreading associated with the Ontong Java, Manihiki, and Hikurangi Plateaus. After the cessation of spreading along these ridge axes, the locus of extension jumped southward between Antarctica and the Chatham Rise,

establishing the Pacific–Antarctic spreading ridge (Figure 3g). To the east, the Pacific–Farallon ridge extended to the south connecting with the Pacific–Antarctic ridge at the Pacific–Antarctic–Farallon triple junction. After the cessation of the spreading centers associated with the Pacific mega-LIP formation and breakup, the Pacific plate became the dominant plate in Panthalassa, and it is at this time that Panthalassa morphs into the Pacific Ocean.

In the Caribbean, spreading in the proto-Caribbean Sea ceased at 80 Ma, whereas the Caribbean Arc subduction zone continued its northeastward rollback. The rollback of this subduction zone along the Caribbean Arc led to the consumption of the actively spreading proto-Caribbean ocean floor and encroachment of the Farallon plate into the Caribbean domain (Figure 3f, g). The continued rollback of the Caribbean Arc subduction zone led to the formation of the Yucatan Basin as a back arc in the late Cretaceous with cessation occurring at 70 Ma when the Caribbean Arc accreted to the Bahaman Platform. The accretion led to a jump in the locus of subduction westward along the newly developed Panama–Costa Rica to accommodate the continued eastward motion of the Farallon plate, trapping Farallon oceanic lithosphere onto the Caribbean plate.

Rifting between India and Madagascar in the Mascarene Basin initiated at 87 Ma (Gibbons et al., 2013). The southwest Indian ridge connected with spreading in the Malvinas plate in the southernmost Atlantic at 83.5 Ma and the American–Antarctic ridge (established after the cessation of spreading in the Weddell Sea) (Figure 3g). The mid-Atlantic ridge propagated northward into the North Atlantic with the initiation of seafloor spreading in the Labrador Sea (between North America and Greenland) and between the Rockall Plateau and Greenland at 79 Ma. Spreading propagated from the Labrador Sea to Baffin Bay by 63 Ma across the Davis Straits via left-lateral transform faults and connected to the Arctic via the Nares Strait.

60 Ma

In the Pacific, the Pacific–Izanagi ridge started to subduct under the East Asian margin between 55 and 50 Ma, signaling the death of the Izanagi plate coincident with a dramatic change in spreading direction from N–S to NW–SE between Kula–Pacific spreading. The Kula–Pacific ridge connected with the Pacific–Farallon ridge and Kula–Farallon ridge from 60 to 55 Ma (Figure 3h). After 55 Ma, the eastern Pacific was dominated by the rupture of the Farallon plate close to the Pioneer fracture zone, forming the Vancouver plate. The breakup resulted in minor relative motion along the Pioneer fracture zone. Further south, spreading continued along the Pacific–Farallon, Pacific–Antarctic, Farallon–Antarctic, and Pacific–Aluk ridges (Figure 3h). The fracture zones associated with the Pacific–Antarctic ridge close to the Campbell Plateau record a change in spreading direction at

55 Ma, coincident with other events that occurred in the Pacific at this time.

In the southern Pacific, spreading continued along the Pacific–Antarctic ridge, extending eastward to connect with the Pacific–Farallon and Farallon–Antarctic spreading ridges. At 67 Ma, a change in spreading direction is recorded in the fracture zones of the South Pacific initiating the opening of the Aluk plate in the South Pacific. In the Indian Ocean, spreading was occurring along the Wharton ridge, SEIR, SWIR, and in the Mascarene Basin (Figure 3h). Spreading in the Mascarene Basin ceased at 64 Ma jumping northward, isolating the Seychelles microcontinent, and initiating spreading between India and the Seychelles along the Carlsberg ridge. The SWIR connected with spreading in the Malvinas plate until 66 Ma. After this, the SWIR connected directly with the American–Antarctic and South Atlantic ridge. Seafloor spreading propagated into the Eurasia–Greenland margin along the Reykjanes ridge by 58 Ma, forming a triple junction between North America, Greenland, and Eurasia (Figure 3h). The Jan Mayen microcontinent rifted off the margin forming the fan-shaped Norway Basin along the Aegir ridge. The Aegir ridge connected to the Mohns ridge to the north and Reykjanes ridge to the south via a series of transform faults. Spreading in the Eurasian Basin to the north initiated around 55 Ma along the Gakkel/Nansen ridge.

40 Ma

In the Pacific, spreading between the Kula–Pacific and Kula–Farallon ceased at 42 Ma, leading to the Pacific plate consisting of the Pacific, Vancouver, Farallon, Aluk, and Antarctic plates (Figure 3i). The intersection of the Murray transform fault with the North American subduction zone around 30 Ma led to the establishment of the San Andreas Fault and corresponds to the establishment of the Juan De Fuca plate at the expense of the Vancouver plate.

In the western Pacific, spreading in the proto-South China Sea ceased at 50 Ma coincident with the clockwise rotation of the neighboring Philippine Sea plate. The dramatic change in motion of the Philippine Sea plate reorganized the plate boundaries in the area leading to the establishment of a subduction zone between Palawan and the proto-South China Sea and the subduction of the proto-South China Sea after 50 Ma (Figure 3i). Further south, spreading initiated in the North Loyalty Basin behind the proto-Tonga–Kermadec Trench. Spreading in the West Philippine Basin ceased at 38 Ma, whereas spreading continued in the Celebes Sea. The formation of the Caroline Sea occurred behind a rapidly southward migrating subduction zone. By 30 Ma, spreading initiated in the Shikoku and Parece Vela Basins behind the west-dipping Izu–Bonin–Mariana Arc. Spreading terminated in the Celebes Sea. In the SW Pacific, spreading initiated in the Solomon Sea at 40 Ma and in the South Fiji Basin at 35 Ma.

The Indian Ocean was dominated by a series of mid-ocean ridges such as the Wharton ridge, SEIR, SWIR, and Carlsberg ridge (Figure 3i). Prior to 55 Ma, subduction was occurring along the Tethyan subduction zone, consuming crust that formed during meso- and neo-Tethys spreading. At 55 Ma, the northern tip of Greater India marks the start of collision between India and Eurasia and the uplift of the Himalayas. Closure of the Tethys Ocean in this area occurred by about 43 Ma. Full closure of the neo-Tethys between India and Eurasia also corresponds to the cessation of spreading in the Wharton Basin, which describes Australia–India motion.

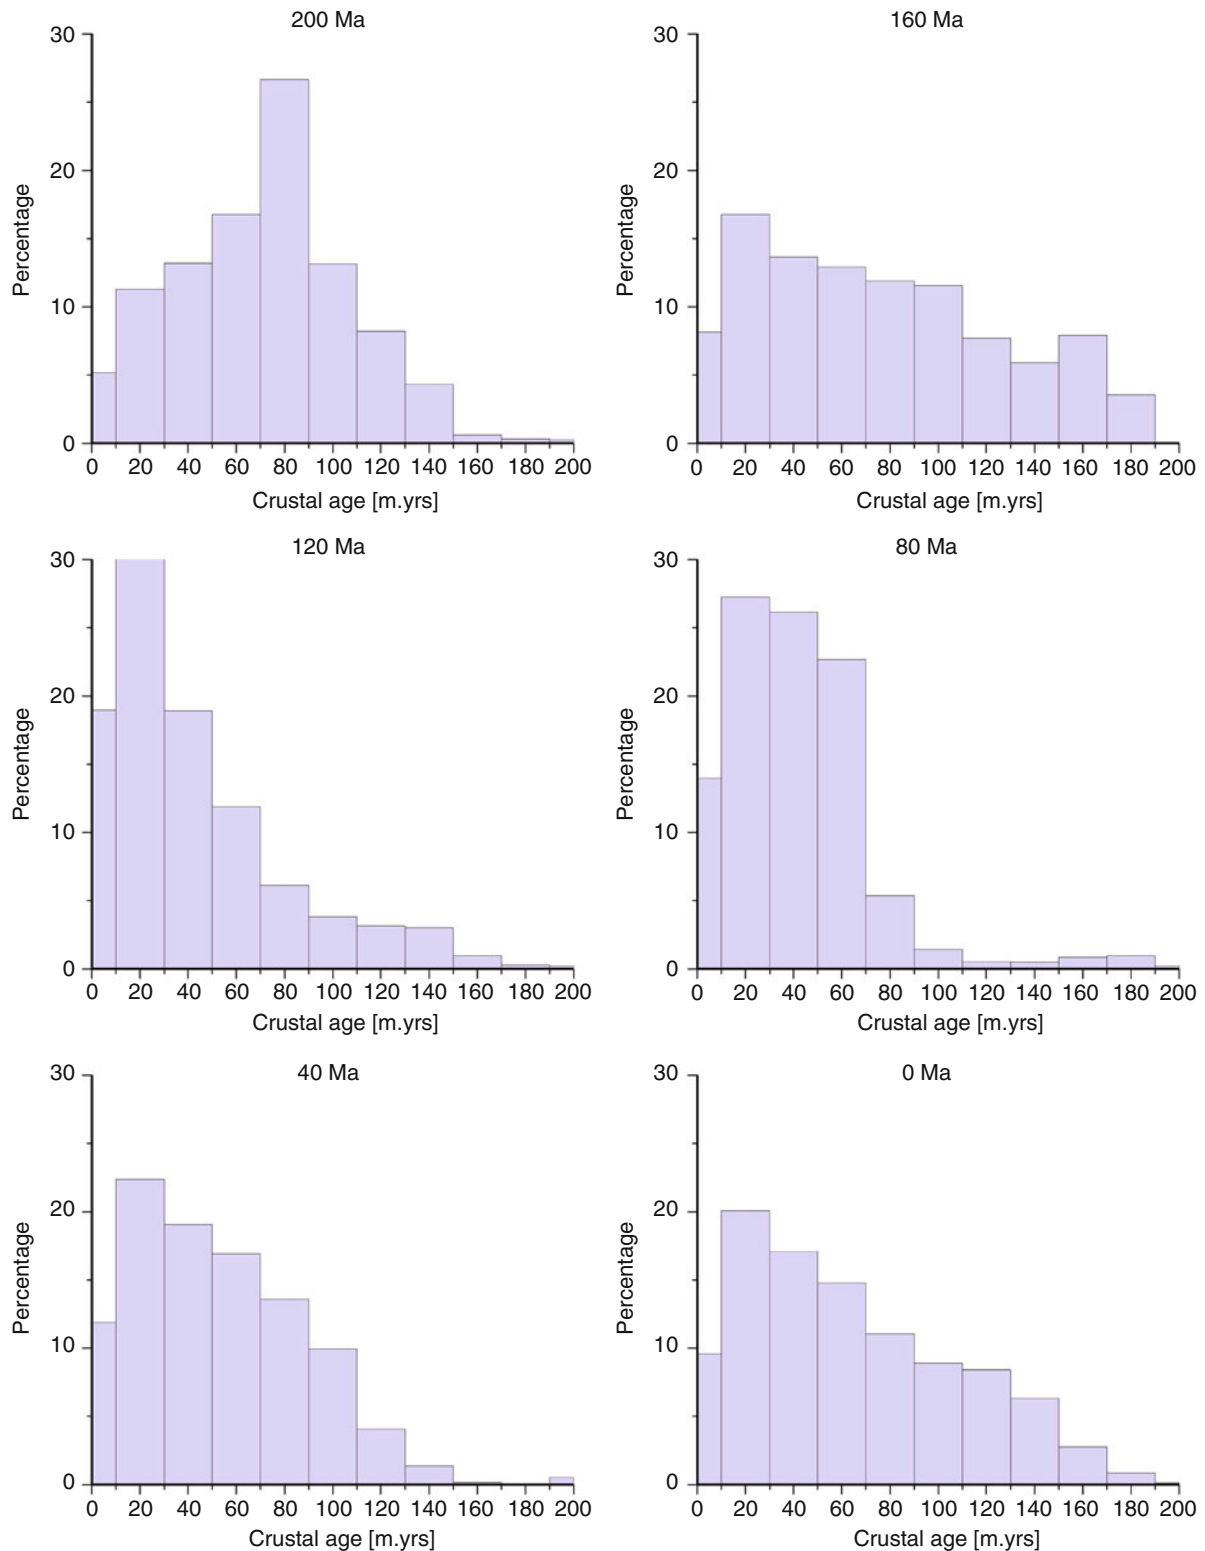
20 Ma to present day

In the Pacific, spreading continued along the Pacific–Juan De Fuca, Pacific–Nazca, Pacific–Cocos, Cocos–Nazca, Pacific–Antarctic, and Nazca–Antarctic ridges (Figure 3j, k). The Bauer microplate formed along the East Pacific Rise at 17 Ma and continued until 6 Ma. The locus of spreading then jumped back to the East Pacific Rise (between the Pacific and Nazca plates). The East Pacific Rise is the fastest spreading ridge system (excluding back-arc opening) and currently encompasses microplate formation at the Easter, Juan Fernandez, and Galapagos plates. Currently, the Juan De Fuca plate is limited at its southern end by the Mendocino Fracture Zone and is subducting slowly along the Cascadia subduction zone.

The western Pacific is dominated by the opening of a series of back-arc basins due to the rollback of the subduction hinge of the Tonga–Kermadec and Izu–Bonin–Mariana trenches (Figure 3j, k). Spreading in the Shikoku and Parece Vela Basins and South China Sea ceased at 15 Ma. By 9 Ma, spreading initiated in the Mariana Trough. We model complete closure of the proto-South China Sea at around 10 Ma behind a subduction zone located along Palawan and the North Borneo/Kalimantan margin. In the SW Pacific, spreading in the Lau Basin initiated by 7 Ma with back-arc extension occurring in the Havre Trough.

A further rupture of the Farallon plate occurred at 23 Ma leading to the establishment of the Cocos and Nazca plates and initiation of the East Pacific Rise, Galapagos Spreading Center, and Chile ridge. Cessation of spreading in the South Fiji Basin occurred at 25 Ma.

In the Indian Ocean, spreading continued along the SWIR, SEIR, CIR, and Carlsberg ridge (Figure 3j, k). Extension along the East Africa rifts was established at 30 Ma leading to the breakup of Africa into Somalia plate. Rifting along the Sheba ridge separating Arabia from Africa/Somalia initiated at 30 Ma. A zone of diffuse deformation occurring in the middle of the Indo-Australian plate led to the development of the Capricorn plate in the central-east Indian Ocean at 20 Ma. Further west, spreading is initiated along the Sheba ridge at 20 Ma. The Sheba ridge propagated into the Red Sea at 15 Ma.

Spreading in the South and North Atlantic continued unabated, with the westward motion of the North


Paleophysiography of Ocean Basins, Figure 4 Age-area histograms of ocean basins from 200 Ma to the present day in 40 Ma intervals. The histograms reflect changes in the average age of the ocean basins through time, from a generally older ocean floor at the time of Pangaea breakup to generally young seafloor in the Cretaceous corresponding to the Cretaceous seafloor spreading pulse, toward an aging and deepening of the ocean basins toward the present day.

American plate relative to the slow moving Caribbean plate causing the opening of the Cayman Trough (Figure 3j, k). Subduction of Atlantic Ocean crust is observed along the Lesser Antilles Trench.

Ocean gateways

The present-day oceanic realm is divided into numerous large ocean basins, the Pacific being the largest. Each of these ocean basins is surrounded by continental areas and connected to neighboring oceans via narrow, shallow, and diffuse connections, called oceanic gateways. These oceanic gateways are focal points for the large-scale exchange of heat, water, salinity, and genes between the oceans and play a major role in influencing global climate, ocean circulation, and species diversity. The most well-known examples of ocean gateways include the Tasman Gateway, Drake Passage, Fram Strait, Panama Isthmus, Greenland–Scotland ridge, Tethyan Seaway, and Indonesian Throughflow. Their shape, size, and depth change over geological timescales and are largely controlled by large-scale lateral and vertical motions of the many blocks and basins that form during protracted periods of continental breakup and extension (or collision, uplift, and shortening during oceanic gateway closure). Global ocean basin reconstructions, such as those presented in Figure 3, provide a broad basis for assessing the opening and closure of deep-water ocean gateways through time and thus how plate tectonic movements influence global climate and oceanography. The physiographic reconstructions presented here highlight the timing of separation or amalgamation of continental blocks, assuming these areas to be rigid features. However, we know that extensive deformation occurs over protracted periods at plate boundaries. Therefore, the detailed evolution of many gateways such as the Drake Passage, the Tasman–Antarctic Passage, and the Panama gateway is dependent on understanding the subsidence history of submerged fragments of continental crust or volcanic arc fragments (Lawver et al., 2011). These are not included in the reconstructions presented in Figure 3.

Ocean basin physiography and the age-area distribution of ocean floor through time

Ocean basin reconstructions from 200 Ma to the present imply that old mid-ocean ridge flanks in the proto-Pacific and the Tethys oceans are gradually destroyed between 200 and 150 Myr ago, while new mid-ocean ridge systems are initiated in a stepwise fashion between the late Jurassic and early Cretaceous. This cycle leads to a substantial younging of the ocean basins from the Jurassic to the Cretaceous period, followed by a gradually aging of the oceanic lithosphere from the Cretaceous seafloor spreading pulse to the present day (Figure 4). The age-area distribution of ocean crust from 200 Ma to the present day implies a mid/late Cretaceous sea-level high linked directly to the transition from supercontinent stability to initial and mature dispersal, first creating many new mid-ocean

ridges and flanks, which later experience stepwise subduction (Müller et al., 2008b). These cycles can also be linked with long-term fluctuations in seawater chemistry, leading to alternations between so-called aragonite and calcite seas (Müller et al., 2013).

Summary and conclusions

Complete reconstructions of the physiogeography of the ocean basins, starting with the breakup of Pangaea, have only been achieved recently for the first time, reflecting the difficulties involved in recreating now vanished ocean basins and assimilating many types of geological and geophysical observations into complete models through time. Although these ocean physiogeographic reconstructions are limited as they only account for broad-scale processes, they do provide an essential framework for creating boundary conditions for understanding ocean circulation, sediment accumulation, and ocean chemistry through time, as well as paleoclimate and long-term sea-level fluctuations. Further studies on refining global plate motions within a deforming plate framework as well as accounting for vertical motions associated with areas of continental breakup and collision will lead to more accurate reconstructions of ocean basins.

PALEOPRODUCTIVITY

Paul Loubere
Department of Anthropology, Northern Illinois University, DeKalb, IL, USA

Definition

Biological productivity involves the synthesis of biogenic materials (skeletal and nonskeletal). Paleoproductivity refers to the record of synthesis in the past. Generally, the term is applied to production that occurred prior to times when direct measurements are available.

Introduction

Production can be primary, when organic matter is synthesized from inorganic antecedents (e.g., plant synthesis based on chemicals and sunshine), or secondary, when it is based on previously made organic matter. Most analysis of paleoproductivity aims to reconstruct past changes in primary production.

The interest in paleoproductivity stems mostly from research into three different issues in paleo-oceanic/paleoclimate studies. Ocean-basin-scale patterns of production reflect the location and extent of past/current systems. Also, regional changes provide information about variation in exchange between deep and surface ocean
Paleoproductivity, Figure 1 Distribution of marine algae in the surface ocean, revealed by chlorophyll concentrations (*darker green* = more chlorophyll) calculated from satellite observations (source: http://oceancolor.gsfc.nasa.gov/SeaWiFS/). Higher algal concentrations are associated with upwelling of deeper, nutrient-rich waters or with enhanced vertical mixing of the water column.

waters. Also, decay of settling organic material alters the chemical properties of the subsurface ocean (e.g., oxygen concentration). Finally, changes in both quantities and systems of production could influence global climate through regulation of atmospheric carbon dioxide content (Loubere, 2012; Sigman and Hain, 2012).

What controls marine production?

Biological production depends on the availability of sunlight and required macronutrients (classically: carbon, nitrogen, phosphorus) and micronutrients (with iron receiving most attention, Sarmiento and Gruber, 2006; Boyd et al., 2007). The intensity of sunlight useable by phytoplankton (marine algae, the dominant marine primary producers) depends on latitude, water depth, water clarity, and water column stability. Latitude controls the day length and the angle of the sun on the sea surface. Water depth is important because light intensity drops exponentially with depth and penetration is generally negligible below 50–100 m. Because of this, any production over most of the ocean will depend on populations of floating algae. A stable water column will be resistant to vertical mixing, which means that plankton can remain close to the sunlit surface most of the time. Near shore, an unstable water column and vertical mixing can lead to increased turbidity from sediments, reducing light.

Essential nutrients are concentrated at depth in the oceans, so resupply for upper ocean plankton consumption depends on processes which bring deep water to the surface (Figure 1; upwelling, deep vertical mixing; Sarmiento and Gruber, 2006). Some nutrients are also delivered by rivers and prevailing winds (as dust). Supply depends on continental geography and climatology.

New production: a key global environmental variable

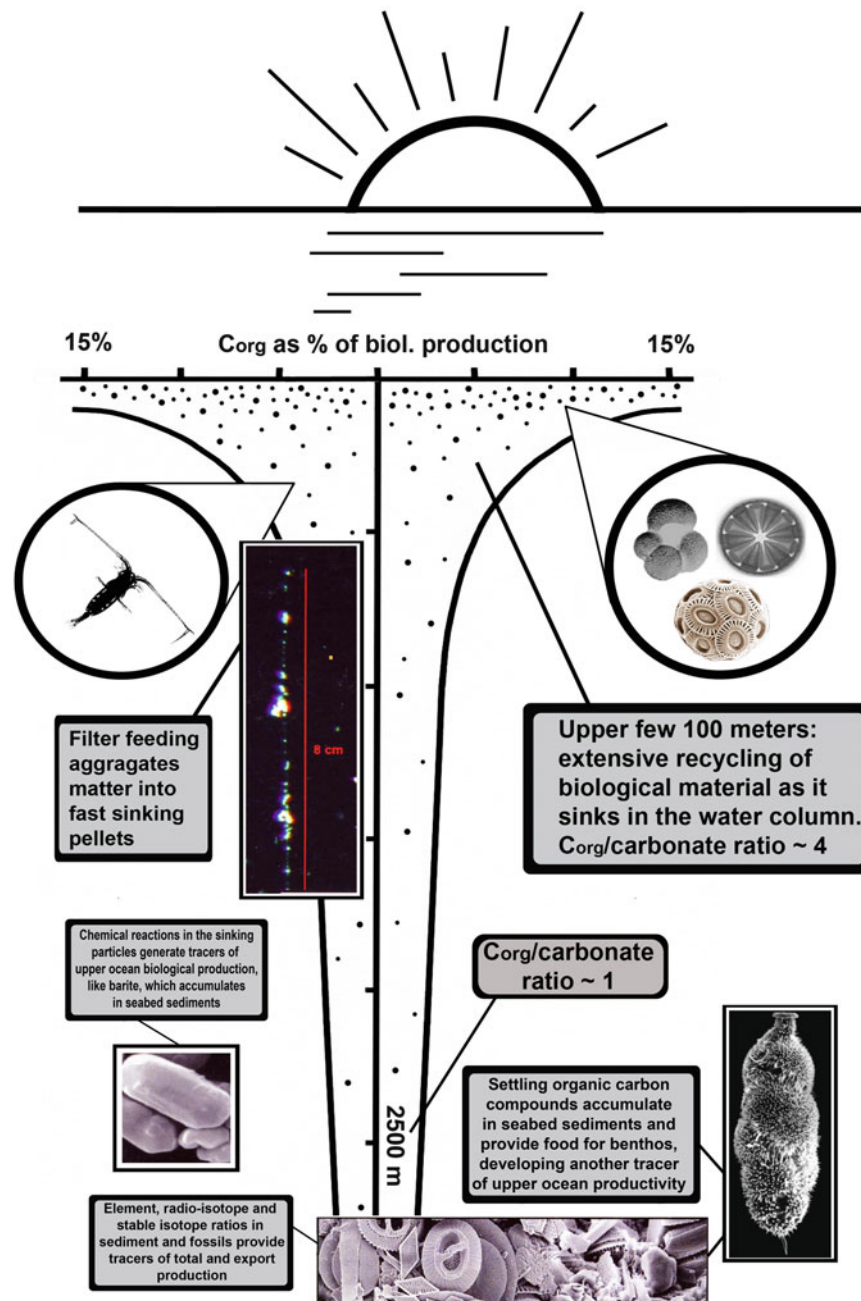
Algal primary production in the oceans is based on locally recycled nutrients and on "new" nutrients supplied from the deeper ocean reservoir (Sarmiento and Gruber, 2006). In most of the ocean, the majority of production is maintained by local recycling of nutrients in the near-surface water column. Since this recycling is not 100 % efficient, however, there is transfer from the shallow to the deep ocean. Consequently, replenishment of the surface, via upwelling and mixing, is necessary for biological production to continue (Palter et al., 1991).

The supply of biological materials to the seafloor and geological record depends on the production engendered from the "new" nutrients reaching the upper ocean. This is different from the "total" (recycled + new) production which biologists routinely measure. In this way, analysis of paleoproductivity provides insight to the rates of exchange of waters (and their load of nutrients) between ocean depths and the surface. This vertical cycling of chemicals, since it includes carbon dioxide, is important to the global climate (Sigman and Hain, 2012).

The efficiency of biological recycling in the upper ocean's productive zone is not constant. Efficiency drops as production increases (Wassman, 1998; Antia et al., 2001). Variation of recycling efficiency and associated change in plankton communities can also affect the distribution of CO_2 in the oceans and global climate (Matsumoto et al., 2002).

Making a record of past changes in productivity

In principle, reconstruction of paleoproductivity should be simple, requiring only measurement of accumulation rates of sedimentary biogenic material. Sadly, this is complicated by a number of factors.

The materials incorporated into the ocean floor are those which were produced in the upper ocean, survived recycling in the upper water column while sinking, and then survived the passage to greater depth and the recycling processes at the seabed. Observations with sediment traps in the ocean have demonstrated that attenuation of sinking biological particles is strong, especially in


Paleoproductivity, Figure 2 Transfer of materials from the productive upper ocean to the deep sea. Plot of organic carbon flux with water depth as percent of total primary production (after Antia et al., 2001).

the upper few hundred meters of the water column (Figure 2; Antia et al., 2001; Honjo et al., 2008). There is an exponential decrease in flux with depth (flux = weight of material, per volume of water or area of seabed, per unit of time). Additionally, different components of the sinking material degrade at different rates, so the composition of the sinking material changes with depth. Particle incorporation into larger, fast sinking

pellets by filter feeders in the water column is important to material delivery to the seabed.

The changes in the flux of biological material through the water column are strongest for labile (high food quality) organic matter and for mineral matter which is undersaturated or reactive to the conditions in the water column or pellet environment. The latter includes, for example, silicate (as in the frustules of diatoms). By contrast, calcite

shell or bone material is far more resistant until carried to undersaturated conditions usually at considerable depth in the ocean (Dittert et al., 1999; Berger and Wefer, 2008) or within seabed sediments.

Interestingly, as organic matter undergoes diagenesis in sinking particles, reactions occur which add new material to the debris. The reactions lead to precipitation of new minerals, like barite. It appears that the amount of biogenic barite created is related to the quantity of reactive organic matter settling to depth (Paytan and Griffith, 2007). The diagenetic products accumulate at the seabed and can provide a record of biological organic matter production.

Diagenesis (recycling, consumption) continues at the seafloor, which is actually a highly reactive interface where biological activity and chemical reactions alter what arrives. Benthic fauna feed on reactive organic compounds and biotic activity combined with dissolution reactions destroy skeletal materials (Ragueneau et al., 2000; Zeebe and Wolf-Gladrow, 2001; Sarmiento and Gruber, 2006).

Tracers of past biological production

Historically, tracking paleoproduction was attempted first by measuring contents of organic carbon and carbonate in deep-sea sediments. In the equatorial Pacific, for example, there are distinct cycles of carbonate percent in Pleistocene-age sediments (Berger, 1992). Percent organic carbon content was also observed to vary regionally and in time, in ways that related to patterns of biological production in the ocean. However, the analysis of the carbonate cycles was confounded by argument about whether they were due to changes in production or preservation (Berger, 1992). The cycles could alternatively reflect variation in biological production in the upper ocean or changes in the properties of deep ocean waters (changes in degree of corrosiveness to carbonate) related to climate shifts.

The problem with contents is that, for each biogenic material, it depends on the supply and preservation of *all* the components going in the sediments, so interpreting content data is complicated. Because of this, measuring accumulation rates (weight of material accumulated per cm^2 of seabed per 1,000 years) offers a better avenue to reconstruction paleoproduction.

Accumulation rates of biogenic components have been used extensively to infer changes in productivity in times past. However, these rates are still subject to the problem of varying preservation (what accumulates is a function of supply minus diagenetic loss). Also, the simple use of accumulation rates for inference of supply changes assumes that delivery of materials from the surface ocean to the seabed is completely vertical, with no lateral transport or redeposition.

Examination of accumulation rates requires correction for changes in preservation and for possibly variable water column or seabed transportation. These issues remain problematic. Methods have been developed to quantify changes in carbonate preservation (Mekik et al., 2002), and methods based on thorium-230 concentrations in deep-sea sediments have been derived for measuring lateral sediment transport (Francois et al., 2004). Application of the method has produced some notable disagreements over the Pleistocene cycles of carbonate and organic carbon accumulation in the eastern equatorial Pacific (Loubere and Richaud, 2006).

Tracers not dependent on accumulation rate calculations offer escape from the complications described above. Relative abundances (percentages) of benthic (bottom dwelling) foraminifera (shell-producing microorganism) species in deep-sea sediments have been found to reflect flux of labile organic carbon reaching the seafloor. This is because the carbon flux is food to the benthic community whose ecology is structured depending on how large that flux is. Composition of benthic fossil assemblages has been empirically calibrated to both average annual organic carbon production and seasonality of that production for the open ocean (Loubere and Fariduddin, 1999a, b).

Tracers of paleoproductivity are also available in biogenic components which are thought to be highly resistant to alteration in the water column and seabed or whose characteristics are set in the upper ocean. These include barite (biogenic barite produced as explained above and a tracer of reactive organic carbon flux from the upper ocean), alkenones (lipids) whose concentration has been taken to reflect productivity of the *Prymnesiophyceae* algae (including coccolithophorids and *Phaeocystis*) (e.g., Sachs and Anderson, 2005), elemental ratios in pelagic sediments (Anderson and Winckler, 2005), and elemental or isotope ratios in planktonic material (e.g., Stoll et al., 2007; see Fischer and Wefer, 1999, pp. 315–468).

Has oceanic productivity varied in the past?

In principle, we would expect that global and regional marine productivity would vary in response to changes in nutrient concentrations in seawater and to the structure of the upper ocean water column (degree of stability influences availability of sunlight). In short to intermediate geological timescales, nutrient concentrations will depend on the whole ocean exchange between deep and surface waters and on regional patterns of upwelling and vertical mixing (Sarmiento and Gruber, 2006). Changes in ocean circulation should be linked to global climate change. On the longer geological timescale, ocean circulation will change in response to shifting continents, and nutrient concentrations might change in the global ocean due to variations in the ultimate supply, the erosion of continents (the key element phosphorus is an example; Filippelli, 2002).

On the grandest scale, strong decreases in marine biological productivity have been inferred for major extinction events in global history (e.g., Coxall et al., 2006). The exact causes are unclear as yet, but impacts on both planktonic community composition and changes in ocean circulation and nutrient supply likely all played a role.

Closer to the present, large changes in marine productivity have been inferred from the Neogene to Pleistocene glacial-interglacial cycles (e.g., Schmiedl and Mackensen, 1997; Diester-Haass et al., 2005; Loubere et al., 2011; Murray et al., 2012). These have been ascribed to changes in exchange between the deep and upper ocean (primarily in the Southern Ocean), change in strength of winds that induce upwelling in tropical regions, or fluctuating supply of micronutrients like iron. There is currently disagreement on the relative importance of the local, wind-related, and more distant, ocean circulation-related factors in productivity change.

Variation in exchange between the deep and surface ocean on the glacial-interglacial timescale provides a mechanism for explaining why atmospheric carbon dioxide concentrations have changed in step with climate change (and, indeed, helped cause it; Toggweiler, 1999). Another possible explanation is change in the relative fluxes of carbonate and non-carbonate biological material produced in the upper ocean and delivered to the deep sea (Matsumoto et al., 2002). A shift toward a higher ratio of organic carbon to carbonate in the sinking biogenic matter of the oceans could provide lower atmospheric carbon dioxide concentrations during glacial intervals. This requires a change in the relative production of different materials by the ocean's planktonic organisms. There is some evidence that this happened (Richaud et al., 2007).

Summary

Biological production in the oceans generates a complex mix of materials, much of which is recycled near the ocean's surface, but some of which sinks into the deep sea and influences global climate, as well as generates a record of past production. Tracking the history of the major components of production has only been partly accomplished due to complications with interpretation of that record. Nevertheless, the evidence, at least qualitatively, shows clearly that oceanic biological production has been variable in the past in ways linked to global climate and oceanographic conditions.

PALYNOLOGY (POLLEN, SPORES, ETC.)

Anne de Vernal
Centre GEOTOP, University of Québec in Montréal, Montréal, QC, Canada

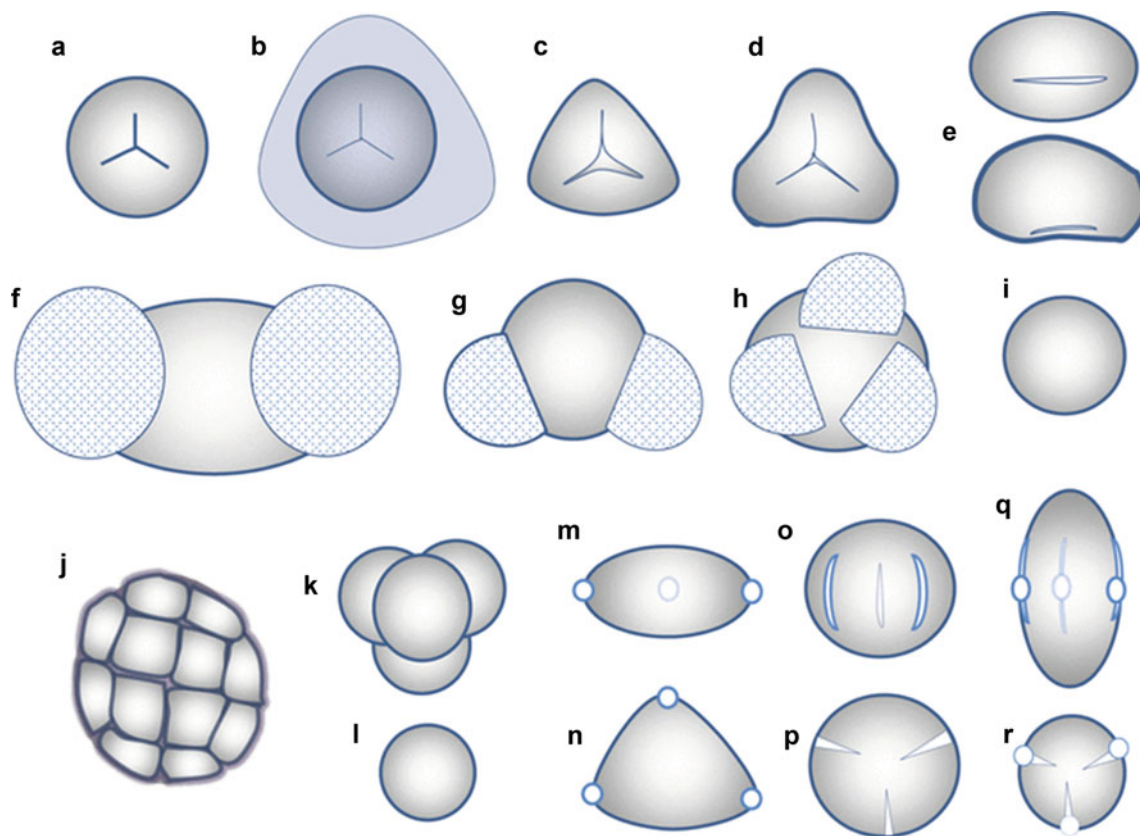
Palynology sensu stricto and sensu lato

The word "palynology," which is the study of pollen, comes from the Greek word palunein (to sprinkle) in reference to the pollen that is sprinkled as dust during the blooming season. Palynology became a scientific discipline in the early 1990s after the pioneer works of Lennart von Post, a Swedish geologist who produced the first pollen diagrams based on the identification and count of pollen grains from peat deposits, to reconstruct the postglacial vegetation of Western Europe (cf. Manten, 1967). Since then, palynology has been widely used to reconstruct the history of vegetation through time and past climate/environmental conditions. In botany and ecology, palynology is often associated with the study of pollen from flowering plants. In geosciences at large, palynology is used in a much broader sense because palynological slides prepared from sediment for the observation of pollen grains in optical microscopy contain many other biogenic remains. By extension, palynology thus corresponds to the study of all microfossils composed of highly resistant organic matter, also called sporopollenin, which is recovered after chemical digestion of carbonate and silica particles with hydrochloric and hydrofluoric acid treatments, respectively.

In marine sediments, the acid-resistant organic-walled microfossils or palynomorphs may include remains from the planktonic organisms such as cysts of dinoflagellates (or dinocysts), phycoma of prasinophytes, acritarchs, tasmanids, cysts and lorica of tintinnids, copepod eggs, etc. (e.g., Jansonius and McGregor, 1996). They may also include organic linings of benthic foraminifers (de Vernal et al., 1992) and allochthonous remains from freshwater environments such as Chlorococcales (e.g., *Pediastrum* spp.), in addition to pollen and spores from the terrestrial vegetation (e.g., Traverse, 2007). Here, we focus on pollen and spores that are particularly useful in marine geosciences as they permit land-sea correlations in addition to the reconstruction of past vegetation and climate in terrestrial areas from where pollen and spore assemblages originate.

Sediment sample processing for pollen analyses

The preparation of sediment samples for palynological analyses consists in mechanical and chemical procedures to concentrate organic-walled microfossils (e.g., Traverse, 2007; de Vernal et al., 2010). Mechanical procedures include wet sieving for eliminating small silt size and sand fractions and/or dense liquid separation. Chemical procedures consist in hydrochloric acid (HCl) and hydrofluoric acid (HF) maceration to dissolve carbonate and silica particles. They may also include oxidation with potassium hydroxide (KOH) or acetolysis, which is a treatment with acetic anhydride $((CH_3CO)_2O)$ and sulfuric acid (H_2SO_4) to eliminate labile organic matter. While oxidation techniques are often used for pollen and spore studies from lake sediment or peat, they are avoided in marine palynology as they can alter the preservation of some marine palynomorphs such as dinoflagellate cysts. Moreover, the palynology of marine sediment rarely requires oxidation as the organic carbon content is generally low especially in deep-sea settings due to its degradation in the water column and because of diagenetic processes.

Pollen and spores are usually observed, identified, and counted with optical microscope at $\times 400$ to $\times 1,000$


Palynology (Pollen, Spores, etc.), Figure 1 Schematic illustration of the main morphological types of spores and pollen grains. (**a**–**e**) Spores from seedless plants: trilete spores with circular shape (**a**) and a perine (**b**), trilete spores with subcircular and triangular shape (**c**, **d**), monolete spores (**e**). (**f**–**i**) Pollen grains of gymnosperms: bisaccate pollen of conifers in proximal (**f**) and lateral (**g**) views, polysaccate pollen of fossil gymnosperm (**h**), and inaperturate pollen without saccus (**i**). (**j**–**r**) Angiosperm pollen grains: polyade (**j**), tetrad (**k**), and single pollen grains with no aperture (inaperturate (**l**)), with pores (**m**, **n**), colpi (**o**, **p**), and colpi and pores (**q**, **r**). The figures **m**, **o** and **q** show oblate, spherical, and prolate pollen grains in equatorial view, and the figures **n**, **p** and **r** show the same pollen types in polar view. The schemes of figures **m**–**r** correspond to pollen type with three apertures: triporate, tricolpate, or tricolporates. Any combination with 1 to >10 apertures in equatorial or evenly distributed position is possible and serves in identification key. Beyond the geometry of apertures in pollen grains, the structure of the exine and ornamentation are important criteria for taxa identification.

magnification. Ideally, a minimum of 200 or 300 pollen grains are identified and counted for calculation of concentration (number of pollen grains per dry weight or volume) and percentages of taxa. The resulting spectrum (pollen representation in a given sample) is then combined with others to prepare a diagram of pollen assemblages against depth or age, which provides a picture of pollen input changes through time. Concentration can be estimated from the analyses of an aliquot of the sample from the marker-grain method, which consists in adding a known number of exotic grains to the sample (e.g., Matthews, 1969; de Vernal et al., 2010).

Systematics, biology, and morphology of spores and pollen grains

Spores and pollen grains directly relate to the reproductive stage in the life cycle of land plants also designated as embryophytes. Hence, the systematics of pollen grains and spores follow that of the plant kingdom, with taxa designated after the botanical name of their corresponding plants.

Spores are produced by seedless plants, including mosses (bryophytes), club mosses (lycophytes), and ferns (pteridophytes). They develop in capsule or sporangium on the sporophyte and are adapted for dispersal and survival over extended periods. Spore germination produces gametophytes, which in turn produce the sperms and eggs merging into a zygote to form a new sporophyte. Spore size ranges from 5 to 150 μm. The content of the spore is protected by a membrane composed of sporopollenin, which can fossilize. The membrane or sporoderm is usually characterized by a simple shape (round, triangular, ellipsoid, or bean shaped) and by an aperture, which can be simple (monolete slot) or triaxial (trilete slot) (see Figures 1a–e and 2a–f). The sporoderm can be
Palynology (Pollen, Spores, etc.), Figure 2 Photographs of common spore and pollen taxa. The magnification is the same for all photographs and the scale shown in **a** is 10 μm. (**a–f**) Photographs of spores from seedless plants: trilete spores of *Sphagnum*, which belongs to bryophyte (**a**); trilete spores of the pteridophyte *Osmunda* (**b**); trilete spores of the lycopodiophytes *Lycopodium* (**c**, **d**) and *Selaginella* (**e**); monolete spore of undetermined pteridophyte (**f**). Photographs of pollen grains from conifers: bisaccate pollen grain of *Picea* (**g**) and *Pinus* (**h**) and vesiculate pollen of *Tsuga* (**i**). (**j–s**) Photographs of pollen grains from angiosperms: Cyperaceae (**j**), Poaceae (**k**), *Betula* (**l**), *Alnus* (**m**), Chenopodiaceae (**n**), *Artemisia* (**o**), Tubiflorae (**p**), *Quercus* (**q**), *Salix* (**r**), and Rosaceae (**s**).

characterized by ornamentation (reticulation, ridges, spines, etc.), and some taxa may have an outer wall called perine.

Pollen grains are produced by seed plants or spermatophytes, which involve reproduction on the sporophyte instead of reproduction with alternation of generations (sporophyte and gametophyte) as for seedless plants. Spermatophytes include the flowering plants or angiosperms (magnoliophytes) and the gymnosperms (pinophytes or conifers, ginkgophytes, gnetophytes, cycadophytes). The pollen grains contain the male reproductive body, which is protected by the exine, an envelope composed of sporopollenin. Pollen is formed in the anther of flowers or in the male cone of gymnosperms. When mature, pollen grains are blown away by wind or carried by animal vectors to fertilize either the ovule in the pistil of flowers or the female cones of gymnosperms. The fertilization of the ovule also called pollination can be referred to as anemophilous or entomophilous in the case of pollination from wind or insects, respectively. In general, anemogamous plants produce more pollen grains than entomophilous plants.

Pollen grains of gymnosperms are generally distinguished on the basis of their shape, subspherical with or

without vesicles or sacci (see Figures 1f–i and 2g–i). Conifer pollen grains are often characterized by a pair of sacci and are designated as bisaccate. The size of gymnosperm pollen is variable, ranging from about 10 μm in simple forms to about 200 μm for large bisaccate taxa.

The pollen grains of angiosperms have a great morphological diversity (see Figures 1j–r and 2j–s). They are identified on the basis of their geometry (spherical, oblate, prolate), the type of aperture (circular (pore) or elongate (colpus)), the number and distribution of apertures, the ornamentation (smooth, spiny, reticulate, striated), and structure of the exine or pollen grain outer membrane. Their size is usually comprised between 5 and 50 μm.

In contrary to many other microfossil groups, pollen grains and spores are characterized by homogenous morphology within their taxonomical categories, at family, genus, or species level. Hence, keys based on the abovementioned characters have been developed for the identification of pollen and spores (e.g., Faegri and Iversen, 1989; Moore et al., 1991; Reille, 1992; Kapp et al., 2000).

One particularity of pollen and spores is the chemical compound of the sporopollenin that forms the exine and sporoderm, respectively, and which consists in extremely resistant biological polymers (e.g., Traverse, 2007). The chemical composition of sporopollenin, however, is very complex and differs according to the taxonomical affinities of pollen and spores (e.g., Hemsley et al., 1993; Hemsley and Poole, 2004).

Evolution of land plants and pollen and spore stratigraphy

The evolution of land plants through the geological history has been mostly documented from microfossils, including pollen and spores. The land plants or embryophytes developed from green algae ancestors in the Paleozoic. Their first occurrence might be inferred from spores recovered in mid-Ordovician deposits dated of ca. 470–460 Ma (e.g., Steemans et al., 2009), and the diversification of vascular plants occurred in the Silurian about 420 Ma ago (e.g., Kenrick and Crane, 1997; Kenrick et al., 2012). Seedless plants remained dominant until about 320–300 Ma ago when the first spermatophytes developed. Seed plants were first represented by the gymnosperms, which diversified during the Carboniferous and Permian with the successive development of cycadophytes, ginkgophytes, gnetophytes, and pinophytes (e.g., Magallón et al., 2013). The occurrence of angiosperms or flowering plants, which are characterized not only by a reproduction from the sporophyte but also by flowers and protected seeds, took place much later but with a spectacular diversification of taxa during the Jurassic and early Cretaceous, from about 200 to 130 Ma (e.g., Magallón et al., 2013).

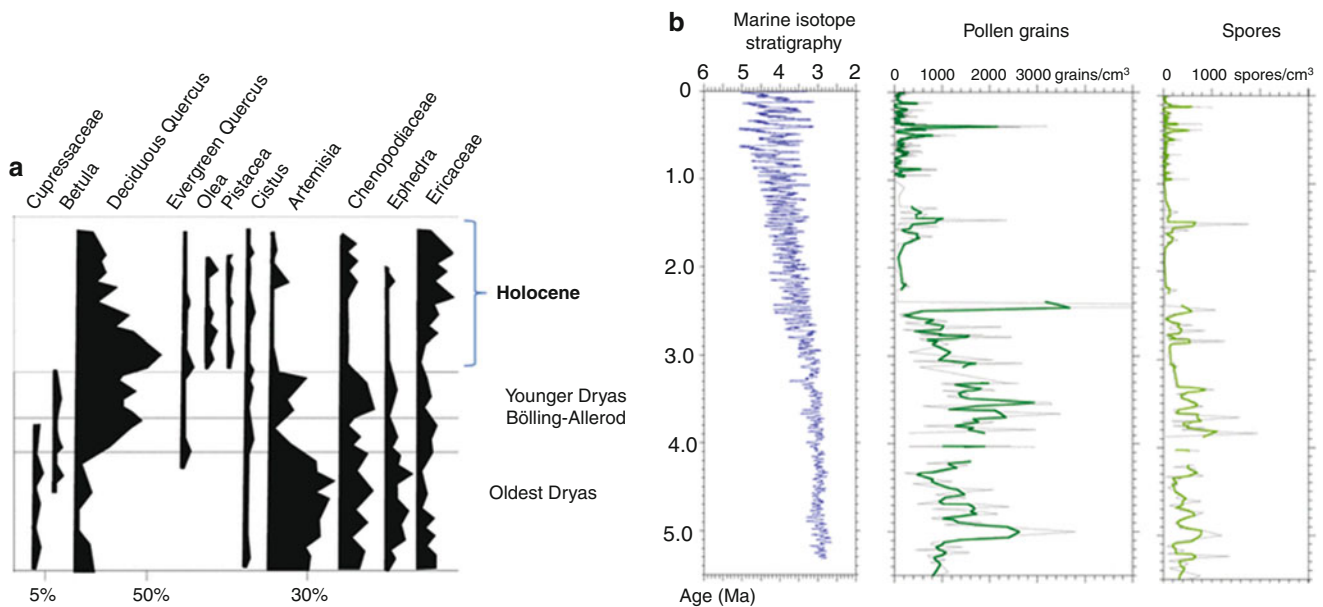
From a stratigraphical point of view, spores date from the Ordovician, whereas inaperturate and saccate pollen grains date from the Carboniferous. Pollen grains of angiosperms bearing pores and colpi range mostly from the Cretaceous.

Because the sporopollenin is highly resistant to diagenetic alteration, except under highly oxidizing conditions, all sedimentary rocks dating from the Ordovician to recent potentially contain fossil pollen and spores. Hence, reworked Paleozoic or Mesozoic pollen and spores are frequently recovered in late Cenozoic sediments. The distinction of "fresh" versus old reworked pollen and spores can be made from taxa identification and from the state of preservation as aged pollen grains and spores have lost the ultrastructure and fluorescent properties of their exine or sporoderm through diagenetic processes.

Pollen and spore transport into marine sediments

Pollen and spores are routinely recovered in marine sediments from coastal areas and continental margins. They are necessarily allochthonous, and their occurrence depends upon production in the source area in addition to transport mechanisms through air or water. Pollen and spore deposition decreases rapidly with the distance from source areas. Pollen grains produced at high elevation above ground, from the tree canopy, for example, are more prone to be carried by wind than pollen produced from the herb strata closer to the ground. Moreover, pollen grains from anemophilous plants have attributes fostering transport by wind. in particular, the pinophytes characterized by saccate morphology. In addition to atmospheric transport, hydrodynamic transport through runoff, rivers, and marine currents has to be taken into account.

The long-distance atmospheric transport of pollen results in a nearly asymptotic decrease of pollen and spore concentration with the distance of the source area (e.g., Rochon and de Vernal, 1994). It also results in important modifications of taxa percentages in assemblages, because of their selective transport by wind. For example, as shown from the distribution of pollen in surface sediment samples, there is an offshore overrepresentation of some tree taxa and especially of *Pinus* pollen grains that have particularly efficient aerial dispersion properties (e.g., Heusser and Balsam, 1977; Mudie, 1982; Sun et al., 1999).

The transport of pollen grains and spores with water is less selective than that in the atmosphere. In estuarine environment, deltas, and epicontinental seas, pollen grains and spores can be very abundant reaching concentration of 10^5 g^{-1}, which are comparable to those of lakes (e.g., de Vernal and Giroux, 1991; Marret et al., 2001; Traverse, 2007). Detailed studies from neritic settings along southwest European margins, where relatively humid climate prevails, have shown that most pollen and spores recovered in marine sediments are intimately related to fluvial inputs from adjacent lands, allowing direct land-sea correlations (e.g., Sánchez Goñi et al., 1999; see Figure 3a). In a different context, the distribution pattern of pollen grains off northwest Africa permitted to identify aeolian transport through trade winds, in addition to input by rivers,


Palynology (Pollen, Spores, etc.), Figure 3 Examples of pollen diagrams from marine sediment cores. (**a**) Summary pollen diagram (percentages of the main taxa) of the Late and Postglacial interval (last 15,000 years) from core SU8118 (37°46′N, 10°11′W; 3,135 m water depth) off the Iberian margin (Redrafted from Sánchez Goñi et al., 2000). High percentages of *Artemisia* during the Late Glacial indicate input from open tundra or steppic-like vegetation. The overall pollen assemblages permit direct correlation with the land-based climatostratigraphy (cf. also Sánchez Goñi et al., 1999). (**b**) Isotope stratigraphy from Lisiecki and Raymo (2005) and diagram of pollen and spore concentrations in Pliocene and Quaternary sediments at ODP Site 646 (58°12.56 N, 48°22.15 W; water depth 3,460 m) off southwest Greenland (cf. de Vernal and Mudie, 1989). Relatively high concentrations of pollen and spores are recorded in Pliocene sediments and some interglacial stages of the Quaternary, indicating inputs from dense vegetation on the Greenland (cf. also de Vernal and Hillaire-Marcel, 2008). Pollen assemblages are dominated by gymnosperm taxa (mostly *Pinus* and *Picea*), which are selectively transported over long distance, in addition to angiosperm taxa such as *Betula* and *Alnus*. Among spores, *Lycopodium* (lycopodiophytes) and *Sphagnum* (bryophyte) dominate.

which together relate to vegetation belt displacement on adjacent continents in response to climatic changes (e.g., Hooghiemstra et al., 2006).

The use of pollen and spores in marine geosciences

Pollen and spores are generally well preserved in sediments that contain a fine silt or clay-sized matrix. While oxidation can be an issue in some continental deposits, marine sediments are usually suitable for a good conservation of pollen grains and spores. Because pollen and spores originate from land vegetation, their occurrence relates to biogenic inputs from the continent. Hence, the ratio of pollen and spore versus marine palynomorphs such as dinocysts has been used to document the origin of organic matter, allochthonous versus pelagic, as the $\delta^{13}C$-values or C/N ratios, which also serve to identify organic input from land (e.g., Thibodeau et al., 2006; de Vernal, 2009). Since the sporopollenin of palynomorphs is less affected by early diagenetic processes than other organic compounds, the use of pollen/dinocyst ratio is particularly suitable to document the source of biogenic matter in sedimentary sequences. Moreover, the nature of pollen and

spores recovered in sediment may give a clue on erosional activity, notably from the occurrence of spores and pollen reworked from old sedimentary rocks (e.g., de Vernal and Mudie, 1989).

In marine geosciences, pollen and spores from sediment cores have been particularly useful to document the vegetation and climate over terrestrial areas adjacent to study sites and to establish land-sea correlations. Because such sedimentary sequences are more continuous than those in terrestrial setting, pollen and spore records from marine sediment cores revealed much useful in paleoclimatology. Examples can be given from Pleistocene and Holocene records that document large amplitude changes of climate over Western Africa (e.g., Dupont and Agwu, 1992), western North America (e.g., Heusser and Shackleton, 1979), New Zealand (Heusser and Van de Geer, 1994), or Western Europe (e.g., Sánchez Goñi et al., 2008; see Figure 3a). Other examples include records documenting variation in vegetation and climate in areas now occupied by ice sheet, such as Greenland (de Vernal and Mudie, 1989; de Vernal and Hillaire-Marcel, 2008; see Figure 3b) or Antarctica (Warny et al., 2009).

Advantages and disadvantages of palynological approaches in marine geology and paleoclimatology

Marine palynology is an important discipline in the field of marine geosciences with applications in biostratigraphy, paleoclimatology, and paleogeography. There are three main advantages of palynological approaches among other micropaleontological methods for the study of marine sediment. First, organic-walled microfossils such as pollen and spores are well preserved in sediments, whereas biogenic minerals such as opal silica and calcium carbonate are susceptible to dissolution leading to poor representation of the original diatom, foraminifer, or coccolith populations in the sediments. Second, organic-walled microfossils include representatives from several ecological settings (marine, terrestrial, lacustrine, pelagic, benthic) and all latitudes, from poles to equator, thus allowing assessment on the depositional environments, biogenic productivity, and biofacies, in addition to provide biostratigraphic markers. Third, among palynomorphs, pollen and spores occupy an important place for paleoclimatological studies as they permit to document the vegetation and climate. Hence, in marine environments, the advantage of their study is for establishing direct correlation between the continental and oceanic stratigraphy. Because terrestrial sedimentary sequences are usually discontinuous unlike marine series, pollen and spores offer a unique tool for direct land-sea correlation.

Palynological approaches, however, are moderately useful in distal offshore ocean settings characterized by oligotrophic conditions because of low concentration of palynomorphs, especially pollen and spores, making it difficult to do statistically representative counts. Another difficulty of the palynological approaches is the post-sedimentary reworking of palynomorphs that can be preserved despite erosion and subsequently transported with bottom current and redeposited. Hence, it is sometime difficult to distinguish reworked palynomorphs from others. Finally, one important limitation, which concerns mostly pollen and spores, is the fact that they necessarily relate to long-distance transport through winds and water resulting in distortion in the proportion of taxa and making it difficult to identify the precise source area.

Summary

Marine palynology is an extremely useful discipline as it may provide information on biostratigraphy in addition to environmental and climatic conditions. In particular, pollen grains and spores may give clues on terrestrial vegetation and climate, whereas the respective proportion of terrestrial and marine palynomorphs may provide indication on the paleogeography. The interpretation of palynological records from marine sediments is not unequivocal, and the transcription of pollen assemblages in terms of vegetation is not straightforward as it requires taking into account specific properties of pollen grains and spores: the species morphology and size as well as taphonomic

processes such as dispersion and sedimentation. Nevertheless, marine palynology offers one of the best means for direct land-sea correlations and linkage of paleoceanography with continental paleoclimatology.

PASSIVE PLATE MARGINS

Paul Mann
Department of Earth and Atmospheric Sciences,
University of Houston, Houston, TX, USA

Synonyms

Trailing edge margin, rifted margin, divergent margin, Atlantic-type margin, geosyncline (pre-plate tectonic term), pull-apart margin (used by some in the oil and gas community for non-strike-slip, Atlantic-type passive margins)

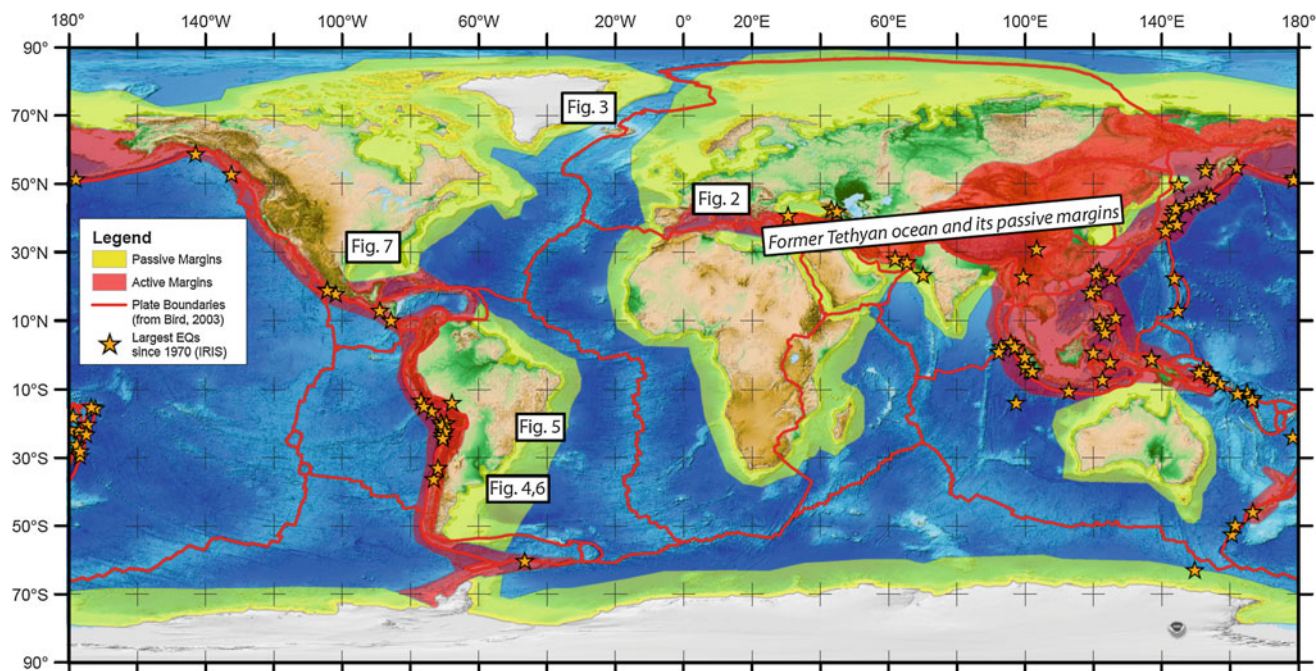
Definition

Passive margins are the most common type of crustal boundary on Earth with present-day passive margins having an aggregate length of 105,000 km which is greater than either spreading ridges (65,000 km) or convergent plate boundaries (53,000 km) (Bradley, 2008; Figure 1). In general, passive margins are not zones of crustal tectonic activity and therefore lack associated earthquake activity (Figure 1).

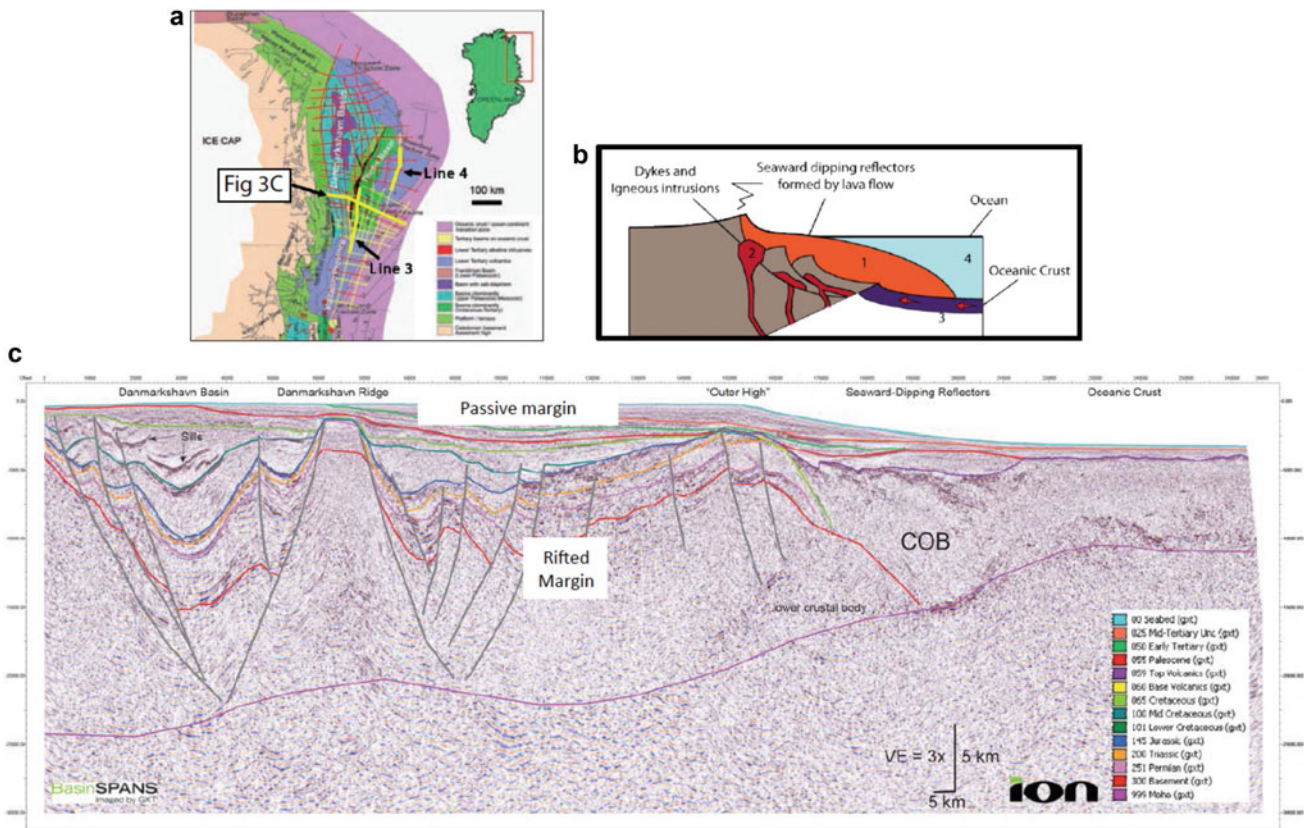
Passive margins are one of the main stages in the Wilson cycle of ocean opening and their ages, and ages of deformation are key indicators of the timing of ocean openings and closings through geologic time. Passive margins are known to contain a major part of the Earth's hydrocarbon reserves. In their compilation of giant oil fields of the world, Mann et al. (2003) identified passive margins as containing 35 % of the world's giant oil fields discovered up to 1999.

Passive margins are sedimentary wedges that overlie an inactive and subsiding weld between rifted continental crust and newly formed and younger oceanic crust. When rifting continental margins overlain by passive margins face each other, they are known collectively as "conjugate margins" as shown in the Black Sea example in Figure 2.

Rifted margins underlie passive margins

Passive margins are thick, sedimentary wedges overlying rifted, continental margins. The fundamental crustal weld or boundary for rifted continental margins is also called a "continent-ocean boundary"(COB) and can form narrow or broad features – as defined and imaged using deeply penetrating geophysical methods as seen in Figures 2, 3, 4, and 5. The stretched continental crust or "transitional crust" is generally characterized by seaward-dipping normal faults, a prominent "breakup" unconformity that records the end of the syn-rift phase, and an overlying, post-rift sag basin formed by slower and gradually dissipating thermal subsidence following rifting. Faulting deforming the passive margin section that postdates the breakup unconformity is commonly associated with gravitational sliding, rather than tectonically driven crustal deformation as observed on the western end of the Black Sea line as shown in Figure 2b.


Passive Plate Margins, Figure 1 Map of passive (*green*) and active (*red*) margins of the world modified from passive margin compilation by Bradley (2008). Stars show largest earthquakes since 1970 that are confined to the active plate margins shown with red shading. Locations of data shown in Figures 2, 3, 4, 5, 6, and 7 are indicated.

Note complexities in the conjugate passive margins including downslope slumping to the west and eruption of late Cretaceous-Eocene volcanoes to the east.


Passive Plate Margins, Figure 3 (**a**) Major tectonic elements of northeast Greenland from GEO ExPro (2010) showing existing, deep-penetration seismic data in yellow and planned lines in *red*. Location of line shown in **c** is indicated. (**b**) Schematic section of a volcanic passive margin with volcanic and intrusive rocks in *red* from https://en.wikipedia.org/wiki/Passive_margin. Note that layered, volcanic flows, or seaward-dipping reflectors, prograded onto oceanic crust in the area of the continent-ocean boundary. (**c**) Deep-penetration seismic profile (vertical scale is 30 km) showing the volcanic passive margin of northeast Greenland. The Danmarkshavn and Thetis basins are continental rift basins overlain by a relatively thin, passive margin section. The volcanic nature of the passive margin is indicated by the presence of sills in the Danmarkshavn rift, the presence of SDRs near the continent-ocean boundary (*COB*), and the nearby presence of a "lower crustal body" likely composed of high-density, intrusive rocks.

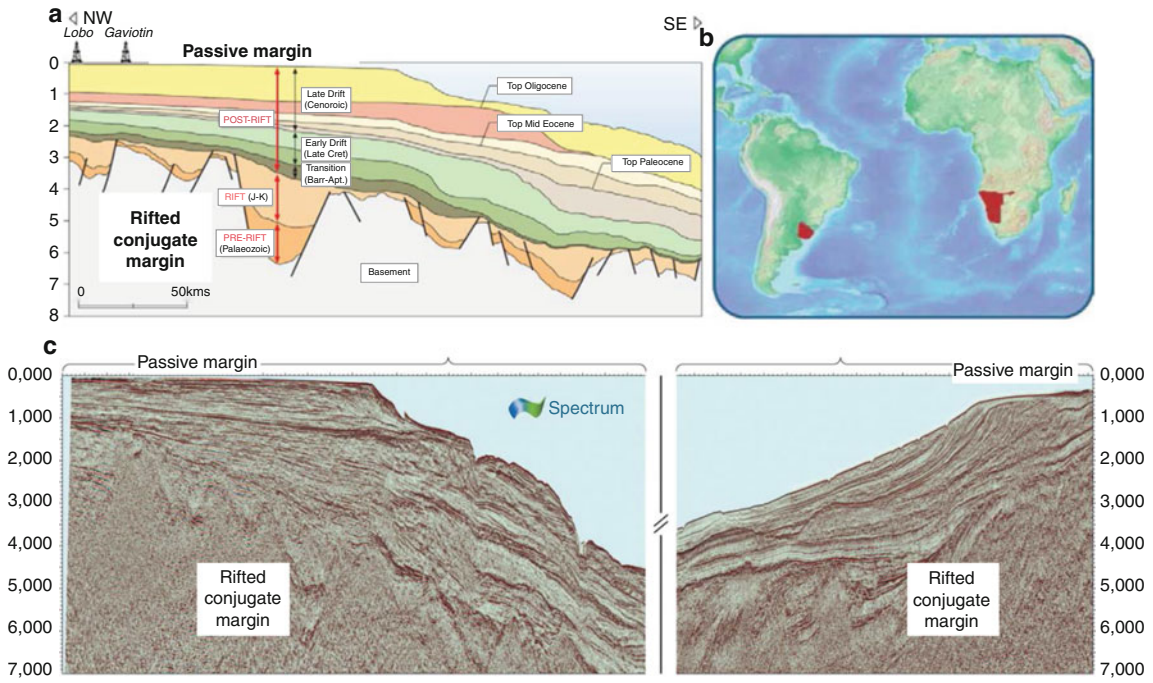
Tectonic origins of passive margins

The subsidence of passive margins is driven by thermal subsidence of the lithosphere following rifting and sea-floor spreading and for that reason forms the thickest sedimentary environments on Earth with up to 18 km of sedimentary rock, especially in the presence of deltas fed by river systems draining large continents. Due to their great thickness and wide extent, sedimentary rocks originally deposited along passive margins are commonly preserved in deformed, on-land mountain belts.

Passive margins occur as conjugate margins that originated as contiguous areas of continental crust that become separated by oceanic basins of varying widths and can be reconstructed by removing the area of oceanic crust and subtracting the width of extended continental crust deformed during the early rift period. Well-known examples of passive margins include the conjugate margins of the Arctic Ocean, most of the margins of Africa, Greenland, India, Australia, and the South Atlantic Ocean as shown on Figures 2, 3, and 4.

Passive margins are distinct from active margins that are characterized by strike-slip faulting, collisional faulting, and subduction-related faulting along major plate boundaries (Lallemand, this volume). Active margins exhibit plate-driven, active subsidence and uplift, and the occurrence of earthquakes in linear belts along the plate boundary (Figure 1). In addition to thermal subsidence, passive margins can locally exhibit active, gravity-driven deformation that includes both normal faulting in the higher elevation and updip areas and thrust faulting in the lower elevation and downdip areas. Downdip areas of thrust faulting are called "passive margin thrust belts" and are a major object of deepwater oil exploration (Rowan et al., 2004; Figures 6 and 7).

Passive margins in cross section

The direction of early rifting and continental separation fundamentally affects the cross-sectional profile of passive margins. Transform passive margins can form above former transform plate boundaries characterized by


Passive Plate Margins, Figure 4 Conjugate passive margins overlying rifted continental margins of Uruguay in South America and Namibia in West Africa now widely separated by oceanic crust of the South Atlantic Ocean modified from GEO ExPro (2012). (**b**) Sag basins of the passive margin modified from GEO ExPro (2012). Salt mobilization mainly occurs by sediment loading onto the salt layer, rather than downslope gravitational sliding.
Passive Plate Margins, Figure 6 (**a**) Map of the southeastern coast of Brazil showing location of the deep-penetration seismic lines of the Pelotas basin; the heavy *red line* is the line shown in **b**. (**b**) Deep-penetration seismic line of the Pelotas passive margin fold belt modified from GEO ExPro (2013). The updip zone of normal faulting gives way to a downdip zone of folding and thrusting. (**c**) Schematic cross section of a passive margin fold belt from Rowan et al. (2004) illustrating updip normal faulting and downdip shortening as seen in b.

transtensional faults, pull-apart basins, and narrow, marginal continental ridges parallel to the transform fault as observed in the equatorial region of the South Atlantic Ocean. Passive margins formed above rifts accommodating orthogonal extension are generally much wider that transform passive margins as can be observed for the passive margins bounding the South Atlantic (Figure 4).

Volcanic versus nonvolcanic margins

This distinction is determined from the amount of volcanism that accompanies the rifting process. Rift-related volcanism can occur in large piles of "seaward-dipping reflectors" centered near the continent-ocean boundary as seen in the Greenland passive margin (Figure 3). Nonvolcanic boundaries lack widespread and voluminous volcanic eruptions and are generally characterized by slower rates of extension and a higher degree of crustal stretching.

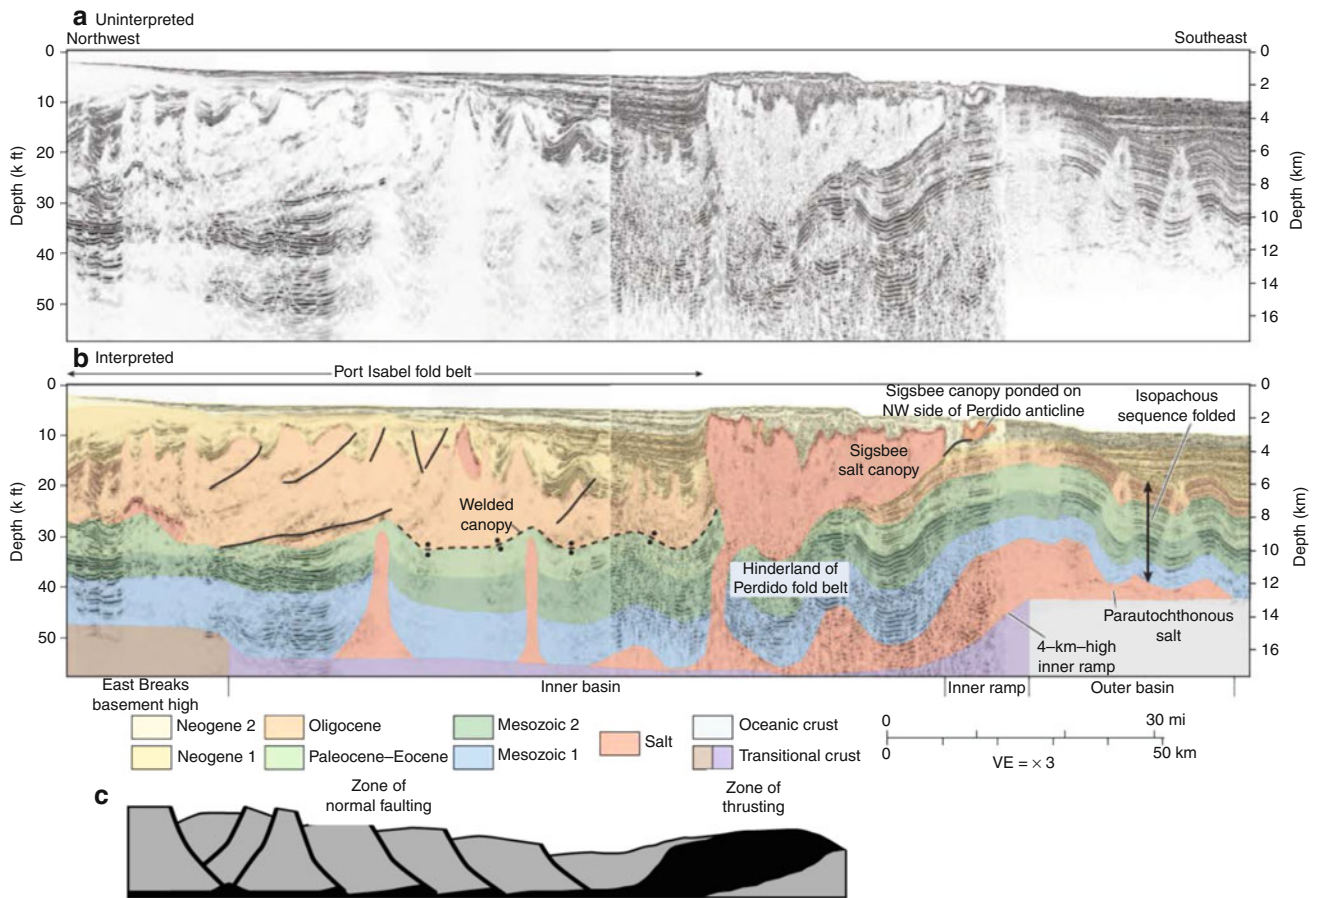
Passive margin morphology and sedimentation

In profile, wedge-shaped passive margins share common morphologies including a continental shelf, a continental slope, a continental rise, and an abyssal plain, although these can vary in width, largely controlled by the

extensional or strike-slip origin of the margin (Figure 4). Wedge-shaped geometries as seen on Figure 4 result from the seaward progradation of shelf facies into deeper water.

Accommodation space for continued sedimentation is driven by continued thermal subsidence of the underlying and rifted continental crust and lithosphere. Sea-level lowstands imprint passive margins with canyons incised into the outer continental rise and slope. Semicircular protuberances on passive margins generally mark the sites of either active river deltas, including the modern deltas of the Mississippi, Nile, and Amazon deltas, or ancient deltas no longer connected to an active river system. Deltaic settings on passive margins are excellent areas for the concentration of hydrocarbon resources due to the merger of high-quality, "big river" sandstone reservoirs, maturation of source rocks due to the enhanced burial by the delta, and structural traps related to gravitationally induced stabilities of the delta front. Examples of productive, large deltas include the Mississippi, Nile, and Niger.

Sag basins as transitions between rifting and passive margins

Sag basins above rifts and below passive margins represent structural and stratigraphic transitions between the rift


Passive Plate Margins, Figure 7 (**a**) Uninterpreted seismic line through the Port Isabel passive margin fold belt of the northern Gulf of Mexico from Hudec et al. (2013). (**b**) Interpreted seismic line from **a** showing a large fold forming above the 4-km-high step between continental crust to the northwest and oceanic crust of the southeast. (**c**) Schematic cross section of a passive margin fold belt from Rowan et al. (2004) showing how the extrusion of a large salt mass in the lower contractional zone.

sequence below and the unfaulted, passive margin sequence above (Figure 5). Sag basins in areas like Brazil are less deformed by gravitational movements of passive margin fold belts and more affected by salt tectonics activated by sedimentary loading (Figure 5). Sag basins have been shown in recent years to be excellent habitats for petroleum due to their more moderate faulting than the underlying rift basin, their finer-grained facies – including high-quality, lacustrine source rocks and carbonate-hosted reservoir rocks – and regional sealing by overlying evaporate deposits.

Definition and significance of passive margin fold belts

Passive margin fold belts are broad zones of deformed passive margin deepwater areas that have resulted from the horizontal translation of the post-rift cover driven by gravitational failure of the margin (Rowan et al., 2004). Margin failure – occurring on a large scale and spanning zones that are hundreds of kilometers wide – is driven by a combination of gravity gliding above a basinward-

dipping detachment and gravity spreading of a sedimentary wedge with a seaward-dipping bathymetric surface. For example, the Pelotas passive margin of Brazil exhibits an updip zone of normal faults that generally dips seaward and soles onto a basal, basinward-dipping detachment (Figure 6). The upper surface of the passive margin also forms a seaward-dipping bathymetric surface. Sliding occurs on a mobile salt layer. The base of the zone is characterized by a zone of thrusting that is more narrow than the upslope zone of normal faulting (Figure 6). These thrusts also sole onto the same basinward-dipping detachment as the normal faults upslope. The material between the thrusts is folded and forms large folds at the level of the seafloor.

The Port Isabel passive margin fold belt in the northern Gulf of Mexico is wider and more complex than the Pelotas example. In this case, the downslope transport of material has occurred on two different salt detachments with the upper plane largely evacuated of salt and marked by a weld (Figure 7). A 4-km-high inner ramp marks the COB (oceanic side to the south in the Gulf of Mexico is

higher; stretched continental crust to the north is lower) (Hudec et al., 2013). This preexisting crustal ramp causes the salt at both levels to ramp upward to form a large anticlinal structure in the contractional part of the passive margin fold belt that contrasts to the smaller and more distributed folds in the Pelotas example shown in Figure 4. Both the more distributed folds and single larger fold localized along the crustal ramp provide excellent structural traps for hydrocarbons in these deepwater, passive margin settings.

PERIDOTITES

Eric Hellebrand
Department of Geology & Geophysics, SOEST,
University of Hawaii, Honolulu, HI, USA

Definition

Peridotites are the main lithology of the Earth's upper mantle. According to the IUGS classification (Le Bas and Streckeisen, 1991), they are defined as a coarse-grained ultramafic rock type, containing more than 40 % olivine. Other minerals that coexist with olivine are low-Ca orthopyroxene (opx), high-Ca clinopyroxene (cpx), and chromian spinel (always present in very low modal abundance). In oceanic mantle rocks, plagioclase can also occur as a minor phase in about 20 % of all collected samples, attesting to a low-pressure (<0.8 GPa) reequilibration predicted by laboratory experiments. At high pressures (>2.5 GPa), spinel peridotites transform into garnet peridotites, which have not been found on the ocean floor, but which are occasionally brought to the Earth's surface as xenoliths in Ocean Island Basalts.

Peridotite subgroups

Peridotites are subgrouped into:

– Dunites (>90 % olivine)
– Harzburgites (<5 % cpx, >5 % opx, 40–90 % olivine)
– Wehrlites (<5 % opx, >5 % cpx, 40–90 % olivine)
– Lherzolites (>5 % opx, >5 % cpx, 40–90 % olivine)

Abyssal peridotite

Peridotites exposed on the ocean floor are called "abyssal peridotites." Hydrothermal interaction with seawater at or near the seafloor transformed most of the mantle minerals into serpentine. Despite the seawater overprint, original minerals can still be identified, and mineral proportions can be reconstructed by point counting. Most abyssal peridotites are harzburgites and lherzolites. Dunites are rare, wehrlites are exceptionally rare. Pyroxenites, which are also coarse-grained ultramafic mantle rocks, mainly occur as rare cm-dm sized veins inside peridotite (Dick et al., 1984).

Melting processes

The MORB source, depleted MORB mantle (DMM), is believed to be dominantly composed of fertile lherzolite. During adiabatic decompression melting, basaltic components are incrementally removed from the peridotite. With increasing degrees of melting, the modal abundance of cpx decreases until all cpx is exhausted, producing a refractory harzburgite. Higher degrees of melting, which would turn harzburgites into dunites, are generally not found at mid-ocean ridges. Instead, dunites are interpreted as former melt transport channels, an inference largely built on observations in ophiolites. At subduction zones, where flux melting in the presence of slab-released fluids reduces the melting temperature of peridotite, melting can continue beyond cpx-out, leading to more refractory residues.

PHOSPHORITES

Hermann Kudrass
MARUM-Center for Marine Environmental Sciences,
University of Bremen, Bremen, Germany

Definition

Phosphorite is a sedimentary component consisting of a significant portion of phosphate minerals, mostly francolite of the apatite group. Some large deposits with a high concentration of phosphorite possibly have an economic value.

Phosphorite types and regional distribution

Phosphorite mainly consists of microcrystalline francolite, a calcium fluorapatite, which is chemically and mechanically stable in most marine sedimentary environments. Phosphorite occurs in various forms and shapes as pellets, ooids, peloids, nodules, laminae, crusts, and friable nodules; as phosphatized shells, tests, whale bones, and coprolites; as phosphatized limestone clasts, chalk surfaces, and hardgrounds, as well as molds of foraminiferal tests and mollusk shells; and as a fill of cracks in manganese crusts. This variety reflects different types of authigenic precipitation, diagenetic replacement, and repeated mechanical reworking (Bentor, 1980; Föllmi, 1996). Fine-grained phosphorites and friable phosphatic nodules are often dispersed in diatomaceous ooze, while the coarser phosphoritic components are typical for sedimentary hiatus and often associated with glauconitic sand.

Most of the phosphorite-bearing sediments occur in the condensed sediment sequences of the western tropical and subtropical continental margins, which have a long history of upwelling (Figure 1). The predominant portion of this phosphorite is relict deposit from the Miocene. Isolated phosphorite occurrences on seamounts of the western Pacific Ocean are mostly early tertiary phosphorite-bearing manganese crusts or fossil guano deposits.

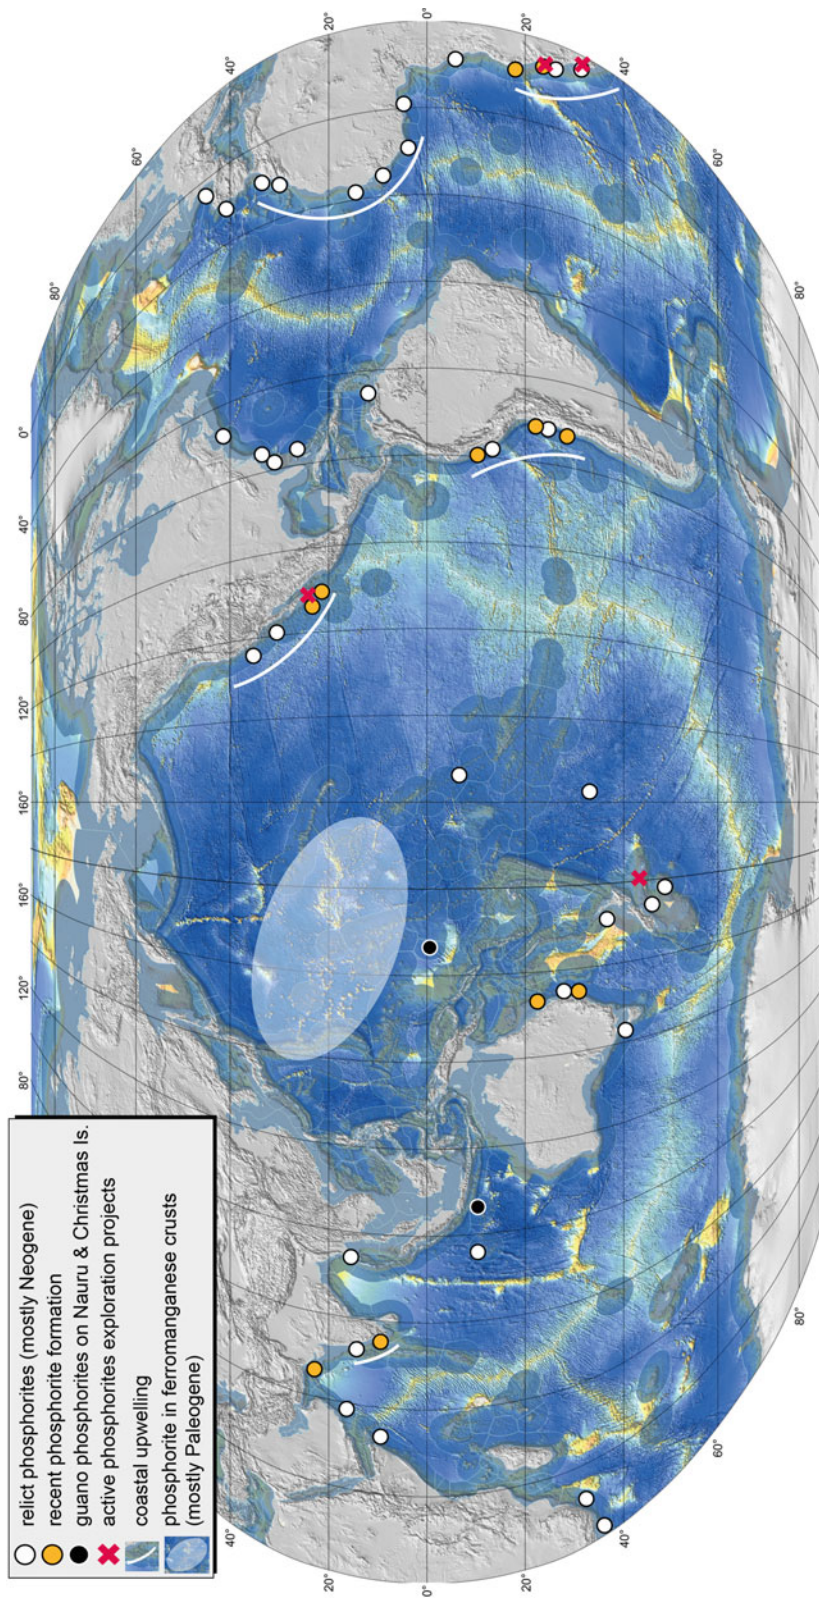
Authigenic precipitation and diagenetic phosphatization

Modern precipitation of phosphorite is confined to the upwelling areas off Baja California/Mexico (Jahnke et al., 1983), Peru (Burnett et al., 2000), Chile (Schulz and Schulz, 2005), Namibia (Baturin 2000; Goldhammer et al., 2010), and the margins of the Arabian Sea (Schenau et al., 2000; Figure 1). In these fertile areas the high flux of marine organic detritus with a C:P ratio of 106–117:1 from the productive zone at the surface to the sea floor is the main sink of phosphorus in the oceans (Benitez-Nelson, 2000).

The decay of the highly reactive organic detritus creates suboxic to anoxic conditions in the water masses on the shelf and upper continent slope. In this environment abundant colonies of the sulfur bacteria like the genera *Beggiatoa*, *Thioploca*, and *Thiomargarita* flourish in uppermost 10-cm layer of the Corg-rich sediments. These bacteria feed on the rich organic material by oxidizing hydrogen sulfide from the mud with nitrate from the sea water. In their cells they accumulate polyphosphate as an additional energy supply, which can be rapidly released during oxic/anoxic changes of the bottom water (Schulz and Schulz, 2005; Goldhammer et al., 2010). Consequently the phosphate concentration in the pore water becomes high enough to precipitate as Ca phosphate (Schenau et al., 2000), to phosphatize carbonate components, or to precipitate with calcium and fluorine as francolite. The authigenic francolite or its precursor phases preferentially aggregate on existing phosphorite grains forming laminae or ooids (Arning et al., 2009). In addition, but with much smaller contributions, dissolved phosphorus near the surface of the upwelling mud can be released by the comparatively slow decay of organic material, by the desorption from oxic/hydroxic iron phases (Froelich et al., 1988), and the direct input from organic phosphates from fish and cetacean teeth and bones (Suess, 1981).

Formation of phosphorite mineral deposits

Deposition of marine organic matter in coastal upwelling systems is the main sink for phosphorus in the oceans (Benitez-Nelson, 2000), and most phosphorite deposits presumably originated in this oceanographic setting. As the content of phosphorus in the marine organic matter is close to 1 %, the accumulation of a large phosphorite deposit requires many cycles of mud deposition and phosphorus sequestration. The recent diatomaceous ooze of the Namibia upwelling system, which is accumulating with a rate of 0.5 cm year^{-1}, contains about 6 µmol cm^{-3} phosphorus in the marine organic matter (Goldhammer et al., 2010). The entire organic-bound phosphorus contained in 30-m-thick Namibian mud would produce a condensed layer of 0.6 g phosphorus cm^{-2} accumulated in 6,000 years. However, as only a small portion of the phosphorus of the organic matter is finally transferred into phosphorite (Föllmi, 1996; Schenau et al., 2000) and as the bacterial-mediated phosphorite precipitation is concentrated in the uppermost 10 cm of sediment, the upwelling sediments had to be frequently removed for concentrating the phosphoritic grains.

Thus upwelling, the associated phosphorite precipitation and episodic reworking must have continued over much longer periods to produce a sizable phosphorite


Phosphorites, Figure 1 Distribution of upwelling areas and occurrences of relict and recent phosphorites (Modified from Föllmi 1996). Ongoing offshore exploration projects are indicated.

deposit. Climatic cycles like the presently active El Niño/La Niña changes of the upwelling areas off Peru and Chile with their drastically changing current regimes offer a suitable model for reworking with a decadal frequency. Sea-level changes with a much smaller frequency are further significant agents to enrich the dispersed phosphorite aggregates in lag deposits (Föllmi, 1996). Thus, the larger phosphorite deposits off South Africa (Compton et al., 2002), Baja California/Mexico (D'Anglejan 1967), and on the Chatham Rise/New Zealand (Kudrass and von Rad, 1984), which are presently explored by various industrial groups, have a complex accumulation history, which probably extends over several hundred thousand years (Arning et al., 2009; Burnett et al., 2000).

Summary

Phosphorite deposits are confined to upwelling at continental margins, where a high flux of organic material supplies phosphorus to the sea floor. In this environment anaerobic sulfur bacteria concentrate and release phosphorus, which then precipitates as francolite. The formation of a phosphorite deposit requires a long-term delicate balance of mud sedimentation and episodic reworking, and consequently phosphorite deposits only accumulate at continental margins with a very slow average sedimentation rate.

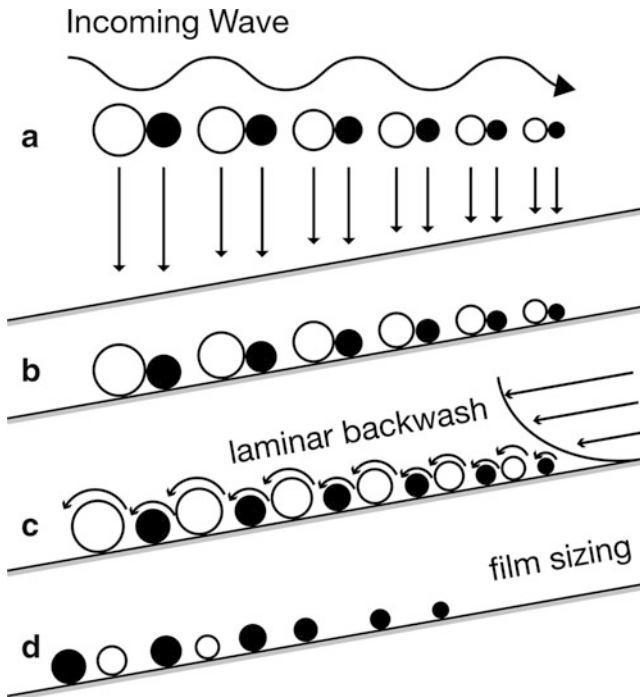
PLACER DEPOSITS

Hermann Kudrass
MARUM-Center for Marine Environmental Sciences, University of Bremen, Bremen, Germany

Placer deposits are accumulations of dense "heavy" minerals ($\rho > 2.85$ g cm^{-3}), which are enriched in comparison to the common "light" minerals ($\rho < 2.65$ g cm^{-3}) like quartz and feldspar. The placer minerals must be mechanically and chemically stable to survive weathering and transport in rivers and along the beach. Most of the placer minerals have a grain size of fine and medium sand (63–250 µm), and they can only be enriched to form commercially interesting deposits under special sorting conditions at the beach. In the highly turbulent flow of the waves entering the surf zone, light and heavy minerals are jointly transported according to the principles of hydraulic equivalent diameters (Figure 1a, Rittenhouse, 1943), i.e., grains of larger light minerals are suspended and deposited together with smaller heavy minerals with the same settling velocity (Figure 1a, b). A strong vertical gradient develops in the laminar flow at the bottom-water interface of the water masses flowing back from the beach. Thus, larger grains of light minerals are faster transported, and the smaller heavy minerals are enriched as a lag deposit (Figure 1c). With a continuing supply of unsorted sediment, this panning and film sizing processes can form finely laminated heavy-mineral deposits (Figure 1d).


Placer Deposits, Figure 1 Transport and enrichment of light (*circles*) and heavy minerals (*solid*) in the surf zone (modified from Seibold and Berger, 1993).

Rutile (TiO$_2$), ilmenite (FeTiO$_3$), magnetite (Fe$_3$O$_4$), zircon (ZrSiO$_4$), monazite ((Ce,La,Th)PO$_4$), and garnet (Fe$_3$Al$_2$(SiO$_4$)$_3$ are the commercially most important minerals in these beach placer deposits. In most shelf areas, the placer deposits formed during glacial periods of lower sea-level were not preserved, as the bulldozing effect of the transgrading sea completely destroyed the former deposits or partially moved them landwards (Kudrass, 1987). The Holocene transgression disseminated a rich placer deposit with ilmenite, rutile, and zircon on the outer shelf off the Zambezi mouth/Mozambique (Beiersdorf et al., 1980). The magnetite-bearing shelf sediments off the North Island/New Zealand are another potential offshore placer deposit.

The more dense heavy minerals like cassiterite (SnO$_2$, $\rho = 7$ g cm^{-3}) and gold (Au, $\rho > 15$ g cm^{-3}) usually are coarser grained, and consequently these minerals are transported as bed load in the river beds. Their offshore deposits as the cassiterite deposits of Sundaland between Indonesia and Malaysia are exploited from drowned river valleys, which originated during glacial periods of lower sea-level. Diamonds (C, $\rho = 3.5$ g cm^{-3}), the most valuable heavy mineral, are presently mined on the shelf off South Africa and Namibia from beach deposits and the coarse sediments directly overlying the rocky bedrock (Garnett, 2000a). Moraines of the high latitudes may locally contain rich gold placers in Alaska (Garnett, 2000b) and offshore New Zealand.

PLATE MOTION

R. Dietmar Müller and Maria Seton
School of Geosciences, The University of Sydney, Sydney, NSW, Australia

Definition

Plate motion can be relative or absolute. Relative plate motion describes the motion of one tectonic plate relative to another. Absolute plate motion describes the motion of one plate relative to a fixed reference system. Plate motion can be described by a pole of rotation and an angular velocity about this pole.

Introduction

A tectonic plate is defined as a portion of the outer shell of the Earth that moves coherently as a rigid body without any significant internal deformation over geological time-scales. The Earth's surface is composed of a mosaic of rigid plates that move relative to one another over hotter, more mobile mantle material. Plates interact at plate boundaries, which are dynamically evolving and continuous features.

History

Alfred Wegner's idea of "continental drift" (Wegener, 1915) to explain the geometrical, geological, environmental, and paleontological similarities between now distant continents lacked a physically plausible mechanism to explain the vast distances travelled by the continents. The interpretation of ocean floor data during a rapid increase in seafloor mapping after World War II led Hess

(1962) and Dietz (1961) to propose the concept for sea-floor spreading. They suggested that new seafloor is created at mid-ocean ridges, where a cold, strong surface boundary layer diverges, dividing tectonic plates. The new seafloor then spreads away from the mid-ocean ridge as it ages and is eventually subducted at deep-sea trenches, where it detaches from the surface and is recycled back into the Earth's convecting mantle. Wilson (1965) developed the concept of plates and transform faults, suggesting that the active mobile belts on the surface of the Earth are not isolated but continuous and that these mobile belts, marked by active seismicity, separate the Earth into a rigid set of plates. These active mobile belts consist of ridges where plates are created, trenches where plates are destroyed, and transform faults, which connect the other two belts to each other.

Euler's theorem

All tectonic plates can be viewed as rigid caps on the surface of a sphere. The motion of a plate can be described by a rotation about a virtual axis that passes through the center of the sphere (Euler's theorem). In terms of the Earth, this implies that a single angular velocity vector originating at the center of the globe can describe the motion of a plate. The most widespread parametrization of such a vector is using latitude and longitude to describe the location where the rotation axis intersects the surface of the Earth and a rotation rate that corresponds to the magnitude of the angular velocity (in degrees per million years or microradians per year). The latitude and longitude of the angular velocity vector constitute the so-called Euler pole (Figure 1).

Plate tectonic hypothesis

The formal hypothesis of plate tectonics states that the Earth is composed of an interlocking internally rigid set of plates in constant motion. These plates are rigid except at plate boundaries, which are lines between adjoining plates. The relative motion between plates gives rise to earthquakes; these earthquakes in turn define the plate boundaries. There are three types of plate boundaries: (1) divergent boundaries, where new crust is generated as the plates diverge; (2) convergent boundaries, where crust is destroyed as one plate dives beneath another; and (3) transform boundaries, where crust is neither produced nor destroyed as the plates slide horizontally past each other. Not all plate boundaries are as simple as the main types discussed above. In some regions, the boundaries are not well defined because the deformation there extends over a broad belt, a plate-boundary zone (Gordon, 2000). These plate-boundary zones tend to have complicated geological structures and earthquake patterns as they involve at least two large plates and one or more microplates caught up between them.
Plate Motion, Figure 1 Euler's theorem describes the motion of a tectonic plate by a rotation about a virtual axis that passes through the center of the sphere. The Euler poles are the intersections between the rotation axis and the surface of the sphere. *Small circles* describe the angular motion of a given plate. The set of *small* and *great circles* describing the rotation pole coordinate system is equivalent to a tilted (rotated) version of the familiar geographic coordinate system of the Earth represented by parallels and meridians.

Relative plate motions
Present-day plate motions

Relative plate motions at the present are represented by so-called instantaneous rotations described by angular velocity vectors and follow standard vector algebra, i.e., the angular velocity vectors $_A\mathbf{w}_B$ and $_B\mathbf{w}_C$ describing the rotations of plate B relative to plate A and plate C relative to plate B can simply be added vectorially to obtain $_A\mathbf{w}_C$, the rotation of plate C relative to plate A. Models of present-day plate motions are often called "geologically current" plate models and can be measured using satellite technology (e.g., GPS measurements (Argus and Heflin, 1995) or space geodesy (Argus et al., 2010)) and/or a number of other observations:

1. The orientation of active transform faults between two plates can be used to compute their direction of relative motion. The relative motion of two plates sharing a -mid-ocean ridge is assumed to be parallel to the transform faults and in turn assumed to follow small circles. Based on two or more transform faults between a plate pair, the intersection of the great circles, which are perpendicular to the small circles paralleling transform faults, approximates the position of the rotation pole (e.g., Morgan, 1968).

2. The spreading rates along a mid-ocean ridge as determined from magnetic anomaly patterns (e.g., Müller et al. (2008)) can be used to compute a rotation pole, since the spreading rate varies as the sine of the colatitude (i.e., angular distance) from the rotation pole.

3. Fault plane solutions (focal mechanisms) of earthquakes at plate boundaries can be utilized to compute the direction of relative motion between plates. Only the location of the pole, but not the spreading rate, can be determined this way. A global model for current plate motions based on data of types (1), (2), and (3) has been constructed and reviewed by DeMets et al. (2010), utilizing data which cover 3.2 million years of plate motion.

4. Geological markers are used along plate boundaries on land, in particular along strike-slip faults, to determine geologically recent local relative motion. Markers used include streambed channels, roads, and field boundaries that have been offset by strike-slip motion.

5. A satellite method called very-long-baseline interferometry (VLBI) uses quasars as signal source and terrestrial radio telescopes as receivers. The difference in distance between two telescopes is measured over a period of years.

6. Satellites have made it possible to measure present-day plate motions in real time at many more stations than possible using the VLBI technique, which depends on permanent radio telescopes as the receivers. Satellite laser ranging techniques using the Global Positioning System (GPS) have been used very successfully recently to measure plate motions all over the world, especially in areas that are subject to earthquake hazards. A current plate motion model based on a few decades of GPS data was constructed by Kogan and Steblov (2008).

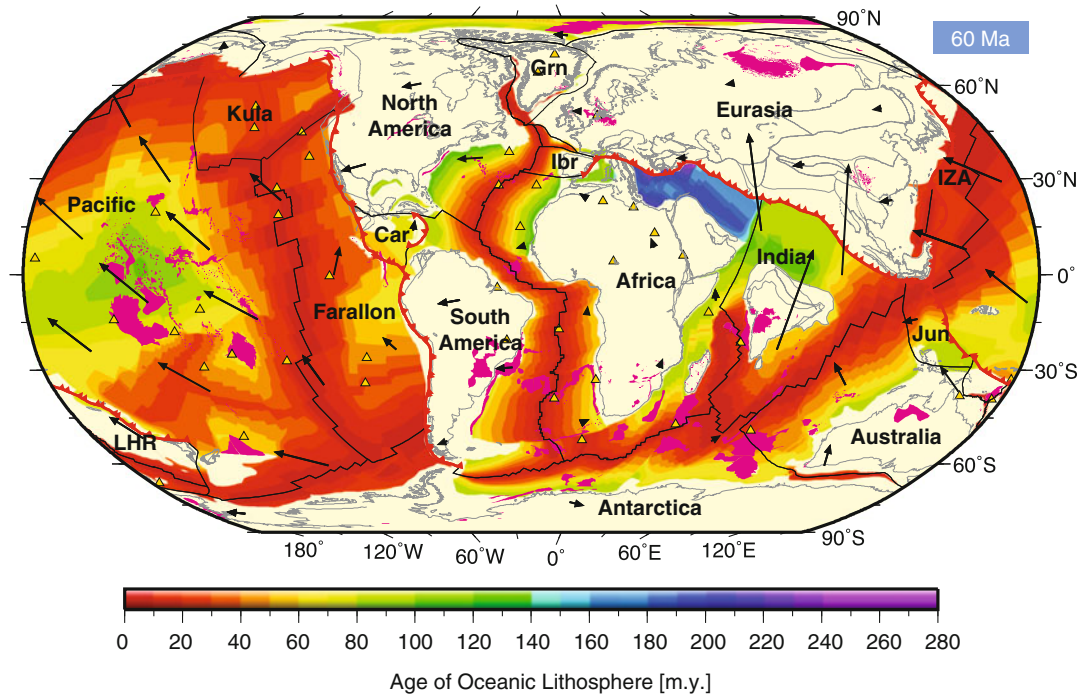
7. Coupled geodynamic plate models, which model plate boundary locations and mantle density heterogeneity, have been used to predict present plate motions (e.g., (Stadler et al., 2010)). These predicted motions are entirely model driven and sensitive to the mantle properties used but can be compared to present-day observations.

Plate motions through geological time

The reconstruction of plate motions through geological "deep" time requires the use of finite rotations whose manipulation is considerably more complex than those used for current plate motion (Cox and Hart, 1986). Relative plate motions for plate pairs which have preserved ocean floor generated by seafloor spreading at a common mid-ocean ridge can be reconstructed by fitting marine magnetic anomalies and fracture zones from conjugate ridge flanks. The Earth's magnetic field experiences reversals over geological time, leading to linear bands of ocean crust magnetized during a normal or reversed state of the Earth's magnetic field as seafloor spreading progresses. Thus, the ocean floor acts like a giant tape recorder and the magnetic anomalies caused by the alternating bands of normal and reversely polarized crust on the ocean floor can be fitted back together with the additional aid of fracture zones (Matthews et al., 2011), which are passive traces left on the seafloor by the transform fault offsets at mid-ocean ridges. A qualitative method for fitting such data visually ("visual fitting method") is provided by the community GPlates software (Boyden et al., 2011), and a quantitative method including the computation of uncertainties ("Hellinger method") has been developed by Hellinger (1981) and Chang (1988).

When only one flank of a spreading system is preserved due to partial subduction of an ocean basin, the computation of rotations describing plate motion is more complicated and relies on a "half-stage rotation" methodology described by Stock and Molnar (1988). This method involves computing a stage rotation between adjacent seafloor spreading isochrons on one flank and doubling the angle (assuming spreading symmetry) to obtain a "full-stage rotation." In instances where crust from both ridge flanks has been subducted, we rely on the onshore geological record (e.g., mapping of major sutures, terrane boundaries, and active and ancient magmatic arcs) to help define the locations of paleo-plate boundaries and use inferences from younger, preserved crust to estimate earlier spreading directions and rates. Where continental terranes have crossed ocean basins, a combination of paleomagnetic and geological data can be used to reconstruct terrane migration (Stampfli and Borel, 2002) and the now subducted ocean basins (Seton et al., 2012).

Absolute plate motions

Absolute plate motions represent the motion of individual plates relative to a reference system regarded as fixed, such as the Earth's mesosphere or the center of the Earth, in accordance with the forces that drive the plates. Relative plate motions are merely consequences of absolute plate motions, yet absolute plate motions are much more difficult to reconstruct. The main methodologies to constrain absolute plate motions are based on paleomagnetic data and volcanic hot spot tracks (Torsvik et al., 2008). Paleomagnetic data can be used to determine the orientation and latitude of a plate through time. However, since the Earth's magnetic dipole field is radially symmetric, paleo-longitudinal information cannot be deduced from paleomagnetic data alone. Seamount chains with a linear age progression (i.e., hot spot tracks) can be used to restore plates to their paleopositions with the assumption that hot spots are either fixed or nearly fixed relative to each other ("fixed hot spot hypothesis" (Morgan, 1971)). In considering seamounts and island chains as markers of past plate motion over stationary hot spots, Morgan (1971, 1972) suggested that such trails should form sets of co-polar small circles on the Earth's surface as a consequence of Euler's theorem for plate motions on a sphere. Wessel and Kroenke (1997) refined this method by introducing


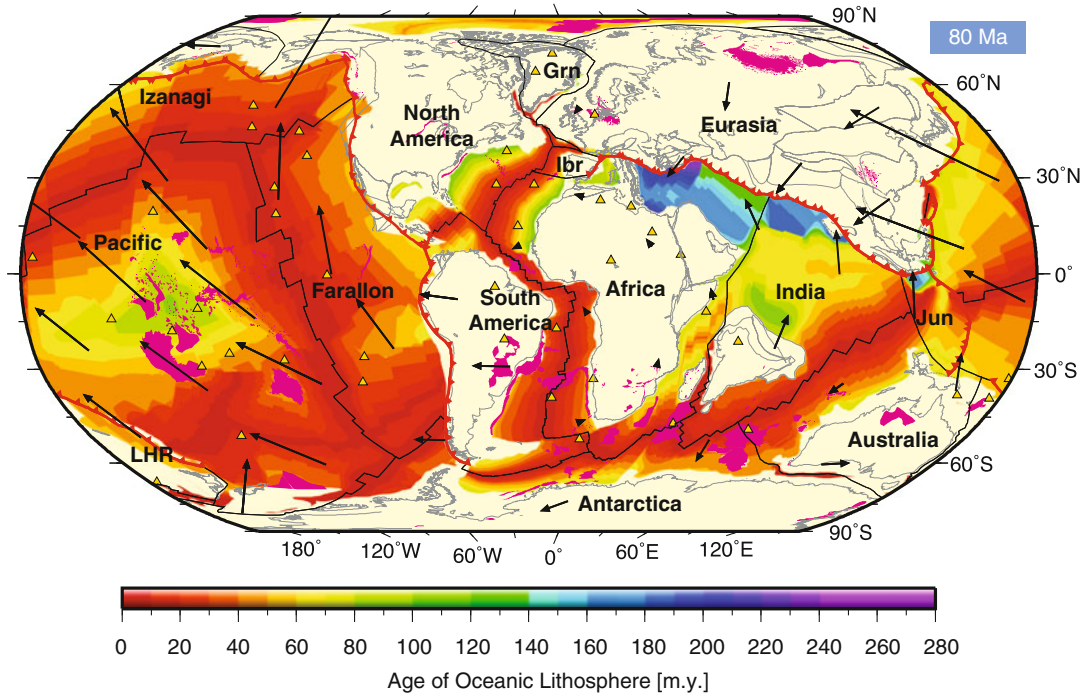


Plate Motion, Figure 2 (continued)
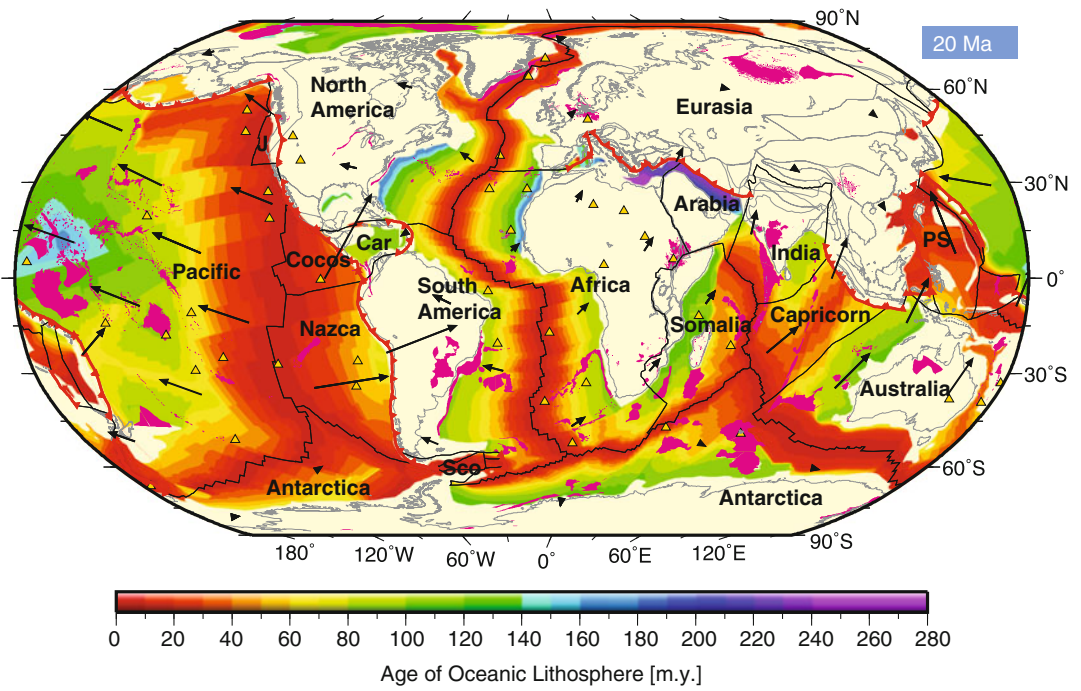

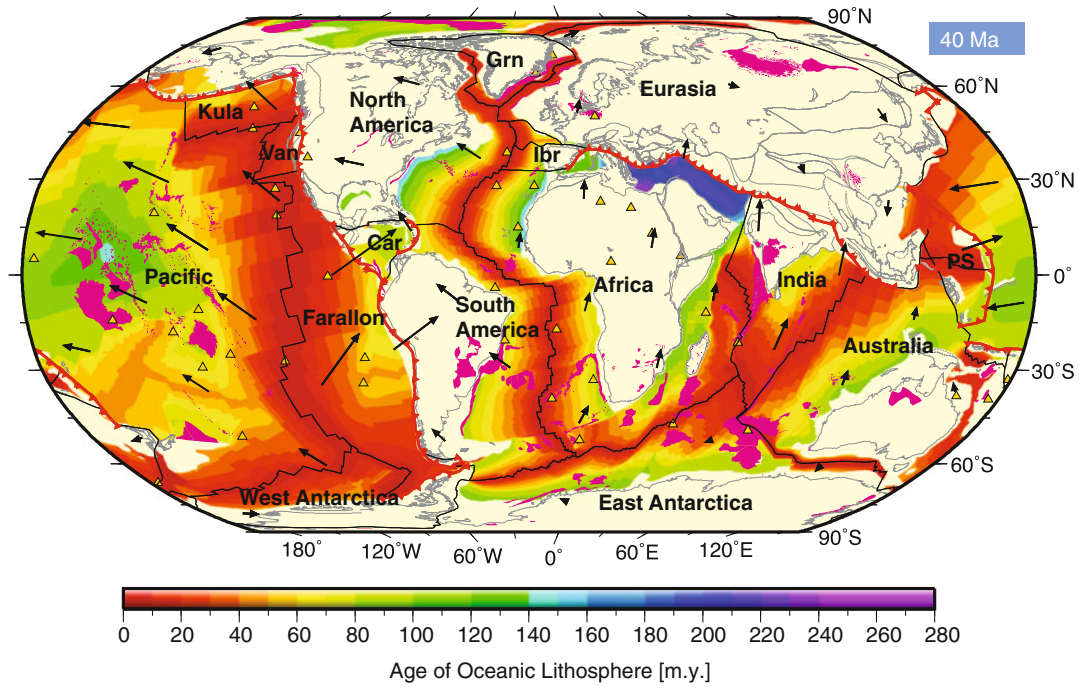

Plate Motion, Figure 2 (continued)
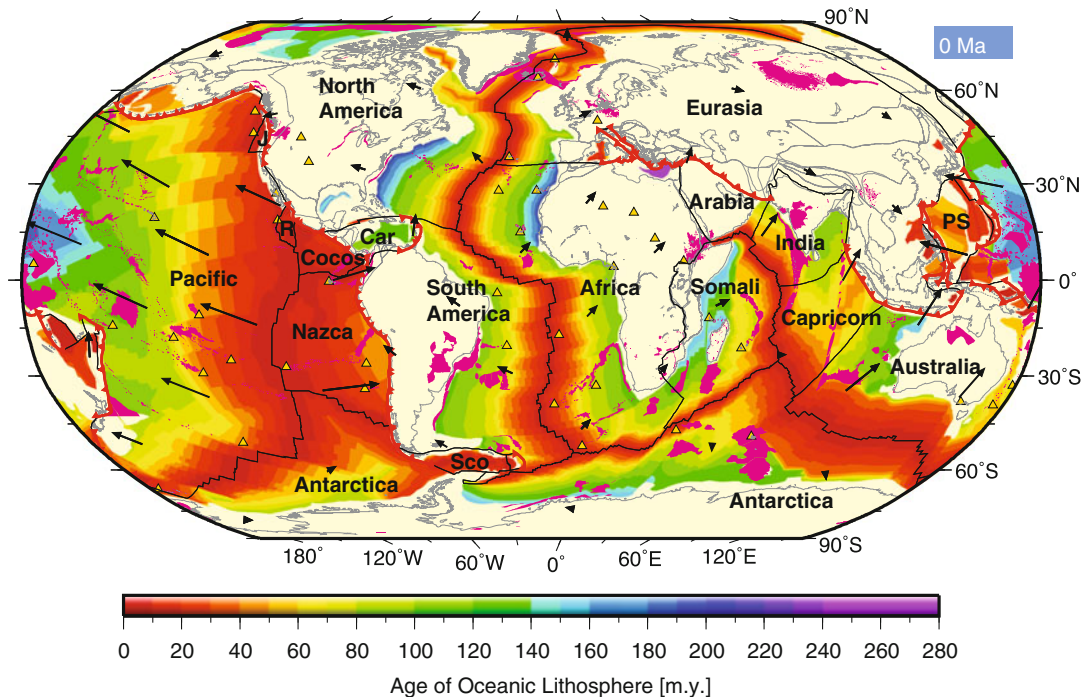

Plate Motion, Figure 2 Global plate reconstructions from 200 Ma to the present day in 20 million year time intervals. Base map shows the age-area distribution of oceanic lithosphere. *Red lines* denote subduction zones and *black lines* denote mid-ocean ridges and transform faults. *Pink polygons* indicate products of plume-related excessive volcanism (e.g., LIPs and volcanic plateaus). *Yellow triangles* indicate present-day hot spot locations. Absolute plate velocity vectors are denoted as *black arrows*. Major plates are labeled. Abbreviations include *Car* caribbean, *Col* colorado, *Flk* falkland, *Grn* greenland, *Ibr* iberia, *J* juan de fuca, *Jun* junction, *LHR* lord howe rise, *Man* manihiki, *Pat* patagonia, *PS* philippine sea, *R* rivera, *Sco* scotia sea, *Van* vancouver.

the "hot-spotting" technique which constructs seafloor flow lines backward in time using a combination of seamounts with and without age constraints. Another class of models combining plate motion and mantle convection (Steinberger and O'Connell, 1998) is designed to move away from the fixed hot spot hypothesis and consider the deflection of plumes through time in a convecting mantle. Absolute plate motion models in which seamount chains with age progression are assumed to be due to the interaction of plates relative to non-stationary hot spots are termed moving hot spot models (Doubrovine et al., 2012; O'Neill et al., 2005). Moving hot spot models only work well for the last 70–100 million years at most and thus require a changeover to an alternative reference frame (e.g., paleomagnetic-based) for earlier times. These models, which combine reference frames using two techniques, are termed "hybrid models." Another complication for constructing absolute plate models is the process of true polar wander, the wholesale rotation of the Earth relative to its spin axis (Torsvik et al., 2002). True polar wander is believed to occur mainly in response to the changing mass distribution in the Earth's convecting mantle due to the time dependence of subduction (Steinberger and Torsvik, 2010). When true polar wander is much faster than the average speed of the tectonic plates, it is expressed in all plates on the same hemisphere exhibiting the same sense of rotation. This method can be used to construct a true polar wander corrected absolute plate motion model (Steinberger and Torsvik, 2008).

Global plate motion models through time

The most up-to-date global plate motion model is that by Seton et al. (2012). It combines relative and absolute plate motions in a global plate model, including the reconstruction of the global network of plate boundaries and the plates themselves through time. It uses a hybrid reference frame, which merges a moving Indian/Atlantic hot spot reference frame (O'Neill et al., 2003) back to 100 Ma (from "Megannum," meaning millions of years before present) with a paleomagnetically derived true polar wander corrected reference frame (Steinberger and Torsvik, 2008) back to 200 Ma. This reference frame links to the global plate circuit through Africa, as Africa has been surrounded by mid-ocean ridges for at least the last 170 million years and has moved relatively little since the breakup of the Pangaea supercontinent. The model (Figure 2) is freely available on the internet in a GPlates-compatible (Williams et al., 2012) format.

Pre-200 Ma plate motions are based entirely on continental paleomagnetic data due to the absence of preserved seafloor spreading histories. Although paleomagnetic data on continents do not provide paleo-longitudes, the relative plate motions and tectonic unity of two continental blocks can be inferred from commonalities in the apparent polar wander (APW) paths (Van der Voo, 1990). If two or more continents share a similar APW path for a time period, then it can be inferred that these continents were joined for these times. Similarly, tectonic affinities can be deduced from the continuity of orogenic belts, sedimentary basins, volcanic provinces, biofacies, and other large-scale features across presently isolated continents (Wegener, 1915). A community plate motion model covering most of the Phanerozoic Eon, i.e., the last 550 million years, has been published by Wright et al. (2013). It builds on the models of Golonka (2007) and Scotese (2004) and provides examples for the use of paleobiology data as additional constraints for absolute and relative plate motions.

Summary and conclusions

The main outstanding challenge for understanding plate motion through time is to further develop models that treat the tectonic plates and the convecting mantle as a coupled system, as well as extending plate models further in time that include plate boundary geometries and locations as well as reconstructed ocean basins. This is essential for understanding absolute plate motions in terms of plate driving forces through time and to evaluate to what extent mantle plumes and the surface hot spots they cause may have been moving relative to each other. In order to advance our understanding of the coupling and feedbacks between deep earth processes and plate kinematics, new software tools and workflows need to be established in which observations, plate kinematics through time, geodynamic modeling, and model/data visualization are seamlessly linked, based on open standards and open-source tools. The burgeoning fields of simulation and modeling and "big data" analysis are likely to enable key advances in this area.

PLATE TECTONICS

Martin Meschede
Institute of Geography and Geology, Ernst-Moritz-Arndt University, Greifswald, Germany

The Earth is a dynamic planet which continuously changes its surficial shape since it came into existence about 4.5 billion years ago. All the changes are caused by convection processes in the Earth's mantle which formed by segregation of different spheres in early times of the Earth. The processes of plate tectonics as we know it today started about 2.5–3 billion years ago and operated since that time (Stern, 2005, 2008; Hamilton, 2007). However, nothing of the Earth's surface is of constancy even if it appears so in the form of several-billion-year-old rocks. The entire surface of the Earth is subject to a permanent reconstruction. Heat either inherited from the early times of the Earth and stored in its interior or newly formed by radioactive decay of unstable elements is constantly released. The heat conductivity of rocks, however, is poor, and a rigid and stiff outer crust formed over time which prevents the direct heat loss. Therefore, convection currents in the more plastically behaving mantle are needed to maintain the heat output (Figure 1). These currents are responsible for the upward transportation of hot rock material, which is a little bit lighter than cold material of the same composition, to the surface. In return cold rock material is being transported down into deeper regions of the Earth. The result is a kind of conveyor system to provide the thermal output that is transporting the rigid plates along at the surface.

Heat emission occurs at zones of weakness. The most important are the mid-oceanic spreading centers that circle the globe for more than 67,000 km in length (Bird, 2003). Most of the volcanic activity on Earth occurs at these divergent plate boundaries (Perfit and Davidson, 2000). On the other hand, cold rock material is being transported into the Earth in subduction zones at convergent plate boundaries. There exist two fundamentally different types of rigid and stiff lithospheric plates (Greek *lithos*: stiff): oceanic and continental lithosphere. The differences of these crustal types have already been recognized by Alfred Wegener (1880–1930), a German meteorologist and pioneer of plate tectonics who first formulated the continental drift theory (Wegener 1912, 1915). Wegener recognized the different mean heights of continents and oceans. He could, however, not yet explain the reason for the plate movements, which is why he encountered strong resistance against his theory. Despite his conclusive explanation for, e.g., identical fossils on both sides of the Atlantic Ocean or traces of glaciation in the Sahara desert in Africa, it needed another 50 years to establish the actual plate tectonic theory. Today, this theory is generally accepted and discussed in a number of textbooks (e.g., Frisch et al., 2011).

Movements resulting from convection currents leave their traces on the Earth's surface. Normally, these movements occur very slowly with only a few millimeters or centimeters per year, and we are not able to perceive it directly. However, we recognize the dynamics of the Earth in cases of large earthquakes or spectacular volcanic eruptions. This happens when stress has been accumulated in the rigid and stiff lithosphere that is suddenly released or when a magma chamber erupts, which has been filled and pressurized until it loses its resistibility.

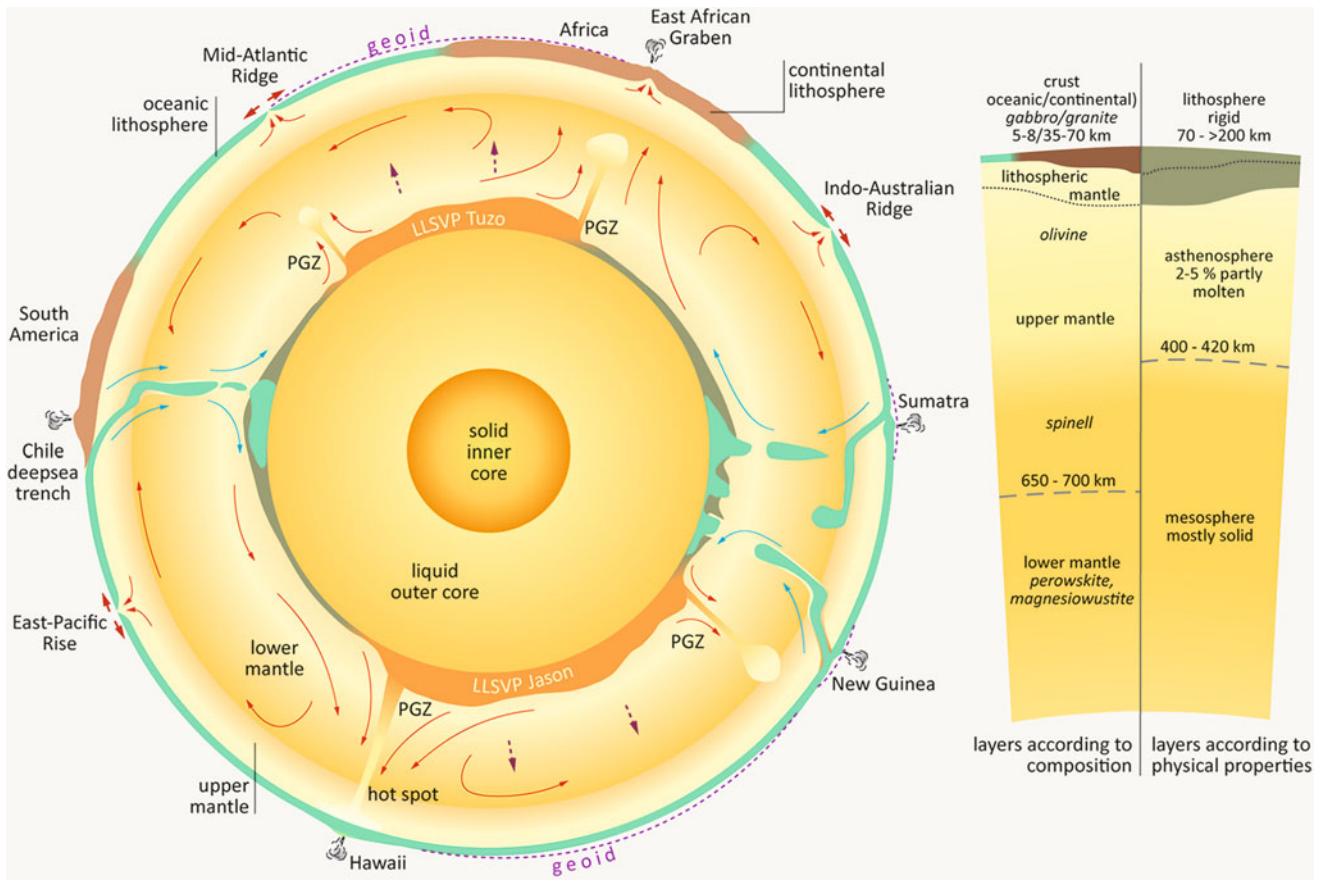
The stiff lithospheric plates are very different in size (Bird, 2003). Their thickness varies in general between 70 and 150 km, and they are thicker underneath the continents as compared to the oceans. In some cases below large mountain chains, they may achieve a thickness of


Plate Tectonics, Figure 1 *Left*: Convection currents in the Earth's interior. The thickness of oceanic and continental lithosphere is exaggerated to clarify the differences between the two crustal types: if drawn with true proportions, the lithosphere could be less than 1 mm thick (see also Fig. 2). The viewing direction of the cross section through the Earth's interior is from the South Pole (Modified and completed according to Condie (1997), Schubert et al. (2001), Tackley (2008), and Torsvik et al. (2014)). *LLSVP* large low shear-wave velocity provinces beneath Africa (Tuzo) and the Pacific (Jason), *PGZ* plume generation zones; *thin arrows* above Tuzo and Jason indicate the rise of lighter material resulting in a deflection of the geoid at the surface (*dashed line*). *Right*: comparison of the mantle and lithosphere layers according to composition (mineralogy, petrology) and physical properties (geophysical characteristics) (modified after Stüwe 2000).

more than 200 km. Lithospheric plates are composed of the Earth's crust, either of oceanic or continental type, and the lithospheric mantle (Figure 1). Oceanic crust has an average thickness of 5–8 km and is mainly composed of gabbroic and basaltic rock material. The mean density of oceanic crust is about 3.0 g/cm³. Continental crust on the other hand has an average thickness of 30–35 km and may reach more than 70 km beneath young mountain ranges. In its upper part, it comprises of less dense rock material (e.g., granites, granitoids, sedimentary rocks) and has a mean density of 2.6–2.8 g/cm³.

The lithospheric mantle and the asthenosphere differ in their physical properties but not in their average composition (Figure 1). In contrast to the solid lithospheric mantle, the asthenosphere is to a small degree (about 1–5 %) molten causing its ability for plastic flow. However, the molten part encompasses only a few percent of the total rock material. The velocity of movement of the lithospheric plates ranges in the order of centimeters per year. This may add to several thousand kilometers in geological periods. To illustrate the dimension of movement, let's have a look on a lithospheric plate slowly moving with 1 cm/year. With this velocity, it moves 10 km in 1 million years and sums up to 1,000 km in 100 million years. Recent plate movement velocities range from less than 1 cm/year to more than 15 cm/year at the central East Pacific Rise (i.e., 7.5 cm/year to each side). In the past, even faster velocities of more than 20 cm/year have been detected (e.g., Kumar et al., 2007). Therefore, it is obvious that the distribution of continents and oceans on the surface of the Earth is only a snapshot in the Earth's history and has consistently changed since the onset of the currently active plate tectonic processes.

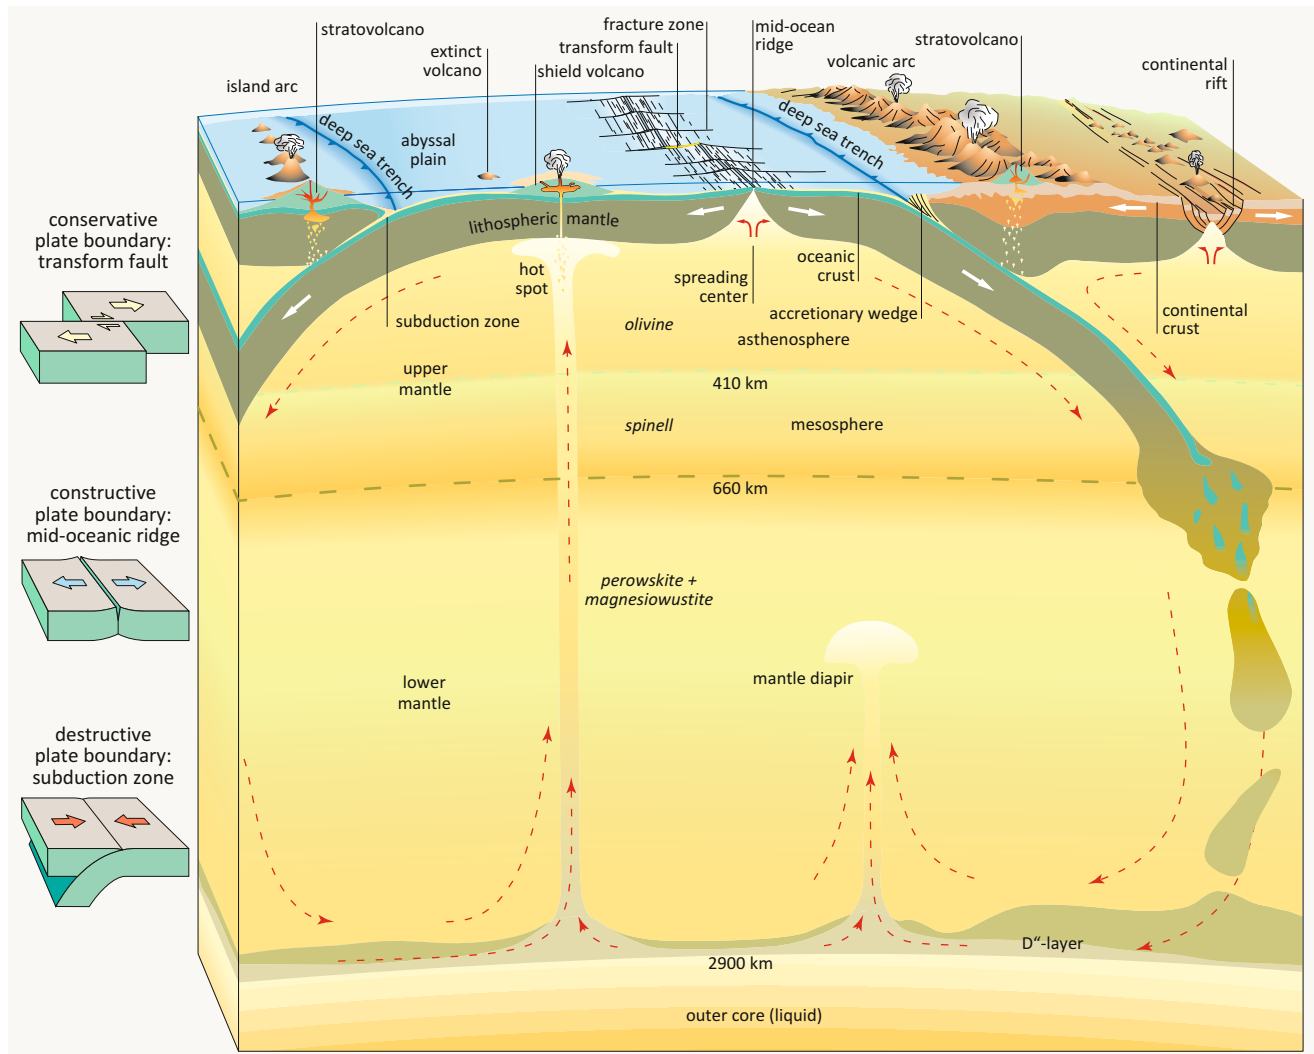
Lithospheric plates move with different velocities and different directions and interact with other plates. If plates move apart, new oceanic lithosphere is formed in between. These plate boundaries are called constructive or divergent boundaries (Figure 2), and they are characterized by


Plate Tectonics, Figure 2 Schematic overview of plate tectonic processes at the surface and in the Earth's crust and mantle.

a mid-oceanic spreading center. On the other hand, plates collide and subduction zones form when one lithospheric plate descents beneath the other and is returned back into the mantle. These plate boundaries are called destructive or convergent plate margins. Frequently, a deep trench evolved along the plate boundary, and the deepest point on Earth, the Challenger Deep with a depth of 10,994 ($\pm$40) m, was determined in the typical deep-sea trench of the Mariana arc. In many cases accretionary wedges are developed at the surface along convergent plate boundaries where sedimentary material from the subducting plate is offscraped and thrust as nappes onto the overriding plate. About half of the convergent plate boundaries are characterized by such accretionary wedges, whereas the other half is dominated by subduction erosion or at least non-accretion. A third type of plate boundaries exists where two plates slide along each other and lithospheric material is neither formed nor destroyed.

This plate boundary is characterized by transform faults and is called a conservative boundary.

Continent-ocean boundaries are subdivided into convergent and passive plate margins. In the case of a subduction zone along the continent, e.g., the west coast of South America, it is called an active continental margin. If the continental lithosphere is connected to the oceanic lithosphere without a plate boundary, it is called a passive continental margin. Active continental margins are mostly characterized by a high mountain range formed mainly by magmatic activity. Passive continental margins, on the other hand, frequently have a low coastal mountain range as a remnant of the former rifting stage. They are characterized by a wide shelf area where strong subsidence caused by dilatational thinning of the continental crust occurs and thick layers of sediments were accumulated.

Oceanic crust is constantly being formed at mid-oceanic spreading centers of constructive plate

boundaries. The mid-oceanic spreading centers are in the crest of long submarine ridges in the middle of an ocean, which are in part more than 3,000 m higher than the abyssal plains at its flanks. For instance, the water depth at the Mid-Atlantic Ridge is in average about 2,500 m below sea-level; the neighboring abyssal plains, on the other hand, are more than 5,000 m deep. The spreading centers are the most active volcanic chains on Earth. More than three-fourths of the global annual volcanic production happens on these ridges (Schmincke, 2004). However, since these volcanoes are nearly entirely hidden under water, we generally do not notice their activity. In contrast, subduction zones are characterized by a large number of superficially visible volcanoes arranged at the surface in long chains. The major part of about 550 historically active volcanoes on Earth is located above subduction zones.

The composition of continental crust is much more complicated and variable than oceanic crust. Oceanic crust, mainly made up of gabbroic and basaltic rocks, is normally transported back into the Earth's mantle where it becomes recycled. Based on high-pressure metamorphic processes, basalt and gabbro are turned into eclogite when they enter a depth of more than 35–40 km. Eclogite is with an average density of 3.4 g/cm^3 heavier than peridotite of the lithospheric mantle with an average density of 3.3 g/cm^3 and is thus able to pull down the subducting slab into the asthenosphere. Continental crust, in contrast, remains at the surface since it is too light to become subducted. The modern continental crust is thus a product of several billions of years of relocations, deformations, and transformations such as metamorphism. The rocks of the continental crust conserve the entire history of the Earth, however, often in very concealed or even unrecognizable conditions. On the other hand, the oldest oceanic crust preserved in its original context has an age of only about 195 million years (Muller et al., 2008). Captured oceanic crust of the Neotethys Ocean in the eastern Mediterranean, which is not yet added to the continental lithosphere by obduction, was formed in the Triassic. All other, older remnants of oceanic crust are part of ophiolites that were added to the continental lithosphere by accretionary processes along convergent plate margins. Therefore, rocks of the continental crust are partly more than 20 times older than the present oceanic lithosphere. This indicates that the oceanic crust may have been completely recycled more than 20 times through the Earth's history.

Subduction zones are characterized by strong earthquakes and volcanic activity. The collision of lithospheric plates leads to the accumulation of considerable stresses that often result in devastating earthquakes such as the earthquakes at Sumatra (2004), Japan (2011), and Chile (2010, 2014). In these zones the oceanic lithosphere is subducted into a depth where it becomes metamorphosed and molten. Parts of the downgoing slab may be transported down to the mantle-core boundary where it is incorporated in the so-called D" layer (named by Bullen 1950; Figure 2). Caused by thermal convection and heat transfer from the core to the mantle, the material of the D" layer is heated. This results in the development of mantle diapirs fed from the D" layer (Peltier, 2007). Thus, after hundred millions of years, remnants of subducted material may be transported back to the surface in mantle diapirs where hot mantle material rises upwards forming hot spots on the surface (Hofmann and White, 1982).

Sediments are deposited on the oceanic lithospheric plates during their drift from the mid-oceanic spreading center to the subduction zone. Sediments, however, are too light to be transported downward into the asthenosphere. Therefore, they are scraped off at the plate boundary and accumulated in an accretionary wedge or transported down to a relatively shallow depth of 110–120 km. In this depth the light rocks are molten and incorporated into magmatic melts which rise to the surface and may feed volcanoes or crystallize in plutonic bodies of the magmatic arc. The magmatic rocks are mostly of andesitic/dioritic to rhyolitic/granitic composition.

Volcanic eruptions far away from plate boundaries are mostly caused by hot spot activities. At these locations mantle diapirs with hot asthenospheric material rising from deep areas in the mantle form plume heads beneath the rigid lithosphere that feed magma chambers in the continental or oceanic crust (Figure 2) and cause upward bulges in the lithosphere. In addition to the mid-oceanic spreading centers, these mantle diapirs also play an important role in the thermal budget of the Earth. Mantle diapirs may feed volcanic eruptions of gigantic dimensions and global catastrophic consequences, e.g., Yellowstone, about 640,000 years b.p., or Toba, about 74,000 years b.p. (Sparks et al., 2005). These types of volcanoes are called supervolcanoes, which are not expressed by volcanic edifices on the surface but by large calderas of several tens of kilometers in diameter (de Silva, 2008).

Plate tectonic processes repeat in long-lasting cycles, called Wilson cycle, named after J. Tuzo Wilson (1908–1993). The Wilson cycle starts with the continental breakup and the development of a rift system between two newly diverging plates. Rising and partly molten asthenosphere forms new oceanic lithosphere in the middle of an evolving ocean. This ocean may evolve from an elongate narrow basin to a wide ocean of several-thousand-kilometer width. The oceanic lithosphere is being subducted and transported back into the mantle after its drift on the surface, which lasts in maximum about 200 million years. The collision of two continental plates leads to the orogenesis of a mountain chain. After the gradation of this mountain chain, the Wilson cycle may start again with the breakup of the continental lithosphere.

Definition

Pteropods were first described as a group in 1804 by Georges Cuvier. The name derives from the fact that the molluscan foot (−poda) has been modified to form paired swimming wings (ptero-). There are two different orders, (1) the Thecosomata, also known as "sea butterflies" with suborders Euthecosomata (shelled and with a good fossil record) and Pseudothecosomata (shelled and shell-less), and (2) the Gymnosomata (shell-less as adults), commonly known as "sea angels" (Table 1). Recent molecular studies (Klussmann-Kolb and Dinapoli, 2006; Jennings et al., 2010) provided convincing evidence that the two orders are sister groups, hence the superorder Pteropoda is now considered a taxonomic entity.

Introduction

Pteropods are found throughout the world's oceans and are holoplanktonic, meaning that they spend their entire life cycle in the open water column. They represent an extraordinary diversity in morphological forms (Figure 1) and can be numerically and functionally important components of marine food webs (Lalli and Gilmer,

Pteropods, Table 1 Hierarchical subdivisions of the Pteropoda including the orders Thecosomata and Gymnosomata. Genus names and species numbers are taken from the World Register of Marine Species (WORMS). Pending further revisions we have taken a conservative approach and have not included recent revisions including superfamilies and subgenera

Phylum Mollusca

Class Gastropoda	
Subclass Heterobranchia	
Order Thecosomata	Order Gymnosomata
Suborder Euthecosomata	Family Clionidae
Family Cavoliniidae	Genus *Clione* 1 sp.
Genus *Cavolinia* 6 spp.	*Fowlerina* 2 spp.
Diacavolinia 19 spp.	*Paedoclione* 1 sp.
Diacria 8 spp.	*Paraclione* 2 spp.
Clio 9 spp.	*Thalassopteris* 1 sp.
Creseis 5 spp.	*Thliptodon* 3 spp.
Hyalocylis 1 sp.	*Cephalobrachia* 2 spp.
Styliola 1 sp.	*Massya* 1 sp.
Cuvierina 5 spp.	Family Cliopsidae
? *Vaginella*	Genus *Cliopsis* 2 spp.
Family Limacinidae	*Pruvotella* 1 sp.
Genus *Heliconoides* 1 sp.	Family Notobranchaeidae
Limacina 6 spp.	Genus *Notobranchaea* 8 spp.
Thielea 1 sp.	Family Pneumodermatidae
Suborder Pseudothecosomata	Genus *Abranchaea*
Family Cymbuliidae	*Platybrachium* 1 sp.
Genus *Cymbulia* 4 spp.	*Pneumoderma* 3 spp.
Corolla 6 spp.	*Pneumodermopsis* 9 spp.
Gleba 1 sp.	*Schizobrachium* 1 sp.
Family Desmopteridae	*Spongiobrachaea* 2 spp.
Genus *Desmopterus* 4 spp.	Family Hydromylidae
Family Peraclidae	Genus *Hydromyles* 1 sp.
Genus *Peracle* 8 spp.	Family Laginiopsidae
	Genus *Laginopsis* 1 sp.

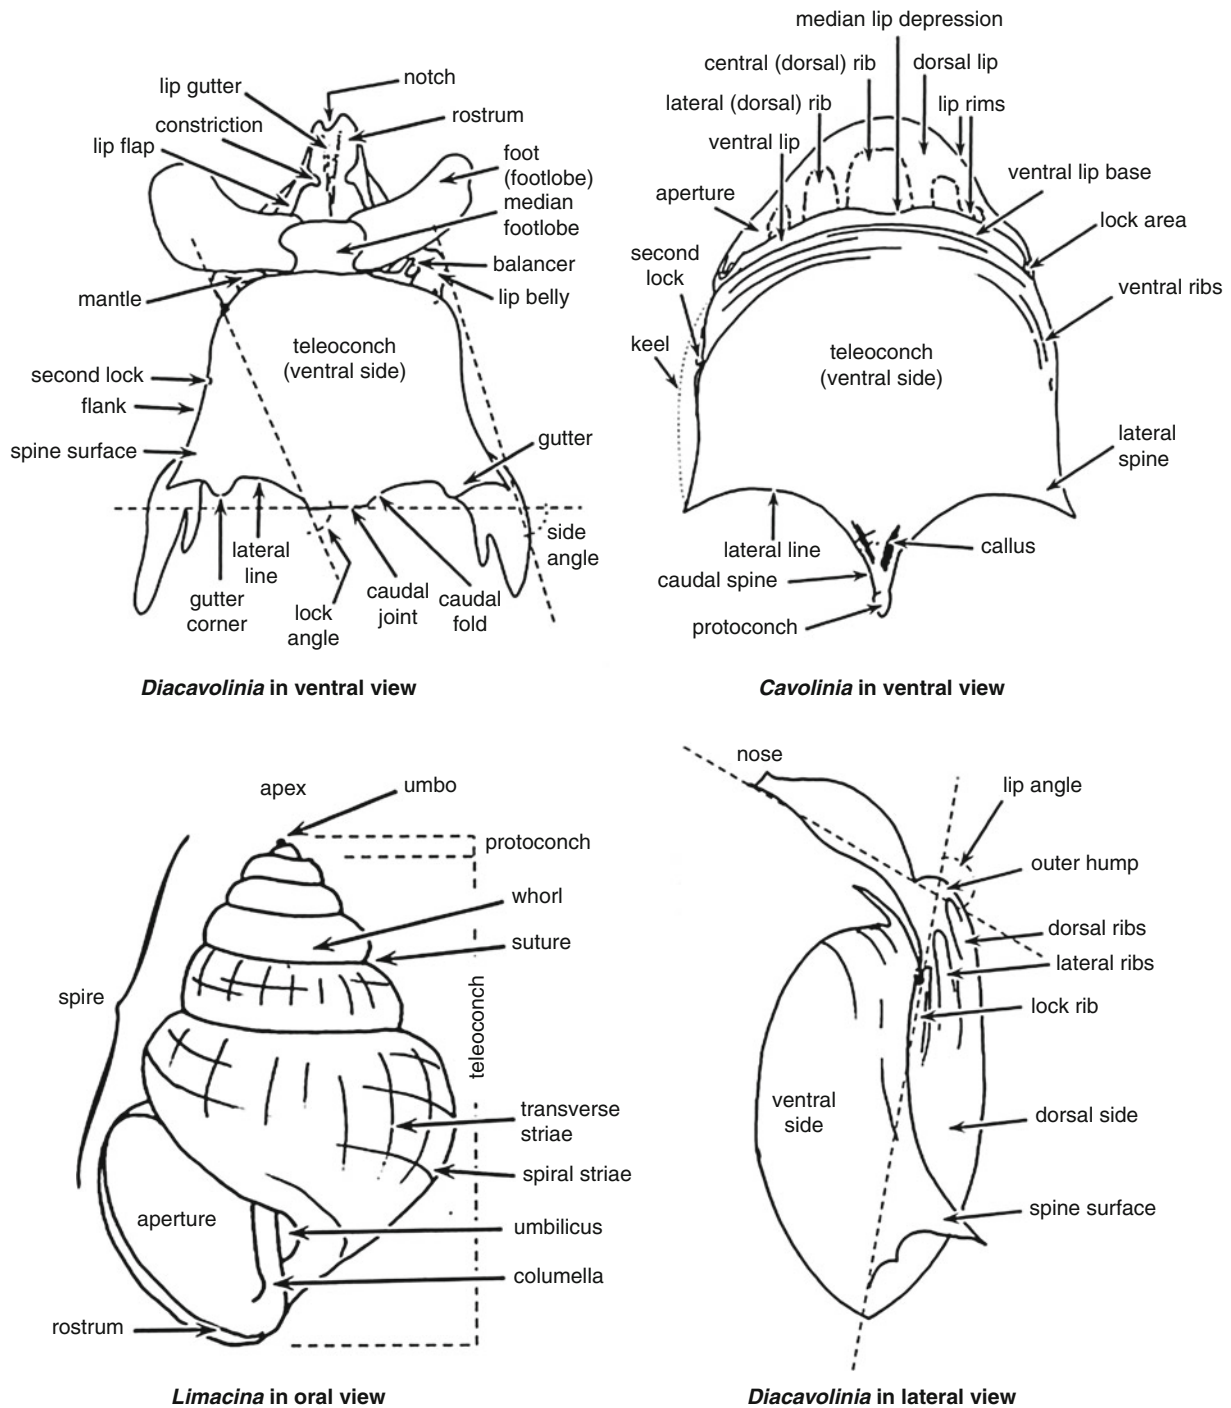
1989). Shelled pteropods affect the ocean carbon cycle by producing aragonite shells that can accelerate the export of organic matter from the surface into the deep ocean. Because of their delicate aragonite shells, pteropods have been identified as extremely vulnerable to the effects of ocean acidification (e.g., Feely et al., 2004). Hence, they have become the subject of intense recent research in this area. About 40 gymnosomatous and ~100 thecosomatous pteropod species are currently recognized. The fossil record almost exclusively concerns members of the Euthecosomata so the focus in this short overview will be put there. About 200 fossil euthecosome species are currently described.

Thecosomata

Suborders Euthecosomata and Pseudothecosomata

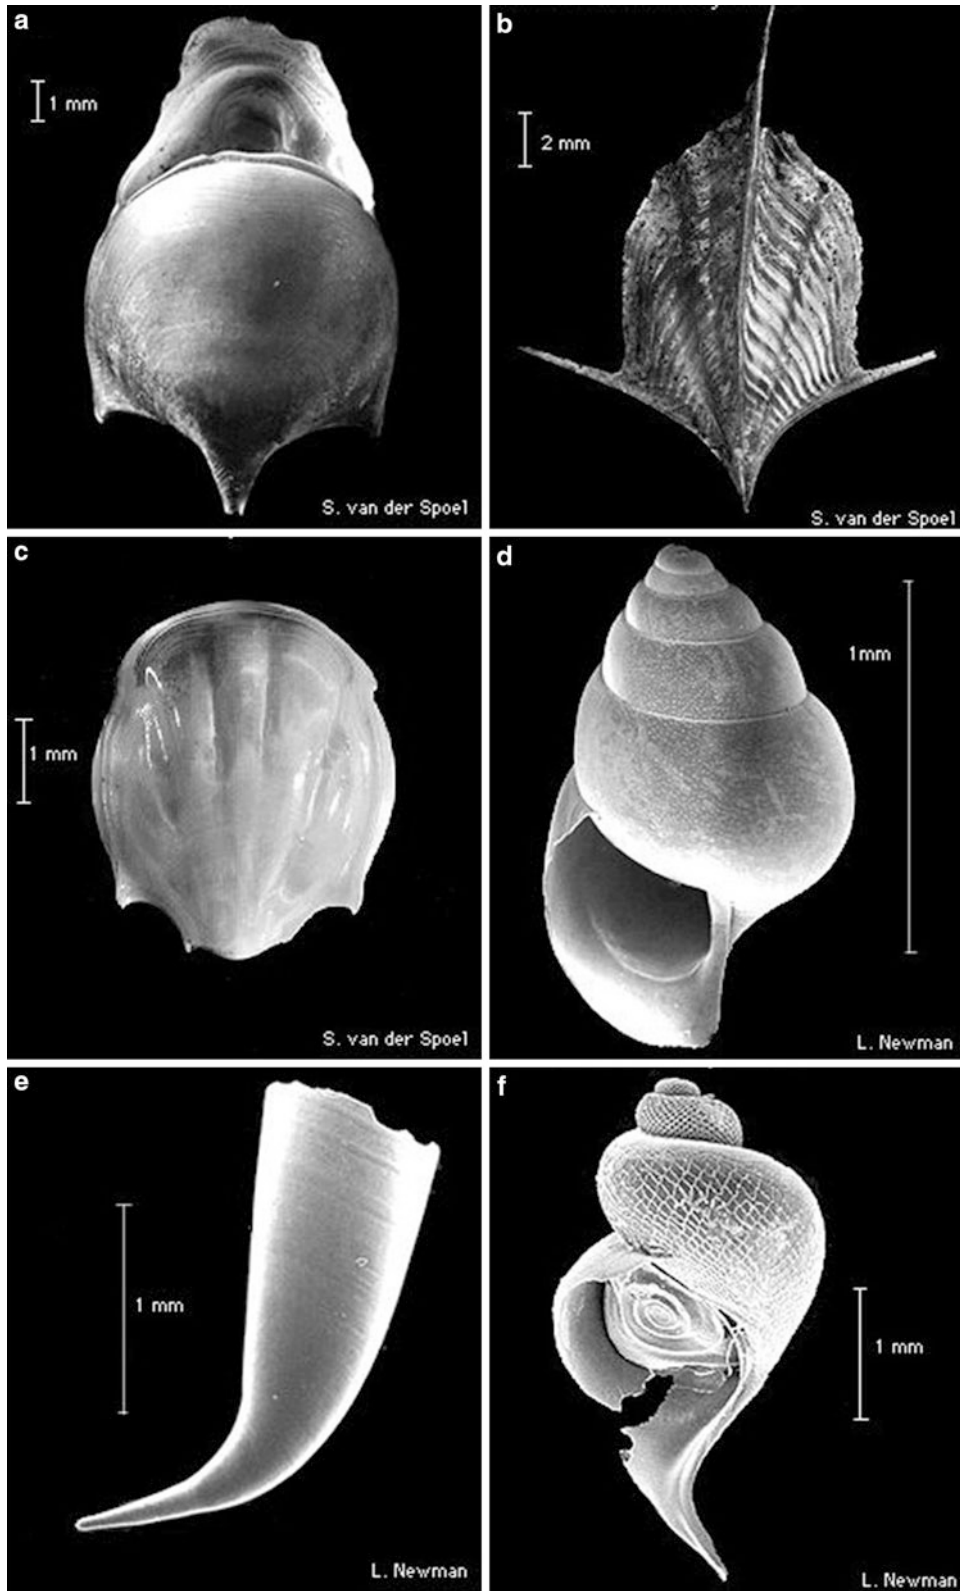
For identification of Thecosomata, mainly the form and dimensions of the shells are used. Figure 2 shows the main features of the soft body and the shell. The paired wings are homologous to the gastropod foot and serve a dual function for swimming and feeding. The slit-like mouth between the lips opens into the radula sac where the radula and salivary glands are found. The radula can also be a distinguishing character for species. The shells may be sinistrally coiled as in Limacinidae, or uncoiled, conical or bilaterally symmetrical as in Cavoliniidae (Figures 2 and 3). The small and fragile shells can be found along the beach but they may be easily overlooked, and only fragments are usually found. The shells of both Limacinidae and Cavoliniidae are constructed of aragonite, a less stable form of calcium carbonate than calcite, but their microstructures are very different. The Limacinidae possess a crossed-lamellar shell microstructure. By contrast, the Cavoliniidae have a helical microstructure that is unlike that of any other molluscan group (Bé et al., 1972; Bé and Gilmer, 1977). The poorly known Pseudothecosomata belong to the Thecosomata but two of the three families do not have a shell. Only in the genus *Peracle* is a shell present in the adult stage.

Gymnosomata

The Gymnosomata include some 50 described species though they remain relatively little known. Gymnosomes are shelled only in an early life stage, the protoconch shell is formed in the egg and shed after hatching. They usually do not form swarms and do not contribute much to the zooplankton biomass except for some species in the polar seas like *Clione limacina*. Gymnosomes have very different anatomical features compared to thecosomes. Besides
Pteropods, Figure 1 (**a**) *Clio pyramidata* (Euthecosomata) (**b**) *Limacina retroversa* (Euthecosomata) (**c**) *Diacria major* with protoconch (Euthecosomata) (**d**) Cuvierina atlantica (**e**) Peracle bispinosa (**f**) Desmopterus pacificus (**g**) *Pneumodermopsis macrochira* (Gymnosomata) (**h**) *Clione limacina* (Gymnosomata) (Permission of ETI).


Pteropods, Figure 2 Diagrams of Diacavolinia, Cavolinia, Limacina, and Diacavolinia in different orientations (from Van der Spoel and Dadon, 1999).

the shell also the mantle and mantle cavity are absent. The anatomy of the wings and footlobes differs, and the head and mouth are found anterior to the wings. The digestive tract is shorter than in the Thecosomata so that the caudal part of the body seems empty. Van der Spoel and Diester-

Haass (1976) found the first fossil gymnosomatous protoconchae in the East Atlantic and several more gymnosomatous larval shells have since been found, though none of them could be reliably identified to species.


Pteropods, Figure 3 (**a**) Shell of *Cavolinia teschi* (Euthecosomata) (**b**) Shell of *Clio cuspidata* (Euthecosomata) (**c**) Shell of *Diacria schmidti* (Euthecosomata) (**d**) Shell of Limacina bulimoides (**e**) Shell of *Creseis virgula* (Euthecosomata) (**f**) Shell of Peracle reticulata (Pseudothecosomata) (Permission of ETI).

Distribution

Pteropods are widely distributed and abundant in all oceans, and the distribution patterns of individual species are generally closely related to the hydrographic conditions. As in other holozooplankton typical horizontal distribution patterns are (1) broad in the tropics and subtropics in all three oceans, (2) more narrowly distributed in the tropics usually restricted to the Indo-Pacific, (3) distributed in northern and southern transition or temperate zones, and (4) cold-water species, including bipolar distributions. Most pteropod species occur in warm water. A striking pattern is the high species diversity in tropical and subtropical oceans, which contrasts with the low species diversity in cold water regions. Angel (1997) stated "species richness decreases and dominance increases as organic inputs become more seasonally pulsed." The lowest biomass and the highest species richness is found in the permanently stratified subtropical gyres, with more than 80 taxa of Thecosomata and Gymnosomata. Even though poor in species richness, pteropods are most abundant in Subarctic and Subantarctic waters and sometimes dominant components of the plankton. Here they are the main contributors to vertical particle flux and also an important food source for whales and large fish such as cod. Swarms were found of *Limacina retroversa* with densities of >13,600 ind. per 1,000 m^3 in Norwegian waters (Bathmann et al., 1991) and of *L. helicina* with densities of >10,000 ind. per 1,000 m^3 south of the Antarctic Convergence near 65°S (Chen, 1968b).

Species with large latitudinal ranges or occurring in different ocean basins tend to reflect the influences of environment as phenotypic variation in e.g., shell shape, size, and color. Many species are thus represented by one or more subspecific taxa (Van der Spoel, 1967; Van der Spoel et al., 1997). It has long been thought that isolation is rare in the marine pelagic realm where all water masses eventually mix and isolating barriers are essentially lacking resulting in slowly evolving species. However, upon reviewing all primary population genetic studies of open ocean zooplankton, Peijnenburg and Goetze (2013) find that genetic isolation can be achieved at the scale of gyre systems in open ocean habitats (100 s to 1,000s of km) and suggest that most marine zooplankton are well poised for evolutionary change. Molecular work on pteropods has shown that some circumglobal species or subspecific taxa are supported by genetic evidence, whereas others are not (e.g., Jennings et al., 2010; Gasca and Janssen, 2014; Maas et al., 2013; Burridge et al. 2015), suggesting the need for further work and taxonomic revisions. One example is the euthecosome *Limacina helicina* with a cold-water bipolar distribution pattern. Based on morphological evidence, this species is currently recognized as a species complex comprising two subspecies and at least five "formae." Molecular results, however, convincingly demonstrated that the Arctic *L. helicina helicina* and the Antarctic *L.h. antarctica* differ at least at the species level (Hunt et al., 2010).

Although pteropods occur at all depth layers, most species and higher abundances are found in the epipelagic. Species richness and abundances are lower in the meso- and bathypelagic as in many other pelagic groups. For example, of the 92 species found in the South Atlantic 50 are epipelagic (0–200 m), 29 occur both in the epipelagic and mesopelagic (200–1,000 m), four occur only in the mesopelagic, five both in the meso- and bathypelagic (>1,000 m) and four are only found in the bathypelagic (Van der Spoel and Dadon, 1999). Typical mesopelagic species are *Clio recurva*, *Peracle* spp. The euthecosomes *Thielea helicoides*, *Clio chaptalii*, and *Clio andreae*, and the gymnosomes *Massya* sp. and *Schizobrachium* sp. are bathypelagic.

Although there are no species restricted to the neritic environment several Creseis and Diacavolinia taxa may occur in very high abundances in coastal areas.

Ecology

Pteropods are protandric hermaphrodites, meaning that the same individuals first have a male stage and later a female stage. It is thought that cross fertilization is the rule, although self fertilization may also be possible. The sperm is stored in an accessory sac of the gonad and oocytes are fertilized internally by the stored sperm. The fertilized eggs are usually released into the water as floating egg masses in the form of gelatinous ribbons or spheres. A veliger larva hatches, metamorphoses, and develops into a juvenile stage. In the Thecosomata, the juvenile produces the protoconch II after the embryonic stage and then the soft parts grow regularly to maturity, when the teleoconch shell is formed. The euthecosome *Heliconoides inflata* has an unusual development with brood protection. Adults of this species brood their embryos and early veligers in their mantle cavity. Some deep-sea species such as *Thielea helicoides* and *Clio chaptalii* are viviparous and do not have free-swimming larval stages. Like in other plankton groups growth rate and generation time is dependent on seasonality and temperature. For most species, there is probably one generation per year.

Most Thecosomata are herbivorous or omnivorous mucus feeders. They catch their food by making a mucous web that is much larger than the organism itself. The food consists of particulate matter as well as small organisms such as dinoflagellates, coccolithophorids, radiolaria, tintinnids, foraminifera, and diatoms, the particles are wrapped in mucus, swallowed, and ground by the radula. Gannefors et al. (2005) found a change in diet from diatom-dominated food items in spring to dinoflagellates in summer/autumn and also evidence of ingestion of copepods in *Limacina helicina*. Herbivorous euthecosomes often show swarming behavior resulting in very patchy distributions and varying effects on the local ecosystem. Some bathypelagic euthecosomes, e.g., *Thielea helicoides*, are carnivorous and usually occur as solitary individuals. Gymnosomata are active carnivores and

usually occur as solitary individuals as well. They are often specialized feeders preying upon certain species of Thecosomata. An extreme example being that of *Clione limacina* feeding exclusively on *Limacina helicina* in the North Atlantic and on *L. helicina* and *L. retroversa* in the South Atlantic. Most other species are less specialized in their diet but all feed either exclusively or mainly on a few Thecosomata species (Conover and Lalli, 1974).

Many pteropods undergo more or less pronounced diel vertical migrations, feeding at night near the surface and migrating to greater depths during the day. Most species are influenced by specific hydrographic conditions so that day and night levels differ by place and season. Migration ranges vary in different species, for example, *Diacavolinia* species migrate daily only over some 10 m, whereas *Clio pyramidata* migrates over hundreds, even up to 1,500 m (van der Spoel, 1973). *Clio andreae* and *Thielea helicoides* undergo ontogenetic vertical migration, juveniles occurring higher in the water column than the adults.

Bednaršek et al. (2012) found that shelled pteropods constitute a mean global carbonate biomass of ~23 mg $CaCO_3$ m^{-3} (based on non-zero records). Total biomass values were lowest in the equatorial regions and equally high at both poles. Pteropods were found at least to depths of 1,000 m, with the highest biomass values located in the surface layer (0–10 m) and gradually decreasing with depth, with values in excess of 100 mg carbon (C) m^{-3} only found above 200 m depth. By extrapolating regional biomass to a global scale, they established global pteropod biomass to add up to 500 Tg C.

Geology

Pteropods are geologically a rather recent group only present since the Caenozoic. The oldest pteropod species, *Heliconoides mercinensis* is known from Late Paleocene deposits in Europe and the United States (e.g., Janssen and Peijnenburg, 2014). Pteropods probably originated from an Atlantic center of speciation (van der Spoel and Heyman, 1983). This hypothesis is based on the distribution patterns of some groups, such as the mesopelagic genus *Peracle*, whose species are all found in the Northeastern Atlantic off Dakar. In bathypelagic species, like *Thielea helicoides*, climatic influences on distribution patterns are probably negligible. Restriction of this bathypelagic species to the Atlantic Ocean and its deep water outflow may indicate that it originated in the oldest (late Cretaceous) deep-sea basin, the North Atlantic Ocean.

Conclusions

Shelled pteropods can be important in paleoclimatic, paleoceanographic, and paleocologic studies (Herman and Rosenberg, 1969; Diester-Haass, 1972; Janssen and Peijnenburg, 2014; Wall-Palmer et al. 2012). The fact that many groups have extensive horizontal distribution patterns and show a rapid morphological evolution makes them ideal candidates as index fossils for biostratigraphical purposes. However, aragonite is highly

undersaturated in the deep sea and dissolves away before it can be buried. Consequently, sediments containing >30 % pteropod shells ("pteropod ooze") are found predominantly in the tropics and sub-tropics, at <2,800 m depth in the Atlantic and <500 m in the Pacific, and none are present in the Southern Ocean (Bednaršek et al., 2012). Overall, only 2.4 % of the Atlantic Ocean sea floor comprises pteropod ooze. Nevertheless, one major advantage of using pteropods for biostratigraphy is that their fragile shells do not survive extensive transportation and are rarely reworked from one sedimentary unit into another (Janssen and Peijnenburg, 2014). Biostratigraphic applications were made by Chen (1968a) who correlated the Pleistocene pteropod zones with planktonic foraminifera zones, oxygen isotope analyzes and ^{14}C data. Gürs and Janssen (2004) refined the pteropod zonation for the later Miocene in the North Sea Basin and Cahuzac and Janssen (2010) correlated time intervals in the Aquitaine Basin with the zonation scheme for the North Sea Basin.

Definition

Pull-apart basins are structural depressions that are localized on the geometric irregularities along strike-slip faults where the master fault is overstepping or bending.

Introduction

Strike-slip faults form linear and continuous fault systems, but they are typically segmented, resulting in localized regime changes across a variety of discontinuities or steps (e.g., Dooley and Schreurs, 2012). Pull-apart basins have been recognized originally along major strike-slip faults throughout the world where the segmented faults cause extension/transtension. Quennell (1956), who was the first to recognize a pull-apart basin without using this term, proposed that the Dead Sea is a void in the crust caused by the overlapping segments of the Dead Sea fault zone. For the same purpose, the first use of the term "pull-apart basin" by Burchfiel and Stewart (1966) was chosen for the interpretation of the Death Valley basin. The term pull-apart basin is a well-used and well-understood term for strike-slip basins (Mann et al., 1983) both in marine and terrestrial environments.

Model for pull-apart basin development

As indicated above, there are several synonyms of pull-apart basins (see Mann, 2007 for references) that reproduced from the identified tectonic, structural, geometric, and geomorphic features of pull-apart basins in nature. Tectonically, the basins are located along strike-slip faults and transform zones; structurally, they form when strike-slip faults bend or overstep; geometrically, while the overstepping master strike-slip faults are parallel or subparallel, the secondary basin-bounding faults perpendicular or diagonal to the main faults give the basin its characteristic shape; and geomorphologically, they are sharp-bounded and deep depressions. All these

characteristics of pull-apart basins in nature help us to draw an ideal model for pull-apart basin that represents its mechanism of formation (Figure 1).

Detailed properties of natural pull-apart basins have been obtained through using experimental models. Although experimental laboratory studies have been used to investigate strike-slip faults since approximately the first quarter of twentieth century (e.g., Cloos, 1928), they have been used to simulate the mechanism and geometries of pull-apart basin formation in the last quarter. Because these basins differ considerably from simple strike-slip mechanism, their development processes share properties with both strike-slip and extensional settings (Rahe et al., 1998). Physical and/or numerical model studies have been a profitable approach, producing good geometric matches with natural examples of pull-apart basins (e.g., Rodgers, 1980; Gölke et al., 1994; McClay and Dooley, 1995; Katzman et al., 1995; Bertoluzza and Perotti, 1997; Dooley and McClay, 1997; Rahe et al., 1998; Basile and Brun 1999; Sims et al., 1999; Atmaoui et al. 2006; Wu et al., 2009; Mitra and Paul, 2011; Dooley and Schreurs, 2012). While the physical (analogue) modeling experiments used a variety of apparatus and different materials (e.g., sand, clay, and rock), the numerical experiments use a wide range of parameters and quantitative values. Thus, the results are helpful to understand the mechanical and geometrical aspects of natural large-scaled cases under different conditions.

Mechanical aspects

As detailed above, the basic mechanism of pull-apart basin development can be defined simply as local extension between two overstepping strike-slip faults (e.g., Aydın and Nur, 1982; Mann et al., 1983, Figure 1). Distributed strike-slip and Riedel shear mechanisms are two alternative mechanisms that have been proposed for pull-apart basin formation (e.g., Atmaoui et al., 2006; Dooley and Schreurs, 2012). Distributed shear deformation is developed in weak layers, such as evaporates or shales,
Pull-apart Basins, Figure 1 Formation and geometric model of pull-apart basin.

above a broad strike-slip fault zone in the basement, and pull-apart basins can develop at releasing steps during fault interaction, coalescence, and linkage (An and Sammis, 1996). The Riedel shear mechanism causes development of pull-apart basins along Riedel faults connected by segments of strike-slip faults in the basement (Dewey, 1978; Hagglauer-Ruppel, 1991).

Independent of the formation mechanism, the extension which develops within pull-apart basins depends on the local crustal rheology. While the displacement along the master strike-slip faults links to each other by normal faults in a brittle crust, in a ductile crust it accommodates by other mechanisms (e.g., continuous extension inside the basin; Reches, 1987). Another necessary condition for a pull-apart basin formation is a mechanical detachment between the brittle part of the crust and rheologically strong uppermost mantle (Petrunin and Sobolev, 2006). The strength of décollement zones of pull-apart basins, which are observed or postulated to form within ductile or viscous zones at depth, also affects structural development in most tectonic regimes (Molnar and Lyon-Caen, 1988) and likely exhibits some control on the development process (Sims et al., 1999).

The elastic stress field in the surroundings of a fault step was firstly analyzed by Rodgers (1980) and Segall and Pollard (1980) with two different approaches. However, their conclusions were consistent with each other: while the mean shear stress decreases inside the pull-apart basin, the maximum stress increases at fault ends with a slight larger increase outside the basin boundaries (Reches, 1987). The theoretical models of these authors provide clues to the orientation of the different faults that can form inside a pull-apart basin (Bertoluzza and Perotti, 1997).

The development of new strike-slip faults inside the basins which are diagonal to master faults, has defined as the extinction process of pull-apart basins first by Zhang et al. (1989). Similar tendencies and real-time observations have been made by different researchers in experimental models and earthquakes (e.g., McClay and Dooley, 1995; Sims et al., 1999; Gürbüz and Gürer, 2008). The pull-apart basins are structurally defined by three evolutionary stages: incipient, early, and mature stages by comparison with physical modeling experiments (e.g., Rahe et al., 1998). Dramatically this type of basins tends to link the master faults in the last stage (Rahe et al., 1998; Sims et al., 1999). While the development of through-going cross-basin faults in the mature stage indicates the decreasing activity along major boundary faults, their formations increase the probability for large-magnitude earthquakes. The best examples of such process and related destructive earthquakes have been seen in China and Turkey in the last century (e.g., Zhang et al., 1989; Gürbüz and Gürer, 2009).

Geometrical aspects

The shape, fault system, and sedimentation features of a pull-apart basin depend upon the geometry associated
Pull-apart Basins, Figure 2 Typical shapes of pull-apart basins: (**a**) spindle-shaped, (**b**) lazy Z-shaped, (**c**) rhomboidal (modified from Mann, 2007).

with the step in the master strike-slip fault system (Carton et al., 2007). Likewise, the geometry of a pull-apart basin is controlled by the amount of master fault overlap, separation, and displacement, and the size of the basin is varied and well defined by these parameters (Rodgers, 1980). Therefore to understand their anatomies and evolutions, we need to define some geometric parameters because many uncertainties complicate their interpretations. As demonstrated by some authors, shape, scale, and angular characteristics of pull-apart basins are useful to discuss their initiation and structural evolutions (e.g., Aydın and Nur, 1982, 1985; Bahat, 1983; Mann, 2007; Gürbüz, 2010).

Pull-apart basin structures are usually rhomb-shaped depressions, but they vary from the lazy Z- or S-shaped to spindle- or almond-shaped to extreme-shaped examples in nature (e.g., Mann, 2007, Figure 2). Mann et al. (1983) proposed that the rhomboidal form of pull-apart basins results from the lengthening of an S- or Z-shaped basin with increased master fault overlap. Regardless of offset geometry, they evolve progressively from narrow grabens bounded by oblique-slip-linked faults to wider rhombic basins (Dooley and McClay, 1997). Within these shapes, they can be asymmetric, symmetric, or hybrid forms depending on the activity and connectivity of basin-bounding faults (e.g., Rahe et al., 1998).

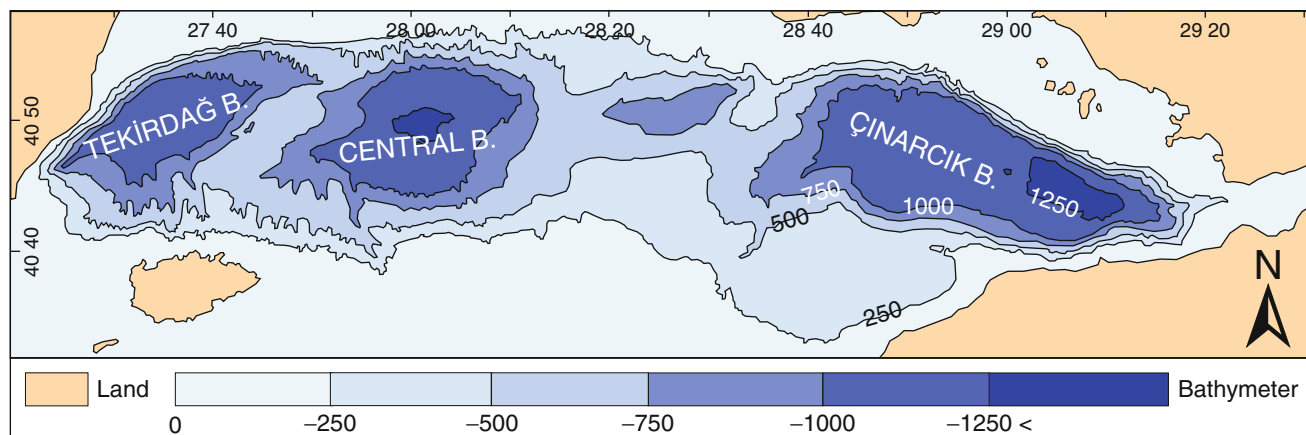
Within angular meaning, the results of substantial experimental studies and natural pull-apart basins from all over the world represent the acute angles (α angle in Figure 1) between the oblique bounding faults and the master strike-slip faults of pull-apart basins are generally clustered at 30°–35° (e.g., Bahat, 1983; Gürbüz, 2010). Otherwise, the boundary condition (i.e., pure strike-slip, transtension, transpression) is the major parameter determining the acute angle thereby the shape of the basin (Bertoluzza and Perotti, 1997).

Pull-apart basins have a specific scale ratio. Aydın and Nur (1982) showed a well-defined linear correlation between the length and width of pull-apart basins with a value of 3:1 through analyzing of over 60 natural examples and proposed that the value may vary widely, depending on the structural, physiographic, or active dimensions of the basin. In addition, experimental models show similar results with an approximately constant length versus width ratio (2.2:1–3.8:1; Basile and Brun, 1999). In the same vein, a step further, a three-dimensional relationship between the length, width, and depth of pull-apart basins has suggested by Gürbüz (2010) through using the natural examples.

Pull-apart basins represent the same mechanical and geometrical features both in marine and terrestrial environments (except extreme types which can lengthen very much due to spreading ridges; see Mann, 2007 for details), and sometimes they represent a complex basin system scene. Marmara Sea of Turkey is located on the North Anatolian fault zone which is one of the world's famous strike-slip faults with its length of ∼1,200 km (e.g., Şengör et al., 2005), and its internal structure includes such a basin system (Figure 3). Each of the basins has developed by the strike-slip tectonics of the North Anatolian fault zone (e.g., Okay et al., 2000; Armijo et al., 2002) and represents similar geometric features while varying in shapes, sizes, and also depths (e.g., Gürbüz, 2010).

Sedimentary aspects

Sedimentation features of pull-apart basins are generally related to kinematic, geometric, geomorphic, and crustal properties. Strike-slip faults that bound these basins have a large component of normal slip. Thus, while the basin inside is represented by a deep depression, the basin margins surrounded by steeper uplifted and deeply eroded highlands.

In continental pull-apart basins, along the strike-slip margins of the basin, coarser sediments in the form of talus breccia and debris-flow-dominated alluvial fans grade into fine-grained sediments toward the center of the basin (Crowell, 1974; Hempton and Dunne, 1984). As a result of such geomorphic and geometric characteristics, higher sedimentation rates, greater thicknesses in smaller areas,


Pull-apart Basins, Figure 3 Bathymetric map of the Marmara Sea pull-apart basin system.

displaced fan-source relationships and skewed fans, and depocenter migrations differentiate pull-apart basins from other extensional depressions (Hempton and Dunne, 1984). In marine environments, similar sedimentary patterns are valid for pull-apart basins by coarser sediments along basin margins transported through submarine canyons instead of rivers and submarine landslides along fault scarps and fine sediments toward the deepest parts (e.g., Beck et al., 2007; Görür and Çağatay, 2010). Basins far away from efficient sediment sources may include pelagic sediments and deposits of gravity mass movements (Einsele, 2000).

Strike-slip basins have high amounts of sediment thicknesses in spite of their small sizes and short life spans, typically in existence in 3–10 My (Woodcock, 2004). This would be related to their rapid cooling character within thermal meaning which gives the way to rapid subsidence (e.g., Pitman and Andrews, 1985; Mann, 2007). The major parameter that controls the basin-fill thickness during this process is the thickness of the brittle layer (Petrunin and Sobolev, 2006).

Summary

Pull-apart basins are located along strike-slip faults and transform zones and are developed when the master fault bends or oversteps extensionally. While the master faults are parallel or subparallel, the secondary basin forms with faults perpendicular or diagonal to the master faults giving the basin its characteristic shape. The extension which develops within the pull-apart basins depends on the local crustal rheology. Stress fields suggest that the mean shear stress decreases inside the basin and the maximum stress increases at fault ends. The anatomies and evolutions of pull-apart basins are closely related to their geometric aspects. Their shapes, scales, and angular characteristics are useful to discuss their structures. Pull-apart basins are generally shown as rhomb-shaped depressions. But the shape of the basin varies widely, from spindle to lazy Z or S to other extreme examples. In an ideal rhomb-

shaped pull-apart basin, while the acute angle between the master faults and basin-bounding diagonal faults is generally a value between 30° and 35°, the 2D scale characteristics of pull-apart basins represent a mean aspect ratio of 3:1, and 3D characteristics represent a quantitative relationship between length, width, and depth. These values are suggested for basins shown in ideal geometries, and they can vary in a wide range due to their spatial and temporal positions in an evolving environment. The changing and intersecting tectonic regimes and local crustal, lithological, or climatic properties can also influence basin geometry. In contrast to their small-sized and short-lived characters, pull-apart basins have great thicknesses of basin-fill deposits. Higher sedimentation rates, displaced fan-source relationships and skewed fans, and migrated depocenters are some sedimentary aspects of pull-apart basins that differentiated this type of basin from the other tectonic depressions.

Definition

Push-up blocks are topographic uplifts that localize on the geometric irregularities along strike-slip faults where fault segments form a compressive stepover or bend.

Introduction

Push-up blocks are an integral part of intraplate and interplate strike-slip fault zones (e.g., Sylvester and Smith, 1976; Christie-Blick and Biddle, 1985; Sylvester, 1988) and are very important structures for hydrocarbon accumulations. They represent structural traps as *en échelon* anticlines in places combined with stratigraphic traps (Harding, 1974, 1990; McClay and Bonora, 2001). Many large strike-slip fault zones commonly have large-scale push-up blocks associated with overstepping and bending both in marine and terrestrial environments (e.g., Angelier et al., 2004; Wakabayashi et al., 2004; Mann, 2007; Dooley and Schreurs, 2012). Probably, Trevisan (1939) was the first to define the push-up blocks, without using the term, to explain the development of the Brenta Mountains in the Lombardy Alps as the displacement along two wrench faults, which stepped with respect to each other and generated local folding and thrusting (Reches, 1987). The first use of the term "push-up block" by Mann et al. (1983) was chosen for describing compressional uplifts along strike-slip fault discontinuities.

Model for push-up block development

Whereas pull-apart basins reflect localized extension along a strike-slip fault, push-up blocks reflect local contraction. Basins develop where a right-lateral sense of slip steps to the right and left-lateral to the left, but push-up blocks develop when the sense of slip along the master faults falls afoul to stepped sides (Figure 1). Push-up blocks typically form uplifts, commonly with folds and reverse and/or thrust faults. In plan view they are broadly in form, whereas in cross section they are commonly bounded convex-up faults forming positive flower or palm tree structures (e.g., Sylvester, 1988; Dooley and Schreurs, 2012).
Push-up Blocks, Figure 1 Formation model of push-up block along a right-lateral fault.

Mechanical aspects

Push-up blocks combine elements of strike-slip and compressional regimes. Thus, they share the properties of both simple shear and pure shear. In these blocks, exposure of older rocks is produced as the result of the oblique intersection of the fault with the direction of the plate or block motion (Mann, 2007).

The kinematic mechanism for the formation and extinction processes of push-up blocks is related to the "switchyard behavior" of the main strike-slip fault (Brown et al., 1991). These uplifted regions develop if the master fault oversteps or bends displacement accommodation provided by oblique-slip flanking fault which rejoins the master fault on another lateral ramp further along the strike (Swanson, 1989). In case the accommodated displacement bypasses the flanking faults during progressive offset of the master fault, push-up blocks become extinct (e.g., Mann, 2007). Experimental models also show cutoff faults that transect the uplifted zone (e.g., McClay and Bonora, 2001), particularly where the model does not utilize a set of basement plates, in order to generate the restraining stepover (e.g., Dooley and Schreurs, 2012).

Like several other features, the stress field in and around a push-up block represents contrasting characteristics to pull-apart basins: the mean stress decreases outside the step, whereas the maximum shear stresses increase inside the block (Segall and Pollard, 1980). Thus, the internal structure of push-up blocks is highly variable both in space and time, owing to this stress field and heterogeneous internal lithology and crustal rheology.

Several cases of block rotations have been identified in push-up blocks both in nature and analogue models (e.g., Ron et al., 1984; Sarıbudak et al., 1990; McClay and Bonora, 2001). The paleomagnetic recognition of significant vertical axis rotations in the field has led to block models which propose that large rigid blocks experience greatest rotations in the restraining bend areas (e.g., Luyendyk, 1991; Dickinson, 1996). According to physical modeling studies, the upper surfaces of the push-ups showed rotation with a maximum 16° after 10 cm displacement for the 150° overlapping stepovers (McClay and Bonora, 2001).
Push-up Blocks, Figure 2 Types of push-up structures: (**a**) transpressional uplift, (**b**) sharp restraining bend, and (**c**) gentle restraining bend (modified from Mann, 2007).

Geometrical aspects

Push-up blocks represent various shapes, like the planforms of pull-apart basins, but commonly in lozenge-shaped types (e.g., Dooley and Schreurs, 2012, Figure 1). Although there are some published works that studied natural examples, fundamental data about the geometric features of push-up blocks are based on physical modeling studies. According to these researches, their geometries were strongly controlled by the geometry of stepover (i.e., underlapping and overlapping), the width of the stepover in the rigid basement beneath the experiment material (e.g., sandpack), and the thickness of this material (McClay and Bonora, 2001; Mitra and Paul, 2011, Dooley and Schreurs, 2012). Related to increase in the amount of stepover, push-up blocks become wider (e.g., McClay and Bonora, 2001) like the pull-apart basins (e.g., Hempton and Dunne, 1984; Gürbüz, 2010).

Geomorphic aspects

Push-up blocks are topographic uplifts that sometimes reach several kilometers in elevation and are areas of exposed older and crustal rocks (Mann, 2007). Therefore, geomorphic features are more important for their understanding. On the other hand, well-described natural examples of push-up blocks are uncommon due to the complex three-dimensional geometries of the fault systems, and also due to their easy erodible structures as topographic uplifts (e.g., McClay and Bonora, 2001).

Mann (2007) has classified the restraining bends into three types: transpressional uplifts, sharp restraining bends, and gentle restraining bends (Figure 2). Transpressional uplifts are adjacent to straight segments of strike-slip faults which are directed oblique to plate or block movement. Sharp restraining bends represent the push-ups which form at fault stepovers and produce rhomboidal uplifts. These two structures are less common than the last gentle one. Gentle restraining bends produce elongate to domal uplifts. The inner parts consist of exposed older and deeper crustal igneous and metamorphic rocks, and their boundaries are surrounded by a radiating pattern of alluvial fans and fan deltas (Mann and Gordon, 1996).

The topographic lineaments related to the master fault traces inside the push-up block are sometimes bedimmed by the crinkled topography of the core of block but are well denoted by the valley of the master faults on either side of the block (Mann, 2007).

Summary

Large strike-slip fault zones are fundamentally segmented (e.g., the North Anatolian fault zone, Herece and Akay, 2003, Şengör et al., 2005; San Andreas fault zone, Sylvester, 1988, Powell et al., 1993) and have contractional structures (i.e., folds and reverse/thrust faults) formed in regions of overstepping and bending in the fault zone. Push-up blocks are located along strike-slip faults and transform zones and are developed between steps or long bends which produce localized contraction. They are very similar to pull-apart basins within the tectonic origin and plan view geometries, but they generate positive topography along the fault zone. Unlike the pull-apart basins, push-up blocks develop when the sense of step, or bending, of the master faults is opposite to the sense of slip on the fault zone, i.e., restraining stepovers in left-lateral faults step to the right, and in right-lateral systems, they step to the left. Push-up blocks share properties of both strike-slip and compressional regimes. The mean shear stress decreases outside the step, whereas the maximum stresses increase inside the block. They have been classified by Mann (2007) as transpressional uplifts, sharp and gentle restraining bends according to their morphologies and setting. The internal structure of push-up blocks is highly variable both in space and time owing to stress field changes and heterogeneous internal lithology and crustal rheology. Although push-up blocks are the opposite reflections of pull-apart basins, there are more synonyms for these uplifted areas as demonstrated under the title. However, pull-apart basins are far more numerous than push-up blocks in nature (e.g., Aydın and Nur, 1982; Bahat, 1983). Push-up blocks are not as well understood and well-studied as pull-apart basins, probably because of the complexity of fault geometries, and because they are regions of uplift, which once formed rapidly become eroded (e.g., McClay and Bonora, 2001).

Therefore, more surface and subsurface methods (i.e., seismic imaging) should be operated for a better understanding of this tectonic structure.

Introduction

Carbon

Carbon (chemical symbol C) is an element with six protons in a nucleus circled by six electrons. In addition, the nucleus may contain six, seven, or eight neutrons, which leads to three forms of carbon having 12, 13, and 14 mass units (^{12}C, ^{13}C, ^{14}C) with a natural relative abundance of 98.9 %, 1.1 %, and ca. 10^{-10} %, respectively. These three natural forms of carbon, called isotopes, have the same chemical properties but slightly different, mass-dependent, physical properties. The isotope carbon-14 (^{14}C) is also called *radiocarbon*, because it is radioactive, showing beta decay. Carbon is a key building block for life on earth, and its isotopes can be used to study physiological and environmental processes.

Production, dispersion, and decay

Radiocarbon is produced in the upper atmosphere, near the boundary between the stratosphere and troposphere (9–15 km altitude). There a neutron (n), produced by incoming cosmic radiation and slowed to thermal energies by collisions, enters the nucleus of an atmospheric nitrogen-14 and shoots out a proton (p) ($^{14}_{7}$N + n $\rightarrow$ $^{14}_{6}$C + p). This ^{14}C is instable and decays back to nitrogen-14, when a neutron turns into a proton, while emitting an electron (e^{-}, beta particle) and an antineutrino ($\bar{\upsilon}$) ($^{14}_{6}$C $\rightarrow$ $^{14}_{7}$N + e^{-} + $\bar{\upsilon}$). By consensus, the value used for the half-life of this decay is 5,730 $\pm$ 40 years (Godwin, 1962; Roberts and Southon, 2007), which means half of the ^{14}C atoms decay in this time.

The newly formed radiocarbon is oxidized to ^{14}CO$_2$, mixed globally with CO$_2$ in the atmosphere, incorporated into organic compounds by photosynthesis, and dissolved as bicarbonate in rivers, lakes, oceans, and groundwater. Carbon exchange between the different global carbon reservoirs (atmosphere, biosphere, soils, sediments, and ocean (surface, intermediate, deep)) maintains a flow of radiocarbon from its atmospheric production site to its decay in the various reservoirs and, thereby, offers the possibility to study the dynamics of the global carbon cycle.

Measurement

The potential of radiocarbon as a research tool was recognized and developed by Libby in the 1940s (Libby, 1965). He determined the ^{14}C concentration of a sample by comparing its rate of ^{14}C decay with that of a modern standard and a ^{14}C-free background sample, measured under identical conditions. Libby initially used Geiger-Müller counters with solid carbon to count the number of ^{14}C decays per minute; later proportional gas counters and liquid scintillation counters were used. Direct mass spectrometric measurement of the relative abundance of ^{14}C was prevented by its very low concentration (one ^{14}C atom per 10^{12} atoms ^{12}C) and the abundance of ions of ^{14}N and isobaric molecular fragments like ^{12}CH$_2$ and ^{13}CH in the ion beam. Application of nuclear physics technology in the 1970s made direct measurement of ^{14}C via accelerator mass spectrometry (AMS) feasible (Tunis et al., 1998). Crucial were the initial use of negative ions, which eliminates the isobaric ^{14}N, and the stripping-off of electrons after initial acceleration to produce positive ions, which destroys isobaric molecular fragments, plus the ability to identify and count single ions. Typical AMS ^{14}C count rates range from several hundreds to 0.1 particles per second for samples from modern to over 50,000

years old. For a modern sample, the usual 0.3 % standard deviation (equivalent to $\pm\,25$ years) of ^{14}C counting statistics can be obtained in less than half an hour, compared with several days needed in ^{14}C decay counting. The main advantage of AMS is, however, the direct detection of all ^{14}C atoms in the sample, instead of only those that decay during the measurement (one in a million in a typical 3-day measurement). Thus, despite a low efficiency in the production of negative ions in the ion source (only a few percent), AMS has reduced the sample size routinely required for a radiocarbon measurement from grams to milligrams of carbon and allows special measurements down to the 10 µg level. This makes it possible to select for analysis organic macrofossils or specific organic compounds closely associated with the event to be studied. In ocean studies, the size of water samples can be reduced by a factor of 1,000 or more, and, instead of bulk carbonate, monospecific planktic foram samples can be used to date sediments. Dissolved organic carbon (DOC) can complement DIC studies of the water column; benthic forams and pore waters can reveal carbon cycling at the ocean-sediment interface and in the sediment.

Clock: radiocarbon dating
The clock

Radiocarbon decay provides a clock that starts running the moment exchange of carbon with the environment, in particular with the atmosphere, stops and thus tells us how long ago this happened. Through metabolic processes and gas exchange, the radiocarbon concentration in living organisms and surface waters is kept in equilibrium with the environment. Upon death and when waters lose contact with the atmosphere, the radiocarbon uptake stops, and radioactive decay results in a ^{14}C concentration decreasing with time. This is the "radiocarbon clock." Measurement of the remaining ^{14}C concentration allows the calculation of the time elapsed since "death" with a precision of a few decades, provided several assumptions are valid: (i) after death no carbon was lost from, or added to, the sample (closed system assumption), (ii) the initial ^{14}C concentration is known, and (iii) the decay rate is constant and known. Of these three assumptions, the last one is valid. Extensive chemical cleaning to remove contaminants is usually needed to satisfy the first.

Initial concentration: tree-ring calibration

The original assumption (ii) that the atmospheric ^{14}C concentration was constant, everywhere on earth and over the full range of the radiocarbon method (ca. 50,000 years), was proven invalid early on (Suess, 1955; de Vries, 1958). This resulted in much research aimed at establishing a high-resolution, high-precision record of atmospheric ^{14}C concentrations in the past with which a measured ^{14}C age can be translated in a "real or calendar" age. Tree-ring research over the past 50-plus years has resulted in a dendrochronological ^{14}C calibration record going back about 14,000 years (Reimer et al., 2013). This

record reveals atmospheric ^{14}C concentrations of 20 % or more above the standard atmosphere during the last part of the glacial-to-interglacial transition (14–11.7 ka), implying ^{14}C ages too young by 1,460 years or more. The Holocene has initially a varying ^{14}C excess of 7–11 % that decreases gradually over the last 5,000 years and reaches a minimum of a 2 % deficit (^{14}C age 160 years too old) around 1,400 years ago (Stuiver and Braziunas, 1993; Reimer et al., 2013). This long-term trend probably reflects changes in ^{14}C production related to the strength of the earth's magnetic field. Climate-related redistribution of carbon between ocean and atmosphere may contribute ^{14}C changes on centennial and longer time scales. Variability on time scales of decades to centuries is attributed to the modulation of the atmospheric ^{14}C production by variable magnetic shielding by the sun (Stuiver and Quay, 1980), while solar energetic particle (SEP) events may cause sporadic jumps in atmospheric ^{14}C concentration (Miyake et al., 2012; Usoskin et al., 2013).

Initial concentration: carbonates

Carbonate fixed in foraminifera in high-quality ocean-sediment cores, in corals, and in speleothems has been used to determine (local) initial ^{14}C concentrations in the surface ocean and in cave waters, going back over 50,000 years. Under the assumption of a constant offset in ^{14}C concentration between the local surface ocean and the atmosphere and between cave waters and the atmosphere, respectively, these data have also been used as an approximation of atmospheric ^{14}C concentrations beyond the range of tree-ring calibration (Reimer et al., 2013). The Japanese Lake Suigetsu has provided the first continuous atmospheric ^{14}C record, based on terrestrial macrofossils in a set of laminated lake-sediment cores, going back beyond 14,000 to more than 50,000 years ago (Bronk Ramsey et al., 2012). Although construction of a reliable absolute Suigetsu time scale based on annual layer counting is difficult and still needs further work, comparison of the atmospheric Suigetsu ^{14}C record with the carbonate-based records indicates that the assumption of a constant offset, used so far to convert the carbonate-derived ^{14}C data to "atmospheric" values, is violated to varying degrees. This is a problem for the construction of a reliable atmospheric ^{14}C calibration record beyond 14,000 years. Yet, it offers the perspective that once an atmospheric ^{14}C calibration record has been established, the ^{14}C record of ocean-sediment cores, with an age-depth relationship determined independently, may be used to determine local ocean-atmosphere gas exchange and local oceanic mixing in the past.

Tracer: exploring the carbon cycle
Mixing and reservoir age

The use of radiocarbon as a clock requires that the ^{14}C concentration of a sample has a simple, known relation to that of the atmosphere (extended assumption ii). For carbonates this is generally not the case. The dissolved

inorganic carbon (DIC), mostly bicarbonate $HCO_3{}^-$, in the waters from which carbonates precipitate, may derive in varying proportions from sources with different ^{14}C concentration (e.g., the atmosphere, young and old organic material, and carbonates). The difference in ^{14}C concentration between DIC and contemporaneous atmospheric CO_2 is frequently expressed as a "reservoir age," defined as the time it would take the atmospheric ^{14}C concentration to reach the concentration of the reservoir DIC by decay. This reservoir age, although it may reflect mixing instead of the age of the water, can be used to trace DIC origins and through them large-scale oceanic transport and mixing processes.

^{14}C in oceanic circulation

Early water samples from the Atlantic and Pacific Oceans (Fonselius and Ostlund, 1959; Broecker et al., 1959; Bien et al., 1960) showed significant differences in oceanic DIC ^{14}C concentrations. Large-scale systematic sampling of the Atlantic, Pacific, and Indian Oceans for ^{14}C was first carried out during the Geochemical Ocean Sections Study (GEOSECS) of the 1970s. This revealed a systematic apparent aging of abyssal waters by up to 1,680 years, when going from the northern North Atlantic, via the circumpolar waters south of 50°S, to the north of the Indian and Pacific Oceans (Stuiver et al., 1983). This provided a time frame for the deep limb of the thermohaline circulation (Stommel, 1961; Rahmstorf, 2006), which as "the great ocean conveyor" (Broecker, 1991) plays a major role in global climate variability. The measure of time, introduced by the decay of ^{14}C in the ocean, gave a better understanding of large-scale oceanic transport and mixing processes, documented by conservative tracers such as salinity and nutrients. It indicated that deep waters (>1,500 m) of the entire world ocean appear to be replaced on average every 500 years, with a replacement time for deep waters of the Pacific, Indian, and Atlantic Ocean of approximately 510, 250, and 275 years, respectively (Stuiver et al., 1983). Penetration of atmospheric ^{14}C excess, created by atmospheric testing of nuclear weapons, into the ocean provided a sensitive tracer for atmosphere-ocean CO_2 exchange and oceanic mixing (Rafter and O'Brien, 1970; Ostlund, 1983; Quay et al., 1983; Broecker et al., 1985; Nydal and Gislefoss, 1996).

Modern ocean and climate: latest radiocarbon survey

The oceans have been identified as a key element in the global climate system because of their capacity to transport heat and freshwater and to sequester from (and release to) the atmosphere major amounts of carbon. Thus, the World Ocean Circulation Experiment (WOCE) was performed as part of the World Climate Research Program (WCRP) to provide coherent global ocean observations of unprecedented extent and quality between 1990 and 1998. WOCE included ^{14}C as a tracer for carbon, complemented by CFCs and tritium as tracers of anthropogenic influences. Initial ^{14}C analyses were via β-decay counting like in GEOSECS (Stuiver et al., 1996), because AMS was not ready yet to meet the stringent quality requirements of WOCE. Thousandfold reduced sample requirements for AMS allowed detailed sampling of ocean profiles and produced large numbers of samples. These were analyzed in the newly created NOSAMS laboratory at Woods Hole (Key et al., 1996; McNichol et al., 2000). In GLODAP (Global Ocean Data Analysis Project), the data gained under GEOSECS, WOCE, and further ocean research programs were integrated and processed into a "global ocean carbon climatology," providing a detailed picture of the state of the current ocean for use in ocean and climate modeling (Key et al., 2004).

Ocean, carbon, and climate of the past

Oceanic sediments were radiocarbon dated on carbonate right from the start. A preindustrial ocean reservoir age of 400 years for the Northern Hemisphere (360 years in the Southern Hemisphere), based on limited data measured on pre-bomb mollusks (Stuiver and Braziunas, 1993), was used later to correct for the oceanic DIC offset from the atmospheric ^{14}C concentration. These reservoir ages were assumed to be constant. GLODAP shows, however, large spatial variability for the modern surface ocean as well as for the deep ocean (Matsumoto, 2007).

The advent of AMS in the late 1970s allowed the selection of monospecific planktic foram samples for ^{14}C dating, which significantly improved the quality and interpretability of the results. Over the past years, comparisons of planktic foram ages in sediment cores with independent age information increasingly showed that local reservoir ages of the surface ocean have varied over time (Ingram and Southon, 1996; Voelker et al., 1998; Reimer and Reimer, 2001; Thornalley et al., 2011; Bard et al., 2013). Together with variations in the difference in ^{14}C concentration between paired benthic and planktic foram samples, this provides snapshots of the carbon cycle under different climatic and deep-ocean conditions in the past. These offer the potential to further develop and test models of the interaction between climate, the ocean, and the carbon cycle under different boundary conditions. A new method of age control in ocean-sediment cores, complementary to the classical volcanic event markers and isotopic correlations, may allow a significant systematic increase in available data. The so-called ^{14}C plateau tuning (Sarnthein et al., 2007, recalibrated to the Lake Suigetsu record by Sarnthein et al., 2015), uses the close connection between ^{14}C concentrations in the surface ocean and the atmosphere that has been the basis for the use of oceanic data in the construction of the atmospheric ^{14}C calibration beyond the realm of tree-ring calibration. High-precision, high-resolution dating of sediment cores with high sedimentation rates, made feasible by AMS, produces irregular age-depth curves with a series of plateaus that can be correlated with the distinct suite of plateaus in the atmospheric ^{14}C calibration curve. Although

local oceanographic and/or sedimentological changes may deform and mask some of the plateaus, the use of a suite of seven or more plateaus usually allows the correlation of several and thus provides both a calibrated age of the plateau boundaries and a ^{14}C offset for the locality at that time. Provided an apparent global linear relationship of ~1.22 μmol DIC/kg water per $-1‰$ ^{14}C between ^{14}C offset and concentration of modern DIC in the deep ocean ($>$2,000 m) also is valid in the past (Sarnthein et al., 2013), the paleo-^{14}C offsets offer a unique opportunity to reconstruct past changes in ocean circulation and the ocean carbon cycle over glacial-to-deglacial times. Although many of the available ocean climate-carbon models have not been tuned to these data yet, first positive results using this information have been obtained. It may thus be possible to further exploit the power of ^{14}C as a paleo-oceanographic tracer and dating tool for long-distance correlation and understanding of oceanographic and climatic changes in the coming years.

Summary

Radiocarbon in the ocean provides both a dating tool and a tracer for the carbon cycle. Because oceanic mixing processes on time scales of centuries to millennia are not short compared to the half-life of ^{14}C, they can be studied via the differences in ^{14}C concentration caused by ^{14}C decay during this mixing. Detailed sampling, made possible by AMS, has produced a ^{14}C database that contributes significantly to our understanding of the modern ocean and its role in the global climate. Quantifying ^{14}C deficiencies in key ocean-sediment cores from the LGM up to the present may be expected to provide further important insights.

Synonyms

Dating; Isotopes; Stratigraphy; Tracers

Isotopes can be characterized to be stable, cosmogenic, radioactive, or radiogenic. Stable isotopes do not change their relative abundance in the environment as long as no isotopes are added or extracted from the system. Cosmogenic isotopes are produced by high energetic cosmic rays in the upper layers of the atmosphere and are usually radioactive also. Radioactive isotopes change their abundance in the environment according to their half-life ($T_{1/2}$), whereas radiogenic isotopes are not radioactive itself but change their abundance according to the half-life of their mother isotope. There are several important radiogenic systems known, and the most important are $^{238}U/^{206}Pb$, $^{190}Pt/^{186}Os$, $^{147}Sm/^{143}Nd$, $^{87}Rb/^{87}Sr$, $^{187}Re/^{187}Os$, $^{176}Lu/^{176}Hf$, $^{232}Th/^{208}Pb$, $^{40}K/^{40}Ar$, $^{40}K/^{40}Ca$, $^{235}U/^{207}Pb$, $^{129}I/^{129}Xe$, $^{10}Be/^{10}B$, $^{26}Al/^{26}Mg$, $^{36}Cl/^{36}Ar$, $^{14}C/^{14}N$, etc. For the geological sciences, the most important radiogenic isotope systems are the radiogenic systems of three natural decay chains $^{238}U/^{208}Pb$ ($T_{1/2}$:4.468 Gyr; Gyr = 1 billion years), $^{235}U/^{207}Pb$ ($T_{1/2}$:0.7038 Gyr), and $^{232}Th/^{208}Pb$ ($T_{1/2}$:14.01 Gyr) as well as $^{87}Rb/^{87}Sr$ ($T_{1/2}$:49.44 Gyr) and $^{147}Sm/^{143}Nd$ (106 Gyr), respectively. For practical reasons and their application, the radiogenic isotopes are usually normalized to a stable isotope of the same element, for example, $^{208}Pb/^{204}Pb$, $^{207}Pb/^{204}Pb$, $^{206}Pb/^{204}Pb$, $^{87}Sr/^{86}Sr$, and $^{143}Nd/^{144}Nd$. The latter "radiogenic isotope ratios" are considered tracers because of their radiogenic characteristic; they can be applied for absolute (isochron age dating) and stratigraphic age dating as well as for provenance studies. Provenance studies are possible because the radiogenic isotope ratios in minerals and mineral-forming rocks are characterized by both the time interval of the mineral since mineral formation and the abundance of the radiogenic mother nuclide.

Concerning age dating besides the $^{87}Rb/^{87}Sr$ and $^{147}Sm/^{143}Nd$ systems, the U/Pb dating system is the most important one, because its great advantage over other absolute dating methods is that any sample provides two clocks, one based on $^{235}U/^{207}Pb$ with a $T_{1/2}$ of ~0.7 Gyr and one based on $^{238}U/^{206}Pb$ with a $T_{1/2}$ of ~4.5 Gyr, both providing independent verification of the calculated ages that allows accurate determination of the age of the sample even if the "closed-system behavior" of the sample is violated. The data are plotted in a "concordia diagram," where the samples plot along an isochron, line of equal ages, which intersects the concordia curve at the age of the sample (Faure, 1986; Dickin, 1995).

Radiogenic isotope stratigraphy relies on the recognized variations of certain radiogenic isotope ratios ($^{87}Sr/^{86}Sr$, $^{88}Sr/^{86}Sr$, $^{44}Ca/^{40}Ca$, etc.) over time in seawater and their recording in marine inorganic and biogenic carbonates. Records of radiogenic isotopes in marine carbonates are unique time series and documents (e.g., Veizer, 1989) of the chemical history of seawater since its formation until today as well as of the tectonic, biological, and climatic history of the embedded continental land masses.

RADIOLARIANS

Kjell R. Bjørklund
Museum of Natural History, University of Oslo, Blindern, Oslo, Norway

Definition

Radiolaria are single-celled marine eukaryotes, also some colonial forms, existing from the Cambrian (ca. 530 Ma) to recent. Thus, radiolarians are one of the longest ranging groups of fossil microorganisms. The founders of radiolarian taxonomy were two German scientists, C.G. Ehrenberg (1795–1876) and E. Haeckel (1834–1919). Ehrenberg described more than 70 genera and 500 species, while Haeckel contributed more than 700 genera and 4,000 species. Haeckel's (1887) system is the basis of some modern taxonomic systems. One proposed by Riedel (1967) is the most commonly used: *kingdom* Protista, *phylum* Sarcomastigophora, *subphylum* Sarcodina, *class* Actinopoda, *subclass* Radiolaria, *superorder* Polycystina, and *orders* Spumellaria (SiO_2), Nassellaria (SiO_2), and Phaeodaria (SiO_2 + organic compound). In this scheme, Acantharia ($SrSO_4$) and Heliozoa (SiO_2) also are assigned to the class Actinopoda but in separate subclasses. This system is mainly based on skeletal material and general morphology, as well as internal cellular structures. New phylogenomic studies show that this Haeckelian system is artificial (not representing evolutionary relationships), and new systems based on molecular genetic data establish more natural relationships among the six supergroups of eukaryotes as proposed by Cavalier-Smith (2002, 2003).

The first description of living colonial forms, such as *Sphaerozoum fuscum*, was made by Meyen (1834). Since then, we have recorded about 2,500 high-rank taxa (genera/subgenera) and 15,000 species, of which, 800–1,000 are currently living in the oceans (Suzuki and Aita, 2011).

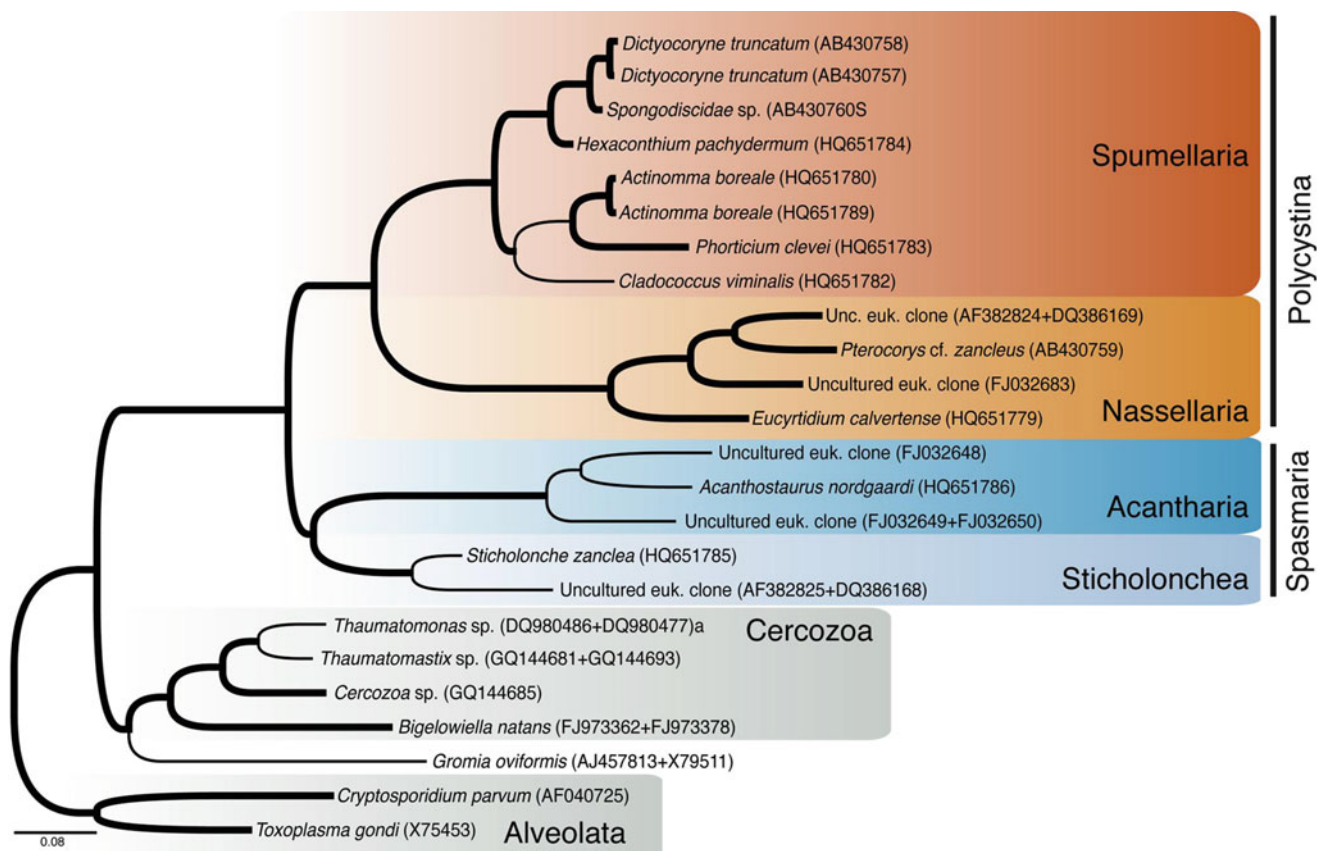
Taxonomic position

Today, molecular work on radiolarians is an active field of research, and the taxonomical scheme is constantly adjusted as new data are made available. Cavalier-Smith (2003) suggested the following system: kingdom Protozoa, subkingdom Biciliata, phylum Retaria, and subphylum Radiozoa, with classes Acantharea, Polycystinea, and Sticholonchea, a system that has not stabilized and is under development. The Phaeodaria are no longer included in the general category of "Radiolaria" (previously in the phylum Retaria), but placed in phylum Cercozoa. The Radiolaria 18S rDNA phylogeny trees presented in recent publications are rather similar to each other and suggest a polyphyletic status for the polycystines but are limited by using only the 18S gene. By contrast, Krabberød et al. (2011), using both 18S and 28S rDNA, show that Spumellaria group with Nassellaria, thus suggesting they form a natural phylogenetic group (Figure 1). Their data provide a more convincing monophyletic status for the polycystines (Spumellaria together with Nassellaria), as well as a close relation between Acantharea and Sticholonchea, a group given the name Spasmaria (Cavalier-Smith, 1993). In contrast, when only 18S rDNA is used, Acantharea branch with Spumellaria. These results show that combining the 18S and 28S rDNA genes may greatly improve the resolution of the radiolarian phylogeny.

Organization of the cell

The *central capsule* is the inner part of the cell, made up of endoplasm and some organelles like the nucleus and the axoplast. The shape of the siliceous skeleton depends on the organization of the central capsule, and an individual that is reduced to this stage can regenerate all missing parts. Its shape varies from species to species and increases with age. The soft-bodied central capsule is not fossilized, but Dumitrica (1999) observed some very rare, well-preserved, Mesozoic capsular membranes. The *capsular membrane* (made of chitinous or pseudochitinous material) is perforated by small fusules and fissures, through which axopodial filaments extend from the axoplast to the outer parts of the shell. In Spumellaria, the fusules and fissures are evenly distributed over the surface of the central capsule, while in Nassellaria, they are located at one end on the capsular membrane.

The *endoplasm*, on the inside of the capsular membrane, contains one or several *nuclei* (latter typically during reproduction) in addition to *mitochondria* (cell's supply of energy, adenosine triphosphate (ATP)), the *Golgi* apparatus (processing of proteins for secretion), and some *vacuoles* (lipid droplets) and the *axoplast* (area where the microtubules of the slender and stiffened *axopodia* originate). Often, there is a main axopod called *axoflagellum* (Figure 2).

The *ectoplasm*, outside of the capsular membrane, is a complex body, appears spongy, and can retract if disturbed by external objects. Ectoplasm is divided in three parts: (a) an inner thin layer, *sarcomatrix*, a pigmented and granular cytoplasm; (b) a middle part, *calymma*, a sticky, gelantinous cytoplasm with numerous *alveoles* (filled


Radiolarians, Figure 1 A phylogenetic tree of Radiolaria using the 18S and 28S rDNA genes. *Thick* branches are well supported with maximum likelihood bootstrap value higher than 95 and Bayesian posterior probability higher than 0.95 (modified from Krabberød et al., 2011).

with liquid or gas, looks like a soap-bubble-like frothy layer, especially in Spumellaria) and digestive vacuoles and often colored by the presence of symbionts (*zooxanthellae*, often dinoflagellates); and (c) the outer part, the *sarcodictyum* (a thin network of protoplasm on the surface of the calymma of a radiolarian).

The *pseudopodia* are mobile elongated extensions of the cytoplasm extending outside the cell. This includes
Radiolarians, Figure 3 Ultrathin sections of early shell deposition showing organic granules (**a**) and preceding silica deposition (**b**). Sample B has been HF treated demonstrating the resistance of these particles. Scale = 250 nm (after Anderson and Swanberg, 1981).

the filopodia (slender, tapered, unstiffened) and the axopodia (stiffened), sometimes also the axoflagellum.

Organization of the skeleton

For the micropaleontologists, the skeleton is the most interesting part of a radiolarian cell. In the following, only the Polycystina with a pure silica skeleton ($SiO_2 + nH_2O$) will be discussed, as the Acantharia and Phaeodaria do not produce skeletons that are fossilized (see above). Paleontologists study the skeletons in soft sediment and hard rock samples and thereby have limited information on the growth stages of the different species and specimens. However, this can be done when living specimens are taken from the plankton and studied in the laboratory. In culture experiments, juvenile radiolarians have been kept alive until gamete formation (Anderson, 1983; Kimoto et al., 2011), but nobody has so far succeeded rearing radiolarians through successive generations.

In general terms, the skeleton in all radiolarians is extracapsular, only in adult Spumellaria and Entactinaria can the innermost shells be found in the capsular cytoplasm (De Wever et al., 2001). The radiolarian skeleton is enclosed in a sheath of cytoplasm that protects the surface against immediate dissolution by seawater and also provides a strict physiological control over the rate of deposition and the ultimate shape of the skeleton.

The skeletal morphology is also affected by environmental conditions but even more dependent on the physiology of the cell (Matsuoka, 1992). Immediately before the silica deposition starts (Figure 3a), a granular matrix was observed that is resistant to HF dissolution (Figure 3b) showing that the granules are not silica (Anderson and Swanberg, 1981).

They concluded that the densities of these siliceous granules dictated the porosity of the shell, an important aspect with respect to fossilization of the skeleton,

different for each species, depending on its cellular organization. The silica, absorbed from the seawater, is deposited by intermittent episodes, based on observations of rates of growth of Radiolaria in laboratory culture (Figure 4).

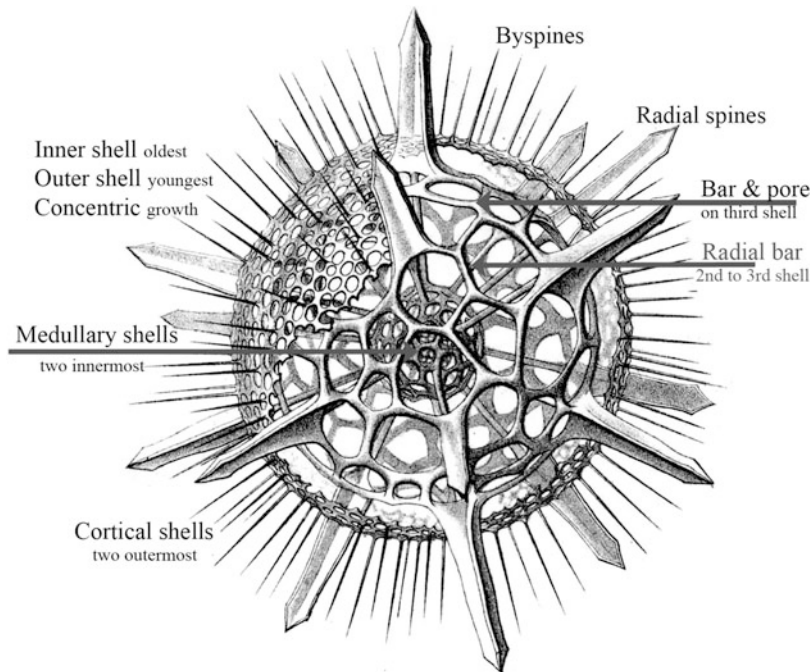
Also SEM observations of concentric layering in fractured and dissolved segments of radiolarian skeletons obtained from sediments (Figure 5) document the stepwise growth. Brandt (1881) believed that a still not identified organic substance is connected with the silica deposition. He noticed that some shells of *Collosphaera huxleyi* consisted only of albuminous substances and had the size and shape of the future latticed shell. Brandt never came to a final conclusion whether the organic substance in the *C. huxleyi* shells is, completely or only partially, subject to the silicification process. This has so far not been clarified. However, Anderson (1983) used the term "cytokalymma" and defined it as a cytoplasmic sheath that encloses, molds, and deposits the skeleton. This is in remarkable good harmony with what was proposed by Brandt (1881). It is also important to note that within the cytokalymma, silica deposition at the growing edge of the skeleton is deposited on apparently organic granules that form the initial framework for the growing skeleton (Anderson and Swanberg, 1981). The spumellarian shells have a centrifugal, concentric, growth pattern, meaning that the innermost shell, the *microsphere*, develops first, and outer shells are constructed sequentially outward. Therefore, the innermost structures are more conservative and are of more importance in taxonomic work than structures on the outermost (cortical) shells. The radial spines grow first from the microsphere, and their number and position are fixed by the position of the pores (*fusules*) on the capsular membrane, so is also the number of spines. Spumellarian skeletons have different structures and shapes. In spherical forms, all three axes are of equal length. A shortened z-axis gives a discoidal shape, and
Radiolarians, Figure 4 Stepwise growth curves of individual *Spongaster tetras tetras* grown in laboratory culture (Anderson et al., 1989).
Radiolarians, Figure 5 Growth rings: *left*, *Rhizosphaera* sp. from Upper Eocene, the Norwegian Sea. *Right*, *Gorgospyris perplexus* from Upper Miocene, California (photo by K.R. Bjørklund and R.M. Goll, 1982).

when the other axes are more extended, the shape becomes ellipsoidal. If all three axes are of different length, the skeletons will have a system of three successively larger elliptical girdles distributed in three mutually perpendicular planes. A general morphologic outline of a spherical spumellarian shell includes the radial spines, fine byspines, and thickened bars connecting concentric shells (Figure 6).

For the nassellarians, one character is their *bilateral symmetry* situated around the first skeletal element, the *median bar (MB)*. From one end of this structure, an *apical spine (A)* points upward, while one *dorsal spine (D)* and two *secondary lateral spines (l_l and l_r)* point downward. From the other end of the MB, an unpaired *ventral spine (V)* (also called vertical) points upward, while a pair of *primary lateral spines (L_L and L_R)* point downward. These principal bar and spine structures are the first skeletal elements to be seen in juvenile forms, Figure 7.

The next skeletal element to develop is the first segment, the *cephalis*, then the *thorax*, and finally the *abdomen* (one or more segments). At the junction between two segments, there may appear heavily silicified internal rings, called the *collar ring* (or stricture) and the *lumbar ring*, separating the cephalis-thorax-abdomen, respectively. In addition to the arrangement of pores (longitudinally, transversally, or obliquely), the presence of spines and their different shapes on different segments are of taxonomic importance. See De Wever et al. (2001) for further skeletal characters and taxonomical notes.

Longevity

Of the estimated 800–1,000 living radiolarian species (Suzuki and Aita, 2011), there are no data of the exact *longevity* of any species. Different estimates have been made for cultured juvenile forms and until they made


Radiolarians, Figure 6 *Line* drawing modified from Haeckel (1887, pl. 30 Figure 1), the most important structures are named.

swarmer cells. The longest survival observed in the laboratory was 75 days (Matsuoka, pers. com., 2009), but other observations indicate much shorter periods, longer than 3 weeks. Other experiments by estimating the turn-over time based on the study of sediment trap samples gave a shorter longevity, 0.44–37 days in the California Current (Casey et al., 1971) and 16–42 days in the North Pacific (Takahashi, 1983).

Reproduction

The reproduction within radiolarians is still not fully understood. Stages with swarmer production have been observed by Anderson (1976, 1978), a probable sign for sexual reproduction. Similar findings were done by Kimoto et al. (2011) in *Cypassis irregularis* Nigrini (Spumellaria). These swarmers, in the range of <3 μm, gave 18S rDNA sequences that fell within those of typical

radiolarian families. This may explain that the deep-water radiolarian 18S rDNA sequences found in the picoeukaryote size fraction from deep water, by several authors (Not et al., 2009; Lovejoy and Potvin, 2011), are gametes or swarmers released for reproduction.

Binary fission or asexual reproduction was demonstrated already by Brandt (1902) and confirmed by Hollande and Enjumet (1953). Vegetative reproduction is probably an important aspect as Itaki and Bjørklund (2007) reported on conjoined skeletons, in several combinations, as two sets of medullar shells are incorporated within one cortical shell. This is also observed within and between different species and genera, indicating that the present taxonomy based on morphology alone needs to be modified and combined with molecular support. Finally, hybridization was discussed by Goll (1976) and Lazarus (1983). Goll convincingly showed that the geographic distributions of his inferred hybrid taxa correspond to regions of geographic overlap in the inferred parental species and to oceanic regions of upwelling. Some of the old radiolarian reports (Hertwig, 1879; Brandt, 1902; Enriques, 1919, to mention a few) described different types of spores which were associated with reproduction. However, these have by later workers been demonstrated to be motile stages of endosymbiotic dinoflagellates.

Nutrition

Radiolarians feed on a variety of prey and can be divided into herbivorous, carnivorous, and omnivorous. Anderson et al. (1984) demonstrated that some of the spinose species easily can trap and digest zooplankton prey. As for the non-spinose species, algae are more common than animal prey. Other species may be more specialized with preferential prey (Anderson, 1978). The prey is trapped by the numerous pseudopodia. When prey has been made immobile, it is encapsulated in tick membranous vacuoles where digestion takes place. A practical upper size of the prey can be set at about 1 cm, but prey as small as bacteria are caught. Furthermore, some species, especially those living in the photic zone, may be the host for **symbionts**, most frequently these are dinoflagellates. Colonial spumellarians have the highest concentration of symbionts, and Swanberg and Harbison (1980) described *Collozoum longiforme*, up to 3 m long, with 14–50 algae per central capsule. Swanberg and Anderson (1981) described *C. caudatum*, up to 2 m long, with 58 (40–70) central capsules per cm, and 311 (250–350) algae per central capsule, indicating that a 2 m long colony would have a number of about 3.6×10^6 algae. Swanberg and Harbison (1980) found that colonial radiolarians can produce 14,000–41,000 ng C/colony/h. Similarly, Anderson et al. (1989) found that some large solitary radiolarians could produce from 35,000 to 110,000 ng C/individual/h. These values are directly linked to the large size of the species investigated and the high number of symbiotic algae.

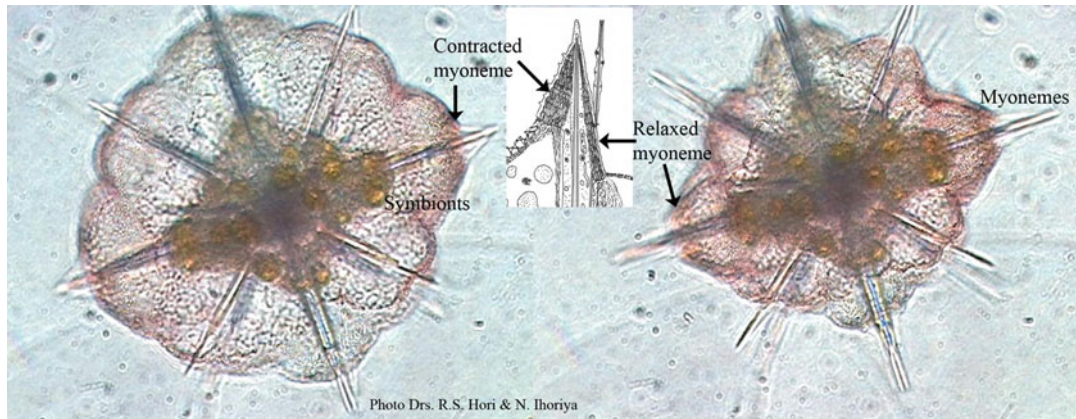
Migration

Radiolarians are planktonic organisms passively drifting around, carried by the different currents in the world ocean. Therefore, their lateral motion is not controlled by the organism itself. **Lateral transportation** is well known (see below), as well as their **vertical migration** has been observed. Their buoyancy is explained by the vacuolar cytoplasm and its content of oil droplets, important for their position in the water column, as well as consuming (eating) or shedding their oil droplets and symbionts. The volume of an individual radiolarian cell can be controlled by extending and retracting its pseudopods. By extension, the volume increases, so does the buoyancy, and the specimen is lifted in the water column. Similarly, the symbionts will be exposed for the diurnal photosynthetic cycle. During daytime, CO_2 is consumed due to the photosynthetic activity in the cell, causing a downward migration, while during the nocturnal phase, CO_2 is accumulated in the cell. This increases the uplift resulting in an upward migration. Anderson (1983) indicated a diurnal migration in the range of 200 –350 m up and down. In the acantharians, Schewiakoff (1926) described slender contractile myonemes in the pericapsular cytoplasm that can contract (Figure 8, left) and relax (Figure 8, right) and thus change the volume of the cell, causing it to rise or sink. The two images are one and the same specimen, demonstrating the effect of the myonemes.

Luminescence

This phenomenon has been reported to take place in both solitary and colonial radiolarians. It seems to take place in the gelatinous extracapsulum (Anderson, 1983), but at present, it is not known whether it is the dinoflagellate symbionts or the radiolarian cytoplasm that is the source of this luminescence. However, Herring (1979) reported that the rhythmic discharges within the unicellular *Thallasicolla* sp. are clearly very different from that of dinoflagellates both in its physiology and its chemistry.

Diversity

It has been estimated (Suzuki and Aita, 2011) that at present we have about 800 living polycystine species. Some species are cosmopolitan, but the majority are confined to particular water masses, where they are most adapted. The fauna is further restricted to zoogeographical provinces (tropical, subtropical, transitional, subpolar, and Antarctic zones) (Johnson and Nigrini, 1980) as well as in vertical or environmental zones (surface, subsurface, moderately deep, bathypelagic, and abyssal (Reshetnyak, 1955)). The highest number of species is found in the tropics diminishing toward the poles, being most abundant in the upper ca 200 m, with 5,000–15,000 individual/m^3 (Petrushevskaya, 1971), but abundances of up to 394,000 individuals/m^3 have been reported (Boltovskoy et al., 2003) of a monospecific assemblage of *Lophophaena rioplatensis* of Argentina.


Radiolarians, Figure 8 An acantharian cell with perispicular cytoplasm that includes myonemes. Same cell with contracted (*left* image) and relaxed (*right* image) myonemes (photo by Drs. R.S. Hori and N. Ihoriya 2005).

Radiolarians were earlier considered to be oceanic indicators (Casey et al., 1970; Casey, 1971) and only adventitiously found in coastal waters (Casey, 1971). However, Swanberg and Bjørklund (1986) demonstrated that typical abundances of radiolarians greater than 2000/m^3 are present in landlocked Norwegian fjords, with a maximum of 9800/m^3 in Finnabotn.

Currents can transport radiolarians and carry them far from their home areas, where they may occur abundantly in alien oceans, or from one ocean to another where they may have variable reproduction success. Recently, it was documented that a warmwater spumellarian *Didymocyrtis tetrathalamus* was observed in plankton off northern Svalbard, together with several other warmwater (tropical) spumellarian and nassellarian species (Bjørklund et al., 2012). Assuming these radiolarians originated in the Gulf of Mexico, where an estimated 450–500 species occur, most of this fauna will not survive during advection from the tropical-subtropical region to the Arctic. Based on an advection time for the warm water of 5–7 years from the Florida Strait to the Fram Strait and with a radiolarian longevity of about 30 days, this warmwater assemblage would require 60–84 generations to complete this traverse. This is an example of unexpected warmwater fauna in a cold water realm. Keeping this in mind, there have been similar events in the past, thus obscuring paleoecological interpretations. For example, an almost 100 % tropical planktonic foraminifera associations have been reported in the Laptev Sea (Matul et al., 2007).

Preservation in sediments

The ocean is undersaturated with respect to dissolved SiO$_2$. Diatoms and radiolarians, the two most important contributors of suspended silica, are most common in the photic zone, from where the silica for the skeletons is extracted. This results in a strong dissolution of the skeletons, and some loss of siliceous microfossils occurs initially in the upper part of the water column. Lizitsin

(1972) indicates that only 1–10 % of siliceous skeletons produced in the upper 200 m are eventually deposited in the bottom sediments. Takahashi (1991) reported that radiolarian skeletons collected in shallow sediment traps have porous surface layers due to dissolution. Similarly, I have observed completely hollow skeletons of *Lithomitra lineata* in surface sediments in the Norwegian Sea. Johnson (1974) reported on selective dissolution of siliceous skeletons with increasing detrital input in the eastern equatorial Pacific. Abundance and preservation patterns of radiolarian skeletons in the surface sediments of the northern and southern Atlantic (Goll and Bjørklund, 1971, 1974, respectively) indicated that the preservation of their skeletons is closely related to their relative abundances. Radiolarian ooze in the sediments (>30 % radiolarian SiO$_2$) is located in the equatorial regions of the Pacific and Indian Oceans, which is a direct result of surface water production as well as CaCO$_3$ dissolution at great depths.

The living radiolarian surface water associations will certainly be different from the fauna associations observed for their skeletons in the bottom sediments, due to dissolution, as exemplified by Boltovskoy et al. (1993). In the east equatorial Atlantic, they compared radiolarian faunas in sediment traps and surface sediments. They convincingly showed that the spumellarian shells occurred with 35 % in the sediments while only 19 % in the water column. The nassellarians showed the opposite, being more abundant in the water column (80 %) than in the bottom sediments (64 %).

A rather interesting phenomenon is found in the anoxic and superhaline basins in the Mediterranean Sea (Bjørklund and De Ruiter 1987), Red Sea, and Gulf of Mexico. In the Orca Basin, the salinities are >260 psu, due to seepage from salt domes, and with measured silica levels of up to 235 µM, while it is 25 µM in normal ocean water. In these basins, siliceous skeletons are found in high abundance and with perfect preservation of fine skeletal structures.

Zoogeography through time

Radiolarians were one of the main groups to be studied in the 1970s and 1980s during the CLIMAP project (Climate: Long-range Investigation, Mapping, and Prediction). Its main objective was to study and map the climatic situation during the last glacial maximum (LGM) versus the present-day conditions. In the north Atlantic, one of the main results was that the polar front had moved down from the present position between Iceland and Greenland to about 45 °N, almost east-west from Newfoundland to the northern tip of the Iberian Peninsula. This can be illustrated by the arctic radiolarian *Amphimelissa setosa*, at present making up ca. 70 % of the cold water fauna on the Iceland Plateau. However, traces occurred about 5 °N of the Azores during LGM, indicating much colder water. Similarly, the apparently deep and cold water radiolarian *Cycladophora davisiana* reached values in excess of 20 % (Morley, 1983).

The onset of the Deep Sea Drilling Project (DSDP) in the late 1960s, and continuing under different names, has cored the ocean bottom sediments and produced a tremendous sediment core archive for scientific use, especially

Radiolarians, Figure 9 An example of a detailed Quaternary – middle Neogene (0–14.5 Ma) Norwegian Sea radiolarian biostratigraphy (IODP Leg 104). Many endemic species used as zonal markers allow this scheme only to be used as a local to regional biostratigraphic tool. Early Neogene (14.5–21.7 Ma) Norwegian Sea radiolarian biostratigraphy (IODP Leg 104).

for biostratigraphy, paleoceanography, and paleoclimatology. The Integrated Ocean Drilling Program (IODP) expedition 306 to the north Atlantic cored a continuous sediment column spanning the last ca. 3 Ma at site U1314. At this site, it was nicely demonstrated that the northern hemisphere glaciation started at about 2.7 Ma and that the radiolarian fauna fluctuated between a glacial, transitional, and interglacial assemblage corresponding to the 41,000 year Milankovitch obliquity cycle. The fauna changes became even more pronounced when the glacial-interglacial cycles shifted from a recurrence of 41,000–100,000 years at about one million years ago.

When an ocean site over time receives alternating warm, transitional, and cold water radiolarian fauna, this indicates that the different fauna provinces are migrating from north to south during glacial periods (an expanding arctic fauna province that shrinks the other fauna provinces) and opposite during interglacial periods (a shrinking arctic fauna province that expands the other fauna provinces).

At a longer time scale, such as during ocean basin development, for example, opening of the Norwegian Sea, different episodes in the tectonic evolution (opening and closing of water gateways) are depicted in the radiolarian biostratigraphy. Biostratigraphy is important for

correlation between sites. It is not possible to compose one radiolarian biostratigraphic scheme applicable for the entire world, which would have been possible if all species had been cosmopolitan. Due to the phenomenon of endemic species, and particular species dwelling in zoo-geographical provinces, only the tropical provinces of the Pacific, Indian, and Atlantic Oceans can be worked out with a common biostratigraphic framework. High-latitude faunas in the Atlantic are different from those in the Pacific, which again are different than in high southern hemisphere latitudes. In other words, the radiolarian bio-stratigraphic schemes are only of regional use and very dependent upon the radiolarian preservation. An example of a rather detailed local Neogene-Quaternary stratigraphy established by Goll and Bjørklund (1989) is shown in Figure 9.

Coconut Creek, FL, USA

Synonyms

Atoll; Bank; Barrier reef; Carbonate mound; Cay; Coral
island; Coral reef; Fringing reef; Key; Organic reef; Rock
barrier; Sandbar; Shoal; Skerry

Definition

In nautical terms, a *reef* is a rock, sandbar, shoal, or other
topographic feature lying at 10 fathoms (20 m) or less
beneath the surface of the water (Jackson 1997) and is so
recognized because these features form an obstruction to
navigation. From a geological point of view, a reef may
be a mass or ridge of rock (i.e., hogback ridge, whaleback,
dike, or sill) that lies below, at, or somewhat above the sur-
face of the sea or lake.

A more commonly recognized form of reef is the con-
temporary *coral reef* (e.g., Done 2011), which may consti-
tute the shore with no other land (atoll), may touch a
terrestrial shore (fringing reef), or may occur some dis-
tance offshore with an adjacent landward lagoon on the
continental shelf (barrier reef). Coral reefs are thus com-
monly defined as: "A mound or ridge of living coral, coral
skeletons, and calcium carbonate deposits from reef biota
such as calcareous algae, mollusks, and protozoans," com-
posed mainly of coral and other organic matter of which
parts have solidified into successive layers of limestone
(e.g., Done 2011; Jackson 1997). Coral reefs that are
now separated from the shore by sea-level change and/or
tectonic movements (i.e., uplifted or drowned) are referred
to as bioherms or biostromes.

Artificial reefs such as shipwrecks or debris piles are
sometimes created to enhance physical complexity on
generally featureless sand bottoms in order to attract a
diverse assemblage of organisms, especially fish.

A reef coast thus may be regarded as a shore that is
dominated by underwater or shallowly surfacing rock
ridges, sandbars, coral mounds, ridges, or islets,, including
short coastal segments that are dominated by the place-
ment of artificial reefs.

Etymology and usage

According to Fox (2005) and Gove (1971), for example, the word reef seems to be derived from the Old Norse word *rif* (ridge), which literally means rib (but by the fourteenth century meant "horizontal section of sail"), and hence "reef of a sail," the connotation eventually referring to the shape or morphology of this coastal feature. Other derivations probably stem from Middle English *rif*, from Proto-Germanic *rebjan* ("rib, reef"), from Proto-Indo-European *rebh-* ("arch, ceiling, cover") and its cognate with Dutch *rif* ("reef"), Low German *riff*, *ref*, and *reff* ("reef"), German *riff* ("reef, ledge"), Danish *reb*, Swedish *ref*, and Old English *ribb* ("rib"). The various origins show similarity of intent to convey the same message that was subsequently used to describe these coastal marine features in the scientific literature. When the hypernym reef is used to modify a noun as in the case of *reef coast*, it refers to a special kind of coast (q.v.) that is dominated by non-coral and coral reefs.

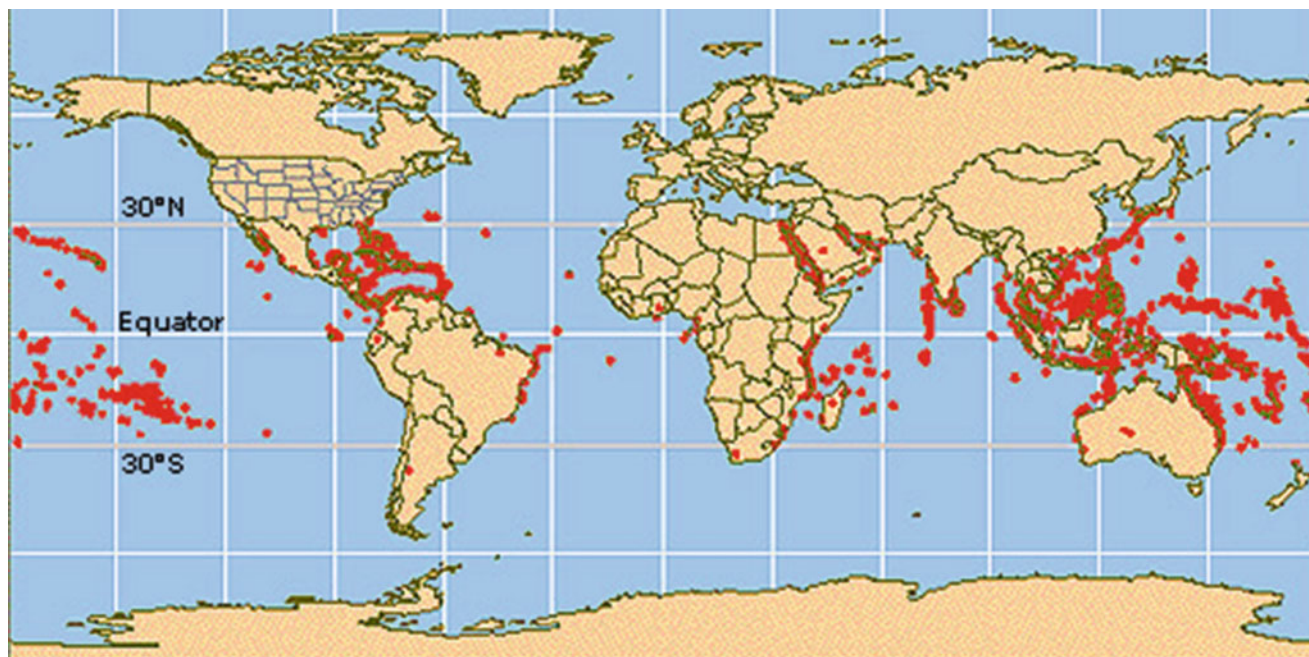
Rock reefs and non-biogenic reefs

Rock reefs result from abiotic processes, such as the deposition of sand, wave erosion planning down rock outcrops, glaciation of bedrock and surficial covers to form glacial residuals (i.e., moraines, kames, eskers, drumlins, whalebacks [rock drumlins, tadpole rocks, streamlined hills], roche moutonnée ["sheepback"] rock), drowning of weathering residuals (i.e., tors, corestones ["woolsacks"]), and other natural processes that result in exposure and drowning of rock or geochemically indurated materials such as laterite or silcrete. Modern non-biogenic reefs thrive in a wide range of environments extending from sponge reefs in the Arctic to chemosynthetic algae and *Halimeda* reefs found near methane seeping faults at depths of 600 m (Wood 1999).

Coral reefs

The best-known reefs, however, are the coral reefs of clear tropical and subtropical waters where they occur adjacent to land or around submerged volcanic peaks, as so clearly described long ago for the Pacific Ocean, for example, by Agassiz (1898), Dana (1872), and Darwin (1842). These reefs were developed through biotic processes dominated by communities of corals and calcareous (coralline) algae.

Although rock reefs may occur along all coasts, coral reefs exhibit restricted geographic distribution due to ecological requirements of the coral ecosystem. Figure 1 shows the global distribution of major coral reef systems in tropical and subtropical regions. Shallow-water coral reefs do not occur just anywhere in this geographical zone but are concentrated in specific areas indicated by the red dots on the maps. Reefs thrive in these areas where ecological conditions are favorable for their growth.

Coral reefs are found in circumtropical shallow tropical waters (mainly in regions where the water temperature is always above 18 °C in winter) along the shores of islands and continents (Figure 1). Coral reef coasts are found in the Indo-Pacific province, which is traditionally subdivided into eastern (Red Sea, the western part of the Indian Ocean, and the eastern part of the Indian Ocean) and western (central part of the tropical Pacific, Malaysia, the Philippines, and Indonesia) subregions, and the


Reef Coasts, Figure 1 Global distribution of coral reefs showing concentrations in tropical and subtropical regions (source: NOAA Coral Reef Information System: http://coris.noaa.gov/about/what_are/welcome.html).

Atlantic (Bermudas, Caribbean Sea area, coasts of northern Brazil and West Africa) province (i.e., Woodroffe 2002). The Indo-Pacific province contains about 500 species of corals where the dominant genus of branching corals (*Acropora*) consists of more than 150 species, compared to only two species prominent in this genus in the Atlantic province (i.e., Wood 1999; Woodroffe 2002).

Shallow-water reefs require a minimum temperature of 18 °C and therefore occur less frequently on the eastern Atlantic and Pacific coasts than on the warmer western coasts. The reef substrate is mainly composed of calcium carbonate from living and dead scleractinian corals. Corals live in very nutrient-poor waters and have certain zones of tolerance to water temperature, salinity, UV radiation, opacity, and nutrient quantities (Wood 1999). In spite of these ecological requirements, coral communities can thrive under the proper conditions to form large features in the sea and adjacent to land masses.

Australia has the most extensive and pristine coral reef systems in the world where the northeast coast is dominated by the Great Barrier Reef (GBR). Ningaloo Reef, along the northwest coast of Western Australia, is the largest fringing reef in the world (Short and Woodroffe 2009). The GBR, a continental-shelf reef system that can be seen from the outer space, is the world's most extensive coral reef system that stretches 2,300 km over an area of approximately 344,400 km^2 making it the largest biologically built structure in the world (Short and Woodroffe 2009; Woodroffe 2002). The GBR contains more than 3,600 individual reefs and 900 islands. More than 750 fringing reefs occur along the mainland coast and on "high" islands where bedrock outcrops. Other notable coral reef coasts in the world include the New Caledonian reefs, the Mayotte reefs, the Belizean reef system, and the Florida Reef Tract.

All coral reefs have distinctive horizontal and vertical zones created by differences in depth, wave action, current movement, light, temperature, and sediment along different parts of the reef (Woodroffe 2002). Although the exact characteristics of each zone may vary slightly depending on the location and type of reef, all shallow-water coral reefs have a forereef, or seaward slope, and a backreef. The backreef is the part of the reef closest to shore, while the forereef is farther out to sea. In addition to these distinctive zones, coral reefs are grouped together on the basis of dominant morphological characteristics and classified on the basis of variable properties (i.e., Stoddart 1969a). Although there are different classification systems, several basic types are commonly recognized, viz., atolls, fringing reefs, and barrier reefs. All of these types of coral reef are subdivided to produce a wide range of morphological reef coasts.

Classification

There are many different types of coral reefs and their subdivision can become quite complicated. Shallow-water coral reefs vary in form, plan, and origin in an almost infinite number of ways (Nunn 1994; Parnell 2011); it is also difficult to get scientists to agree on any one particular schema because of the complexity involved. Even though it is impossible to identify all types of coral reef coasts, general impressions may be obtained from the following brief summaries that are based on seminal and much earlier works that are still relevant today. Darwin's (1838, 1842) original descriptions of the basic reef forms (i.e., fringing, barrier, and atoll reefs) are still in common use today. Although the original reef coast terms are somewhat modified and subdivided, they still form the basis of modern understanding. Working in the Australian Indo-Pacific region, for example, Fairbridge (1950) originally focused on the Great Barrier Reef (GBR) but later extended his system to include the whole of the Australian region (Fairbridge 1967), detailing reefs on the west coast continental platform as well as those occurring along the northern margins of the continent in the Arafura Sea and Torres Strait. This basic classification of fringing, barrier, atoll, and platform reefs, along with five varieties of coral island, was expanded by Maxwell (1968) and later more completely in examples from Hopley (1982, 2011), Hopley et al. (2007), Wood (1999), and Woodroffe (2002).

Atoll

An atoll is a ring (annular) reef that surrounds a shallow lagoon (Darwin 1842), the definition being based on the only forms that Darwin visited in the Cocos (Keeling) Islands in the eastern Indian Ocean. The term "atoll" is derived from the Maldivian word, *atolu* (Woodroffe and Biribo 2011). Most atolls occur in the Pacific Ocean as well as the central Indian Ocean, but there are only a few in the Caribbean where morphological descriptions and actual number vary between 10 and 27 according to the authority cited (cf. Stoddart 1965; Milliman 1973; Riegl and Dodge 2008). The three Belizean atoll reefs are formed on submarine ridges, Turneffe and Glover's on one ridge and Lighthouse (Figure 2) on another to the east. Atolls were classified by Ladd (1977) into ocean atolls and shelf atolls, but a more complete description is provided by Woodroffe and Biribo (2011). The reef rim may be continuous or broken by a few channels as occur in the central Pacific, or many shallow passes (*hoa*) as in French Polynesia, or deep passages as in the Maldives (McLean 2011). Fairbridge (1950) reports that there is no marked difference in appearance between an "annular reef" (one that is perfectly enclosed) rising from an oceanic cone or platform and one rising from the continental shelf. Examples of some morphologically perfect atolls occur on Australia's North West Shelf in the Indian Ocean and on the Sahul Shelf where Seringapatam Reef is a *perfectly enclosed reef* with a central lagoon approximately 36 m deep. Boulders typically occur along reef crests and small shingle often forms "hammerhead" spits. Wide reef flats may accommodate a radial zone that is produced by algae, boulders, and sediment. A "sanded zone" often breaks up into coral patches toward the lagoon.

Reef Coasts, Figure 2 This fringing reef in Belize is shore attached, growing seaward in an irregular manner where it can find suitable seafloor substrate. The seaward margin of the coral reef drops off precipitously to deeper water, whereas the landward margin merges with the carbonate rock of the island on Lighthouse Reef Atoll, where this fringing reef is part of the larger atoll development (photo: Istockphoto.com).

Some atoll-like reefs have a facing edge of stronger established coral reef and a more weakly developed back edge, due to prevailing ocean currents and dominant weather. The well-developed edge faces the direction of high oceanic energy where corals access nutrients that provide greater growth potential (i.e., Nunn 1994; Short and Woodroffe 2009).

Microatolls are individual subcircular colonial corals, usually of the genus *Porites*, that occur on reef flats (i.e., Nunn 1994). These reefs expand by growth of their outer edges, but they are very sensitive to emergence as described by Woodroffe and McLean (1990).

Fringing reef

Fringing reefs develop close to the shore and may or may not be attached (approach or touch the foreshore) to the land, which may be mainland or an island (cf. Figure 2), as seen in Figure 3 for a reef system on the seaward margin of Long Island in the Bahamas. They are linear reefs that grow along shelving coastlines and across embayments (Done 2011), as shown in the center of Figure 3, with a backreef area that may be shallowly submerged (Smithers 2011). These relatively simple structures can be geomorphologically subdivided into three main zones: forereef, reef crest, and backreef (e.g., Kennedy and Woodroffe, 2002). The width of a fringing reef is an indication of its age and the kind of substrate available as a foundation for reef growth. Symmetries of reefs and islands seem to be controlled by wave direction where the reefs may be markedly asymmetrical around islands

that are affected by waves from a constant direction (Parnell 2011). Some examples of well-known fringing reefs include Hanauma Reef on the island of Oahu in Hawaii, along the coast of Mahé in the Seychelles, Kolombangara and Gizo Islands in the Solomon Islands (Stoddart 1969b), the Tuamotu Archipelago (Montaggioni et al. 1985), eastern coast of Belay (Palau in the northwest Pacific) (Easton and Ku 1980), and off many islands in the GBR (i.e., the Whitsundays, Lizard Island, Fantome, Orpheus, Hinchinbrook Island, Cape Tribulation) (Short and Woodroffe 2009).

Fringing reefs are an important component of the GBR with more than 750 being identified and an additional 200 incipient fringing reefs that are shore attached or near-shore but not yet reaching the sea surface. Fringing reefs along mainlands tend to be the poorest of reef types due to rigorous conditions near the shore, excessive sedimentation, dilution of seawater by fresh water, and acidic waters running off the land (Fairbridge 1950). More vigorous fringing reefs on the other hand often encircle offshore continental islands where growth conditions are more favorable. Hopley, Smithers, and Parnell (2011) have additionally shown that fringing reefs of the GBR have experienced several critical growth phases since the mid-Holocene where there is apparent synchronicity of growth-and-quiescent phases over wide geographical areas that influenced by climatic cycles and sea-level change. But, in general, episodic living coral growth is confined to the outer reef edge, where there may be a *Lithothamnion* ridge, whereas behind it there is dead reef,

Reef Coasts, Figure 3 Example of Bahamian coral reef complex. In the photo foreground are deeper-water (>20 m depth) reefs on the edge of the Bahamian carbonate platform fronting the open Atlantic Ocean. Fringing reefs are shown along the photo center as shore-attached coral reefs that front beach-dune systems and low calcarenite cliffs but also which cross small embayments. Barrier reefs lie farther offshore as shelf-edge reefs. Both barrier and fringing reefs contain reef gaps filled with carbonate sands (photo: C. W. Finkl).

about a meter below low-water springs, lightly sand covered, and marked by the radial pattern of seaweed (Fairbridge 1950). Lord Howe Island has the southernmost fringing reef in the Pacific Ocean (Short and Woodroffe 2009).

Barrier (ribbon) reef

A barrier reef forms a calcareous barrier along a segment of mainland or around an island resulting in a lagoon between the shore and the reef. They are also often referred to as platform, continental shelf, or shelf-edge reefs such that dominate the GBR (e.g., Done 2011; Fairbridge 1950; Hopley 1982; Short and Woodroffe 2009) or the Florida Reef Tract (Florida Keys reef tract plus northern extensions), which stretches 125 km along the southeast coast of the Florida Peninsula (Banks et al. 2008). The Belizean section of the Mesoamerican Barrier Reef System (Mexican Yucatan, Belize, Guatemala, and Honduras) is about 200 km long (Andréfouët and Cabioch 2011), but the entire system stretches for about 1,000 km. The example shown in Figure 4 is part of the barrier reef around Roatan (Honduras) in the Caribbean. Platform reefs colonize topographic highs that provide suitable foundations. Barrier reefs are always strongly asymmetric in plan view and cross section, being steep-to on the ocean side and grading toward the land with a sediment wedge dotted by small reef patches, pinnacles, and coral heads (i.e., Fairbridge 1967; Nunn 1994; Short and Woodroffe 2009). Figure 5 shows a Bahamian example of a complex barrier reef system composed of a seaward shelf-edge barrier with landward complexes of patch reefs and aggregated reefs. Incipient barriers may include small fringing reefs around islands within the main lagoon. Discontinuous reefs may be genetically linked to the barrier type, but from a morphological point of view, they are only patch or platform reefs, as described by Fairbridge and Teichert (1948).

Ribbon-shaped reefs, also referred to as "linear reefs" by Jukes (1847), occur as festoons along the outer edges of continental shelves. The ribbons are separated from one another by narrow passages, some up to a kilometer or more in width, called reef gaps (Finkl 2004; Finkl and Andrews 2008; Lidz et al. 2006) as found in the Florida Reef Tract. Typically there is an outer, parapet-like fringe of living corals that are furrowed by wedge-shaped channels or chutes, also referred to as spur and groove topography. Grooves are commonly floored with coral rubble or carbonate sand and may function as sediment conduits from backreef or inter-reefal areas to deeper water (Finkl 2004).

In the Australian region, for example, the reef crest rises gently from here, often including a *Lithothamnion* rim of calcareous algae about 1–2 m above low-water springs. Landward of the crest there is debris containing broken corals, boulders, shells, and sand, all cemented together. The so-called trickle zone or radial zone occurs on wider parts of the backreef where sediment debris and algae form a definite pattern normal to the reef edge. A shallow "inner moat" occurs inside of the rim, partly filled with clumps of living coral, boulders, and sediment. From here the floor deepens gradually and tends to be covered with white coral sand of the "sanded zone." Farther out in deeper waters of the lagoon, only a few larger coral heads reach the surface. This typical morphological sequence was reported early on by Agassiz (1898).

Reef Coasts, Figure 4 Barrier reef on Roatan (Bay Islands), Honduras, as an example of the Caribbean-type coral barrier. The Bonacca Ridge is the second longest barrier reef system (Great Western Barrier Reef) in the world (after the Great Barrier Reef in Australia) and extends over 400 km from Roatan to Belize. The deeper dark blue water lies seaward of the barrier, whereas the light green-colored water occurs in the lagoon between the reef and shore. Roatan lies on the edge of the Cayman Trench that provides clear water from the depths where the trench plunges thousands of meters off the west end of the island (photo: C. W. Finkl).
Reef Coasts, Figure 5 Example of a barrier-type coral reef system along the ocean side of Long Island, Bahamas, showing the forereef spur and groove topography in the lower right-hand corner, numerous patch reefs on the reef flat, and a lagoon between the reefs and shore. The reef edge drops off into water that is hundreds of meters deep (photo: C. W. Finkl).

Patch reefs

These are young patches of coral, roughly equant in plan view, that grow up off the bottom of the sea to form an isolated small platform in a lagoon or behind a barrier reef or atoll rim (Hopley 1982). These comparatively small reefs (cf. Figure 5), which often reach the surface and spread outward forming a pool in the center, are commonly surrounded by a sand halo or sea grass (i.e., Finkl and Vollmer 2011). An example of non-lagoonal patch reef coast occurs off northern St. Croix (Caribbean Sea) where small reefs (up to 20 m across) rise out of 10–15 m of water. They are locally referred to as "haystacks" (KellerLynn 2011) because of their broken and piled-up coral branches. Fairbridge (1950, 1967) applied the term

Reef Coasts, Figure 6 Construction debris used to build an artificial reef offshore southeast Florida, USA. This man-made reef structure was constructed by placing steel rails and circular concrete culverts within a specific zoned area on a sandy seafloor landward of the Florida Reef Tract. Over time, marine organisms, such as sponges and scleractinian coral colonies, utilized the artificial reef substrates to adhere and grow, just as they would on natural reefs. Colonization along the steel rail transecting the photo center shows a wide range of biological marine life upon its surface (photo: Christopher Makowski).

"patch reef" (also referred to as shelf, bank, table, or hummock reef) to the smaller reefs (<2 km long) and "platform reef" to larger ones (>2 km long), but there are many other definitions of the types of reef coral formations that constitute a patch reef (e.g., Hubbard 1997). Many patch reefs occur in the GBR lagoon, in the Torres Straits almost blocking the channel between Australia and Papua New Guinea, and scattered along the northern edge of the Sahul Shelf.

Coral reefs with islands

Many different types of islands are associated with coral reefs. Initial studies of reef islands were made in the nineteenth century in Southeast Asia and the Australian GBR and later in the Pacific and Indian Oceans and in the Caribbean Sea (Steers 1937; Smithers and Hopley 2011).

The islands have traditionally been differentiated as "high" islands composed of continental rocks (with associated coral reefs) (e.g., Steers 1929) and "low" islands (coral cays) composed of biogenic carbonate sediments produced by reef organisms. There is a great diversity of forms of coral cays and numerous classifications have been developed from investigations of the GBR, the largest shallow-water coral reef province in the world (combined with Torres Strait) that contains about 350 coral cays (Smithers and Hopley 2011). Most coral cays occur on reef flats (many occurring on small reefs <1 km^2) at or very close to sea-level as, for example, on Pacific atolls and on the Cocos (Keeling) Islands where less than one-third of the island surface is more than 2 m above

sea-level (i.e., Woodroffe and Biribo 2011), but some may develop on lagoonal sediments (Kench et al. 2005).

By way of an example from one approach, Fairbridge (1950, 1967) grouped reef islands into (1) simple sand cays (islands that are commonly unstable and which migrate seasonally, found in all areas except on fringing reefs), (2) vegetated sand cays (islands that are moderately stabilized with beach rock, widely distributed but generally lacking from the outer reefs), (3) shingle cays (moderately stabilized islands that are widely distributed but found mostly on smaller, more exposed reefs), (4) sand cays with shingle ramparts (unvegetated to vegetated islands, including mangrove swamp), and (5) emerged reef islands (reef islands with or without a fringe of recent sand or shingle beach ridges or ramparts). More comprehensive summaries of these complicated coral reef coast features may be found in examples from Barnes and Hughes (1999), Hopley (1982, 2011), Ladd (1977), Maxwell (1968), Stoddart and Steers (1977), and Wood (1999), among others.

Artificial reefs

An artificial reef is an underwater structure that is positioned to promote marine life in areas with a generally featureless bottom, control erosion, block ship passage, or improve surfing. The purpose of fish attracting devices (e.g., concrete blocks, streamers, scuttled ships, and oil-drilling rigs) is to enhance fish abundance, species richness, and biomass (Sherman et al. 2002). Figure 6 is an example of construction debris that was placed on a

featureless sandy seafloor to provide habitat for marine life off the coast of southeast Florida along the leeside of the Florida Reef Tract. These types of reefs contain objects of natural or human origin (i.e., rocks, ships, railcars, tanks, sculptures) deployed on the seafloor to favorably influence physical, biological, or socioeconomic processes related to living marine resources. Initial attempts to construct an artificial surfing reef were made in El Segundo (near Los Angeles, in California) and at Mosman Beach (Perth, Western Australia). Many coastal segments around the world now host various types of artificial reefs.

Conclusions

The term *reef coast* refers to a complex of coastal types that range from rock reef coast to coral reef coast to artificial reef coast. Of these types, shallow-water coral reefs are the most well known, most widely studied, and most used for recreation and tourism. Rock reefs occur along most shores of coastal oceans, whereas coral reefs are restricted to ecologically favorable sites in tropical and subtropical regions. Artificial reef coasts are most common in warmer waters where they attract sports fishermen, snorkelers, and scuba divers.

REEFS (BIOGENIC)

Christian Dullo
GEOMAR Helmholtz Centre for Ocean Research, Kiel, Germany

Definition

Reefs are submarine, three-dimensional elevations on the shelf or on the continental slope formed by the activity of sessile organisms.

Introduction

Reefs are in situ organic deposits which exhibit different sizes from few cubic meters to several hundreds of kilometers length and even several hundreds of meters in thickness (Spalding et al., 2001). Modern reefs are formed predominantly by stony corals which are the equivalent of the taxonomic order Scleractinia. Corals and other calcifying organisms produce hard skeletons, which lead to the accumulation of biogenic carbonates as a result of individual growth, bioerosion, sedimentation, and cementation due to wave energy during several hundreds of years. On millennial and much longer timescales, sea-level changes are the major driving force of reef growth. Today coral reefs cover more than 284,000 km^2 (Spalding et al., 2001), and they are the largest marine structures on earth formed by biota, having a long geological record and evolution (Wood, 1999). At present, coral reefs suffer from overfishing, climate change (Wilkinson, 2004), and ocean acidification, which impacts on calcification and reef stability (Andersson and Gledhill, 2013). The classical coral reef system thrives in subtropical to tropical, warm, and sunlit waters, thereby forming wave-resistant structures. Stony corals do also exist in deep, dysphotic to aphotic depths where water temperatures are much lower where they can form three-dimensional structures of substantial size. These cold-water coral systems are referred to as coral mounds and mud mounds (Roberts et al., 2009).

Tropical reefs

Tropical shallow-water reefs are built by zooxanthellate scleractinian corals, which live in symbiosis with photosynthetic dinoflagellates. The lower temperature limit of tropical coral reefs is 20 °C, which corresponds to the tropical realm between 30°N and 30°S (Spalding et al., 2001). The most northern coral reefs occur in the Gulf of Aqaba (29°30′ N) and the southernmost ones around Lord Howe Island (31°30′ S). The photosynthetic activity of the symbionts further limits their depth range between the base of the photic zone and the surf zone of the intertidal environment. Since wave action influences such setting, shallow-water reefs exhibit a distinct zonal pattern of biota and sedimentary facies. The beach and shore facies is under the influence of the tides and shows accumulations of skeletal rubble and sand. Sea grass, sea urchins and other echinoderms, several calcified and noncalcified algae, and few soft corals may settle the lagoon. The back reef exhibits isolated scleractinians; some may form microatolls. The reef crest is a small and elongated area of intensive scleractinian coral growth where the waves brake and which may be subaerially exposed during nip tides. Together with the fore reef, the reef crest is characterized by the highest biodiversity of reef-building and reef-dwelling organisms, therefore representing the center of biogenic reef accretion (Figure 1). The fore-reef area, including the slope with the reef talus, faces the open ocean. Due to sea-level changes in course of the last glacials, the fore-reef slope may be structured in terraces witnessing ancient sea-level positions.

Reefs (Biogenic), Figure 1 View from the reef crest down to shallow fore reef. Fringing reef, Gulf of Aqaba, Red Sea Saudi Arabia (photo: C. Dullo).

Major reef types

Tropical coral reefs can be differentiated with respect to their setting and formation (Spalding et al., 2001). *Fringing reefs* follow parallel to the coastline and exhibit elongated depositional environments of up to several tenth of kilometers length but normally less than 100 m of width. They start to grow close to the coast as possible and migrate toward the open sea during time. Their lateral extension is controlled by the inclination of the underlying slope. Some older fringing reefs have lagoons developed. The highest variation of fringing reefs is seen in the Red Sea.

In contrast, *barrier reefs*, among which the Great Barrier Reef off Australia is one of the most prominent reefs of today, have very large lagoons of several kilometers in width and may cover several thousands of square kilometers. The reef front and crest has not migrated from the shore in offshore direction but started to grow on a preexisting relief and remained where it is. Major driving forces are sea-level changes and subsidence; therefore, barrier reefs have a much longer history than fringing reefs.

Atolls are mid-ocean reefs that enclose a central lagoon. *Atolls* started their evolution as a fringing reef on an oceanic volcano. Continued slow subsidence of the volcanic edifice forces the reef-building organisms to form barrier reefs and finally atolls, with or without a central island in the center. Due to the biogenic activity and in combination with sea-level variations, some of the atoll reef crests turn into "land." The most prominent atolls are found in Polynesia or in the Maldives.

Platform reefs grow on the open shelf, where the shallow bathymetry of the sea floor promotes reef growth. They expand in all directions and reach dimensions of several square kilometers. Due to coral growth and carbonate accumulation, some parts of the platform reefs may turn into land, forming small islands, which can be fringed by reefs themselves. Prominent representatives are found in the southern Red Sea and in the southern part of the Great Barrier Reef. A very old and extremely expanded platform reef is the Bahama platform.

Coral mounds and mud mounds

All non-zooxanthellate stony corals may live in much greater water depth under much cooler conditions (Roberts et al., 2009). Most of them are solitary corals, but few species form real reef structures. At present, the largest cold-water reef is the chain of biogenic structures of Europe, ranging from the Iberian Peninsula up to northern Norway (Figure 2). Distinct cold-water reef structures of living corals are up to 50 m high and up to 2 km long. However, some of these reefs have a long geological history, like their shallow-water counterparts. Such structures cover much larger areas of several square kilometers and form dome or mound-shaped elevations of more than 350 m above the surrounding seafloor. In contrast to shallow-water tropical reefs, they generally do not show any strong unidirectional zonation pattern of different depositional environments but concentrically shaped facies patterns. Coral mounds and mud mounds occur in different water depths ranging from 100 m down to 1,000 m. The habitat-forming corals act primarily as
Reefs (Biogenic), Figure 2 Living cold-water coral reef in the Stjernsund, Northern Norway, seen from the submersible JAGO (photo: GEOMAR).

sediment baffler rather than as frame builders like in the shallow water. Moreover, the nutrient level in these "mounds" is much higher than in the oligotrophic environments of tropical shallow-water reefs. That is why their occurrence is ascribed to the DDD environment (dark, deep, and dirty = lots of nutrients, Wilson, 1975).

Reef growth

The accumulation of carbonate and reef growth is controlled by four major processes: carbonate accretion, carbonate destruction, sedimentation, and cementation (Flügel, 2004). *Carbonate accretion* consists of the formation of a primary biogenic fabric being constructed by colonial and sessile organisms such as sponges, hydrozoans or scleractinian corals, and algae. This primary fabric is subsequently stabilized by secondary frame builders due to incrustations by bryozoans, benthic foraminifera, serpulids, sponges, and calcareous algae. Sediment fixation and stabilization play important roles as baffler and binder such as in sea grass meadows, crinoids, and cyanobacteria. *Carbonate destruction* is controlled by the physical processes of wave action and currents, frequently intensified by storms. This mechanism is accompanied by bioerosion which makes the primary and secondary fabrics prone to storm damage. Bioerosion takes place by boring, rasping, biting, and chemical leaching by algae, cyanobacteria, sponges, worms, mollusks, echinoids, and fish. Although destruction seems to have a negative impact on reef growth, it is essential and an important process to produce carbonate particles which fill the interstices between the biogenic fabrics. Therefore, *sedimentation* leads finally to the formation of a reef rock. In addition to particles derived from bioerosion, several other calcareous reef biotas contribute to the volume of carbonate by disintegration after death, like the green algae *Halimeda. Cementation* is the final stabilization by marine carbonate cements, which precipitate in intraparticle and interparticle porosities.

Reefs in the geological past

Both reef types are primarily made up of carbonate and carbonate-secreting biotas, among which corals, sponges, and algae are very prominent. Therefore, reef growth depends on calcification rates of reef biota (Dullo, 2005). During earth history, reefs played an essential role since almost all carbonates originated from biogenic activity (Wood, 1999). Most parts of the Northern Calcareous Alps, the Dolomites, and other mountain ranges containing thick carbonate sequences are formed by reefs and associated sediments. Due to the evolution of organisms, also the ecosystem reef exhibits dramatic evolutionary changes during earth history. The earliest reef assemblages were formed by stromatolites, a unique ecosystem consisting primarily of cyanobacteria and other microbes, which fixed and trapped sediment. During the Cambrian spongelike organisms, the archaeocyathids took over and built larger carbonate bodies. Paleozoic reefs were formed by tabulate "corals" and stromatopores, which belong to the large group of sponges. During the Devonian, rugose corals were essential until the end of the Permian. During the Carboniferous and mainly during the Permian, phylloid algae were important reef builders. Although many of the Paleozoic reefs look more like the modern cold-water reef bodies being either coral mounds or mud mounds, some Devonian (Canning Basin: Figure 3) or Permian reefs (Guadeloupe Mountains) exhibit already a modern type of facies arrangement. The onset of reef growth after the Permo-Triassic extinction event, which had led to a complete decline in reef formation, was characterized by the first occurrence of scleractinian corals. Since then, they are the major frame builders, except few interruptions during the Upper Cretaceous. Together with calcareous sponges, they formed large carbonate bodies in all Alpine mountain belts. Siliceous sponges acted during the Upper Jurassic as reef builders in some settings, while the Upper *Cretaceous* witnessed giant reefs formed by sessile mollusks, so-called rudists.

Reefs as reservoir rocks

Reef building irrespective of shallow-water reef or cold-water reef settings results in the accumulation of carbonate which exhibits distinct elevations with respect to the surrounding beds. Such structures are called bioherms in contrast to biostromes, which consist of calcified reef biota as well; however, biostromes are not elevated structures but rather thick non-stratified limestone beds. In both cases, the resulting rock is frequently not entirely cemented and filled with sediment. Therefore, a primary porosity may remain. In addition, reef biotas are predominantly formed by metastable carbonate minerals which are affected by diagenesis subsequently to their formation, resulting in

Reefs (Biogenic), Figure 3 The classic face of the Devonian reef outcropping in Windjana Gorge, Canning Basin, Australia. The inclined fore-reef beds, the massive reef limestone, and the well-bedded lagoonal strata are well exposed (photo: C. Dullo).

secondary porosity. Furthermore, dolomitization as a diagenetic process may also increase porosity. This makes carbonates important reservoir rocks for hydrocarbon accumulations at distinct times during earth history (Ahr, 2011). The majority of giant oil fields hosted in carbonates are of Permian, Jurassic, predominantly of Cretaceous, and Cenozoic ages. Fore-slope reef talus, reef debris, and reef crest sediments as well as in part lagoonal sediments are the preferred facies types to develop larger quantities of porosity to accumulate hydrocarbons. The most giant hydrocarbon field occurs in the Cretaceous rudist reefs of the Arabian Peninsula. Apart of hydrocarbons, lead-zinc accumulations are also frequently linked to carbonates and associated reef limestones which have been exposed subaerially and became karstified prior to the impregnation of lead and/or zinc.

Definition

Methods to image and to physically parameterize the subsurface geologic structures and conditions by means of

artificially generated shock waves that travel through the subsurface and return to the surface.

Overview

Controlled-source seismology comprises a variety of geophysical methods to image and to physically parameterize the subsurface geologic structures and conditions. All these methods base upon the principle that artificially generated shock waves travel through the subsurface and that the returned signal can be analyzed regarding the properties of the subsurface. During the last decades the discrepancies between marine seismic equipment as used by the academic marine research community and that used by the hydrocarbon (HC) exploration industry increased significantly, caused by different research targets and the simple fact that gear commonly used for HC exploration is much too costly. In this entry we will focus on those systems which are typical for academic marine research.

In principle, seismic data acquisition requires an energy source, a receiver, and a recording system. The two most important seismic methods are reflection and refraction seismology (Figure 1).

Reflection seismologists deal mainly with steep angle reflections, which means that the source to receiver distance is small compared to the target depth. This method utilizes the fact that a small part of the down-going energy is reflected on geological layer boundaries. The main fraction of the energy is transmitted and travels deeper where reflections occur at the next layer boundary and so on. This method results in a good vertical and horizontal structural resolution of the subsurface. Earth scientists benefit from the technical and methodical developments

of the exploration industry which uses reflection seismology for the detection of oil and gas in depths of up to several kilometers below the seafloor.

In refraction seismology, seismic waves are recorded that propagate along layer boundaries or as arcuate "diving waves" mainly subhorizontally. This method is either used in engineering geology for near-surface investigations or (the other extreme) to analyze deep crustal structures, the crust–mantle boundary and the upper mantle. Wide-angle reflections recorded at large distances between source and receivers are part of this data analysis scheme. Geophysicists often use the abbreviation WARRP (wide-angle reflection/refraction profiling) for these techniques. The main advantage of WARRP is that the inversion procedure directly results in crustal depth sections; its major disadvantage is the relatively low structural resolution.

History of refraction and reflection seismology

One of the founders of the seismic refraction method was German scientist Ludger Mintrop (1880–1956) who received a patent in 1917 for a so-called portable field seismograph and a method to locate artificial shock sources. In fact, he used this method in World War I to locate the position of Allied heavy artillery pieces. After the war he reversed this method: He released an explosive blast in a known distance to the seismograph and used the underground travel time of the shock wave to calculate the depth of geological features. In 1919 the seismic refraction method was successfully used to constrain the location of a salt dome in northern Germany.
Reflection/Refraction Seismology, Figure 1 Basic principles of reflection and refraction seismology. Reflection seismologists deal mainly with steep angle reflections, which means that the source to receiver distance is small compared to the target depth. Refracted waves propagate along layer boundaries or as arcuate "diving waves" mainly horizontally. This method is either used in engineering geology for near-surface investigations or (the other extreme) to analyze deep crustal structures, the earth crust–mantle boundary and the upper mantle.

Marine reflection seismology evolved from work by Reginald Fessenden who developed a sonic sounder to find icebergs (after the sinking of the *Titanic*) (Roden, 2005). The first reported usage of seismic reflections for subsurface studies was in 1921 when a small team of geophysicist and geologists performed a historical experiment in Oklahoma (Dragoset, 2005). The team analyzed the return time of reflected waves generated by small dynamite charges and detected the boundary between two subsurface geological layers. The success of this so-called Vines Branch experiment stimulated a boom in seismic exploration when the oil price rose in 1929.

During the first decades each subsurface point was imaged by a single set of source and receiver. Multichannel seismics became more common in the 1950s. This method allowed for significant noise reduction and for computing of layer velocities, enabling the conversion of travel times to depth. The advent of the digital technology in the 1960s represented a giant step forward because digital post-processing opened a wide variety of possibility to enhance seismic data and image quality. Several technical developments in the 1980s such as plotters for wiggle trace display or color maps as well as methodical progress including seismic stratigraphy or seismic attribute analysis became available for earth scientists and stimulated academic frontier research.

The hydrocarbon industry benefited largely from the introduction of the 3D seismic method which enhanced understanding of petroleum reservoirs and reduced exploration risks. However, the earth science community has had quite limited access to these data, also because 3D seismic experiments for nonprofit-oriented research are generally too costly.

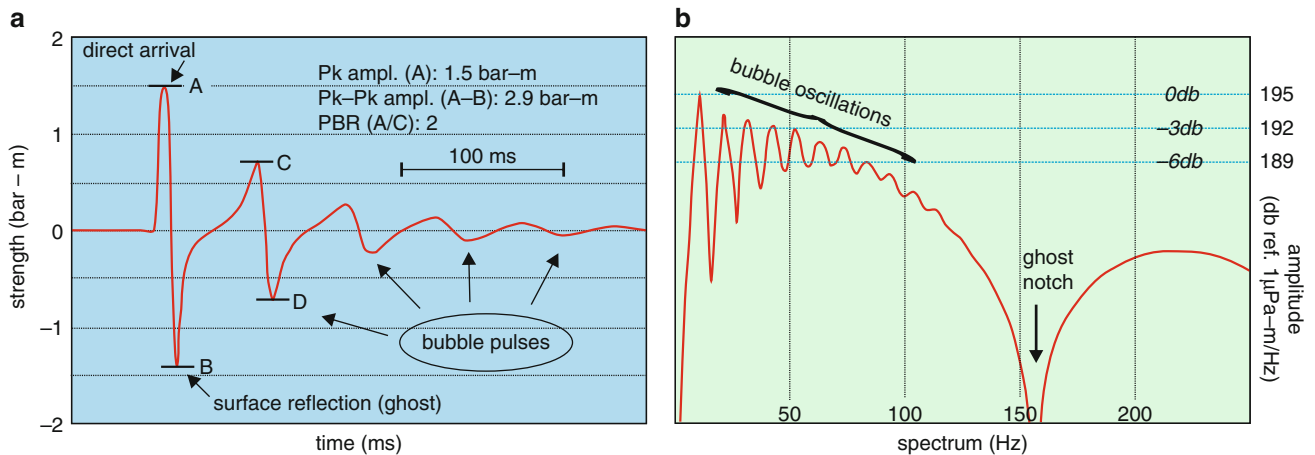
Seismic energy sources

The theoretical optimum seismic source produces a Dirac delta function like signal (called wavelet) which is infinitesimal short in time by having a maximum spectral bandwidth. In the real world, a "good" seismic source creates a high energy and temporally short signal with repeatable characteristics in terms of wavelet signature and frequency content.

Marine seismic sources are subdivided into exploders and imploders. Exploders create the wavelet by an expanding volume (solid material or gas/air). Imploders generate the signal by the collapse of a volume, created for instance by cavitation. We can further distinguish between chemical, mechanical, electrical, and pneumatic/hydraulic sources (Parkes and Hatton, 1986). Chemical sources comprise various explosives. Explosives can create very strong signals; however, the shot interval is relatively low and the signal characteristics are reproducible to a limited amount due to surface waves and explosion depth. Mechanical sources, such as a boomer or piezoelectric transducers, rely on physical vibration to transmit seismic waves into the water. Sparkers are electrical sources that discharge large electrical charges into the water. The steam bubble that vaporizes along the spark collapses, thus producing the desired signal. Pneumatic/hydraulic sources dispel gas (usually air) or fluid (usually water) under high pressure into the water. For instance, a water-ejecting water gun produces a cavitation and its subsequent collapse generates a seismic wave-field. The water is accelerated in the water gun by a piston, whereas the driving pressure consists usually of compressed air.

The pneumatic so-called air gun is nowadays the most common source in marine seismics (Dragoset, 1990). Compressed air of usually 140–210 bar is released into the water every few seconds. The rapid expansion creates the highly reproducible primary signal (Figure 2a). The reflection at the sea surface creates a similar strong but phase-reversed signal, the so-called ghost. Signal strength is described either as the peak amplitude pk (level A in Figure 2a) or as pk-pk amplitude which includes the amplitude of the ghost arrival (A–B in Figure 2a), both traditionally expressed in bar-meter (bar-m). If the peak amplitude is 1.5 bar-m as in Figure 2a, a hydrophone located in a distance of 1 m to the source would measure peak amplitude of 1.5 bar, in 3 m distance 0.5 bar. A second important source characteristic is the spectral bandwidth (Figure 2b). Amplitude spectra are usually shown on a logarithmic scale. A reasonable parameter for the bandwidth is the range between the -3db (71 % of maximum) or -6db (50 % of maximum) points. The frequency notch in the spectra results from the destructive interference between the primary and the surface (ghost) reflection. It is a function of the source towing depth and can be easily calculated by $f_{Notch} = V_{H_2O}/(2 * \text{towing depth})$. V_{H_2O} is the seismic wave speed in water which amounts to ca. 1,500 m/s.

The bubble signal is an undesired effect which results from an oscillation of the air bubble. Consequently, an important characteristic of a single air gun or an array of air guns is the peak to bubble (amplitude) ratio (PBR) (Figure 2a). There are several possibilities to enhance the PBR. As the bubble period depends on the same parameters as the primary signal, the bubble can be suppressed by simultaneously firing several air guns with different bubble frequencies. The PBR can be further enhanced if the separation distance between the air guns is small enough that the air bubbles interact (Strandenes and Vaage, 1992), which is the so-called cluster effect. Many modern air gun arrays consist of several pairs of clustered air guns. A high-end system frequently used by geophysicists is the so-called GI-Gun (by Sercel), which consists of two air gun chambers built into a single housing. The first chamber, called generator, releases highly compressed air. The air bubble expands, and just before it starts to oscillate, an additional volume is injected by the second air gun chamber (the injector), thus stabilizing the air volume in order to prevent oscillations.

Amplitude and spectral bandwidth (Figure 2b) can be adjusted by air pressure, air chamber volume, towing depth, and geometry of discharge ports. Air chamber


Reflection/Refraction Seismology, Figure 2 (**a**) Definitions of time-domain air gun specifications (after Dragoset, 1990, 2005). The signal is composed of the primary signal, the phase-reversed sea surface reflection (ghost), and the bubble signal, caused by oscillations of the air bulb. Signal strength is measured in bar-m. Values are either given for the strength of the peak amplitude of the primary signal (pk amplitude. Marked by an "A") or the ghost amplitude marked by a "B" is included (pk-pk amplitude. (**b**) The spectral bandwidth is usually shown on a logarithmic scale. A reasonable parameter to characterize the bandwidth is the range between the −3db (71 % of maximum; ca. 10–52 Hz) and −6db (50 % of maximum; 8–80 Hz) points. The bubble oscillations are visible in the low-frequency domain. The ghost signal forms a notch at a frequency depending on the source depth due to destructive interferences.

volumes may vary between 32 l to less than 1 l. Large air chambers are used for low-frequency, high-amplitude sources which are desirable for deep crustal refraction and wide-angle reflection seismics. Small air guns of up to a few liters chamber volumes are used for high-resolution shallow reflection seismics.

Data acquisition and processing: reflection seismology

A seismic recording system comprises a sensor or receiver that converts the seismic wave into an electrical signal, an analog–digital converter and a recorder. The most common sensors in marine seismics are hydrophones, which are piezoelectric elements that produce an electric potential difference caused by the pressure pulses of the seismic wave. Usually groups of hydrophones are used to eliminate translational accelerations and to enlarge the signal-to-noise ratio by signal summation (Telford et al., 1990).

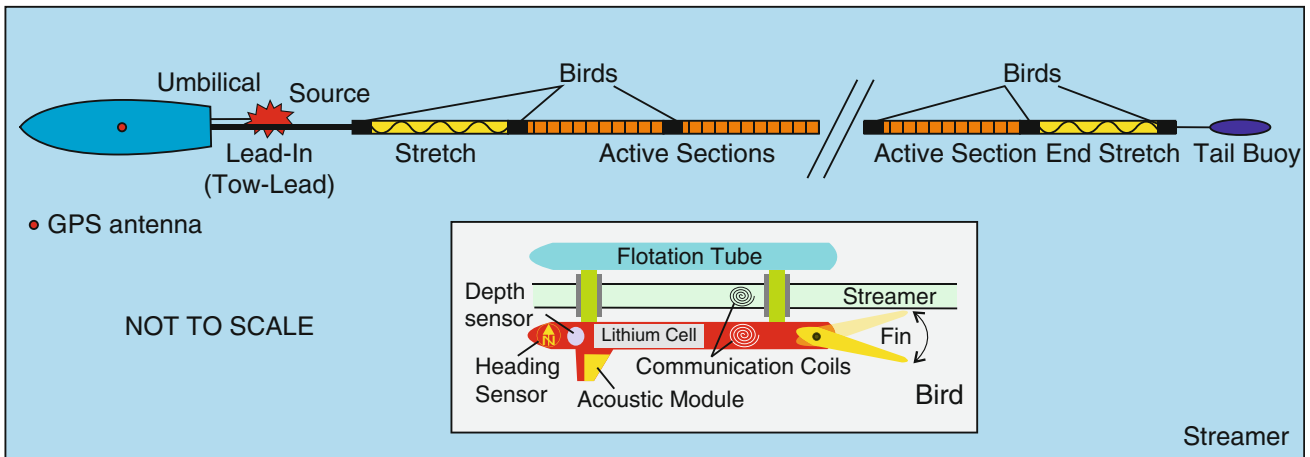
Seismic streamers

The standard device for marine reflection seismics is the streamer (also towed array, seismic cable) which comprises hydrophone groups (so-called channels) or single hydrophones (Figure 1). There is a huge variety in the length and number of channels. A streamer geometry quite common for systems operated by academic research institutes comprises a lead-in cable (also tow-lead) which is a heavy, steel mash protected cable with negative buoyancy which connects the streamer with the streamer winch (Figure 3). The next part of the streamer is the elastic stretch section (also passive or compliant section) which mechanically decouples irregular ship accelerations from

the active sections, consisting of the hydrophone channels. Another stretch section decouples the streamer from the tail buoy.

The length of the individual sections may vary. Typical values for systems operated by academic institutions are front stretch 50–200 m, active length 300–3,000 m, and end stretch 50–100 m. Depth levelers, so-called birds, are connected every 100–200 m.

Typical hydrophone group distances are integer multiples of 6.25 m. This number results from times when no satellite positioning was available. A good trade-off between water current-induced noise and progress is a ship speed of about 5 kn (5 nautical miles per hour). This speed corresponds to 2.5 m/s. A shot interval of 5 s results in 12.5 m shot distance, an interval of 10 s in 25 m. With those figures the geometry of the multichannel data could be easily calculated (see below). The number of hydrophones within and the total length of a hydrophone group control its spatial response characteristic (Hübscher and Spieß, 1997).

The towing depth of the streamer should be a quarter of the wavelength (λ/4) of the expected seismic signal in order to prevent destructive interferences within the frequency range of the source. Buoyancy of a streamer is controlled both by the average density of the stretch and active sections and by cable levelers. For several decades, the sections have been filled by kerosene and later by Isopar. These fluids have a density less than that of seawater. The volume of the oil is calculated in a way that the average density of the section containing hydrophones and towing and data cables is close to that of seawater to yield neutral buoyancy. So-called solid streamers filled with polyurethane and similar solid materials have


Reflection/Refraction Seismology, Figure 3 A marine seismic streamer typically used for academic 2D reflection seismic surveys comprises a lead-in cable, a stretch section that mechanically decouples ship movements from the active sections, an end stretch, and a tail buoy. The streamer is depth controlled by cable levelers also called birds (insert).

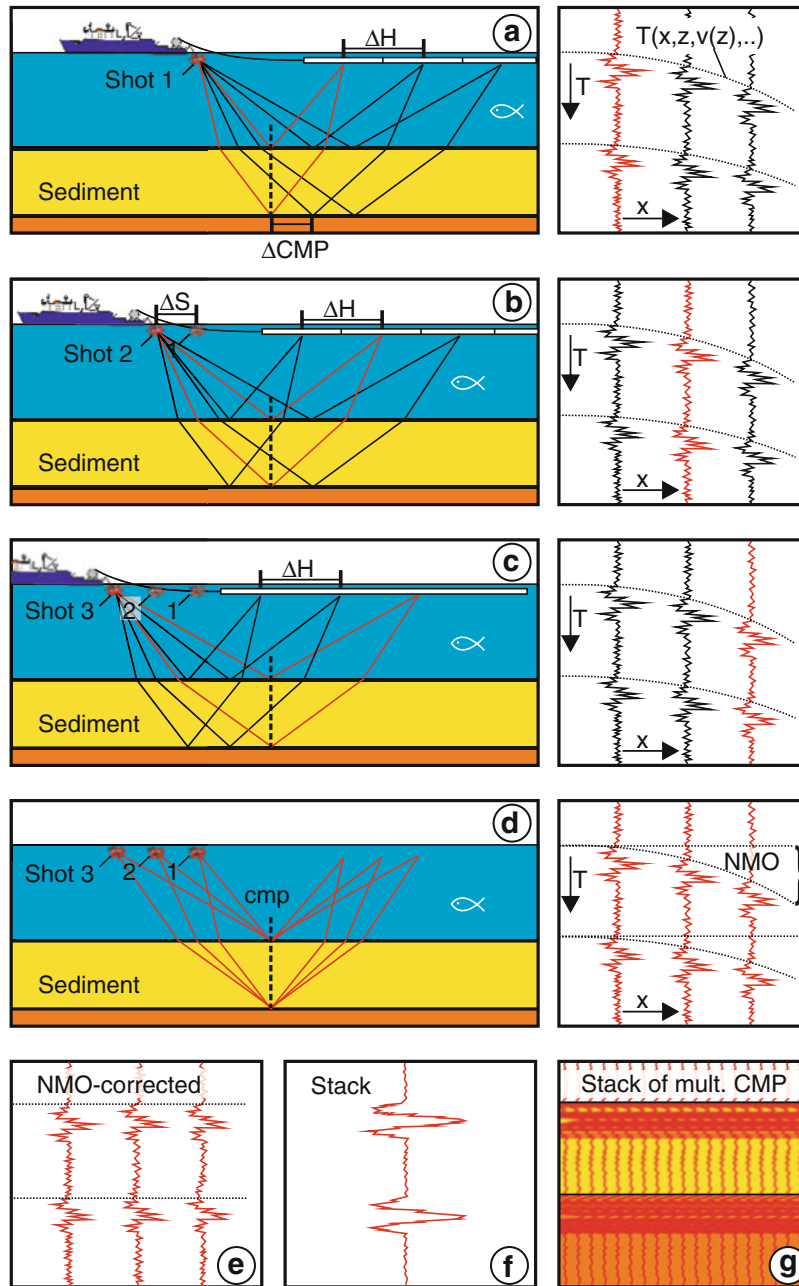
replaced more and more the conventional oil-filled ones, because they have proven to be more robust. Birds allow for an active control of the streamer depth (insert Figure 3). The bird is attached to the streamer by bird collars and can rotate freely around. Depth sensors determine the actual depth. Inductive communication coils within birds and streamer allow data transmitting to the shipboard controller system where depth values are averaged depending on the swell. If depth correction is necessary, the controller sends a signal to the birds, which turns the fins accordingly, and the streamer segment is dragged up or down. Heading sensors (fluxgate magnetometers or mechanical compass) allow for geometric corrections if the streamer drifts off the track by currents. On the opposite side of the bird, a flotation tube is also attached to the collars. The flotation tube eliminates the negative buoyancy of the bird and keeps the bird always beneath the streamer and, consequently, the fins parallel to the sea surface. For 3D applications the precise position of each streamer segment with respect to the air guns is determined by acoustic triangulation. This requires acoustic senders (so-called pingers), e.g., close to the air guns, and acoustic modules (Figure 3) in the birds which receive the pings and send travel times to a control PC.

Seismographs

The term "analog acquisition" refers to a receiver–recorder system where the electrical signal is digitized by a seismic recording unit, which is a data recorder specially designed for seismic data recording, located in the vessel. The seismic recorder fulfills several tasks. Prior to analog–digital conversion, data is usually preamplified and low-pass filtered in order to avoid spectral aliasing. Since the suppression of frequencies becomes significant at about 60–70 % of the Nyquist frequency, the A/D conversion frequency should be about three times the

maximum signal frequency. High-pass filtering can be wise to apply in order to suppress high-amplitude ship propeller noise. After A/D conversion, data are normally formatted to standard formats developed by the Society of Exploration Geophysicists (SEG), e.g., the SEG-D or SEG-Y formats. Analog data transfer via cables results in some loss in data quality, e.g., due to the antenna effects. This disadvantage is overcome by digital systems which digitize the electric signal representing the incoming seismic wave inside the streamer. More expensive digital receivers are standard in exploration geophysics, while the scientific community still operates many analog systems. The disadvantage is less significant for the often near-surface applications.

Acquisition schemes

The classical acquisition scheme for academic marine reflection seismic surveys is the 2D geometry. The first dimension is the 1D acquisition geometry and the second one the travel time of the seismic waves. This acquisition scheme is designed for common midpoint (CMP)-based processing (Figure 4). If a shot is released, the seismic signal travels from the shot point down to the seafloor. Assuming a horizontal seafloor, the reflection points have a distance half of the hydrophone group spacing $\Delta H/2$ (Figure 4). Let us focus on the reflection point of the ray traveling from the shot point down to the seafloor and up to the nearest hydrophone group (Figure 4a). If the shot spacing is also $\Delta H/2$, the same reflection point on the seafloor is covered by the ray between the second shot point and the second channel (Figure 4b), but the travel time is longer and so is the travel time of the wavelet between shot 3 and channel 3 (Figure 4c). The effect that travel time increases with offset is called normal move-out (NMO). During data processing, the individual shot records are sorted to CMP gathers which comprise all those records which have the common midpoint between shot and


Reflection/Refraction Seismology, Figure 4 CMP-based 2D multichannel seismic acquisition scheme (after Mutter, 1987). See text for detailed description.

receiver coordinates (Figure 4d). Analysis of the offset-dependent travel time discrepancies allow – if offset is not much less than reflector depth – calculating interval velocities and reflector depth. During data processing (see below), recordings of each CMP gather (Figure 4e) are NMO corrected and stacked (summed to one single trace) which results in a constructive superposition of primary information (reflections) and destructive superposition of (incoherent) noise (Figure 4f). Displaying of all

CMP traces along a profile (Figure 4g) gives an image of subsurface strata.

In the exploration industry, 2.5D, 3D, and 4D data acquisition schemes are more common. Sequential acquisition of parallel and fairly narrow-spaced 2D lines results in a 3D subsurface model. However, this is called 2.5D seismics because azimuth-dependent factors are not considered. In a strict sense, the term 3D seismics refers to acquisition geometry only if seismic waves are recorded

by a 2D pattern of receivers; thus, the seismic waves are measured with different azimuth angles. Repeated measurements within the same area with a 3D geometry are called time-lapse monitoring or 4D seismics, enabling the interpreter concluding on subseafloor fluid dynamics. Recently a highly mobile 3D seismic system has been introduced which allows imaging the upper 1–2 km with high lateral and vertical resolution. A bundle of 12 short streamers containing 8–16 channels is towed behind the survey vessel (e.g., Berndt et al., 2012).

Data processing

Seismic data processing comprises a vast of different methods for the analysis of recorded seismic signals to reduce or eliminate unwanted components (noise), to create an image of the subsurface to enable geological interpretation, and eventually to obtain an estimate of the distribution of physical material properties in the subsurface (inversion) (Chowdhury, 2011). Processing is a science by its own and it is impossible to give a complete overview here (for a comprehensive text book, see Yilmaz, 2008).

One of the primary goals is the enhancement of the seismic *signal* and the suppression of *noise*. The term signal refers commonly to primary reflections, which is seismic energy reflected only once during its path from source to receiver. Everything else can be considered as noise; it comprises random and coherent noise (Kumar and Ahmed, 2011). Random noise does not correlate with neighboring channels. Coherent noise includes multiple reflected energy, side wipes (out-of-plane reflections), and energy from previous shots or processing artifacts. Ambient noise means noise resulting from other sources such as waves, swell, ship propeller, or marine animals. Noise suppression is easy if its frequency lies outside the signal frequency range; otherwise more sophisticated methods have to be applied.

A fundamental parameter which is crucial to know for several processing steps is the distribution of the seismic wave speed, called "velocity." For example, the velocity controls the propagation of the seismic wave, its reflection, refraction, and diffraction as well as the geometrical spreading of the wave front and the related amplitude loss (spherical divergence). Vice versa, seismic velocities are crucial to correct for amplitude losses, travel time differences within a CMP gather, and dislocated reflections and to bring the seismic energy smeared along diffraction hyperbola into focus (called migration). The conversion from a seismic time section to a depth section can be only correct if the velocity distribution is well known. Further, velocity functions can be used to remove multiple reflections. Basically, the velocity distribution can be calculated from the move-out in CMP gathers. The bigger the move-out, the more accurate are the derived velocities. If the reflector depth is much higher than the maximum offset (streamer length), the move-out becomes neglectable and no reliable velocity calculation is possible. For example,

if a 600 m streamer is used – a quite typical value for streamers operated by academic institutions – accurate velocities beneath depths of 1,000 m can hardly be derived. The necessary computation of velocity is a relatively easy task if the subsurface is a horizontal layer cake, but geological formations are often not formed in this simple matter. It becomes more difficult if strata are tilted, deformed, disrupted, and anisotropic, all resulting in lateral velocity changes.

The supreme discipline in seismic data processing is seismic migration (Yilmaz, 2008; Gray, 2011). It comprises a set of techniques for transforming reflection seismic data into an image of reflecting boundaries in the subsurface. It brings the seismic energy distributed along a diffraction hyperbola into focus and corrects geometric effects caused by dipping reflectors and velocity effects. If the velocity model is well known, pre-stack migration gives best results; however, it is quite costly in terms of CPU time. Migration can result either in time or depth sections. Pre-stack depth migration (PSDM) is the ultimate goal of seismic data processing.

A basic processing sequence for marine seismic data includes the following steps:

- Preprocessing: Set amplitudes of bad traces to zero, correct misfires, assign geometry (CMP numbers) to traces. Suppress noise outside signal frequencies by band-pass filtering.
- Pre-stack processing I: Mute direct wave; balance energy between individual channels.
- Velocity analysis: Sort shot gathers to CMP gathers; calculate velocity model.
- Pre-stack processing II (based on velocity model): Correct amplitudes for spherical spreading, absorption, and energy partitioning at interfaces; suppress multiples with the help of velocity model.
- Pre-stack time or depth migration (optional).
- Stacking: Flatten reflection events by NMO correction using velocity model within CMP gather; stack all traces.
- Post-stack time or depth migration (optional).

Data acquisition: refraction seismology

Modern ocean-bottom seismometers (OBS) or hydrophones (OBH) are autonomous receiver and recording systems which are deployed on the seafloor where they remain for days or even several months and where they record seismic profiles during this time. The decoupling between seismic source and receiver allows for great distances which is necessary to receive refracted waves from the deep crust and upper mantle. These systems consist of a data logger, batteries, a three-component seismometer and/or a hydrophone, a radio beacon, a xenon flashlight, and a flag. These components are either mounted on a steel frame, which is kept afloat by syntactic foam bodies, or are installed within and on top of a floatable glass sphere. Either system type is connected to an anchor frame via an acoustic releaser. On hydroacoustic signaling, the

releaser opens a hook to release the OBS/OBH system from its anchor and the system ascends to the sea surface. Recording parameters such as sample rate (e.g., 200 Hz) and gain are set before deployment, and data are retrieved from the data logger after recovery. Most commonly the data logger is programmed such that it records continuously.

Data processing and signal enhancement

Data processing of standard seismic refraction records is – compared to that of the seismic reflection technique – relatively straightforward. As a major component of the record analysis and modeling is focused on extracting seismic velocities from the relationship of seismic travel times to source-receiver offsets, the accurate determination of source and receiver coordinates is of great importance. While this is a trivial problem to be solved in land surveys, the exact location of an ocean-bottom seismometer, which may have drifted on its sinking path to the seafloor, can in most cases only be estimated by using the direct acoustic water wave phase in the record. After this so-called re-localization process of each OBS, the remaining data processing includes mainly band-pass filtering for enhancement of the signals which have their largest amplitudes between 5 and 12 Hz in deep crustal seismics. Deconvolution filters can be applied in some instances to improve the identification of the time onset of particular refraction phases. Some workers use coherence filters in order to enhance seismic phases of a particular dip range or to suppress the so-called wrap-around, which is the direct acoustic wave-field through the water emitted from the previous shot. As this direct wave travel with only 1.5 km/s water velocity, it is still recorded at large offsets and is sometimes superposed on reflected or refracted phases from the deep crust or upper mantle. Most commonly, seismic refraction records are displayed with travel times reduced (Figure 5) in order to include all refraction and wide-angle reflection phases of interest into a reasonably sized display window and to provide the viewer with a visual impression of the velocities of the main refraction phases. For instance, a record displayed with travel time T reduced with a velocity V_{red} of 8.0 km/s ($T_{red} = T - X/V_{red}$, where X is offset) shows refractions with an apparent P-wave velocity of 8.0 km/s as horizontal phases.

The processing flow is similar for the four components (hydrophone h, vertical z, horizontal x, horizontal y) of an OBS record or the three components of a land instrument record. When searching for S-waves or converted wave phases (P-to-S or S-to-P), records are displayed with the corresponding main reduction velocity applied to travel time.

Modeling, inversion, and tomography

Various modeling strategies are exercised to derive physical properties of the subsurface, the crust and/or the upper mantle from the seismic refraction, and wide-angle
Reflection/Refraction Seismology, Figure 5 Example of a seismic refraction OBS record with travel times reduced with 8 km/s (*top*), picked and modeled refraction phases (*middle*), and a crustal cross-section model with traced rays corresponding to the picked refraction phases (*bottom*) (from Suckro et al., 2012). Pc1 and Pc3 are refraction phases from the middle to lower crust, while PmP denotes a wide-angle reflection from the crust–mantle boundary (Moho discontinuity).

reflection records. Deriving the seismic velocity–depth distribution along a surveyed 2D profile or in a 3D area is the most widely desired aim for modeling because of the strength of seismic refraction technique to provide firsthand information on P- and S-wave velocities of the layers penetrated. While basic geometric methods such as the plus-minus method, the intercept-time method, the delay-time concept, and reciprocal methods (e.g., Palmer, 1986) are sufficient to represent simple 2D subsurface geometries, even with irregular interfaces, as often approximated for the shallow subsurface, deep crustal complex layer structures and heterogeneous velocity–depth distributions can only be modeled with more sophisticated numerical methods using a ray-geometric or elastic wave-field inversion approaches. A short overview of commonly used modeling schemes is given here.

Forward ray-tracing and travel time inversion: Based on acoustic wave propagation laws, software for ray-tracing in complex multilayered media was first developed in the 1970s (e.g., Cerveny et al., 1977). The method of ray-tracing is performed by an efficient numerical solution of the 2D ray-tracing equations coupled with an automatic determination of ray takeoff angles. The model response is iteratively optimized by approaching a best fit to the observed travel times. This ray-tracing method was further optimized by Zelt and and Smith (1992) who implemented a travel time inversion by a best-fit approximation with a damped least-square algorithm. Due to its nonlinear nature, the inversion process is controlled by strict boundary conditions on travel time picking uncertainties as well as model parameterization and resolution bounds. Due to its efficiency, the open-source software RAYINVR, originally developed by Zelt and and Smith (1992), is still the most widely used 2D ray-tracing scheme in academic research to date (Figure 5), although different modifications exist, mainly improving model parameterization and visualization and adding more features (Zelt, 1999). The software was further developed to allow modeling in 3D subsurface media (Zelt and and Barton, 1998). Ray-tracing can also be used to calculate synthetic amplitudes that can be compared with the observed ones. However, this has limitations as it does not take into account the full elastic properties of the subsurface layers and interfaces.

Travel time tomography: A 2D and 3D travel time inversion by using an iterative first-arrival seismic tomographic (FAST) algorithm, in which a regularized inversion routine is computed rapidly over a regular grid using finite-difference extrapolation (Vidale, 1990), was developed by Zelt and and Barton (1998). This routine was originally developed for mid- and deep crustal seismic refraction tomography (e.g., Zelt et al., 2004; Stankiewicz et al., 2008) but has been utilized for shallow subsurface imaging by appropriately adjusting model parameters (Deen and and Gohl, 2002). As required for a linearized inversion, an initial model has to be implemented first. From this initial velocity–depth model, a series of iterations improves the model with respect to the picked travel times. Each subsequent iteration of the model is developed using both a finite-difference forward calculation of travel times and ray-paths and a regularized inversion incorporating a combination of smallest, flattest, and smoothest perturbation constraints, the weights of each being allowed to vary with depth. An advanced tomographic inversion based on a Monte Carlo scheme with an implementation of automated model regularization and a polynomial expansion of the probability function has been developed by Korenaga and and Sager (2012).

Wave-field inversion: One of the first widely used wave-field inversion techniques was developed by Pratt et al. (1996) and is based on finite-difference modeling of the wave equation, thus allowing very general wave types to be incorporated and enhancing the resolution when compared to travel time methods. Their method operates in the frequency domain and allows modeling and inverting velocity structure as well as inelastic attenuation factors. The inversion can be iterated to improve the data fit and to take account of some nonlinearity. Some of the nonlinearity can be dealt with by using starting models that have been developed with standard forward ray-tracing. Despite advances in computational speed, full wave-field inversion techniques that incorporate (visco-) elastic and anisotropic wave equations on full crustal model scales still remain in a small user niche as parameterization is cumbersome and computational requirements are not always met. However, it is a matter of time until this method will be taken to the next level of being accepted for more regular use in the academic research and exploration communities.

Seismic interpretation

As seismic methods can be considered as a way of remote sensing into the earth, all interpretations can be significantly corroborated by ground truthing, meaning to calibrate the interpretation by drilling results, which includes both coring and well logging. The understanding of large-scale crustal structures can be significantly supported by modeling and inversion of gravity and magnetic data.

The interpretation of reflection seismic data consists of two major steps. During the first one data are described by an association-free nomenclature in order to prevent a biased point of view. For example, "disrupted horizons" is descriptive; the denotation "normal fault" is a possible interpretation of this pattern. From that objective description of the data, conclusions are drawn regarding tectonic and sedimentary processes.

The seismic interpreter should start with the evaluation of recording and processing parameters. From this he/she will get a first idea about the reliability of his observations. The description of reflection seismic images should follow the following scheme:

1. Identification and mapping of unconformities and correlated conformities

2. Determination of termination style (e.g., onlap, toplap, downlap, offlap, etc.)
3. Classification of internal reflection pattern (e.g., parallel, wavy, divergent, etc.)
4. Recognition of clinoforms, structural highs and lows
5. Categorization of seismic attributes (interval velocity, instantaneous frequency, etc.)

From the yet described data, the interpreter derives the processes which led to the observed features. Both the inductive and deductive approaches are used. The consensus about earth processes is used for deductive reasoning, which means propositions generally accepted by the scientific community are used for explaining specific observations. New general propositions about earth processes evolve from inductive reasoning by arguing that a specific example is representative for other cases. A "good" interpretation explains a maximum of observations and makes minimum assumptions about unknowns.

In all cases the interpreter should have a sound knowledge about both geology and geophysics. Since a quantitative failure discussion is often not possible, the interpreter needs a sound knowledge and experience to distinguish between imaging or numerical artifacts and geological features.

The primary information content of seismic refraction data consists of P-wave and – if properly recorded – S-wave velocities of the penetrated subsurface layers. As seismic velocities translate to ranges of sediment and rock types, velocity–depth distribution models are used to help interpret shallow subsurface to deep crustal 2D cross-sections or 3D depth-slices, ideally in combination with complimentary seismic reflection and/or potential field (gravity, magnetic) data. Interfaces of first-order impedance discontinuities or layers with strong vertical velocity gradients with respect to wavelength are well recognizable in travel time phases and can be meaningfully modeled. Amplitude analyses of either refracted or wide-angle reflected wave-fields, using ray-geometric or wave-field inversion techniques, are useful for characterizing layer interface properties such as thin lamination or intercalation. For instance, such analyses have revealed a complex formation and composition of the crust–mantle boundary in some regions (e.g., Levander et al., 2005).

Contribution to earth science

Classical applications of the reflection and seismic refraction method to earth science are seismic stratigraphy and structural geology. Both approaches are needed to unravel the dynamics of continental and oceanic basins. Structural geology deals with the imaging of 3D distribution of rock units; its interpretation aims on the reconstruction of their deformational histories.

Seismic refraction surveying has largely contributed to the understanding of the architecture and composition of the earth's crust and uppermost mantle. Crustal thicknesses of the ocean and continental lithosphere have been determined largely due to the frequently encountered strong impedance contrasts at the crust–mantle boundary.

Intra-crustal reflection interfaces are deciphered from analyses of amplitude characteristics in wide-angle reflection and refraction records. Being a powerful tool in the studies of continent–ocean boundaries, refraction surveying and the resulting velocity–depth models have revealed that these boundaries are often transitional zones of various widths in continental margins of both volcanic and non-volcanic types (e.g., Mjelde et al., 2005; Voss and and Jokat, 2007; Suckro et al., 2012). While the normal-incidence seismic reflection technique largely fails to properly image sub-salt and sub-basalt sedimentary formations and structures, the seismic refraction technique is used as a complimentary tool to provide velocity information from such "hidden" zones.

Sequence stratigraphy is a methodology that provides a framework for the elements of any depositional setting, facilitating paleogeographic reconstructions and the prediction of facies and lithologies away from control points (Catuneanu et al., 2011). Seismic stratigraphy is the approach to conclude on sequence stratigraphy by seismic interpretation. A special discipline of seismic stratigraphy is the analysis of depositional geometries in terms of oceanic currents, which may influence deposition processes forming so-called contourites or contourite drifts (Nielsen et al., 2008). Geophysicist therefore may contribute to paleoceanographic and related paleoclimate studies.

The contribution of the reflection seismic method to chemical processes and the migration of fluids and volatiles, both producing particular characteristics in seismic images, were acknowledged in the 1990s, stimulating research cooperation with biologists and chemists. Further, the transition of free gas to overlying gas hydrate, mainly consisting of methane trapped inside cages of hydrogen-bonded water molecules, gives a strong reflection crosscutting depositional strata, which is easy to detect in seismic data.

The assessment of geohazard potential caused by landslides including their tsunamigenic potential is a fast-developing research field. Owing to the specific internal and external deformation pattern, large submarine landslides are easy to detect in seismic data. The imaging of the internal geometry of volcanoes allows for conclusions on acting volcanism processes and recurrence rates.

The seismic refraction technique is successfully employed in geotechnical and engineering surveys to determine the depth to bedrock. Applications range from the detection of fracture zones in hard rocks in connection with groundwater prospecting, to delineating unconsolidated strata in civil engineering (road and tunnel constructions), to hazardous waste disposal projects.

Conclusions

Seismic reflection and refraction methods are two of the most commonly used geophysical methods in exploring the earth's subsurface for both hydrocarbon exploration and academic research of the buildup of the crust and its sedimentary cover. Both techniques have provided data to

constrain the development of the earth's crust from the sedimentary basins down to the transition to the uppermost mantle of the continents and oceans. Their relatively high structural resolution capacity is one of their greatest advantages. Future developments will see further improvement of 3D imaging and 4D monitoring capabilities from observing resource reservoirs and hydrological systems to geotectonic hazards in regions at risk of earthquake and tsunami.

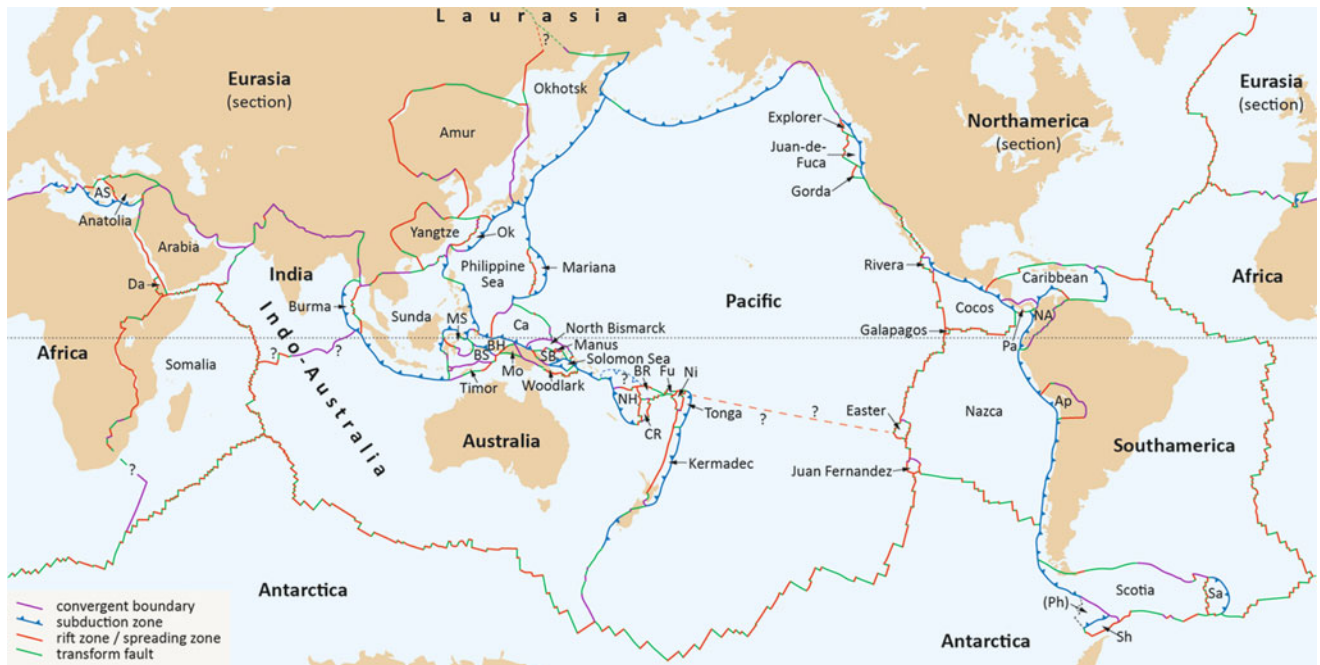
REGIONAL MARINE GEOLOGY

Martin Meschede
Institute of Geography and Geology, Ernst-Moritz-Arndt University, Greifswald, Germany

The oceans and their marginal seas cover approximately 71 % of the Earth's surface. They contain about 97 % of the total water of the Earth and they have an average depth


Regional Marine Geology, Figure 1 Lithospheric plates on Earth: *AS* aegean sea, *Ap* altiplano, *BH* birds head, *BR* balmoral reef, *BS* banda sea, *Ca* carolina, *CR* conway reef, *Da* danakil, *Fu* futuna, *Ke* kermadec, *Mn* manus, *Mo* maoke, *MS* molucca sea, *NA* north andes, *NH* new hebrides-fiji, *Ni* niuafo'ou, *Ok* okinawa, *Pa* panama, *(Ph)* former phoenix (now merged with Antarctica), *SB* south bismarck, *Sa* sandwich, *Sh* shetland, *To* tonga. of approximately 3,680 m. The largest ocean is the Pacific Ocean with more than 181.3 Mio. km^2 corresponding to 35 % of the Earth's surface. The Atlantic Ocean encompasses almost 89.8 Mio. km^2, corresponding to about 18 % of the Earth's surface. The Indian Ocean (74.9 Mio. km^2), Southern (Antarctic) Ocean (20.3 Mio. km^2), and Arctic Ocean (14.1 Mio. km^2) are smaller and cover about 14.7 %, 4.0 %, and 2.7 % of the Earth's surface. The deepest known structure in the oceans is the Mariana Trench in the western Pacific Ocean near the Northern Mariana Islands. The deepest point of 10,920 m ($\pm$10 m) was named "Challenger Deep" after the British survey ship HMS Challenger that made the first recordings of this depth (expedition 1872–1876).

The geographical subdivision of the Earth into oceans and continents does, however, not match the subdivision of oceanic and continental plates in terms of plate tectonics (Figure 1). In the following the regional distribution of plates is described with special emphasis on the oceanic areas.

The lithosphere of the Earth is subdivided into a number of lithospheric plates. All plates are separated from the others by plate boundaries, which are defined by differential movement of the two plates on both sides of the boundary. Three types of plate boundaries are subdivided (Figure 2): divergent or constructive (spreading center, rift zone), convergent or destructive (subduction zone, continental collisional), and conservative (transform fault). New lithosphere is formed by seafloor spreading at

divergent plate boundaries. At convergent boundaries two plates move against each other forming either a subduction zone where oceanic lithosphere descents into the asthenophere or a collisional orogen where two continental plates collide. Transform boundaries occur at locations where two plates slide past each other along transform faults without forming of destructing lithospheric material. All plate boundaries are characterized by seismic activity.

The seven largest plates are the African, Antarctic, Eurasian, North American, South American, Australian, and Pacific plates (Figure 1), and there is no question about smaller plates like the Caribbean, Cocos, Nazca, Juan-de-Fuca, Scotia, Arabian, Philippine Sea, or the Sunda Plate. So-called microplates like the Easter, Explorer, Juan Fernandez, Gorda, Caroline, Woodlark, Sandwich, and several other microplates are also accepted as plate tectonic entities. However, a number of small plates and microplates exist, which are not clearly defined in every case, e.g., Somalia, Danakil, Panama, Altiplano, and several others. Bird (2003) counts a total number of 52 plates, in Figure 1 a total number of 55 plates are shown.

The North American and Eurasian plates are generally taken as two separate plates. The plate boundary between these two plates in the area of eastern Siberia is, however, not clearly defined. The mid-oceanic spreading center in the North Atlantic separating the North American and Eurasian plates continues into the spreading zone of the Gakkel ridge. The spreading velocity at the Gakkel ridge
Regional Marine Geology, Figure 2 Three different types of plate boundaries (after Frisch et al., 2011).

decreases from 1.24 cm/year in the area of Northern Greenland to 0.73 cm/year at the Siberian shelf. The spreading center continues toward south into a rift zone in the Laptev Sea and follows the valley of the Lena River in Northern Siberia. A distinct plate boundary is missing further to the south. On the other side, a convergent plate boundary exists west of Japan running through the eastern part of the Japan Sea. It separates the Amur and Okhotsk plates (Figure 1), which in other plate distribution maps belong to the Eurasian Plate. The northern continuation of the convergent plate boundary is, however, unclear and there is no direct connection to the rift valley of the Lena River. It is, therefore, suggested that the North American and Eurasian plates are still connected in their central part in Northeastern Siberia. The two plates are thus defined as the North American and Eurasian sections of the large Laurasian Plate.

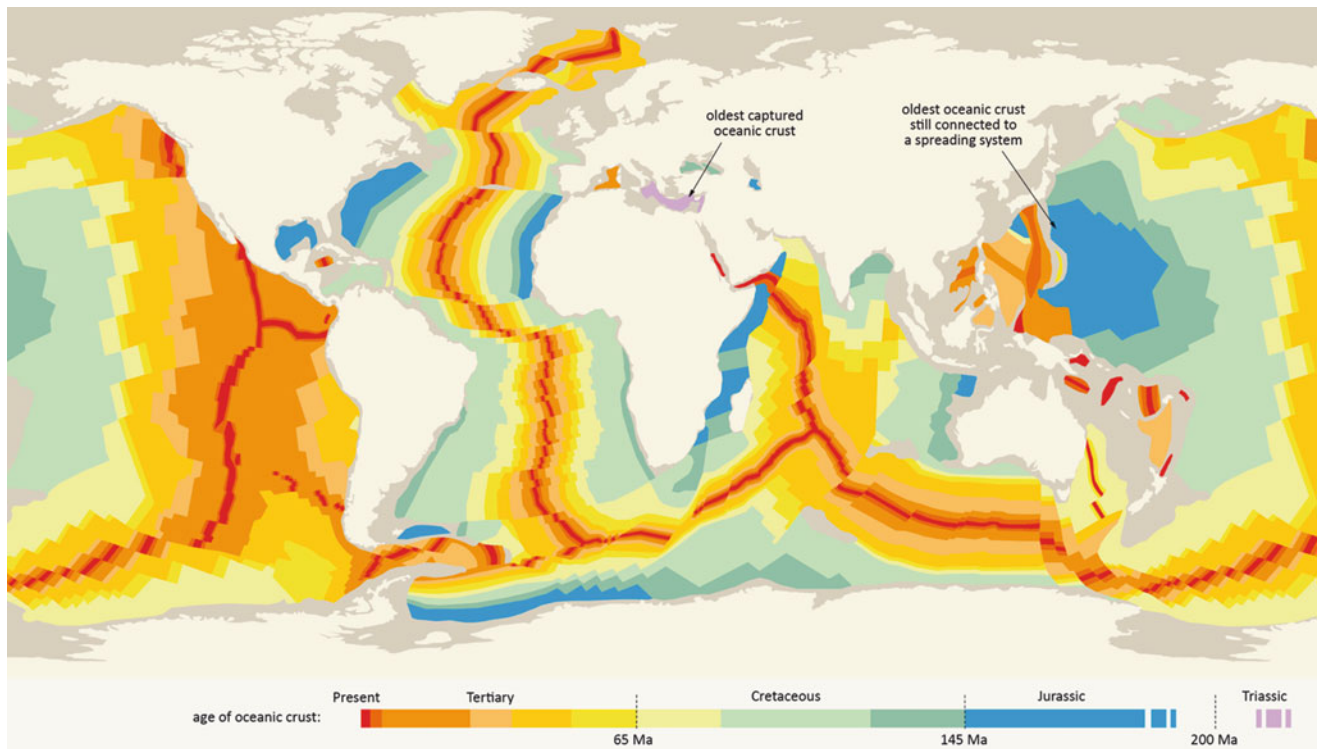
The Indo-Australian Plate is marked by two large landmasses, India and Australia. An ongoing debate exists whether a plate boundary separates the Australian from the Indian Plate. The suggested mostly convergent plate boundary (Bird, 2003) is located west of Sumatra and south of the Maldives islands (Figure 1). Many other authors, however, do not subdivide an Indian and Australian plate. The formation of a new plate boundary may be indicated by strong earthquakes occurring in the equatorial area of the Indo-Australian Plate (Wiens et al., 1986; Delescluse et al., 2012; Shen, 2012). The earthquakes are interpreted to indicate the ongoing process of plate boundary formation. At the eastern plate boundary of the Australian Plate a flip in the subduction polarity can be observed in the area of New Zealand. The North Island of New Zealand is characterized by the subduction of the Pacific Plate beneath the small Kermadec Plate, which is

separated by a back-arc spreading center from the Australian Plate. The morphological expression of the subduction zone is the Hikurangi Trough. The subduction zone continues on the South Island into the New Zealand Alpine Transform Fault. Further to the southwest in the Tasman Sea the Australian Plate is subducted beneath the Pacific Plate thus having an opposite subduction polarity.

The Somalia Plate is separated from the African Plate by the Central African rift system. The rift system was initiated about 25 Myrs ago (Roberts et al., 2012). It is characterized by strongly thinned continental lithosphere beneath the graben axis and a deep graben structure on top of the rising asthenosphere that produces a typical rift volcanism. The volcanoes of Central Africa, e.g., the Kilimanjaro, the Nyiragongo, or the Ol Doinyo Lengai illustrate the ongoing rifting process. The southern boundary of this plate, however, is not clearly defined and still under discussion (Calais et al., 2006; Stamps et al., 2008).

The most complicated area in terms of plate tectonic boundaries is the Indonesian archipelago. A large number of small plates are acting together forming a number of special situations. Up to about 20 different small plates, microplates, or terranes are subdivided, all of them separated by one of the three types of plate boundaries (Figure 2). A well investigated situation exists in the Woodlark Basin where an asymmetric rift led to the denudation of mantle material in the direct neighborhood of an oceanic spreading ridge (e.g., Taylor et al., 1994). Other plate boundaries are apparently just in the stage of formation as there are indications that a morphological trench between the Tuvalu and Solomon islands represents the initial stage of a forming subduction zone (Okal et al., 1986).

The Tonga-Kermadec subduction zone marks the western boundary of the Pacific Plate. It is a classical situation of an oceanic convergent plate boundary with the formation of a back-arc spreading center that defines the small Kermadec and Tonga plates located between the Pacific and Australian plates. A similar situation exists with the Mariana Plate between the Pacific Plate subducted beneath the Mariana Plate and the Philippine Sea Plate west of the back-arc spreading center of Mariana. Other situations with back-arc spreading centers forming small independent plates exist in the New Hebrides-Fiji Plate separated by a back-arc spreading center from the Conway Reef Plate, the Okinawa Plate separated from the Yangtze Plate, and the Sandwich Plate separated from the Scotia Plate (Figure 1).

The Pacific Ocean is with approximately 181.3 Mio. km^2, the largest oceanic basin of the Earth. However, only a little less than two thirds of the ocean belongs to the Pacific Plate which is the largest lithospheric plate on Earth covering an area of about 108 Mio. km^2. It is mainly made up of oceanic crust except some small areas in its surroundings, e.g., the area of Baja California in northwestern Mexico or part of the Southern Island of New Zealand. It is bordered by the East Pacific Rise in the east,


Regional Marine Geology, Figure 3 Distribution of ages of oceanic lithosphere (based on Müller et al. (2008) and Frisch et al. (2011)).

a mid-oceanic rift system of about 9,000 km length. The East Pacific Rise continues toward north into the transform/rift system of the Gulf of California, the San Andreas transform fault, and is followed by the rift system between the Pacific and Gorda/Juan-de-Fuca/Explorer plates and further to the north by the Queen-Charlotte transform fault. This transform fault ends in a series of destructive plate margins: Aleutian trench, Kurile-Kamchatka trench, and the so called IBM system consisting of the Izu, Bonin, and Mariana trenches. The southernmost part of the East Pacific Rise is the rift zone between the Pacific and Antarctic plates. The western part of the Pacific Plate encompasses the oldest oceanic crust on Earth with more than 185 Ma (Figure 3; Müller et al., 2008) that is still in direct connection to the mid-oceanic ridge where it was formed. A discussion exists whether the Pacific Plate may split up in the near future into two parts along a break-up zone between the Tonga Plate in the west and the Easter Plate in the east (Figure 1). This zone is marked by an abnormal concentration of intraplate volcanism (Clouard and Gerbault, 2008), which may represent the first indications of a future plate reorganization that will break the Pacific Plate into a southern and a northern plate.

The Pacific Plate is bordered in the east by a number of differently sized plates (from north to south): Explorer, Juan-de-Fuca, Gorda, Rivera, Cocos, Galapagos, Nazca, Easter, Juan Fernandez, and Antarctic plates. With the

exception of the Antarctic plate, all these plates are entirely composed of oceanic crust and are partly remnants of the former Farallon Plate, which has been one large single oceanic plate formed at the East-Pacific Rise spreading center formed in the Mesozoic and early Cenozoic until it was nearly completely subducted beneath the American continents. It was split up into several parts by the subduction of the mid-oceanic rift system about 30 Ma ago. 25 Ma ago the three-phase Cocos-Nazca spreading system came into existence (Meschede et al., 1998; Meschede and Barckhausen, 2001) that separated the largest remnant of the Farallon Plate into the Cocos and Nazca plates. The Cocos Plate is subducted beneath the North American and Caribbean plates. The easternmost part is subducted beneath the Panama Plate whose boundaries with the Caribbean Plate, however, are not clearly defined in all places. The Nazca Plate is subducted beneath the South American Plate that includes the North Andes and Altiplano plates defined by Bird (2003).

With exceptions in the eastern Caribbean and eastern Sandwich plates, the Atlantic Ocean is nearly entirely bordered by passive plate margins without plate boundaries. The oceanic crust of the northern part of the Atlantic Ocean belongs to the North American and Eurasian plate sections of the Laurasian Plate. The southern part belongs to the South American, Scotia/Sandwich, African, and Antarctic plates. There is no separate Atlantic Plate as it

exists in the Pacific. In the middle of the Atlantic Ocean, the Mid-Atlantic rift zone separates the American plates in the west from the European and African plates in the east. Subduction of oceanic crust of the Atlantic Ocean occurs currently along the eastern boundaries of the Caribbean and Sandwich plates in the north and south of South America, respectively. According to seismic data and earthquake observations (Gutscher et al., 2002; Gutscher, 2004; Spakman and Wortel, 2004), a subduction zone in the process of formation is interpreted beneath the Betic cordillera in southern Spain and the Atlas mountains in Morocco. The oldest part of the Atlantic oceanic crust is located in the Central Atlantic along the coasts of the eastern United States and western Africa (Figure 3). With an age of about 175 Ma, it is only slightly younger than the oldest oceanic crust of the Pacific Plate.

The Indian Ocean is the third largest of the world's oceans. In its northern part the Carlsberg Ridge as part of the Central Indian Ridge separates the African Plate from the Indo-Australian Plate (Figure 1). The Carlsberg Ridge ends at the Rodrigues Triple Junction. The mid-oceanic ridge running from this triple junction towards southwest separates the African and Antarctic plates whereas the other branch running towards southeast separates the Indo-Australian and Antarctic plates. An ongoing discussion exists about a plate boundary separating the northern Indian part of the Indo-Australian Plate from its southern Australian part (see above). The oldest oceanic crust of the Indian Ocean is located in the western part off the coast of Somalia, Kenya, and Mozambique (Figure 3).

RELATIVE SEA-LEVEL (RSL) CYCLE

Jan Harff
Institute of Marine and Coastal Sciences, University of Szczecin, Szczecin, Poland

Definition

Relative sea-level (RSL) is the position of sea surface relative to the base level. Its cyclic change between transgression and regression takes into account two main components: eustatic change and vertical movement

(tectonic/isostatic) of the sea floor (modified from Posamentier and Allen, 1999).

Introduction

One of the main achievements in stratigraphy in the beginning of the twentieth century was to use sedimentological fingerprints of global transgressions and regressions for a general division of the Phanerozoic earth history. Suess (1906) developed the concept of eustasy to link physical stratigraphy of different regions with the frame of global transgressions and regressions. This concept was refined by von Bubnoff (1954) who subdivided the geological history during the Phanerozoic on the global scale into six megacycles, each consisting of two transgression phases followed by an inundation, differentiation, regression, and emersion phase. The assumption of a decreasing period of the cycle from 175 Mio yrs ("pre-Caledonian cycle") to 20 Mio yrs for the latest (still ongoing) cycle led to the "time-snail" model (von Bubnoff, 1954) describing the tectonically driven history of the earth.

Sloss' (1963) and Vail et al.'s (1977) pioneering studies of global and regional relative sea-level change and its stratigraphic response on passive continental margins are used in geology today to provide a spatial–temporal framework for genetic and environmental studies of sedimentary rocks. Vail et al.'s work was based on the interpretation of onshore seismic reflection profiles at Exxon Production Research Company (EPR) to identify sea-level changes using unconformities in the stratigraphic record. The Ocean Drilling Program (ODP) provided the tools to link the onshore records with offshore sediment records starting with the New Jersey sea-level transect. Based on oxygen isotope ratios ($\delta^{18}O$), the relative sea-level change has been reconstructed from the Mesozoic to the Cenozoic (Haq et al., 1987). High-resolution sea-level records for the Quaternary are based on interpretation of isotope signals from corals and the Late Pleistocene and Holocene geodetic position of radiocarbon-dated paleo-coastlines (Fairbanks, 1989; Lambeck and Chappell, 2001).

Factors influencing relative sea-level cycles

It is assumed that the change of relative sea-level can be split into different components:

$$\Delta S = \Delta E + \Delta V + \sum_i \Delta E_i. \tag{1}$$

Here ΔS stands for the relative sea-level change, ΔE marks eustatic change, ΔV is the vertical crustal movement (tectonically or isostatically induced), and ΔE_i stands for other effects of varying importance, such as compaction, local tectonics, gravitational forces, and others. Global eustatic changes are controlled by the volume of water filling the ocean basins or by changes in the volume of these basins. According to Allen and Allen (1990), these changes are due to differentiation of lithospheric material as a result of plate tectonic processes, changes in the basin volume because of accumulation of sediments, and

changes in the volumetric capacity of ocean basins because of volume changes in the mid-ocean ridge systems. Here also the subduction of oceanic crust and the resulting shrinking of marine basin volume have to be taken into account (ocean closure). Cloetingh and Haq (2015) give a comprehensive view of the interplay between geodynamic processes and sea-level change. A very important factor is the change of water volume due to climate-related terrestrial storage of water in the form of continental ice sheets. To these can be added changes in volume due to storage and release of groundwater (Hay and Leslie, 1990).

The isostatic/tectonic vertical crustal movement is specific for different regions and superimposed on the global eustatic changes. Basin formation, changes in subsidence rates due to internal mantle dynamics or external loading, folding, faulting, magmatism, and diapirism determine the regional vertical displacement of the crust.

Eustatic and tectonic/isostatic cycles are superposed and on passive continental margins result in cyclic successions of transgressions and regressions. On continental margins this process produces time-equivalent sediment packages bounded by correlative physical surfaces (sedimentary sequences and parasequences). Based on the sedimentary correlation of the relative sea-level changes, Vail et al. (1991) ordered the sea-level cycles by their periodicity (duration) into six classes (see Table 1).

According to Allen and Allen (1990), long-term changes in the volume of mid-ocean ridges resulting from changes in spreading rates are the cause of first-order cycles. Second-order cycles ("supercycles" after Vail et al., 1977) have been globally traced by Vail et al. (1977) based on onlapping of the strata of a sequence in relation to its lower boundary. Figure 1 compares global (second-order) cycles of Vail et al. (1977) and the age of rift–drift transitions on different continental margins after Watts (1982). The latter author suggests a close relation between the rift–drift transition during the continental breakup of the supercontinent Pangaea and the initiation of coastal onlap.

Other possible causes of the second-order relative sea-level changes are plate boundary reorganizations and glacial/deglacial cycles (Allen and Allen, 1990).

Relative Sea-Level (RSL) Cycle, Table 1 Duration (period) of each order of RSL cycles (Vail et al., 1991)

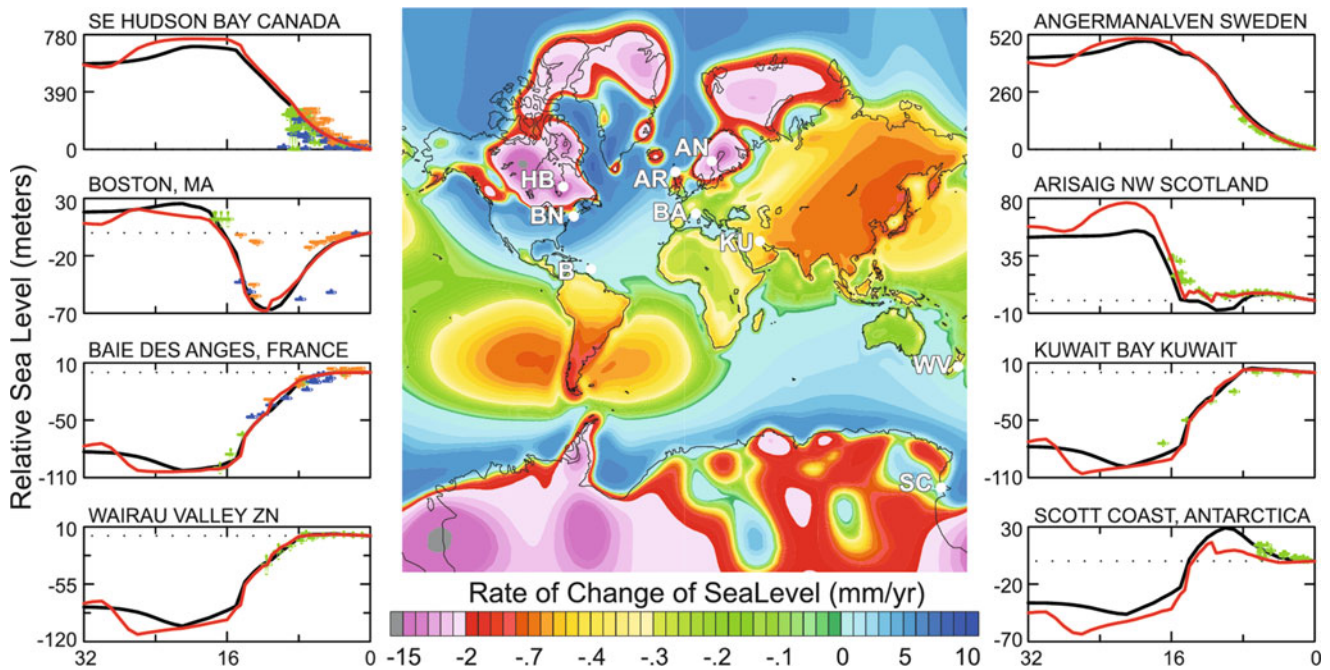
Order	Duration (period)
1	50 + Ma
2	3–50 Ma
3	0.5–3 Ma
4	0.08–0.5 Ma
5	0.03–0.08 Ma
6	0.01–0.03 Ma
Relative Sea-Level (RSL) Cycle, Figure 1 Comparison of global (2nd-order) relative sea-level cycles after Vail et al. (1977) and the age of the rift–drift transition at different continental margins (modified from Allen and Allen, 1990; Watts, 1982).
Relative Sea-Level (RSL) Cycle, Figure 2 Climate and sea-level of the last 450 kyrs after Carlson (2011): (**a**) June insolation at 65° N (Berger and Loutre, 1991), (**b**) atmospheric CO_2 concentrations from Antarctic ice cores (Siegenthaler et al., 2005), (**c**) East Antarctic change in temperature (*dashed line* denotes present-day temperature) after Jouzel et al. (2007). (**d**) Sea-level records from the Red Sea (*black line*): *black squares*, individual sea-level estimates; *dashed line*, present-day sea level (Clark et al., 2009; Rohling et al., 2009); *gray bars*, deglaciations; *yellow bars*, interglaciations.

Haq et al. (1987) have used the concept of second-order tectonically initiated global sea-level change for a chronology of the Earth's history since the Triassic. It has to be mentioned that even after 50 years of research, the causes for rapid sea-level shifts, in particular during the Cretaceous, are not completely understood. Due to recent studies of Haq (2014), a fourth-order (400 kyr) cyclicity related to orbital eccentricity seems to play an important role not only during the Cretaceous but also for the whole Phanerozoic.

Glacial and postglacial relative sea-level cycles

Cycles of third-to sixth-order can have different causes. Whereas tectonic processes affect relative sea-level changes on the regional scale, global sea-level cycles of third-to sixth-order are mainly caused by climatically controlled changes in the marine water volume (Vail et al., 1991). The history of climate change is recorded in high resolution for the Quaternary. Milankowitch (1930) calculated the cyclic variations of the earth's orbital parameters proposing that the changes in insolation and consequently

energy supply to the Earth were the cause of glacial/interglacial shifts. Berger and Loutre (1991) assume that cyclic changes in boreal summer insolation are responsible for the cyclicity in the buildup of continental ice sheets during the glacial periods and their melting during interglacial periods. This interdependence between boreal insolation, continental ice volume, and global sea-level also correlates with the atmospheric CO_2 concentration as an effect of interglacial ocean warming. Figure 2 shows the summer insolation at 65° N, the atmospheric CO_2 concentrations from Antarctic ice cores, East Antarctic change in temperature, and sea-level data from the Red Sea during the last 450 kyrs (after Carlson, 2011).

The solid Earth deforms under the influence of changing loads on its surface; the loads of continental ice cause differential subsidence whereas the unloading by melting during the interglacial results in uplift of the crust. This means that the ice/water volume change has quite different effects on the changes in relative sea-level observed in glaciated and non-glaciated parts of the world. Different models have been elaborated to describe these processes


Relative Sea-Level (RSL) Cycle, Figure 3 Intercomparisons between observed and predicted relative sea-level histories at eight different geographical locations using two different versions of the ICE-5G(VM2) model of the deglaciation process: versions 1.1 (LGM at 21 ka BP, *black curve*) and 1.2 (LGM at 26 ka BP, *red curve*) (after Peltier, 2007). The positions of the eight sites are shown in the central part of the figure superimposed upon a Mercator projection of the present-day predicted RSL rate using Peltier's (1998) SLE.

for the last glacial cycle (Lambeck and Chappell, 2001; Peltier, 2007).

Buildup and decay of the continental ice sheets cause glacio-isostatic adjustments (GIA) of the Earth's crust, and redistribution of meltwaters filling marine and freshwater basins causes hydro-isostatic processes. Peltier (1998) has developed a sea-level equation (SLE) that describes the complex interactions between melting ice sheets, crustal deformations, and sea-level changes.

Applying this SLE Peltier (2007) has used the ice load history model ICE-5G(VM2) (Peltier, 2004) to predict the relative sea-level curves for eight different geographical locations in high and low latitudes from 32 ka BP to present day including the Last Glacial Maximum (LGM) and deglaciation period. In Figure 3 the relative sea-level curves for six locations are depicted for two different assumptions: the occurrence of the LGM, i.e., the time of which the greatest concentration of land ice existed, at 21 ka BP (black curve) which was conventionally assumed, and 26 ka BP (red curve) which corresponds to more recent assumptions about the timing of the maximum ice sheet extent during the LGM. According to Clark et al. (2009) nearly most of the continental ice sheets had reached their maximum extents around 26.5 ka BP. The comparison with geologically inferred relative sea-level data (marked in the RSL plots of Figure 3) shows that the model reasonably reconstructs the sea-level history for all selected sites despite different assumptions about

the LGM maximum. The differences in the vertical crustal deformation are evident in comparing the sea-level curves from the formerly glaciated high-latitude regions and those at low latitudes not influenced by continental ice sheets. Formerly glaciated regions show the relative sea-level fall in response to glacio-isostatic uplift beginning about 16 ka BP whereas the neotectonically relative stable low-latitude sites show the continuous sea-level rise due to the water volume effect of the deglaciation between 16 and 6 ka BP. In a global atlas Pirazzoli (1991, 1996) gives an overview of the empirical RSL data for the Holocene showing the regional differences caused by tectonic and GIA effects.

For future projection of relative sea-level change, in particular in its regional effect on coastline migration, besides the already mentioned factors, gravitational forces (geoid effects) have to be taken into account. So postglacial GIA (for instance, of Scandinavia, see Richter et al., 2012) and climatically controlled changes of ice sheet mass (for instance, of Greenland, see Kopp et al., 2010) cause considerable deformation of the adjacent sea surface.

Summary

The relative sea-level changes periodically between regression and transgression of the sea and acts on different – hierarchically superimposed – temporal and spatial scales. Eustasy and tectonic (isostatic) vertical crustal

movements are the main components of relative sea-level records reconstructed for the Phanerozoic by indirect geological methods. The younger geological history, in particular the glacio-isostatic adjustment's influence on coastline change, can be reconstructed by models describing the effect of loading and unloading of continental ice shields. The empirical data have to be analyzed very carefully in order to separate vertical crustal movements from the eustatic (climatically controlled) components.

SALT DIAPIRISM IN THE OCEANS AND CONTINENTAL MARGINS

Sergey S. Drachev
ExxonMobil House, ExxonMobil International Ltd.,
Leatherhead, UK

Definition

Salt diapir is a multiform-shaped body of crystalline aggregate of evaporite minerals (mainly halite) that has discordant contacts with the encompassing sedimentary strata and formed due to salt movement. The process of SD formation, often referred to as diapirism, is accompanied by deformations significant in scale and magnitude of both overburden rocks and salt itself. It is an integral part of the phenomenon known as salt tectonics, or halokinesis. The word "diapir" comes from the Greek verb diaperein ($\delta\iota\alpha\pi\epsilon\rho\epsilon\acute{\iota}\nu$) – "to pierce."

Introduction

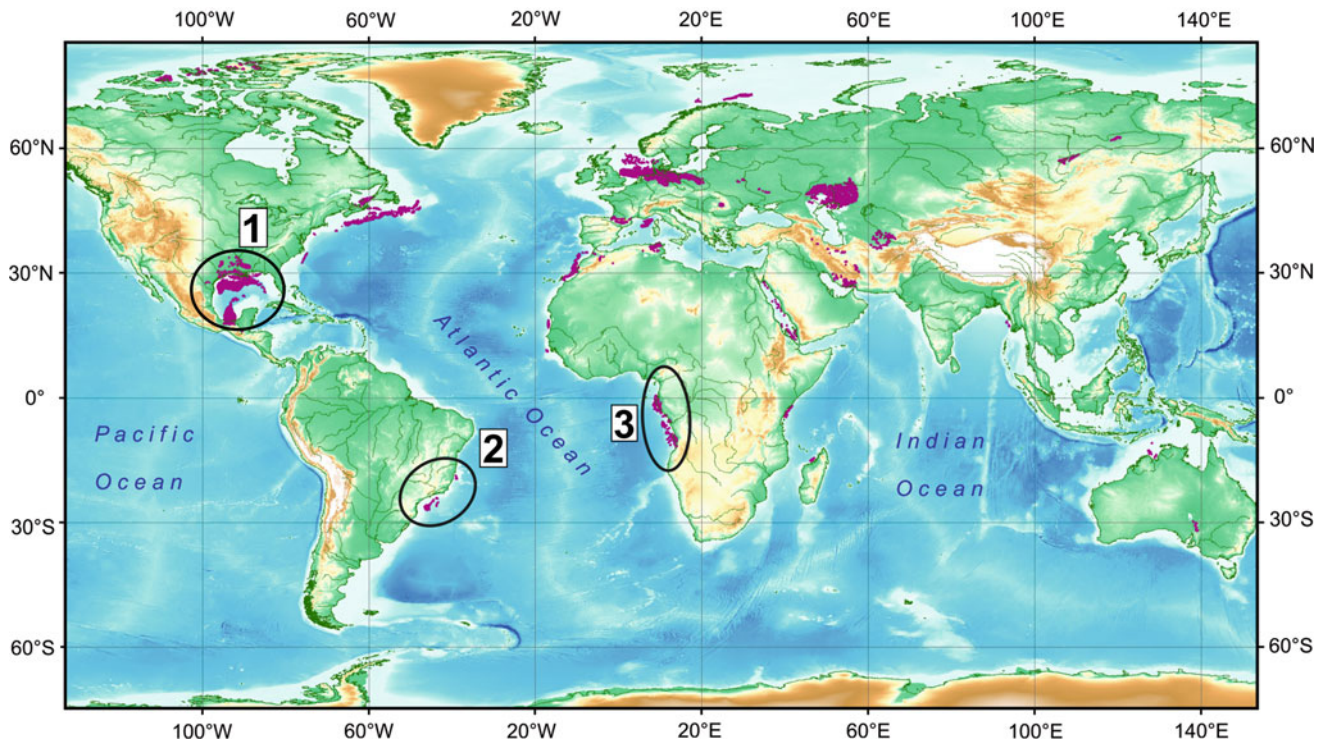
Historically the salt diapirs have for long been known in the northern German Plain, around the northern Caspian Sea, in western Iran, coastal areas of the Mediterranean Sea and the Red Sea, East Texas, Zagros, and many other areas on all continents except for Antarctica (Figure 1). In 1901, the Spindletop Dome discovery in Beaumont (Texas) revealed an important role of salt in formation of the hydrocarbon accumulations, which has later been confirmed by discovery of the world's largest hydrocarbon provinces in salt-bearing sedimentary basins (e.g., Gulf of Mexico, North Sea, Campos and Santos basins, Lower Congo Basin, Zagros Fold Belt). Since then the prime interest in salt tectonics comes from the petroleum industry.

Post-WWII expansion of petroleum exploration offshore and development of marine geophysical methods, especially multichannel seismic reflection technique, led to discovery of the salt diapirs on many continental margins of Atlantic and Indian oceans (Figure 1). In the recent times with the intensification of deep-water petroleum exploration the salt diapirs have been revealed at the water depth of 3000 m and greater.

As many deep-water salt-bearing basins have been proven to contain tremendous volumes of hydrocarbons, the structural styles produced by the salt tectonics are well studied and characterized. Among those, the Gulf of Mexico, Brazilian, and Angolan Atlantic continental margins (Figure 1) are the best explored and represent a unique natural laboratory for studying formation of the salt diapirs. Significant progress in imaging complex salt-related deformations has been achieved due to recent developments in the 3D multichannel seismic reflection method and in the seismic data processing with implementation of new migration algorithms such as reverse-time migrations (Leveille et al., 2011; Davison et al., 2013). A considerable effort has also been focused on development of various numerical (Poliakov et al., 1996; Chemia et al., 2007; Fuchs et al., 2011) and analog (Vendeville et al., 1995; Rowan and Vendeville, 2006; Fort and Brun, 2012; Warsitzka et al., 2013) models, which represent inexpensive and powerful tools for studying the salt tectonics in various structural and geodynamic settings.

Classification of salt diapirs

There are several ways to characterize the salt diapirs. The most common classifications are based on morphological characteristics of the features and on inferred mechanisms of their formation.

Jackson and Talbot (1991) characterized the salt diapirs as masses of salt that have flowed ductilely and appear to have discordantly pierced or intruded the overburden. Diapirs begin as anticlinal or domal uplifts and evolve into


Salt Diapirism in the Oceans and Continental Margins, Figure 1 Global occurrence of salt-bearing sedimentary basins. Salt diapirs are shown in magenta. Black ellipses outline three deep-water salt tectonics regions referred to in text: *1*, Gulf of Mexico; *2*, Brazilian Atlantic margin; *3*, West African Atlantic margin.

pillows, domes, and mushroom-shaped diapirs, columns, canopies, bulbs, tongues, walls, and more complex features (Figure 2).

Salt density can be higher or equivalent to the overburden density during commencement of salt deformation (Hudec et al., 2009), and in order for a salt diapir to be emplaced into its overburden any rock occupying that space must be removed or displaced (Hudec and Jackson, 2007). Vendeville and Jackson (1992) demonstrated that even when a stiff overburden buries a less dense rock salt, this may never lead to formation of a diapir unless the overburden is thinned and weakened by a tectonic extension. Therefore, the overburden has to be weakened by tectonic faulting until salt starts to rise up (Vendeville and Jackson, 1992; Jackson and Vendeville, 1994). This concept has been utilized by numerous analog models (Nalpas and Brun, 1993; Withjack and Callaway, 2000; Le Calvez and Vendeville, 2002) and successfully applied to natural structures interpreted on seismic lines (Seni and Jackson, 1983; Koyi et al., 1993).

Dynamically, the salt diapirs can be reactive, active, passive, or dormant (Yin and Groshong, 2006). Figure 3 illustrates different stages of the diapir formation. The diapirism can be triggered when the overburden rocks are subjected to extension, compression, uplift, and erosion (reactive diapirism). Very often salt rises in the footwalls of normal faults where the sedimentation rate remains low (Vendeville and Jackson, 1992; Quirk and

Pilcher, 2012). The faulted overburden lets a reactive diapir move up (Figure 3a). This gives way to an active diapirism (b). Once salt reaches the surface, it can continue to rise by passive diapirism (c), in which the diapir grows as sediments accumulate around it. A rapidly rising passive diapir may spread over the sediment surface to form an allochthonous salt sheet (d).

According to Koyi (1998), the salt diapir geometry may be the result of different combinations of six parameters, namely, the rates of sediment accumulation, rate of salt supply, and rates of extension/erosion/dissolution/shortening at different times.

Driving forces

The initiation of salt diapirs can be realized by several driving forces and/or their combinations including buoyancy, tectonic stresses, gravity-driven gliding or differential loading (Ge et al., 1997; Hudec and Jackson, 2007). The latter two are being discussed as primary forces causing salt movement at the continental margins (Brun and Fort, 2011, 2012; Rowan et al., 2012).

According to Brun and Fort (2011), available numerical and physical models of salt tectonics at the passive continental margins fall into two end-member categories: (i) dominant gravity gliding primarily driven by margin tilt and (ii) pure gravity spreading driven only by sedimentary loading (Figure 4).
Salt Diapirism in the Oceans and Continental Margins, Figure 2 Main types of salt structures that develop from linear sources (**a**) and point sources (**b**) (modified from Hudec and Jackson 2007).
Salt Diapirism in the Oceans and Continental Margins, Figure 3 Progressive development of a diapir from reactive to passive stage. *Black* represents the salt layer and *white-gray* layers sedimentary overburden (modified from Hudec and Jackson 2007).
Salt Diapirism in the Oceans and Continental Margins, Figure 4 Two models of salt tectonics: Dominant gliding (**a**) and pure spreading (**b**) (modified from Brun and Fort 2011).

Dominant gliding models: salt tectonics primarily driven by margin tilt

The dominant gliding concept that drives a two-layer salt-sediment system down an inclined basal surface has mostly been inspired by studies carried out on the South Atlantic Western African (Duval et al., 1992; Tari et al., 2003) and Brazilian (Cobbold and Szatmari, 1991; Demercian et al., 1993) continental margins and in the North Sea (Nalpas and Brun, 1993; Stewart and Coward, 1995). Different types of laboratory experiments (Cobbold and Szatmari, 1991; Mauduit et al., 1997; Fort et al., 2004; Brun and Mauduit, 2009) or numerical modelling (Ings et al., 2004; Albertz et al., 2010; Quirk et al., 2012) have been carried out to characterize the structures produced by this mechanism.

The dominant gliding model (Figure 3a) utilizes the updip extension represented by a broad rafted domain, which is balanced by the downdip contraction in the form of salt tongues, sheets, canopies, and the progressive inflation of a massive salt domain at the basinward edge of the salt basin. Downdip migration of extension and updip migration of contraction lead to a contractional inversion of previously extensional structures and produce the squeezed diapirs (Brun and Fort, 2011). The efficiency of this gravity sliding across the whole margin is due to the more or less uniform original distribution of salt in the postrift succession forming a continuous detachment level (Tari et al., 2003).

Pure spreading models: salt tectonics only driven by differential sedimentary loading

Apart from the buoyancy, basal slope, and tectonic forces, diapirism can also be driven by a pressure gradient caused by differential loading induced by thickness or density variation in the overburden (Ge et al., 1997; Gaullier and Vendeville, 2005; Vendeville, 2005; Hudec and Jackson, 2007). This concept rose from the Gulf of Mexico studies (Rowan, 1995), where the salt is very thick and sedimentation rates rather high. Different types of laboratory experiments (Ge et al., 1997; Gaullier and Vendeville, 2005; Vendeville, 2005; Krézsek et al., 2007) and numerical modeling (Cohen and Hardy, 1996; Gemmer et al., 2004; Ings et al., 2004; Ings and Shimeld, 2006; Gradmann et al., 2009) were carried out to characterize the salt tectonic systems driven by sedimentary wedge progradation on top of salt either covered or not covered by sediments at the distal oceanward flank of the basin.

The pure spreading models require (Brun and Fort, 2011): (a) thick sedimentary overburden and significant water depths (c. 4,000–4,500 m), (b) high sediment density, (c) high fluid pore pressure in the sediments, and (d) a seaward free boundary of the salt basin. In pure spreading, extension is located inside and contraction at the tip of the prograding sedimentary wedge (Figure 3b). Both extension and contraction migrate seaward with the sediment progradation. Migration of the deformation can create an extensional inversion of previously contractional structures (Brun and Fort, 2011).

The growth of an individual salt diapir is considered in many models and interpretations as a product of upbuilding due to the classical Rayleigh–Taylor instability (Schmeling, 1987). However, it has for long been clear that many salt diapirs formed already during sedimentation by downbuilding in a brittle overburden when the salt diapir top remains at the surface all the time during its formation (Barton, 1933; Parker and McDowell, 1955; Seni and Jackson, 1983; Vendeville and Jackson, 1992; Koyi, 1998).

SAPROPELS

Rüdiger Stein
Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research (AWI), Bremerhaven, Germany

The term "sapropel," originating from the Greek *sapros* (rotten) and *pelos* (soil) and already introduced by Potonié (1904) as international term for the German word *faulschlamm*, is used in marine geosciences to describe dark-colored, unconsolidated, fine-grained, and often laminated sediments that are enriched in organic carbon. Following the first more quantitative definition proposed by Kidd et al. (1978), the organic carbon content of common sapropels is greater than 2 wt%.

Sapropels seem to be a characteristic deposit in a variety of settings, including semi-isolated basins with restricted bottom circulation (e.g., Mediterranean Sea, Japan Sea, Santa Barbara Basin) and portions of continental margins that lie within the mid-water oxygen minimum zone and below upwelling zones. The late Pleistocene to Holocene Mediterranean sapropels, however, are probably the best studied ones. After the first recovery of these sapropels during the Swedish Deep-Sea Expedition in 1947 (Kullenberg, 1952), they have been sampled in numerous conventional gravity cores as well as drill cores (recovered during the Deep Sea Drilling Project – DSDP – and the Ocean Drilling Program – ODP) over the last decades, and several different hypotheses on their origin and significance have been published since then (e.g., Ryan and Cita, 1977; Rohling and Hilgen, 1991; Cramp and O'Sullivan, 1999; Emeis and Weissert, 2009). During ODP Expedition 160, a complete Pliocene to Holocene sequence containing more than 80 discrete sapropels was recovered in the Eastern Mediterranean (Emeis and Weissert, 2009), though the earliest reported occurrence is from the Middle Miocene (Kidd et al., 1978).

The strong correlation between sapropel formation and minima in the precession index, already recognized by Rossignol-Strick (1985), suggests an orbital forcing control. That means, an intensified summer monsoon may have resulted in increased freshwater/river discharge in the eastern Mediterranean. At that time periods, the freshening

(and warming) of surface waters enhanced stratification and inhibited or weakened deepwater formation and oxygen advection, and – finally – led to dysoxic to anoxic bottom waters that allowed the formation and preservation of sapropels (Rohling and Hilgen, 1991; Emeis and Weissert, 2009). In addition, increased river discharge may also have caused enhanced primary production due to river-borne nutrient supply as well as increased input of terrigenous organic matter, both positive feedback mechanisms for the formation of organic carbon rich sediments. For further detailed discussion of different hypotheses of sapropel formation, the reader is referred to the reviews by Rohling and Hilgen (1991) and Emeis and Weissert (2009).

SCLEROCHRONOLOGY

Christian Dullo
GEOMAR Helmholtz Centre for Ocean Research, Kiel, Germany

Sclerochronology is the record of different periodicities expressed as chemical and physical variations in mineralized endo- or exoskeletons of living, fossil, and even extinct aquatic organisms.

Sclerochronological periodicities are documented in growth increments of different shapes and sizes, depending on the time span they represent (Schöne and Surge, 2005). Such increments may portray days, lunar cycles, months, or years. Their individual width and pattern reflect either specific taxonomically related and therefore biologically controlled signals or environmental conditions in which the organism grew. These skeletal chronologies may comprise individual lifetimes of organisms ranging from several decades to several hundreds of years. Prominent organisms are scleractinian corals, calcified sponges, mollusk shells, or otoliths from fish. Along with the record of growth increments, the chemical composition of the mineralized skeleton based on elemental ratios such as Sr/Ca and Mg/Ca or the isotopic ratios of oxygen or carbon provides valuable information for the proxy-related reconstruction of paleoenvironmental, paleoecological, and paleoclimatological conditions as well as for the evaluation of pollution and global change. Since direct measurements of marine physical and chemical parameters are very limited in time, such sclerochronological data provide information both on the lifetime and history of the organism and on the dynamics of the environment for longtime series. This sclerochronological approach is the only way to study past climate dynamics on oceanographic and meteorological scales for several 100 years and to constrain and validate models for prediction. The term sclerochronology was first coined by Buddemeier et al. (1974) in order to present the growth bands of coral revealed by radiographic studies. Sclerochronological patterns are the aquatic equivalent to tree rings, known as dendrochronology from terrestrial settings. Like in dendrochronology, composed time series of skeletons of different ages enlarge the chronology further back in time, which is currently under development for mollusks.

SEA WALLS/REVETMENTS

Louise Wallendorf
Hydromechanics Laboratory, United States Naval Academy, Annapolis, MD, USA

Seawalls are vertical walls built to delineate the border between sea and land, in an area where the upland contains infrastructure that requires protection from storm surge and wave overtopping during an extreme storm event. Seawalls are often constructed in regions that have experienced high

erosion and have limited or no beachfront, unless with fore-sight they are embedded in a natural dune on a beach and only become exposed during an extreme storm; one of the most well-known seawalls is the Galveston Seawall constructed after the hurricane of 1900 and 1915 and chronicled in detail (Larson, 1999). Seawalls are typically constructed from concrete, with deep heavy foundations often tied to the backshore to prevent overturning of the structure and caps to prevent erosion of the backfill. Critical design parameters during extreme events are the crest elevation and the depth of the wall below the existing sea bottom. The wall structure needs to withstand the weight of the soil backfill and cap and the hydraulic forces on the front and back of the wall; a means of draining water from rainfall and flooding from behind the wall is necessary. In contrast, a bulkhead is a vertical wall constructed of timber and pilings or sheet pile and designed to retain soil at the shoreline without accounting for flooding; its strength is derived solely from the soil backfill. Seawall construction on a shoreline with existing beach is a controversial topic with the public, who feels they cause excessive beach erosion and/or changes in bottom topography which alter swimming and surfing wave conditions. A thorough investigation of the effects of seawalls on the beach (Krauss, 1988) provides recommendations for their use.

Revetments are sloped surface layers designed to protect the shoreline from erosion from waves and currents. They can be as simple as grass on packed clay, as is in river levees, or as more complex armored layers of rock or interlocking man-made elements on top of a soil slope. The revetment design evolved from dike construction in the Netherlands and is discussed in detail (Pilarczyk, 1990). Slopes are selected to prevent sliding of the soil and armor material, with protection at the toe to prevent undercutting. Heights are chosen to prevent flooding in the lee.

Geotextiles are used in the design of both revetments and seawalls to (a) stabilize an upland bank/bluff, (b) retain the soil behind the structure, and (c) protect the toe and prevent the erosion of soil back to the sea. Care needs to be taken at the transition areas at the ends of a revetment/seawall to prevent flanking erosion, defined as leakage of fill at the ends, or discontinuities in the shoreline erosion rates. A smooth vertical front face of a seawall is a perfect wave reflector. Curving or roughening the front surface helps attenuate some of the wave energy.

SEA-LEVEL

Reinhard Dietrich
Institute of Planetary Geodesy, Technical University of Dresden, Dresden, Germany

Definition

The surface which separates the global ocean and the atmosphere is called the sea surface. A measure of this boundary surface is called a sea-level measurement. There are several definitions for quantities related to sea-level (Figure 1). The distance between a reference ellipsoid and the instantaneous sea-level is called an instantaneous sea-surface height. The distance between the reference ellipsoid and a mean sea-level is called mean sea-surface height. The geoid can be defined as the equipotential surface of the Earth's gravity field which fits best to the global mean sea surface at a given epoch. The separation between geoid and mean sea surface is called mean sea-surface topography, whereas the distance from the geoid to the instantaneous sea-level is called absolute dynamic topography. The sea-level with respect to the solid Earth is called relative sea-level.

Observation of the sea-level

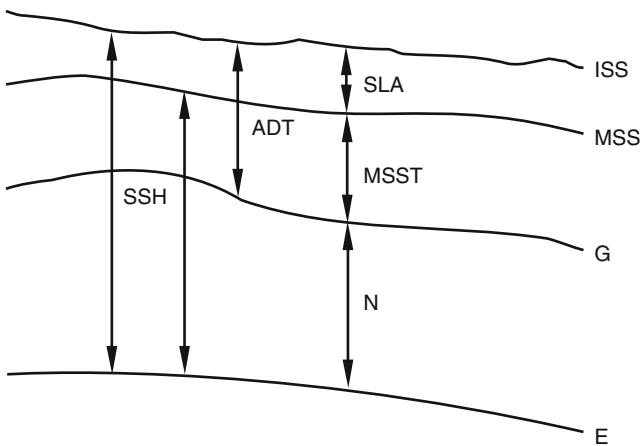
Geological records

There exist a variety of geological indications of former (relative) sea-level heights. For a good review, see Church et al. (2010). Techniques include the use of salt marsh data (e.g., Gehrels and Woodworth, 2013). Also corals can help to reconstruct sea-level curves at specific sites (e.g., Yokoyama et al., 2006). Deposits of marine shells or other species which are located above the present sea-level (Pluet and Pirazzoli, 1991; Weidick, 1996a) can provide limits on former sea levels heights. Also archeological sites below or above the present sea-level can be used to set constraints on historical sea-level heights (Weidick, 1996b; Antonioli et al., 2007; Lübke et al., 2011).

Instrumental period

The relative sea-level can be observed with tide gauges. Any changes of the sea-level are in this case related to the tide gauge benchmark. If a parallel set of measurements of the vertical movement of the tide gauge benchmark with respect to the ellipsoid is obtained, e.g., by GPS (Figure 2), relative sea-level changes can be converted into absolute sea-level changes with respect to the ellipsoid.

In the nineteenth century, the first recording tide gauges were developed which were installed especially in harbor sites for local navigation purposes (Figure 3).

For the open sea, there exist pressure gauges which are moored on the sea bottom (Figure 4). Here, the pressure caused by the water column above the gauge is recorded. Since the air column (air pressure) above the sea surface also affects the recorded pressure, it has to be known in


Sea-Level, Figure 1 Sea-level and related quantities (*E* ellipsoid, *G* geoid, *MSS* mean sea surface, *ISS* instantaneous sea surface, *SSH* sea-surface height, *N* geoid height, *ADT* absolute dynamic topography, *MSST* mean sea-surface topography, *SLA* sea-level anomaly).
Sea-Level, Figure 2 Observation of sea-level with tide gauge (*TG*, *B* tide gauge benchmark, *GPS* provides the ellipsoidal height h of B), bottom pressure gauge (*BPG*) and altimeter satellite S (the known ellipsoidal height h of S and the altimeter measurement a allow the determination of SSH).

Sea-Level, Figure 3 Tide gauge in a harbor site with GPS setup at a tripod (*left*).

order to reduce the obtained pressure record. In order to convert the (reduced) pressure into the height of the water column above the gauge, the density of the water column (i.e., its temperature and salinity) and the local acceleration due to gravity also have to be known.

For several decades now, the sea-level is also observed by satellite altimetry. In this case the travel time of a microwave or a laser pulse emitted by the satellite and reflected by the ocean surface back to the satellite is measured. With known satellite position with respect to the reference ellipsoid, the range measurement is used to calculate the instantaneous sea-surface height (see, e.g., Bosch et al., 2014).

The variability of sea-level in time and space

The sea-level is never on rest. There exists a variety of effects which cause an instantaneous change of the sea-surface height. On short time scales of seconds to minutes, there are waves (see "Waves"); on minutes to hours, there may be tsunamis (see "Tsunamis"), storm surges, and seiches; and from hours to days, there are the tides. Furthermore, a variation of air pressure will cause a change of the sea-surface height (inverse barometer effect – IB). If these short-term variations of the sea-surface height are averaged, one gets the mean sea-surface height.

The mean sea-surface height also changes on longer time scales. There are effects due to ocean dynamics (weeks to decades), thermal expansion (months and longer), the glacial eustacy (see "Eustasy") (months to

millennia) and glacial isostasy (see "Glacio(hydro)-isostatic Adjustment") (years to tens of millennia), and finally also tectonic processes that may be either fast (earthquakes) or slow (time scales of millennia to millions of years). For more details of many of these processes, see Pugh and Woodworth (2014).

Tides

One important component of sea-level variability concerns the ocean tides. The tides are caused by the gravitational forces of the moon and the sun. The tidal potential can be separated into semidiurnal, diurnal, and long-period tides (Figure 5). The tidal variations are not uniform around the globe. The distribution of land masses and the bathymetry of the ocean floor are the reason for large variations of tidal amplitudes and phases, with maximum amplitudes up to 8...10 m, e.g., in the Bay of Fundy and the Bristol Channel. Tidal currents play an important role in sediment dynamics (see "Sediment Dynamics").

Seiches

Seiches are oscillations of the sea-level in semi-enclosed basins, bays and harbors. The period depends on the size and the depth of the water body. In the Baltic Sea, for example, the largest periods have been determined to be 39.4, 22.5, 17.9, and 12.9 h (Lisitzin, 1974). Seiches are resonance phenomena, and therefore even a small forcing caused, for example, by sudden changes of wind conditions may result in large amplitudes.

Storm surges

Specific meteorological conditions, especially strong and rapidly changing wind fields in shallow water areas, play a key role in generating storm surges. Usually catastrophic floodings are the result of an overlay of wind-driven water mass changes with high tides and/or seiches (Figure 6).

Tsunamis

Tsunamis occur whenever large volumes of water are displaced and equilibrium is restored by the propagation of long waves across the ocean. The most devastating tsunamis are caused by undersea earthquakes with the resulting waves traveling across the ocean at the same speed as the tide, often impacting on distant shorelines. However, they can also originate from geological

Sea-Level, Figure 4 Bottom pressure gauge with mooring frame in operation.
Sea-Level, Figure 5 Spectrum of tides with semidiurnal (*right*), diurnal (*center*), and long-period (*left*) tides.
Sea-Level, Figure 6 Historical tide gauge record of a storm surge at the southern coast of the Baltic Sea in 1904/1905.

processes such as terrestrial and submarine landslides and volcanic eruptions and from asteroid impacts. They can also be caused by man-made explosions. Meteotsunamis are tsunami-like waves caused by abrupt changes in meteorological conditions that are amplified at the coast by local seiching (see also "Tsunamis").

Ocean dynamics

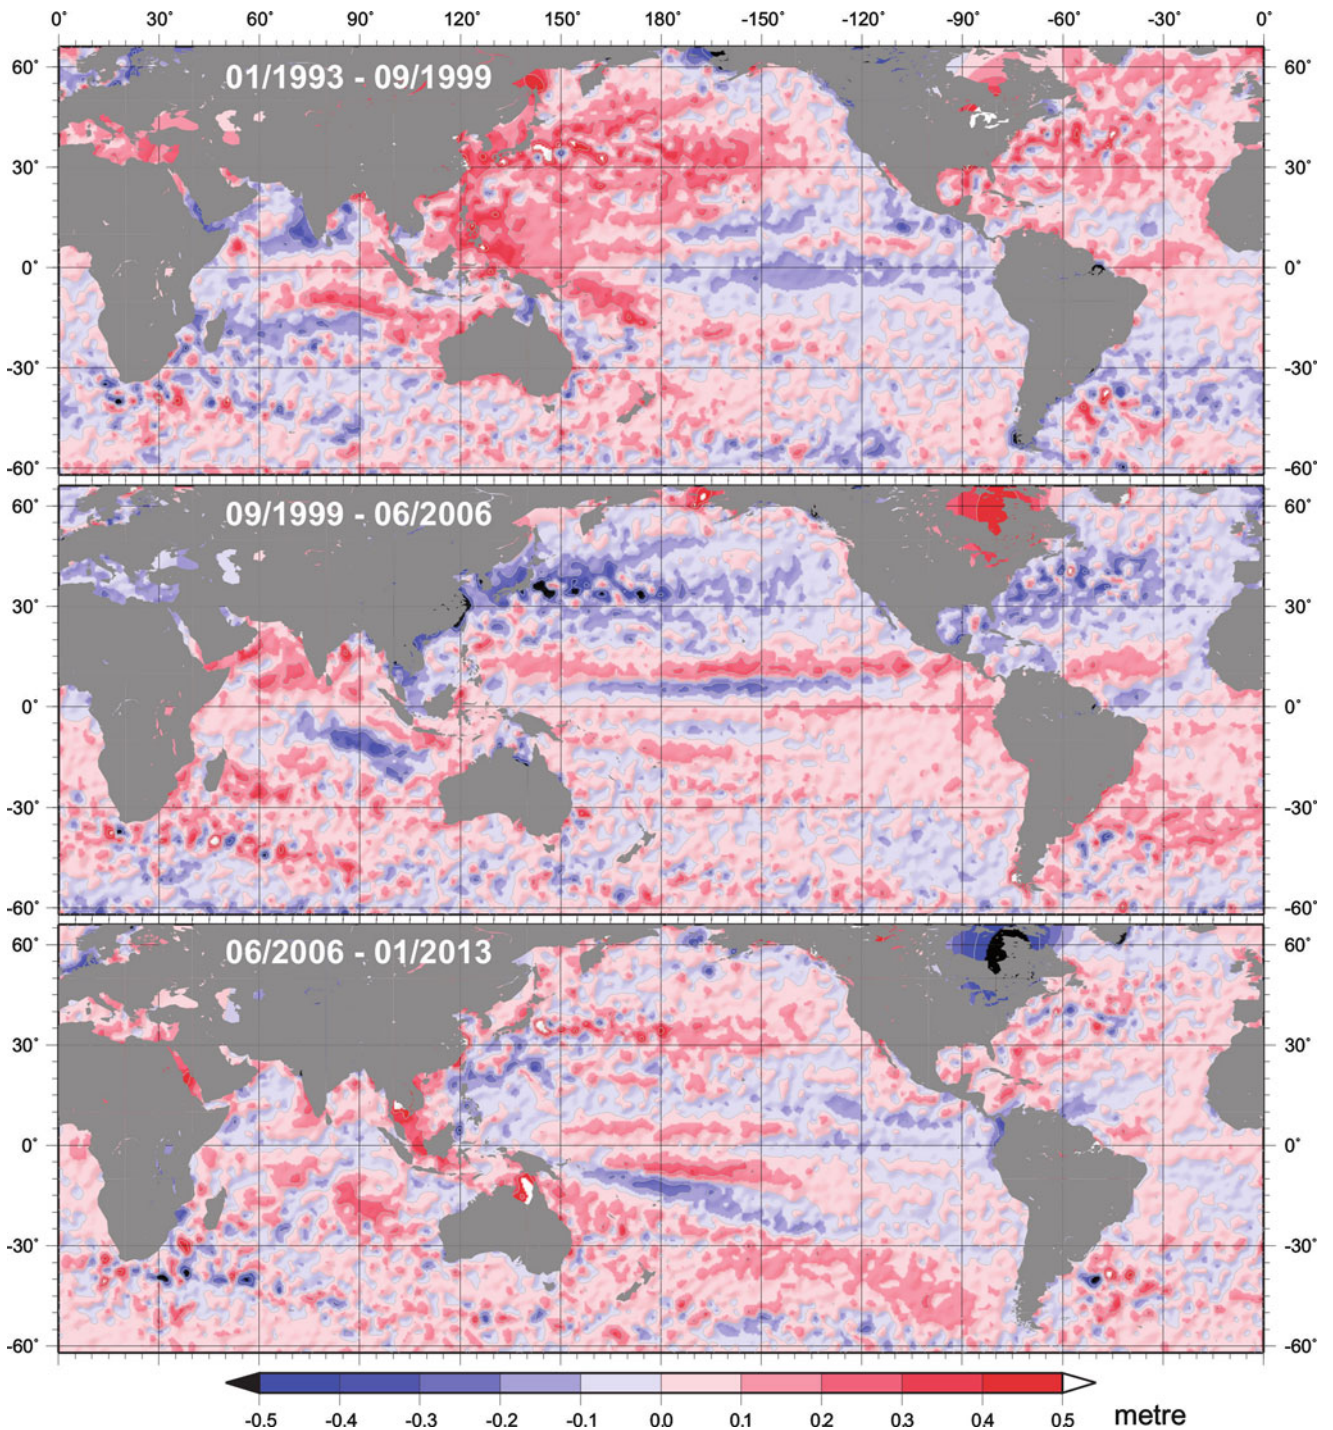
The deviation of the sea-level from the geoid (the dynamic topography) is a result of ocean dynamics. It can be obtained by oceanographic modeling or by subtracting a precise geoid from instantaneous sea-level heights observed by satellite altimetry (Bosch et al., 2012). The mean value of this deviation is in the order of 1–2 m. Specific spatial patterns (e.g., the Gulf Stream, the Kuroshio, or the Antarctic Circumpolar Current) are clearly visible. Furthermore, also phenomena with time scales of weeks to years like eddies or the El Niño Southern Oscillation (ENSO) may cause sea-level variations in the order of several decimeters (Figure 7).

Information on long-term trends, present-day sea-level rise, and future projections

For large time scales (millennia and more), there exists an excellent compilation on relative sea-level data from geological measurements (Pluet and Pirazzoli 1991). For the instrumental period, many data are collected by the Permanent Service for Mean Sea Level (PSMSL). Here tide gauge records with revised local reference (RLR) are especially valuable (Figure 8). RLR means that the observed sea-level is related to a fixed tide gauge benchmark. Sea-level changes observed with satellite altimetry within the last decades are summarized, e.g., by Bosch et al. (2014). Recent sea-level trends and projections up to the year 2100 are discussed in Church et al. (2010) and IPCC (2013).

Summary and conclusions

The sea-level is never on rest. Its dynamics affects many marine geoprocesses in time scales from seconds (waves) up to millennia (glacial isostasy). Of special socioeconomic importance are sudden events like storm surges and tsunamis as well as the observed present-day mean sea-level rise.

The observation of the sea-level on ground (tide gauges) and from space (altimetry) is of special importance for an improved understanding of all processes connected with the sea-level and for a more reliable prediction of its future changes.


Sea-Level, Figure 7 Regional sea-level change [m] for three equally long sections of the two-decade period from 01/1993 to 01/2013 as derived by satellite altimetry. Each panel exhibits different pattern with changes of up to ± (0.2–0.4) m. For 6.67 years this is more than 10 times the mean rate of global sea-level rise of some 3 mm/year (courtesy Wolfgang Bosch, München).

Definition

Seamounts are literally mountains rising from the seafloor. More specifically, they are "any geographically isolated topographic feature on the seafloor taller than 100 m, including ones whose summit regions may temporarily emerge above sea-level, but not including features that are located on continental shelves or that are part of other major landmasses" (Staudigel et al., 2010). The term "guyot" can be used for seamounts having a truncated cone shape with a flat summit produced by erosion at sea-level (Hess, 1946), development of carbonate reefs (e.g., Flood, 1999), or partial collapse due to caldera formation (e.g., Batiza et al., 1984). Seamounts <1,000 m tall are sometimes referred to as "knolls" (e.g., Hirano et al., 2008). "Petit spots" are a newly discovered subset of sea knolls confined to the bulge of subducting oceanic plates of oceanic plates seaward of deep-sea trenches (Hirano et al., 2006).

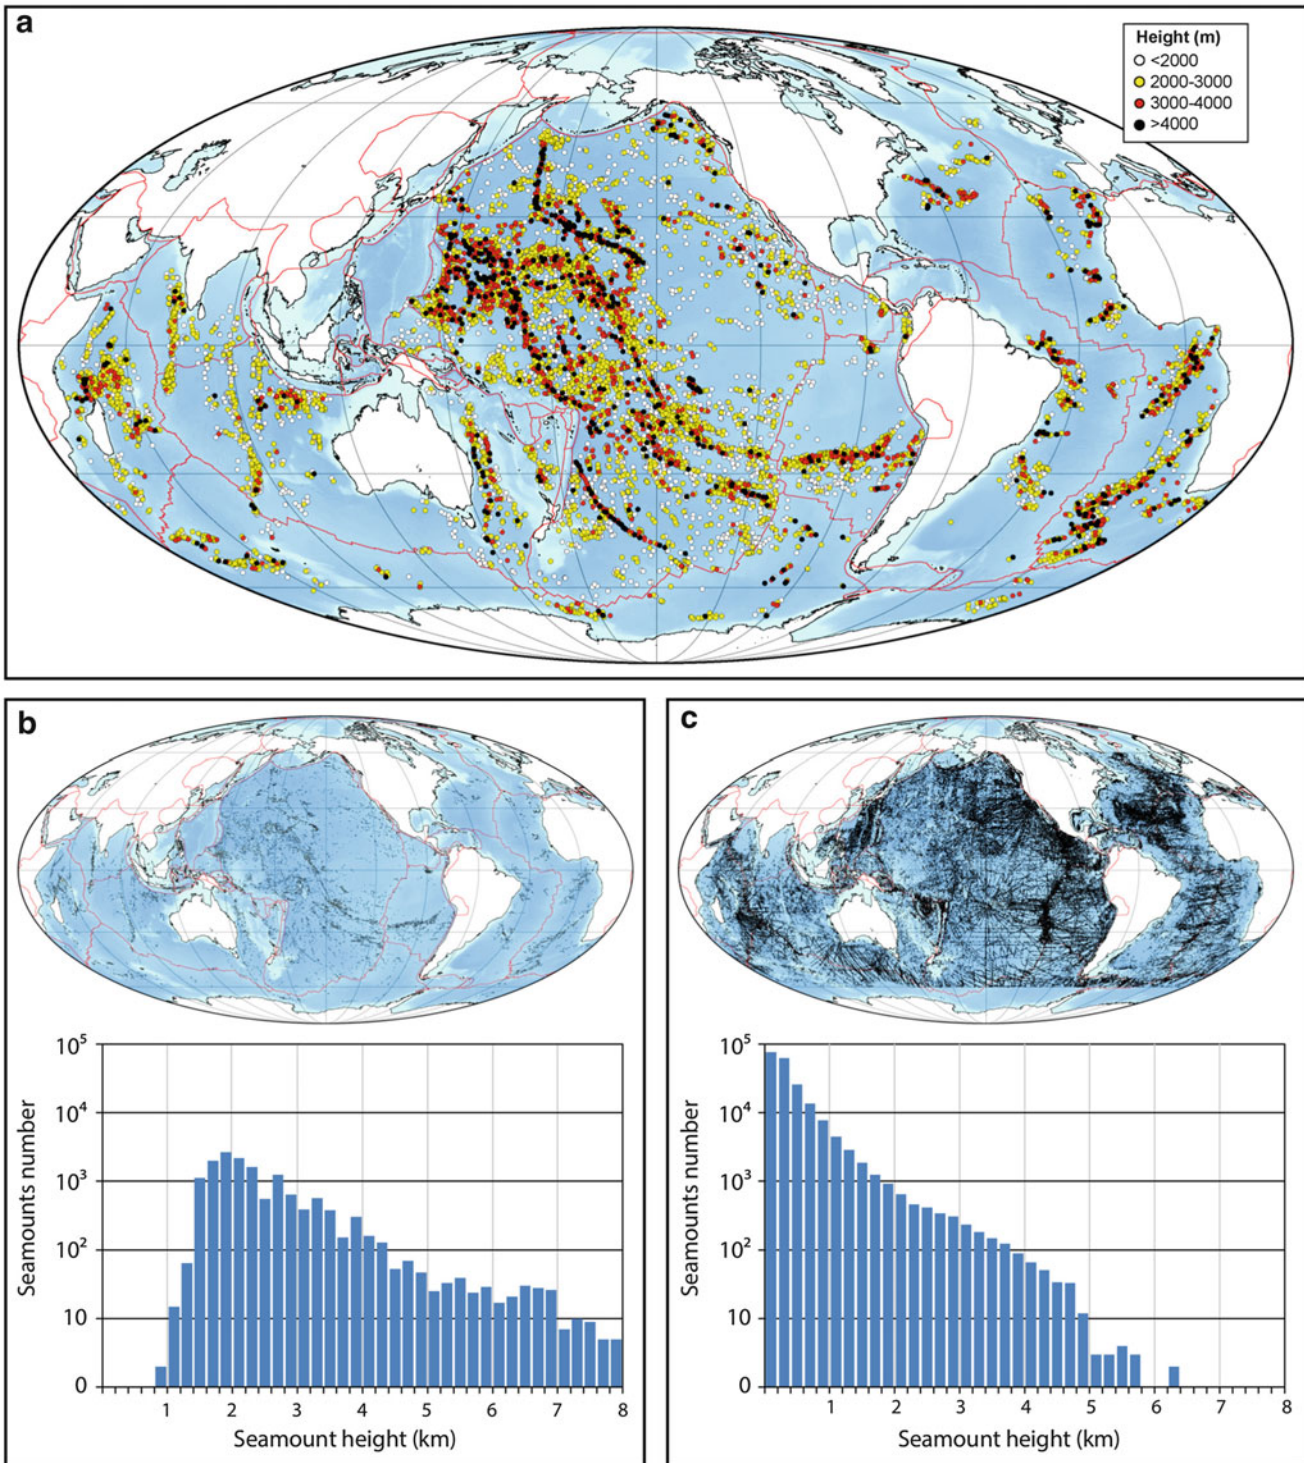
Charting, abundance, and distribution

Seamounts form one of the most common bathymetric features on the seafloor. Two techniques, both with advantages and disadvantages, have been used to chart them. The first technique is satellite altimetry that measures the height between a satellite and the instantaneous sea surface. This distance can be used after correction for oceanographic effects on the sea surface to derive the geoid undulation, which (with assumptions) can be used to derive gravity anomalies. These are then converted (with assumptions) to seafloor bathymetry (Wessel, 2001). This technique permits full coverage of the ocean floor in the $\pm 72°$ latitude range. However, oceanographic noise at the sea surface limits the identification of seamounts smaller than ~1.5 km in most areas of the ocean (Wessel et al., 2010). The second type of technique uses ship SONAR (e.g., multibeam echo-sounding systems) or towed/autonomous underwater vehicles (AUVs), allowing topographic mapping at high resolution of the ocean floor. This technique permits recognition of seamounts of virtually any size provided that they are not entirely covered by sediment. However, the spatial coverage of the multi-beam swath is restricted to a narrow stripe beneath the vehicle conducting the measurements, with the width of the stripe increasing with water depth between the vehicle and the seafloor. As a consequence, <10 % of the global seafloor has been charted using this method.

Size–frequency relationship of seamounts based on satellite and ship track data can be combined to estimate the total number of seamounts (Hillier and Watts, 2007). It is therefore speculated that there are 3–80 million seamounts greater than 100 m in height on the seafloor. The total number and global distribution of smaller seamounts, however, remains poorly constrained due to relatively limited coverage of the seafloor by echo sounding. Around 90 % of the seamounts, a fraction primarily including the smallest, <100 m-tall edifices, remain to be charted (Wessel et al., 2010). Only a very limited number of seamounts are currently included in open-source databases like the Seamount Catalog (http://earthref.org/SC/) or the General Bathymetric Chart of the Oceans (GEBCO, http://www.gebco.net/). There could be more than 50,000 seamounts taller than 1 km, representing only a minor fraction of the total seamount number (Figure 1). Many of these larger seamounts are distributed along clusters or lines that can reach several thousands of kilometers in length (e.g., the Hawaiian–Emperor seamount chain in the NW Pacific). These seamount/island chains provide important insights into plate motions, the formation of oceanic intraplate volcanoes, and the dynamics of the oceanic lithosphere and underlying mantle.

Origins

Most seamounts are formed by igneous activity close to mid-ocean ridges, island arcs, or in mid-plate settings (Koppers and Watts, 2010). Due to percolation of fluid-rich material through the upper plate, small mud or serpentine seamounts (volcanoes) can form between the volcanic arc and trench in intra-oceanic subduction zones (Kopf, 2002). Blocks of continental crust, stranded during the opening of ocean basins, can form nonvolcanic seamounts (e.g., Stuttgart seamount around 1,000 km east of New Zealand, Mortimer et al., 2006).

Seamounts of igneous origin formed at mid-ocean ridges are called *on-axis* seamounts. Those formed within a few hundreds of kilometers of mid-ocean ridges on relatively young lithosphere, but not directly at the ridge axis, are commonly referred to as *near-ridge* or *off-axis* seamounts. Estimates suggest that more than 50 % of seamounts are emplaced on oceanic crust younger than 20 Ma (Hillier, 2007), and, thus, on-/near-/off-axis seamounts probably compose the largest part of the seamount population. Even large seamount provinces, such as the Christmas Island seamount province in the northeast Indian Ocean (e.g., Hoernle et al., 2011) or the earlier Mid-Pacific Mountains in the central western Pacific Ocean (e.g., Hillier, 2007), are believed to have been formed in a near spreading center environment. Their emplacement is intrinsically related to upwelling beneath spreading centers and the formation of the oceanic crust (entries "Lithosphere: Structure and Composition" and "Mid-ocean Ridge Magmatism and Volcanism").


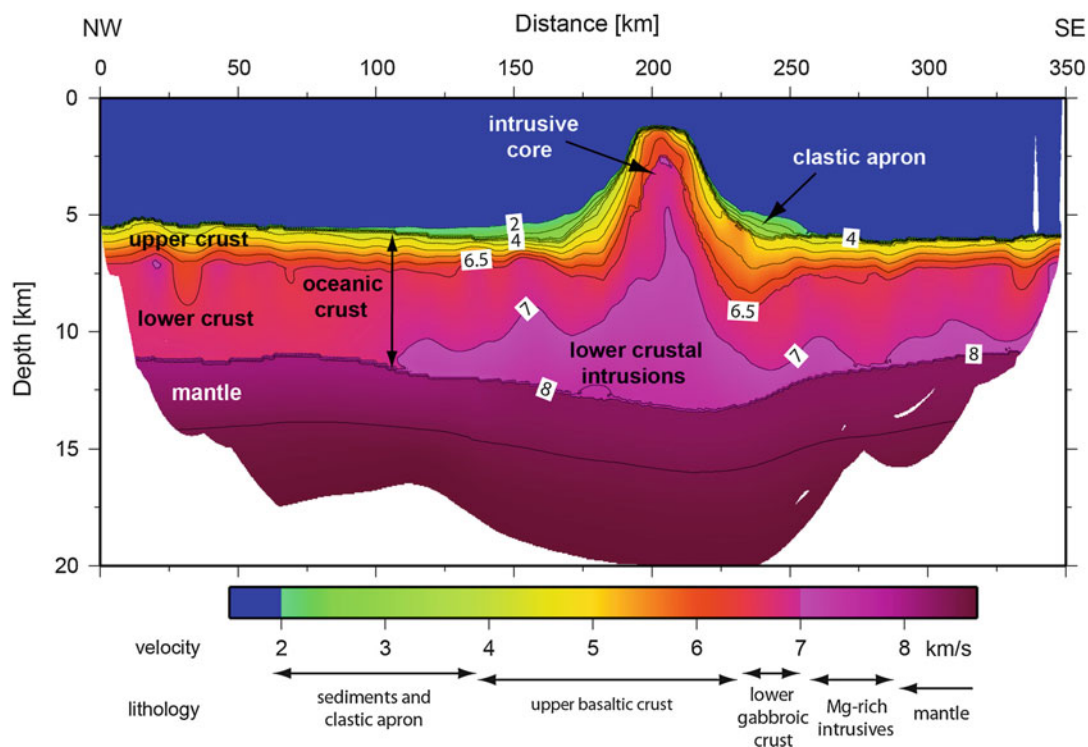
Seamounts, Figure 1 Global distribution of seamounts. (**a–b**) Large seamounts identified by satellite altimetry in the $\pm72°$ latitude range (n = 14'675) (Wessel, 2001). It should be noted that island volcanoes have also been included in as "seamounts," extending to heights >8 km. (**c**) Seamounts identified by ship echo sounding over an area representing <10 % of the total ocean floor surface (n = 201'055) (Hillier and Watts, 2007). This histogram illustrates that the largest number of seamounts has sizes that cannot be detected with satellite altimetry. Only submarine seamounts are included, explaining why there are no seamounts with elevations of >6.5 km.

Seamounts formed in mid-plate settings are called "oceanic intraplate volcanoes." Intraplate volcanoes that are formed near spreading centers, i.e., on young and thus thin lithosphere, consist primarily of tholeiitic magmas (e.g., Niu et al., 2002). Most intraplate seamounts, however, are emplaced on older and therefore thicker lithosphere. These volcanoes comprise abundant alkaline igneous rocks that result from lower degrees of partial melting at greater depth compared to the production of tholeiitic volcanism (entry "Intraplate Magmatism"). The formation of intraplate seamounts can be due to local melting anomalies or "hotspots" that underlie the lithosphere (entry "Hot Spots and Mantle Plumes"), plate cracking allowing preexisting melt in the upper mantle to rise to the surface (e.g., Natland and Winterer, 2005; Valentine and Hirano, 2010), or localized mantle upwelling in the shallow asthenosphere (e.g., Geldmacher et al., 2008). Hotspot volcanism is commonly associated with the presence of mantle plumes that bring hot, and thus buoyant, fertile mantle from a thermal boundary layer, such as the core–mantle or upper–lower mantle boundary, to the base of the lithosphere where the mantle melts. As the lithosphere moves over the plume, volcanism forms an age-progressive island/seamount chain (Morgan, 1972). The most prominent and thus well-known example of hotspot/plume volcanism is the Hawaiian–Emperor island/seamount chain, where seamounts become progressively older with increasing distance from the active volcanoes forming the Hawaiian Islands (Clague and Dalrymple, 1987). Seamounts can also form along cracks resulting from stress in the oceanic lithosphere, e.g., as a result of plate cooling, plate bending outboard of subduction zones, collision of continental blocks, or abrupt changes in plate motions (Natland and Winterer, 2005; Valentine and Hirano, 2010). Petit-spot volcanoes near Japan and Pliocene volcanism on Christmas Island near Indonesia, for example, formed outboard of subduction zones due to plate bending (Hirano et al., 2006; Hoernle et al., 2011). Plate cracking formed by extension can not only facilitate the rise of melts through the lithosphere but also can trigger asthenospheric upwelling causing decompression melting (O'Connor et al. 2015). Because seamounts are generally formed by lower degrees of partial melting and over a larger range of melting than normal mid-ocean ridge basalts (MORB), their igneous rocks exihibit a much larger spectrum of chemical compositions than MORB, since they preferentially sample fertile anomalies in the asthenospheric mantle (e.g., Niu et al. 2002; Hoernle et al. 2011). Seamount volcanism has played an important role in our understanding of mantle dynamics, chemical heterogeneity of the mantle, and magmatism in general (entries "Intraplate Magmatism" and "Hot Spots and Mantle Plumes").

Formation and evolution

Seamounts are formed by eruptive and intrusive products with an estimated ratio of approximately 70:30 (Staudigel and Clague, 2010; Flinders et al., 2013). Eruptive products broadly include pillow lavas that reflect low to medium effusive rates in submarine environments, massive sheet flows formed at higher effusive rates, and volcaniclastics formed through disaggregation of pillows or sheet flows on steep slopes or through explosive volcanism. Intrusive products generally consist of dikes, sills, and gabbroic to ultramafic rocks. The growth of a seamount is controlled by successive stacking of eruptive products and inflation due to emplacement of intrusives. Explosive volcanism occurs when the magma interacts explosively with water or when the magma rapidly outgasses in response to a decrease of pressure. Degassing of CO_2 can occur at great pressure and can lead to explosive volcanism in the deepest parts of the ocean. Overall, the style of submarine eruptions reflects variation in the composition, physical properties, and supply rate of magma, as well as the tectonic setting of formation of the volcanic edifice (Rubin et al., 2012). Volcanoes several kilometers tall can form over hundreds of thousands of years (Clague and Dalrymple, 1987), whereas smaller seamounts may form in days to months.

Large seamounts follow a particular pattern of evolution primarily controlled by the relative intensity of magma supply and erosional processes through time. This pattern of evolution can be subdivided into six main phases (Staudigel and Clague, 2010):

1. A small seamount forms during incipient volcanism after a possible phase of magma interaction with seafloor sediments. The magmatic plumbing system of the volcano is restricted within the oceanic crust. Commonly, the magma supply wanes quickly and the seamount remains small.
2. More rarely, the seamount will experience continued or increased volcanic activity that results in formation of a much larger volcano. The magmatic plumbing system migrates upward within the volcanic structure.
3. When the summit of the seamount approaches sea-level, explosive volcanism becomes more abundant. The amount of clastic deposits emplaced on the volcano slopes increases. The seamount emerges and forms an island when the eruption rate is high enough to overcome erosion by sea-surface waves, mass wasting, eustatic changes, and subsidence due to isostatic adjustment of the lithosphere under the fast-growing seamount.
4. The seamount goes through a subaerial, island phase with continued volcanism. Incipient carbonate reefs can develop along the shorelines.
5. The main magmatic phase ceases and the island volcano stops growing and starts to erode. Slope failure can lead to removal of major parts of the volcanic edifice with the potential for tsunami formation; such events may occur throughout the evolution of the seamount (Masson et al., 2006). The volcano can go through a period of quiescence for several million years until small volumes of lava are erupted during short periods of volcanic rejuvenation. Continued erosion eventually leads to formation of a flat-topped to


Seamounts, Figure 2 Seismic velocity structure of the Louisville seamount chain (data from Contreras-Reyes et al., 2010).

slightly dome-shaped (if subsidence occurs during erosion) seamount with a plateau just beneath wave base. As the volcano is cut off, i.e., moved away, from its heat/magma source, lithospheric cooling leads to subsidence of the "guyot" seamount to depths up to thousands of meters below sea-level. Under appropriate environmental conditions, carbonate reefs can develop on top of the volcano and form an atoll, while the top is still in shallow water. The atoll becomes submerged when the growth of the reef can no longer compensate for seamount subsidence and/or sea-level rise. The location at which an atoll drowns is sometimes referred to as the "Darwin Point" (e.g., Flood, 2001).

6. Most seamounts are ultimately transported to subduction zones, where flexure of the downgoing plate and the formation of bending-related faults can cause partial collapse of the volcanic edifice. During subduction, the seamount and related collapse products can be accreted (transferred to) and preserved in the accretionary wedge of a subduction zone (Hoernle et al., 2002; Portnyagin et al., 2008; Buchs et al., 2011). If not accreted, seamounts can contribute to the petrogenesis of arc magmas (e.g., in Central America, Hoernle et al., 2008).

Architecture and structure

Crustal structure derived from seismic surveys reveals insights into the melt generation and the internal architecture of volcanic seamounts. The architecture of a seamount can be revealed using a structural comparison between an intraplate seamount and normal oceanic crust, using the correlation between P-wave velocity structure of seamounts and typical oceanic crust. Since non-explosive extrusive processes prevail during the deepwater stage, dominantly producing pillow basalts (~75 %) (Staudigel and Clague, 2010), the seismic velocity structure of small seamounts of <1,000 m roughly mimic thickened oceanic crust. However, tall edifices show average P-wave velocities, which are significantly lower than those generally found in oceanic crust. The low velocities found in the uppermost crust beneath the summits and the clastic aprons of tall seamounts (Figure 2) are indicative of low densities and high porosities, consistent with shoaling sequences composed dominantly (~70 %) of clastic deposits (Staudigel and Clague, 2010). Accumulation of large volumes of clastic material in the summit region and upper flanks of a seamount volcano can generate debris flows that contribute to the clastic apron around the volcano and can extend into the abyssal plains beyond the apron. Some of the individual debris avalanches are 100–200 km long and 100–500 km^3 in volume (e.g., Watts and Masson, 1995). Apron sediments may extend out to several hundreds of kilometers from a seamount or ocean island (e.g., Wolfe et al., 1994). On the summit and flanks, clastic sediments and rocks show low seismic velocities of 2.8–3.2 km/s (Weigel and Grevemeyer, 1999; Contreras-Reyes et al., 2010), but can also reach

velocities of 4.0–5.0 km/s in the deep portions of the moat around the volcano (Wolfe et al., 1994; Weigel and Grevemeyer, 1999).

Below the summit, the transition to rocks with velocities of >6.5 km/s occurs generally at 2–4-km depth (Weigel and Grevemeyer, 1999; Contreras-Reyes et al., 2010), indicating the presence of gabbroic rocks and hence a central conduit or a plutonic suite (Figure 2). Seismic velocities exceeding 7.0–7.2 km/s in the lower crust beneath seamounts suggest that significant proportions of magma feeding seamounts are trapped, i.e., intruded, near the base of the crust (White and McKenzie, 1989; Holbrook, 1995). The high-magnesium basalts generated from abnormally hot mantle typically exhibit high densities and hence velocities when they crystallize (White and McKenzie, 1989; Keleman and Holbrook, 1995). The base of the crust forms a marked density contrast, so it is likely that melts generated at depth will accumulate near the base of the crust, where they either underplate the crust or intrude it as sills. High-velocity, lower-crustal rocks are an integral part of large seamounts, including the Hawaiian chain (Watts et al., 1985), Ninetyeast Ridge (Grevemeyer et al., 2001), and Louisville seamounts (Contreras-Reyes et al., 2010).

Implications for topographic anomalies on the seafloor

The morphology of seamounts in the oceans controls several processes of global significance.

Seamounts play an important role in influencing local and global oceanic currents by redistributing the energy from surface tides, blocking water flow and creating eddies, and generating hydrothermally induced plumes in the water column (Lavelle and Mohn, 2010). For example, it was suggested that the New England Seamount chain in the Northern Atlantic can induce gyres with a stabilizing effect on the dynamics of the Gulf Stream (Ezer, 1994).

Large subducting seamounts can substantially modify the geometry of the plate interface at convergent margins, causing indentations in margins. They can locally "jam" subduction zones, trigger earthquakes or modify regional patterns of seismicity (Watts et al., 2010). They may also influence the patterns of fluid release in the subduction zone by creating preferential circulation paths within the deforming upper plate.

Seamounts represent areas of the ocean floor where the volcanic basement outcrops above the relatively impermeable layer of pelagic sediments on the seafloor. They therefore serve as preferential areas of recharge and discharge for hydrothermal fluids and permit extended exchange of heat and solutes between the ocean and the igneous crust (Fisher and Wheat, 2010; entry "Hydrothermalism").

Seamounts host a large variety of mineral deposits, including hydrogenous ferromanganese crusts (Fe–Mn crusts) or nodules, hydrothermal iron and manganese oxides, hydrothermal sulfide, sulfate and sulfur deposits, and phosphorite deposits (Hein et al., 2010). Formation of these mineral deposits is related to hydrothermal, diagenetic, or precipitation processes that take advantage of magmatic heat. As the supply of some critical metals on land becomes more challenging (mining moves to greater depths and/or to more remote locations) or inaccessible for political or environmental reasons, these resources become more expensive, and new techniques to explore and mine the seafloor are currently being developed. The exploitation of mineral resources at seamounts will no doubt become economically advantageous at some stage in the future (entry "Marine Mineral Resources").

Volcanic islands and atolls constitute particular habitats that can remain isolated from major landmasses for tens of millions of years. This isolation fosters development of endemic taxa, which stimulated the postulation of the theory of natural selection in the nineteenth century. Similarly, seamounts (or submerged parts of oceanic islands) form barriers for ocean currents, causing upwelling of deeper nutrient-laden waters that supply sustenance for a wide range of marine organisms. Larger fauna, e.g., fish, feeds on the smaller organisms, and thus seamounts serve as oases for life in the ocean (entry "Deep Biosphere"; Clark et al., 2010). Interestingly, the location of seamounts can often be inferred from the presence of large numbers of seabirds feeding off fish above the seamount. Understanding the exact nature of biodiversity and fauna connectivity on seamounts, however, is still limited due to spatially and temporally restricted sampling. Fishing and trawling has caused substantial damage to some seamount habitats, and monitoring is needed to permit sustainable development of anthropogenic activities at seamounts.

Lithospheric flexure beneath seamounts

Seamounts define loads that deform the oceanic lithosphere on which they sit. It has been shown that seamounts emplaced on young oceanic crust are characterized by local Airy-type isostasy (Watts, 2001), similar to icebergs floating in the ocean. With increasing age, however, the oceanic lithosphere becomes stronger, and rather than forming a local rootlike structure, it deforms elastically by flexure, like an elastic plate. The Dutch geophysicist and geodesist Felix Vening Meinesz introduced the effective elastic thickness (Te), to describe the deformation of the lithosphere. Thus, loads emplaced on older lithosphere are compensated regionally (see Figure 2), causing prominent flexural moats and bulges along major seamounts chains, like the Hawaiian–Emperor seamounts (Watts, 1978). Oceanic settings provide Te values ranging from zero (Airy-type isostasy) to 40 km. Since the oceanic crust is approximately 6 km thick, it is clear that not only the crust but also the lithospheric mantle is involved in supporting the load of seamounts (Watts, 2001).

Seamounts and true polar wander

Paleomagnetic data from seamounts support a mobile Earth and hence plate tectonics. Assuming that the Earth's magnetic field is aligned with the spin axis, paleomagnetic data from volcanic and sedimentary rocks allow the reconstruction of the location of the magnetic pole. In the past 5 Myr, the geomagnetic field was axial geocentric dipolar within confidence limits of ~3° (Merrill and McElhinny, 1983). However, in older geological time intervals, the geomagnetic pole from a given region seems to move away from the spin axis (Creer et al., 1954) and is called apparent polar wander (APW). APW paths are composed of two components: plate motion and polar wander. Polar wander is the shift of the entire Earth with respect to the rotation axis. On an Earth where plates are constantly moving, it is difficult to define a reference frame. Therefore, true polar wander (TPW) has been introduced as a definition of polar wander, where paleomagnetic poles are viewed in a fixed hotspot reference frame (e.g., Besse and Courtillot, 1991). However, measurement of the paleomagnetism of samples from the Hawaiian–Emperor seamount chain, i.e., volcanic track formed above the Hawaiian hotspot, provided evidence for a significant southward motion of the Hawaiian mantle plume from 81 to 47 Myr ago. This motion was a dominant factor causing the trend and morphology of the Hawaiian–Emperor chain and the famous bend, i.e., change in orientation, of the Hawaiian hotspot at ~47 Ma (Tarduno et al., 2003; O'Connor et al., 2015). Tarduno (2007) concluded that "an important corollary of this finding is that true polar wander (i.e., polar wander calculated in a fixed hotspot reference frame) is illusory; the solid Earth has been relatively stable with respect to the spin axis for at least the past 130 million years. The paleomagnetic data from the Hawaiian–Emperor tracks, and other oceanic sites, indicate that the geometry of hotspot tracks contains a rich history of both mantle flow and plate processes."

Summary and conclusions

Millions of seamounts on the seafloor have a large, multidisciplinary significance. Seamounts can provide constraints on the tectonic evolution of the seafloor and serve as a window into mantle compositional heterogeneity and dynamics. They can cause significant hazards for coastal populations by triggering earthquakes during subduction or tsunamis during major flank collapse. Seamounts can host extensive hydrothermal activity and mineral resources of increasing significance to a planet with an exploding population growth. They are morphologic oases in the deep sea serving as stepping stones for marine biota. Clearly, there is a strong need for additional seamount research, and it is expected that forthcoming decades will see significant advances in our understanding of one of the most common but least studied features on Earth.

Sedimentary processes

Definition

Sediment dynamics refers to the motion of sediment particles during their formation, transport, and settling processes.

Introduction

Sediment dynamics is an interdisciplinary research field integrating the knowledge of physical oceanography, geology, biology, and chemistry. Since centuries ago, it has been a subject of study for geologists and engineers. Many different theories and formulas have been developed to describe the motion of sediment particles during their formation, transport, and settling. Some of the approaches have been applied widely to solve engineering and environmental problems, and some still remain on a theoretical level. Since most of the existing formulas describing sediment dynamics are derived empirically, results obtained from different approaches often differ drastically from each other even though they are based on the same initial conditions (Yang, 1996). Gaps are always shown between theoretical results and field observations. The difficulty in matching theoretical results to sediment dynamics is due to the vulnerability of sediment particle mobility to many environmental factors and processes occurring at different temporal and spatial scales. Although the history of study on sediment dynamics is long, some of the basic concepts, driving mechanisms, and interrelationships among them have become clear to scientists only in recent decades. The complexity of sediment dynamics makes it among the most complicated and least understood subjects in earth sciences.

Rather than gaining more insight into the complexity of sediment dynamics, this entry aims at providing a summary of the most basic concepts and driving mechanisms involved in the motion of sediment particles in coastal and marine environment.

Origin of sediment

Any solid fragment of organic or inorganic material can be termed sediment. Marine sediments originate from a variety of sources. The origin of a sediment particle determines its dynamics to a large extent. According to the ways a sediment particle is formed, sediments can be classified into two broad categories: granular sediments and chemical sediments. Granular sediments result from the fragmentation of inorganic or organic materials. Fragmentation of the parent material may be caused by mechanical

(e.g., weathering and erosion of rocks), biological (e.g., shell secretion and cell wall mineralization), or volcanic processes (ejection). According to these production processes, granular sediments can be further categorized into three major groups: lithogenic, biogenic, and volcanogenic sediments. Chemical sediments are formed from chemical reactions of dissolved compounds in seawater. They include the precipitation of minerals in seawater (e.g., manganese and phosphorus nodules), evaporites (salts), metalliferous compounds produced by hydrothermal vents, as well as fragments of limestone and limestone-like rocks (e.g., chert, chalk, and dolomite) that come from compacted, buried, and mineralized remains of marine organisms. Chemical sediments are also called authigenic or hydrogenic sediments.

Sediments can also be classified by particle grain size. The three major categories are gravel (>2 mm), sand ($0.063–2$ mm) and mud (<0.063 mm). They can be further classified into subgroups according to a refinement of the grain-size distribution. Gravel, sand, and silt (a subgroup of mud with diameter > 0.002 mm) are granular sediments originating mainly from weathering or erosion of rocks. Their dynamics can be studied by tracing the motions of individual particles driven by external forces. This marks their basic distinction from another subgroup of mud, i.e., clay that refers to the finest-grained sediments with diameter <0.002 mm and characterized by cohesion. Clay includes many combinations of one or more clay minerals with traces of metal oxides and organic matter. It can be produced by chemical weathering of rocks, biogenic processes, and chemical reactions of dissolved compounds in seawater. The cohesive force inherent in clay sediment enables the formation of bonds between particles and eventually leads to aggregation of tens of thousands of fine particles. Due to the cohesive force between particles, dynamics of clay sediments is quite different from that of non-cohesive sediments. As in natural environments, clay is normally mixed with silt; thus, they are both considered as cohesive sediment in engineering practice, despite the fact that the cohesive properties of silt are primarily due to the existence of clay. Gravel and sand sediments are termed non-cohesive sediments.

Sediment transport

Transport of sediments is triggered mainly by currents in marine environment, by waves in the near shore and by wind in subaerial coastal environment. When the near-bed fluid velocity increases to a certain level, some sediment particles start to move intermittently by sliding and rolling along the seabed. With a further increase of fluid velocity, more sediment particles are involved in migration and the bed form tends to become uneven due to different movement speeds and actions of different-sized particles, forming small perturbations on the seabed. These perturbations increase the roughness of the bed and induce an enhanced fluid friction, which further enrolls more sediment particles into the movement as a

sediment particles goes through two processes. Initially the freshly deposited sediments form a loose layer called fluffy layer with a thickness of several centimeters or even develop a fluid mud with a thickness of some tens of centimeters, depending on the total amount of sediment that settled within a certain time interval. In the latter case, the entire suspended sediment layer may act as a non-Newtonian fluid (Williams and Williams, 1989). If these sediments are undisturbed, they will gradually consolidate by a depletion of the interstitial water. Primary consolidation is caused by the self-weight of sediment, as well as the deposition of additional materials. It normally has a period of one or two days. Secondary consolidation is caused by the plastic deformation of the bed under a constant overburden. It begins during the primary consolidation and may last for weeks or months (Yang, 2006).

Once the fluid velocity increases above a certain level, sediment particles resting on the seabed surface come into recycling again. The most widely used semiempirical criteria to determine the thresholds for sediment motion are Shields (Shields, 1936) and Hjulström-Sundborg (Hjulström, 1939; Sundborg, 1956) diagrams. The threshold of fluid velocity for erosion of a sediment particle is normally larger than that for deposition. The difference between the relevant threshold velocities can play an important role in the landward transport of sediments through two processes called settling and scour lag (e.g., Postma, 1954). Non-cohesive sediments require larger threshold velocity for erosion than cohesive sediments that are resting loosely on the seabed surface. However, the threshold velocity for erosion of cohesive sediments increases drastically when they are consolidated. Macroflocs are likely to break into micro-flocs once they are resuspended by strong shear stress. A mixture of different-sized sediments on the seabed may increase the threshold velocity for erosion (Wilcock and Crowe, 2003). This is because that fine particles fill the interspaces among large particles, increasing their resistance to pore water erosion. Also large, heavier particles may help to increase the rate of consolidation of fine particles (e.g., mud).

Biological impacts may significantly influence the sediment settling and recycling processes. Their extension still remains poorly understood. Benthic organisms are able to entrain, disperse, and sort sediments (e.g., Scoffin, 1987). In particular, bioturbation by benthic fauna has been found to counteract the consolidation process by loosening the surface bed structure. Contrariwise, biostabilization by bacteria and benthic diatoms helps to increase the cohesion of the seabed through secretion of extracellular polymetric substances. Macrophytes also help to increase the seabed resistance to erosion through their root system.

Summary

Sediment dynamics in coastal and marine environment is an extremely complicated and not fully understood process. Movement of sediment particles is subject to the influence of many environmental factors and processes occurring at different temporal and spatial scales. A comprehensive understanding of sediment dynamics requires systematic analysis of the joint contributions of geophysical, biological, and chemical processes and their coupling.

Morphodynamic models

Definition
Sediment transport models refer to numerical models that describe mobilization, migration, and settling of sediment in fluids (e.g., water and air).

Introduction
Sediment transport is a dynamic process occurring persistently in the earth system wherever there is moving water or air. Its direct consequence is a gradual change of the earth surface landform, which may significantly affect the habitats not only for human but also for large ecosystems. In shallow water, sediment transport is caused mainly by a combined action of surface gravity waves and currents, while in deep sea it is mainly controlled by dense water circulations and internal waves. Benefited from a continuous development of computational facilities, sediment transport modeling has become a popular tool for addressing many environmental and engineering problems.

Sediment transport in natural waters can be divided into two major modes, namely bed-load and suspended-load transport (Figure 1). Bed-load transport refers to the migration of sediment grains within a thin layer just above the seabed. It includes rolling, sliding, and saltation of grains. Though some literature consider saltation as a form of suspended-load transport, it seems more proper to treat it as bed-load transport in numerical models. This is not only because of a high settling velocity of saltating particles which is difficult to resolve numerically but also due to a strong interaction between saltating particles and bed surface. Suspended-load transport refers to the entrainment and transport of sediment by a fluid flow in which sediment particles sink slowly and are carried over a long distance before settling. There is no clear boundary between these two modes because the range of relocation of a sediment particle greatly depends on the ambient water motions.

Although our understanding and numerical modeling of waves and currents have improved greatly in recent decades, sediment transport by water motions remains poorly understood. The difficulty in matching theoretical results to observations is due to the sensitivity of sediment particle mobility to many environmental factors and processes at different temporal and spatial scales. By now there exist no mathematical formulas which can accurately predict the motion of a large number of sediment particles in natural environment. Most existing formulas are derived empirically and their applicability is restricted to a narrow range of environmental settings. Results obtained from different models often differ drastically from each other even though they are based on the same initial conditions (Yang, 1996).

Three major obstacles hinder precise modeling of sediment transport in marine environment. The first is the genetic diversity of sediment particles. Their different physical and biochemical properties lead to various dynamic responses to ambient water motions. For example, grains of granular, noncohesive sediment like sands and gravels normally migrate as individual particles, possibly interacting with each other by direct collisions, through which momentum and energy is transferred. Fine sediment particles with a diameter <0.063 mm show quite different behaviors due to the existence of a cohesive force. They rarely exist as individual particles but rather tend to aggregate together, forming much larger structures which may consist of tens of thousands of particles. During the transport, these flocculated structures may further attract more fine particles or break down to smaller ones, depending on a bunch of parameters (e.g., turbulence strength, particle concentration, ion concentration, temperature, organic matters) in the ambient water. Such dynamics are still poorly understood.

Another major obstacle is the stochastic nature of sediment particle movement in fluids. A primary source of randomness of particle movements is turbulence, which remains still one of the most challenging problems in fluid dynamics. Another important source contributing to this

result (e.g., Raudkivi, 1990; Allen, 1997). Smaller particles may roll upward along the upstream slope of these perturbations and jump out from the crest into the fluid flow, while larger particles roll to the downstream side of the perturbations. Some particles entrained by the flow may travel for a short distance before they fall down to the seabed again (i.e., saltation), while others may stay in suspension for a longer period, depending upon their physical (e.g., density, grain size, and shape) and biochemical properties (e.g., interaction with organic matter and ions). In general, three types of movement occur: rolling, saltation, and suspension. Gravels and sands are usually transported in the form of rolling and saltation in marine environment, while very fine sands, silts, and clays can be easily entrained by fluid flow and are normally transported as suspended matter. Cohesive sediments may interact with each other, flocculate or de-flocculate during the collision. During the movement, some particles may hit others and transfer their energy and momentum, increasing the complexity of the entire system.

Even in the simplest steady flow in a straight channel, sediment movements reveal a high degree of complexity. For non-cohesive sediments, a reasonable way to quantitatively describe their dynamics is to trace the motion of individual particles under different boundary conditions and via the multitude of collisions. With a development of computational devices, it is possible now to examine the validity of existing theories on granular sediment dynamics by the use of particle-based modeling (e.g., Herrmann et al., 2007; Radjaï and Dubois, 2011). The dynamics of cohesive sediments is more complicated and least understood. The major uncertainty of their movement comes from the cohesion between particles, which allows specific types of interactions (flocculation and de-flocculation) among sediment particles. Brownian motion, turbulence, and differential settling are recognized as the three major mechanisms to cause collision within a suspension under laboratory conditions (Krone, 1972; Winterwerp, 1999). In natural estuarine and coastal marine environments, studies (e.g., Stolzenbach and Elimelich, 1994) show that the contribution of Brownian motion and differential settling to sediment flocculation is minor, and turbulence plays the major role in controlling the interaction among cohesive sediments. Only in the case of high sediment concentration (e.g., on the order of magnitude of 10 kg/m^3 and higher), the effect of differential settling becomes substantial. Other parameters that affect the sediment flocculation in marine environment are salinity, the existence of ions, temperature, organic matter, temperature, and local suspended matter concentration (e.g., McAnally and Mehta, 2001; Winterwerp and Van Kesteren, 2004).

Sediment settling and recycling

Sediments settle down on the seabed when the fluid velocity drops below a certain level. Grain size is an important factor in determining the settling velocity of granular sediment particles. Large grains may settle quickly, while small, unflocculated grains like silts and clays may stay in the water column for a much longer time. Stokes' law is normally used to calculate the settling velocity of fine grain-size (<0.125 mm) particles. It is originally derived based on the assumptions of (1) small Reynolds number (i.e., laminar flow), and (2) spherical particles consist of homogeneous material and (3) none particle interactions. This hinders its application to particles with irregular shapes in turbulent flows. In natural estuarine environments, direct observations show that micro-flocs (<0.125 mm) are almost spherical, with width to length ratios normally in the range 0.8–1.5. Within this range, Stokes' law can be considered to apply (Gibbs, 1985). Macro-flocs (>0.125 mm) often show more complicated outlines and have variations in transparency that suggests a complex composition made up of smaller denser micro-flocs. Some researchers proposed modified versions of Stokes' law to take into account the shape irregularity of large particles (e.g., Lerman et al., 1974; Sternberg et al., 1999), while some other researchers tried to separate the numerical description of settling velocity of large particles from small particles (e.g., Van Rijn, 1984; Baugh and Manning, 2007). Grain size is a poor predictor for settling velocity of carbonate sediments, and some researchers built up relationships between fluid threshold velocity and settling velocity to describe the resuspension and settling of bioclastic sediments (e.g., Kench, 1997; Paphitis et al., 2002).

The sinking process of sediment particles is complicated due to the influence of turbulence and interactions among particles. Higher sediment concentration in the ambient water increases the possibility of particle interactions. This facilitates the formation of macro-flocs from micro-flocs and thus increases the sediment settling velocity. A certain level of turbulence is also proven to facilitate flocculation, although a strong turbulent shear will act to destroy the bonds between particles and induce a de-flocculation. The transition from positive to negative impact on particle flocculation by turbulence is often ambiguous, depending on not only the mineralogy and biological properties of the particles but also the local water environmental factors, e.g., sediment concentration, temperature, and salinity. The relationship between turbulence and sediment movement is not one-way. Sediment can also impose significant effects on the turbulence when its concentration is high enough. For example, close to the seabed often a concentrated benthic suspension is formed where suspended sediments interact strongly with turbulent flow through buoyant effects, and this may eventually lead to the formation of a fluid-mud vertical structure with a lutocline developed between the relatively clear water on top and the fluid-mud underneath. Sediment-induced density gradient (e.g., at the lutocline) as well as thermohaline pycnocline acts to damp turbulence and allows deposition of fine grain-size sediments.

Different from a direct resting of non-cohesive sediment particles on a rigid seabed, settling of cohesive
Sediment Transport Models, Figure 1 Sketch of sediment transport in open water (modified from Wang and Andutta, 2013). Note that the vertical flow structure is not scaled.

uncertainty is the fundamental ambiguity of pickup process of particles from the seabed. It is commonly recognized that sediment particles only start to move when the moments of the driving forces (exerted by the ambient water motion) exceed those of the stabilizing forces. Although the physics behind this phenomenon is clear, mathematical description of the pickup threshold is still ambiguous. Most sediment transport models treat the pickup threshold by the use of a critical shear stress following Shields (1936). Some other studies (e.g., Einstein, 1942; van Rijn, 1984; Nelson et al., 1995) suggest that such critical shear stress is not a deterministic value but rather lies in a range of values characterized by certain probability distributions (e.g., a Gaussian or Gamma distribution). The usual presence of a mixture of different-sized sediment particles on the seabed further complicates the problem to define a reliable pickup threshold.

The third major obstacle is the presence of greatly different scales in the process of sediment transport. Coastal and ocean sediment transport models are normally developed at a scale (both spatially and temporally) that is much larger than the one on which turbulence, sediment particle–particle interactions and particle–fluid interactions occur. These small-scale processes have to be either parameterized by subgrid modeling techniques or simplified by empirical formulae. In either case errors are inevitably induced and different formulations may produce significant differences in the results (Amoudry and Souza, 2011). Despite great efforts in recent decades to reduce errors of medium to large scale sediment transport models, such as data assimilation (e.g., van Dongeren et al., 2008; Lahoz et al., 2010) and improvement of numerical

schemes (e.g., Spotz and Carey, 2001; Roelvink, 2006; Zhang et al., 2012), even the most advanced model to date can only predict sediment transport within an accuracy of ± 50 % at best and higher uncertainties are common (Amoudry and Souza, 2011).

According to the strategy in treating the uncertainty of sediment motion in fluids, existing sediment transport models can be divided into deterministic and probabilistic models. Deterministic models treat sediment transport in a time- and space-averaged manner. Usually the entire system is divided into smaller (grid) cells and a single value for each physical parameter is evaluated as representing its properties in the entire cell at each time step. Probabilistic models specify a possible range of the parameters and provide a collection of values characterized by different possibilities. Microscale (particle-based) sediment transport models such as discrete element models are not discussed here as they are not applied to open environments due to an intrinsic restriction of computational capacity and memory space. Nevertheless, outcomes of microscale particle-based models that are further validated by laboratory observations may help to improve numerical models for sediment transport in natural environments.

Deterministic models

Although transport of individual sediment particle is often seemingly stochastic, it does not hinder a development of numerical models that describe the sediment transport in a deterministic manner (Hardy, 2013). Deterministic models are mostly built on process-based descriptions of sediment transport and they are able to provide detailed

insights of the physics of transport, which is often not possible in probabilistic models. Quite often the deterministic models show good performance on capturing medium to large spatial scale (of tens of meters to tens of kilometers) and short-term (of days to months) sediment transport phenomena.

Deterministic sediment transport models usually treat sediment as a continuum rather than individual particles. This assertion makes it possible to represent the presence of sediment in a spatial unit by a concentration. In this case suspended sediment transport in each fluid cell is calculated by either a presumption of a Rouse profile (Rouse, 1937) or by solving a mass balance equation formulated in a fully three dimensional Eulerian framework:

$$\frac{\partial C}{\partial t} + \frac{\partial uC}{\partial x} + \frac{\partial vC}{\partial y} + \frac{\partial (w - W_s)C}{\partial z}$$
$$= \frac{\partial}{\partial x}\left(A_h \frac{\partial C}{\partial x}\right) + \frac{\partial}{\partial y}\left(A_h \frac{\partial C}{\partial y}\right)$$
$$+ \frac{\partial}{\partial z}\left(K_h \frac{\partial C}{\partial z}\right) + S, \tag{1}$$

where C is the suspended sediment concentration, Ws is the setting velocity, A_h is the horizontal eddy diffusivity, K_h is the vertical eddy diffusivity, and S represents the sediment source/sink term at the boundary. With a set of appropriate initial and boundary conditions the models produce values for sediment distribution at each time step.

Because sediment is implicitly assumed to be homogeneously distributed over each computational cell, deterministic models are not able to directly resolve near-bed sediment transport processes such as bed-load transport that is largely influenced by particle–particle interactions in a thin near-bed region of high sediment concentration. In order to approximate bed-load transport and sediment flux at the seabed, deterministic models usually relate these transport rates to the bottom shear stress. For example, the bed-load transport rate (Q) is usually represented as

$$\frac{Q}{\sqrt{(\rho_s - \rho)gD_{50}/\rho}} = m\theta^n(\theta - \theta_{cr})^p, \tag{2}$$

where ρ_s and ρ are sediment and fluid density, respectively; m, n, p are empirical parameters; θ is the nondimensional bed shear stress (i.e., Shields parameter); and θ_{cr} is the critical Shields parameter for initiation of sediment particle motion. A representative particle grain size D_{50} is often adopted to derive the critical values for initiation of the motion.

Deterministic models normally classify sediment into two types, namely noncohesive and cohesive, and calculate the transport of these two types of sediment independently. Each sediment type may be further divided into several groups represented by different D_{50} values. Though some models are able to replicate the interaction among the cohesive sediments (flocculation and deflocculation), there seems to be a lack of model which treats the interaction between cohesive and noncohesive sediment explicitly.

By the use of mean or representative parameters, elaborate deterministic models are able to capture medium to large scale sediment transport phenomena in an efficient way. This facilitates their development for both engineering and research purposes. However, much progress is still needed to improve the accuracy of deterministic models, e.g., on the choice of parameters. As deterministic models are very sensitive to initial and boundary conditions, any perturbation may lead to a significant difference in the result. Thus a proper way to use deterministic models involves a sensitivity study which allows us to derive the "what if" scenarios for an optimum solution of the problem.

Probabilistic models

Probabilistic models emphasize the uncertainty of sediment transport in their formulation. The scope of uncertainty encompasses many aspects, from basic measurements to our inability to derive the true underlying relationship that governs the complex phenomena observed in the natural environments. This imposes great challenges to researchers to construct a numerical model to properly represent such uncertainties. Many existing probabilistic models deal with only a certain part of the uncertainties which are believed to be most crucial to sediment transport at the scales of interest.

The first probabilistic model to describe sediment transport was introduced by Einstein (1942). It was stated that the threshold of a sediment particle motion is when the ratio of the hydrodynamic force to the submerged weight force acting on the particle exceeds a certain limit that is determined by the particle geometry and the particle Reynolds number. The submerged weight of a particle is a constant for a given diameter while the hydrodynamic lift force varies depending on the near-bed turbulent flow and the relative position of the particles. Hence, the pickup probability for a bed particle can be defined as that of the instantaneous lift force being greater than the submerged weight force of the particle. With Einstein's approach, a pickup probability may be used to derive the total load transport function. This inspired a series of studies into probabilistic transport such as Kalinske (1947), Engelund and Fredsoe (1976), and Fredsøe and Deigaard (1992). In addition to Einstein's type transport theories, new probabilistic methods such as Bayesian statistical models have been proposed in recent years (e.g., Schmelter et al., 2011) for a better estimation of credible intervals for the critical shear stresses (for incipient motion and deposition) and their variances.

Another well-known type of probabilistic transport models uses the Lagrangian framework. Such models are widely used to trace the suspended transport of individual sediment particles in coastal and marine environment. Lagrangian models may include both advective and diffusive components of the motion of particles. Advection is the transport associated with the numerically simulated flow properties in grid cells while diffusion is associated

with subgrid-scaled motions that are not resolved by the underlying flow model. The flow field is usually provided by an Eulerian model, and the random motions can be calculated by a random walk scheme (e.g., Hunter et al., 1993) or a trajectory path scheme (e.g., Döös et al., 2013).

Cellular Automata (CA) models, which include Lattice Gas and Lattice Boltzmann models, are a relatively new type of probabilistic transport models (Fonstad, 2013). Common characteristics for CA type models include: (1) The model area is divided into a set of connected cells (i.e., the lattice), (2) A limited number of state variables are defined at each cell, (3) The change of cell state is defined by a limited set of rules which act only on the local cell and its limited neighbors, and (4) The rules are applied at every time step of simulation. Although based on relatively simple rules that govern the evolution of the cell states, CA models have amazing capabilities in reproducing almost all types of transport patterns with a high computational efficiency (e.g., Werner, 1995; Pilotti and Menduni, 1997; Ladd and Verberg, 2001).

Summary

When targeting the numerical solution of a specific sediment transport problem, the choice of a model has to consider several aspects, e.g., the nature and complexity of the problem, the capabilities of the model to simulate the problem adequately, data availability for model calibration and verification, and overall available time and budget for solving the problem (Papanicolaou et al., 2008). One should be cautious of the advantages as well as disadvantages of a model when applying it to a specific problem. Error estimation is always necessary to define credible intervals of the simulation results. A hybrid coupling of deterministic and probabilistic models seems to provide the optimum means to study coastal and marine sediment transport phenomena but much effort is still needed to develop such models.

SEDIMENTARY SEQUENCE

Christopher George St. Clement Kendall
Earth and Ocean Sciences, University of South Carolina,
Columbia, SC, USA

Introduction

Sequence stratigraphy

The methodology of sequence stratigraphy uses a framework of genetically related sedimentary geometries and their bounding surfaces to determine the depositional setting of the sedimentary section of the earth's crust. This framework is built from the interpretation of seismic, well data, adjacent outcrops and knowledge of regional geology tied to an understanding of sedimentology, and modern and ancient depositional systems (Figure 1). This template can then be extrapolated to predict sediment character in the nearby subsurface and outcrops.

NB: *Visit the SEPM STRATA website (http://www. sepmstrata.org/) for explanations of the sequence stratigraphic terminology used here. Terminology on the sites is displayed on pop-up boxes containing information that clarify the understanding and use of this discipline of sequence stratigraphy.*

Sequence stratigraphic units

The sequence stratigraphic framework of erosional and depositional surfaces subdivides the stratigraphic section into gross sediment geometric units. In order of increasingly higher frequency, these sequence stratigraphic packages are:

- Sequences
- Systems tracts
- Parasequences and/or cycles

These geometric end members have similar sediment strata and are defined by their lithology, sedimentary structures, fauna, and bounding surfaces. These evolved in response to changes in accommodation (the space available to be filled) created by changes in eustasy (worldwide sea-level variation), tectonics, and sediment fill (Jervey, 1988). The characterization of these packages is the key to interpreting the depositional setting of the sedimentary sections that contain them. Once the depositional systems are better understood and described in terms of the above hierarchy, their lithofacies, and elements, better stratigraphic interpretations and predictions result (Figure 2).

Sedimentary sequence

Sedimentary sequences are the fundamental low-frequency stratal units of sequence stratigraphy (Catuneanu et al., 2011). A "sequence," as originally defined by Sloss et al. (1949) and Sloss (1963), is an unconformity-bounded stratigraphic unit. Mitchum Jr. (1977) modified this to "a relatively conformable succession of genetically related strata bounded by unconformities or their correlative conformities. Through the 1980s and 1990s, these definitions (Catuneanu et al., 2011) evolved to:

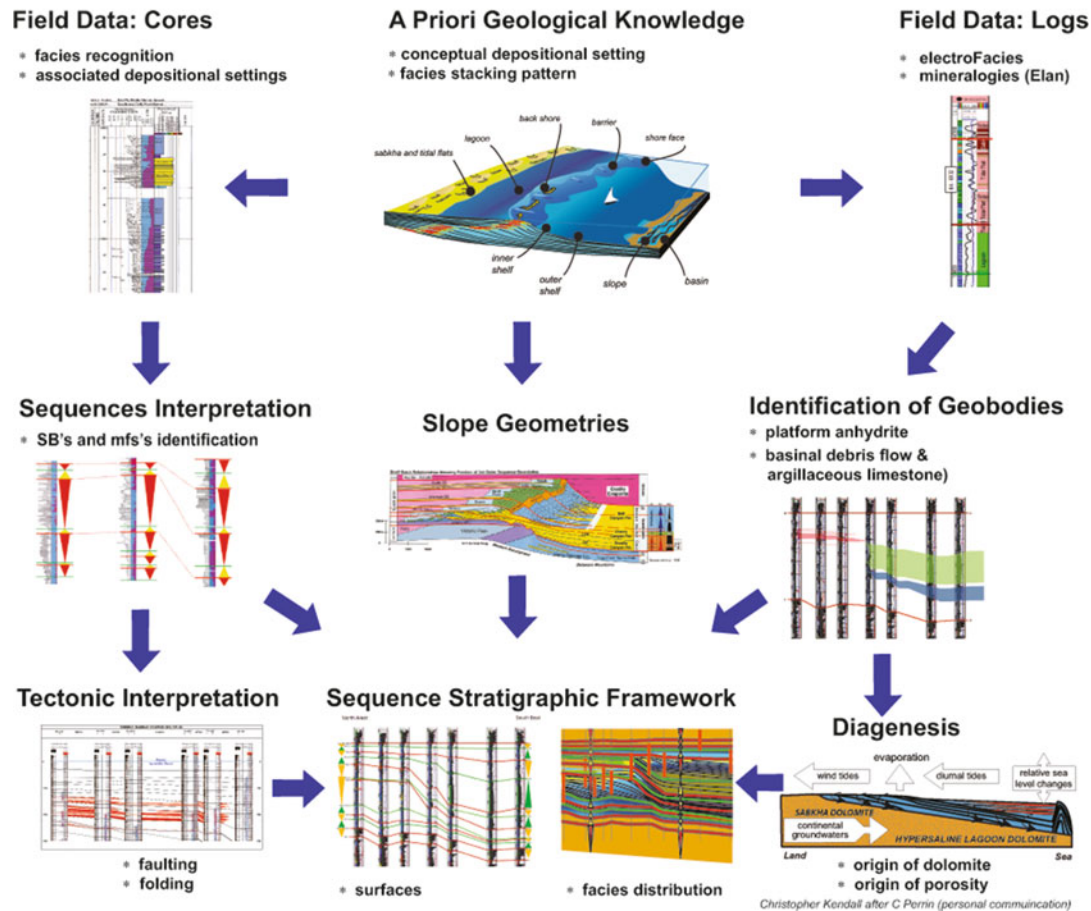
- *Depositional sequences*: bounded by subaerial unconformities and their marine correlative conformities (Vail, 1987; Posamentier et al., 1988; Van Wagoner et al., 1988, 1990; Vail et al., 1991; Hunt and Tucker, 1992)
- *Genetic stratigraphic sequences*: bounded by maximum flooding surfaces (Galloway, 1989)
- *Transgressive-regressive (T-R) sequences or T-R cycles*: bounded by maximum regressive surfaces (Johnson and Murphy, 1984; Johnson et al., 1985), subsequently redefined as a unit bounded by composite surfaces including subaerial unconformities and the marine portion of the maximum regressive surface (Embry and Johannessen, 1992)

These depositional sequences represent a relatively conformable succession of genetically related sedimentary strata generated by cyclic changes in accommodation. Enclosed by similar stratigraphic surfaces with the same general origin through geologic time, sequence fill is the result of the same geological events and processes that generate and occlude accommodation. The cyclic character of a sequence may be symmetrical or asymmetrical. The main cause of the cyclic character of sequences is commonly ascribed to eustasy since a sequence accumulates between eustatic-fall inflection points (Posamentier et al., 1988) forming successions of genetically linked deposition systems (systems tracts).

Sequences start and end with a surface generated by the same kind of event, including the onset of a relative sea-level fall (sequence boundary – SB), the end of relative sea-level fall (sequence boundary – SB), the end of regression (regressive surface of marine erosion – RSME), the start of a transgression (transgressive surface of erosion –TS), or the end of transgression (maximum flooding surface – MFS). These erosional and depositional surfaces mark changes in depositional regime that abrupt thresholds in depositional processes cause. The boundaries of sequences contrast with systems tract and parasequence boundaries, matching different "events" within a relative sea-level cycle and enabling the distinction of sequences from component systems tracts and parasequences.

Sedimentary systems tracts

Systems tracts are subdivisions of a sequence. Generated by "contemporaneous depositional systems" (Brown and Fisher, 1977), their fill of accommodation is associated with specific phases of the relative sea-level cycle (Posamentier et al., 1988; Hunt and Tucker, 1992; Posamentier and Allen, 1999; Catuneanu, 2006; Catuneanu et al., 2009; Catuneanu et al., 2011). Systems tracts commonly include falling stage systems tract

Sequence Stratigraphy Work Flow


Sedimentary Sequence, Figure 1 Linkage between "a priori" geological knowledge, subsurface, and outcrop data with a sequence stratigraphic framework to predict facies distribution.

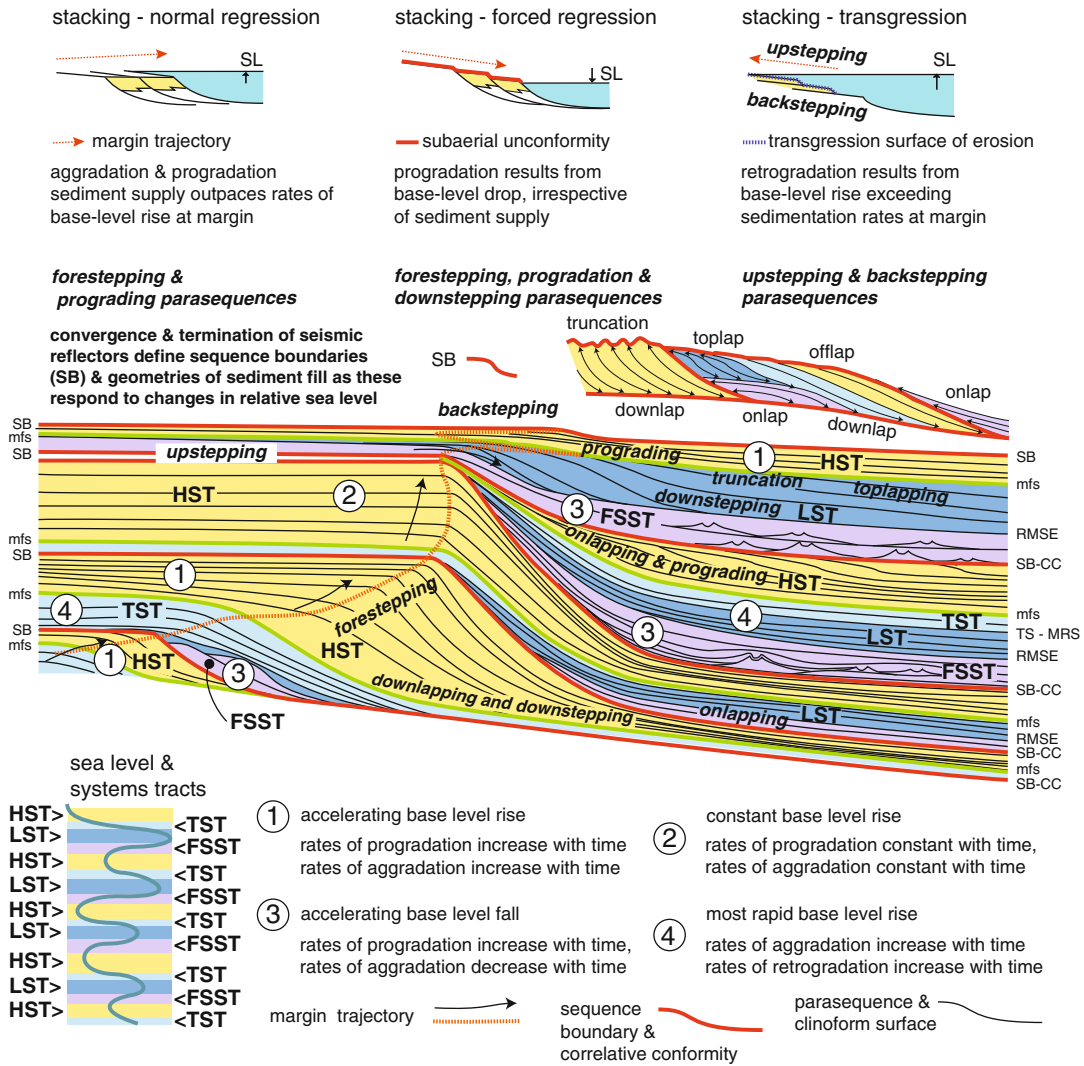
(FSST), lowstand systems tract (LST), transgressive systems tract (TST), and highstand systems tract (HST) (Figure 2). An exception to this is the regressive systems tract (RST) of Embry (1995), interpreted as regressive fill of accommodation generated independently of a specific phase of sea-level.

The internal architecture of systems tracts includes parasequence sets and/or high-frequency cycles driven by orbital forcing of eustasy or higher-frequency tectonic cycles, though the latter are usually assumed to be low-frequency events. Systems tracts relationships to the phase of the sea-level cycle are interpreted on the basis of stratal stacking patterns, position within the sequence, and types of bounding surface (Van Wagoner et al., 1987, 1988, 1990; Posamentier et al., 1988; Van Wagoner, 1995; Posamentier and Allen, 1999). Tracts consist of a relatively conformable succession of genetically related strata bounded by conformable or unconformable sequence stratigraphic surfaces. Systems tracts may be linked to particular types of shoreline trajectory, be this a forced regression, normal regression, or

transgression and, defined from stratal stacking patterns (Figures 2 and 3), where a genetic link to coeval shorelines cannot be determined, may be shoreline independent (Catuneanu et al., 2011).

Parasequence

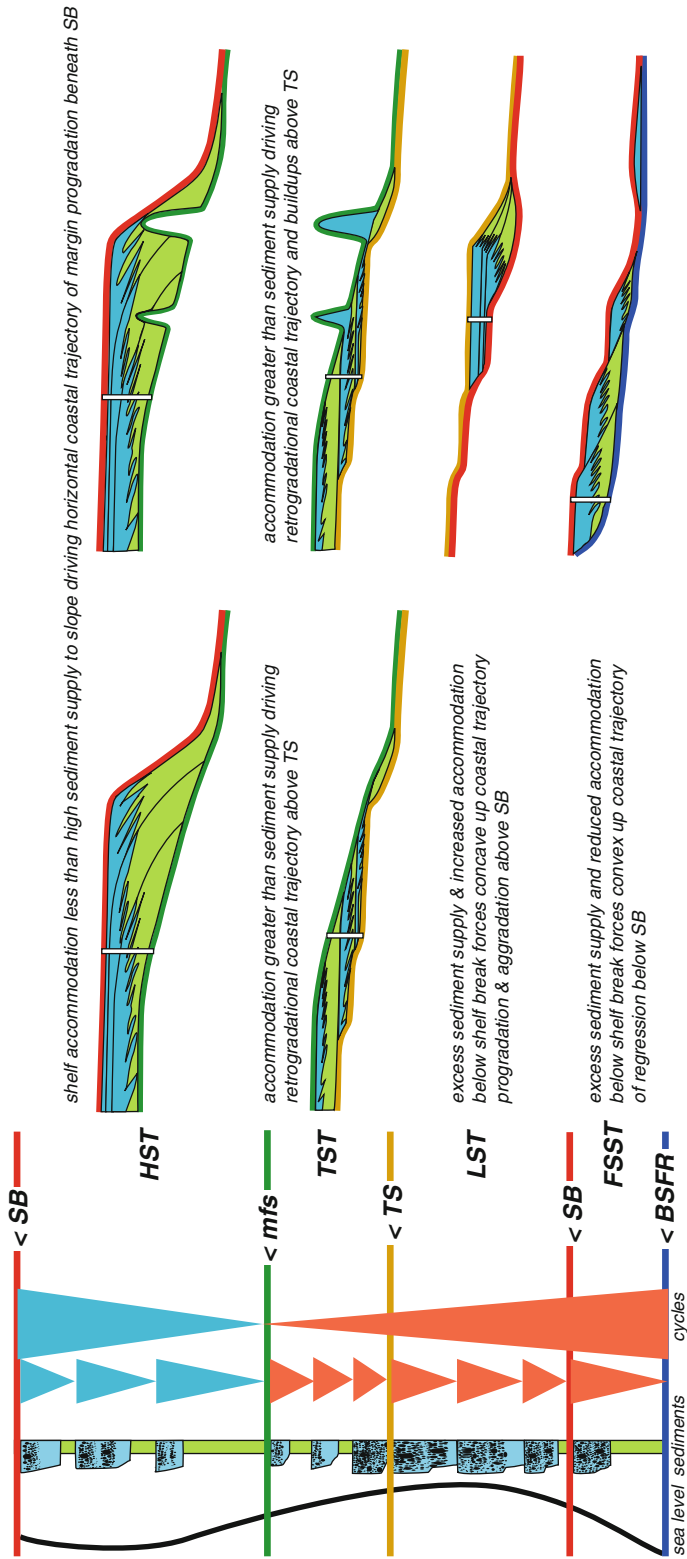
Though the term may be applied to carbonates, it is more common for siliciclastics. Parasequences are a relatively conformable succession of genetically related beds or bedsets bounded by marine flooding surfaces or their correlative surfaces (Van Wagoner, 1985). Patterns of stacked parasequences, parasequence sets, are used in conjunction with boundaries and their position within a sequence to define systems tracts (Van Wagoner et al., 1988) and their relationship to eustasy (Figure 3).

Parasequences are commonly characterized by a cycle of sediment that either coarsens or fines upward and the subdividing flooding surfaces are usually identified by abrupt and correlatable changes of the grain size of the sediments on either side of that flooding surface. This


Sedimentary Sequence, Figure 2 Sequences defined by sequence boundaries (*SBs*); systems tracts defined by geometry of stacking patterns of parasequences and phase of sea-level curve, namely: aggrading, thinning, and prograding parasequences, highstand systems tract (*HST*); downstepping and prograding parasequences, forced by falling stage systems tract (*FSST*); aggrading, thickening, and prograding parasequences, lowstand systems tract (*LST*); and aggrading, thickening, and retrograding parasequences, transgressive systems tract (*TST*). Right-hand side of the diagram illustrates a deeper-water setting, with submarine fans just below wave base form forced regression of the FSST. The base of the FSST is an erosional surface, or sequence boundary that extends seaward and deeper to the correlative conformity (*CC*) sensu Posamentier and Allen (1999). The surface capping the FSST is a regressive surface of marine erosion (*RSME*) (Plint, 1988) within the depth of wave-cut scour related to a shallow-water setting, too shallow for a deeper-water CC sensu Hunt and Tucker (1992)

Step 1 cross section has an "accelerating base level rise," at the base of HST. This is followed by a decelerating base level rise and approaching a zero rate at the end of rise. The initial accelerating base level rise marks the onset of transgression. When the base level is falling, whether accelerating or decelerating, during the entire falling stage, the unit is an FSST.

change in grain size is often caused by the abrupt changes in energy associated with the waves or currents of the sea transgressing across the sediment interface and can be identified in well logs, outcrop, and seismic. In carbonate settings, a parasequence corresponds to a succession of facies commonly containing lag deposit or thin deepening interval followed by a thicker shallowing-upward part, as, for example, in peritidal cycles.

In contrast to sequences and systems tracts, which may extend across an entire sedimentary basin from fluvial into the deep-water setting, parasequences are geographically restricted to the coastal to shallow-water areas where marine flooding surfaces may form (Posamentier and Allen, 1999). In the case of carbonate settings, peritidal cycles can in some cases be correlated into slope and basinal facies (e.g., Tinker, 1998; Chen and Tucker, 2003).


Sedimentary Sequence, Figure 3 Systems tracts and parasequence geometries of a composite sequence stratigraphic framework for a carbonate platform with (*right-hand side*) and without (*left-hand side*) buildups. In the falling stage system tract (*FSST*), initially a forced regression causes the parasequences of the carbonate margin to prograde and downstep seaward in response to lost accommodation of a relative sea-level fall. The three downstepping parasequence wedges build out over the basal surface of forced regression (*BSFR*) and terminate seaward in a basin-floor fan. Above the fan is a correlative conformity, while up-dip a subaerial unconformity forms a sequence boundary (*SB*) over the downstepping parasequence wedges of the forced regression. The lowstand systems tract (*LST*) overlies the unconformity, and the trajectory of shoreline parasequences rises seaward. There follow three onlapping retrograding carbonate parasequences of the transgressive systems tract (*TST*) overlying a transgressive surface (*TS*) topped by a maximum flooding surface (*MFS*). A highstand systems tract (*HST*) carbonate margin follows expressed as three shoaling-upward parasequences which lie below the next depositional sequence boundary (*SB*). The designation of sequence boundary in this diagram follows Hunt and Tucker (1992), while Posamentier and Allen (1999) choose the BSFR as the sequence boundary. The vertical section on the left-hand side is a schematic column of the stacked sediments that accumulated within each systems tract. Approximate position of sedimentary column indicated by white strips on sections, no one locality provides a complete section through all the systems tracts and parasequences, the FSST is represented by a section that is situated and extending basinward, the LST has a section even farther basinward, and the section for the TST and HST parasequences is better expressed further onto platform.

Summary and conclusions

Sequence stratigraphy uses a framework of genetically related sedimentary geometries, namely:

- Sequences
- Systems tracts
- Parasequences and/or cycles

  and their bounding surfaces:

- Sequence boundary – SB
- Regressive surface of marine erosion – RSME
- Transgressive surface of erosion – TS
- Maximum flooding surface – MFS

  These are used to determine the depositional setting of the sedimentary section.

- The framework is built using the interpretation of seismic, well data, adjacent outcrops and knowledge of regional geology tied to an understanding of sedimentology, and modern and ancient depositional systems
- The sequence stratigraphic framework is extrapolated to predict sediment character in the subsurface and outcrops.

SEISMOGENIC ZONE

Eli Silver
Earth and Planetary Sciences Department, University of California, Santa Cruz, CA, USA

The seismogenic zone is the depth interval of unstable (stick-slip) behavior where earthquakes can nucleate and slip coseismically (Scholz, 2002; Marone and Richardson, 2010). Earthquake nucleation usually occurs in the range of a few kilometers to 40 km depth. Variations are related to lithologic differences along the fault interface (Sibson, 1986), cementation, mineral dehydration, and diagenesis (Moore et al., 2007); pore fluid pressures and stress state (Saffer and Tobin, 2011); the structure of the lower plate interface (Heuret et al., 2011); the depth of the crust-mantle boundary beneath the upper plate; and the thermal regime (Oleskevich et al., 1999).

Updip and downdip limits are determined by locating aftershock distributions of earthquakes along the fault zone and by geodetically determining the zone over which locking occurs on the interface (Moore et al., 2007). The zone of coseismic slip can exceed that of nucleation alone. Tsunami modeling can constrain the slip distribution during large earthquakes (Yamazaki et al., 2011) and provides one measure of the full coseismic displacement.

The physical characteristics of the seismogenic zone are generally inferred from geophysical observations, such as seismic velocities, density, and electrical conductivity. Direct measurements have included drilling through the San Andreas Fault (Zoback et al., 2010) and through splay faults of the Nankai Trough subduction zone (Tobin and Kinoshita, 2006), which have provided material samples and allow long-term monitoring of temperature, fluid pressure, and fluid chemistry that may change during seismic events.

Slow earthquakes, including tsunami earthquakes (Kanamori and Kikuchi, 1993), and episodic tremor are often generated in the transition between the seismogenic zone where high-velocity slip earthquakes are generated and the region of conditionally stable or stable slip behavior above and below this zone (Schwartz and Rokosky, 2007). Slow slip is generally determined by geodetic observations, while episodic tremor is seen on seismographs.

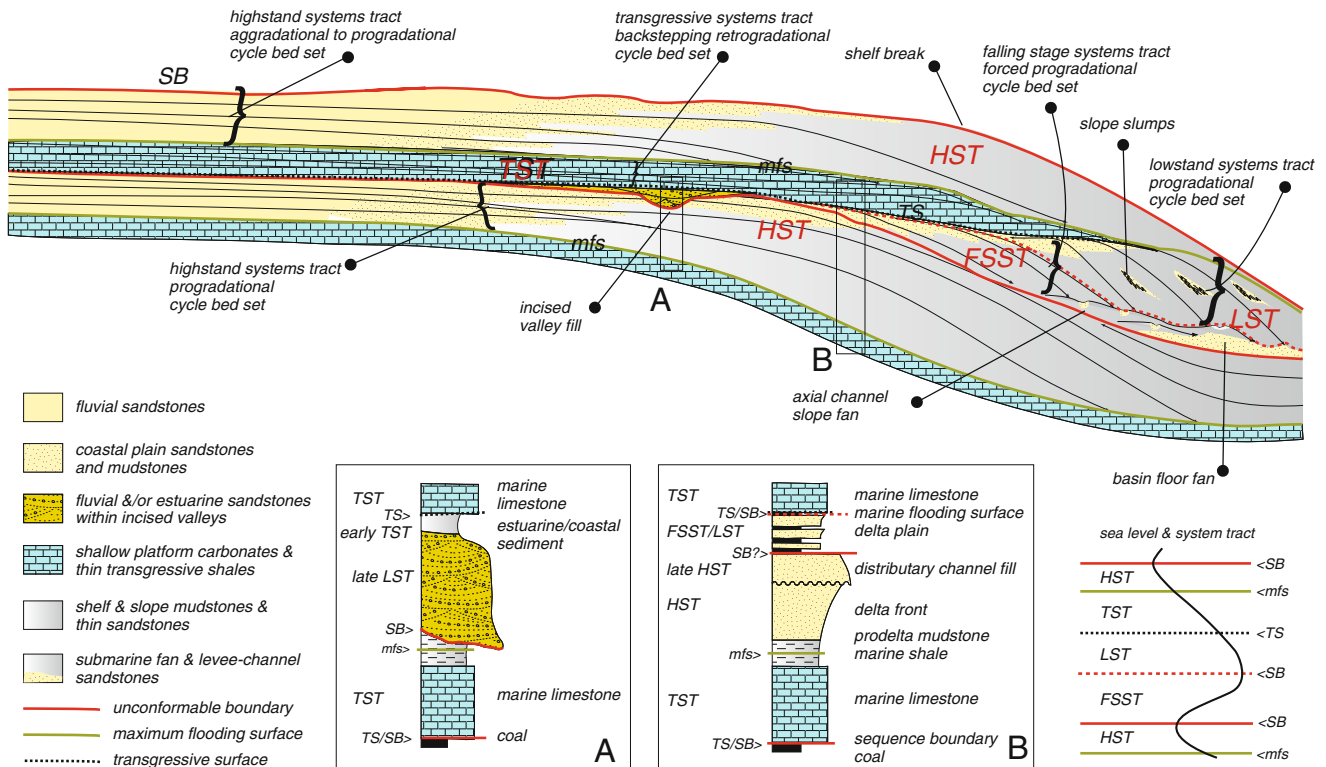
SEQUENCE STRATIGRAPHY

Christopher George St. Clement Kendall
Earth and Ocean Sciences, University of South Carolina, Columbia, SC, USA

Definition

A methodology of stratigraphic interpretation that uses a framework of genetically related stratigraphic surfaces,


Sequence Stratigraphy, Figure 1 Sequence stratigraphic model and cycle types for a mixed carbonate-clastic succession based on the Yoredale cycles of the mid-Carboniferous of northern England. The schematic logs show (*A*) a cycle with an incised-valley fill sandstone cutting into shales that overlie marine carbonate and (*B*) coarsening-up deltaic clastics that have onlapped the marine carbonate.

and the sedimentary facies and geometries these surfaces bound, to determine the depositional setting of sedimentary rocks.

Introduction

Stratigraphy is the science of the layered character of rocks, be these sedimentary, volcanic, metamorphic, or igneous rocks. Sequence stratigraphy, a branch of sedimentary stratigraphy, is a methodology that uses the order sedimentary strata accumulated within a framework of major depositional and erosional surfaces to interpret the depositional setting of clastic and carbonate sediments from continental, marginal marine, basin margins, and downslope settings. The surfaces that bound and subdivide the strata are often interpreted to be generated during changes in relative sea-level causing associated deposition and erosion. The resulting template of surfaces and the lithologic facies, sedimentary structures, and fauna they bound are used to interpret the depositional setting and predict the heterogeneity, extent, and character of the lithofacies.

Sequence stratigraphy is based on the premise in that "the present is the key to the past" (Lyell, 1830, 1832, 1833). It supports the contention that the sedimentary record of the earth's crust is the product of uniform and common physical processes that interacted with sediments as they accumulated. The section that follows is based on Catuneanu et al. (2011) and a summary of a collective understanding of sequence stratigraphy that is available on the website SEPM STRATA.

A major problem with sequence stratigraphy is that the definition, terminology, and interpretation of the surfaces of sequence stratigraphy can be complex and sometimes contentious. **NB**: *Visit the SEPM STRATA website* (http://www.sepmstrata.org/) *for explanations of the sequence stratigraphic terminology used here, which is linked to pop-up boxes containing information that clarify the understanding and use of this discipline of stratigraphy.*

Bounding surfaces of sequence stratigraphy

Evidence that the relative position of the sea has varied through geologic time is recorded in the Earth's marine sedimentary strata from the Precambrian through present by the major bounding and subdividing surfaces of the sedimentary section (Figure 1). These surfaces are commonly generated by the changing position of relative sea-level when the volume of water in the oceans varies

and/or ocean relief changes. The bounding surfaces are the key to sequence stratigraphy.

A cycle of the rise and fall of relative sea-level will likely produce a corresponding response in the sedimentary section and marked changes in the flow regime that form subdividing sequence stratigraphic surfaces. For instance, when eustasy, worldwide sea-level, rises or the local crustal substrate subsides, a relative rise in sea-level occurs. The resulting transgression floods the shore and a nearshore transgressive surface (TS) forms. When the rate of sea-level rise reaches its most rapid increase, sediment accumulation seaward of the shore is reduced. Meanwhile pelagic and benthic fossils and organic matter continue to accumulate in the open sea. As a result condensed accumulations of fossils are found on the sediment surface or within a thin sedimentary zone, and, coincidentally, the organics sequestered radioactive elements producing a strong radioactive signal on the gamma logs. This zone and/or surface is known as the maximum flooding surface (mfs). Following the highest position of the sea, a drop in sea-level may cause the shore and the nearshore to be eroded, forming an unconformity or sequence boundary (SB).

Sequence stratigraphic interpretation identifies the subdividing surfaces of TS, mfs, and SB described above. These surfaces envelope the discrete sediment geometries of the sedimentary section. Interpretation involves conceptually reversing the order of deposition and back-stripping the geometries from oldest to youngest. They are then reassembled in the order of accumulation, using as a template the subdividing surfaces, lithofacies geometry, and fauna to interpret the evolving character of depositional setting. The reassembly tracks the evolution of the sedimentary system, its hydrodynamic setting, and accommodation.

The back-stripping analysis is aided by the subdivision of the sequence stratigraphic section on the basis of major depositional and erosional surfaces alluded to above. A variety of elements are subdivided by the surfaces. Their hierarchy from low frequency to high frequency includes:

- Sequences: fundamental stratal units of sequence stratigraphy (Catuneanu et al., 2011) composed of relatively conformable successions of genetically related strata generated by cycles of change in accommodation (the space available to be filled) (Jervey, 1988), and/or sediment supply are bounded by similar stratigraphic surfaces which have same origin through geologic time.
- Systems tracts: subdivisions of a sequence linked to "contemporaneous depositional systems" (Brown and Fisher, 1977) and sea-level position. Include highstand systems tract, falling stage systems tract, lowstand systems tract, and transgressive systems tract.
- Parasequences and/or cycles: relatively conformable successions of genetically related beds or bed sets (within a parasequence set) bounded by marine flooding surfaces or their correlative surfaces (Van Wagoner, 1995). Stacking of parasequence sets is used

in conjunction with boundaries and position within a sequence to define systems tracts (Van Wagoner et al., 1988) and their relationship to eustacy.

As sediments are reassembled, the genetic character of the sequences, systems tracts, and parasequences is determined as products of changes in accommodation and the regional setting. A limit to this analytical strategy is often the extent of the understanding of the inferred depositional setting.

Sequence stratigraphy of depositional systems

Understanding how modern and ancient depositional systems are tied to sequence stratigraphy and the processes that formed them aids the interpretation of depositional systems. The sequence stratigraphic framework is used to analyze and explain how sedimentary rocks acquire their layered character, lithology, texture, faunal associations, and other properties. These properties explain how the mechanisms of sediment accumulation, erosion, and interrelated processes produced the current configuration of the rocks. This strategy leads to new questions and more realistic interpretations and enhances predictions of lithofacies heterogeneity. These systems include:

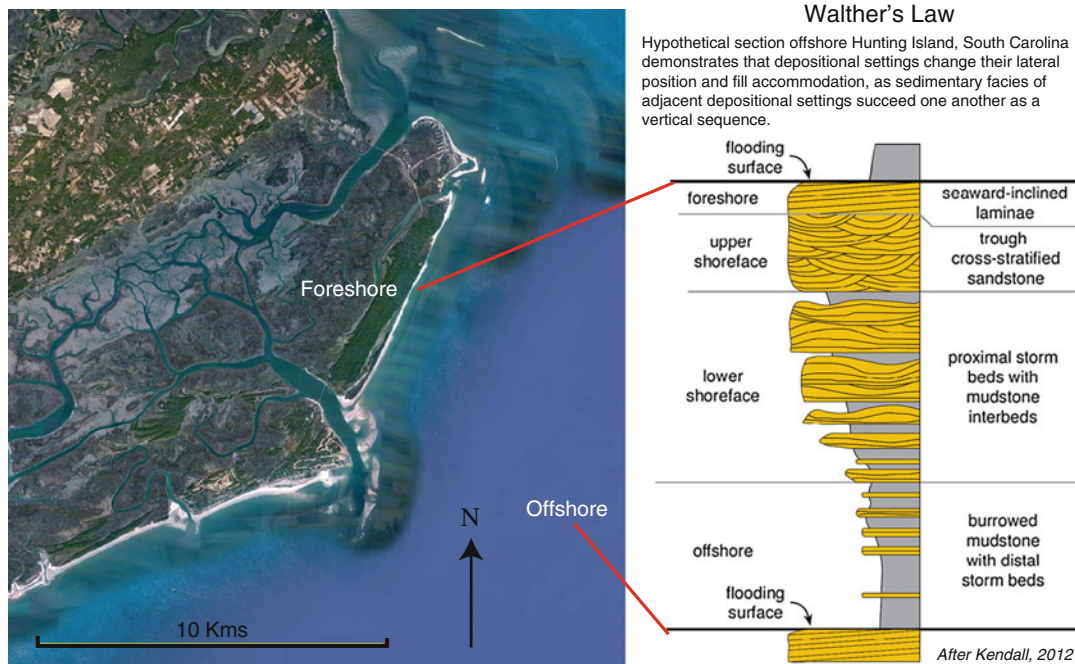
- Clastic systems
  - Marine: barrier island coasts; deltaic systems; deepwater fans; deepwater basins
  - Continental: glacial; eolian; alluvial fans; braided streams; coarse and fine-grained fluvial systems; lacustrian
- Carbonate systems
  - Inner carbonate shelf; outer carbonate shelf and margins; deepwater carbonates

Both respond to changes in base level and are subdivided by similar surfaces, the major difference being carbonate accumulation tending to be "in situ production" while clastics are transported to their depositional setting. Rates of carbonate production are linked to photosynthesis and depth dependent with rates greatest close to the air/sea interface, so carbonate facies and their fabrics are often clear indicators of sea-level position. Additionally organisms have the capacity to produce and accumulate sediments above the hydrodynamic thresholds associated with clastic systems generating the ecological accommodation of Pomar (2001).

Niels Stensen and Johannes Walther

The interpretation is better, and predictions of local and regional stratigraphy are more accurate when the sequence stratigraphic framework is integrated with:

- Steno's laws of sediment accumulation (Dott and Batten, 1976)
- Walther's law (Middleton, 1973) of the vertical and lateral equivalence of sediments

Steno established that younger rock sedimentary layers overlie in order older layers (principle of superposition),


Sequence Stratigraphy, Figure 2 Hypothetical section offshore Hunting Island, South Carolina, demonstrating that, as Steno (Dott and Batten, 1976) indicated, sediments accumulate vertically from oldest to youngest and extend laterally while, as Walther (Middleton, 1973) indicated, depositional settings change their lateral position and fill accommodation, so that sedimentary facies of adjacent depositional settings succeed one another as a vertical sequence.

sediments fill over basal irregular surfaces enclosed above by a smooth surface (principle of original horizontality), and sediment layers have continuity to where they pinch out, or are prevented by a barrier to spread further, or are disrupted by folding and/or faulting (principle of lateral continuity). Walther recognized that as sediments fill the accommodation of their depositional settings, those laying laterally side by side change their lateral position as the sedimentary facies of adjacent depositional settings succeed one another as a vertical sequence (Figure 2).

Stacking patterns and geometries

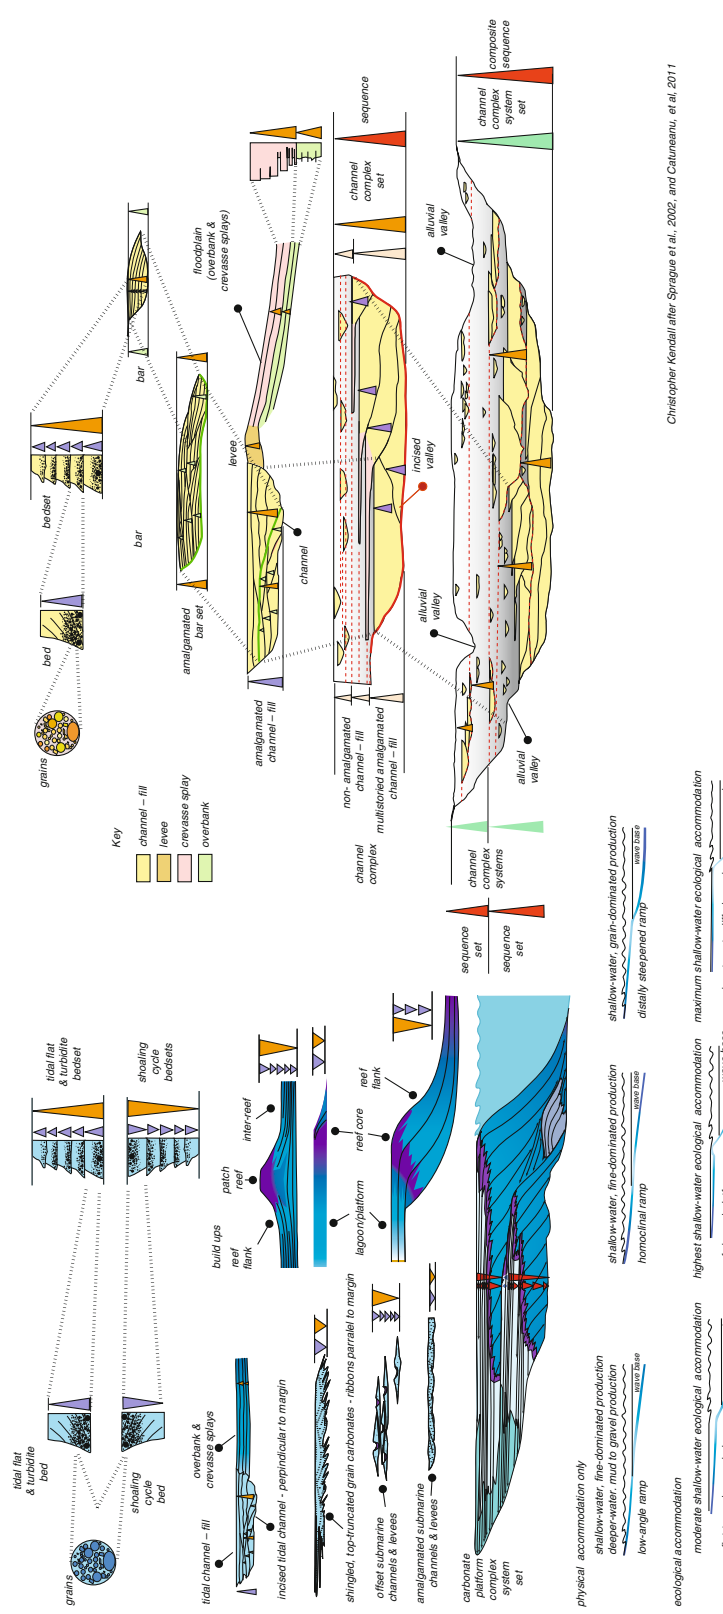
Sequence stratigraphy methodology establishes the depositional setting of a sedimentary section by analyzing the geometric arrangement of sedimentary fill or stacking patterns. These patterns are represented by the vertical succession of sedimentary facies geometries and their enveloping surfaces. The geometries and stacking patterns of uncemented carbonates and clastics are similar, as both respond to changes in base level in the same way, both can be subdivided by similar surfaces and both respond to wave and current movement similarly.

However major differences in the sequence stratigraphy of the sediments exist. All clastics are transported to their depositional resting place while carbonates are produced and accumulate "in situ." Rates of carbonate production, and so accumulation, are linked to photosynthesis and are depth dependent. Their rates of

accumulation are greatest close to the air/sea interface. Thus carbonate facies and their fabrics are often used as indicators of sea-level position. Similarly siliciclastic coastal sediments, especially tidal sediments, can also be used as sea-level indicators. Additionally rates of carbonate accumulation often have a biochemical and physico-chemical origin influenced by the chemistry of the water from which they are precipitated. Stacking patterns of both sediments are expressed by geometric bodies that may be (Figure 3):

- Unconfined by topography
- Confined within eroded topography

Stacking patterns for both clastics and carbonates that are the product of physical accommodation vary between:

- Unconfined sheets that:
  - Prograde (step seaward)
  - Retrograde (step landward)
  - Aggrade (built vertically)
- Unconfined prograding carbonate sheets that are the product of physical accommodation are further subdivided below into:
  - Low-angle ramps of fine shallow-water carbonate that in deeper water pass to gravels
  - Homoclinal ramps of fine shallow-water carbonate
  - Distally steepened ramps of shallow-water grain-dominated carbonate


Sequence Stratigraphy, Figure 3 Hierarchical differences between carbonate and clastic architectural elements. Comparison of grains to cycles and bed sets to channels to reefs, carbonate platform, and channel complex system sets that respond to physical and/or ecological accommodation and are used to define depositional sequence boundaries, transgressive surfaces (TS), and maximum flooding surfaces (mfs).

- Unconfined carbonate platform sheet geometries influenced by organisms or ecological accommodation form
  - Flat-topped open shelves with moderate shallow-water ecological accommodation
  - Reef-rimmed platform with highest shallow-water ecological accommodation
  - Massive steep to cliffed margins with maximum shallow-water ecological accommodation

Confined bodies represented by fill of incised topography include:

- Subaerial incised valleys
- Submarine incised valleys

Channel fill and stacking of confining valleys and unconfined lobes and sheets may be expressed as:

- Organized bodies
  - Randomly organized bodies
  - Multistoried
  - Amalgamated

Other stratigraphic tools utilized with sequence stratigraphy

Prediction and interpretation improves not only when sequence stratigraphy is coupled to the laws of Steno and Walther but when tied to indicators of deposition and time. Indicators of depositional setting include:

- Ichnofacies and fossils
- Sedimentary structures
- Volcanics
- Storm layers or tempestites
- Sequence stratigraphic boundaries

Chronostratigraphic markers include:

- Fossils
- Magnetostratigraphic
- Radioactive markers or gamma ray log signal markers
- Radiometric markers

Terminology

Though the linkage between the sequence stratigraphy and the other subdisciplines of stratigraphy can be "fuzzy," these links are important to prediction and interpretation. The links are strengthened when sequence stratigraphic terminology carries connotations related to the interpretation of the surfaces used to interpret the stratigraphic section but also a consideration of sedimentology and chronostratigraphy. How the terminology is defined and used and/or fits preconceived classifications is tied to the character of the data and stratigraphic techniques used. In the end it is up to the users to consider their data and the goals of their interpretations. They should be able to explain their choice of terms and then make their interpretation!

Use of the "over simplification" of time as it relates to sequence stratigraphy

The sedimentary layering of a stratigraphic section has a vast array of dimensional hierarchies. These range from units millimeters thick that may have accumulated over seconds to thousands of meters thick and collected over millions of years. As much of the literature related to surfaces and the layers they enclose indicate, whatever the dimension of a layer is and the time involved in its deposition, each layer is bounded by surfaces that transgress time (Wheeler, 1958; Middleton, 1973; Vail et al., 1977; Galloway, 1989; Catuneanu et al., 1998; Schwarzacher, 2000; Catuneanu, 2002; Embry, 2002). All sedimentary sections are subdivided by these diachronous surfaces. If most sedimentary sections are cut by diachronous surfaces, then their depositional setting cannot be interpreted using Walther's law, since this would be contravened. However most interpreters accept that the layered units bounded by these surfaces formed at different times, and believe that the subdividing surfaces are of a higher order frequency than the time envelope of the section being considered. In other words, the setting and problem are oversimplified and the surfaces are ignored and it is assumed that the sediments accumulated continuously. So despite the surfaces and the sedimentary layers transgressing time for the sake of interpretation, these are assumed to have filled continuously.

Thus it should be recognized that in sedimentary interpretation the application of Steno's principles and Walther's law assumes the simplification that the sediments packaged by surfaces accumulated within length of time of the accumulation. These simplifications do not contravene logic (which is literally fuzzy) but aid in the interpretation of the sedimentary section. For a more complete and thorough discussion of this topic, one should read Catuneanu et al. (2012).

Summary and conclusions

The flow of sequence stratigraphic interpretations of sedimentary sections involves:

- Data sources
  - 2-D and 3-D seismic sections
  - Well log data
  - Outcrops
- Subdivision of sections into sequences, parasequences, and/or their associated systems tracts
- Identification and correlation of the following surfaces
  - Erosion and nondeposition (sequence boundaries [SB])
  - Transgressive surfaces [TS]
  - Maximum flooding surfaces [mfs]
- These surfaces provide:
  - A relative time framework for the sedimentary succession
  - The interrelationship of the depositional settings and their lateral correlation
  - A compartmentalization of hydrocarbon reservoirs

- Results include:
  - Depositional setting is determined.
  - Extent of their lithofacies is characterized.
  - Predict the above into unknown areas, particularly when associated with hydrocarbon reservoirs and aquifers.

In summary this section explains how "sequence stratigraphy" can be used to study sedimentary rock relationships within a time-stratigraphic framework of repetitive, genetically related strata bounded by surfaces of erosion or nondeposition or their correlative conformity (Posamentier et al., 1988; Van Wagoner et al., 1988).

Definition

"Serpentinization" is the process leading to the formation of serpentinites, metamorphic rocks derived from hydrous alteration of olivine-rich ultramafic rocks and consisting mainly of serpentine group minerals.

Introduction

Serpentinization denotes the hydrous alteration of olivine-rich ultramafic rocks, which can occur everywhere, where
Serpentinization, Figure 1 Schematic cross section through the oceanic lithosphere showing the main locations where serpentinization takes place in the marine realm: at detachment faults and transform faults at mid-oceanic ridges, at rifted continental margins, due to seawater ingress on bending-related faults near the subduction trench and above the subduction zone causing serpentine mud volcanism. Ophiolite complexes are parts of the oceanic lithosphere obducted onto continents and often featuring serpentinization of the lithospheric mantle.

these rocks and aqueous solutions react under suitable pressure and temperature conditions. In the oceanic realm, seawater-derived fluids are abundant; however, ultramafic rocks (peridotites) are typically found in the Earth's upper mantle. Serpentinization will only take place where these rocks get in contact with seawater fluids, either by deep fluid infiltration in fracture zones and bend faults or by uplift and exposure of peridotites at or near the seafloor. During serpentinization, the primary minerals contained in a peridotite (i.e., mainly olivine + orthopyroxene + clinopyroxene) are altered to form mostly serpentine group minerals (e.g., lizardite, chrysotile). The stability of these OH-bearing phyllosilicates ($T < 400$ °C; at low pressures) sets the limit for the occurrence of serpentinization in nature to low-temperature conditions (i.e., $T < 400$ °C; at low pressures). If all boundary conditions (P-T-X) are suitable, serpentinization causes dramatic changes of the physical and chemical properties of peridotites, i.e., transformation of a dense ($\rho = 3.3$ g cm^{-3}), anhydrous, and weakly magnetic rock into a less dense ($\rho = 2.4$–2.7 g cm^{-3}), hydrous (>12 wt% H_2O), and strongly magnetic rock. In consequence, these changes influence the rheological behavior of the oceanic lithosphere, and the large amount of water contained in serpentinites makes them an important aspect of the global water cycle. Furthermore, hydrogen produced during serpentinization plays an important role for life in the deep sea. These various aspects underline that serpentinization is a critical process that acts at the interface between the lithosphere, hydrosphere, and biosphere.

Geological setting of serpentinization in the marine environment

In marine environments, serpentinization occurs where fractures or faults allow for seawater ingress into the oceanic crust to reach ultramafic rocks (Figure 1). Oceanic fracture zones, transform faults, and detachment faults facilitate serpentinization at constructive plate boundaries. At convergent plate boundaries, serpentinization is associated with bending-related faults as well as in the supra-subduction mantle wedge. Finally, serpentinites are found at nonvolcanic continental rifted margins, where peridotites have been emplaced during continental rifting in the earliest oceanic crust or stretched continental crust. Many insights into serpentinization processes are derived from outcrops in ophiolite complexes, where serpentinized rocks are mantle peridotites and dunites as well as cumulate dunite in the lowermost ocean crust.

Mid-oceanic ridge spreading centers

Intermediate- and fast-spreading centers are magmatically robust and feature a layer-cake crustal architecture, consisting of a 6–7 km thick succession of gabbros, sheeted dikes, and lavas. This mafic crust does not serpentinize and protects the underlying ultramafic rocks from reaction with seawater. With the exception of sparse fracture zones and in the Hess Deep, a tectonic window at the intersection of the East Pacific Rise and the Cocos-Nazca spreading center, serpentinization is uncommon where spreading rates exceed 50 mm year^{-1} full rate.

At slower spreading rates, however, lithospheric extension is largely accommodated by tectonic processes and magmatism may be episodic. Depending on the magma budget and lithospheric thickness of a slow-spreading center, the extension may be dispersed across many normal faults or it is focused on low-angle detachment faults. The latter commonly lead to the formation of oceanic core complexes, which expose mantle rocks at the seafloor. In recent years more and more exposures of harzburgites and dunites at the seafloor have been found (e.g., Smith et al., 2006), which led Cannat et al. (2010) to suggest that up to 25 % of slow-spreading seafloor consist of ultramafic rocks. Slow-spreading ridges are dissected by numerous large-offset transform faults, which are an

important, albeit understudied, setting where serpentinization is common, because the strike slip faults extend into the lithospheric mantle and tectonic movement facilitates seawater ingress. A prominent example is the Vema fracture zone in the Atlantic Ocean, where flexural uplift of the oceanic plate in a transverse regime generates suitable conditions for deep fluid ingress and serpentinization of mantle rocks (Bonatti et al., 1971; Melson and Thompson, 1971; Bonatti et al., 2005). This strong segmentation is missing along some ultraslow-spreading ridges (full rates <18 mm year^{-1}), where long stretches of amagmatic spreading with abundant serpentinite at the seafloor are separated by large volcanic centers (Dick et al., 2003).

Both slow- and ultraslow-spreading centers feature hydrothermal activity, which is hosted in basaltic or ultramafic rocks. Some of these systems are clearly related to magmatic activity, but abundant hydrothermal activity has also been documented for the amagmatic and ultraslow-spreading SW Indian Ridge 10–16°E (Bach et al., 2002), the Gakkel Ridge in the Arctic Ocean (Edmonds et al., 2003), and the Cayman Trough (German et al., 2010).

While the structural controls on venting along ultraslow-spreading ridges are to be revealed, there appears to be a relation between detachment faulting and hydrothermal vent distribution in slow-spreading segments. McCaig et al. (2007) proposed that fluids emanating from black smokers in hydrothermal systems are focused along the low-angle detachment faults, allowing for occurrence of hydrothermal vent fields far away from magmatically active zones.

Convergent plate boundaries

At convergent plate boundaries, serpentinization and deserpentinization (i.e., breakdown of serpentine and brucite to olivine) processes are intimately linked. Serpentinization occurs at the trench where the incoming lithospheric plate bends down prior to subduction (Figure 1). This flexure causes the development of bend faults, which can extend down to 20 km off Costa Rica (Ranero et al., 2003; Grevemeyer et al., 2005). These faults provide pathways for seawater ingress and serpentinization of the mantle. Although direct sampling of this system is currently not possible, geophysical measurements provide insights into hydration of mantle rocks in the subduction trench area. Furthermore, serpentinized peridotites have been recovered from several non-accretionary convergent margins (e.g., the Puerto Rico trench and the Tonga trench). Serpentinites in these areas may have been exposed due to deep faulting during initiation of the subduction zone, or they represent sheared-off and exhumed portions of the subduction channel. When the hydrated slab experiences increased pressure and temperature conditions in the subduction zone, partial deserpentinization takes place. At higher temperatures, the fluids released from the downgoing slab can trigger mantle wedge melting and thus arc volcanism; at lower temperatures serpentinization takes place in the mantle wedge (e.g., Fryer, 2002). Subduction of serpentinites is critical in the Earth's water cycles, as it keeps the mantle viscosity low and sustains mantle convection (Rüpke et al., 2004).

Insights into serpentinization in subduction zone settings have been gained by studies of serpentinites recovered from mud volcanoes in forearc regions (e.g., the Izu Bonin/Mariana arc system). There, the involvement of slab-derived fluids in serpentinization is reflected in the stable isotope composition of serpentinite clasts (Alt and Shanks, 2006) and the composition of fluids issuing from the mud volcanoes (Mottl et al., 2004).

Nonvolcanic continental rifted margins

The occurrence of ultramafic rocks in passive margin settings is explained with tectonic movements during continental breakup and subsequent development of an oceanic spreading center. Serpentinites occurring at continental rifted margins generally represent parts of the subcontinental lithospheric mantle that have been emplaced due to low-angle detachment faulting (e.g., Lavier and Manatschal, 2006). Whether emplacement of serpentinites as diapiric bodies can occur in this setting is under debate. In the case of the Iberian abyssal plane, it has been observed that shearing and uplift occurred prior to serpentinization. Sediment pore waters were involved in the serpentinization reactions (Sharp and Barnes, 2004); the fully serpentinized rocks show unusual hydrogarnet- and diaspore-bearing assemblages (Beard and Hopkinson, 2000). Sulfur isotope studies of serpentinites from the Iberian abyssal plane reveal that sulfate-reducing bacteria formed some of the pyrite found in veins, indicating the presence of a deep serpentinite-hosted biosphere (Alt and Shanks, 1998).

Ophiolite complexes

Ophiolites are remnants of oceanic lithosphere that are obducted onto continental margins. Outcrops in ophiolite complexes have contributed to our understanding of the architecture of the oceanic lithosphere. Prominent examples are the Semail ophiolite in Oman, the Troodos massif in Cyprus, and the Josephine ophiolite in the USA. Although serpentinization is commonly observed in the exposed lithospheric mantle, the process of serpentinization did not necessarily take place under in situ conditions. Serpentinization might well have occurred during or after obduction, possibly involving meteoric waters under comparatively low temperature (e.g., Neal and Stanger, 1985; Harper et al., 1988). Therefore, examination of ophiolites cannot fully substitute observations made in in situ oceanic lithosphere.

Mineralogical and geochemical changes during serpentinization

The interaction of seawater and peridotite, which consists mainly of olivine of forsterite-rich composition, can be described by the following simplified exothermic mineral reaction:

$$\text{Mg}_{1.8}\text{Fe}_{0.2}\text{SiO}_4 + 1.37\,\text{H}_2\text{O} = 0.5\,\text{Mg}_3\text{Si}_2\text{O}_5(\text{OH})_4 + 0.3\,\text{Mg(OH)}_2 + 0.067\,\text{Fe}_3\text{O}_4 + 0.067\,\text{H}_2$$
$$\text{Olivine} \quad + \quad \text{H}_2\text{O} \quad = \quad \text{Serpentine} \quad + \quad \text{Brucite} \quad + \quad \text{Magnetite} + \text{H}_2 \tag{1}$$
When rocks are undeformed, olivine is pseudomorphously replaced by the secondary mineral assemblage, which builds up an hourglass or mesh texture. Such a mesh is bordered by magnetite inwards followed by serpentine (mostly lizardite) and eventually a relict of olivine in the mesh center (see Figure 2a, b). Brucite is not always present, but may form at the interface between olivine and serpentine or is intergrown with serpentine. Primary pyroxenes of the ultramafic precursor rock also undergo serpentinization:

$$3\,\text{Mg}_2\text{Si}_2\text{O}_6 + 3\,\text{H}_2\text{O} = \text{Mg}_3\text{Si}_2\text{O}_5(\text{OH})_4 + \text{Mg}_3\text{Si}_4\text{O}_{10}(\text{OH})_2$$
$$\text{Orthopyroxene} + \quad \text{H}_2\text{O} = \quad \text{Serpentine} \quad + \quad \text{Talc(simplified reaction in an Fe} - \text{free system).} \tag{2}$$
Pseudomorphic replacement textures of pyroxenes (in rare cases also of amphibole or phlogopite) are referred to as bastite (Figure 2c, d). Bastites typically lack magnetite, but often also do not contain talc. This indicates that Mg and Si can be exchanged across local domains. Silica may react with brucite in adjacent mesh textures to form additional serpentine, explaining why serpentinized harzburgites rarely contain talc.

Apart from the aforementioned replacement textures, serpentine can also form veins of variable thickness (μm to cm) crosscutting serpentinites (Figure 2e, f). They consist of fine-fibrous serpentine and have been interpreted as evidence for volume expansion related to serpentinization (e.g., Andreani et al., 2007).

Unlike in the simplified mineral reactions given above, the product phases serpentine and brucite are typically not Mg end-members; they contain some iron, which results in a smaller amount of magnetite being formed. Magnetite contains both divalent and trivalent iron, and the amount of primary Fe^{+2} that is oxidized to secondary Fe^{+3} in magnetite determines the amount of hydrogen produced. With decreasing serpentinization temperature successively more Fe-rich brucite and serpentine are formed and the amount of magnetite decreases. However, ferric iron in serpentine can also cause the release of hydrogen, although the yields are lower than in magnetite-pulled hydrogen production (Klein et al., 2009). Recent field, experimental, and spectroscopic work has provided evidence for a lack of magnetite and the existence of serpentine rich in ferric iron (Evans et al., 2009; Andreani et al., 2013).

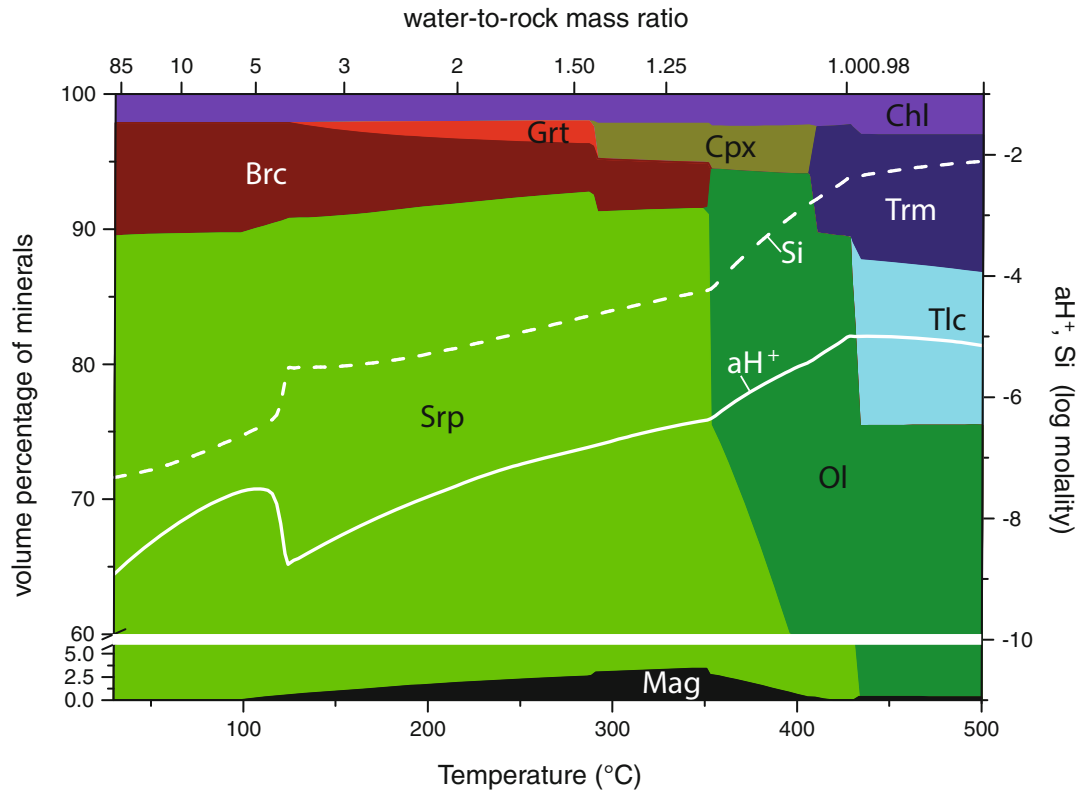
Geochemical reaction path models have been employed successfully in examining the reaction sequence during serpentinization in the course of decreasing temperatures and water-to-rock ratios (e.g., Klein et al., 2009; McCollom and Bach, 2009). The isobaric (1 kbar) model presented in Figure 3 predicts that olivine is stable (bar minor reaction to talc and magnetite) at $T > 430\,°C$, where ortho- and clinopyroxene are expected to be completely replaced by tremolite, talc, and magnetite. Serpentine appears just below 430 °C, initially from breakdown of olivine, talc, and magnetite. Below 415 °C, olivine reacts with dissolved silica to produce serpentine and magnetite. Tremolite gives way to secondary clinopyroxene and serpentine at $T < 405\,°C$. Below 350 °C, brucite is stable, and olivine is predicted to be consumed by serpentine and brucite. The strongly decreasing silica activities associated with the olivine-out reaction stabilize magnetite (Frost and Beard, 2007) and generate driving force for hydrogen production (Klein et al., 2009).

Below about 290 °C, grossular-rich hydrogarnet is predicted to replace secondary clinopyroxene. In the course of continued cooling and intensified water flux, magnetite should decrease in abundance at the expense of increasing Fe contents in the hydrogarnet and brucite. Below 100 °C, magnetite is no longer stable in serpentinites. The thermodynamically stable assemblages at the lower-temperature end of the reaction path do form occasionally, but clinopyroxene and magnetite are often preserved due to kinetic inhibition of the reactions. The metastable diopside-brucite-serpentine assemblage accounts for the exceptionally high pH and high Ca concentrations in many serpentinization fluids.

Spinel rich in chromite (FeCr_2O_4) is an accessory primary mineral commonly contained in oceanic serpentinites. Under typical P-T-fluid conditions of serpentinization, chromite is comparatively unreactive and therefore preserved even in completely serpentinized peridotites. Furthermore, Fe-Ni-Co sulfide minerals as well as native metals and alloys are commonly found, e.g., pentlandite ([Fe, Ni]$_9$S$_8$), awaruite (Ni$_3$Fe), Heazlewoodite (Ni$_3$S$_2$), and wairauite (CoFe). Their
Serpentinization, Figure 2 Microtextures of serpentinites. (**a**, **b**) Partially serpentinized harzburgite showing olivine relicts in centers of a mesh texture. Olivine breaks down to form serpentine and magnetite. (**c**, **d**) Serpentine as breakdown product of former orthopyroxene, forming a bastite texture. The bastite is almost magnetite free. (**e**, **f**) Serpentine forming a vein crosscutting a serpentinized harzburgite. A vein-parallel zonation points to multiple crack openings and polystage serpentine growth. Figures (**a**, **c**, and **e**) taken under plane-polarized light; (**b**, **d**, and **f**) under cross-polarized light.

occurrence is a result of the strongly reducing nature of the serpentinization fluids (Frost, 1985; Klein and Bach, 2009). Completely serpentinized rocks have exhausted their reducing capacity and may contain polysulfides (pyrite, FeS_2; vaesite, NiS_2; cattierite, CoS_2) and thiospinels (polydymite, Ni_3S_4; violarite, $FeNi_2S_4$), indicative of higher oxygen and sulfur fugacities. Other minerals that are occasionally reported are iowaite (Mg_4Fe $[OH]_8OCl \times 2$–$4\ H_2O$), calcite, aragonite, and dolomite.

These minerals, however, require addition of chemical constituents such as Ca, Cl, or CO_2, whereas serpentinization sensu stricto is defined as a pure hydration process.

The major chemical change due to serpentinization is the addition of water. The whole-rock geochemical composition of abyssal serpentinites therefore has a strong control on the abundance of secondary phases in serpentinites. The composition of mantle peridotites is


Serpentinization, Figure 3 Predicted modal abundances of a mantle peridotite (80 % olivine, 15 % orthopyroxene, 5 % clinopyroxene; see Klein et al., 2009 for details) that underwent reaction with seawater at a pressure of 1 kbar. The influx of seawater will cool the system, and hence temperature and water-to-rock rations are inversely correlated in the model. Note that the reaction of olivine and water to serpentine and brucite causes a marked decrease in silica activity.

affected by the degree of mantle melting and melt extraction as well as melt-refertilization (Niu, 2004). The consequences of modal variability of abyssal ultramafics and the addition of melts have been investigated by Klein et al. (2013) and Jöns et al. (2009).

Serpentinites exposed at the seafloor are not stable and weathering reactions will dissolve brucite and turn relict olivine into clay and iron-oxyhydroxide (iddingsite). Serpentine is often preserved metastably, but may be partially replaced by talc and calcite in heavily weathered serpentinites.

Related rock types

The thick lithospheric mantle underneath slow-spreading ridges features large gabbroic bodies and dikes of variable thickness. Soapstones (monomineral talc rocks, also known as steatites) form when seawater-derived fluids equilibrated with gabbro encounter serpentinite. In contrast, rodingites (Ca-metasomatized gabbros) form when serpentinization fluids react with gabbroic rocks. These metasomatic rocks are common in abyssal serpentinite massifs, and the abundance of talc at the interface between large gabbroic bodies and hosting mantle rock constitutes a discrete zone of mechanical weakness that may play

a role in the tectonic exhumation of oceanic core complexes (Ildefonse et al., 2007).

Serpentinization, hydrothermal vents, and life

Ultramafic-hosted hydrothermal systems in the deep sea are below the zone where photosynthesis provides energy to make life possible. Instead, chemosynthetic microbial organisms gain metabolic energy from hydrogen contained in hydrothermal fluids (cp. Reaction 1) and use this energy to produce biomass. Consumption of the biomass by higher organisms is the basis for establishment of complex food webs that are independent of photosynthesis. The presence of hydrogen also promotes abiotic formation of methane and other hydrocarbons, and it has been speculated that the early development of life on the Earth took place under similar conditions.

Known deep-sea hydrothermal vents hosted in serpentinite comprise high-temperature (350–370 °C) systems such as Logatchev (MAR 14°45′N) or Rainbow (MAR 36°14′N), and the low-temperature (90–110 °C) Lost City Hydrothermal Field (MAR 30°N). Hydrogen and methane provide most of the energy for microbial metabolism in all these systems, with reduced metals being another energy source in the acidic hot fluids (Amend et al., 2011).

The less hot fluids from Lost City are alkaline and low in metal concentrations (Kelley et al., 2001). The Lost City system features spectacular carbonate-brucite chimneys that are up to 60 m tall. Lost City is situated on top of an oceanic core complex, and the hosting rocks reveal a multistage, coupled tectonic and metamorphic history (Boschi et al., 2006). Geochemical and geochronological studies show that the systems have been active for >30,000 years (Früh-Green et al., 2003). The seawater-like isotopic compositions indicate that the carbonates form in response to venting of the highly alkaline fluids (pH 11).

The serpentine mud volcano vents in the Mariana forearc feature even more extreme compositions with pH ranging up to 12.5 (Mottl et al., 2004). Serpentinization fluids are strongly enriched in H_2, and dissolved CO_2 is no longer thermodynamically stable. Reduction of CO_2 leads to the abiotic generation of alkanes and organic acids (Proskurowski et al., 2008; Lang et al., 2010).

The organisms that inhabit these serpentinization systems are specifically adapted to the energy and carbon sources available (Takai et al., 2005; Perner et al., 2007; Petersen et al., 2011). Because of the unique capacity for reducing CO_2 and the highly alkaline nature of the vent fluids, serpentinization systems are believed by some to resemble hydrothermal systems in which life may have developed on Earth and perhaps other planetary bodies (Martin et al., 2008).

Societal relevance of serpentinites

More than half of the world's Ni resources are bound in Ni-bearing regoliths/laterites, which originate from intensive weathering of serpentinites under tropical humid conditions. While the precursor rocks – olivine-rich ultramafic rocks – contain less than 0.5 wt% Ni, enrichment to >5 wt% Ni is observed during regolith formation and lateritization. Nickel is hosted in either oxide minerals (limonitic ore) or hydrous Mg silicates (e.g., népouite, kerolite, garnierite) or clay silicates (nontronite, saponite; for details, see Butt and Cluzel, 2013). Additionally, these ores are important cobalt deposits. Furthermore, starting in the nineteenth century, serpentinites were intensively mined for asbestos, thin fibrous forms of serpentine and amphibole. Asbestos was used as electrical and thermal insulators and building material until the late 1980s. Already in the 1930s, asbestos-related diseases were reported, and nowadays, the use of asbestos is banned due to serious health concerns (causing mesothelioma and asbestosis). Talc and magnesite are other mining products from metasomatized portions of serpentinite bodies on land.

The replacement of serpentine and olivine by carbonate is a process predicted to take place at low temperatures and low CO_2 contents of the interacting fluid (e.g., Klein and Garrido, 2011). Because the carbonation reactions are expected to proceed rapidly at moderate temperature and create permeability, ultramafic rocks have been proposed as possible site for CO_2 storage (Kelemen and Matter, 2008).

Summary and conclusions

Serpentinization is a common process in marine environments and is of both environmental and societal relevance. In abyssal peridotites, olivine is replaced by lizardite or chrysotile, which might be intergrown with brucite. Magnetite and hydrogen are important by-products of serpentinization. The mineralogical transformations during serpentinization cause dramatic changes in the mantle rock physical properties, which have important implication for tectonic processes. The chemical exchange with seawater makes serpentinization an important part of the global cycles of water and solutes. Serpentinization-related hydrothermal systems in the deep sea harbor abundant microbial life, which is intimately linked with serpentinization reactions. Some major ore deposits nowadays mined on land trace back to serpentinization processes in the marine environment, and there is potential future relevance of peridotites and serpentinites for sequestering CO_2. In summary, serpentinization occurs at the interface between the lithosphere, hydrosphere, and biosphere and is demonstrably one of the most important hydration processes on Earth.

Synonyms

Continental shelf; island shelf

Definition

In marine science, a "shelf" is a shallow underwater extension of a land area, either a continent "continental shelf" or large island "island shelf."

The first use of the term "continental shelf" appears to have been by Hugh Robert Mill in his 1888 publication titled "Sea-temperatures on the continental shelf": "The term "continental shelf" is applied to the shallow portion of the continental slope, lying within the 100-fathom line, which is usually terminated seawards by a very abrupt descent to abyssal soundings." This definition has generally been followed but restated in various forms:

1. The relatively shallow belt of sea-bottom bordering a continental mass, the outer edge of which sinks rapidly to the deep ocean-floor (*Oxford English Dictionary*)
2. The extended perimeter of each continent and associated coastal plain (Wikipedia)
3. A submerged border of a continent that slopes gradually and extends to a point of steeper descent to the ocean bottom (Free Online Dictionary)

4. A shallow submarine plain of varying width forming a border to a continent and typically ending in a comparatively steep slope to the deep ocean floor (Merriam-Webster)
5. The edge of a continent that lies under the ocean (National Geographic)
6. The sea bed surrounding a continent at depths of up to about 200 m (100 fathoms), at the edge of which the continental slope drops steeply to the ocean floor (*Collins English Dictionary*)

The United Nations' Law of the Sea Treaty Article 76 gives a legal definition of the "continental shelf" in very different terms, largely unrelated to its geomorphological-physiographic definition (http://www.un.org/Depts/los/convention_agreements/texts/unclos/part6.htm).

History

Knowledge of the configuration of the ocean floor was very limited before the middle of the nineteenth century. Depth soundings were made by "lead line" with a heavy weight at the end of a rope or wire, sensing the change when the weight touched the bottom. However, at water depths greater than a few hundred fathoms, it became impossible to determine when the weight had reached the bottom. It was the laying of the first telegraph cables across the Atlantic that provided insight into the nature of the boundary between the continent and deep ocean.

Because of the time and difficulty of making soundings by lead line, progress in mapping the seafloor was slow until the development of SONAR (*SO*und *N*avigation *A*nd *R*anging). The idea of using sound arose as a means of detecting icebergs after the sinking of the Titanic in 1912. It was rapidly developed as a means of detecting submarines during World War II, but it incidentally provided information on depths of the seafloor and detected the presence of the flat-topped submarine mountains known as "*guyots*" in the Pacific, one of the first clues to the mobility of the seafloor. After the war, SONAR became a means of mapping the ocean floor, at first for Cold-War military purposes (Doel et al., 2006). Although the developing knowledge of the detailed bathymetry, primarily by the United States and Soviet Union, was secret, Bruce Heezen and Marie Tharp, at Lamont Geological Observatory in the United States, devised a method of producing a physiographic depiction the data that was allowed to be published. The first detailed maps showing the edges of the continental shelves on both sides of the North Atlantic as marked by the break in slope were made by Heezen and Tharp and were published in Elmendorf and Heezen (1957) and Heezen et al. (1959). Although known best for its graphic depiction of the ocean floor, the map showed that the edges of the continental shelves, marked by the shelf breaks on the US North American and African margins, fitted together much better than the shorelines used by Alfred Wegener in developing his theory of continental drift. At the time Heezen favored the

Shelf, Table 1 Areas of shelves to the break in slope along the margins of oceans bordering continents, on fragments of continental crust, and in marginal seas. The areas of major epicontinental seas, representing flooding onto the continental blocks, are also shown (After data from Hay and Southam 1977)

Continental margin shelves	Area (10^3 km^2)	Island margin shelves	Area (10^3 km^2)	Marginal sea shelves	Area (10^3 km^2)	Epicontinental seas	Area (10^3 km^2)

idea of an expanding Earth, and this was seen as supporting evidence.

Detailed publicly available mapping of the continental shelves varies from region to region because of coastal states proprietary economic and military interests. The GEBCO (General Bathymetric Chart of the Ocean) sheets generally show only a 100 m contour in the shelf regions, but in a few areas, shallower contours are also shown. Much more detailed information is available in the ETOPO5 global elevation model data set (US NOAA National Geophysical Data Center [NGDC] Marine Geology & Geophysics Division), and Google Earth includes several large data sets of seafloor depths. There are many local and regional studies of the continental shelves, but the only comprehensive basin-wide account is that of Emery and Uchupi (1984) in "The Geology of the Atlantic Ocean."

The geologic basis for the continental and island shelves

Continental shelves are, by definition, subsea extensions of the peripheries of the seven continents. Geologically, they represent the regions over continental crust thinned by erosion during uplift early in the process of rifting to form passive margins as the continents separated. The average width of the thinned crust is of the order of 130 km; the average width of the subsea portion, the continental shelf, is 70 km. As subsidence has occurred with drifting, they have accumulated thickness of several kilometers of sediment; in the Atlantic margins, these are typically 4–8 km thick. Oceanward slope of the shelf is of the order of 1–2 m/km, but some areas may be flat or have

local relief of up to 18 m reflecting sand waves, megaripples, sand ribbons, furrows, and scour. Continental shelves are much narrower along active margins, such as those around the Pacific, and typically have only thin accumulations of sediment. However, back-arc seas along active margins, such as the East and South China Seas, may have broad shelves and thick accumulations of sediment. Also, although not continents, the shelves of large islands, such as Iceland, New Zealand, and Kerguelen, and carbonate banks, such as the Bahamas, are often included in discussions of continental shelves, sometimes as "island shelves." In some areas, continental shelves merge inland with low-lying areas of the interior of the continental block that are flooded as shallow marginal seas: the Baltic Sea, Hudson Bay, the North Sea/English Channel, Arafura Sea/Gulf of Carpentaria, Gulf of Thailand, etc. The areas of continental shelves, marginal seas, and carbonate banks are indicated in Table 1.

Along passive margins, the regions over thinned crust extend inland as coastal plains. At present these are generally less wide than the submerged shelf, but during glacial maxima the coastal plains extended to the shelf edge in many areas. The shoreline is an almost arbitrary divide between the coastal plain and continental shelf and is typically in motion, moving inland or seaward in response to ongoing isostatic adjustment, wave action, sea-level rise or fall, the detrital sediment supply from rivers, and carbonate deposition. Similarly, the depth of the oceanward limit of the continental shelf, the shelf break, varies according to the balance between sediment supply and subsea erosion by waves and currents. Figure 1 shows the varying widths and depths of the shelf break along

the classic passive margins of the Atlantic. There is great variability on both sides of the Atlantic, but as a gross generalization, the shelves are wider and the shelf breaks deeper in high latitudes and narrower and shallower in low latitudes. This is due to the state of postglacial isostatic readjustment, sediment supply, and carbonate content of the sediments. Although there may be local pockets of carbonate shell debris at high latitudes, the carbonate content of the sediment generally increases from minimal amounts (isolated shells) at high latitudes to >30 % about 35°N and S and may approach 100 % between 20° N and S. At lower latitudes most of the carbonate is aragonite, produced by algae. It is converted to calcite upon exposure to fresh water during sea-level falls and becomes cemented into a solid layer unaffected by waves and current.

Figure 1 also shows that the original choice of 100 fathoms (∼200 m), a typical depth of the shelf break off Scotland included in many definitions, is abnormally deep. The average shelf break depth in the Atlantic is 122 m (Emery and Uchupi, 1984). The global average for the shelf break is variously given as 133 m (*Encyclopedia Britannica online*) and 167 m (Brown et al., 1989).

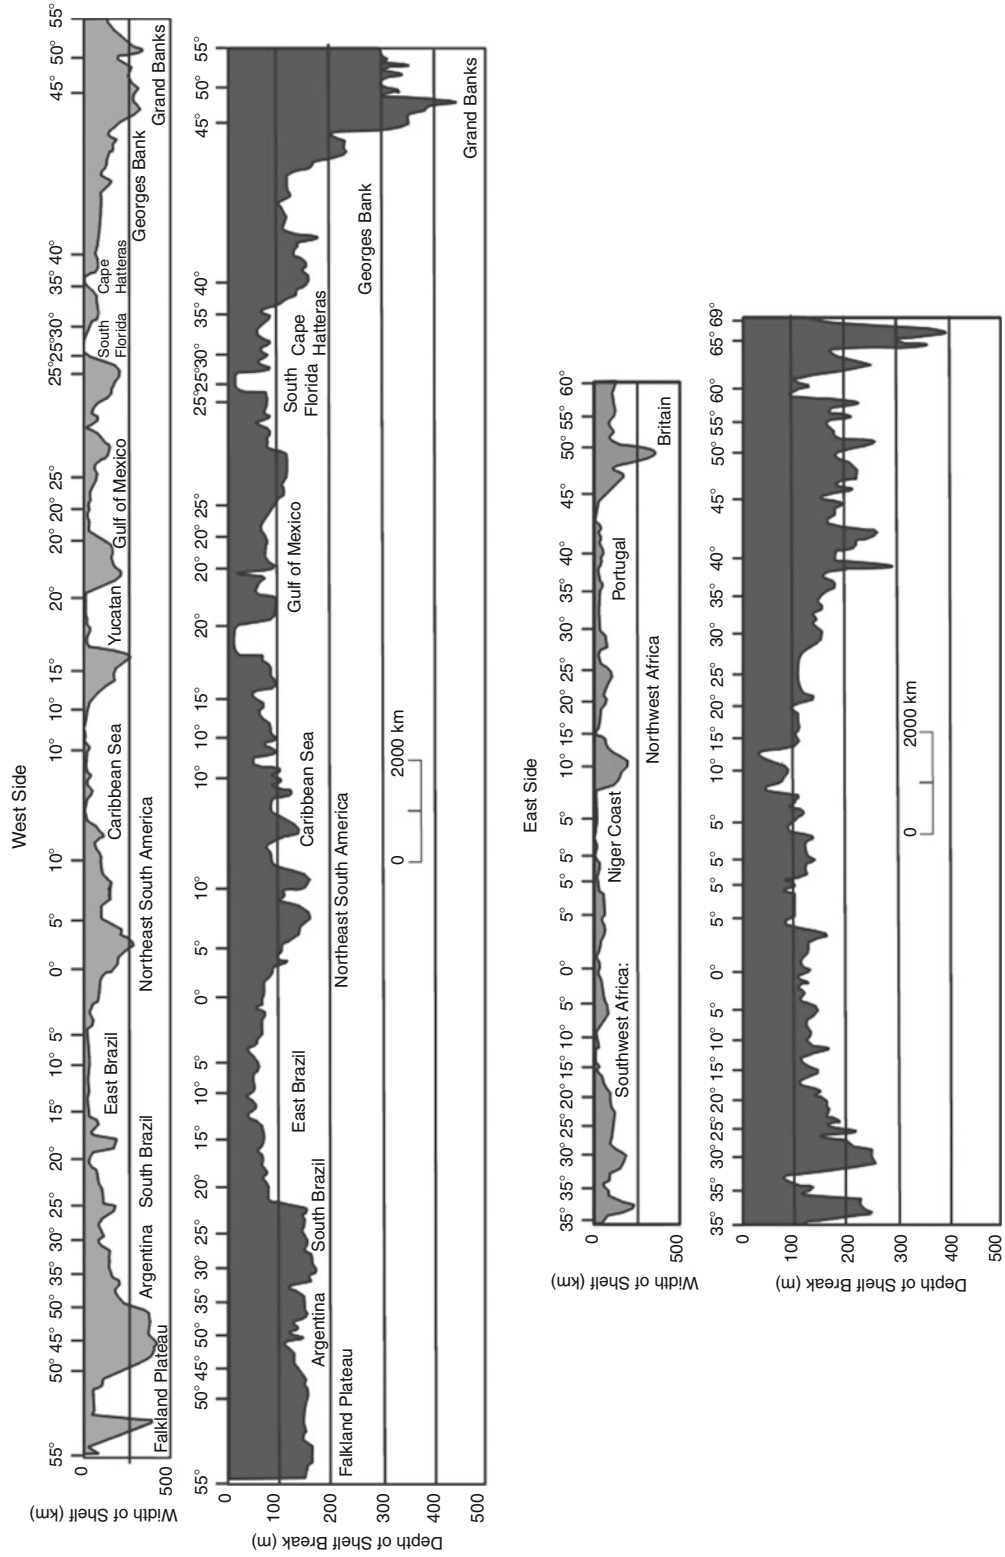
The shelves are narrowest where rivers supply sediment and build up deltas which have surfaces above sea-level and where they are the margins of carbonate banks now land (e.g., South Florida, Yucatan). They are widest where estuaries and bays extend inland. Similarly, the shelf break is shallowest off large rivers and deepest where there is no nearby sediment source.

Antarctic shelves are different from those of the rest of the world. The shelf breaks are very deep, 400–800 m, and the slope is downward toward the ice-covered continent.

What controls the configuration of the continental shelf?

The examples cited here are from the Atlantic, the most classic passive margin region, described in detail by Emery and Uchupi (1984):

1. Original width of thinning of continental crust. The pull-apart separations between the east coast of the United States and northwest Africa and between South America south of the eastern tip of Brazil and southern Africa south of the Niger Delta occurred about 180 and 130 Ma, respectively. The separation between the northeast coast of South America east of the Amazon and the Ivory Coast of Africa occurred along a transform fault about 130 Ma, with much less thinning of the adjacent continental blocks. All of these are now "old" slowly subsiding margins. Shelves along the pull-apart margins are typically 100 km wide; those along the transform margin are much narrower, only about 25 km wide.
2. Detrital sediment supply. Rivers act as point sources for sediment which can then be redistributed by wave and current action. Globally, the total sediment supply by rivers is larger than can be accommodated in the space available on shelves, but it is very unevenly distributed. Some areas are oversupplied, others sediment starved. Where the local sediment supply is very large, as in the case of the Mississippi, Niger, or Ganges/Brahmaputra complex, the river's delta may extend the shelf edge. However, if there are strong coastal currents, as in the case of the Amazon, the water with its sediment load can flow out into the ocean as a plume and deposit its load over broad areas in the deep sea.
3. Carbonate deposition. Where there is no detrital sediment supply, as in southern Florida and Yucatan, the continental margin resembles a carbonate bank. Carbonate banks accumulate sediment until they are typically only a few meters below sea-level highstands. Because the sea-level highstand of the last interglacial was about 10 m higher than today, some of the carbonate areas are exposed as land today with only a narrow flooded fringe, a very shallow (20 m) shelf edge break, and a very steep continental slope.
4. Wave action. Where the water depth is less than half the wavelength, wave motion affects the bottom sediment and can cause detrital particles to be brought into suspension. Below the littoral zone between the shore and depths of 10–20 m where waves continuously perturb the bottom sediment, it is storm waves that periodically cause sediment to be set in suspension. Once suspended, the sediment can be carried by tidal or other currents on the shelf and redeposited. However, although not yet well documented, it is possible that the depth of the edge of detrital shelves is controlled by the persistent swell coming from distant sources. Swell typically has wavelengths of 300–600 m and so can set sediment at depths of 150–300 m into suspension. The most active region generating swell is the Circum-Antarctic, where the constant westerly winds force a circum-global current unobstructed by land and the fetch is so long that huge waves can develop. The swell generated in this region extends throughout the Pacific Basin, but in the Atlantic is restricted by the S-shaped configuration of the basin. The Antarctic shelf margin is covered by cobbles and boulders rather than sand and clay.
5. Currents. Shelf seas are characterized by persistent longshore currents and short-term tidal currents. Tidal currents onto and off the shelves are not symmetrical either in terms of velocity or location. They can move the sediment suspended by storm waves and cause it to redeposit far from its original site. Similarly, shelf currents can redistribute sediment.

One of the peculiarities of some shelf seas, but particularly the Middle Atlantic Bight, the eastern Bering Sea, Norwegian Sea, Celtic Sea, and along the margin of Southern Australia, is that the shelf waters are separated from those of the open ocean by a frontal system tied to the shelf break (e.g., Gawarkiewicz and Chapman, 1992; Condie, 1993). This separates the muddier "brown" waters of the shelf from the blue waters of the


Shelf, Figure 1 Width and depth to the shelf break of shelves along the margins of the Atlantic Ocean (after Emery and Uchupi, 1984).
Shelf, Figure 2 The present continental shelf in the context of the Quaternary rises and falls of sea-level. In lower latitudes the modern shelf is almost completely isostatically adjusted to the deglacial flooding, but at higher latitudes near the centers of glaciation isostatic adjustment continues. The rapidity of sea-level change is such that the shelves are always out of adjustment during rises and falls (after Hay and Southam, 1977).

open ocean and inhibits transport of suspended sediment beyond the shelf break.

6. Sea-level. High sea-level stands like that of the modern interglacial are characteristic on less than 10 % of the past few million years. Similarly the extreme lowstands are characteristic of only relatively brief periods of time. Water depths change not only because the global sea-level rises and falls, but in response to isostatic adjustment due to water and ice loading and unloading. The most rapid sea-level changes are in excess of 45 mm/year over times of several thousands of years, whereas isostatic response requires many thousands of years. Hay and Southam (1977) analyzed the effects of water and sediment loading and unloading during glacials and interglacials and concluded that the present shelf slope is adjusted to sea-level lowstands. During those Quaternary lowstands, sediment would have been eroded off the shelves and deposited in the deep sea. As sea-level has risen since the last glacial, the shelf has been depressed by the load of water. However, both the highstands and lowstands are brief; sea-level is usually moving upward or downward with isostatic adjustment following. The average sea-level over the past half million years was about −60 m relative to that of today.

The effects are summarized in Figure 2.

Hay and Southam (1977) noted that when the glaciations began and sea-level fell, the shelves would be eroded and reach a new equilibrium state. They concluded that the detrital sediment supply from rivers during the brief highstands could not rebuild the shelves to their original

height and that the present configuration of the shelves is in equilibrium with sea-level lowstands. Their estimate of the original surface, prior to the onset of the Northern Hemisphere glaciations, is shown in Figure 2. The slope on the shelf would be slightly less than that of the adjacent coastal plain. This would reflect the lesser angle of repose of sediment underwater compared to that of drier sediment above water.

Summary

A "shelf" is a shallow underwater extension of a land area, either a continent "continental shelf" or large island "island shelf." Most shelves represent the heavily sedimented regions over continental crust thinned by erosion during uplift early in the process of rifting to form passive margins as the continents broke up. The configuration of the shelf is determined by subsidence rate, sediment supply, waves and currents, and rises and falls of sea-level.

SILICA

Paul Treguer
European Institute for Marine Studies (IUEM), University of Bretagne Occidentale (UBO), Plouzané, France

Silicon is the seventh most abundant element in the universe and the second most abundant element in the Earth's crust. It is a key nutrient element in the ocean, required for the growth of diatoms and some sponges and utilized by radiolarians, silicoflagellates, several species of choanoflagellates, and potentially picocyanobacteria. The world ocean silica cycle has been recently updated by Tréguer and De La Rocha (2013) who described and quantified source and sink fluxes.

Four pathways serve as external sources of silicic acid (also called dissolved silica, DSi) to the ocean, all of which ultimately derive from the weathering of Earth's crust. DSi from the chemical weathering of continental rocks is discharged into the coastal zone by rivers and groundwater. Rivers also transport significant quantities of particulate amorphous silica that may dissolve, as may dust deposited on the ocean's surface. Lastly, terrigenous silicates in sediments of continental margins may dissolve, and submarine basalts react with high- and low-temperature hydrothermal fluids, releasing DSi. The total net input of DSi to the ocean is 9.4 ± 4.7 T ($=10^{12}$) mol Si year^{-1}.

The permanent removal of silicon from the water column of the ocean occurs mostly via the burial of biogenic silica in sediments. Abiotic precipitation of amorphous silica can occur in hydrothermal vent plumes, and authigenic aluminosilicate formation may occur in sediments, but these two processes support minor export fluxes compared with biogenic silica burial. Siliceous sponges might also act as a significant silica sink, at least regionally. The total net output of biogenic silica to the ocean is 9.9 ± 7.3 T mol Si year^{-1}.

The overall residence time for silicon in the ocean (τ_G) is equal to the total amount of DSi in the ocean (97,000 T mol Si) divided by the net input (or output) flux. The updated budget suggests a mean residence time of approximately 10,000 years. The residence time relative to biological uptake of DSi (τ_B) from surface waters is calculated by dividing the total DSi content of the world ocean by gross silica production by diatoms (240 T mol Si year^{-1}) and sponges (3.7 T mol Si year^{-1}): τ_B is approximately 400 years. The difference between τ_B and τ_G implies that silicon delivered to the ocean passes through the biological uptake and dissolution cycle an average of 25 times [(240 + 3.7)/9.9] before being removed to the seabed.

SOURCE ROCKS, RESERVOIRS

Rüdiger Stein
Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research (AWI), Bremerhaven, Germany

Definition

A *source rock* is any type of rock that may generate hydrocarbons in the future, depending on the amount of organic matter present and adequate temperature and pressure conditions at a specific burial depth as well as sufficient time to reach the needed maturity. A good source rock should have a total organic carbon (TOC) content of larger than 1 %. Most prominent source rocks are sapropels and black shales but also TOC-rich carbonate rocks.

Reservoir rocks are rocks that have sufficient porosity and permeability to store and transmit fluids and gas. Typical reservoir rocks are sandstones and carbonate rocks.

"Source rocks" and "reservoirs" are major components of the *Petroleum System*, consisting of a mature source rock, migration pathway, reservoir rock, trap, and seal (e.g., Tissot and Welte, 1984). For the accumulation and preservation of hydrocarbons, the appropriate relative timing of the formation of these elements is of major relevance.

Source rocks (or organic carbon-rich sediments in general) can be formed under very different environments, including oceans, lakes, deltas, and swamps. In marine environments, organic carbon-rich sediments are especially formed in anoxic basins (such as the modern Black Sea characterized by increased preservation rate due to oxygen deficiency), upwelling areas (characterized by high primary production causing increased marine organic carbon flux), and continental margins with high fluvial input (characterized by increased flux of terrigenous organic matter and high sedimentation rates causing rapid burial and increased preservation). Anoxic environments as well as high-productivity environments allow the accumulation and preservation of a large amount of marine (algae type) of organic matter (kerogen type I and II), resulting in the formation of oil-prone source rocks. Under oxic conditions and in environments with high fluxes of terrigenous organic matter, on the other hand, kerogen type III (originated from higher plants) is predominant, resulting in the formation of gas-prone source rocks.

In Earth's history, the most prominent occurrence of good to excellent source rocks was during Jurassic and Cretaceous times, i.e., during a period with widespread occurrence of regional to global oceanic anoxia and black-shale formation (e.g., Schlanger and Jenkyns, 1976; Stein et al., 1986; Emeis and Weissert, 2009; Jenkyns, 2010; and references therein). More than 50 % of the known petroleum was probably generated from these (dominantly oil-prone) source rocks (Klemme and Ulmishek, 1991; Emeis and Weissert, 2009). The huge deltaic systems such as the Gulf Coast, Niger, and Mackenzie deltas characterized by an enormous supply and accumulation of sediment (including terrigenous – kerogen type III – organic matter) during the Tertiary are further important origins of (predominantly gas-prone) source rocks (e.g., Tissot and Welte, 1984).

Reservoir rocks are rocks that have sufficient porosity and permeability to store and transmit fluids and gas. Typical reservoir rocks are sandstones and carbonate rocks.

SUBDUCTION

Serge Lallemand
Geosciences Montpellier, University of Montpellier, Montpellier, France

Synonyms

Convergent plate boundary; Destructive plate boundary; Plate consumption

Definition

At a convergent plate boundary, one of the plates necessarily passes beneath the other. This process, first termed *subduction* by A. Amstutz in 1951 when discussing the evolution of alpine structures, allows nearly all oceanic lithosphere to be recycled into the mantle. By contrast, only the lower portion of the continental lithosphere (the lithospheric mantle) may, under certain conditions, be transported into the deep mantle. Since the continental crust resists subduction at depths beyond about 100 km due to buoyancy forces, this type of convergence is typically called *collision* and forms an "orogenic" or a "mountain" belt of which the Alps or the Himalayas are classical examples. Subduction zones can generally be traced at the surface of the Earth because they are associated with large earthquakes, active volcanoes, and sometimes mountain building.

Classification

There are two main types of subduction (Figure 1), depending on the nature of the downgoing plate (hereafter called *slab*):

- Oceanic subduction (often just called subduction) when an oceanic plate subducts
- Continental subduction (often just called collision) when a continental plate subducts

Oceanic subduction can last tens or hundreds of millions of years without a significant change in the topography and tectonics in the upper plate, whereas continental subduction, which typically occurs after a period of oceanic subduction, rapidly causes either a plate reorganization or mountain building. Below, we will focus primarily on oceanic subduction processes (see "Orogeny" entry for details on continental subduction).

Each of these subduction types can be divided in two "subtypes" depending on the nature of the overriding plate. The most common situation at a convergent plate boundary is the subduction of an oceanic plate beneath
Subduction, Figure 1 Two types of subduction mainly depending on the nature of the downgoing plate: oceanic subduction, 82 %, and continental subduction, 18 %, modified after Lallemand (1999).

a continental plate (∼67 %, 45,000 km, see entry "Active Continental Margins"). Among the remaining 33 %, the converging continents contribute for about half, i.e., 17 % (11,200 km), of the total, intra-oceanic subduction zones for about 15 % (10,000 km) and continents subducting beneath oceanic plates for only 1 % (600 km) (Lallemand et al., 2005a).

Many other criteria or combinations of criteria have been proposed to describe the wide variety of subduction zones (Jarrard, 1986). The most commonly used, first introduced by Uyeda in 1984, is the opposition between the Chilean-type and the Mariana-type subductions. The Chilean-type is characterized by a young subducting plate with a shallow slab dip, a high degree of interplate coupling, inducing high stresses and producing large earthquakes, mountains, and thus terrigenous sediment supply feeding an accretionary wedge. On the contrary, the Mariana type is characterized by an old subducting plate with a steep slab dip; a low degree of interplate coupling, producing low stresses; and only moderate seismicity, the presence of back-arc extension, and a low topography unable to feed the trench. Despite the correct description of these two end-member subduction zones, Heuret and Lallemand (2005), based on revised global datasets, have shown that some of these associations of parameters are not statistically verified. Those which are statistically verified in modern subduction zones are the combination of upper plate compressional stress (typically Chile), shallow-dipping slabs (less than 50°), and upper plate seaward absolute motion, or, reversely, upper plate extensional stress (typically Mariana), steeply dipping slabs (more than 50°), and upper plate landward absolute motion (Lallemand et al., 2005b). The other characteristics such as plate age, seismicity, or the presence of an accretionary wedge do not show simple correlations.

Distribution on Earth

Ninety percent of the oceanic subduction zones are concentrated around the Pacific Ocean and in Southeast Asia (48,700 km). The rest are distributed in the Atlantic Ocean (5,000 km) and the Mediterranean Sea (1,350 km). This asymmetric distribution at Earth's surface results from the breakup of the Pangaea in Late Paleozoic and Early Mesozoic time accompanied by the rifting of the Atlantic and Indian oceans and the closure of the Tethys and Panthalassa oceans. Because the most rapid subduction rates are presently observed in the Western Pacific and Southeast Asia, Xavier Le Pichon in 1990 (lessons at Collège de France) compared this relatively small region with a huge pit centered on the Philippine Sea where oceanic plates are recycled into the mantle. Subduction rates generally range between 1 cm/year off Sicily, for example, and 10 cm/year off Japan, except in Southwest Pacific where it exceptionally reaches 24 cm/year offshore the northernmost Tonga archipelago.

Distinctive characteristics of subduction zones

The plane forming the interface between converging plates has distinctive properties compared with a "classical" active fault. It accommodates the underthrusting of one plate beneath another. Its dip angle may vary between 10° and 35° for the shallow part which is seismogenic (Heuret et al., 2011), and it can reach 60° in its deepest part. The subduction interface outlines the contact surface between the plates, i.e., from the trench down to the limit with the convecting mantle. The main differences with a "classical" active fault are:

− A great size in both downdip width (typically between one and two hundreds of km) and lateral extent (length between a few hundreds and a few thousands of km).

– A lower thermal gradient along the interface because of the continuous advection of low-temperature rocks (top of subducting plate). The thermal state depends on the age of the incoming plate and the rate of subduction (Stein and Stein, 1996).

– Fluid overpressure along the interface caused by the progressive dehydration of the subducting plate. Fluid pressure at a given depth depends on the available input from the subducting slab, temperature, and pressure that control phase changes and permeability of the rocks of the hanging wall (see review by Saffer and Tobin, 2011).

The great size of the fault and the low temperature increases the seismic potential. This is the reason why all giant earthquakes occur at subduction zones. When the subducting plate is old and the subduction rate is fast (e.g., below Japan), the subducting plate is characterized by a cloud of intraslab earthquakes termed the "Wadati-Benioff" or "Benioff" zone (Wadati, 1928; Benioff, 1949, see entry "Wadati-Benioff-Zone") down to 660 km, which is the depth of the discontinuity between the upper and the lower mantle.

The last distinctive characteristic is the volcanic arc that generally outlines the oceanic subduction zones. Fluids stored in the subducting plate are released at various depths from the first kilometers of subduction near the trench (pore fluids) down to about 150 km (hydrous minerals) depending on the thermal state of the slab. At depths between 80 and 150 km, slab dehydration is responsible for the metasomatism of the overlying mantle wedge. A small fraction of the asthenospheric wedge undergoes partial melting and migrates upward. Volcanoes thus develop at a given distance depending on the slab dip because melts migrate vertically from the slab.

Slab shape and dynamics

At a large scale, oceanic plates behave elastically when they are forced to bend in subduction zones. We often observe a small bulge seaward of the trench before the plate sinks into the mantle. The trench is the deepest surface expression of the oceanic plate. Its depth depends on the age of the subducting plate and the amount of sediment infill. The deepest trenches are the Mariana Trough (10,938 m revised depth by Fujioka et al., 2002) and the Philippine trench (10,100 m after Lallemand et al., 1998). It is interesting to note that the deepest trenches are located right in the area of maximum downwelling of oceanic lithosphere on Earth as computed by Lithgow-Bertelloni and Richards (1998). Some authors argue that the elastic properties of the sinking lithosphere help the slab to unbend below the arc so that it recovers a flat profile. In detail, other forces may also contribute in the unbending of the plate such as the suction force exerted by the overriding plate and mantle wedge. Slabs may exhibit various shapes such as flat and horizontal in their upper section (Peru or Central Chile), shallow dipping (Japan or Kurile), intermediate dipping (Tonga or

Kermadec), steeply dipping (Izu-Bonin), vertically dipping (Mariana), or even overturned (Luzon or New Britain).

In modern subduction zones, active compression in the overriding plate is always observed for shallow-dipping slabs ($<50°$), whereas active back-arc extension is always observed for steeply dipping slabs ($>50°$). Lallemand et al. (2005b, 2008) have shown that the slab shape is not simply linked with the age of the subducting plate (the common assumption is that an old plate is thick and dense and thus prone to sink steeply or even vertically in the mantle) but rather with the combination of absolute velocities between converging plates and the regional mantle dynamics. Moreover, the upper plate strain appears to directly result from this kinematic interaction.

Main driving and resistive forces in subduction zones

Today, the main driving mechanism for plate motion in general (see "Driving Forces: Slab Pull, Ridge Push"), and for subduction in particular, is the gravitational sinking of the slab (Turcotte and Schubert, 1982) which is usually slightly denser (about 1 %) than the surrounding mantle because of its lower temperature (thermal contraction). This force is called *slab pull* (Figure 2). The viscous mantle opposes a resistance to plate motion from the ridge to the trench called *mantle drag*. The upper portion of the asthenosphere is known to have a low viscosity so that the *mantle drag* should be moderate. The viscous shearing increases considerably as the plate sinks into the mantle because it exerts on both sides – top and bottom – of the descending slab and because the viscosity is pressure dependent (Karato and Wu, 1993). It probably increases by at least one order of magnitude between the top and the bottom of the upper mantle. This resistance to penetration drops again when the slab reaches the discontinuity between the upper and the lower mantle near 660 km as a result of phase changes in minerals. The mantle opposes another resistance called *anchoring*, which accounts for mantle reaction to slab facewise translation (Scholtz and Campos, 1995; Lallemand et al., 2008). Since it is a viscous pressure force, it will depend on the velocity of slab rollback or advance associated with trench migration and increase with depth. The slab also resists to bend and unbend when passing the trench. This resisting force called *bending moment* increases with the stiffness of the plate and thus its age. It is inversely proportional to the radius of curvature of the slab (Buffett and Rowley, 2006; Wu et al., 2008).

Among these main internal forces, two are always resisting: the *mantle resistance to penetration*, by definition, which is effective as soon as a slab dives into the mantle, and the *bending moment*, also called *bending resistance*, as the plate bends and unbends. All the other forces can shift from driving to resisting depending on the geodynamic context. Let us first consider *slab pull* whose name comes, by definition, from the capacity of
Subduction, Figure 2 Description of driving and resistive forces in a subduction zone modified after Lallemand et al. (2008). Many forces can point in two opposite directions depending on the geodynamic context. *Full lines* are the most frequent directions, and *dotted lines* are less frequent directions but still observed. Far-field forces commonly originate from ridge-push, slab pull, or collision.

the slab to sink into the mantle because of its negative buoyancy. Most of the time, it is considered as a driving force, but in about 10 % of cases, we observe "flat" slabs, i.e., subducting slabs sliding horizontally beneath the upper plate over hundreds of kilometers before sinking. Gutscher et al. (2000) attributed this flatness to a positive buoyancy of the oceanic plate and a delay in the basalt to eclogite transition due to the cool thermal structure of the two overlapping lithospheres. The best examples are the Nankai or Cascadia subduction zone where the subducting crust is very young, or the Peru and Central Chile segments along the Andean margin where buoyant ridges or plateaus are subducting. The *mantle drag* generally offers resistance to plate motion near subduction zones except when mantle convective cells, produced by another mechanism rather than the subduction, drive the plate down. This could be the case when a spreading ridge subducts like in South Chile or in Cascadia. The *anchoring force* always offers resistance to facewise translation of the slab but not much to its downward penetration.

There are also second-order external forces originating from the far field (Figure 2). Their magnitude and direction depend on the geodynamic context. The so-called ridge-push results from the gravitational collapse or subsidence of the oceanic plates as they drift away from the ridge. Fowler (1990) estimates that, on average, the *slab pull* force is one order of magnitude greater than the *ridge-push* force. If the active ridge is located seaward of the trench, the *ridge-push* force will push the plate toward

the trench, but if the spreading ridge is located landward of the trench, it will push the upper plate onto the subducting plate (like in South America with the East Pacific Rise on one side and the mid-Atlantic Ridge on the other). Far-field slab pull can also provide an additional force acting in the subduction zone. For example, the Izu-Bonin-Mariana arc overrides the subducting Pacific plate but is carried by the Philippine Sea plate which is dragged northwestward as a consequence of the slab pull acting along the Ryukyu subduction zone (Pacanovsky et al., 1999). In this case, the upper plate is pulled away from the trench. Another source of external stress is the effect of a collision like the Ontong Java Plateau with the Solomon trench that impacts the stress field over a huge area from New Guinea to New Hebrides (Mann and Taira, 2004).

Subduction interface

The shallowest part of the subduction interface often corresponds to an aseismic *décollement zone* characterized by overpressures resulting from the pore fluids release as lithostatic pressure increases (Saffer and Tobin, 2011). At rather low temperatures between 100–150° and 350–450° (Oleskevich et al., 1999; Hyndman, 2007), the plate interface becomes frictional and thus seismogenic (see "Seismogenic Zone" and Dixon and Moore, 2007). All "subduction earthquakes" nucleate in this region. The *seismogenic zone* generally extends from a depth of 11 ± 4 to 51 ± 9 km. It is about 112 ± 40 km wide and dips
Subduction, Figure 3 Schematic illustration of the subduction interface in an oceanic subduction zone. U_z is the upper limit and D_z the downdip limit of the seismogenic zone. Z_{dec} is the decoupling depth. Below that depth, the convective mantle is dragged down (coupled) with the subducting plate. *NVT* nonvolcanic tremors and *SSE* slow-slip events are observed in some subduction zones at depths between D_z and Z_{dec}.

$23 \pm 8\,°$ (Heuret et al., 2011). At temperatures higher than $350–450°$, the slip along the interface is either continuous (creep) or characterized by slow-slip events (SSE) associated with nonvolcanic tremors (NVT) (Rogers and Draggert, 2003). The downdip limit of the subduction interface is marked by the coupling between the descending plate and the overlying mantle (Figure 3). Furukawa (1993) called the depth below which the plates are uncoupled on the long term Z_{dec}. Downdip of this depth, a significant thickness of mantle is dragged with the slab, called "viscous blanket" by Kincaid and Sacks (1997). The thickness depends on the temperature contrast between the slab and the mantle wedge. Beyond Z_{dec}, there is no more plate interface, the slab being overlain by the convective mantle wedge.

There is a debate on the nature of the plate interface. Is it an $\sim 1–20$ m thin "décollement" zone like those drilled in Nankai (Bangs et al., 1996) or an $\sim 100–1,000$ m thick channel across which the shear distributes like in the exhumed Franciscan complex (Cloos and Shreve, 1988)? The discovery of erosional processes at the hanging wall of the subduction interface in Japan, Middle America, and Izu-Bonin-Mariana trenches since the early 1980s (von Huene et al., 1980; von Huene and Lallemand, 1990; von Huene and Scholl, 1991; Lallemand et al., 1992; Meschede et al., 1999) has been decisive in promoting the concept of *subduction channel*. It has been later confirmed, thanks to the increasing resolution of seismic images as in the Ecuadorian margin (Sage et al., 2006;

Collot et al., 2008) and the reinterpretation of some outcrops of exhumed subduction interface like in the Shimanto belt (Kitamura et al., 2005) or in the Apennines (Vannucchi et al., 2008). Several processes of upward migration of the roof décollement or downward migration of the basal décollement delimiting the subduction channel have been discussed by Vannucchi et al. (2012) and are not yet completely understood. Hydrofracturing of the hanging wall rocks under increasing fluid pressure coming from the dewatered downgoing plate (von Huene et al., 2004) very probably contributes to the upward migration of the deformation front as well as the subduction of oceanic reliefs such as seamounts and ridges (Dominguez et al., 1998, 2000).

At the scale of the plate interface, two forces govern local tectonics and hazards: friction and pressure. The net pressure or normal stress exerted along the subduction interface combines the lithostatic pressure, increasing with depth, and the non-isostatic "dynamic" pressure, which accounts for the slab pull, the slab-mantle interactions, and the far-field "tectonic" forces. The idea, developed by Shemenda (1992) in laboratory analog models, where far-field forces and mantle drag and anchoring are neglected, is that a dense (old) and long subducting plate tends to pull the upper plate down producing a subsidence of the forearc, whereas a light (young) or a short subducting plate tends to push the upper plate up producing uplift of the forearc. In nature, not only the age and length of the subducting plate but mantle and

far-field forces also contribute to the normal stress along the interface. The second force is frictional shear, which resists subduction. The stress is released intermittently as it overcomes the yield strength of the fault, through repeated earthquakes and subsequent fault ruptures.

Seismicity with special emphasis on mega-thrust earthquakes

Subduction zones are the locus of most earthquakes occurring on Earth because the plate boundaries have to accommodate the largest relative motions and subsequent strain, because the plate interface is continuously cooled and because the slab still remains cool at large depths. "Subduction earthquakes" are thrust events occurring along the seismogenic plate interface. They represent most of the seismic energy released at subduction zones and in the world (Scholz, 2002). There are also intraslab shallow, intermediate, and deep earthquakes that accommodate the high level of stress during the plate bending and penetration into the viscous mantle and the upper plate earthquakes that accommodate the part of the stress transmitted through the plate interface. See entries "Earthquakes", "Active Continental Margins" and in particular Figure 2 of "Active Continental Margins."

One specificity of the subduction zones is that they can generate giant earthquakes with magnitudes ≥ 8.5, most of them being tsunamigenic like the 2004 M9.2 event off Sumatra (Indonesia) or the 2011 M9.0 event off Tohoku (Japan). Back to the 1900–2012 period, Figure 4 shows the rupture areas associated with the M ≥ 8.0 earthquakes and the segmentation of the seismogenic zones mainly based on past earthquake ruptures. It is easy to see that they don't distribute equally along the subduction zones. Based on available global datasets, Heuret et al. (2011, 2012) have shown that giant earthquakes preferentially occurred near slab edges, where the upper plate was continental, the back-arc strain neutral to compressive, and the trench fill larger than 1 km. A possible explanation would be that the rupture propagation could be facilitated if the plate interface is smooth (Ruff, 1989) and the normal stress on the interface large enough to accumulate strain but not too large to allow rupture propagation. The continental nature of the upper plate could be preferred because it is associated with wider (downdip) seismogenic zones. The dependence of earthquake magnitude with the subduction velocity and plate age, first proposed by Ruff and Kanamori (1980, 1983), is not statistically verified using revised databases. However, none of the Sumatra and Tohoku earthquakes were expected to occur based on our knowledge at the time they happened, because the recurrence time of such huge events is often underestimated and because we generally do not have access to paleoearthquake archives (McCaffrey, 1997, 2008; Lay and Kanamori, 2011).

The degree of coupling between the converging plates may be used to estimate the seismic hazard at a given subduction zone. For many years, authors calculated the seismic coupling coefficient as the ratio between the observed seismic moment release rate and the rate calculated from plate tectonic velocities (Brune, 1968; Davies and Brune, 1971). Scholz and Campos (1995) have shown that this coefficient should be used cautiously because the seismic slip was generally computed over a short time period (typically a hundred years) compared with the recurrence time for large earthquakes (sometimes up to a thousand years). During the last two decades, the advent of monitoring of subduction zones with GPS stations allowed geodesists to measure the interseismic strain accumulation rate in the upper plate, which gives a better picture of the interplate coupling than the earlier measure of energy release rate by summing the earthquake moment over a short period. By doing this, Scholz and Campos (2012) have revised their estimate of the seismic coupling coefficient in many subduction settings. They concluded that this new approach agrees well with the revised "classical way" of measuring the coefficient accounting for major earthquakes older than a century when available. It is also more satisfactory for the balance of forces acting along the plate interface like the normal stress and the friction making assumptions on their respective origins (see above). They confirm the observation of Chemenda et al. (2000) that high coupling, and thus high friction, is observed in regions of high normal stress. The limitation of the method, consisting of measuring the interseismic elastic strain, is that most of the time the coupled area in a subduction zone is located offshore, whereas GPS receivers are deployed onshore. The resolution of the models should be improved in the future when a significant number of GPS stations can be installed offshore like off Japan. Tremendous developments must be further done to precisely map the complexity of the coupling distribution along the subduction interface because large lateral variations are predicted by authors (Ruff, 1992; Bilek, 2007; Scholz and Campos, 2012).

Upper plate tectonics

The upper plate is the visible part of a subduction zone, also called *active margin*. The tectonic regime of the active margin depends on interactions between the converging plates at the level of the trench, the plate interface, and even the whole overriding plate.

At the trench, sediment carried by the subducting oceanic plate may be offscraped and incorporated at the front of the overriding plate. This process, called *frontal accretion*, contributes to the growth of an *accretionary wedge* (see entry "Accretionary Wedges" for more details or Moore and Silver, 1987). Von Huene and Scholl (1991) have shown that half of the growth of an accretionary prism can be accounted for by subcrustal or basal accretion, also called *underplating*. They also estimated that only half of the modern convergent margins are accretionary. The other half undergoes what they called *tectonic erosion*. This process has been definitely demonstrated in the late 1970s (e.g., Scholl et al., 1980) after

Subduction, Figure 4 Map of the subduction interface seismic rate, trench segments, and major rupture areas of the $M_w \geq 8.0$ 1900–2012 events updated from Heuret et al. (2011). *Pale blue arrows* indicate subduction relative velocities after Heuret and Lallemand (2005).

observations from both deep-sea drilling and reflection seismic imaging, which the Japan margin underwent a Miocene subsidence of at least 2 km. Such large subsidence increasing seaward, together with the absence of an accretionary prism, erosional features at margin's front, and simultaneous retreat of the volcanic arc, led the authors to propose a model in which part of the margin was removed both frontally and subcrustally during subduction. Since 1980, other margins appeared to also undergo tectonic erosion like in mid-America, Peru, Tonga, Mariana, or Izu-Bonin (von Huene and Lallemand, 1990; Lallemand, 1995; Meschede et al., 1999; Clift and Vannucchi, 2004). See entry "Subduction Erosion" for more details.

The convergent margins deform in response to the stress transmitted across the plate interface but also in response either to frontal or basal accretion or frontal or basal tectonic erosion. The tectonic regime is often compressive in the frontal part of the overriding plate, but it is also quite common to observe normal faults dipping either landward or seaward in active convergent margins, especially when they are subject to tectonic erosion. These faults reflect either a trenchward collapse as the margin progressively steepens (Aubouin et al., 1984), or a buckling as underplating occurs (Lallemand et al., 1994). Another mechanism, coseismically induced, has been recently suggested. Indeed, a seaward dipping normal fault has been activated at the front of the Japan margin during the 2011 Tohoku mega-earthquake. The explanation provided by McKenzie and Jackson (2012) would be that both the release of gravitational potential energy and the elastic strain account for this coseismic behavior.

Trench-parallel strike-slip faults may also be observed in the forearc in case of oblique convergence like off Sumatra (Mentawai Fault) or the southern Ryukyus (Yaeyama Fault). These transcurrent subvertical faults accommodate part of the lateral component of the oblique convergence, whereas the slip along the frontal part of the subduction thrust is closer to trench normal (e.g., McCaffrey, 1992). This mechanism is verified by the direction of slip vectors of subduction earthquakes that are often deflected toward trench normal when the convergence is oblique. This process called *slip partitioning* has been observed not only at the scale of the forearc but also at the scale of tectonic plates. Indeed, several oblique subduction systems develop transcurrent faults. Chemenda et al. (2000), for example, have investigated using physical models the effect of the pressure and the friction along the plate interface on slip partitioning in a context of oblique convergence. They conclude that slip partitioning can occur in the models only when interplate friction is high and when the overriding plate contains a weak zone. As a matter of fact, lithospheric transcurrent faults develop either at the toe of the rigid backstop (rear of accretionary wedge like off East Taiwan), along the volcanic arc (Sumatra, the Philippines, South Kuriles), at the back-arc rift axis, or spreading center (Andaman Sea, Le Havre Trough).

Ultimately, the global strain rate map (Kreemer et al., 2003) indicates that most subduction systems deform far from the plate boundaries, or one may consider that the plate boundaries are wider than a single fault. They can potentially affect a strip several hundreds of kilometers large at upper plate edge. In addition to interseismic elastic deformation, there are many areas where permanent (plastic) deformation localizes. We have seen above that, in some oblique geodynamic settings, transcurrent faulting may occur, but even more *shortening*, *rifting*, or *spreading* can also occur. Significant shortening (>1 cm/year) is observed, for example, along the eastern margin of the Japan Sea, the southern margin of the Okhotsk Sea, or the eastern cordillera of the Andes. Opposingly, rifting or spreading develops in the Sumisu rift and the Mariana Trough (Izu-Bonin-Mariana arc), the Lau Basin and Le Havre Trough (Tonga-Kermadec arc), the Andaman Sea (Andaman arc), the Central Kamchatka graben (North Kurile arc), the Manus Basin (New Britain arc), the North and South Fiji basins (New Hebrides arc), the Scotia Sea (South Sandwich arc), the Tyrrhenian Sea (Calabria arc), or the Aegean Sea (Hellenic arc). Several mechanisms have been invoked to account for this upper plate deformation playing with interplate stress resulting from plate kinematics (Dewey, 1980; Lallemand et al., 2008) and/or mantle wedge dynamics (Sleep and Toksöz, 1971; Lagabrielle et al., 1997; Faccenna et al., 2010).

Magmatism at subduction zones

Volcanic arcs are the second worldwide magmatic contributor to crustal growth on Earth after the oceanic spreading centers (nearly 1 km^3/year according to Crisp, 1984). Most subduction zones are characterized by an active *volcanic arc*. Sometimes, the volcanic activity ceases for a few million years and resumes again. The reason for the cessation of volcanism is commonly either the collision with a continent or the geometry of the slab which is incompatible with the presence of a mantle wedge. This is the case, for example, with flat slab segments in the Andes (Gutscher et al., 2000). Arc magmatism results from the metasomatism and partial melting of rocks of the mantle wedge that are hydrated by the water extracted from hydrous minerals in the subducting plate at depths ranging between 80 and 150 km. Further details on arc magmatism can be found in Tatsumi (1989) or Tatsumi and Kosigo (2003). See also entries "Magmatism at Convergent Plate Boundaries", and "Island Arc Volcanism, Volcanic Arcs".

Access to a database on kinematic, geometric, seismologic, and structural parameters of oceanic subduction zones can be found via url: *submap.fr*.

Summary

Subduction is a lithospheric process which occurs at convergent plate boundaries. One plate underthrusts another and sinks into the Earth mantle. The subduction mainly involves a subducting oceanic plate, but sometimes,

a continental plate enters into the subduction zone. In this last case, a collisional chain develops. This process generates a high level of seismicity as the rocks deform in the vicinity of the plate boundary. All mega-earthquakes occur in subduction zones. Oceanic subduction creates favorable conditions for arc magmatism.

SUBDUCTION EROSION

Martin Meschede
Institute of Geography and Geology, Ernst-Moritz-Arndt
University, Greifswald, Germany

Definition

Subduction erosion defines a process in a subduction zone where material of the overriding upper plate is scraped off from its bottom by the downgoing lower plate. The offscraped material is transported downward within a subduction mélange into deeper parts of the subduction zone where it is added to the upper plate by melting and comprehension into magmatic melts of the volcanic arc.

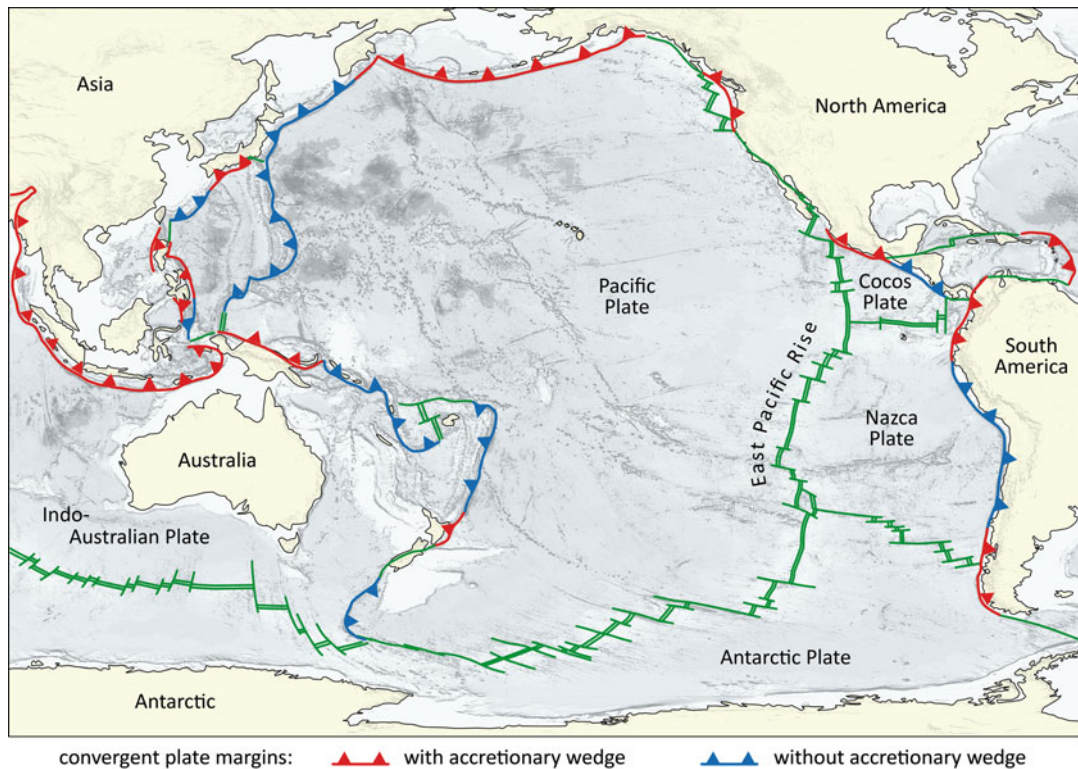
Occurrences

About half of the convergent plate boundaries on Earth are dominated by the process of subduction erosion or at least non-accretion instead of accretion in an accretionary wedge (von Huene and Scholl 1991), which is the opposite process characterized by the formation of sedimentary accretionary wedges (Figure 1). Examples of such accretionary wedges are represented in SW Japan, Sumatra, large portions of the Gulf of Oman (Makran subduction zone), in the Lesser Antilles, and in smaller areas of western North America. During subduction erosion, rock material is scraped off from the bottom of the upper plate and transported downward with the subducting plate. Such basal erosion of the upper plate is known, e.g., from the Marianas, the Tonga Islands, Costa Rica, and Chile. In these cases, an accretionary wedge has not evolved or persisted only temporary before also being subducted. The identification of subduction erosion is thus difficult, since material to record the process does not evolve. Indications, therefore, have to be derived indirectly from other evidences.

Tectonic erosion in a subduction zone

It is assumed that at many modern convergent plate boundaries, accretion occurs at the tip of the upper plate and transport of at least parts of the incoming sedimentary material farther down into the subduction zone. Subduction erosion, on the other hand, transfers a considerable amount of material scraped off from the upper plate to greater depths. In contrast to accretion which leaves a geologic record, subduction erosion produces a hiatus making the process of erosion generally hypothetical (Von Huene, 1986). It is, therefore, necessary to determine secondary effects from subduction erosion such as subsidence of the convergent margin, extensional structures, retreat of the volcanic arc, or the content of some particular radiogenic isotopes.

Subducting pelagic sediments of the incoming plate as well as slope sediments from the convergent margin and volcanic ash layers from the volcanic arc volcanism nearby, oceanic crust of the incoming plate, and tectonically eroded material from the margin wedge of the overriding plate are mixed in a subduction mélange which is transported down into deeper parts of the subduction zone. A well-exposed example of such a subduction mélange can be studied at the Osa Peninsula in Costa Rica. This mélange zone which was already subducted to a depth of more than 10 km has been exhumed by the indentation of the Cocos Ridge since about 4 Myrs (Meschede et al., 1999a) for which we can study it today on land. The mélange is composed of highly sheared basaltic rocks and radiolarian cherts which belong to the Cretaceous Nicoya ophiolite complex occurring at the Central American land bridge, Cenozoic pelagic sediments and carbonatic rocks from seamounts and submarine ridges from the East Pacific basin, and probably of younger basaltic material from the subducting Cocos Plate. The subducted sedimentary material, however, is too light to be recycled into the mantle; it is instead incorporated into the melts feeding the volcanic arc volcanism above the subduction zone. Morris et al. (1990) realized that the occurrence of boron and the cosmogenic isotope beryllium-10 which has a half-life of about 1.5 Myrs indicates the subduction of sediments and their inclusion into melting processes above the subduction zone. ^{10}Be is constantly produced in the atmosphere by sun radiation and subsequently deposited in sediments. However, detection of ^{10}Be in recently formed volcanic rocks above subduction zones without an accretionary wedge indicates subduction of sediments and incorporation into magmatic melts (e.g., Morris et al., 2002). It is assumed that sediments containing a certain amount of ^{10}Be are involved in the melting process above the subduction zone after they were transported downward into deeper parts of the subduction zone. This process has to be performed within a short time span because after about 2–2.5 Myrs, a detection of ^{10}Be would not be possible anymore. The occurrence of ^{10}Be in recent volcanic rocks is thus taken as a reference for subduction of even the youngest sediments going into the subduction zone.

Snyder and Fehn (2002) determined an unusual $^{129}J/J$ ratio in young basaltic rocks from the Costa Rican volcanic arc. The $^{129}J/J$ ratio indicates minimum ages of iodine in fluids and is used to determine the age of the


Subduction Erosion, Figure 1 Map of Circum-Pacific showing location of subduction zones with and without accretionary wedges (after von Huene and Scholl 1991; modified from Frisch et al. 2011).

subducted material. Some of the results, however, are too old to have originated from subducted sediments whose age is well determined. They interpret their results as probably caused by subduction erosion where old sedimentary rocks of the Cretaceous Nicoya ophiolite complex as part of the upper plate are scraped off by the subducting plate and transported down into the subduction zone together with younger sedimentary material. The material mix has been incorporated into the melt above the subduction zone, thus adding the old inherited ^{129}J/J ratios to the ^{129}J/J ratios of younger subducted sediments. Because of this mixing, the ^{129}J/J ratio of the calculated minimum ages becomes too old for being related only to the subducted sediments. The modification of this ratio may thus be taken as an indication for subduction erosion in the Costa Rica convergent margin.

In places where subduction erosion occurs, the outer ridge above a subduction zone as it is evolved in case of an accretionary wedge (e.g., the island of Barbados in the Lesser Antilles or the Mentawai Ridge in front of Sumatra) is not a significant feature because sedimentary material does not accumulate as in an accretionary wedge. The forearc basin commonly grades directly into the trench with little or no topographic rise between the two.

Subduction erosion is particularly effective when the lower plate has a roughly textured surface and is only covered by a thin sedimentary layer (Figure 2). As the lower plate enters the subduction zone and is bent, the upper part of the plate is extended; a series of trench-parallel horst and graben structures are subsequently formed. The roughness caused by these structures acts like a grater on the basal part of the upper plate (basal erosion, Figure 2), much like a cheese grater removes cheese from the base of the cheese block. Material that is scraped off the upper plate enters the subduction zone where it is transported downward into deeper parts of the subduction zone. This process is currently happening in the Mariana Arc.

Subduction of seamounts

Seamounts on the subducting plate create a somewhat different kind of subduction erosion. Single seamounts scrape off material from the frontal tip of the accretionary wedge along the upper plate and carry it into the subduction zone (frontal erosion). A superb example of this setting occurs off the Pacific coast of Costa Rica where seamounts currently buried by the tip of the upper plate leave obvious bulges followed by indentations in the slope of the upper plate. Subsequently, sediment gravity slides may fill up or obscure these indentations (Figure 3).
Subduction Erosion, Figure 2 Subduction erosion *upper*: at the base of the upper plate caused by subducted horsts and grabens; *lower*: at the front of the upper plate caused by subducted seamounts (modified from Frisch et al. 2011).

Migration of the subduction zone

Basal erosion on the upper plate causes the plate boundary to migrate toward the arc, which itself is moving backward in response to the migrating subduction zone. This process occurred along Costa Rica and in parts of the Andes between the Miocene and present (Figure 4). A tectonic mélange, consisting of parts of the scraped off upper plate, has evolved along the decollement zone. The mélange is transported into the depths of the subduction zone along with the plate being subducted.

Controlling factors

Subduction erosion can occur where the subduction zone angle is relatively low and there is a strong coupling between the two plates (Chile type) and where the subduction angle is high and subduction rollback occurs (Mariana type). Examples for the first case include Central America (see below) and parts of South America, and for the second case the Marianas, Tonga, and NE Japan. In Chile-type subduction, subduction erosion occurs because of the strong contact pressure caused by strong plate coupling. In Mariana-type subduction, erosion is caused by
Subduction Erosion, Figure 3 Subduction of seamounts at the plate margin off Costa Rica (von Huene et al., 2000). The indentation of the seamount into the subduction zone leaves deep furrows in the upper plate (Figure after bathymetric data of the research vessel Sonne, made by Wilhelm Weinrebe, GEOMAR Kiel, Germany; modified from Frisch et al., 2011).
Subduction Erosion, Figure 4 Subduction erosion at the plate margin off Costa Rica where the Cocos Plate subducts beneath the Caribbean Plate (Meschede et al., 1999). Backward shift (toward the back-arc) of the volcanic arc is caused by subduction erosion of the upper plate since the Miocene (modified from Frisch et al., 2011).

the rough, sawtooth-like morphology on the subducting plate.

Pore fluids have important consequences in subduction zones and on subduction erosion. Pore fluids originate both from dewatering of hydrous minerals and from expulsion of water from sediments. Pore fluids in the high-stress zone along the plate-boundary decollement actually increase mobility and slippage in this zone by acting as a lubricant. During explosive expulsions of fluids, framework grains break and lose their connectiveness, and the rocks become ground by shearing. Such rocks are called cataclasites. Cataclasis (Greek: strong fracturing) is a common process associated with subduction erosion. Fluids that escape upward through the upper plate may generate mud volcanoes.

Record of subduction erosion

Subduction erosion can be proven only indirectly as the process occurs at depth and the eroded rocks become subducted to even greater depth. In contrast, accretionary wedges can be directly studied. The Central American subduction zone adjacent to Costa Rica is a well-studied example of an active plate margin being the site of subduction erosion. Here, the Cocos Plate is being subducted beneath the Caribbean Plate with a velocity of about 9 cm/year. The volcanic front has shifted 40 km backward (toward the Caribbean) during the last 15 Ma. This shift more or less corresponds to the amount of shortening formed by subduction erosion (Meschede et al., 1999a; Figure 4).

As subduction erosion thins the upper plate, the outer part of the wedge structure subsides. Seismic profiles along erosive convergent margins indicate the existence of tilted blocks and normal faults (Meschede et al., 1999b; Ranero and von Huene, 2000). Sediments deposited in the forearc area can be used to document this subsidence. For instance, benthic foraminifera, single-celled organisms which live within the sediment, indicate the approximate sedimentation depth based on their shell shape and design. If foraminifera and other sedimentological features in layers of decreasing age at a convergent margin indicate increasing water depth, subduction erosion is a likely explanation. At a drill site of the Ocean Drilling Program offshore Costa Rica (ODP Leg 170, Costa Rica convergent margin), shallow-water sediments occur at the deepest part of a hole, whereas near the top of the well core, deepwater sediments occur (Meschede et al., 2002). Accretionary sequences would produce the opposite pattern because the gradual buildup of the accretionary wedge causes a shallowing-upward sedimentation pattern over the wedge.

SUBMARINE CANYONS

William W. Hay
Department of Geological Sciences, University of Colorado at Boulder, Estes Park, CO, USA

Definition

A submarine canyon is a valley cut into the seafloor of the continental shelf, forming a notch in the shelf break and continuing as a steep-sided valley down the continental slope.

History

The discovery of submarine canyons can be traced back to the late nineteenth century. James Dana reported on soundings revealing the Hudson submarine river channel in 1890.

The distribution of submarine canyons

Small submarine canyons are common along active continental margins. They are more widely separated along passive margins. Some submarine canyons have their heads on the continental shelf and are directly associated with large rivers. Others have their head near the break in the slope and have no obvious association with existing rivers.

Canyons cut into continental slopes can be traced down to depths of 2 km or more below sea-level. They can continue as submarine channels on the continental rise extending for hundreds of kilometers.

Origin of submarine canyons

The origin of submarine canyons was proposed to be from flows of dense turbid waters (later "turbidity currents") by R. A. Daly (1936). As isostatic response to sea-level change associated with glaciation and deglaciation became better understood, it became evident that rivers might have cut the canyons into the shelf break at sea-level lowstands. However, the existence of turbidity currents capable of eroding the continental slope was considered hypothetical until the investigations of the effects of the Grand Banks earthquake of 1929 on the seafloor of Nova Scotia.

SUBMARINE LAVA TYPES

Michael R. Perfit[1] and Samuel Adam Soule[2]
[1]Department of Geological Sciences, University of Florida, Gainesville, FL, USA
[2]Woods Hole Oceanographic Institution, Woods Hole, MA, USA

Introduction

Variations: Pillow lava, lobate flow, sheet flow

Most of the Earth's crust surface is comprised of lava – the solid igneous rock created by the extrusion, cooling, and crystallization of magma generated within the Earth's mantle or by partially melting preexisting crust. Lava is the nonexplosive extrusive product of eruptions from volcanoes and rifts in a variety of tectonic environments. Volcanism in the oceans occurs in a number of different tectonic settings including divergent plate boundaries (mid-ocean ridges), convergent plate boundaries (oceanic island arcs and back-arcs), and intraplate settings (hot spot-generated ocean islands and oceanic plateaus). These settings produce eruptive products that are geochemically and physically distinct. At arcs and back-arcs, chemically evolved ($SiO_2 > 52$ wt%) and volatile-rich ($H_2O > 2$ wt%) magmas can lead to explosive eruptions, although effusive eruptions including flows and domes are common. At ocean islands and oceanic plateaus, magmas contain less SiO_2 and are characteristically more mafic (i.e., contain more MgO and FeO) and less volatile rich ($H_2O < 1$ wt%). Consequently, quiescent effusive eruptions are dominant though some explosive eruptions do occur. At ocean islands, eruptions are typically focused at volcanoes leading to the construction of edifices that may eventually breach the sea surface. At oceanic plateaus volumetrically significant outpourings of lava produce thick, aerially extensive platforms. Outside of large oceanic plateaus, mid-ocean ridges produce the majority of erupted lava in the oceans, representing as much as two-thirds of the Earth's annual volcanic output. Mid-ocean ridge magmas are broadly mafic ($SiO_2 \sim 50$ wt%, $MgO \sim 8$ wt%) and volatile poor ($H_2O \sim 0.25$ wt%) and define a geochemical class appropriately named mid-ocean ridge basalt (MORB) that is thought to represent partial melting of an incompatible element-depleted mantle source. Most lava erupted at mid-ocean ridges (MOR) forms lava flows that have morphologic and textural characteristics distinct from those at subaerial volcanoes due to differences in their physical environment of eruption and chemical characteristics. Submarine eruptions are rarely observed because of their great depths and remote locations. However, recent high-resolution mapping and sampling of MOR spreading centers and seamounts together with studies of historic eruptions have provided important information about the various types of lavas that exist in the oceans and the mechanisms that control their emplacement.

Lava flows on mid-ocean ridges

A great majority of lavas erupted on MORs are basaltic in composition and distinctive enough from basalts erupted in other environments that they are known as ocean floor basalts or mid-ocean ridge basalts (MORB). They are characterized by having relatively low silica contents (<52 wt%), high magnesium and iron concentrations, and very low alkali and volatile contents (most notably H_2O and CO_2). In some ridge environments such as overlapping spreading centers and ridge-transform intersections, a greater proportion of cooler, more chemically evolved varieties such as ferroandesites, dacites, and rhyodacites that have higher silica and alkalis and lower magnesium and calcium along with higher concentrations of volatiles have been recovered (e.g., Wanless et al., 2010). MORB exhibit a spectrum of lava flow morphologies (Figure 1) that range from bulbous, pillow shapes to flatter oblate forms known as "lobates" and even to flat, ropy, and folded types of sheets (Ballard et al., 1975; Lonsdale, 1977; Francheteau and Ballard, 1983; Bonatti and Harrison, 1988; Embley et al., 1990; Embley and Chadwick, 1994; Perfit and Chadwick, 1998).

Significant differences in lava morphology, axial structure, and frequency and distribution of magmatic activity along MOR vary with the rate of spreading – a reflection of magma supply rate at ridge crests (Bonatti and Harrison, 1988; Perfit and Chadwick, 1998; Sinton et al., 2002). Slowly diverging plate boundaries, which have relatively lower magma supply rates and volcanic outputs, are dominated by pillow lava, which tends to construct hummocks (<50 m high, <500 m diameter), hummocky ridges (1–2 km long), and small circular seamounts (10–100s m high and 100s–1,000s m in diameter). These constructs commonly coalesce to form axial volcanic ridges (AVR) along the valley floor of slow-spread axial rift zones (Smith and Cann, 1993; Searle et al., 2010; Yeo et al., 2012). At fast-spreading MORs where magma supply is greater, volcanic output is dominated by lobate flows and sheet flows. Sheet flows are further subdivided based on their surface texture as flat, ropy/folded, and jumbled/hackly (e.g., Engels et al., 2003; Soule et al., 2005; Garry et al., 2006; Fundis et al., 2010). Intermediate-spreading rate ridges have mixes of lava types due to periods of low magmatic output punctuated by more voluminous magmatism (Smith et al., 1994; Stakes et al., 2006) or variable magmatic budgets due to differences in along-axis melt supply (Colman et al., 2012). It has also been documented on the fast-spreading
Submarine Lava Types, Figure 1 MORB exhibit a wide variety of lava flow morphologies: (**a**) Pillow lava with characteristic bread crust surface texture. Edges are decorated with small, glassy, finger-like protuberances. (**b**) Partial vertical exposure of sheet flow exhibiting very flat upper, lineated surface overlying another sheet flow and lobate flow. (**c**) Young, glassy lobate flow of 1992 East Pacific Rise flow in contact with older pillow lava on right side. (**d**) Folded to jumbled sheet flow. Scale across bottom of image (**b**) is ~6 m; others are all ~3 m.

East Pacific Rise (EPR) that the relative proportion of flow types correlates with segmentation of the melt lens such that the abundance of pillows increases at segment ends where magma supply is thought to be lower (White et al., 2002).

High hydrostatic pressure and low volatile contents in MORB limit explosive eruptions that would produce submarine pyroclastic deposits. However, accumulations of gasses in sub-seafloor magma chambers are considered a mechanism that can drive mildly explosive eruptions that produce volcaniclastic ash deposits and delicate bubble wall and curved fragments of glass know as "limu o Pele" in the deep sea (Clague et al., 2003; Sohn et al., 2008; Clague et al., 2009; Barreyre et al., 2011; Pontbriand et al., 2012). Explosive eruptions appear to be more common at ocean islands (i.e., hotspots and in submarine arcs (e.g., subduction settings)) likely due to higher initial volatile contents and, in some cases, higher magma viscosity (e.g., Wright et al., 2006; Clague et al., 2011; Helo et al., 2011; Resing et al., 2011).

Lava morphology types

The primary differences between submarine lava flow morphologies (pillows, lobates, and sheets) are the size of individual flow units and their interconnectivity. Pillow flows extrude as ~1-m-scale individual spherical or cylindrical tubes of lava that develop a glassy crust on all sides, generally inhibiting coalescence with neighboring pillows (Moore, 1975). Pillow flows and mounds are produced by the piling up of individual pillow lava lobes whereby the newest pillows are erupted from the top of the stack and flow outward a limited distance before freezing, resulting in the formation of steep-sided mounds, ridges, and haystacks (Figure 2a–c) (Chadwick and Embley, 1994; Perfit and Chadwick, 1998; Embley et al., 2000). Although, by necessity, some continuous pathways must exist within a pillow flow to deliver lava from the seafloor vent to the top or sides of an actively forming mount, the high relief of pillow flows and absence of collapse features that span multiple pillows (although individual pillows may collapse and drain) suggest limited hydraulic connectivity.
Submarine Lava Types, Figure 2 Pillow lavas forming steep-sided mounds, ridges, and haystacks. (**a**) Upper part of the "new mounds" pillow mounds on northern cleft segment (Juan de Fuca Ridge). (**b**) Haystack off axis on southern cleft segment showing tubular forms of pillow lavas. (**c**) Pillow mound with well-formed pillow and elongate tubes formed from breakouts from pillows formed as the mound grew. (**d**) Large pillows and tubes formed from high-silica lavas. The pillows are > 2 m in diameter and have well-defined surficial bread crust textures. Field of view across bottom ~6 m in each photo.

In rare MOR environments where high-silica lavas have erupted, unusually large (>2 m diameter) pillows or glassy angular blocks are observed. These pillows may exhibit flow banding, have well-defined surficial bread crust textures (Figure 2d), and are commonly highly vesicular (Stakes et al., 2006).

Lobate flows are comprised of individual flow units that are similar to pillows but larger in width, several to >10 m. The lobes develop a quenched crust on their top and sides but are emplaced rapidly enough they can coalesce into one interconnected flow (Figure 3a). Lobate flows commonly inflate (similar to terrestrial inflated pahoehoe sheet flows (Hon et al., 1994)) producing relatively smooth and flat upper crusts that may later collapse if the molten interior of the flow subsides or trapped vapor from heated seawater condenses beneath them (Perfit et al., 2003). Flows that become ponded and later collapse are sometimes referred to as "lava lakes" but lack a direct

connection to a crustal magma supply and are more akin to lava ponds described in subaerial basaltic volcanic terranes (e.g., Wilson and Parfitt, 1993). Inflated lobate flows and lava lakes commonly display "lava pillars" in their collapsed interiors (Figures 3b and 6b; Ballard et al., 1979; Francheteau et al., 1979; Gregg and Chadwick, 1996; Chadwick et al., 2013).

Sheet flows erupt with an upper surface of uniform height, but they are typically modified into folded, lineated, jumbled, or hackly morphologies (Figure 4a–c) that reflect a variety of processes that may include flow through restrictions, flow along channel margins, and repeated inflation/deflation episodes. Sheet flows are typically laterally extensive but can also be confined to axial valleys or the axial summit trough (AST). In some locations on fast-spread MOR, sheet flows extend as far as ~3 km from the AST as a result of rapid, high-volume flow that forms lava channels (Sinton et al., 2002; Soule et al.,
Submarine Lava Types, Figure 3 Lobate flows. (**a**) Down-looking image of glassy lobate flow erupted on the East Pacific Rise in 2005–2006. The flow was emplaced rapidly enough that individual lobes coalesce into one interconnected flow. (**b**) Inflated lobate lava showing characteristic collapse features with thin, smooth upper crust, with talus and a "lava pillar" in the evacuated interior. Scale across bottom of image (**b**) is ~3 m.
Submarine Lava Types, Figure 4 Various morphologic types of sheet flows. (**a**) Young-looking, glassy, lineated sheet flow (down-looking picture). (**b**) Lineated sheet flow with thin sediment cover showing some folding at edge of flow. (**c**) Lightly sedimented folded sheet flow transitioning to hackly flow on margins of the flow. (**d**) Vertical exposure of sheet flow. Thicknesses can range from a few tens of centimeters to a few meters and likely transition into what are known as "massive flows" (>3 m thick) that may have formed as lava ponds. Horizontal scale in images (**d**) ~6 m and ~2–3 m in the others.

2005, 2007). Vertical sections of oceanic crust exposed along fault scarps (e.g., Karson et al. 2002a, Karson et al. 2002b; Stakes et al., 2006) or revealed by drilling during the Integrated Ocean Drilling Program (IODP) (e.g., Tominaga and Umino, 2010) show that some sheet flows can attain thicknesses of a few meters and likely transition into what are known as "massive flows" (>3 m thick) that may have formed as lava ponds (Figure 4d). A massive flow known to be at least 75 m thick drilled at IODP site 1,256 is proposed to represent a flow that originated at the axis and ponded in a depression more than 3 km off axis (Tominaga et al., 2009).

Variations in lava flow type are observed over short distances along mid-ocean ridges. On most MOR, lavas extrude along linear eruptive fissures commonly found within the axial summit trough and axial valley that can be a few to tens of kilometers long. The eruptions can be sourced from melt lenses directly below the fissures (Carbotte et al., 2013) or from magmatic dikes that travel along the length of ridge axes (Dziak et al., 1995; Delaney et al., 1998). At fast-spreading ridges, it has been noted that lava at the ends of magmatic segments produces markedly more pillows than at the middle of the segments (White et al., 2000). A similar increase in pillows has been observed at the ends of eruptive fissures, which commonly coincide with magmatic segment boundaries (Sinton et al., 2002; Fundis et al., 2010). At slow- and intermediate-spreading rate ridges, lavas erupted near the segment center where ascending melts are focused within the shallow crust have greater abundance of lobate and sheet flows relative to pillows than toward the segment ends, where melts are transported through lateral diking to eruption sites (Cann and Smith, 2005; Behn et al., 2006). At the intermediate-spreading rate Galapagos Spreading Center, melt supply systematically increases along axis toward the intersection with the Galapagos hot spot, and the relative abundances of lobate and sheet flows to pillow flows are positively correlated with inferred melt supply (e.g., Behn et al., 2004; White et al., 2008; Colman et al., 2012).

Controls on morphology

Early studies suggested a variety of intrinsic and extrinsic parameters may influence the development of distinct flow morphologies including lava rheology (i.e., composition, temperature, and crystallinity that all control viscosity), preexisting slope and terrain, and eruption rates (e.g., Bonatti and Harrison, 1988). Included in these studies are laboratory analogue experiments involving the extrusion of molten wax into a cold liquid under various physical conditions that have greatly increased our understanding of the significance of submarine flow morphologies (Fink and Griffiths, 1992; Griffiths and Fink, 1992; Gregg and Fink, 2000; Garry et al., 2006). These experiments have clearly shown that submarine flow morphology is a function of flow rate as well as cooling rate and lava viscosity.

Detailed investigations of historic eruptions suggest that preexisting slope and terrain do not significantly affect the morphology of the flows on mid-ocean ridges where the slopes are low (<5°, e.g., Kurras et al., 2000), although other studies have found that correlations are present where slopes are higher (Gregg and Fink, 2000). MORB viscosity, largely controlled by lava composition and eruption temperature, does not vary significantly along the global MOR (Rubin and Sinton, 2007). In addition, petrologic and geochemical analyses of lava samples indicate that lava rheology remains relatively constant throughout the course of an eruption (e.g., Soule et al., 2012). Cooling rate, controlled by the temperature difference between seawater and lava, is likewise similar for nearly all MOR eruptions. As a result, flow morphology can be thought of as a proxy for the rate of lava extrusion or magma supply rate. Pillow lavas form at the slowest flow rates, lobate flows at intermediate rates, and sheet flows at the highest flow rates.

Intra-flow variations

Variations in flow rate during emplacement can lead to the formation of multiple morphologies within a single submarine lava flow. Transitions between different surface morphologies can be gradational due to changing flow conditions or abrupt due to superposition of separate flow units (e.g., Cann and Smith, 2005; Soule et al., 2005; Fundis et al., 2010; Chadwick et al., 2013). Gradational transitions are observed between sheet and lobate flows and lobate and pillow flows but not between pillow and sheet flows (Figure 5). Transitions between sheet flows of different varieties are common. For example, it is common for a smooth sheet flow to transition into a folded flow – with a surface characterized by small folds – as the partially cooled and more brittle surface deforms due to continued flow of the underlying molten lava. Folded flows commonly transition into jumbled or hackly flows as the folded surface continues to deform, ultimately breaking the glassy surface crust. The gradation from sheet to hackly flows typically occurs over distances of 1–10 m (Fundis et al., 2010) and tends to occur on the margins of lava channels where there are significantly higher rates of shear (Soule et al., 2005). Transitions from lobate to pillow lavas occur over short distances (<1 m) and are characterized by pillows branching out of well-defined lobate flows. Lobate flows near these transitions have more surface decoration and have distinct lobes that are minimally coalesced.

Overall, the general trend in the distribution of flow types normal to the ridge axis is that lava morphologies associated with higher flow rates (i.e., sheet, hackly, and flat-lying lobate flows) occur near the eruptive source and transition into morphologies that are typically associated with lower flow rates toward the termini of the flow. Collapse pits and collapsed lava lakes and ponds are common features of submarine lava flows at fast- and superfast-spreading MORs that form in response to flow
Submarine Lava Types, Figure 5 Contact relations between different flow types. (**a**) Terminus of a well-decorated pillow flow on an older slightly folded sheet flow. (**b**) Pillow mound, possibly formed at an eruptive fissure to the *upper left*, overlying a sheet flow. Horizontal scale in (**a**) is ~3 m and in (**b**) is ~5 m.

inflation followed by post-eruption drain back (Fornari et al., 1998; Perfit and Chadwick, 1998; Sinton et al., 2002). Collapse pits are typically concentrated near eruptive vents and decrease in abundance with distance from eruptive centers (Engels et al., 2003; Fundis et al., 2010; Figure 6a). Larger collapse areas form where lava accumulates in preexisting depressions in the terrain (e.g., fault bounded, between inflated flows, or in preexisting AST) and drains before solidifying causing the upper crust to founder, leaving a talus-strewn floor and lava pillars that commonly support archways in the upper surface (Gregg and Chadwick, 1996; Gregg et al., 1996; Figure 6b). These pillars form where vapor phase and hydrothermal fluids flow through and exit the ponded flows and provide structural buttresses after roof collapse (Engels et al., 2003). Features such as lava drips and cusps on the undersides of lava crusts also indicate that vapor formed by lava-seawater interactions is present within lobate flows, allowing lava drips to form in their vapor-supported cavities and ultimately can result in the development of collapse pits as the vapor cools and condenses (Chadwick, 2003; Perfit et al., 2003; Soule et al., 2006, 2012; Figure 6c).

Lavas in subduction zone environments

Discoveries and studies of deep-sea eruptions in subduction zone settings (volcanic arcs and back-arc basins) provide another perspective on submarine lava types because the compositions and mode of eruption can be quite different from those at MOR (Chadwick et al. 2005; Embley et al., 2006; Chadwick et al. 2008; Deardorff et al., 2011). In these settings, eruptions can occur along linear fissures, in the case of back-arc spreading centers, and commonly form localized, long-lived vents that result in the development of seamounts in submarine arc environments. Although much of the volcanism along the Lau Basin back-arc spreading centers in the southwest Pacific

is quite similar to that along MOR, active submarine eruptions in the northeast Lau Basin, associated with the Tonga-Kermadec arc, were dominated by dramatic pyroclastic and active effusive pillow lava eruptions (Clague et al., 2011; Resing et al., 2011; Rubin et al., 2012). Volcanic activity at the submarine volcano NW Rota-1 in the Mariana arc is characterized by the repeated buildup and collapse of a cinder cone at the vent. Both eruptions are considered to be Strombolian-like (i.e., driven by magmatic gas rising through the eruptive conduit) producing mildly explosive eruptions that generate volcaniclastic material including scoria. Detailed studies and real-time observations indicate that eruptions in subduction zone environments are generally more explosive (generating large volumes of volcaniclastics) and produce more continuous, low-effusion-rate eruptions that construct isolated composite cones with unstable slopes (Rubin et al., 2012). In large part these characteristics are due to the inherently higher volatile content of the magmas and their higher viscosity due to greater silica content and crystallinity.

Conclusions

Submarine volcanism on MORs is dominated by quiescent eruptions due to high hydrostatic pressure and low volatile contents. Submarine lavas differ from their subaerial counterparts in that their outer surfaces cool rapidly in the cold seawater that surrounds them. With variations in eruption rate, three morphologic types are commonly produced including pillows, lobates, and sheets. Eruptions in subduction zone environments can be explosive due to the more viscous and volatile-rich nature of arc lavas, and consequently pillows and volcaniclastics are the dominant effusive types of deposits. However, the discovery of widespread volcaniclastic deposits along some MORs (Gakkel Ridge – Sohn et al., 2008; EPR and Juan de Fuca Ridge – Clague et al., 2009) suggests that there are exceptions to this model.
Submarine Lava Types, Figure 6 Submarine features associated with lava collapse and possible interaction of lava flows with a seawater vapor phase. (**a**) Collapsed lobate flow showing pieces of thin roof crust lying in collapse pit. These features are typically concentrated near eruptive vents and axial summit troughs (*AST*) and decrease with distance from the axis. Horizontal scale ~2 m (**b**) Portion of collapsed lava lake with remnant lava pillars and archway surrounded by talus formed from collapsed roof. To the *left* is a largely undisturbed sheet flow with lava whorl. Horizontal scale ~10 m. (**c**) Closeup view of lava drips on underside of lobate roof crust in place on the edge of northern East Pacific Rise AST. Vapor that filled the cavity had to be hot enough to allow molten lava to drip from the upper crust (see Perfit et al., 2003). (**d**) Underside of lobate roof crust showing delicate lava drips and rills formed in a vapor-supported cavity as shown in image (**c**). Pen in *upper left* of image for scale.

The observation that different flow morphologies are dominant at different spreading rates leads to the conclusion that fast-spreading ridges typically have high-effusion-rate eruptions, whereas eruptions at slow-spreading ridges have lower effusion rates. This suggests that dikes may be intruded at higher magma pressures at fast-spreading ridges than at slow-spreading ridges and is consistent with the concept that magmatism dominates over tectonism at fast ridges. At intermediate-spreading rate ridges like the Juan de Fuca Ridge, where the ridge may go through cycles dominated by tectonism or magmatism, the eruption style may vary with time.

In summary, magma supply related to overall spreading rate exerts a major control on eruption rates and the consequent types of lava morphologies that form. It should be kept in mind, however, that very few ridges have been sufficiently well mapped or eruptive events documented in the detail in order to fully understand the volcanic processes occurring in the deep sea.

Definition

Failure of submarine slopes results in underwater landslides, a mass movement of sediment and rock that spills down ocean margin slopes (Hampton and Locat, 1996). Visual observations during submarine mass movement are few, and therefore landslides are commonly recognized by the remnant morphology they leave behind. These remnant slope failure features have been observed along the world's continental margins, on the slopes of volcanic islands, and volcanic island arcs. Initiation of landslides commonly results from dynamic events, generally earthquakes. Landslides are most frequent along margins where converging lithospheric plates form subduction zones and the shear between the upper and lower plates create large earthquakes, however, some large landslides occur without tectonic or seismic triggers. Sedimentary processes have caused failure from loading or unloading. Submarine landslides in the spectrum from fast to slow can be catastrophic, incremental, or creeping. Large catastrophic slides have created unexpected tsunamis that inundate adjacent shores within minutes of an earthquake, making it difficult to mitigate hazards in the affected area.

History

An awareness of how wide spread submarine landslides have been grew through the means to image the seafloor with acoustic instrument systems. Shallow water slides were reported before WWII; however, recognition became more frequent when oceanographic science received increased attention because of its military importance. Convincing evidence of slides was reported as the *precision depth recorder* of the early 1950s imaged profiles of the seafloor rather than spot soundings that controlled contours, as was done with "lead lines" and later with acoustic spot sounding. Perhaps the greatest advance was made with *multibeam bathymetric imaging systems* that map a swath of the seafloor and provide greater resolution than a series of profiles. Satellite navigation with GPS allowed individual multibeam bathymetric swaths to be joined precisely, and the improved resolution revealed many landslide features. Numerous features are inferred to have generated local tsunamis because the morphological character of remnant landslide scars can commonly show whether the slide was sufficiently large and perhaps catastrophic rather than a small translational debris flow. Indeed, the mounting evidence of submarine landslides has reinforced assertions that they were responsible for unexpected tsunamis. As improved resolution of bathymetric imaging became more widespread, it showed that submarine landslides are as common as those on land and can occur on very gentle slopes, sometimes as little as 2°.

Environments of submarine landslides

Slope failure occurs in all ocean depths, from coastal waters to the shelf edge and then down slope to tectonically active features of deep trenches. Along steep shores, landslides that begin above sea-level can travel great distances under water. In 1958, a M = 8.3 earthquake triggered a subaerial rock slide that plunged catastrophically into Lituya Bay, Alaska, generating a wave that ran 1,720 ft (525 m) up the opposite shore (i.e., Geist, 2002). Shallow water failure of delta fronts at the heads of fjords in Norway and Alaska have traveled tens of kilometers and produced damaging tsunamis. For example, during the 1964 Alaska earthquake, the front of the glacial delta on which the town of Valdez was constructed collapsed in a catastrophic 4,000 ft long by 600 ft wide landslide that took with it the harbor and docking area where 32 persons were unloading a freighter (Coulter and Migliaccio, 1966). The slump generated a 30–40 ft tsunami before the shaking of the earthquake subsided carrying the freighter onto land where it nearly capsized before the backwash refloated the ship and returned it to the fjord. Deltaic landslides not associated with an earthquake are
Submarine Slides, Figure 1 A large remnant slide scar on the Chilean margin south of Concepcion extends from the edge of the shelf to the trench (outlined with *white line*). It was probably formed by multiple slides some if which did not reach the trench (from Geersen et al., 2011).

illustrated by the large landslides of the submerged Mississippi River delta (Chaytor et al., 2010).

On continental shelves, landslides begin in local steep topography and small slide scars are observed on the sides of canyons. At the edge of continental shelves where slopes steepen, numerous landslides occur along both convergent and nonconvergent margins. Notable along Atlantic nonconvergent margins are the Storegga slide off Norway (Bryn et al., 2005) and the 1929 Grand Banks slide off North America (Mosher and Piper, 2007). Twenty large slide scars tens of kilometers wide have been identified along the US Atlantic margin (Chaytor et al., 2007). Along tectonically active Caribbean island margins, several slide scars have been mapped with multibeam systems as for instance off Puerto Rico.

The convergent margins of the Pacific have been extensively studied in various places. Along Central America where many smaller slides are documented as well as the 55 km wide rotational slump imaged off the Nicoya Peninsula (Harders et al., 2011). The continental shelf edges off Nicaragua and Costa Rica have 10 large landslide scars some of which may have been caused by subducting relief.

Multibeam mapping of the Chilean margin has revealed multiple huge slides (Geersen et al., 2011) (Figure 1).

Several occur offshore Central Chile and are probably triggered by large earthquakes.

In the north Pacific at the end of the Alaska Peninsula, a local tsunami that ran 42 m high up the rugged terrain destroyed the Scotch Cap lighthouse complex (Fryer and Tryon, 2005; Rathburn et al., 2009). The principal slide mass may have been a 15 km wide block detached from the upper slope that came to rest 10 km from its source on the mid-slope terrace (Miller et al., 2014). Upper slope slides along the US Pacific margin have been observed, such as the one off the Palos Verdes coast of Southern

California. An example on a western Pacific margin is the 1998 landslide off Papua New Guinea that created a tsunami wave locally 15 m high and resulted in more than 2,200 fatalities (Tappin et al., 2001; Geist, 2000; Sweet and Silver, 2003). This tsunami showed the potential for small earthquakes to trigger large tsunamis, if they trigger undersea landslides.

In multibeam imaged morphology of the lower trench slopes of convergent margins, rapid tectonic thickening that produces steep slopes results in considerable small to modest slope failure. Such slope failure is commonly at the limits of resolution of surface ship surveys. The great water depths and long acoustic travel path reduces the resolution because high frequency acoustic waves are attenuated. High resolution is afforded by bottom towed instruments that are deployed near the seafloor. Slope failure at small to modest scales is created as contractile deformation thickens trench sediment and pushes it upward in folds to its critical slope limit. However, much larger landslide features are produced by subducting topographic relief on the lower plate (Harders et al., 2011). Not only are the horst and graben created when the lower plate bends into the trench axis, but numerous seamounts and ridges formed by ocean plate processes produce a disruptive subducting morphology (see Figure 2 below).

Notable are the trails of remnant slope failure left by subducting seamounts as they plow into the lower slope and destabilize it. As relief tunnels into the slope and beneath the seafloor, the dome uplifted above it has steep slopes and causes debris avalanches that flow toward the trench. Theoretical studies indicate that the volume of debris in such an avalanche can be sufficiently large to cause a local tsunami. Unstable kilometer wide slope failure scars and translational debris streams are well imaged off central Costa Rica. Also imaged there and off Peru are rotational slumps 50 km and more wide. If these slumps
Submarine Slides, Figure 2 Submarine slide landslides in the trailing wake of subducting seamounts in the Middle America Trench offshore Costa Rica. Steepening of the seafloor over the seamounts causes translational slides that disintegrate into debris flows and turbidity currents.

failed catastrophically, even a 3–4 km³ volume of slope sediment would displace sufficient water to have created large tsunamis as was shown off Papua New Guinea (Sweet and Silver, 2003).

Causes of slope instability and failure

In some instances the origins of a remnant landslide scar seem obvious, whereas in other instances they are puzzling. More than one factor is commonly involved and one type of failure transforms to another. For instance, rotational slumps or detached blocks can disintegrate into debris flows and then turbidity currents (i.e., Hampton and Locat, 1996). Large scale tectonic addition by accretion and removal by the erosion of material along continental margins are basic causes of the slope instability. These tectonic processes are a precondition to submarine slumps and landslides. Plate convergence can result in accretion of trench sediment thereby steepening the slope by thickening the upper plate. Conversely, convergence can remove material from the base of the upper plate thereby thinning it and causing subsidence. Slope steepening can also be caused by scouring of the seafloor from currents.

Over steepened slopes prone to failure during local earthquakes are a key factor in initiating landslides. During earthquake shaking, stresses increase and the frictional strength along fracture interfaces decreases as pore water pressures fluctuate instantaneously. A slower rise in pore water pressure can also result from accumulation of sediment in deltas, and if sediment permeability and fluid flow is restricted by overlying rock or sediment, the pressures can elevate to a level where the superimposed mass will almost float on a water rich layer. Weak geologic layers certainly contribute to landslides but few observations have confirmed the mechanics that contribute to their failure. Studies have indicated that gas hydrates (an ice like state of gas and water under pressure) might be at the base of some slides. When gas hydrate dissociates, it forms gas charged water as temperatures rise or pressure decreases. If drainage of this fluid is inhibited, the fluid rich layer may reach a level at which slopes become unstable and fail without being triggered by an earthquake.

At non-convergent Atlantic type margins, slides have broken loose at low slope angles (2° and less) and become unstable because of sediment accumulation (Hühnerbach and Masson, 2004; Chaytor et al., 2009, 2010). With increasing sediment thickness, strata of different lithologies change physical properties at different rates as the sediment load increases. The physical property contrasts of strong and weak horizons can result in slope failure under loading by storms or changes in morphology.

At volcanic islands and island arcs, submarine landslides often result from collapse of volcano segments as the volcanos grow with the addition of lava and phyoclastic flows (Masson et al., 2002; Coombs et al., 2007). The large and extensive landslides of the Hawaiian Islands were recognized once high resolution bathymetric data were acquired. Most have occurred within the past four million years and the youngest is thought to be only 100,000 years old. Large tsunami waves carried rocks and sediments as high as 1,000 ft (30 m) above sea-level. Such landslides have the potential for enormous loss of life and property.

Hazards

Landslides that begin near sea-level have destroyed port facilities such as the catastrophic collapse of Port Valdez in 1964 (Coulter and Migliaccio, 1966). They have ripped apart submarine cables in the Grand Banks slide of 1929

almost 600 km from the head of the slide (Mosher and Piper, 2007). They have destroyed seafloor infrastructure associated with offshore oil production. However, little is known of recurrence rates, trigger mechanisms, pre- and post-failure geotechnical conditions, and the role of landslide processes in deep water sediment. Increasing development of seafloor-based offshore platforms, tele-communication and energy transport facilities, and coastal infrastructures asks for better knowledge of seafloor sta-bility conditions, submarine landslide processes and tsunamis.

A potential frequency of landslides has been addressed in theoretical studies. The locations and extent of morpho-logical landslide scars has been documented locally but the observational data for a global assessment is not yet sufficiently complete to produce meaningful constraints. Elementary quantitative models of landslides that produce tsunamis have been formulated and tested against natural examples (Ward, 2001). Another approach is with proba-bilistic analysis (Geist and Parsons, 2009) but again the observational base requires more data. Paleoseismic stud-ies in coastal areas have documented histories of inunda-tion preserved in sediment sequences but whether the cause is from transoceanic sources or local events is diffi-cult to determine without a broad regional data base.

Summary

Areas of the seafloor mapped with multibeam sounding instruments show morphological evidence of considerable mass movement on seafloor slopes from the shore to the deep trenches. Slides and slumps are especially prevalent where large earthquakes occur. Submarine landslides have damaged coastal infrastructure and are costly, they can strike without warning and have been deadly. Key factors in determining whether a landslide will be tsunamigenic are slide volume and the acceleration of a detached mass. Modern oceanographic instrumentation can resolve rem-nant features in areas of potential future slides and outline areas where past slides indicate dangerously unstable slopes. Monitoring critical areas with bottom instrumenta-tion is a means to show where future slope failure can be anticipated. But the distribution and magnitude of tsunamigenic landslides has yet to be fully appreciated. To raise the proper degree of awareness, the hazards need to be assessed quantitatively which requires more data on the physical properties related to slope failure. Long term assessments of all natural hazards should be part of an area's infrastructure.

Landslides are common on inclined areas of the sea-floor, particularly in environments where weak geologic materials such as rapidly deposited fine-grained sediment or fractured rock are subjected to strong environmental stresses. Such stresses are inflicted by earthquakes, large storm waves, and high internal pore pressures. Submarine landslides can involve huge amounts of material and can move great distances: slide volumes as large as 20,000 km^3 and runout distances in excess of 140 km have been reported. They occur at locations where the down-slope component of stress exceeds the resisting stress, causing movement along one or several concave to planar rupture surfaces. Some recent slides that originated near shore were conspicuous by their direct impact on human life and activities. Most known slides, however, occurred far from land in prehistoric time and were discovered by noting distinct to subtle characteristics, such as headwall scarps and displaced sediment or rock masses, on acoustic-reflection profiles and side-scan sonar images. Submarine landslides can be analyzed using the same mechanics principles as are used for occurrences on land. However, some loading mechanisms are unique, for example, storm waves. There is a potential for landslides to transform into sediment flows that can travel exceed-ingly long distances and this is related to the density of the slope material and the amount of shear strength that is lost during catastrophic slope failure.

SUBSIDENCE OF OCEANIC CRUST

David Voelker
MARUM-Center for Marine Environmental Sciences,
University of Bremen, Bremen, Germany

Definition

The average depth of the deep-sea floor relative to the sea surface is a function of the age of the oceanic *crust*. (This is by definition the floor of the oceans that is underlain by normally thick (5–8 km) basaltic ocean crust under normal tectonic loads. Consequently, the age-depth relation does not apply to (a) those parts of the oceans that are underlain by continental crust such as continental shelves, some epeiric seas, or continental fragments, (b) convergent plate boundaries where tectonic loading by subduction leads to deep-sea trenches that exceed the "normal" average depth of the seafloor, and (c) regions where the seafloor was formed by flood basalt events (Large Igneous Provinces) and the ocean crust is thickened.) Newly formed oceanic crust is found at water depths around 2,500 m globally, whereas its depth increases by 1,000 m during the first 10 million years after its formation. This deepening with time is called (thermal) subsidence. Subsidence slows down with time, e.g., it needs ~26 million years more for the seafloor to sink another 1,000 m.

Morphological expression of subsidence

The most obvious demonstration of the age-depth relation of the seafloor is given by *mid-ocean ridges*. Mid-ocean ridges are the places where new ocean floor forms. They stand out morphologically as ridges because of the relative low density of young ocean floor. The average elevation of the crest of the Mid-Atlantic Ridge is rather uniform along all of its length (~10,000 km), and a similar crest elevation is valid for other mid-ocean ridges. Away from the ridge axis, the average depth of the seafloor increases to both sides, resulting in the striking mirror symmetry of mid-ocean ridges. As the age increase of the oceanic crust with distance from the spreading axis is directly related to the spreading rate, fast-spreading ridges are much wider than slow-spreading ridges (Figure 1 cross section across the Mid-Atlantic and Pacific Ridge).

At oceanic fracture zones, where ocean floor segments of different crustal age are aligned by displacement by transform faults, we observe steps (fault escarpments) with a vertical displacement of up to 1,000 m (Figure 1).

The age-depth relation can be expressed as

$$Z = Z_0 - k\sqrt{t}$$

Z: depth of the seafloor of crustal age *t*.

Z0: depth of the seafloor at the spreading axis or zero-age depth (typically 2,500 m).

k: *factor of proportionality or subsidence rate*; this factor was proposed to be ca. 350 m $Ma^{-0.5}$ by Parsons and Sclater (1977), Stein and Stein (1992), and others. A newer statistical analysis gives a lower value of 320 m $Ma^{-0.5}$ as global average (Korenaga and Korenaga, 2008). Although this global average holds for many regions of the world, there are significant regional variations (Marty and Cazenave, 1989):

t: crustal age in Ma

This formula and its graphical expression are known as "Sclater curve" and were originally published in 1977 (Parsons and Sclater, 1977). It describes the age-depth relation reasonably well over 70–80 My of crustal age.
Subsidence of Oceanic Crust, Figure 1 Transform faults forming vertical offsets at a mid-ocean ridge.
Subsidence of Oceanic Crust, Figure 2 Graphical representation of the Sclater relation between crustal age and water depth.

For older crust, the subsidence is lower in reality, an effect known as "seafloor flattening" Figure 2.

Cause of thermal subsidence of the seafloor

The relative height of the seafloor is determined by the density and thickness of the oceanic lithosphere. As the chemical composition and thickness of the oceanic crust that is formed globally at ocean spreading centers show a close similarity on a global scale (the group of *mid-ocean ridge basalts or MORBs*), the density variations of the oceanic lithosphere are closely correlated to its thermal structure.

Ridges are elevated above the surrounding seafloor as they consist of rock that is hotter and less dense than the surrounding older seafloor. As the seafloor cools, it contracts and gets more dense. The hot suboceanic mantle beneath mid-ocean ridges is gradually cooled from above by the seawater (which has a mean temperature of ~3 °C below ~500 m water depth) as it moves away from the spreading centers by plate motion. As *oceanic lithosphere* is constantly recycled and fed back to the mantle at *subduction zones*, its age rarely exceeds 150 Ma and nowhere 200 Ma. Given the very low thermal diffusivity of mantle rocks of ~10^{-6} m^{2}s^{-1} and over this time span, this cooling

only affects the uppermost 100 km of the oceanic crust and mantle.

This thermal evolution can be simulated by a so-called half-space cooling model (semi-infinite half-space). This kind of models describes the thermal evolution by heat diffusion of a body of infinite extension in one direction (ideally infinite in one direction; in reality such a model can be applied to a body of dimensions that is large compared to the scale that is affected by cooling. For the Earth model, a half-space cooling model can be applied as the surface cooling of the oceanic mantle affects the uppermost 100 km of the mantle at most, which is small compared to the depth extent of the Earth's mantle of ~3,000 km (the oceanic mantle) that is in contact with another body of constant temperature, the ocean). A textbook mathematical description is given, e.g., by Turcotte and Schubert (1982) and by Stüwe (2000). A half-space cooling model of the oceanic mantle can predict the temperature-depth relation for ocean floor of a given age as well as the amount of heat loss per surface unit of the seafloor. This latter value can be measured instrumentally as heat flow and a global set of seafloor heat flow measurements were successfully used to constrain the values that were predicted by half-space models (Sclater et al., 1980; Stein and Stein, 1992).

Seamounts and atolls

One of the most striking consequences of thermal subsidence is the fate of volcanic islands that form at *volcanic hotspots* and slowly sink along with the aging seafloor until they are abraded by the breakwater to form flat-topped edifices, called *guyots*. As subsidence continues, those guyots are found as flat-topped seamounts that rise from the seafloor but have their summits at water depths between some hundreds or thousands of meters with their flat tops still documenting wave abrasion. If the oceanic plate moves in relation to the volcanic hotspot, linear chains of slowly subsiding seamounts like the 6,100 km long *Hawaiian-Emperor seamount chain* form.

In tropical seas, coral reefs form on top of subsiding guyots. If coral reef growth can keep up with the rate of subsidence, then the top of the edifice may never sink below the *photic zone*. In this case a thick carbonate cap can develop on top of the volcanic basal edifice. Reef structures on top of seamounts form *atolls*. This explanation for the evolution of atolls was firstly delineated by

Charles Darwin and solved the apparent enigma that coral reefs that need light for their growth rise from lightless depths of the ocean to the sea surface.

Summary

The water depth of the ocean floor in the open ocean (away from the continents) shows a clear relation to the time at which the seafloor was originally formed. Young seafloor that is still close to its place of formation forms chains of submarine mountains, the mid-ocean ridges. When moving away from the axes of the mid-ocean ridges, the seafloor sinks (subsides) with a rate that is related to the square root of the plate age. The reason for subsidence is the progressive cooling of the crust, resulting in contraction and an increase in density of the material, which makes the oceanic lithosphere sink.

TECHNOLOGY IN MARINE GEOSCIENCES

Sven Petersen
GEOMAR Helmholtz Centre for Ocean Research,
Kiel, Germany

Definition

Technology within this chapter defines the instrumentation and technologies used mainly to observe and sample the seafloor and subseafloor for geoscientific purposes. Equipment used specifically to observe or sample for other scientific disciplines may not be listed.

Introduction

Advances in our understanding of ocean floor processes are closely linked to advances in the technology that is being used. We came a long way from measuring ocean depths using simple lead lines to complex (and expensive) submersibles, remotely operated or autonomous vehicles, or tectonic plate-wide cabled observatories (Kelley et al., 2014; Favali et al., 2015). This is largely related to our needs to better understand marine processes and therefore to investigate over longer periods of time and with higher precision and resolution. Also, seabed sampling has changed dramatically from the first sampling programs performed, for instance, during the famous voyage of the VMS Challenger in 1872–1876 to the drilling vessel Chikyu used today by the Integrated Ocean Drilling Program (IODP). The needs to accurately and precisely take samples from the seabed and the data volume collected from the seabed both increased substantially. At the same time working at sea and at the seabed is increasingly logistically challenging due to types of instruments now being used. This new technology in marine geosciences profited over the last couple of years from the advances in technology made by the oil and gas industry associated with their move to deep ocean off-shore fields.

Here we present a list and short description of seabed sampling techniques and instruments used to observe and measure processes relevant for geosciences. This list is by no means exhaustive and complete but is intended to show the main technologies that are being used. Overall, sampling quality and precision is becoming more and more important also because of a changing vision of the ocean and the necessity to minimize our impact on the seabed during scientific sampling (e.g., InterRidge code of conduct, Devey et al., 2007; IMMS, 2011).

Research vessels

Arguably the most important instrument for any seagoing activity is a ship. These research vessels are usually designed, built, and equipped to carry out research at sea with specific winches and cranes to allow scientists to deploy and recover their instruments from various depths. The size of the research vessel often correlates with the working area. Smaller ships tend to stay in coastal environments while larger vessels are working the high seas. Many countries run several research vessels, and even a basic description of their capabilities and differences is beyond the scope of this paper. The interested reader is referred to publicly accessible lists of research vessels (research vessels by country) and live-feeds of ship tracks that are available online under http://www.sailwx.info/shiptrack/researchships.phtml.

Research vessels are commonly built to allow various scientific instruments to be used on a single vessel. Modern ships have increased deck space and storage capacity to allow better use of containerized equipment. Also, the multidisciplinary approach of modern science and the increasing use of high-tech instrumentation with their support crew require more lab space on board as well as additional berths. Certain tasks may, however, still require a

dedicated vessel. Due to the demanding nature of working in polar regions some research vessels have to be ice-breakers. Others use a moon pool to allow better launch and recovery of instrumentation. Additionally, some dedicated vessels support larger infrastructure such as submersibles, large autonomous vehicles, or special seismic systems. Some historical background on research vessels can be found in Wuest (1964) and Thiede and Harff (2015, Marine Geosciences: a Short, Ecclectic and Weighted Historic Account).

Seafloor observation methods

Depth measurements and seafloor topography

One, if not the most, important parameter to understand geologic processes in the oceans is water depth and its variability (topography or bathymetry). Early direct measurements included ropes with rocks or lead weights; however, this is only practical in shallow waters. To fully map the deep oceans other indirect methods have to be used. Since radar, used on land to provide the most accurate topographic maps down to centimeter resolution, cannot penetrate water we need other means to map the ocean floor. Conventional seafloor mapping is using a sound signal that is transmitted from the ship downward to the ship's nadir, and the reflection of the signal is received by a ship-based receiver. Using knowledge about the travel time of sound in seawater and being able to accurately measure time the water depth can be deduced using such acoustic echo sounders. While such single-beam echo sounders were already used in the early to mid-twentieth century, the development of multibeam echo sounding (or swath echo sounding) in the 1960s resulted in a revolution of our capabilities to map the ocean floor topography. These systems use electronic beamforming to create a fan-shaped array of narrow beams (currently several hundred beams) that can map a wide swath on each side of the ship's track reaching out several kilometers (up to 20 times the water depth) resulting in a dramatic increase in coverage compared to single-beam echo sounders. These beams are also narrower than single-beam echo sounders and can obtain a higher resolution (commonly 1 % of the water depth) than single-beam systems. At the same time the characteristic and strength of the returned signal (backscatter) can help to characterize the seabed (grain size, lithology, relative sediment thickness, relative age, roughness). These more accurate multibeam mapping systems came into use on ships in the 1980s, but in the deep ocean, these were deployed primarily along mid-ocean ridges, and mapping the deep ocean basins is still limited. The reason for this is mainly that seafloor mapping is difficult, expensive, and slow. Global seafloor mapping programs such as the "General Bathymetric Chart of the Oceans" (Schenke, General Bathymetric Chart of the Oceans (GEBCO)), the "International Bathymetric Chart of the Arctic Ocean" (Jakobsson, International Bathymetric Chart of the Arctic Ocean (IBCAO)), and the visualization tool GeoMapApp from Lamont-Doherty Earth Observatory (www.geomapapp.org) are combining published data from many sources in order to establish minimum standards for data processing and to provide better access to the data. It has been indicated by Becker et al. (2009) that a systematic mapping of the deep oceans by ships would take more than 120 ship-years of survey time while surveying the shallower parts would take even longer (750 ship years) due to the reduced swath width at shallower water depth.

In order to provide a map of the global ocean sparse ship-based measurements are combined with depth estimates derived from other sources (Smith and Sandwell, 1994, 1997). Currently, the best global data sets for ocean topography come from indirect measurements combining available depth soundings from ships with satellite altimetry measuring the ocean surface height and deriving high-resolution marine gravity information (Ryan et al., 2009; Sandwell and Smith, 1997; Sandwell et al., 2014). Satellite altimetry uses pulse-limited radar to measure height of the satellite over the sea surface with high precision. The difference between this height measurement and an independent value derived from precise tracking of the satellites provides a measure for the sea surface height, which, in turn, is related to the geoid. It is possible to use this satellite-derived data because it has been shown that gravity anomalies are highly correlated with seafloor topography and can be used to recover topography (Dixon et al., 1983). The most recent update of the global data was published in late 2014 (http://topex.ucsd.edu/marine_topo/). The resolution of the topographic data derived from this processing has improved over the years, and the global grid cell size is now close to 1 km. Still, today the topography of the Moon, Mars, and Venus is mapped with higher resolution than most areas of the ocean floor (e.g., Tanaka et al., 2014). The current global ocean floor topographic map shows unprecedented detail and is great for recognizing large-scale (global or regional) morphological features (Harris et al., 2014) and understanding processes such as the evolution of oceanic basins, spreading centers, or microplates over time (Sandwell et al., 2014), it is, however, not good enough for local volcanological processes, landslides, or mapping of small-scale variability. Here we rely on the ship-based multibeam bathymetry with a resolution of several tens to 100 m recognizing our needs to go even closer to the seafloor to improve resolution. Over the last couple of years multibeam echosounding systems have been reduced in size so that they can now routinely be used on remotely operated vehicles (ROVs) and autonomous underwater vehicles (AUVs) providing topographic data with a resolution down to a few centimeters, depending on the altitude at which these surveys are flown (Caress et al., 2012; Yoshikawa et al., 2012; Jamieson et al., 2014; Clague et al., 2014). An example of the difference in resolution from satellite-derived topography and ship-based and high-resolution AUV-based bathymetry is provided in Figure 1.
Technology in Marine Geosciences, Figure 1 Example of resolution increase from satellite-altimetry-derived topography (*left*, 3 km per pixel) to ship-based multibeam echosounding (*middle*; 50 m per pixel) to AUV-based high-resolution data (*right*; 1 m per pixel). Example for the Endeavour Segment on the Juan de Fuca Ridge. Data sources: Sandwell and Smith, 1997 for satellite data; ship-based data recorded during cruise TN146 on RV Thomas G. Thomspson; source GeoMapApp; Ryan et al., 2009; AUV-based bathymetry recorded by MBARI's AUV "D.Allan B." in 2008. Width of the rift valley in each image is approximately 1.5 km (image modified from Jamieson et al. (2014)).

Sidescan sonar and synthetic aperture sonar

The method of choice for imaging large areas of the seafloor in high resolution is sidescan sonar imaging. These sensors transmit one beam on each side (broad in the vertical plane and narrow in the horizontal plane) and cover a large portion of the seabed away from the surveying vessel or platform (Blondel, 2010). A coverage ranging from a few tens of meters to 60 km or more can be obtained depending on the altitude of the sensor. Sidescan sonars can, depending on the frequencies, configuration, and altitude, achieve resolutions down to centimeter scale, by far exceeding those of multibeam echosounding systems flown at similar altitude. The most commonly used sidescan sonars are deep-towed systems for regional mapping (Figure 2a), but sidescan sonar sensors are now also routinely operated on autonomous underwater vehicles for high-resolution surveys at the seafloor. A recent development is the use of synthetic aperture sonar in conjunction with AUVs that provides even better along-track resolution and has shown its potential for seabed resource exploration purposes (Hansen et al., 2015; Denny et al., 2015).

Seismology

The use of seismology in marine geosciences is threefold: (1) usually on-shore global networks record distant arrivals from larger earthquakes that are being used to delineate active plate boundaries and to understand the nature of plate motion and large-scale faulting; (2) passive marine seismology using local networks of seismic recorders at the seafloor (ocean-bottom seismometers, OBS) to detect natural earthquakes, and (3) controlled-source experiments that use pulses of compressed air generated by air guns on the ocean surface (Prodehl and Mooney, 2014).

The latter two are being used to investigate the local structures and processes within the Earth's crust and mantle. These include the supply of magma to form the oceanic crust, faulting, convective and hydrothermal processes, the fate of subducting slabs, the formation of seamounts and hot spots, as well as processes effecting continental margins such as submarine landslides that may generate coastal hazards, or the distribution and fluid flow associated with gas hydrates and mud volcanoes.

Passive seismology uses a local network of ocean bottom seismometers that is deployed for prolonged time (up to 6 months or 1 year) to record natural earthquake swarms or tremor to provide information related to the source mechanisms and source area at depth. Ocean-bottom seismometers (Figure 2b) are, in principle, a carrier platform for a seismic sensor and the recording unit consisting of pressure-tight cylinders hosting the sensors, electronics and batteries in addition to an anchor weight that can be released acoustically, the floats for buoyancy, as well as equipment to ease detection and recovery when afloat such as lights, a flag, and the recovery rope.

Controlled-source or active seismology is aimed at obtaining higher-resolution images of the upper layers of the earth's crust than can be obtained by passive seismology. It is based on the principle that an artificially generated sound wave travels through the subsurface and returns to the surface where it can be analyzed. Two controlled-source seismic methods are being used: reflection and refraction seismology. The classical acquisition method in marine reflection seismology is a 2D geometry where a single seismic streamer is towed behind the vessel recording the reflected waves. New systems use a bundle of several short streamers that is towed allowing for a 3D geometry. In refraction seismology air guns are also being used as transmitters, but the receiving units (OBS) that are similar to those used for passive seismology are stationary at the seafloor. A detailed account of reflection and refraction seismology and their instrumentation used is given in Hübscher and Gohl (Reflection/Refraction Seismology) and (Pecher et al., 2011).

Magnetics

As new oceanic crust is formed at the mid-ocean ridges, it cools and acquires a record of past geomagnetic field variations forming a pattern of normal and reverse polarized crust that are readily identifiable in the magnetic data measured at the sea surface (Gee and Kent, 2007). These patterns of the ocean's magnetic field were fundamental in developing the seafloor spreading and plate tectonic theories (Vine and Matthew 1963; Heirtzler et al., 1968). Marine magnetic measurements are important for

providing a better understanding of the global magnetic field and polarity changes (Gee and Kent, 2007; Tominaga et al., 2008), as global bathymetric data affording to combine modern and old measurements into a single global model are important (Quesnel et al., 2009). Presently a large range of instruments exists that measure from towed platforms thereby avoiding the ship's electric and magnetic field and, more recently, from submersibles, deeptowed vehicles, ROVs, and AUVs (Tivey and Dymont, 2010). These high-resolution surveys allow for a better understanding of local magmatic activity (Shah et al., 2003) and for exploration of seafloor massive sulfides due to changes in the magnetization caused by ascending hydrothermal fluids (Tivey and Johnson, 2002; Tivey and Dymont, 2010).

Electromagnetics (EM)

Similar to seismology marine electromagnetics can be divided into passive (magnetotelluric) or active methods (controlled-source electromagnetics, CSEM). Electromagnetic surveying is used to investigate the distribution of electrical properties, mostly electrical conductivity, of geologic formations in the subseafloor. Marine magnetotelluric EM measures the natural variations of the Earth's magnetic field, which induce electromagnetic fields in the seabed. Controlled-source EM methods measure the electromagnetic fields associated with artificially induced subsurface electrical currents created by magnetic coils or grounded electric wires (Constable, 2013).

For a CSEM survey, an electric dipole transmitter is towed from a ship and passes a time-varying current between electrodes that are spaced apart by up to a few hundred meters, producing an electromagnetic field that diffuses through the conductive surrounding, i.e., the ocean and the seabed, as well as through the air in shallow-water applications. The transmitter is usually towed close to the seafloor to maximize the energy that couples to the seabed. The diffusion of the electromagnetic field away from the transmitter depends on the conductivity of seawater and the seafloor. The resulting attenuation and phase shift of the transmitted electromagnetic field is recorded by an array of receivers. These receivers can be stationary at the seafloor (Figure 2c) or can be towed together with the transmitter (Schwalenberg et al., 2010; Anderson and Mattson, 2010). Details of the varying methods currently in use are given in Edwards (2005) and Constable (2013). The replacement of saline pore fluids in sediments by hydrocarbons and the resulting formation of resistive layers in the subseafloor make controlled-source EM a prime choice in oil and gas exploration and gas hydrate research (Constable, 2010) and the investigation of mud volcanoes (Hölz et al., 2015). Recently, controlled-source EM methods have shown their potential to identify layers with higher conductivity in the subseafloor (Swidinsky et al., 2012) extending marine mineral exploration of seafloor massive sulfides using CSEM (Kowalczyk, 2008) to the subseafloor.

Gravity

We have seen above that gravity data can be important in marine geosciences even from space. However, marine gravity data is also measured from ships and other platforms and is important in recognizing crustal structure and crustal thickness variations because they reflect variations in subsurface mass and density (Watts and Talwani, 1974). Measurements of the gravitational field at sea are compared to the theoretical gravity given by a reference Earth model for the same location and presented as the free-air gravity anomaly (Barckhausen and Heyde, Gravity Field). Variations in the sea surface have to be taken into account and result in the Bouguer anomaly, which is assumed to reflect variations in the density distribution below the seafloor. Considering effects of water/crust, crust/mantle interfaces, as well as temperature, density variations in the underlying mantle are used to calculate the residual mantle Bouguer anomaly that can be interpreted with respect to crustal thickness and structure (Lin et al., 1990, Blackman et al., 2008).

Heat flow

Heat flow measurements in sedimented areas of the ocean crust were instrumental in understanding the processes of seafloor spreading and plate tectonics. Soon after recognizing that seafloor spreading takes place at mid-ocean ridges heat flow studies indicated that conduction of heat through the lithosphere cannot be the only process governing energy exchange between solid earth and the oceans and that convective processes must also occur (Lister 1972; Davis and Lister, 1977; Sleep and Wolery, 1978; Stein and Stein, 1992). These studies came just before hydrothermal activity was actually found near the Galapagos Islands in 1977 (Corliss et al., 1979) and on the East Pacific Rise in 1979 (Spiess et al., 1980). Later heat flow studies have been used to constrain numerical models of crustal fluid flow at ridge flanks and in off-axis sedimented regions where basement outcrops and seamounts have been shown to be important for lithospheric cooling (Fisher et al., 2003) indicating that this off-axis heat flux can be comparable to that of black smoker vent fields (Hutnak et al., 2008). A detailed account of marine heat flow is given in Sclater et al. (Marine Heat Flow).

For heat flow studies temperature gradients are measured by an array of thermistors in a narrow tube that is inserted into the sediment by a corer. Thermal conductivity is obtained by heating a wire for short times and measuring the temperature decay as the heat dissipates through the sediment. Smaller versions of such instruments are also used from submersibles (Johnson et al., 1993). Recent developments using thermal blankets also allow for high-resolution measurement in nonsedimented areas such as volcanic ridges and within hydrothermal vent fields (Johnson et al., 2010).

Sediment physics

The in situ physical properties of sediments are important for marine geoscience related to coastal hazards but also for constructional work in sedimented environments off

shore. Conventional and *free-fall cone penetrometers* (CPTs) have been developed that measure cone resistance, sleeve friction, pore pressure, tilt, and temperature (Lunne et al., 1997; Stegmann et al., 2006). These parameters are used to determine shear strength and excess pore pressure that are important trigger mechanisms for sediment movement and slope stability.

Visual imaging

Visual imaging of the seafloor is a fundamental method in geology. Today a number different systems are in use ranging from simple deep-towed camera systems (Figure 2d) that only use photography and video to image the seafloor to multipurpose towed platforms that can also additionally run other sensors (Figure 2e) to even more complex systems such as manned submersibles, remotely operated vehicles (ROVs), and autonomous underwater vehicles (AUVs). Examples of these kinds of instrumentation are provided in Figure 2f–l.

Today, high-definition cameras are standard on many submersibles and ROVs allowing better control on positioning of the instrument and selection of images. Numerous submersibles (or human occupied vehicles, HOVs) are run by research institutions and include "Alvin" from Woods Hole Oceanographic Institution (WHOI), which started its life 50 years ago but has been refurbished a couple of times (Figure 2f; Humphris et al., 2014). France, Japan, Russia, and China currently also run research submersibles for deep ocean research with Chinas "Jiaolong" being able to reach 7,000 m water depth. The French "Nautile," Japan's "Shinkai6500," and the Russian "Mir" submersibles all have depth ratings beyond 6,000 m. Manned submersibles are usually occupied by three persons and can take one to two scientists to the seafloor. They stay at the bottom for several hours depending on water depth and battery capacity and enable traversing speeds of 1 knot (0.5 m/s). Submersibles have lighting, multiple cameras, and manipulator arms for imaging and working at the seabed. Additionally, they can take various scientific payloads of up to 100 kg or so to the seafloor. Most submersibles need a dedicated ship due to the logistical requirements for deployment and recovery and a large number of crew for support. An exception to this rule is Germany's manned submersible "Jago," which is containerized and can be deployed from smaller vessels but has a depth limit of 400 m (Figure 2g).

Over the last decades manned submersibles have been replaced to some extent by deep-sea remotely operated vehicles that were developed based on existing towed platforms that carried instruments to the seafloor (Figure 2h). They have a couple of advantages over manned submersibles including, in theory, unlimited power supply through the umbilical providing longer endurance. In theory ROVs can stay at the bottom for several days with pilots and scientists being exchanged at regular intervals. ROVs are also smaller, cheaper to run, commonly use less personnel, and provide no risk to humans working at the seafloor.

The ROVs are attached to the vessel by a cable providing energy and allowing data transmission including live video (Figure 2i). The ROVs are not towed but use their thrusters to move at similar speeds as submersibles despite the fact that the ROV and the vessel have to be moved in parallel. The ROV pilots are maneuvering from a control container on the vessel guided by scientists. Instrumentation and payload for work-class ROVs is similar to that of the manned submersibles. Navigation for both types of instruments is by Ultra Short Base Line (USBL) acoustic communication and dead reckoning.

Both manned submersibles and ROVs move slowly at the seafloor, and in order to map larger areas of the seafloor faster and more efficiently autonomous underwater vehicles (AUVs) have been developed that are not attached to the vessel, drive self-propelled, and use batteries to power the instrument. They commonly follow a predefined track and use several sensors (such as sidescan sonar, multibeam echosounding, subbottom profilers, magnetometers, temperature sensors, chemical sensors, or cameras) to investigate the seafloor or the water column (Wynn et al., 2014). AUVs are able to navigate using either acoustic beacons on the seafloor (so-called Long Base Line (LBL) navigation) or a combination of USBL acoustic communication and inertial navigation (based on dead reckoning using a combination of depth sensors, inertial sensors, and Doppler velocity sensors).

Most AUVs are torpedo shaped and can reach a speed of several knots allowing larger areas to be covered with high resolution. Others have a more complex structure and move more slowly providing them with the capability to move or hover over complex terrain at lower altitude. One of the earliest multisensor AUVs for the deep sea was "Abe" run by Woods Hole Oceanographic Institution that was commissioned in 1994 and was the prime AUV of its time before being lost at sea in 2010 after more than 200 scientific dives. It was also famous for its V-shape structure resembling "Starship Enterprise" (Figure 2j). Numerous AUVs are now being used around the globe; however, few systems are able to work at great depths of 5,000 m or more or are working under ice cover such as the most recent addition to WHOI's fleet, the "Nereid" (Figure 2k). The usefulness of such deep-diving AUVs outside of its science usage was demonstrated to the public by the use of three REMUS6000 AUVs during the search of the lost Air France flight AF447 in 2010 and 2011, when these systems found the wreck site (Figure 2l).

One of the biggest advantages of AUVs is that once the AUV is following its predefined track the research vessel is free for other research even at a greater distance to the AUV survey area maximizing ship time use.

Seafloor sampling tools

Simple geologic sampling tools can be divided into three groups (Sterk and Stein, 2015): (1) towed systems that are dragged along the seafloor, (2) cable-linked spot-sampling systems that take a sample from a well-defined

location (box corer, grab systems), and (3) devices that can take samples from the subseafloor. These include simple devices such as gravity corers, lander-type seabed drills, as well as complex drilling operations from surface vessels.

Towed sampling instruments

One of the oldest and most reliable sampling tools are dredges (Figure 3a). These box, bucket, or chain bag dredges are deployed on a steel cable and towed behind the ship for several hundreds of meters or even longer. These simple and cost-effective instruments collect samples over the entire track length, and since they commonly lack a navigation device, the location of the samples from the seabed is only crudely known. Dredges, however, have the advantage that they can be deployed at severe weather conditions, when most sophisticated instruments are long out of business.

Spot-sampling instruments

For surface sediment sampling *box corers* or *multicorers* are commonly used (Figure 3b). Box corers are deployed from a steel wire and use a heavy weight to press a rectangular or square steel box into the substrate. Lifting the box corer first moves a sliding plate across the base of the box enclosing the sediment before lifting the instrument from the seabed. Penetration into the sediment is several tens of centimeters and the area of the seafloor that is sampled is in the order of 0.5 m^2. Box corers cannot be used for sampling consolidated hard rocks. A similar tool for sampling in soft sediment is a multicorer that uses several plastic tubes that are pushed into the sediment by a weight (Figure 3c). The multicorer is also deployed from a wire. Penetration is again in the order of several tens of centimeters; however, the area that is being sampled is much smaller. Multicorers are often used to collect multiple samples from a given area for investigations of the sediment-water interface. For better control and documentation of the actual sampling site camera systems can be used to take either photographs or video information.

A suite of grab samplers that use opposing jaws is used for sediment sampling (simple bucket grabs) or for sampling of indurated material, hard crusts, and rocks (powered TV-guided grab systems). The latter were originally developed for sampling of marine minerals from the seabed in the 1980s and use opposing jaws that close hydraulically and thereby breaking off even massive sulfides and basalt (Figure 3d). These systems have the advantage of being able to sample larger, more representative pieces of the seabed than sophisticated manipulator arms such as those used by submersibles and robotic systems (see above). Such TV-guided grab systems can sample close to 1 m^2 of seabed up to 50 cm deep. The live camera feed allows for a controlled sampling and even resampling (after opening the jaws again) in case the sample size or nature was not sufficient.

Sediment traps are sampling devices in the water column used to measure the quantity of sinking particles over prolonged periods of time (often several months) and to collect them for shore-based analyses. In sedimentology they allow the characterization of the sedimentation processes, their rates, and the fluxes of chemical components to the seafloor. Sediment traps usually consist of an upward-facing funnel that collects sinking particles into a trap. Rotating sampling devices below the funnel commonly allow for discrete subsampling using predefined time schedules thereby recording changes over time.

Subseafloor sampling instruments

In order to sample the upper few meters of sediments a number of corer devices can be used. These include simple gravity corers and piston corers as well as more advanced vibro corers. *Gravity corers* are the simplest form of coring device and consist of a steel pipe, typically with several tens to hundreds of kilograms of weight added to the top, a plastic liner for easier sample retrieval, and a core catcher to prevent sample loss (Figure 3e). The gravity corer is lowered close to the seafloor on a wire and then allowed to freely fall into the sediment. The length of the core barrel and the weight used can vary due to the sampling needs and/or the stiffness of the sediment preventing easy penetration. For longer sediment cores *piston corers* are used that are similar to gravity corers but use a small piston that helps to draw the core into the barrel more effectively. This piston is set at the bottom entrance to the barrel and moves up the barrel as it penetrates the seabed. The longest core recovered using such a system was collected aboard the French research vessel R/V Marion Dufresne and collected 64.4 m of sediment from a single deployment (Sterk and Stein, 2015). In gas hydrate research autoclave piston cores have been developed to retrieve the sediments under in situ hydrostatic pressure (Abegg et al., 2008).

Vibro corers consist in general of a tripod-supported frame containing a vibrating head that is driven by hydraulic, pneumatic, mechanical, or electrical power and which uses vibration and gravity to drive a core barrel into the seabed. The entire vibro corer is launched from the surface vessel via a cable. After sampling the vibration is turned off and the core barrel is withdrawn back into the housing followed by retrieval of the instrument using a winch and cable.

For hard rock sampling a different toolset is necessary. Here, *remotely controlled robotic seabed drills* are being used that are lowered to the seafloor via a winch and cable (McGinnis, 2009). The drill string is handled via robotic machinery at the seafloor and remotely controlled by an operator on the vessel. This isolates the drilling process from vessel motion and subsequently enables critical drilling parameters to be precisely controlled. Research institutes currently run a number of these systems globally, but commercial companies are entering this market. Early versions used single-pass drilling (Figure 3f) while modern systems use

built-in rod racks or carousels (Figure 3g) to store additional drill pipe, casing, and core barrels (Freudenthal and Wefer, 2007). Maximum penetration depths of these drill rigs are currently around 200 m and are determined by the number of rods and core barrels that can be stored. Most drill rigs, however, penetrate only a few tens of meters into the seabed. While this is significant it is not comparable to the penetration depths that can be achieved by *vessel-mounted drill systems* such as the drill ships "Joides Resolution" or "Chikyu," the latter having drilled to 2,466 m below the seafloor in 1,180 m water depth (Figure 3h; Suyehiro, Ocean Drilling). Seabed drilling is, in general, cheaper than the use of dedicated drilling vessels and since the systems are mobile can be done on ships of opportunity. A detailed account of ship-based ocean drilling programs is provided by Suyehiro (Ocean Drilling).

Summary

This chapter describes the most commonly used technologies and instruments for observing and sampling in the field of marine geosciences and refers to a number of special papers within this encyclopedia and beyond. This chapter is meant as an introduction showing the variability and broad scale of intruments being used. Since technology is a vast and rapidly changing field, numerous specific instruments used throughout marine geoscience are undouptfully missing in this compilation.

TERRANES

Maurice Colpron[1] and JoAnne Nelson[2]
[1]Yukon Geological Survey, Whitehorse, Yukon, Canada
[2]British Columbia Geological Survey, Victoria, BC, Canada

Synonyms

Allochthonous terrane; Exotic terrane; Suspect terrane; Tectonostratigraphic terrane

Definition

Rock assemblages of regional extent within an orogenic belt that show internal geological consistency and that differ significantly from rock assemblages in adjacent terranes (Nelson et al., 2013).

Introduction

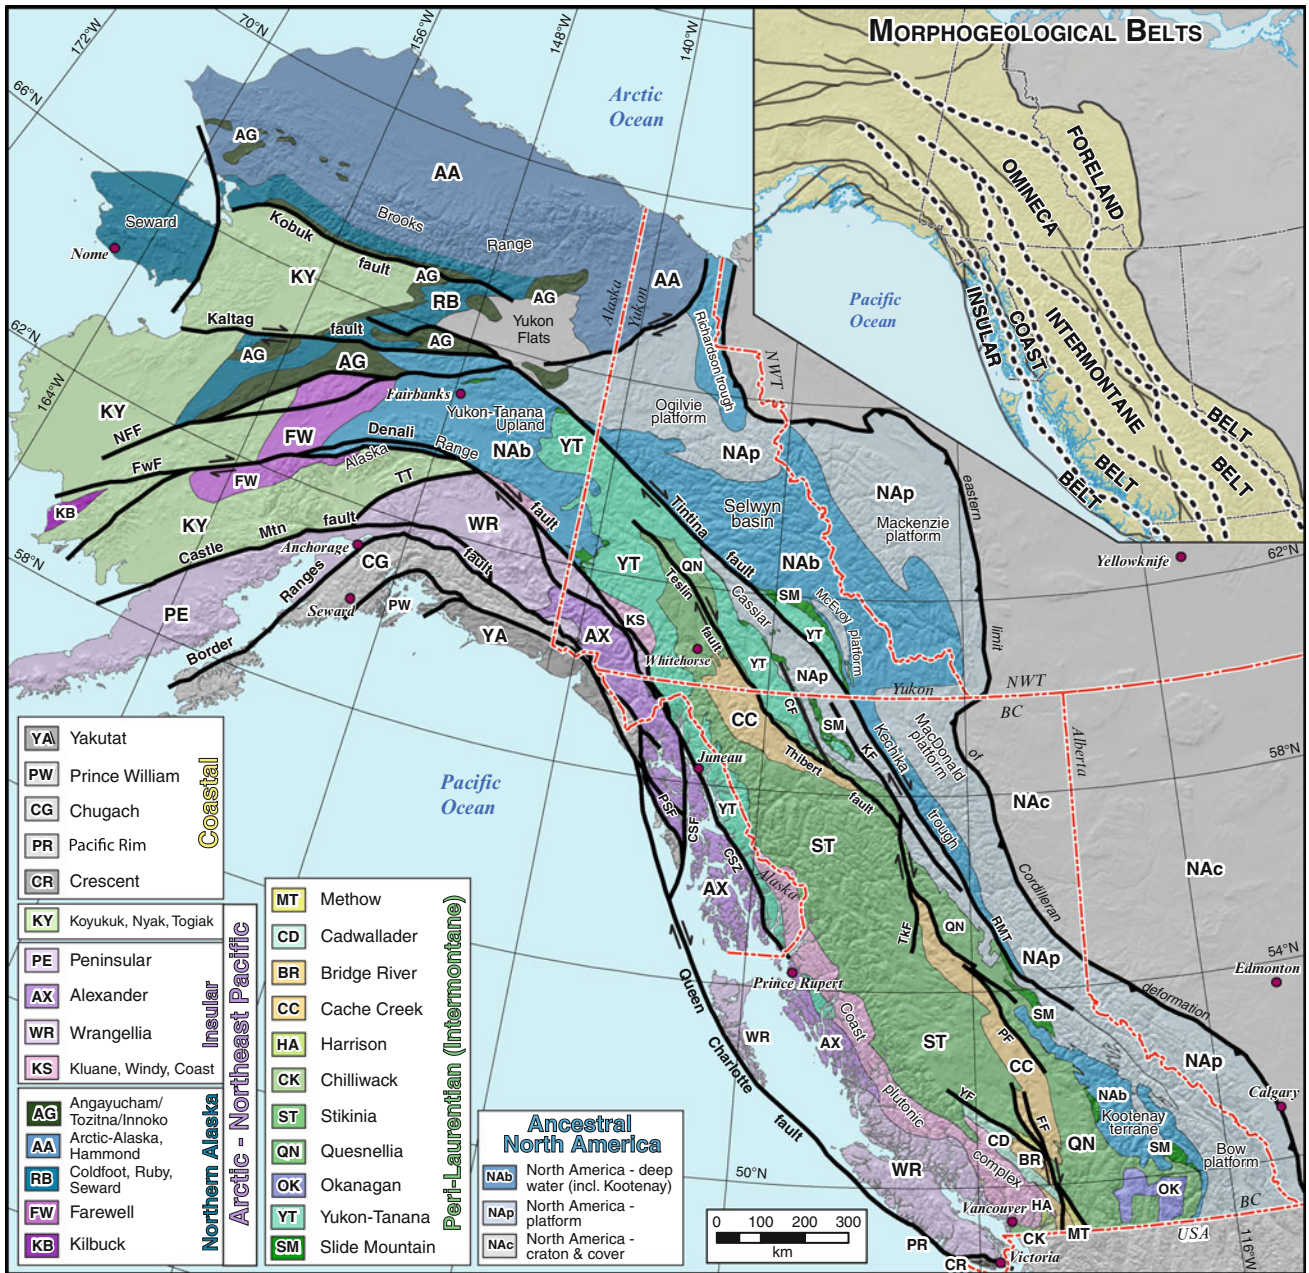
The terrane concept was first applied to the tectonic analysis of the North American Cordillera, one of the world's classic accretionary orogens (Figure 1; Coney et al., 1980; Jones et al., 1983). Terranes were introduced as a means to describe the collage of disparate elements that makes up the Cordilleran orogen (e.g., Helwig, 1974). In the original definition, terranes were considered "suspect" because little was known about their paleogeographic affinities and because most terranes were bounded by faults, thus raising questions about relationships between adjacent terranes. The terrane concept continues to guide tectonic analysis of the North American Cordillera, although new studies have yielded more information about paleogeographic origins and the relationships among many terranes, leading to refinement and evolution of the concept (e.g., Colpron et al., 2007).

Evolution of the terrane concept

Since the original inception of the terrane concept, detailed studies of Cordilleran terranes have repeatedly documented stratigraphic or intrusive links between some of the major terranes (e.g., Klepacki and Wheeler, 1985; Gardner et al., 1988; Colpron and Price, 1995; Colpron et al., 2007). The application of geodynamic interpretations to Cordilleran terranes has also revealed genetic links between paired arcs and accretionary complexes (Nokleberg et al., 2005). In many cases, terrane-bounding faults are now clearly identified as younger, post-accretionary structures that simply reshuffled previously accreted terranes. In places, these younger structures coincide with, or occur near, facies transitions between adjacent geodynamic elements. A useful current definition needs to acknowledge the enduring importance of terranes as recognizable geologic entities while accepting that they may have developed as adjacent, locally linked tectonic elements.

Continuing investigations of the North American Cordillera have also led to a greater understanding of the paleogeographic origins and tectonic evolution of many terranes, such that the "suspect" prefix is no longer appropriate. A growing body of faunal, isotopic, geochemical, paleomagnetic, and geochronological evidence now provides the basis for increasingly more refined paleogeographic and tectonic models of the northern Cordillera in Canada and Alaska (Monger and Price, 2002; Colpron and Nelson, 2009; Nelson et al., 2013, and references therein). Based on the region of origin, sets of related terranes in the northern Cordillera can be grouped into paleogeographic realms in a similar fashion to those identified in the Appalachian orogen (e.g., van Staal, 2007; Figure 2): (1) the Laurentian realm, which includes the autochthon and parautochthon of ancestral North America; (2) the peri-Laurentian realm of marginal arc, basin and pericratonic terranes, and forearc accretionary complexes that evolved in proximity to the western (present coordinates) continent margin of ancestral North America; (3) the Arctic-northeastern Pacific realm, including pre-Devonian terranes of Baltican, Caledonian, and/or Siberian affinity that originated in the present circum-Arctic region and then evolved at high latitudes in the ancestral northeastern Pacific basin, along with younger associated arc and accretionary terranes; and (4) the Coastal realm of later Mesozoic and Cenozoic accretionary complexes that originated near or on the eastern side of the Pacific basin and are accreted (or accreting) along the present North American-Pacific plate boundary (Figure 2). It emerges from this analysis that only terranes of the Arctic-northeastern Pacific realm are truly exotic to western North America.

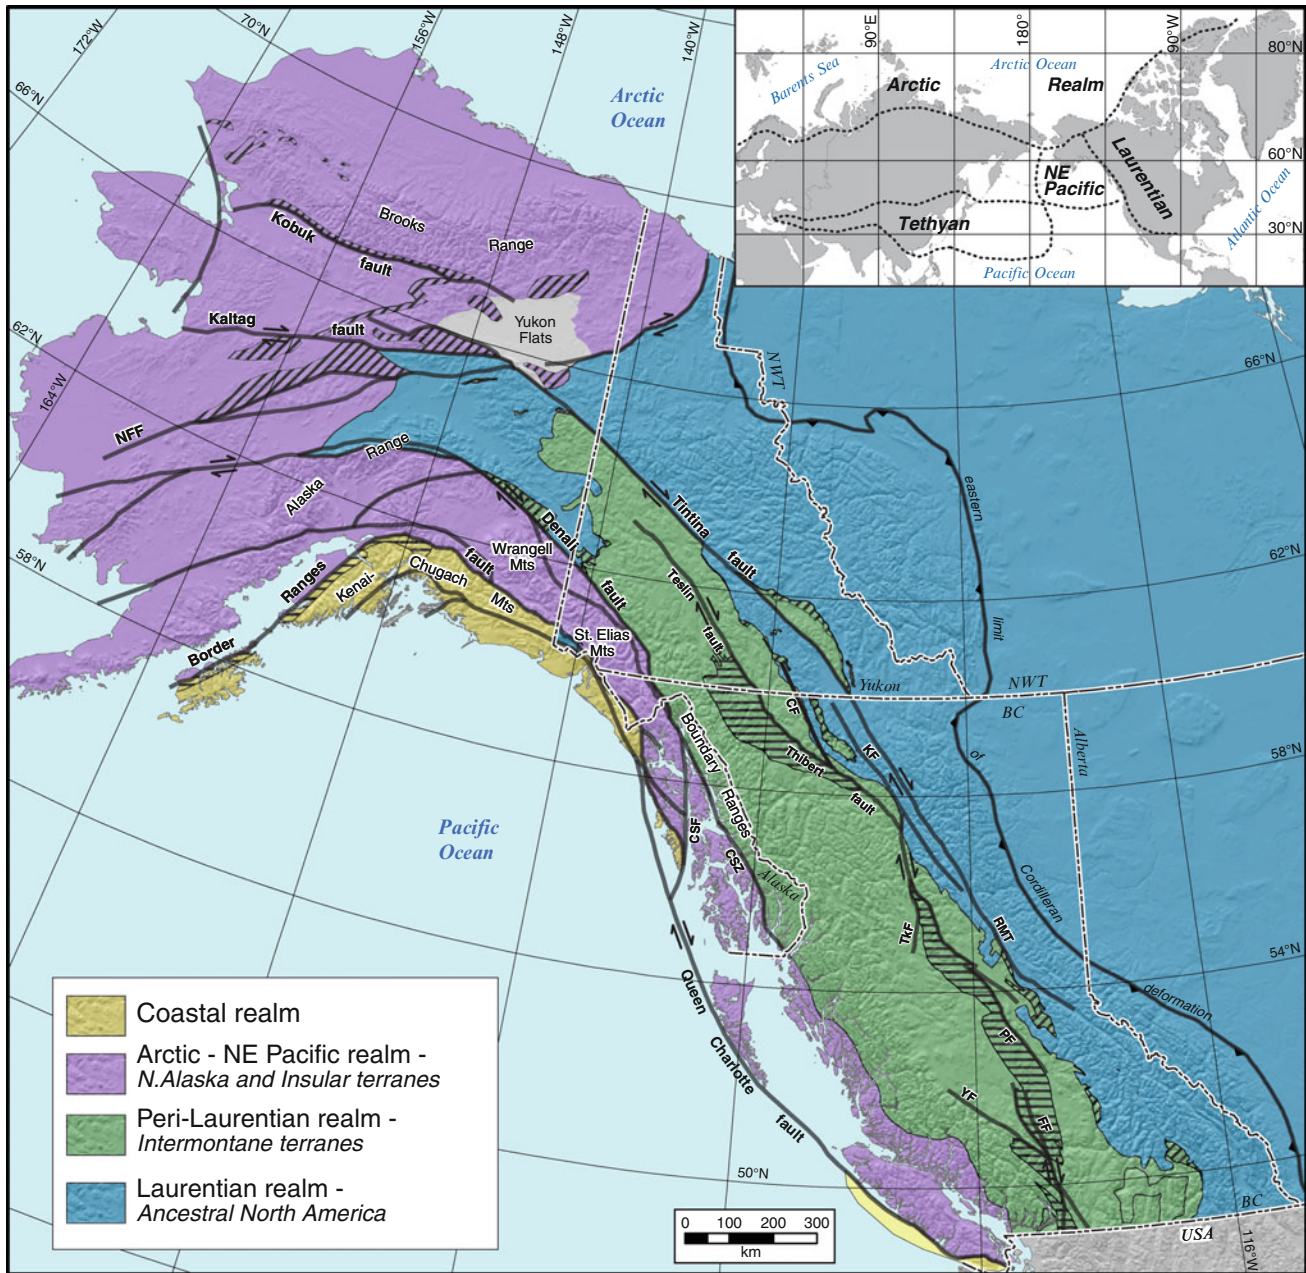
Applications to other orogens

After its introduction in the North American Cordillera, the terrane concept was variably applied to other orogens around the world (e.g., Williams and Hatcher, 1983; Howell, 1989; Audley-Charles et al., 1990; Bluck, 1990) and also debated (Hamilton, 1990; Sengör and Dewey, 1990). Terranes, as used in the North American Cordillera,


Terranes, Figure 1 Terranes of the Canadian-Alaskan Cordillera (after Colpron and Nelson, 2011). Terranes are grouped in the legend according to paleogeographic affinities shown in Figure 2. Inset shows morphogeological belts of the northern Cordillera after Gabrielse et al. (1991). Fault abbreviations: *CF* Cassiar fault, *CSF* Chatham Strait fault, *FF* Fraser fault, *FwF* Farewell fault, *KF* Kechika fault, *NFF* Nixon Fork-Iditarod fault, *PF* Pinchi fault, *PSF* Peril Strait fault, *RMT* northern Rocky Mountain trench, *TkF* Takla-Finlay-Ingenika fault system, *TT* Talkeetna thrust, *YF* Yalakom fault, *CSZ* Coast shear zone.

may be in part equivalent to "allochthons" or "nappes" as used in other orogens, particularly where the geologic record of an allochthon (or nappe) differs from adjacent allochthons. However, the use of allochthon or nappe to describe individual thrust imbrications of a single tectonic element does not correspond to terranes as defined in this article.

Summary

Terranes are regions within an accretionary orogen that are characterized by rock assemblages of internal geological consistency that differ from assemblages contained in adjacent terranes. The terrane concept has been, and continues to be, an important tool in the tectonic analysis of the North American Cordillera and other orogens


Terranes, Figure 2 Cordilleran terranes grouped by paleogeographic affinities. Paleogeographic affinity is assigned according to region of origin in Paleozoic time, except for the Coastal terranes, which originated along the late Mesozoic-Cenozoic eastern Pacific plate margin. Inset shows the main distribution of Paleozoic paleogeographic realms in the circum-Pacific region. Diagonal hatching indicates oceanic terranes in the peri-Laurentian and Arctic realms; horizontal hatching indicates accretionary complex containing elements of Tethyan affinity (e.g., Cache Creek terrane). Fault abbreviations: *CF* Cassiar fault, *CSF* Chatham Strait fault, *FF* Fraser fault, *KF* Kechika fault, *NFF* Nixon Fork-Iditarod fault, *PF* Pinchi fault, *RMT* northern Rocky Mountain trench, *TkF* Takla-Finlay-Ingenika fault system, *YF* Yalakom fault, *CSZ* Coast shear zone.

around the world. In the North American Cordillera, the terrane concept has evolved since the original inception to recognize that not all terranes are necessarily fault bounded and to integrate evolving geodynamic interpretations into the tectonic analysis of the orogen (Colpron et al., 2007).

TETHYS IN MARINE GEOSCIENCES

A. M. Celâl Şengör
Faculty of Mines, Department of Geology and Eurasia, Institute of Earth Sciences, Istanbul Technical University, Ayazaga, Istanbul, Turkey

Synonyms

Central Mediterranean; Mesogea

Derivative terms

Antitethys, Eotethys, Eoparatethys, Greater Tethys, Hemitethys, Meso-Tethys, Mesoparatethys, Neo-Tethys, Neoparatethys, Paleo-Tethys, Paleotethys, Paleothetis, Paratethys, Protoparatethys, Proto-Tethys

Definition

Tethys is the name given by Eduard Suess to an equatorial ocean that extended from the westernmost Mediterranean region of today to eastern Asia during the time interval from the late Paleozoic to the early Cainozoic, the demise of which gave rise to the present-day Alpine-Himalayan mountain ranges. This seaway had been identified earlier, but for the Jurassic time only and called the "Central Mediterranean" by Suess' son-in-law, the great paleontologist,

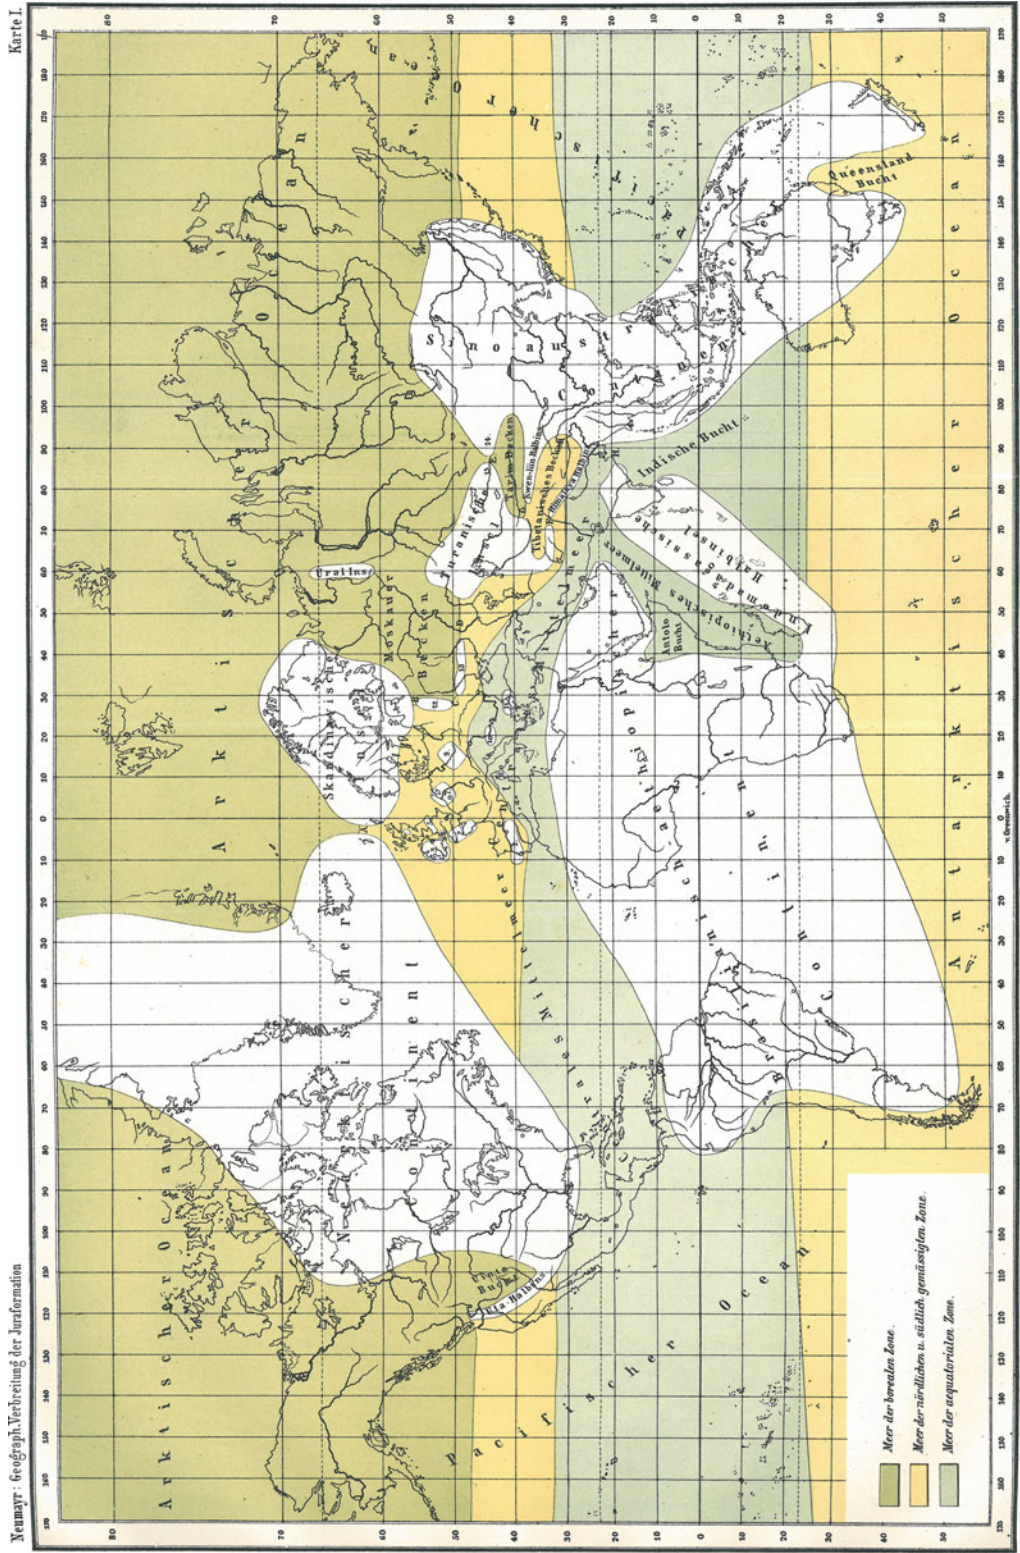
Melchior Neumayr ([1885]; Figure 1). Suess defined the Tethys thus: "Modern geology permits us to follow the first outlines of the history of a great ocean which once stretched across part of Eurasia. The folded and crumpled deposits of this ocean stand forth to heaven in Thibet [sic!], Himalaya, and the Alps. This ocean we designate by the name "Tethys," after the sister and consort of Oceanus. The latest successor of the Tethyan sea is the present Mediterranean" (Suess, [1893], 183; see also Suess, [1901], 25). During his farewell lecture in 1901, Suess added: "The old land to its south was called Gondwana-Land and the one to its north Angara-Land" (Suess, [1902], S. 4). Despite the fact that the theoretical framework in which Suess had defined the Tethys is now abandoned (i.e., the fixist contraction theory), his definition still stands as a precise description of what the Tethys was. The name itself derives, as Suess says, from the ancient Greek mythology, from Τηθύς (Tethys), a daughter of Gaia (the earth) and Uranos (the sky) and as such one of the first generation of Titans and sister and consort of Okeanos. When Suess coined the term Tethys, he already knew that it had been a proper ocean already during the Triassic (Suess, [1895]), with depths exceeding 4,000 m (Suess, [1909], 646), and not just an epicontinental seaway, as some have tried to maintain even into the 1980s of the twentieth century. (The "Shallow Tethys" symposia were initiated by the enthusiasts of an epicontinental Tethys Sea in denial of its oceanic character. It very quickly became clear, however, how untenable that position was, and now the Shallow Tethys symposia bring together mainly paleontologists working on the fossils of organisms that once flourished on the shelves within the Tethyan Realm and in the western Pacific.)

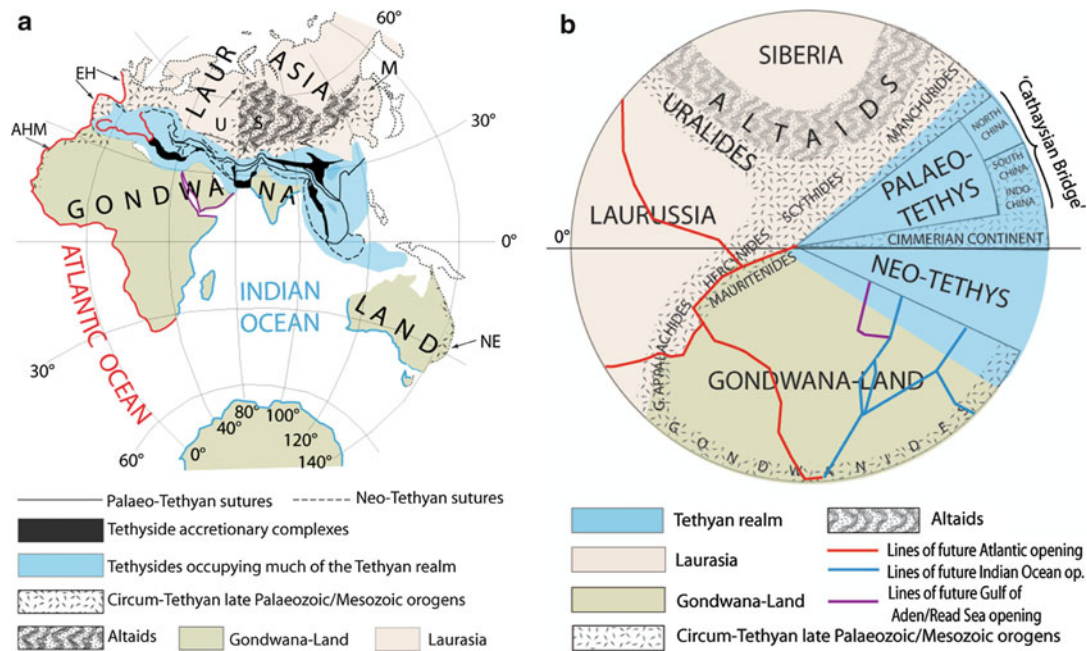
The French paleontologist Henri Douvillé called *Mésogée* "a particular phase of the Central Mediterranean of Neumayr or the Tethys of Suess; it is specifically the sea in which the Rudists have lived and developed" (i.e., Mesogea; Douvillé, [1900], 223). Later French geologists (e.g., Haug, [1908–1911], 661; Aubouin et al., [1977]) have used Douvillé's term as an equivalent of the Tethys, a usage Douvillé clearly did not envisage. Biju-Duval et al. ([1977]) resuscitated this term, but in a somewhat altered meaning again. They suggested to call Tethys "the ocean which existed between Europe and Africa during the early Mesozoic" and to call Mesogea "the fairly broad ocean which was created during Mesozoic." Thus, Biju-Duval et al. ([1977]) and Biju-Duval and Dercourt ([1980]) would call the Eastern Mediterranean and the now-closed Bitlis/Zagros ocean (the "southern branch of the Neo-Tethys" of Şengör, [1979]) Mesogea and the oceans, the remnants of which are now found in the Carpathian, Dinaride, Hellenide, and the north Turkish orogens (the "northern branch of the Neo-Tethys" of Şengör, [1979]) they would call Tethys. Following them Boccaletti ([1977]) employed a similar terminology. This usage is confusing, because all of the oceans mentioned began opening largely during the Mesozoic; only what Biju-Duval et al. ([1977]) then singled out as later Mesozoic

products have now turned out to have started their rifting in the Permian (e.g., Stampfli et al., [1991]). Biju-Duval et al.'s ([1977]) suggested terminology has since fallen out of use.

Laubscher and Bernoulli ([1977]) pointed out that in the twentieth century, the paleobiogeographic designation "Tethyan" had come to mean simply "equatorial marine" and used for a seaway of Mesozoic and Cenozoic age from the Caribbean (which Stille, [1940], had called "Antillian Tethys" on his p. 153 and "Antitethys" on his p. 581; Aubouin et al., [1977], called it "*Téthys de la reconquête*") to northern Australia and Melanesia (which Stille, [1958a], called the "Melanesian Hemitethys"). The Caribbean had nothing to do with any of the Tethyan oceans, and it is therefore simply inappropriate to apply to it any Tethys-based terms. By contrast, not in the Melanesian, but in parts of the northern Australian area, the term "Hemitethys" does have some justification (see Görür and Şengör, [1992]). For a controversy on the original meaning of Tethys in Suess' usage, which resulted from a confusion of the paleogeographic and tectonic meanings of the term Tethys, see Tozer ([1989], [1990]) and Şengör ([1990a]). Stille ([1958b], 153) was the first to emphasize the double meaning of the term Tethys, i.e., a paleogeographic and a tectonic one, and pointed out the confusion their mixing usually causes.

In the 1970s of the twentieth century, it was recognized that the mountain ranges of the Alpine-Himalayan System were the products of more than one major ocean. The Swiss geologist Jovan Stöcklin, working in Iran at the time (Stöcklin, [1974]), called the ocean, the early Mesozoic demise of which had given rise to a part of the mountain ranges in northern Iran, "Paleo-Tethys" (i.e., *old* Tethys) and the ocean which generated the late Mesozoic-Cenozoic ranges (Şengör [1979]) "Neo-Tethys" (i.e., *new* Tethys). Hsü ([1977]) pointed out that the remnants of the Palaeo-Tethys at the longitude of Turkey be looked for in the Crimea. The term Paleo-Tethys had been first introduced, as *Paläothetis*, by the Austrian geologist Franz Kahler ([1939]) for a shallow sea area north of the then-known Tethys from Eastern Europe to China. Kahler's teacher Franz Heritsch ([1940]) took over this term and corrected the orthography to *Paläotethys* but also used it in a tectonic sense, for a geosyncline.

The German geologist Hans Stille also adopted the term Paleo-Tethys but defined it as the Tethys of the Variscan era ([1949], [1951]). Later, he changed his mind and used the term Paleo-Tethys for a hypothetical Tethyan geosyncline of the "Caledonian Era" and introduced the terms Eotethys or Greater Tethys (*Urtethys*) for the Tethyan geosyncline of the Assyntic era and "Mesotethys" and "Neotethys" for the Tethyan geosynclines of the "Variscan" and the "Neoidic" (i.e., Mesozoic + Cenozoic) eras, respectively (Stille, [1958b]). All of Stille's terms are now obsolete as his tectonic world picture in which they were defined. To avoid all confusion, it is best to spell the terms Paleo-Tethys and Neo-Tethys with hyphens, which neither Stille nor his predecessors did.


Tethys in Marine Geosciences, Figure 1 The map of the Central Mediterranean during the Jurassic by Melchior Neumayr (1885). Suess showed within 3 years of the publication of this map that the same ocean minus its Central American parts already existed in the Triassic and that it survived into the Eocene.


Tethys in Marine Geosciences, Figure 2 (**a**) Some of the late Paleozoic to the present tectonic elements of the Old World showing the position of the Tethyan Realm within it. The rifted continental margins of the two different oceans disrupting the Old World are shown in the colors corresponding to the color in which their names are written (except the Red Sea and the Gulf of Aden, whose names could not be written because of limited space). The colours and patterns in this figure correspond to those in **b**. Key to abbreviations: *AHM* African Hercynides including Mauritanides, *EH* European Hercynides, *M* Manchurides, *NE* New England Fold Belt, *S* Scythides, *U* Uralides. (**b**) A schematic illustration of the main tectonic elements of the world during the late Permian including the Tethyan Realm. The colours and patterns in this figure correspond to those in **a**.

Proto-Tethys is a term used by some geologists to refer to a Tethyan ocean before the Tethys (e.g., Flügel, 1972), but this is a contradiction in terms, because there was no space that resembled any of the Tethyan oceans before the Tethys. The term Tethys today has a meaning only with respect to Suess' definition and with respect to Pangaea, in which it was located. When no Pangaea existed, it is meaningless to talk about a "Tethys."

It was later recognized that an entire late Paleozoic-early Mesozoic mountain range lay hidden in the northern part of the Alpine-Himalayan ranges, including the Turkish-Iranian and the Tibetan high plateaux, between the Black Sea and Southeast Asia, which had been created by the subductive removal of an ocean between the early Carboniferous and medial Jurassic; some satellite oceans of this major ocean (marginal basins) survived until the early Cretaceous. Şengör (1979) recognized that this ocean corresponded to what Stöcklin (1974, 1977) and Hsü (1977) had called the paleo-Tethys. Şengör called the resulting orogenic system the "Cimmerides" from the Cimmerian Mountains comprising the Yayla Range in the Crimea, the tiny Serpent Island off the Danube Delta (at 45°15′N and 30°12′E; Острів Змiïний in Ukrainian and *Insula şerpilor* in Romanian), and the North Dobruja (Suess, 1909, 22). The name "Alpides" he confined to the products of the Neo-Tethys. Both the Cimmerides

and the Alpides comprised, in Şengör's definition, the "Tethysides." A long continental strip that rifted off from northern Gondwanaland creating the Neo-Tethys in its wake and closing the Paleo-Tethys in its front, Şengör (1979) called the "Cimmerian Continent." Some later authors, either ignorant of or inattentive to the tradition of geographical nomenclature, have called this major continental strip "Cimmeria," but I would recommend using the term Cimmerian Continent, because Cimmeria, a geographical term in a form normally used for countries (e.g., Mongolia) or geographical regions (e.g., Scythia), gives no information about the geological nature of the object.

Şengör called the entire group comprising the *Paleo-Tethys + the Cimmerian Continent + the Neo-Tethys and their continental margins* the "Tethyan Realm," also called the "Tethyan Domain." Figure 2a shows where in the Old World the remnants of the Tethyan Realm are now located, and Figure 2b is a schematic representation of the Tethyan Realm to give an idea of its internal organization sometime in the early Triassic.

Present usage of the Tethys

Today the term Tethys is used in the sense of the Tethyan Realm as defined above and shown in Figure 2b. Within the Tethyan Realm, the Paleo-Tethys came into existence by the formation of the Pangaea following the Hercynide

collisions along the Hercynian chains in Europe, the "Great Appalachides" comprising the Appalachians, the Ouachitas, the Glass Mountains, and the Huastecan Belt in Canada, the United States, and northern Mexico (Stille, 1940) and the Mauritanides in northwest Africa and the Uralides between the Russian Platform and the Altaids in Asia. Before the collisional events of the Hercynides, the Uralides, and the Altaids, it is meaningless to speak of a Tethys, because the ocean that separated Gondwana-Land from the northern continents did not as yet have a Laurasian counterpart in the north. That counterpart originated only after the closure of the Pleonic Ocean that created the Uralides (McKerrow and Ziegler, 1972). The Paleo-Tethys thus formed by gathering the continents around its frame forming the Pangaea as opposed to the Neo-Tethys that later formed by rifting.

Some of the more recent general publications on the Tethyan Realm are the following. They contain good bibliographies that would lead the interested reader to more specialized publications: Şengör (1990b: this paper is almost a textbook of orogenic structures found in the entire Tethysides), Buffetaut et al. (2009), Crasquin-Soleau and Barrier (1998a, 1998b, 2000), Dercourt et al. (1993, 2000), Hall (2002, 2012), Hall et al. (2011), Metcalfe (1999), Nairn et al. (1996), Roeder (2009), Roure (1994), Şengör (1990b, 1998: this long paper in particular contains a very full bibliography), Şengör and Natal'in (1996), Şengör and Atayman (2009), Sinha et al. (1997), Stampfli et al. (1991, 1998, 2001), Stampfli and Borel (2002), Veevers (2000, 2001, 2004), Yin et al. (2000), Ziegler and Horvath (1996), and Ziegler et al. (2001); for a critique of some of the Tethyan tectonic models in the eastern part of the European Alpides, see Zachner and Lupu (1999). Sonnenfeld (1981) is a book on benchmark papers on the Tethys, but it is thoroughly inadequate and even misleading. An outstanding textbook intended for undergraduates by a master paleoceanographer and sedimentologist, as well as an Alpine geologist, is Weissert and Stössel (2010), in which the evolution of the Neo-Tethys is narrated on classic Alpine examples. Barrier and Francou (1996) and Stow (2010) are two recent popular books on the Tethys. For the most reliable reconstructions of the entire Tethyan Realm through time, go to http://www.scotese.com/ on the web owned by Christopher Scotese, where continuously updated reconstructions through the Phanerozoic are available for free.

Figure 3a shows a schematic tectonic map of the Pangaea during the time when Paleo-Tethys existed, and Figure 3b shows its geomorphology. Figure 3b also shows a hypothetical display of the internal bathymetry of the Paleo-Tethys based on the distribution of the plate boundaries within it that are compatible with the tectonics of its margins (see Şengör and Atayman, 2009, for the details).

Pangaea A versus Pangaea B and the paleo-Tethys

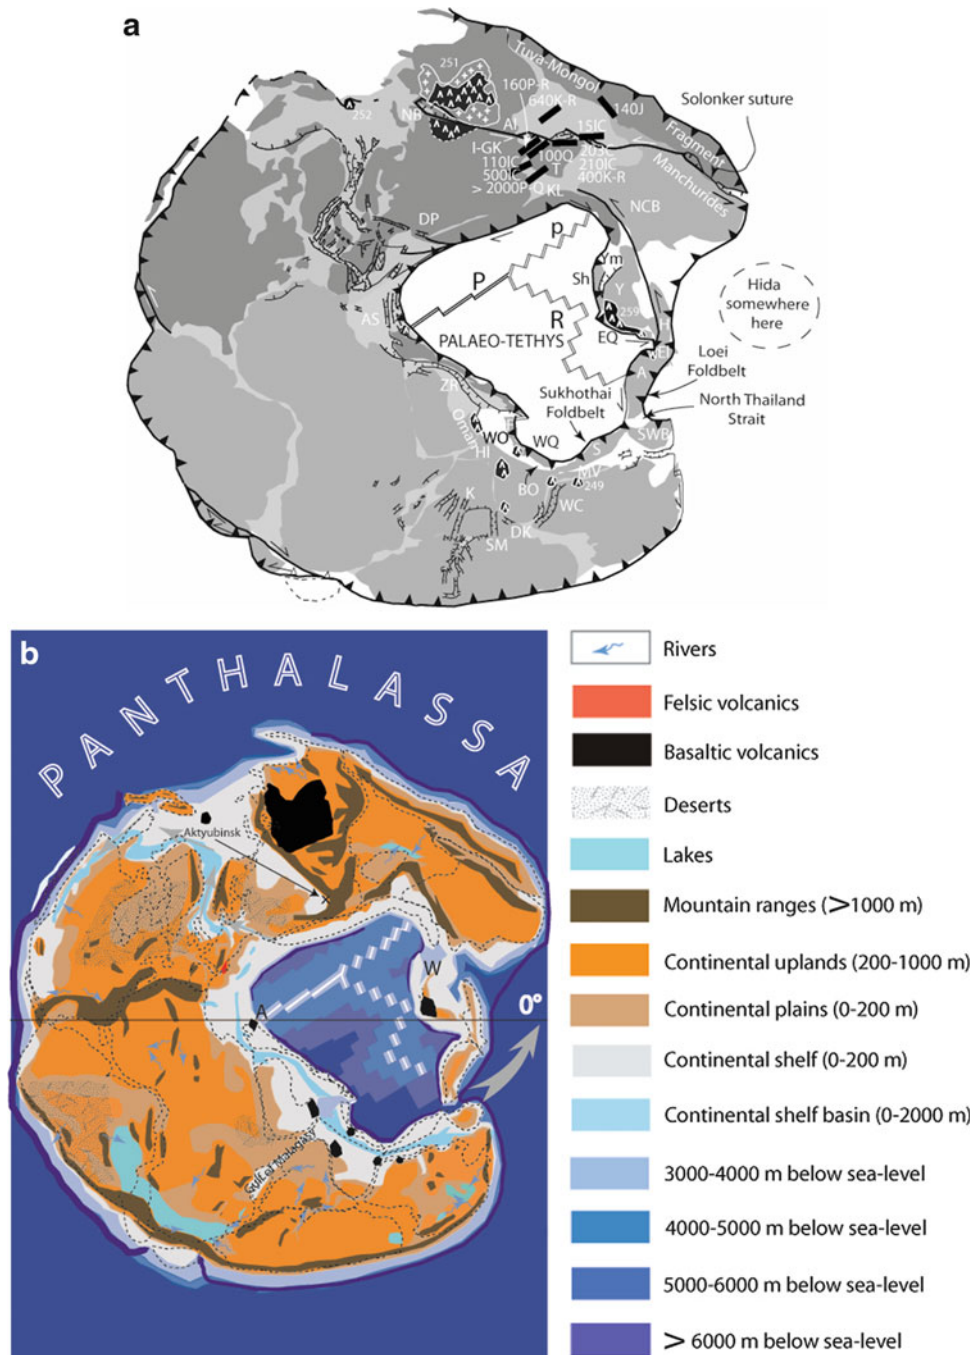
Our view of the geometry of the Paleo-Tethys is dependent on what we think Pangaea looked like. After the publication of the famous "Bullard fit" of the continents

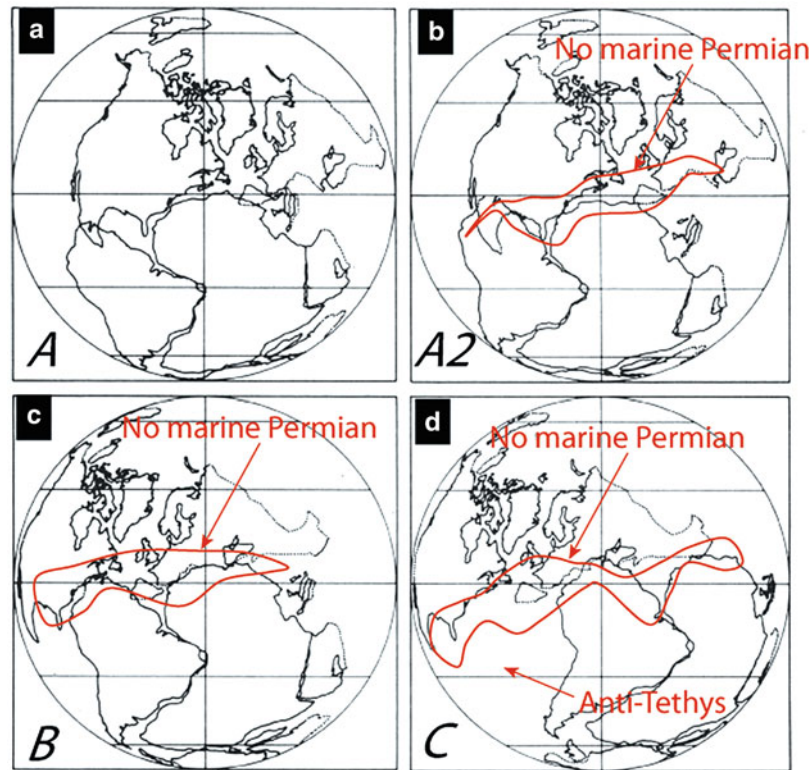
around the Atlantic Ocean (Bullard et al., 1965), it was assumed for more than 20 years that a geometry similar to it had been maintained from the late Carboniferous Hercynide collisions until the early Jurassic opening of the Central Atlantic. That this may not have been so was first recognized by Irving in 1977 when he noticed a major discrepancy between the paleomagnetically determined positions of Gondwana-Land and Laurasia. He pointed out that the paleomagnetic data could only be reconciled with the reconstruction of the Pangaea if Gondwana-Land is shifted some 3,000 km eastward with respect to Laurasia, bringing northern South America against the Appalachian margin of North America. The resulting geometry he named Pangaea B (Irving, 1977). As Van der Voo and French had already improved on the Bullard et al. (1965) fit by making a tighter reconstruction in the area of the Gulf of Mexico between the cratonic edges of northern South America and southern North America, Morel and Irving (1981) decided to call the Pangaea of Van der Voo and French Pangaea A2 and the Bullard et al. Pangaea Pangaea A1 (Figure 4).

In 1981, Smith et al. complained that Irving's solution still did not honour the paleomagnetic data completely, and they instead proposed a more radical Pangaea reconstruction which they called Pangaea C. This reconstruction shoved northern South America all the way under the belly of Central Europe and all but eliminated the Paleo-Tethys, but created what might be called an "Anti-Tethys" between eastern North America and western South America (Figure 4d). Because Pangaea C violates so many geological relationships, it has so far found no adherents except among those who proposed it. Even they later abandoned it (Livermore et al., 1986).

It was later recognized that Irving's original timing of the Pangaea B to Pangaea A2 transition, from the latest Carboniferous to the Jurassic, was wrong, and Irving himself modified his original suggestion by indicating that an early Permian (∼280 Ma ago) Pangaea B had already become Pangaea A2 in the late Permian (∼250 Ma ago). Geological work of the last two decades has discovered more and more Permian dextral strike-slip systems in Central and Southern Europe with a cumulative offset of some 2,500 km (see Şengör, 2013, for a discussion and references) providing strong support for Irving's view. In addition, data on Permian quadrupeds make it likely that they migrated from northern Laurasia to southern Gondwana-Land via western Pangaea that must have had a geometry closer to that of Pangaea B than to that of Pangaea A2 (Cisneros et al., 2012). Figure 5 shows a probable Pangaea geometry that must have existed during the early to medial Permian (i.e., Pangaea B), whereas Figure 3 displays a late Permian Pangaea (Pangaea A2).

The demise of the paleo-Tethys and the opening of the neo-Tethys

Figure 3a shows a continuous rift system between the future Apulian Shelf and Southeast Asia appearing as a


Tethys in Marine Geosciences, Figure 3 (**a**) Latest Permian tectonics of Pangaea and the Paleo-Tethys. Key to lettering: *A* Annamia, *Al* Altay Mountains, *AS* Apulian Shelf, *BO* Banggong Co-Nu Jiang Ocean, *DK* Damodar-Koel Valley rift, *DP* Port of Dobruja, *El* Emei Shan basalts on Annamia, *EQ* eastern Qangtang, *F* Farah Block, *H* Huanan Block, *Hl* Helmand Block, *I-GK* Irtysh-Gornostaev keirogen, *K* Kurduvadi rift, *KL* Kunlun, *MV* Mount Victoria Land block, *NB* Narym Basin, *NCB* North China block, *S* Sibumasu, *Sh* Shaluli Shan ensimatic island arc, *SM* Son-Mahanadi rift, *SWB* south-west Borneo, *T* Tarim Block, *WC* western coastlands taphrogen, *WQ* western Qangtang, *Y* Yangtze Block, *Ym* Yajiang marginal basin, *ZR* future Zagros Mountains. Lone figures are isotopic ages (in Ma) of extensional and/or plume-related igneous rocks, mostly traps. The figures with letters after them represent observed amounts (in km) and times of crustal shortening across the bars associated with them: >2000P-Q: Permian to Quaternary; 160P-R: Permian to Recent; 140 J: Jurassic; 640 K-R: Cretaceous to Recent; 400 K-R: Cretaceous to Recent; 203C: Cenozoic; 203C: Cenozoic; 500lC: late Cenozoic; 110lC: late Cenozoic; 15lC: late Cenozoic; 210lC: late Cenozoic; 100Q: late Quaternary. From Şengör and Atayman (2009). (**b**) The geomorphology of the Permian world including the floor of the Paleo-Tethys. No morphological elements are shown within the Panthalassa except the inferred circum-Panthalassan trench, which, in fact, may not have existed as a topographic feature everywhere. A is where the Aksu Flysch in northern Turkey is seen; W is Wolong in western Sichuan (ancient Xikang) (from Şengör and Atayman (2009)).


Tethys in Marine Geosciences, Figure 4 The four Pangaeas proposed by different authors to account for the large-scale morphological and paleomagnetic data (modified from Livermore et al., 1986). Areas where there are no marine Permian deposits are indicated to show how compatible each reconstruction is with some of the decisive geological data.

long and narrow continental shelf basin in Figure 3b. Along this basin system rifting had already started in the Tournaisian in Southeast Asia (in Thailand) and was underway in the Permian all the way into the Apulian Shelf. However, rifting did not progress regularly from Southeast Asia to future Europe as shown by the fact that continental margin stretching was going on both in the Himalaya and in the Zagros, while an ocean had already opened in Oman. This was largely because an earlier rift separating northern and southern Tibet and northern and southern Afghanistan had turned south along the Sistan suture in Iran and joined a newly developing rift along the Himalaya and the Zagros in what is today Oman (Şengör and Natal'in, 1996). In any event, by the early Triassic, ocean opening had commenced along this southern rift as far west as the Carpathians. It did not propagate westward except to deepen the already existing rift basins on the Apulian Shelf including the southern Alps and the Northern Calcareous Alps, the Transdanubian, and the Bükk Mountains in Hungary (the so-called "ALCAPA" unit). Only with the early opening of the Central Atlantic Ocean did rift branches enter the future Betic-Rif-Tellian Atlas-Apennine-Alpine region and tore open an oceanic corridor that united with the earlier Triassic rifts and rifted to their north new oceanic corridors, for example, along

the Pennine Ocean in the Alps and in northern Turkey along the Intra-Pontide suture.

The rifts that had separated northern Tibet, central Pamirs, and northern Afghanistan from southern Tibet, southern Pamirs, and southern Afghanistan opened what is known as the Wašer/Rushan-Pshart/Banggong Co-Nu Jing Ocean in the Permian (Şengör, 1984; Şengör et al., 1988). That ocean had branches into the main Paleo-Tethyan basin through the central Pamirs (Gaetani, undated (2006)) and along the future Chasa suture in northern Tibet (Şengör et al., 1988; Şengör and Natal'in, 1996). The continental fragments thus created must not have moved independently, however, as they all collided with a long continental strip consisting of southern Tibet, southern Pamirs, and southern Afghanistan before the Aptian/Albian as limestones of that age cover their suture from Iran to Burma. That is why Şengör (1984), Şengör et al. (1988), and Şengör and Natal'in (1996) considered the Wašer/Rushan-Pshart/Banggong Co-Nu Jing Ocean a marginal basin complex of the Paleo-Tethys (which Belov, 1980, called the Meso-Tethys following an earlier established Russian tradition; Shvolman, 1978, and Burtman, 1994, also used the term Meso-Tethys for Tethyan oceans that closed during the Mesozoic, but as Burtman himself admitted, his Meso-Tethyan oceans also

included some that closed during the Cenozoic, blurring the precision of the terminology; that is why I recommend Meso-Tethys not be used).

Şengör (1979) called the entire continental strip that rifted from northwestern Gondwana-Land the Cimmerian Continent. Thus, the Wašer/Rushan-Pshart/Banggong Co-Nu Jing Ocean was an "intra-Cimmerian-Continent ocean" (Şengör, 1986, 1998). The northern continental fragments were active frontal arcs above a southwest-dipping major subduction zone and the southern continental fragments "remnant arcs."

The frontal arcs of the Cimmerian Continent collided with Laurasia during the late Triassic from Southeast Asia to Iran, while farther west in Turkey, the final collision was delayed until the early Jurassic. Some of the frontal arcs of the Cimmerian Continent consisted entirely of subduction-accretion material of earlier arcs onto which the magmatic arc fronts had migrated. This has misled some into thinking that in such places the Cimmerian Continent did not exist (Topuz et al., 2012).

The evolution and end of the neo-Tethys

After the late Triassic-early Jurassic closure of the main Paleo-Tethyan basin, its only remnant was represented by the Wašer/Rushan-Pshart/Banggong Co-Nu Jing Ocean until the early Cretaceous. After the early Cretaceous, the Neo-Tethys became the sole occupier of the Tethyan Realm. It was at this time that a cooling global climate is thought to have caused density stratification and black shale deposition (Weissert et al., 1979) in restricted basins along the Neo-Tethyan north margin (Görür, 1991) as well as in the juvenile Atlantic Ocean (Weissert, 1981).

A major event in the Neo-Tethys was the generation of at least two major subduction zones from present-day Turkey in the east to the Himalaya and possibly beyond all the way into northwestern Sumatra in the east. The northerly subduction zone may have become already active in places such as Iran during the medial to late Jurassic, but it was during the Aptian-Albian interval that a united subduction zone extended from the eastern Alps all the way to Burma. This subduction zone constructed the major continental margin arcs of the southern margin of Eurasia during the Cretaceous to Eocene interval. The other subduction zone must have originated within the Neo-Tethys, much closer to the northern Gondwanian margin, because it soon collided with its continental margin between eastern Libya and Oman and also possibly in the Himalaya, causing gentle orogenic deformation where no ophiolite obduction occurred between Libya and Lebanon and spectacular ophiolite nappes and associated intense metamorphism and deformation from northeastern Syria (Baer-Bassit region) to Oman during the Coniacian to Campanian interval (in some places lasting into the early Maastrichtian). Searle (1986), Corfield and Searle (2000), and Corfield et al. (2005) suggested that the ophiolite obduction in the Himalaya was most likely also

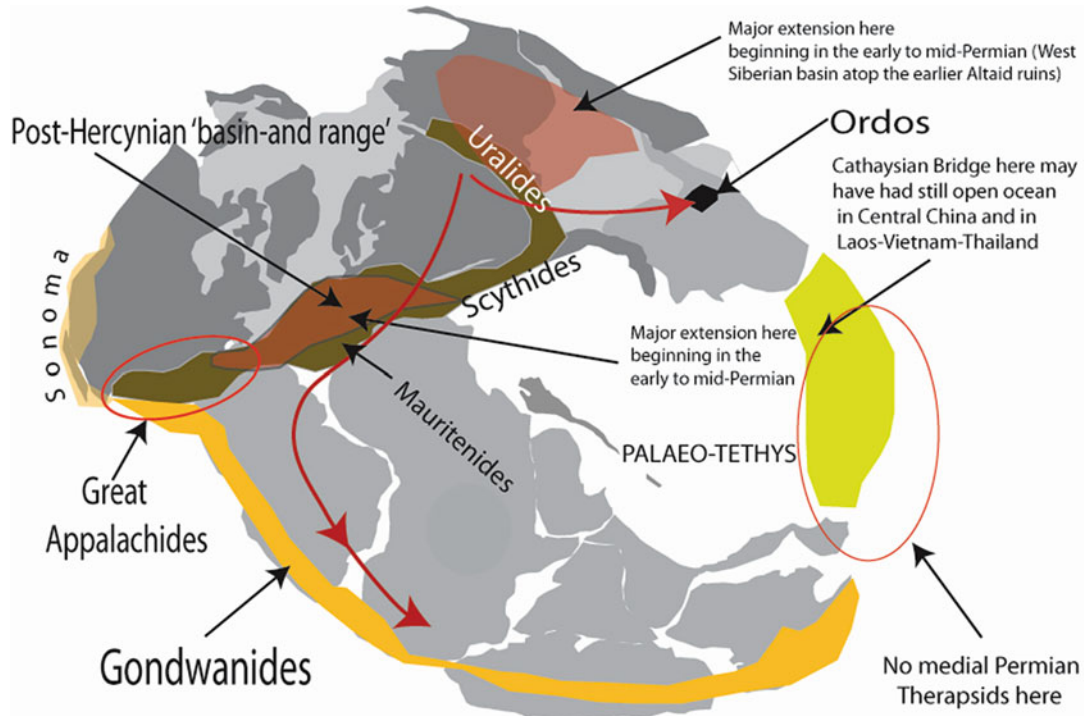
of late Cretaceous age. Jagoutz and Royden (submitted) in fact argued that there must have been two parallel subduction zones active within the Neo-Tethys to account for the very high relative rate of motion of India with respect to Asia during the Cretaceous to Eocene interval. Beyond the Himalaya the two subduction zones probably are now represented by the late Cretaceous Woyla suture in northwestern Sumatra and the presently active subduction zone extending from Burma to the Banda Sea (Görür and Şengör, 1992).

Of the Gondwanian fragments to the south of the Neo-Tethys, the Apulian Platform was probably the first to collide with Eurasia, which happened only in the easternmost Alps in the late Cretaceous. India, after having left the Madagascar margin at the beginning of the Cainozoic, ran into Asia sometime during the medial Eocene.

Between the Alps and Afghanistan, the geometry of the Tethyan collisions was much more complicated, because of the presence of such smaller ensialic arcs in the Neo-Tethys as the Kırşehir in central Turkey and the extreme irregularity of the colliding margins, caused both by the original rifting that created them and by later margin subparallel strike-slip faulting. However, all oceans between the Alps and Iran were closed by the Oligocene, except the Eastern Mediterranean and its continuation into southeastern Turkey and the Zagros. In the latter two places, the Neo-Tethys finally closed between 30 and 10 ma ago (McQuarrie et al., 2003; Şengör et al., 2008). This was coeval with the final collisions in the Rif and Betic Cordilleras at the western extremity of the Mediterranean (Şengör, 1993) finally terminating the circum-global equatorial current and probably triggering the growth of an ice cap in Antarctica (Coxall et al., 2005). Jovane et al. (2007) ascribed the global cooling to an Eocene-Oligocene closure of the Arabia/Eurasia collision. This is probably true because in Eastern Turkey the toe of the East Anatolian Accretionary Complex had already collided with the combined Bitlis/Arabia margin (Şengör et al., 2008) and began blocking deep oceanic circulation, although the full tectonic effects of the collision were not felt until the Miocene.

The Eastern Mediterranean and the Arabian Sea are the only surviving remnants of the Neo-Tethys in our days.

The paratethys

Eduard Suess had already recognized in 1866 that a peculiar sea basin containing brackish waters had extended during the Miocene from Vienna to almost the Aral Sea via the Styrian Basin, the Pannonian Basin, the Euxine Sea, and the Caspian Sea. It was later recognized that this sea had been a dependent of the Neo-Tethys cut off from it by the Alpide orogeny. This isolation helped the formation of a species-poor but individual-rich marine fauna. The Serbian geologist V. D. Laskarev called it Paratethys in 1924, which is a very apt designation, and it is consequently still in use. Today it is known that the Paratethys


Tethys in Marine Geosciences, Figure 5 A Pangaea B reconstruction modified from Cisneros et al. (2012). *Red arrow*s show the migration path of some of the therapsids from Russia into southern Africa and northern China.

existed from the latest Eocene to the Quaternary ice ages. The present-day Black Sea, Caspian Sea, and Aral Sea are its last remnants. The early, medial, and late phases of the Paratethys have recently been divided (Senes and Marinescu, 1974; Rusu, 1988; Olteanu and Jipa, 2006) into Protoparatethys (early to medial Oligocene, i.e., to late Kiscellian), Eoparatethys (latest Kiscellian to Otnangian), Mesoparatethys (Karpathian-Badenian), and Neoparatethys (Sarmatian-Recent). For two most informative reviews of the geology and evolution of the Paratethys, see Steininger and Wessely (2000) and Popov et al. (2004).

Paleo-Tethys and the Permian extinctions

Şengör and Atayman (2009) pointed out that the Paleo-Tethys had become completely continent locked during the late Permian, because a Cathaysian Bridge cut it off from the Panthalassa during the late Permian (see Figures. 2b and 5). They called such a situation, i.e., the presence of an ocean on earth completely cut off from other oceans, a *Ptolemaic condition*. They documented that the waters of the Paleo-Tethys had started becoming anoxic already during the Carboniferous in the deep subduction trenches, and this anoxia gradually invaded the entire ocean, finally flooding its shelves during the latest Permian. They further noticed that almost the entire Capitanian and Changhsingian extinctions were confined to areas that were either within the Paleo-Tethys or in a

2,000-km-wide halo around it and in regions that were receiving the poisonous waters of the Paleo-Tethys. It was also noteworthy that extinctions began in the deep basins of the ocean and gradually spread to its shallower parts. Outside such areas, as seen in many Panthalassan sections in Japan, Klamath Mountains, and New Zealand, there was no anoxia at these times and no extinction. They suggested that this state of affairs may be a result of the eruption of poisonous gases from the Paleo-Tethys that not only killed its inhabitants but also the air-breathing organisms (including the insects!) around it.

Ptolemaic conditions on earth invite marine scientists also to consider the effects of oceans cut off from the major oceans on the evolution of the earth system.

Conclusions

The name Tethys designates a mainly Mesozoic equatorial oceanic area that extended from the Gibraltar to Southeast Asia. In reality, there were two Tethyses: one that literally "popped into existence" when Laurasia and Gondwana-Land collided in the late Paleozoic along the Hercynides and was destroyed by the early Cretaceous when the last remnants of a continental strip, called the Cimmerian Continent, collided with Laurasia. That ocean is known under the designation Paleo-Tethys. The Cimmerian Continent rifted off from the northern margin of Gondwana-Land mostly during the Permo-Triassic opening behind it the Neo-Tethys. The combined areas of the Paleo-Tethys,

the Cimmerian Continent, and the Neo-Tethys constitute, together with their continental margins, the Tethyan Realm. A double orogenic system resulted from the destruction of the Tethyan Realm: the products of the closure of the Paleo-Tethys are the Cimmerides, and the products of the closure of major parts of the Neo-Tethys are called the Alpides. The Eastern Mediterranean and the Arabian Sea are the remnants of the Neo-Tethys, to the north of which the Alpide evolution today forms Andean-type orogenic belts forming parts of the Alpides.

The Tethyan Realm was important both paleobiogeographically and paleoceanographically: It constituted a paleobiogeographic realm that went beyond its borders all the way into the future Central American area. The opening of an equatorial oceanic corridor from Central America to Southeast Asia led to the formation of an equatorial current system that greatly influenced world climate. When the Paleo-Tethys became an entirely closed ocean, it developed a major anoxic water body that probably triggered the end-Permian extinctions. A major water body cut off from it during the latest Eocene by Alpide collisions formed a closed basin. It is known as Paratethys whose deposits range from the Vienna Basin to the Aral Sea.

Tidal Depositional Systems, Figure 1 Global distribution of tidal ranges following the classification scheme of Hayes (1979) (from Flemming (2012)).

sedimentary environments; Tidal sedimentary facies; Tidalites; Tide-dominated environments; Tide-influenced deposits

Definition

Tidal depositional systems are sedimentary environments which are mainly influenced and controlled by tides and tide-related processes. Their occurrence is limited to coasts and shallow shelves having a pronounced tidal range and, in relation to that, moderate wave action. In their vertical extension, tidal depositional systems are not restricted to the intertidal or eulittoral part of the coastal zone which is defined by the tidal range, i.e., the vertical distance between the mean high water level and the mean low water level. They can also be found in supratidal (above mean high water level) as well as in shallow subtidal (below mean low water level) environments. In contrast, deepwater sedimentary environments can also be influenced by tides (for review see Dykstra, 2012) but are not tidal depositional systems sensu stricto, as tides are an ocean-wide phenomenon. Tidal depositional systems are characterized by steep environmental gradients. Besides tide-influenced physical characteristics, numerous other processes like biological activity can play an important role in the formation of tidal sedimentary facies. Tidal depositional systems can both be dominated by siliciclastic and/or biogenic (carbonate or organic-rich) sediments.

Introduction

The majority of tidal depositional systems are linked to coastal environments. Their morphodynamic and sedimentary processes are therefore not only controlled by tides but also by waves. Whether a coast is classified as tide dominated, mixed energy, or wave dominated depends mainly on the ratio of the regional tidal range and wave energy. In general, tidal depositional systems are most frequent where the tidal regime has a meso- to macrotidal character.

The classification of coastal environments with respect to the tidal range is based on Davis (1964, 1980) and Hayes (1979). In contrast to the relatively simple scheme of Davis, who defined only three categories (<2 m microtidal; 2–4 m mesotidal; >4 m macrotidal), the classification scheme of Hayes shows a more detailed subdivision, which takes specific process-related morphological units (e.g., occurrence of barrier islands) into account (Figure 1). Besides the astronomical forces, which regionally can result in extreme differences in neap and spring tides, wind stress in combination with specific shelf topography and shape of the coast can significantly modify the tidal water levels.

Tidal inlets and tidal deltas

Tidal inlets and tidal deltas are typical morphological units of barrier coasts resulting from the tide-controlled
Tidal Depositional Systems, Figure 2 (**a**) Ebb–tidal delta and flood–tidal delta model (modified after Hayes (1979)) with its morphological units. (**b**) 3D compound dunes in a flood–tidal delta of a macrotidal lagoon (Northern Brittany, France, max. tidal range ~9.3 m). Dunes were formed during flood (currents from *left* to *right*) and modified on top during ebb phase, separated by a reactivation surface. Bedforms become inactive during neap tides whose tidal range is half of those of spring tides. (**c**) Dunes of a marginal flood channel from a mesotidal (tidal range 2.7 m) ebb–tidal delta (East Frisian barrier islands, Wadden Sea). Flood currents from *left* to *right*.

exchange of water between the open ocean and the back-barrier tidal basins (see "Wadden Sea," this volume). They are highly dynamic sedimentary systems showing a complex interaction of tide-dominated processes and wave-dominated longshore sediment transport. Also, the tidal prism, i.e., the water volume (as a function of average surface area of the tidal basin and the tidal range) passing the tidal inlet twice during each tidal cycle, and the sediment supply strongly control size, geometry, and morphodynamics of the tidal inlet–tidal delta complex (Hayes, 1979; Davis and Hayes, 1984). According to Fitz-Gerald et al. (2012), the formation of tidal inlet-associated flood–tidal delta and/or ebb–tidal delta results from different processes. Flood–tidal deltas initially originate from storm events, whereas ebb–tidal deltas are mainly influenced by longshore processes and the interaction of tidal and wave energy.

Flood–tidal deltas are characterized by their typical horseshoe-like shape and are situated in the sheltered back-barrier area. Internal morphological units are (i) flood ramp, (ii) flood channels, (iii) ebb shield, (iv) ebb spits, and (v) spillover lobes (FitzGerald, 2005) (Figure 2a). Flood–tidal deltas are best developed under moderate mesotidal conditions. Sediment transport to and from the flood–tidal delta is mainly controlled by the asymmetry in current velocity during tidal cycle (Boothroyd and Hubbard, 1975). At flood phase, highest velocities occur near high water when the flood–tidal delta is completely submerged. This results in a sand transport up the flood ramp (Figure 2b), through the flood channels, onto the ebb shield (Davis and FitzGerald, 2004). During ebb phase, highest velocities of tidal currents are reached at mid- to low tide, when the ebb shield of the flood–tidal delta is already emerged. As a consequence, the ebb flow is split and has to pass the delta laterally, eroding sand from the outer ebb shield and transporting it along the ebb spits. Sand reaching the tidal inlet will then become again part of the above-described transport gyre.

Ebb–tidal deltas are located at the offshore side of the tidal inlet and are therefore exposed to wave action. They display a complex pattern of channels and shoals.

Characteristic morphological units are (i) main ebb channel, (ii) terminal lobe, (iii) swash platform, (iv) channel margin linear bars, (v) swash bars, and (vi) marginal flood channels.

The morphology of ebb–tidal deltas is mainly controlled by the hydrodynamic energy of the tidal forces on the one hand, and the combination of wave action and longshore transport on the other hand. A tide-dominated inlet is characterized by an elongate ebb–tidal delta and a main ebb channel bordered by linear bars extending relatively far offshore. Under mixed energy conditions, the ebb current forms a well-developed main ebb channel. In relation to its narrow inlet, the corresponding swash platform has a broad shape widely overlapping the inlet shoreline. Contrastingly, wave-dominated tidal inlet/ebb–tidal delta complexes are relatively small. Their terminal lobe and/or swash bars just form a small arc marking the periphery of the delta which commonly is entirely subtidal (Davis and FitzGerald, 2004).

Sediment transport in the inlet–ebb delta system follows characteristic pathways. During ebb phase, the water masses of the tidal prism have to pass the narrow inlet in a seaward direction. Once passed, the ebb flow expands laterally which results in a marked decrease in transport energy. This led to a deposition of sediment on the terminal lobe and the formation of ebb-oriented sand waves and swash bars. In the very initial flood phase, water first flows into the tidal basin through the marginal flood channels, while due to momentum, in the main channels still ebb currents prevail. Bedforms in the marginal flood channels (Figure 2c) are therefore flood oriented (landward). Also, the breaking waves generate a landward-oriented flow across the swash platform.

The ebb–tidal deltas in general function as sand depocenters. According to Walton and Adams (1976), the volume of the ebb–tidal delta is a function of the tidal prism. By a given tidal prism, the sediment volume of the ebb–tidal delta is smaller under high wave-energy conditions than under low wave-energy conditions.

Tidal flats

Intertidal flats as morphological units frequently occur in numerous coastal depositional environments (back-barrier areas, embayments, estuaries, deltas, lagoons, and coastal plains). Their formation and depositional processes are mainly controlled by the hydrodynamic energy of tides and waves, sediment supply, climate, and biological processes. Tidal flats are composed of unconsolidated sediments and have a typically gentle sloping surface. Especially when sheltered, the intertidal sand and mud banks are dissected by a network of tidal channels and creeks. Open-coast tidal flats are predominantly related to the large tide-dominated estuaries or river delta complexes and their associated chenier plains (Galloway, 1976; Lee et al., 1994; Allen and Duffy, 1998; Fan et al., 2006). These tidal flats are often composed of mud originating from flocculated suspended material or from resuspended delta deposits distributed by longshore

transport processes. At coasts where river-derived suspension load is missing, open tidal flats can be composed of sandy material. Sheltered tidal flats are mostly related to barrier islands, sand spits, and bars. According to their position on the landward side of these structural coastal elements, they are termed back-barrier tidal flats (see "Wadden Sea," this volume). As barrier islands and sand spits are restricted to micro- and mesotidal coastal environments, the respective tidal flats also develop under low to moderate hydrodynamic conditions. Principally, the continuous decrease in energy from the open sea toward the coastline is still visible in an accordant grain-size trend, from sandy toward muddy sediments. This is also true for open tidal flats. Most prominent physical sedimentary structures are tidal current- and wave-generated ripples of variable size and shape (2D to 3D small-scale ripples, mega ripples, dunes, linguoid current ripples, ladder-back ripples), current parallel alignments, even fine sand to mud sheets, scour structures, water-level marks, and runoff features. Depending on grain-size composition, these surface structures are internally visible as different kinds of ripple cross-bedding, flaser and lenticular bedding, as well as even lamination. Additionally, a high number of surficial and internal sedimentary structures are related to the activity of endo- to epibenthic organisms, including burrows, tubes, traces of locomotion, feeding, and resting (Figure 3a). Biostromal to reef-like structures are formed by microbial mats, polychaetes, and bivalves (e.g., mussel beds, oyster reefs; Figure 3b). Shell pavements reflect autochthonous erosion, concentration, and accumulation of endobenthic bivalve communities or epibenthic mussel beds. In temperate climates (e.g., Georgia Coast), tidal flats are regionally intensely vegetated.

In the main tidal channels, the water level corresponds to the tidal curve at any time as their channel floor lies below the low water level. In the topographic higher portions of the intertidal flats, a dendritic drainage network of subordinate creeks is developed in which water flow is gravity controlled after tidal flats fell dry during ebb phase. In the creeks the water level is inclined, resulting in ebb-directed flow also in the initial flood phase.

Most prominent bedforms in larger channels are subaqueous dunes whose asymmetry indicates predominant formation by tide-related currents. Reverse current direction during flood will modify just the surface of ebb-oriented subaqueous dunes documented by smaller superimposed ripples on top and vice versa. In smaller channels and creeks, meandering causes lateral erosion of tidal flat deposits, as well as point-bar sedimentation (Figure 3c). Lateral shift of channel beds is indicated by shell-lag deposits (partly with mud clasts) and longitudinal cross-bedding (Reineck and Singh, 1980; also termed inclined heterolithic stratification (IHS) Thomas et al., 1987).

Coastal wetlands: salt marshes and mangroves

The intertidal areas can be vegetated by dense stocks of vascular plants in parts where the input of hydrodynamic
Tidal Depositional Systems, Figure 3 Tidal flats of the central Wadden Sea. (**a**) Sandy to mixed tidal flats intensely bioturbated by highly abundant polychaetes. (**b**) Dense oyster reefs forming extended biogenic structures in the tidal flats. (**c**) In the topographic higher portions of the intertidal flats, a dendritic drainage network of subordinate creeks is developed. Note semi-consolidated mud beds of former point-bar sedimentation with inclined heterolithic stratification.
Tidal Depositional Systems, Figure 4 (**a**) Salt marshes at the transition from the uppermost intertidal to the lower supratidal environment (Jade Bay, Wadden Sea) under lower macrotidal regime (tidal range 4.1 m). The low hydrodynamic energy and extreme environmental conditions favor the establishment of microbial mats. Both microbial mats and the vegetation of the salt marsh baffle, trap, and stabilize fine-grained sediment particles. (**b**) Dense standing mangrove stocks significantly reduce hydrodynamic energy by their closely spaced root system which favors settlement and accumulation of suspended fine-grained sediment particles. Additionally, mangroves provide ecosystem services as they protect coasts against storm surges.

energy is low. These conditions generally occur in estuaries, in back-barrier areas, and in higher elevated areas close to the high water level. Two different kinds of ecosystems can be distinguished: the grasslike salt marshes and the mangrove forests covered by woody shrubs and trees. Their global distribution is controlled by climatic factors, of which air temperature is the most limiting, as mangroves do not tolerate freezing. Therefore, salt marshes typically occur in mid- to higher latitudes, whereas mangroves fringe parts of tropical coasts. As a general characteristic of both systems, they mark the transitional zone from the marine toward the terrestrial influenced coastal environment and have therefore the potential to be used as sea-level index points. Additionally, they both strongly act as sediment sinks as their vegetation traps and stabilizes fine-grained sediments. They

are the most productive tidal ecosystems and provide ecosystem services in terms of coastal protection.

Salt marshes start to grow above neap high water level where disturbance by wave action is low, allowing the deposition of fine-grained organic-rich sediments. Zonation of the salt marsh vegetation displays the tolerance or adaptation of the plants to salt water as a function of the topographic level with respect to the tidal range and the frequency of flooding. The lowest part of the salt marsh, the silting-up zone, is typically characterized by the formation of multilayered microbial mats stabilizing and binding the barren sediment surface in front of the densely vegetated salt marsh (Figure 4a).

Sedimentation in the salt marsh environment is restricted to high water conditions (spring tides, extraordinary wind-stressed high waters, storm surges) when the

salt marsh is flooded by suspension-loaded waters. The dense vegetation favors baffling and deposition of fine-grained sediment particles by reducing water motion to a minimum. Once settled, the roots of the vegetation cover will stabilize the muddy sediments. During storm surges coarse-grained sediments will be transported into the salt marshes by bed load processes. Most obvious are distinct shell-rich sand layers intercalating the muddy sediments. Layers of plant debris also indicate storm events. In this context, salt marshes situated on the sheltered side of back-barrier islands can completely be covered by thick layers of sandy wash-over fan deposits. As most of the salt marsh vegetation is resistant against burial, the marsh vegetation will recover through the storm layers within months. Besides well-bedded laminated muddy sediments and intercalated coarse-grained storm deposits, distinct bio- and phytoturbation is common in salt marsh sequences.

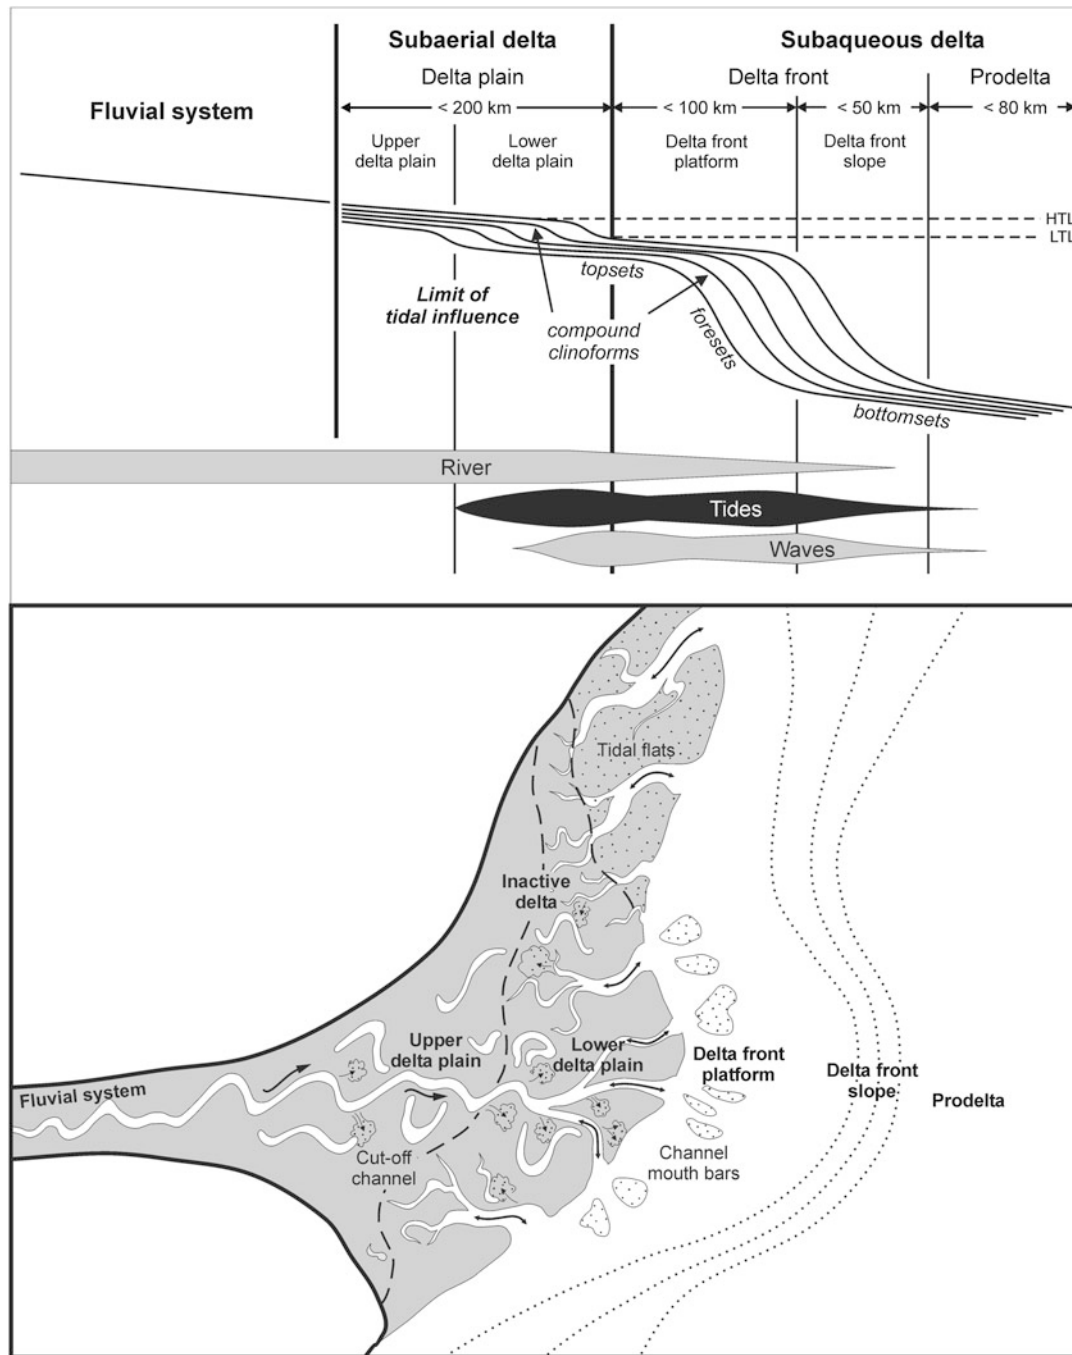
Mangroves cover a wider range within the tidal environment. Nevertheless, they are also restricted to sheltered parts of the coast and to estuaries and creeks where energy input is low. Similar to the salt marshes, they show a zonation depending on their vertical position within the tidal range. The lowest level is covered by the so-called red mangrove *Rhizophora mangle* which passes into the black mangrove of *Avicennia* sp. in the higher intertidal. At high tide levels the mangroves are built up by *Laguncularia racemosa*, the white mangrove. Dense standing stocks especially of the genus *Rhizophora* have a strong impact on sedimentary processes. Their closely spaced root system significantly reduces hydrodynamic energy which favors settlement and accumulation of suspended fine-grained sediment particles (Figure 4b). Additionally, the roots represent a substrate colonized by numerous benthic organisms like oysters which also produce a high amount of fine-grained aggregates (feces and pseudofeces) by their filter-feeding activity. The muddy sediment in between the root system is intensely burrowed by decapod crabs. Due to the resistant root systems, the mangroves display an effective ecosystem protecting the low-energy coasts against physical disturbance of tropical storms and hurricanes by functioning as wave breakers.

Tide-dominated river deltas

In the ternary diagram of river delta classification (Galloway, 1975), which is based on the relative influence of the factors of sediment supply (river), wave energy, and tidal energy, numerous larger river deltas are classified to be tide dominated. Tide-dominated river deltas are characterized by predominantly high-energy sediment transport and a complex hydrodynamic. Due to cyclic fluctuation in tidal energy and seasonal changes in river discharge and sediment load, the sedimentary sequences of tide-dominated river deltas show a vivid intercalation of sandy to muddy beds representing coarsening-upward as well as fining-upward trends in facies association. The most characteristic feature of a tide-dominated river delta is the

formation of a clinothem, i.e., an internally sigmoidal-shaped sequence of the topset-foreset-bottomset, indicating deposition and a progradational trend. Typically, they occur in open coastal settings with meso- to macrotidal conditions and active orogens in the hinterland which, by their enormous sediment supply, allows delta formation under high-energy conditions. Modern examples are Fly, Ganges-Brahmaputra, Indus, Amazon, Irrawaddy, Yangtze, Mahakam, and Mekong. Principally, the sedimentary environments of a tide-dominated river delta can be assigned to the subaerial (upper and lower delta plain) and subaqueous portion (delta front platform, delta front slope, and prodelta) of the compound clinoform (Figure 5; Hori and Saito, 2007). In this context, the boundary of the lower to the upper delta plain marks the limit of tidal influence and other marine processes. Additionally, the lower delta plain and the delta front platform with their respective prograding clinoforms are separated by a broad zone of limited sediment accumulation (Swenson et al., 2005). The lower delta plain is characterized by extended muddy tidal flats and salt marshes and/or mangroves pervaded by a network of tidal channels and tidal creeks. Flaser to lenticular bedding, wavy lamination, and longitudinal cross-bedding related to point-bar sedimentation of laterally migrating channels are typical sedimentary structures of this depositional environment. Rootlets and plant debris-rich sediments indicate the transition to the vegetated delta plain. Large channel-mouth bars, extending from the shallow subtidal into the supratidal, mark the active distributaries of the rivermouth. When accreting laterally and vertically, these bars can be transformed to tidal flats and become part of the delta plain when vegetated (Allison et al., 2003). On tide-dominated river deltas which are also affected by significantly high wave action at their shoreline, sandy beach ridges (partly with eolian dunes) and intertidal longshore bars are frequently developed. At the transition of the outer delta plain platform to the delta front slope hydrodynamic energy increases resulting in coarsening of the sediments. Typical sedimentary structures in this zone are fine- to medium-scale bedding with wave ripples, hummocky and trough cross-stratification, subaquatic dunes, and frequent sharp-based erosional contacts formed by storm-wave scour (Kuehl et al., 1997; Goodbred and Saito, 2012). Toward the deeper part of the delta front slope, the sediment often shows coarsening-upward succession of sands and laminated to bioturbated muds. Internally, beds frequently have a turbidity character with normal grading and sharp basal contacts. The prodelta is dominated by highly bioturbated muddy sediments. Distinct signatures from tidal processes in this part of the delta are strongly overprinted by wave action, storm surges, and bioturbation.

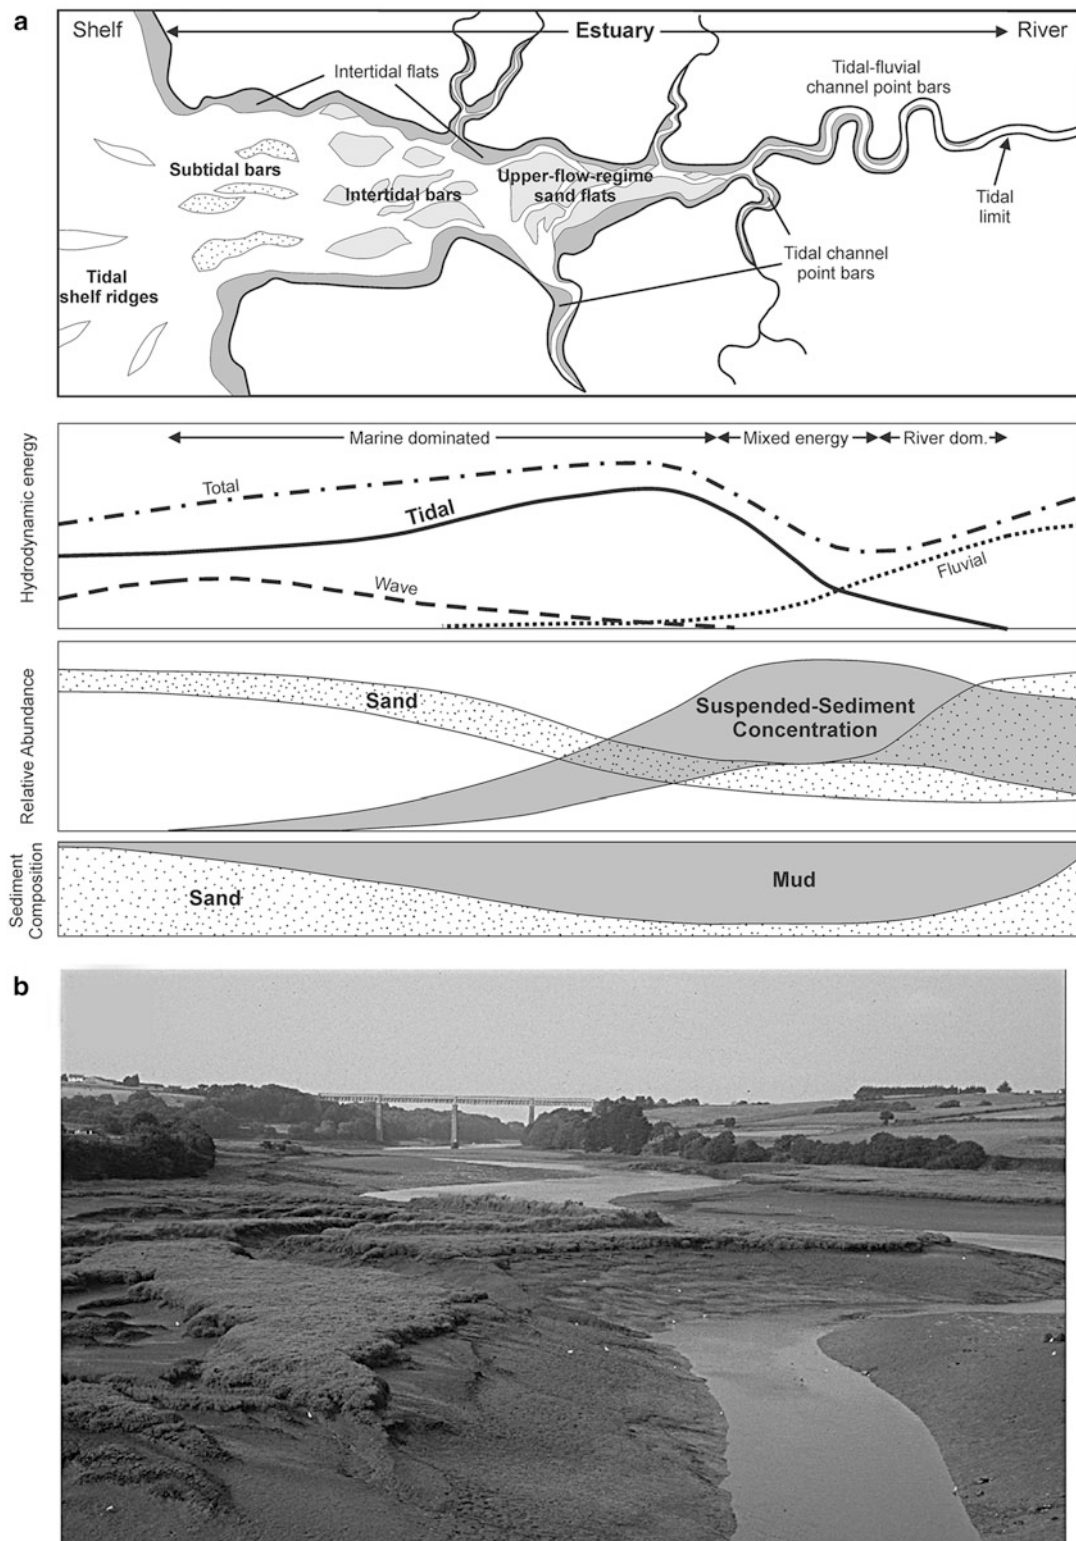
Tide-dominated estuaries

Tide-dominated estuaries are characterized by their funnel-shaped geometry reflecting decrease in tidal flux


Tidal Depositional Systems, Figure 5 Major morphologic units of tide-dominated river delta systems (modified from Hori and Saito (2007) and Wehrmann et al. (2010)).

upstream. The estuary can principally be divided in a broader outer estuary and a narrow inner estuary (Figure 6a, Dalrymple et al., 1990; Dalrymple and Choi, 2007).

The outer estuary is characterized by a complex pattern of elongated, current parallel tidal bars and/or sand flats which are separated by several larger ebb- and flood-

dominated channels. Internally, the linear bars are dissected by minor oblique channels ("swatchways" sensu Robinson, 1960). The sandbar–swatchway–channel system is characterized by a high morphodynamic but becomes simpler organized toward the inner limit of the outer estuary. Typical sedimentary structures are subaqueous dunes whose dimension is mainly controlled by water


Tidal Depositional Systems, Figure 6 (**a**) Schematic model of a tide-dominated estuary and the variation of parameters and processes (modified from Dalrymple and Choi (2007)). (**b**) Macrotidal estuary of the Penzé River (Northern Brittany, France). The maximum tidal range during spring tide is 9.3 m. The channel point bars of the upper estuary are bordered by muddy tidal flats and salt marshes which are internally dissected by a network of tidal gullies. Note slumping structures by collapse of the semi-consolidated mud deposits.

depth, grain-size composition, current velocity, and sediment supply. Dunes can be modified surficially by smaller dunes and ripples when direction of tidal current reverses during tidal cycle, forming compound dunes. Internally, compound dunes mainly show uni- to bipolar cross-bedding frequently separated by a set of reactivation surfaces (Dalrymple and Rhodes, 1995). Bioturbation in this high dynamic sedimentary environment is rare. Laterally, the outer estuary fades into wave-generated beaches and shorefaces as waves are able to enter the estuary at high tide when tidal currents are low and most parts of the estuary are submerged. Where sand flats are present, ripple cross-bedding and parallel lamination (upper plane bed) is most obvious. Longitudinal cross-bedding (or inclined heterolithic stratification (IHS)) indicates point-bar sedimentation in meandering channels.

The inner estuary displays the transition from tide-controlled sedimentary system to the fluvial part of the river–estuary complex. The inner estuary is marked by a main ebb channel partly flanked by flood channels separated from each other by elongate tidal bars. In the channels, subaqueous dunes, internally cross-bedded, are common. The troughs between those dunes can be covered by fluid mud (Schrottke et al., 2006) forming an interbedding with the coarser dune material. Where noticeable input of coarse river-derived sediment is missing, thick fluid mud layers are the prevailing channel bottom deposits. The channels are bordered by muddy tidal flats and salt marshes (or mangroves) which narrow upstream. The mudflats and salt marshes are internally also dissected by a network of tidal gullies, principally oriented perpendicular to the main channel (Figure 6b). Lateral migration of the gullies leads to the formation of mud pebble layers by erosion and collapse of the semi-consolidated mud deposits from the steep outer bank. Bioturbation in the mud flat deposits and associated facies is common to abundant.

Carbonate tidal systems

Modern tide-controlled carbonate depositional environments are globally less widely distributed than their ancient analogs. Today, they are restricted to very distinct regions in the subtropics and tropics (Bahamian Archipelago, Arabian Gulf, Western Australia), whereas modern carbonate factories from the subtidal down to the abyssal occur in all climates up to the polar regions. Looking on the modern examples, carbonate tidal depositional systems are limited to microtidal and lower mesotidal conditions where, however, the influence of local wind effects can significantly exceed the astronomic tidal range. Similar to their siliciclastic counterparts, most of the sediments have an allochthonous origin imported from nearshore subtidal sources. Terrigenous input by eolian sediment transport or episodic sheet floods is typical for arid shorelines. The most important processes in sediment transport of carbonate tidal settings are related to high hydrodynamic energy events (i.e., storm surges) which transport resuspended sediment from shallow subtidal environments onto the adjacent tidal flats. In supratidal settings microbial mats frequently occur.

In the microtidal *Bahamian Archipelago*, subtidal conditions occur in nearshore regions and tidal channels. The sediment surface is sparsely covered with sea grass and calcareous algae. The sediment consists of gray peloidal mud, with scattered skeletal fragments of benthic foraminifera and mollusks, and is extensively bioturbated by thalassinid shrimps. On the flat-topped shallow subtidal platforms, oolitic sand shoal complexes occur predominantly at its margins where tidal currents can reach velocities of more than 2 m/s (Reeder and Rankey, 2009). Bedforms of oolitic sands are of various sizes, ranging from small-scale current ripples to large subaqueous dunes. Due to reverse current direction, most of the active bedforms internally show reactivation surfaces and bidirectional cross-bedding leading to composite dunes. Where shoal sands are not affected by sediment transport for some time, they are stabilized by sea grass, (calcareous) algae, and microbial mats. The tidal flats are affected by semidiurnal tides as well as by wind-driven water-level fluctuations, both onshore and offshore. The intertidal is characterized by red and black mangroves and microbial mat marshes. In the lower intertidal zone, sedimentary structures are almost completely destroyed by bioturbation of polychaetes, shrimps, and rhizoturbation. Decreased bioturbation in the upper intertidal and sediment stabilization by microbial mats result in preservation of the internal sedimentary fabric (lamination, fenestrae, desiccation cracks, intraclasts). Typical morphological units of the supratidal environment are levees, beach ridges, and plains bordering widespread tidal flats. Flooding of this area is limited to major storms resulting in pronounced cm-scale lamination of muddy sediments. Vegetation is dominated by *Scytonema* pincushions and sparse black mangrove. Burrows of the fiddler crab *Uca* are most common at flanks of the levees.

Sabkhas are inter- to supratidal flats which typically occur under semiarid to arid climatic conditions with strong evaporation. Modern sabkha environments can be found along the coasts of the Arabian Peninsula and Africa (e.g., Tunisia, Namibia; Figure 7), but only the sabkhas of the Arabian Peninsula are mainly calcareous. In the subtidal zone, gray muddy peloidal sediments (with up to 30 % dolomite) to coarse bioclastic (gastropods and ooids) sands are deposited, originating from near offshore. Longshore drift form hook-shaped sand spits led to the formation of sheltered lagoons and intertidal flats which are randomly vegetated by black mangrove. The intertidal flats are bordered landward by extended supratidal flats (sabkhas sensu stricto) which are only flooded by extremely high water levels.

Typical sedimentary structures are muddy microbial laminated sediments with fenestrae, intercalated by bioclastic storm lag deposits, anhydrite, halite, and terrestrial-derived eolian quartz sand (Wehrmann et al., 2011). Dolomitization in the supratidal flats results from hypersaline brines due to intense evaporation.

Tidal Depositional Systems, Figure 7 Supratidal sabkha at the arid Namibian coast (lower mesotidal). The sediment surface is covered by microbial mats showing a wavy–crinkly texture. Groundwater level (brackish to hypersaline) is around 40 cm below sediment surface.

Summary

Tidal depositional systems are widely distributed along coastal environments. The character of their sediments, both siliciclastic and biogenic, reflects a complex interaction of numerous physical and biotic factors of which tidal forces are the most prominent. Ranging up from the near-shore subtidal into the supratidal, they represent the direct transition from marine to terrestrial environments and, by tide-dominated deltas and estuaries, also the transition to fluvial controlled processes. They are typically characterized by steep environmental gradients. As tidal depositional systems are highly sensitive to sea-level changes, they are strongly affected by climate change. It has to be noted that tidal signatures can also be found in deeper water settings as tides, in general, are an ocean-wide phenomenon.

TRANSFORM FAULTS

A. M. Celâl Şengör
Faculty of Mines, Department of Geology and Eurasia, Institute of Earth Sciences, Istanbul Technical University, Ayazaga, Istanbul, Turkey

Synonyms
Conservative plate boundary

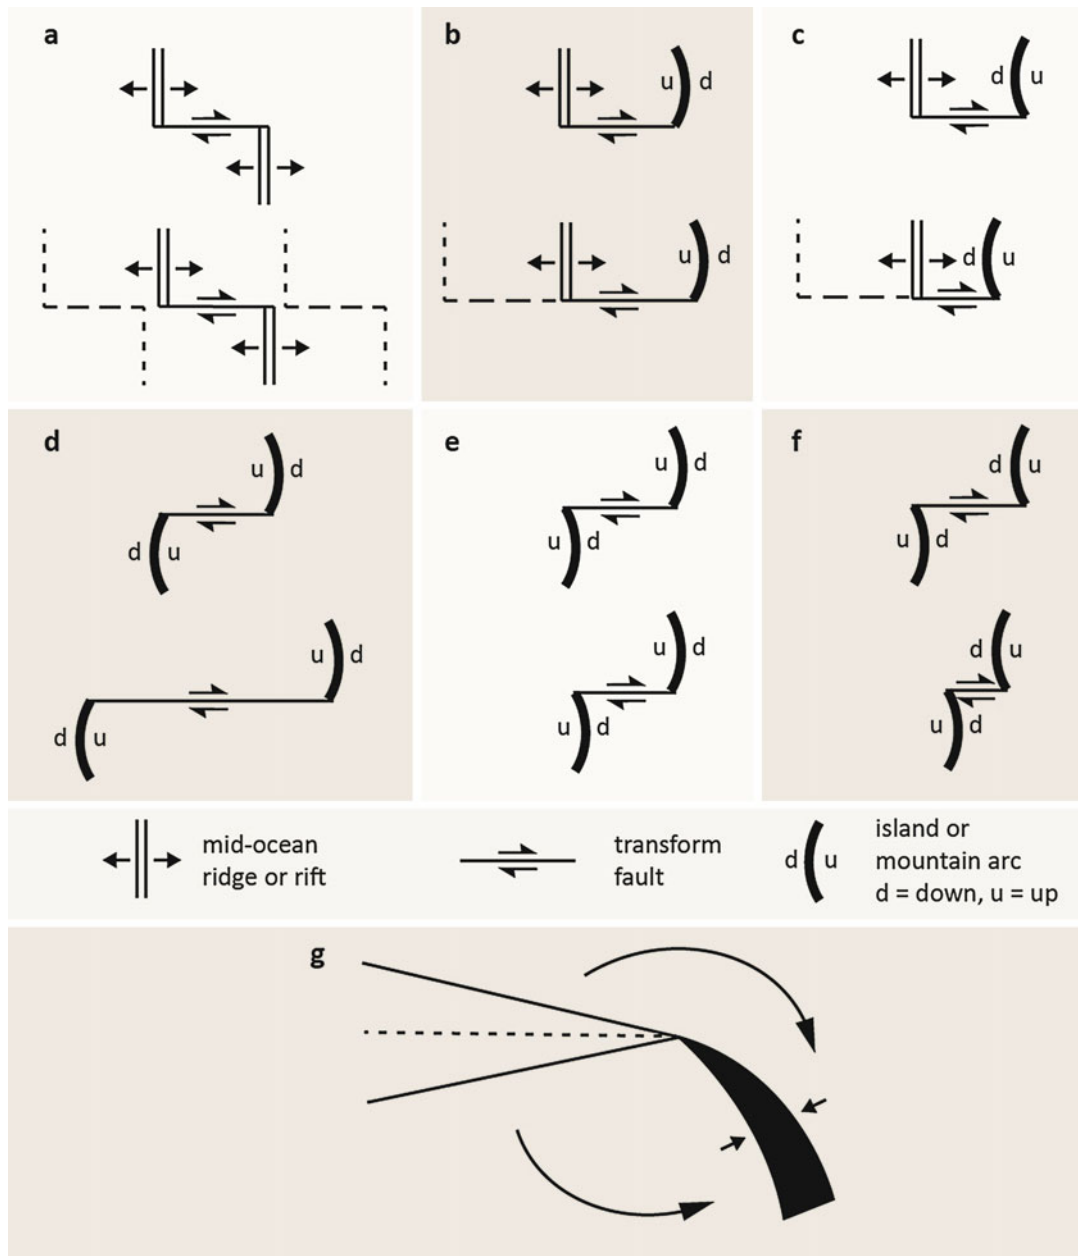
Definition
A *transform fault* is a plate boundary along which plate motion is parallel with the strike of the boundary. Along such a boundary, ideally, crust is neither generated nor destroyed, and that is why they are also called *conservative plate boundaries*. In real life, the thermal and mechanical properties of the crust and upper mantle and the time-averaged behaviour of the spreading centre and subduction zones in the oceans impose a finite width on transform faults in which deformation is complex, forming a fault zone rather than a single clean fault. Large, active, continental transform faults, such as the San Andreas Fault system in California, the North Anatolian Fault system in northern Turkey, the Alpine Fault in New Zealand, and the Altyn Tagh Fault in northern

Tibetan Plateau, constitute veritable *keirogens*. In this entry, the emphasis is on the oceanic transform faults, in keeping with the theme of the volume.

Introduction
The concept of transform faults arose from the observation that many mobile belts taking the form of mountains, mid-ocean ridges, or major strike-slip faults and the seismic activity associated with them often appear to end abruptly at their strike terminations. Lotze (1937), Ketin (1948), and Wilson (1954) offered kinematic solutions to this problem which were revived by Wilson (1965) later. Wilson pointed out that large mobile belts do not end, but that they are connected into a continuous *network of mobile belts* about the earth dividing the surface of the planet into several rigid *plates* in motion with respect to one another (Wilson, 1965). Wilson further pointed out that "Any feature at its apparent termination may be transformed into another feature of one of the other two types (Figure 1). For example, a fault may be transformed into a mid-ocean ridge as illustrated in Figure 1a. At the point of transformation, the horizontal shear ends abruptly by being changed into an expanding tensional motion across the ridge or rift with a change in seismicity" (Wilson, 1965, 343). As is clear, this sentence is also the birth cry of plate tectonics.

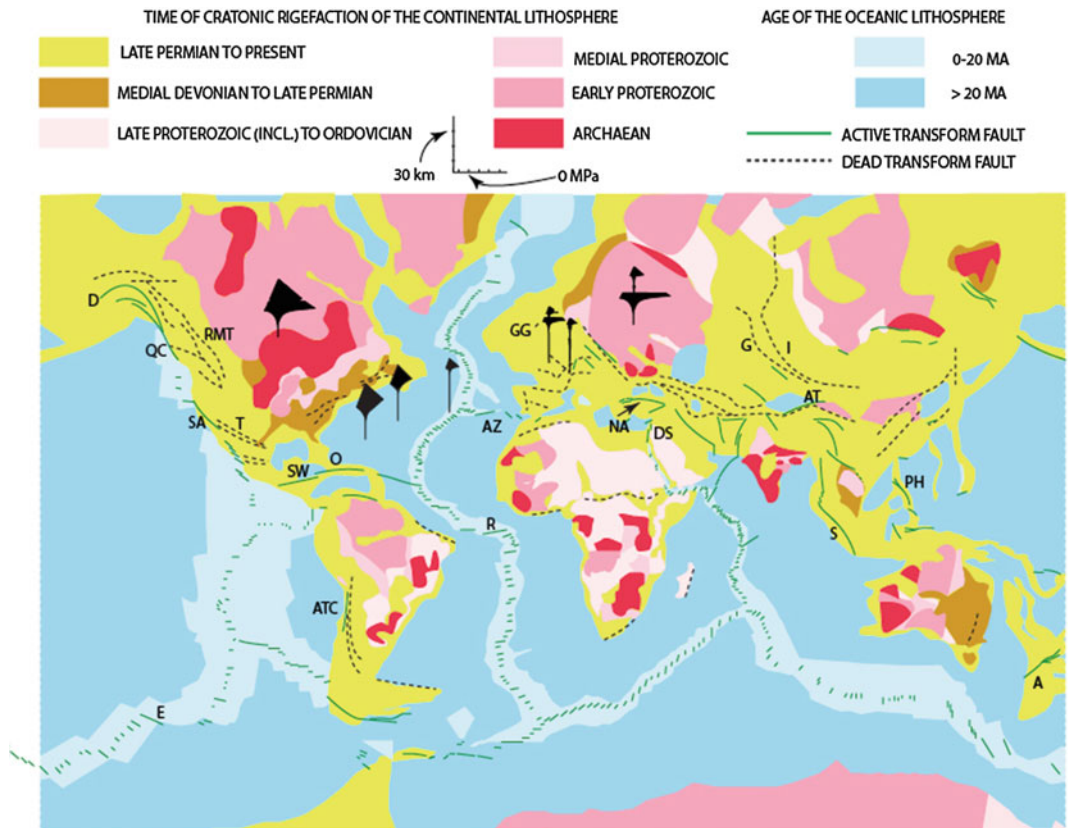
Wilson called the terminations where a feature is transformed into another one *transforms*. Thus, a plate boundary of any one type *must* extend between two transforms (*not* transform faults, although they may indeed extend between two transform faults, to which they must attach at transforms).

Wilson defined transform faults as follows: "Faults in which the displacement suddenly stops or changes form and direction are not true transcurrent faults. It is proposed that a separate class of horizontal shear faults exists which terminate abruptly at both ends, but which nevertheless may show great displacements. Each may be thought of as a pair of half-shears joined end to end. Any combination of pairs of the three dextral half shears may be joined giving rise to the six types illustrated in Figure 2 (herein Figure 1). Another six sinistral forms can also exist. The name transform fault is proposed for the class, and members may be described in terms of the features which they connect (for example, dextral transform fault, ridge-convex arc type)" (Wilson, 1965, 343).

When Wilson pointed out that transform faults should be considered as a separate class of faults, he had Anderson's theory of faulting (Anderson, 1951) in mind, in which the three kinds of faults, namely, normal dip slip, reverse dip slip, and wrench, have been considered to have formed in a medium where the medium is continuous and conserved during faulting. By contrast, transform faults can only form if at both their ends there is material consumption or generation (Wilson, 1965, 344), in other words, if the Earth's outer rocky shell, i.e., the lithosphere, is divided into independently moving spherical caps


Transform Faults, Figure 1 Kinds and behaviours of transform faults after Wilson (1965, Figs. 3 and 4). (**a**) Ridge-ridge, (**b**) ridge-arc facing away from the ridge (later this type was called ridge-trench facing away from the ridge), (**c**) ridge-arc facing toward the ridge (ridge-trench facing toward the ridge), (**d**) arc-arc with arcs facing away from one another (trench-trench with trenches facing away from one another), (**e**) arc-arc with arcs facing the same way (trench-trench with trenches facing the same way), and (**f**) arc-arc with arcs facing toward each other (trench-trench with trenches facing toward one another). Note that the ridge-ridge transform faults and those between similarly facing ridges do not change their length during finite plate evolution (**a** and **e**). Those connecting ridges to trenches facing away from the ridge (**b**) get longer by ½ of the spreading velocity. Those connecting ridges to trenches facing toward the ridge (**c**) become shorter by ½ the spreading velocity. Transform faults connecting two ridges facing away from each other (**d**) become longer with the same velocity as the spreading, and those connecting two facing trenches become shorter with the full spreading velocity. (**g**) Transform fault at which extension changes to shortening.

(Teichert, 1979) that can be destroyed and generated along their boundaries.

Wilson further pointed out that transform faults display habits of growth and diminution different from faults described by Anderson (1951), and he believed that therein lay the great significance of their recognition: They could only occur on a planet where there is considerable horizontal displacement coupled with material generation


Transform Faults, Figure 2 Map showing the active transform faults of the world and some of the dead ones of the Paleozoic and Mesozoic ages. Notice that all transform faults shown in this figure are located in oceanic lithosphere younger than 20 Ma (with a few exceptions as in the Indian Ocean) or in continental lithosphere that was last heated and deformed (and thus began its rigefaction) after the Permian. The *black* tree-shaped figures are strength profiles (for scale, see the small graph showing strength in 1,000 Mpa and steps and depth in 30 km steps) with compressional strength to the *right* and tensional strength to the *left*. Note the immense strengths of the Precambrian cratons. That is why no post-Paleozoic transform fault was able to cut through them (unless they are very narrow as in the Gulf of Guinea/Northeast Brazilian conjugate margins). The strength profiles have been copied from Şengör (1999) with the tensional strength of the Canadian Shield simply extrapolated from the Baltic Shield, because for it no tensional calculations are available.

and destruction at the surface. Figure 1 shows also the six types of behaviour of transform faults in terms of their changes in size; some become longer; others become shorter and eventually disappear; yet others first shorten and then lengthen (for an analysis of the geological implications of these length changes, see Dewey, 1976). In an epoch-making paper, Sykes (1967) showed that what Wilson identified as transform faults indeed showed senses of motion as he had predicted as opposed to what the earlier geological wisdom would have proposed. In the same year, McKenzie and Parker (1967) pointed out that the fault systems in the northwest Pacific Ocean bore out fully the predictions of Wilson's theory of plate tectonics, of which transform faults were a critical component, when tested rigorously by earthquake slip vectors, fault orientations as evaluated within the bounds of Euler's theorem of the motion of a point on the surface of a sphere and as also analyzed in greater detail in an independently conceived presentation by Morgan (1968).

Transform faults as large-scale geological structures

General. Transform faults are strike-slip faults, but they commonly appear not as single faults. Instead, they are commonly broad shear zones in which there are a large number of parallel to subparallel faults that may all be active simultaneously or at different times. The geological behaviour of transform faults depends on four main factors: (1) the nature of the lithosphere they cut and displace, (2) their length and how stable that length is, (3) the behaviour of the plate boundaries they connect (for instance, whether they move in an environment where rotation poles governing their motion are stable for significant periods of time or whether they shift rapidly), and (4) the manner in which they form.

1. *The nature of the lithosphere in which they move has three main elements that are critical for their geological behaviour*: (a) the composition of the lithosphere,

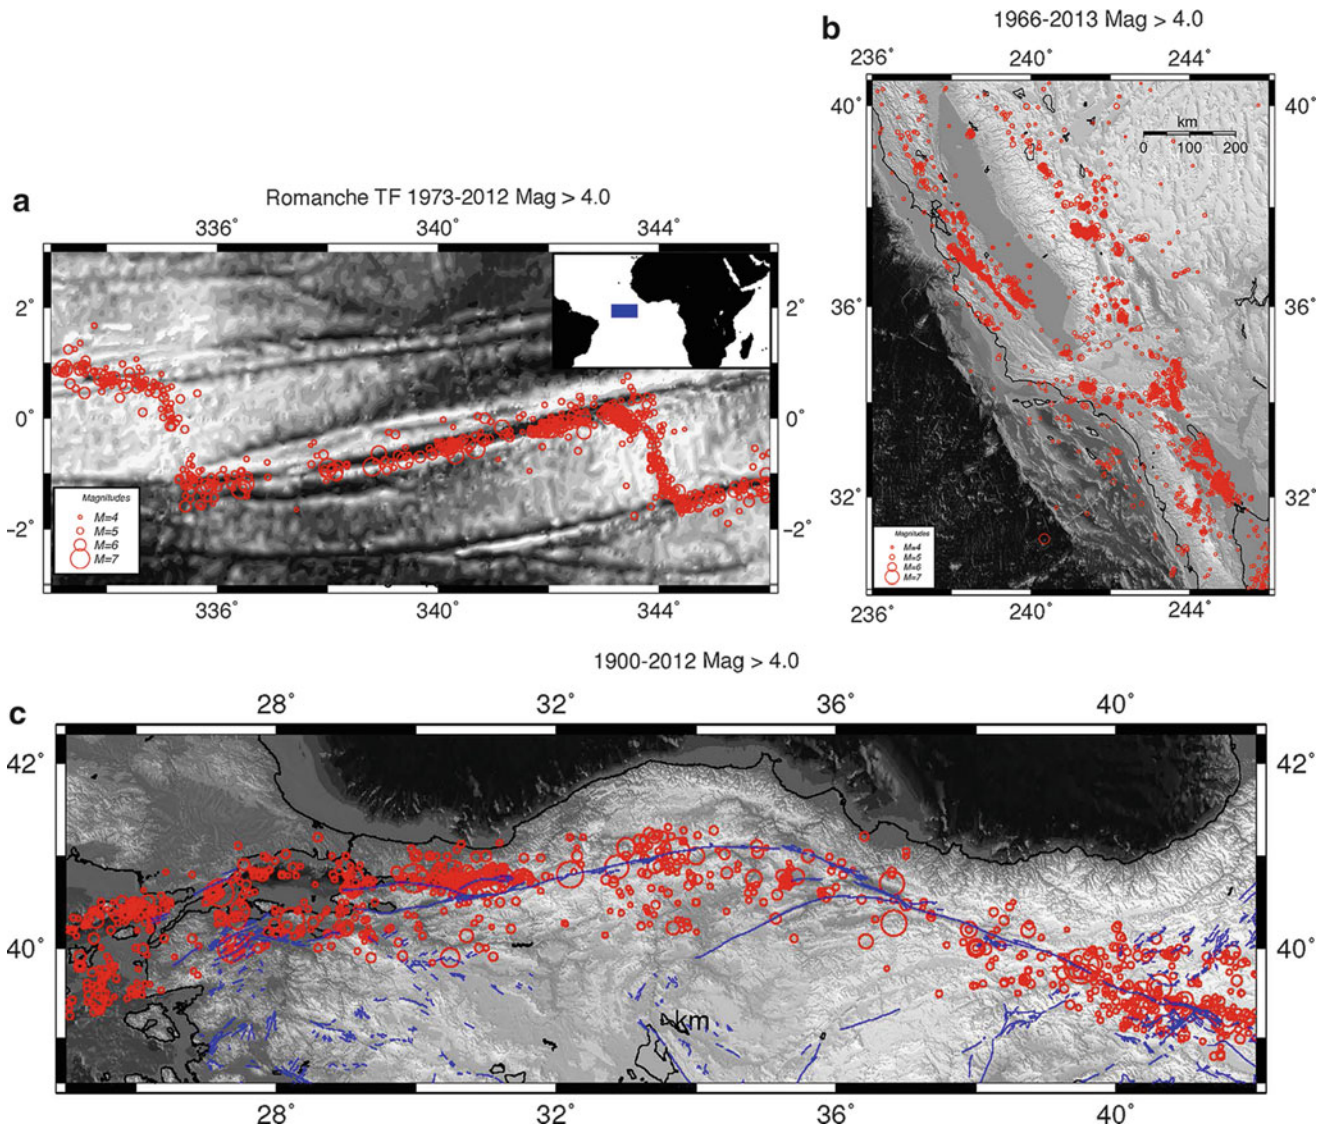
(b) the presence and nature of preexisting structures in the lithosphere, and (c) its thermal structure. All of these, together with the strain rate, determine the deformational behaviour of the lithosphere. If the lithosphere is crust dominated, i.e., if its crust is thicker than its mantle part, its behaviour will be dominated by feldspar strength and consequently such a lithosphere will be weaker than one with a thick mantle part dominated by olivine strength. Thus, old oceanic lithosphere will be stronger than younger continental lithosphere. By contrast, old continental lithosphere (such as observed in Archaean cratons) may be stronger than oceanic lithosphere (see Figure 2; unless the oceanic lithosphere is very much older (>200 Ma) than any seen in the world oceans today; such very old oceanic lithospheric pieces have been claimed to exist under the Pre-Caspian Depression and under the Tarim Basin, where they appear to have resisted all deformation around their periphery: see Şengör and Natal'in (1996)).

The continental crust has an average age of 2 Ga. However, this age cannot be generalized to the continental lithosphere, because the mantle parts of continental rafts may be removed and regrown (cf. Şengör, 2001 and the references therein). By contrast, the oceanic crust has an average age of some 100 Ma, and most oceanic lithosphere carries its own original mantle, except over hot spots (where depth anomalies in the oceans exist; see Şengör (2001) and the references therein). For a continent and an ocean with similar thickness mantle lithospheres, the continents contain a much richer assortment of structures. This renders them weaker.

Young orogenic belts for long have been assumed not to have a thick lithosphere because it was believed that thickened lithosphere would become buoyantly unstable and sink into the asthenosphere, leaving the overlying orogenic belt devoid of a mantle lithosphere (Houseman et al., 1981). However, recent observations have shown that the underthrusting forelands tend to keep their lithospheric keels (Priestley and McKenzie, 2006), but that long-lived continental-margin arc orogens, such as the Andes, necessarily have no mantle lithosphere under them (Şengör, 1990). Because of active magmatism along their axes, arc cores are hot, and without underlying mantle lithosphere, they are among the weakest places in the continents. By contrast, old cratons are extremely strong and are essentially undeformable unless by mantle plumes that may thermally erode their lithospheric armor (Şengör, 1999). Young oceanic lithosphere is also weak and deforms easily.

From the above, one would expect large active transform faults to exist in the younger parts of the oceans and in and near young orogenic belts (see Sandwell, 1986). This is by and large true with exceptions existing only in areas of old continental crust that somehow had lost its equally old lithosphere as in wide areas within the Eurasian foldbelts or under the Pan-African terrain of Afro-Arabia (Figure 2; for a list of some of the more prominent fracture zones in the oceans, see http://en.wikipedia.org/wiki/List_of_fracture_zones last visited on 22 March 2013).

Seismicity associated with oceanic transform faults exhibits epicentral locations confined to a narrow fault zone (Figure 3), whereas in the continents, large transform faults have very broad regions of associated seismicity, because in such zones a number of parallel fault families take up the displacement (Figure 3b, c). This has three reasons: (1) Oceanic transform faults almost without exception cut through the lithosphere not previously highly deformed; in fact in most cases, they separate two pieces of lithosphere that were never continuous, i.e., they work along an already existing surface of separation (for one exception among a number, see Stein and Cochran, 1985, esp. Fig. 2); (2) the superior strength of the oceanic lithosphere prevents deformation from spreading outside the principal zone of displacement along an oceanic transform fault; and (3) most oceanic transform faults acquire a component of extension across their strike, making them weak (cf. Hall and Gurnis, 2005) and preventing shear strain from being exported outside the zone of principal displacement.

2. *The length of transform faults and the stability of that length* can be very variable: Some are very short (on the order of 10 km; there are even shorter ones forming links in a continuous spectrum beginning with intra-rift transfer faults (Karson, 1990) through zero-offset transform faults (Schouten and White, 1980) and ending with transform faults with significant transform separation) connecting two nearby plate boundaries, such as the ones seen offsetting the Mid-Atlantic Ridge in the north and the south Atlantic Oceans (Figure 2). Among the ridge-ridge transform faults, the longest (such as the Romanche or the Eltanin: see Figure 2 for locations) hardly exceed 600 km in length. One factor controlling the length of ridge-ridge transform faults may be large, transform-parallel tensile stresses arising from the thermal contraction of the oceanic lithosphere as it cools (Sandwell, 1986; Haxby and Parmentiar, 1988). The transform faults connecting two subduction zones (such as the Swan and Oriente pair in the northern Caribbean and the complex system bounding the Caribbean Plate to the south, of which the El Pilar Fault is the longest, or the Alpine Fault in New Zealand or the Philippine Fault in eastern Asia; see Figure 2 for locations) reach lengths between 1,000 and 2,000 km.


Transform Faults, Figure 3 Seismicity associated with transform faults. (**a**) Romanche transform fault, one of the longest ridge-ridge-type oceanic transform faults. The seismicity is that of the 1973–2012 interval showing Mw > 4 earthquakes from the National Earthquake Information Center (NEIC) catalog. Bathymetry is taken from GEBCO 30 arc second dataset. Note the extremely narrow seismic zone coincident with the bathymetric expression of the fault zone. (**b**) San Andreas Keirogen. Seismicity of the San Andreas Fault (SAF) system between 1966 and 2013 with Mw > 4. Seismicity of the SAF from the Northern California Earthquake Catalog and National Earthquake Information Center (NEIC) catalog. Bathymetry and topography are taken from GEBCO 30 arc second dataset. The map has the same scale as the map in Figure 6a. Note that the seismicity here is much more diffuse than that in the case of the oceanic Romanche transform fault. However, the diffuseness of the seismicity is largely a function of the keirogenic character of the transform fault system, i.e., of the fact that here we see more than one strand of strike-slip faults that are now active. Along each fault, the scatter of the epicenters is not incomparable to that along the Romanche. The seismicity gets scattered only in the Transverse Ranges (marked by TR) where there are substantial crustal shortening and disruption along many faults (cf. Dickinson, 1996). This is in marked contrast to the North Anatolian Keirogen illustrated in Figure 6c and is commonly attributed to the main strand of the San Andreas' being a weak fault. (**c**) Anatolian Keirogen. The seismicity is that of the 1900–2012 interval with Mw > 4 from the KOERI catalog. Bathymetry and topography are taken from GEBCO 30 arc second dataset. The map has the same scale as the map in Figure 6a, b. Note that although the North Anatolian Fault has only one main strand along much of its length, the seismicity along the entire keirogen is extremely scattered. Although the North Anatolian Fault also moves in a serpentinite-rich milieu (cf. Şengör et al., 2005), it does so in a much more complexly structured suture region, as opposed to the uncollided accretionary complex milieu of the San Andreas.

Others in more complex settings also can be very long (to select from among the active ones: San Andreas, Queen Charlotte, Atacama, Sumatra and North Anatolian; see Figure 2 for locations), being on the order of 1,000–1,500 km. Some of the largest fossil ones have been reported to have lengths of some 2,000–2,500 km (e.g., the Irtysh-Gornostaev, or the Silk Road Keirogens: for locations, see Figure 2).

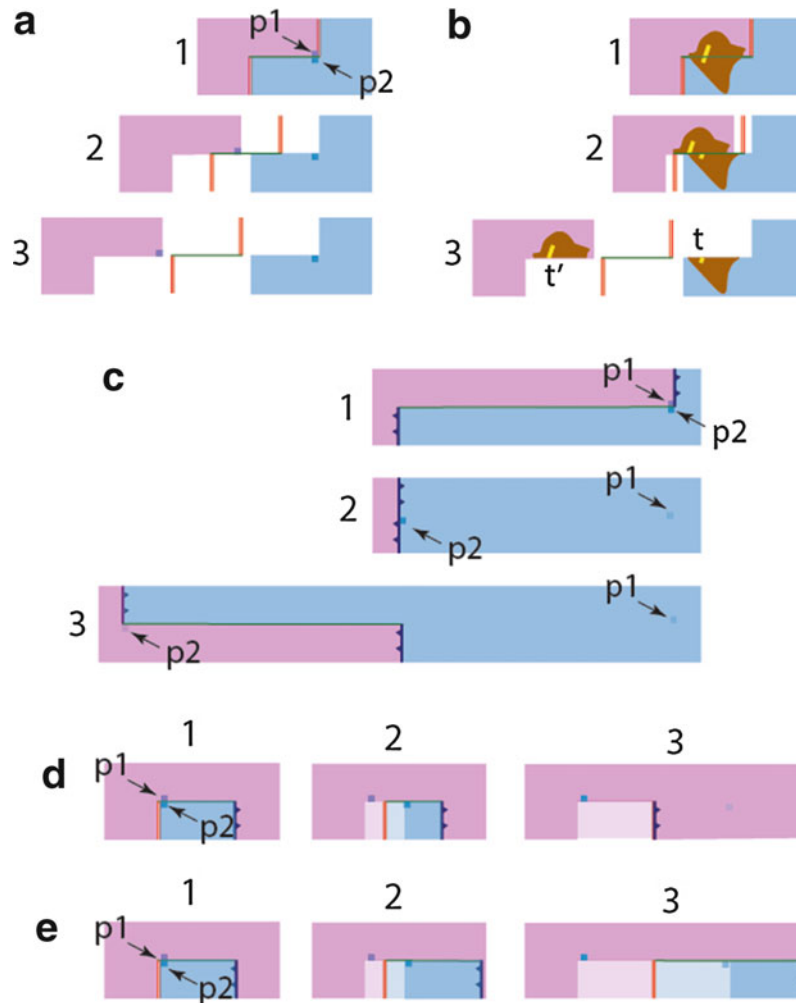
Because material at the ends of transform faults is not conserved and the faults can change their lengths very considerably during their evolution (as Wilson already emphasized in his seminal 1965 paper), it is meaningless to talk about "displacements" along them (Figure 4). One can naturally say that the displacement along a transform fault equals the amount of relative plate motion that has taken place along it, but in many cases, this may not be measurable by any observations one can make along the fault.

3. *The behaviour of the plate boundary*, of which a transform fault forms a part, determines other aspects of the geometry and the kinematics of a transform fault than just its length and how much plate passage may occur along it. Almost all plate boundaries are unstable if given enough time. They change location, slip, and shape, because in any system, where more than two plates interact, at least one of the poles of rotation must shift in the framework of the plate boundary, the evolution of which it governs (Dewey, 1975). Transform faults along a boundary whose pole is shifting must change slip and character or give rise to entirely new plate boundary configurations. A discussion of this question will also illustrate how new transform faults may arise.

Consider the simple plate boundary configuration depicted in Figure 5a. A single plate boundary between plates *A* and *B* consists of three ridge segments and two transform faults. The pole AB_1 governs the motion of *B* with respect to *A*, here held fixed arbitrarily. In Figure 5b, the pole of rotation has moved to a new place shown with AB_2. The plate boundary configuration shown in Figure 5a can no longer satisfy the requirements of the new rotation as indicated in Figure 5b. A new plate boundary configuration is necessary. Figure 5c shows what shape this new boundary most likely will take. The reason for the shape shown in Figure 5c is that the spreading centers try to keep a time-averaged symmetric position between separating plates. They must tear through the weakest part of the lithosphere which is indicated with the brick-coloured strip in Figure 5b. In the new configuration, the spreading centers ideally must keep their orientation along the great circles ("meridians" of the new pole) going through the new pole of rotation, and the transform faults must lie along the small circles ("parallels" of the new pole) concentric around the pole (for possible

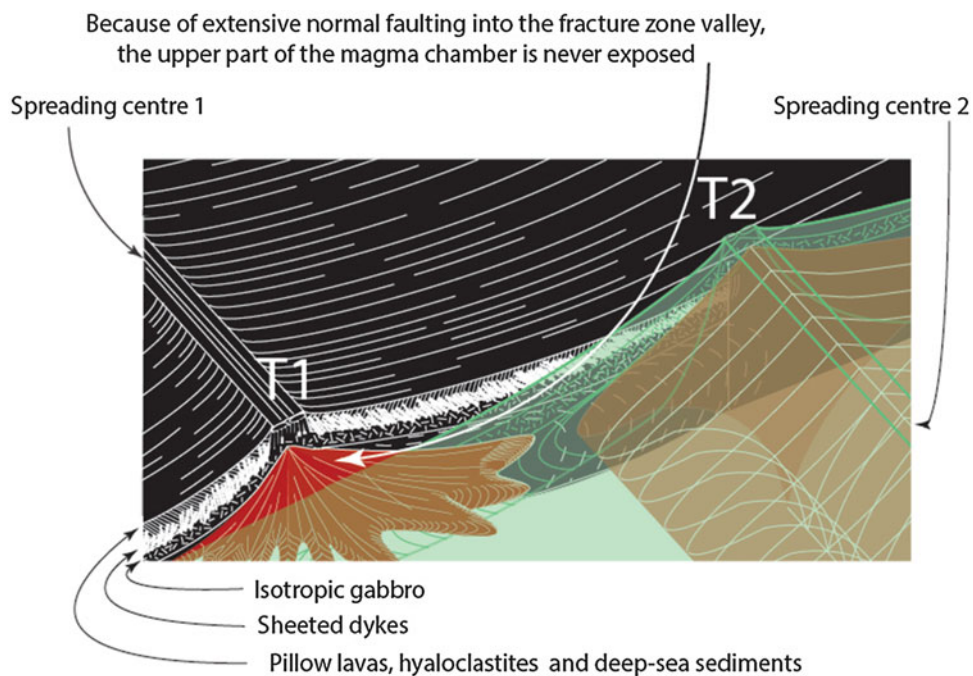
origins of this orthogonal geometry, involving a minimum work argument for the ridges and the anisotropy of the accreting oceanic crust, see Freund and Merzer (1976) and the references 2 through 5 in that paper, but Sandwell (1986) has shown that even if it were not for these factors, the transform faults would still exist as an inherent part of the spreading process). The resultant new plate boundary and plate configuration will be that shown in Figure 5d. Here, one additional factor determining transform fault spacing may be due to thermal bending moments that concentrate bending stresses at a distance from the fracture zone determined by the degree of coupling across the fracture zone and the flexural length of the plate, thus providing a natural length scale controlling the spacing of transforms (Haxby and Parmentier, 1988). In Figure 6c and d, instead of the two original long transform faults, numerous shorter transform faults originated, reminding one of the geometry along the Mid-Atlantic Ridge. In a recent study, Gerya (2010) argued, on the basis of numerical modeling, that asymmetric spreading (see Schouten et al., 1980; Müller et al., 2008, for observations; and Katz, 2010, for possible causes) on alternate spreading segments of a previously straight ridge segment may impose on it an undulatory structure, which, in a few million years, would generate transform faults to avoid further asymmetric spreading. This model implies continuous change of the length of ridge-ridge transform faults with time, and it is not mutually exclusive with the pole shift-generated ridge jumps as shown above.

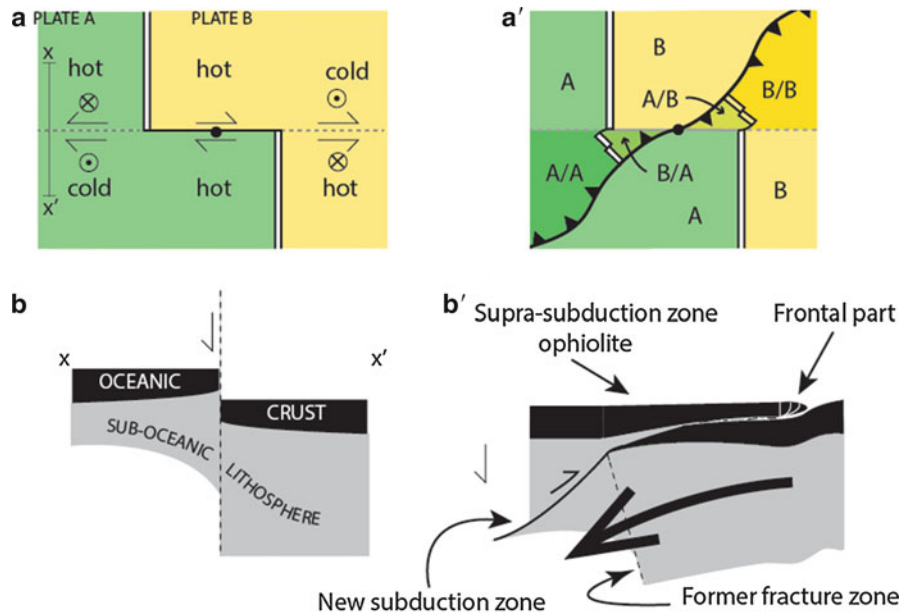
In Figure 5, had the pole shifted toward the right, rather than to the left, obliquely consuming subduction zones would have formed along the former transform faults. This seems a common process (Dewey, 1975; Karig, 1982; Casey and Dewey, 1984, esp. Fig. 7; Dewey and Casey, 2011). Because subduction zones can easily consume the oceanic lithosphere obliquely, there would have been no great necessity to slice the new subduction zones with numerous transform faults, as it happened to the new ridges.

Let us now consider the geometry shown in Figure 6a. This too shows a simple plate boundary between plates *A* and *B*, whereby *B* rotates around the pole AB_1 along two spreading ridges separated by a long transform fault. In Figure 6b, the pole is shown to have shifted to *CD* by 90°. The change here is so drastic that entirely new plate boundaries would need to form. First of all, let us consider the situation along the transform fault: To understand the three-dimensional geometry along the fault and along its non-transform fracture zone extensions (shown by dashed green lines in Figure 6b), look at Figure 7 showing two ridge segments separated by a dextral


Transform Faults, Figure 4 "Difficulty of defining 'displacement'" along different kinds of transform faults: (**a**) In a ridge-ridge-type transform fault, the points *p1,* and *p2* are contiguous, but not originally continuous (**a**1). Therefore, they cannot measure the "displacement" along the transform fault, but their separation in time is equal to the plate displacement that at any one time takes place along the transform fault (**a**2 and **a**3). But that displacement cannot be said to be the displacement along the transform fault, because once *p1* and *p2* clear the fault (**a**3), they are no longer on it and therefore no longer undergo any strike-slip displacement. Their displacement cannot be converted to shear strain along the fault. But if a cylinder with a vertical axis fixed with respect to the two ridges and with surface touching the fault mirrors is assumed to be present along the fault, it will rotate (anticlockwise in a left-lateral fault as shown in Figure 4a and clockwise in a right-lateral fault) as long as the fault moves and will record the total separation of *p1* and *p2* in time. (**b**) If a transform fault cuts through a continent (as in the case of the San Andreas, North Anatolian, and Alpine Keirogens or of the conjugate margins of the northern margin of the Gulf of Guinea and Northeastern Brazil: the *brown* object in **b**1), the displacement of any originally continuous feature cut by the transform fault (for instance, the *yellow* band in **b**1) system will give the real displacement along the fault (**b**2), until the separated segments of the originally continuous feature clear the fault (**b**3).
(**c**) The three maps shown here illustrate a case where a transform fault first becomes shorter (**c**1), disappears for an instant (**c**2), and then grows along the same strike, but with a reversed sense of motion. Although "the fault" (how reasonable is it here to talk about "one fault"?) reverses its motion, the displacement of the points *p1* and *p2* will continue uninterrupted, in the sense that they will get farther and farther apart from one another, but not along the same fault! In fact, only *p2* will stay visible until the fault length reduces to zero, and then it will too be subducted. (**d**) In **d**1, the two points *p1* and *p2* are contiguous, as in Fig. **a**1, but not continuous. In **d**2, the displacement of the points *p1* and *p2* is exactly twice as large as the original length of the fault, but the fault has already lost ¼ of its length. It will eventually totally disappear and we can have no means of defining a meaningful displacement along it. (**e**) In this case, both of the points *p1* and *p2* will remain visible during the evolution of the transform fault that here grows with a rate of ½ the spreading rate. But this is not the rate of displacement, which cannot be defined as the point *p1* is placed in an intraplate position an instant after the situation depicted in **e**1; i. e., it no longer faces a fault along which to be displaced.
Transform Faults, Figure 5 (**a**) A simple two-plate geometry depicted on a stereographic lower-hemisphere projection using a Wulff net. *Red double lines* show spreading centers and single green lines are transform faults. *AB1* is the rotation pole of plate *B* with respect to plate *A*. (**b**) The pole of rotation of the plate *B* with respect to plate *A* has moved to its new location *AB2*. The brick-coloured stripe shows the hottest and thinnest lithosphere. The new plate boundary will try to localize itself along that area. (**c**) The geometry of the new plate boundary between the plates *A* and *B*. *Black lines* are subduction zones with teeth on the overriding plate. Note the numerous new, short transform faults that originated along the new spreading center. (**d**) The new plate boundary between plates *A* and *B*.

transform fault. The transform meets the ridges at the transforms T1 and T2. The two plates subside as they spread away from the ridges following the √age relationship. As a consequence, the left-hand ridge stands higher than the crust created at the right-hand ridge at T1. There is a crossover point, when both segment runs (Tucholke and Lin, 1994) are at the same elevation on both sides of the transform fault (cf. Figures. 6b and 7). When the entire transform fault/fracture zone system is placed under shortening across their strike, the ridge T1 will tend to overthrust the green crustal segment in front of it toward the viewer, whereas the ridge T2 will try to thrust the black crustal segment away from the

viewer. As a consequence, a new subduction boundary may come into existence along the former fracture zone with opposite vergences on both sides of the crossover point. As the two subduction segments recede from one another, a completely new and continuously lengthening transform fault will connect them. In such a drastic change, the former spreading centers between the plates A and B may cease their activity, and the two entirely new plates *C* and *D* may come into existence, carrying the former spreading centers as fossils in them. Such an event often heralds the obduction of large ophiolite nappes (Casey and Dewey, 1984; Dewey and Casey, 2011).
Transform Faults, Figure 6 (**a**) A simple plate boundary between plates *A* and *B*. *B* is rotating with respect to *A* around the pole *AB1* in the sense shown. Symbols as in Figure 5. (**b**): The rotation pole has moved to *CD*. As a result of this drastic shift, two new plates have come into existence, *C,* and *D*. Their boundary is a subduction zone offset by a new transform fault that formed at the point of the crossover shown in (**a**).


Transform Faults, Figure 7 Basic anatomy of an oceanic fracture zone including a transform fault extending between the transforms *T1* and *T2* at which the transform fault is attached to two ridges. The *green* segment is shown transparent so as to expose the interior geometry. *Red* are the magma chambers, here shown to be continuous as in fast spreading centers (ideally). At *T1*, the magma chamber is shown to send dykes into the neighboring cold and low segment causing their metamorphism from granulite to greenschist facies depending on depth and proximity to the magma chamber. The upper part of the magma chamber is never exposed because of extensive normal faulting into the fracture zone valley (here not shown so as to emphasize the ideal form of the magma chamber). The same will happen in the *black* segment at *T2*, but is not seen here because the *black* segment was drawn opaque.


Transform Faults, Figure 8 Maps (**a** and **a**′) and cross sections (**b** and **b**′) showing what might happen when a fracture zone is put into shortening across its strike. The *black* circle in the middle of the transform fault is the crossover point. To the *left* of the crossover point, the upper segment will thrust over the lower one, because the lower segment there is topographically lower. By contrast, the lower spreading segment to the *right* of the crossover point will thrust over the upper one, because the lower segment here is the topographically higher one. This may induce a rotation around the vertical axis of the entire newly formed subduction zone. Such a development, if near a continental margin, may lead to the obduction of giant ophiolite nappes.

However, a tear along the crossover point may not materialize immediately. In such a case, the situation shown in Figure 8 may occur: The subduction zone, which switches its vergence at where the old crossover was, may begin rotating about it in the manner shown in Figure 8a′. The large anticlockwise rotation of Cyprus (50–60°) may have happened because of a geometry similar to the one shown in Figure 8 (cf. Morris et al., 2006).

4. *The manner in which transform faults can form* is discussed above, but the scenarios developed there are not the only ones for the origin of transform faults. They may form intracontinentally in diverse ways. In one of the classic papers relating plate tectonics to continental geology, Atwater (1970) showed how the San Andreas keirogenic system originated when the strike-slip motion between the Pacific and the North American Plates was carried into the continent, creating a broad keirogen with many strike-slip fault segments. Wilson showed that transform faults may be inherited from structures that formed during continental separation (Wilson, 1965, Fig. 6). Figure 9a shows the continent *P* with a number of plume-generated triple junctions of rifts (tj), similar to the present-day Africa (Burke and Dewey, 1973). In Figure 9b, it is shown that the continent *P* was split along the new spreading center *BB*. Notice that the transform fault *t* was inherited from the transform fault margins (for the geology of the sheared margins, see Scrutton,

1979, 1982) connecting two former triple junctions, the now inactive rifts of which have been left on the continental margins as aulacogens (*A*). Sage et al. (2000) found along the Côte d'Ivoire-Ghana transform fault margin that the thermal exchange between the continental margin and the adjacent spreading center was lower than predicted by available geological (e.g., Scrutton, 1979, 303) and thermal models. They ascribed this to the effect of the transform fault and compared it with diminished heat-related features (thinner oceanic crust, reduced magmatism, deeper bathymetry) at the end of spreading segments where a spreading ridge abuts against a transform fault. Especially, the thinner crust would here facilitate the onset of subduction at the ocean/continent boundary, because it reduces the buoyancy of the oceanic lithosphere. In fact, initiation of subduction at continental margins is difficult, especially along the margins of large and old oceans (Cloetingh et al., 1984), and thus it is probably most common along transform fault margins. The short transform faults along the spreading center *BB* in Figure 9b formed shortly after continental separation to avoid significant oblique spreading along the mid-ocean ridge.

Old oceanic lithosphere may also be torn (although not easily) along a new spreading center, which would have its own transform faults (e.g., the Sheba Ridge in the Indian Ocean; Stein and Cochran, 1985, esp. Fig. 2). In that case, formerly continuous markers along
Transform Faults, Figure. 9 (**a**) Continent *P* (drawn on a Wulff net, lower-hemisphere projection) with a number of plume-generated rift triple junctions (*tj*) forming rift stars. (**b**) Continent *P* is now in two pieces (*P1* and *P2*) rifted along the new spreading center *BB*. Of the old rift stars, the now inactive rift arms are left as aulacogens. Note that the transform fault *t* was inherited from an intracontinental transform fault, whose continental traces are now seen at the conjugate transform fault margins (*TM*).

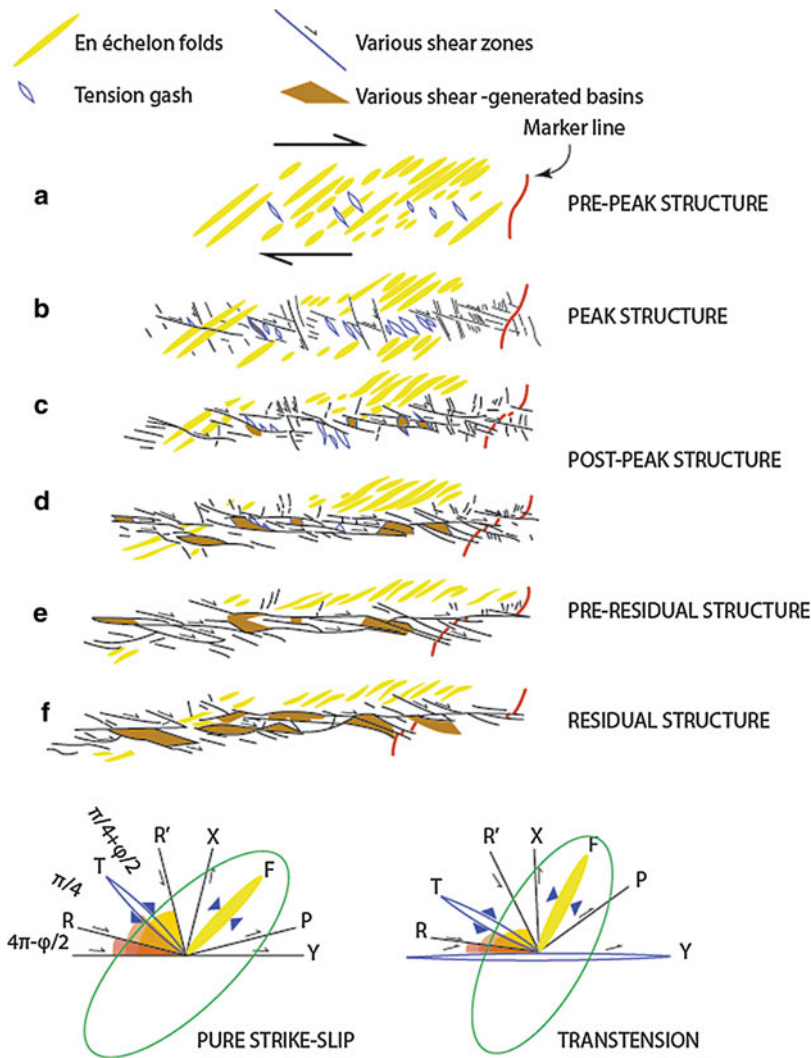
an oceanic transform fault may be found. Another way of tearing an old lithosphere is shown in Figures. 6a and b. As a transform-fault-bounded subduction zone advances onto a lithospheric plate, the downgoing plate must tear, as the part of it outside the subduction front must stay at the surface, whereas the rest must be subducted. This "edge effect" (DeLong et al., 1975, 734) along what Govers and Wortel (2005, 505) called a "Subduction-Transform Edge Propagator," or, in short, STEP, creates complex structural (Şengör, 1983), magmatic (DeLong et al., 1975), and large-scale tectonic (Govers and Wortel, 2005; özbakır et al., 2013) effects. Baes et al. (2011) pointed out that the initiation of subduction along such STEP faults, especially when they occur adjacent to the continents, is facilitated and combined with the thermally controlled weakness reported by Sage et al. (2000), such areas may be preferred locations for new subduction zones to come into existence.

Transform faults that form in the manner of *t*, i.e., by tearing a preexisting piece of lithosphere, do so by following the same steps as all strike-slip faults. These steps are illustrated in Figure 10 (see Tchalenko, 1970 and the synthesis in Şengör, 1995; also see Ahlgren, 2001; Katz et al, 2004). As shearing begins, the associated strain is initially taken up along a broad zone. If this zone contains a horizontally layered structure, folding will be the first response to shearing, and folds (and other sorts of structures of shortening such as thrust faults and/or horizontal stylolites) will form at angles at or close to 135° (measured clockwise from the shear, i.e., the Y plane). Tension gashes at 45° to the shear plane may form earlier or later. When the peak strength stage (Tchalenko, 1970) is reached, first the anti-Riedel (R') and then the Riedel shears (R) begin forming. In the early post-peak strength

stage, the anti-Riedels generally rotate and lock, but the Riedels continue to evolve. They develop "flatter" tips which, in a later stage, join the P shears. In some cases, the X shears also form at this stage. Finally, the R and P shears form a throughgoing fault (generally referred to as the Y shear). The important thing in this evolution is that numerous extensional structures other than just tension gashes may form by the "opening" of the other shear structures giving rise to very complicated geometries of extension. Some of these extensional nodes may localize vulcanicity.

When the transform fault clears the continental margins, which it had originally formed, all such shear-related activities outside the surface of displacement must ideally cease, because the fault in the oceanic lithosphere is born as a fault without needing to tear a previously continuous medium. Indeed, in most oceans, the ridge-ridge transform faults have almost no shear-related structures outside the narrow fault zone. However, this is not universally the case and we must look at the anatomy of an oceanic fracture zone in some detail to see what goes on within it.

The finer geology of oceanic fracture zones

Kohlstedt et al. (1995) and Bercovici (2003) noted that the lower surface of the *oceanic mechanical lithosphere* corresponds with about 600–700 °C and, when about 60 Ma old, with a depth of about 40–50 km. This means that below that depth range, deformation is wholly ductile. The zone of ductile deformation is shallower in younger oceanic lithosphere (ideally at 0 km at the spreading centers, but dyke formation shows that even there the brittle deformation claims a layer whose thickness may vary from a few hundreds of meters to 1.5 km) and deeper in older. In fact, Mckenzie et al. (2005) claimed that the depth of brittle deformation in both oceanic and


Transform Faults, Figure 10 Evolution of a shear zone (modified from Şengör, 1995, Fig. 2.27). The *brown* areas may be basins, or veins or intrusion receptacles depending on where and what scale the shear zone is active. In transtension, notice that all extensional structures become "flatter" and all shortening structures become "steeper" with respect to the Y shear. However, this is only an instantaneous picture, because as the shear zone evolves, all structures will rotate and strains will increase. Key to lettering: *F* is fold axial trace, *P* is P shear, *R* is a Riedel shear, *R'* is an anti-Riedel shear, *T* is a tension gash, and *X* is an X shear. φ is the angle of internal friction of the material being sheared.

continental lithospheres is controlled by the depth of the 600 °C isotherm, although Géli and Sclater (2008) later pointed out that McKenzie et al.'s conclusion was largely, but not entirely, correct, because they found earthquakes deeper than the 600 °C isotherm in the oceans, especially near fracture zones. They noted that "the strong tendency for the intra-plate earthquakes in the Indian Ocean to be located on or near fracture zones suggests that these processes are most important at fracture zones. Hydrothermal circulation, for instance, could be one such process. Seawater circulation likely results in lowering isotherms immediately below faults, thus increasing the maximum depth of brittle failure and explaining the unexpectedly deep occurrences of earthquakes. This provides indirect evidence that seawater circulates deeply along faults off axis in young lithosphere, a process which so far has been documented only at the crest of spreading centers" (Géli and Sclater, 2008; see also Sage et al., 2000). Kusznir and Cooper (2011) made estimates of the density and depth extent of serpentinized mantle at the Iberia-Newfoundland and Nova Scotia margins by comparing seismic refraction and gravity inversion Moho depths for these margins. They argue that "the proposed serpentinisation-depth relationships and gravity inversion suggest that there is little mantle serpentinisation deeper than 5 km, and in which case the average density of serpentinised mantle is 3,000 and 3,100 kg m^{-3}. We predict that where serpentinised mantle penetrates deeper
Transform Faults, Figure 11 (**a**): Map view of a fracture zone including a transform fault segment. Broad-headed *arrows* show extension across the fracture zone due to thermal contraction. The lengths of the *arrows* are indicative of the intensity of extension. (**b**): Cross section along x-x′ (in **a**). (**c**) Schematized geological cross section across a fracture zone (only the crustal part is shown except the cumulate ultramafics). Blue arrows schematically represent the hydrothermal circulation.

than ~2.5 km then its average density exceeds oceanic and continental crustal basement density. This work also suggests that it is unlikely that significant serpentinisation occurs under thinned continent crust at the OCT [ocean-continent transition]." Most Atlantic-type continental margins are under margin-perpendicular compression as revealed by in situ instantaneous strain observations (Zoback, 1992) including significant earthquakes exceeding a magnitude of 7 (Wolin et al., 2012). It is reasonable to assume, in regions where discontinuities in the oceanic lithosphere are being compressed across their planes, that seawater would not circulate to any significant extent, and this would explain the little serpentinization in such environments as noted by Kusznir and Cooper (2011). By contrast, oceanic fracture zones are places where there is thermal-contraction-driven extension across the transform faults and their fracture zone extensions (Collette, 1974; Turcotte, 1974; Sandwell, 1986; Kastens, 1987; Kumar and Gordon, 2009 and further literature therein). Morphologically, fracture zone valleys may be as impressive as some rift valleys (see esp. Franchateau et al., 1976, Fig. 7; and Fox et al., 1980, Fig. 3b), and fracture zone tectonism may very significantly disrupt the coherence of the oceanic lithosphere thousands of kilometers away from spreading centers.

Figure 11 illustrates some of the salient cross-sectional elements of the geology of the fracture zones (for details, see *general*: DeLong et al., 1977, 1979; *in the oceans*: Franchateau et al., 1976; Bonatti, 1978; Bonatti and Hamlyn, 1978; Bonatti et al., 1979; Fox et al., 1980; Hamlyn and Bonatti, 1980; Schouten and White, 1980; Schouten et al., 1980; Karson and Dick, 1983; Searle, 1983; Bonatti and Crane, 1984; CYAGOR II Group, 1984; Fox and Gallo, 1984; Honnorez et al., 1984; Garfunkel, 1986; Loudenr et al., 1986; Sandwell, 1986; Kastens, 1987; Rutter and Brodie, 1987; Allerton, 1989; Smoot, 1989; Tamsett and Searle, 1990; Müller and Roest, 1992; Kastens et al., 1998; Okal and Langenhorst, 2000; Sage et al., 2000; Beutel and Okal, 2003; Behn et al., 2007; Sørensen et al., 2007; *in ophiolites*, *general*: Nicolas, 1989, Chap. 5).

Figure 11a illustrates the map view of an oceanic fracture zone including a transform fault segment between plates *A* and *B*. The black circle in the middle of the transform fault shows the crossover point as explained above (see also Figures. 8 and 9). Beyond the transform fault, the fracture zone displays a complex displacement history: The most obvious motion along the non-transform fault extension of a fracture zone is that it "unfaults itself" in that the high side moves downward with respect to the low side because of faster cooling. At the same time, contraction down the thermal gradient will impose a strike-slip component opposite to that of the main transform fault. Finally, thermal contraction will also cause extension across the fracture zone along its entire length, including the transform segment. Because of this, the cross-sectional morphology of fracture zone valleys greatly resembles that of rift valleys (e.g., Fox et al.,
Transform Faults, Figure 12 Undulatory fracture zone strikes in the Central Atlantic.

1980, Fig. 3b; Tucholke and Lin, 1994, plate 3). The morphology of the fracture zone valleys differs from the morphology of rift valleys only in their perfect continuity and near perfect linearity (see esp. Tucholke and Lin's plate 3) and by the steepness of their sides. This linearity can only be disturbed, if there were one or more pole changes in the history of a transform fault. Such "ondulations" along the strike of many of the long fracture zones in the world's oceans are due to pole changes governing the spreading (cf. Figure 12 for some of the Central Atlantic examples).

The fracture valley slopes are steep (>10°) and both mass wasting and normal faulting are ubiquitous along them (Franchateau et al., 1976; DeLong et al., 1979; Fox et al., 1980). Extension, combined with strike-slip movement, induces a very complex *transtensional* tectonics on the fracture zone. What makes the whole structural picture so complex is that the strike-slip sense along the fracture zone valley reverses past the transforms. So every bit of fracture zone valley rock beyond the transforms will show the effects of two different episodes of transtensional strain (Dewey, 2002) in which the strike-slip components are opposite (but not necessarily of equal magnitude) of each other. No one observational report has yet reported all the expected complexities of the structural picture from any single fracture zone, but, combined, the available observations certainly indicate that what is expected (see esp. DeLong et al., 1979; Dewey, 2002) indeed happens.

The extension across the fracture zone will not only generate structures appropriate for a transtensional regime (which means strong constrictional strain in the more ductile lower parts: Dewey, 2002) but also magmatism (more alkalic as one goes away from the spreading centre), hydrothermal fields, and serpentinite diapirism. Water circulation down into the oceanic layer 3 (i.e., the magma chamber) will not only cause extensive mineralization in hydrothermal fields with varied and rich mineralization (e.g., Gibbs et al., 1993; Hein et al., 1999; Mazarovich et al., 2001) but also high-grade wet metamorphism creating amphibolite gneisses (Honnorez et al., 1984). As the segment run of the lower side of the fracture zone clears the transform fault, it is abutted against the ridge on the other segment. Here, the magma chamber of the high side, if present, will cause injection of mafic dykes into the plutonic foundation of the oceanic crust and the upper mantle. These dykes, depending on the length of the transform fault, can be significantly younger than the plutonic rocks they intrude (cf. Casey et al., 1981).

The steepness of the scarps will also cause the generation of scree breccias, the clasts of which may represent the entire suite of the oceanic crust and even upper mantle. As such, scree breccias accumulate into fans at the base of the slopes; they deform because of the tectonism of the fracture zone, commonly overlie hydrothermal vents, and become rebrecciated. Thus, rich, multicoloured calcite deposits cement them, giving rise to ophicalcites that are in places covered by radiolarites, in other places by distal turbidites, or hemipelagic deposits including deep-sea muds (DeLong et al., 1979; Bernoulli and Weissert,

1985), and in yet others they may be subaerial, possibly forming atop risen fracture zone rocks (Folk and McBride, 1976). Such breccias are often cut by dykes and show a polyphase origin indicated by a number of phases of fragmentation and different generations of cement fills. Ophicalcites form, under different names (e.g., *verd antique*, *verde aver*, *verde tinos*), one of the most popular ornamental stones in the Mediterranean region since antiquity.

Vertical tectonics along fracture zones, especially along their transform fault segments, is considerable (Bonatti, 1978), and atop risen segments, not only subaerial deposits but also localized shallow-water carbonate deposits may form. In the geological record, especially in ophiolitic mélange complexes, such shallow-water carbonate deposits may be confused with former atoll caps or fragments of oceanic plateaux.

Oceanic fracture zones in the geological record

The occurrence of proper oceanic fracture zones outside the present-day oceans is so far confined to ophiolite complexes. Some very young transfer faults in subaerial oceanic spreading centres, similar to those reported by Karson (1990) from the submarine ridges, have been mapped in Iceland (Einarsson, 1967; Sigmundsson, 2006), where even probably shear-related folding has been observed (Sigurdsson, 1967), and in Afar (Tapponnier et al., 1990; Abbate et al., 1995), but these places sit atop large, active mantle plumes. Nevertheless, they would give at least a first-order idea of what the oceanic fracture zones might look like at outcrop. None has been recognized in regions hypothesized to be underlain by trapped very old oceanic lithosphere such as the North Caspian Depression and the Tarim Basin. As yet, there is no modern synthesis of oceanic transform faults and fracture zones combining all the data from the ophiolites, subaerial spreading centres, and the oceans.

Definition

A *triple junction* is ideally a *point* at which boundaries of
three lithospheric plates come together. At such a point,
geological processes belonging to one plate boundary
abruptly give place to others belonging to the other two
boundaries. In real life, thermal and mechanical properties
of the crust and upper mantle and the time-averaged
behavior of the spreading centers and subduction zones
in the oceans impose a *finite volume* on triple junctions
in which deformation and magmatism are complex. Triple
junctions may be stable or unstable, i.e., they may exist for
finite amounts of time or only for an instant, depending on
the geometry of the boundaries meeting at the triple junc-
tion and the motion velocities across them. Triple junc-
tions also behave differently in the oceanic and in the
continental lithosphere. In this entry, the emphasis is on
oceanic triple junctions, in keeping with the theme of the
volume, but at least two important types of triple junction
involving continental plates are discussed, because they
may be important for some oceanic settings also.

Introduction

The concept of triple junctions became prominent with the
rise of plate tectonics, but before that, geologists dealing
with areas characterized by the motion of rigid to semi-
rigid blocks with respect to one another did come across

triple junctions of boundaries of increased displacement
and strain, and they recognized their geological signifi-
cance (e.g., Lotze, 1937). After the recognition of the plate
structure of the lithosphere and the three types of plate
boundaries by Wilson (1965), the subject of triple junc-
tions acquired a rigorously quantitative aspect (e.g.,
McKenzie and Parker, 1967; Morgan, 1968), and in
1969, McKenzie and Morgan presented an analysis of
16 types of triple junctions that they claimed to represent
all possible triple junctions. Figure 1 shows these 16 types
of triple junctions together with their velocity triangles
(see below). In this entry, Figure spelled with a capital
F refers to this entry's figures, whereas if spelled with a
lowercase f, it refers to a figure in the literature not here
reproduced.

Stability of triple junctions

Some triple junctions can exist during a finite lapse of time
without changing their geometries and others cannot.
Because plates are rigid and under ordinary circumstances
holes are not allowed to open at triple junctions, the sum of
the velocities of the plates with respect to one another
around a triple junction must add up to zero. As the plates
are required to be rigid caps moving on a spherical surface,
McKenzie and Parker (1974) showed that the velocity v of
a plate at any point on its surface can be expressed as

$$v = \Omega \, \mathrm{X} r \qquad (1)$$

where Ω represents the plate's angular velocity in a
nonrotating reference frame and r is the spherical coordi-
nate of the point, with the centre of the sphere as the origin
for both r and Ω.

The relative velocity v_{rel} between plates A and B can
thus be expressed as:

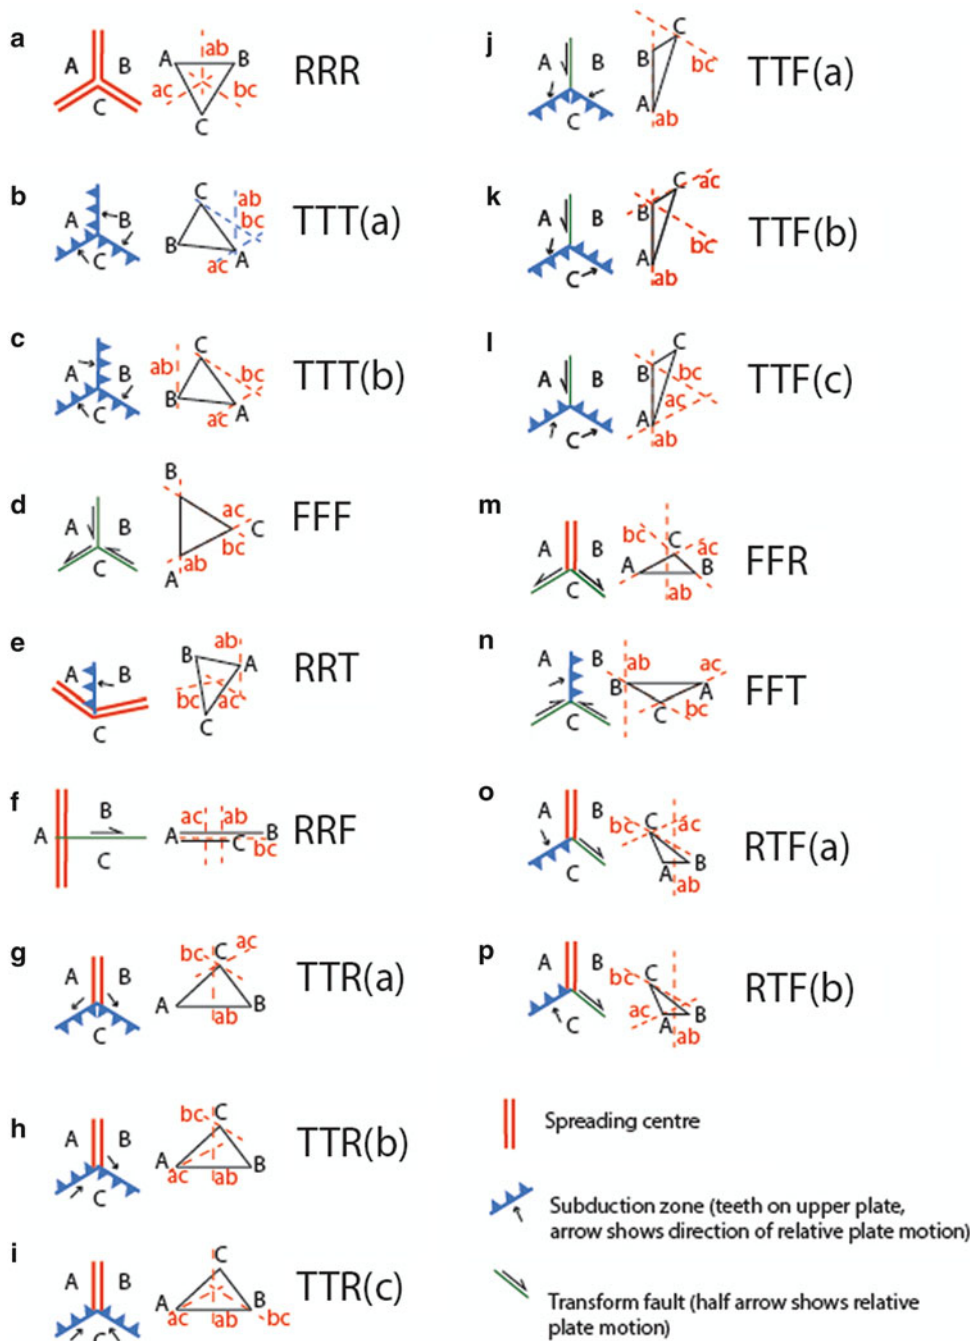
$$v_{\mathrm{rel}} = (\Omega_{\mathrm{A}} - \Omega_{\mathrm{B}}) \, \mathrm{X} r \qquad (2)$$

McKenzie and Parker (1974) pointed out that as only rel-
ative motion between plates can be observed with cer-
tainty, it is convenient to consider only relative angular
velocities given by:

$$_{\mathrm{A}}\omega_{\mathrm{B}} = \Omega_{\mathrm{A}} - \Omega_{\mathrm{B}} \qquad (3)$$

The piercing point at the surface of the sphere of $_{\mathrm{A}}\omega_{\mathrm{B}}$ is
known as the *pole of relative motion* between the plates
A and B. McKenzie and Parker (1967) and McKenzie
and Morgan (1969) pointed out that for a stable triple junc-
tion amidst plates A, B, and C, the following condition
must be satisfied:

$$_{\mathrm{A}}\omega_{\mathrm{B}} + {}_{\mathrm{B}}\omega_{\mathrm{C}} + {}_{\mathrm{C}}\omega_{\mathrm{A}} = 0 \qquad (4)$$

This equation allows one to determine the velocity along a
plate boundary at a triple junction where the velocities on
the other two boundaries are known. This can be of great
help in historical geology in reconstructing past plate
geometries.


Triple Junctions, Figure 1 The geometry and stability of all possible triple junctions according to McKenzie and Morgan (1969, redrawn from their Figure 3. (**a**) *RRR* (Ridge-Ridge-Ridge) junction: stable in all orientations, as long as the three arms are spread more than 180° (York's condition: York, 1973a). (**b**) *TTT* (Trench-Trench-Trench) junction: stable if *ab*, *ac* form a straight line or if *bc* is parallel with the slip vector *CA*. (**c**) Another *TTT* junction: stable if the complicated general condition for *ab*, *bc*, and *ac* to meet at a point is satisfied. (**d**) *FFF* (Fault-Fault-Fault) junction: always unstable. (**e**) *RRT* junction: for stability, *ab* must go through the centroid. (**f**) *RRF* junction: always unstable except where the two ridges make a right angle with one another (York, 1973b; see Figure 5c below). (**g**) *TTR* junction: stable if *ab* goes through *C* or if *ac*, *bc* form a straight line. (**h**) Another *TTR* junction: can be stable if the *ab* boundary can be orientated so as *ab* to go through the centroid. (**i**) Another *TTR* junction: stable if the angles between *ab* and *ac*, *bc*, respectively, are equal or if *ac*, *bc* form a straight line. (**j**) TTF junction: stable if *ac*, *bc* form a straight line or if *C* lies on *ab*. (**k**) Another *TTF* junction: stable if *bc*, *ab* form a straight line or if *ac* goes through *B*. (**l**) Another *TTF* junction: stable if *ab*, *ac* form a straight line or if *ab*, *bc* do so. (**m**) *FFR* junction: stable if *C* lies on *ab* or if *ac*, *bc* form a straight line. (**n**) *FFT* junction: stable if *C* lies on *ab* or if *ac*, *bc* form a straight line. (**o**) *RTF* junction: stable if *ab* goes through *C* or if *ac*, *bc* form a straight line. (**p**) Another *RTF* junction: stable if *ac*, *ab* cross on *bc*.
Triple Junctions, Figure 2 A simple visualization of how to compute relative velocities of three rigid objects with respect to one another. See text for explanation.

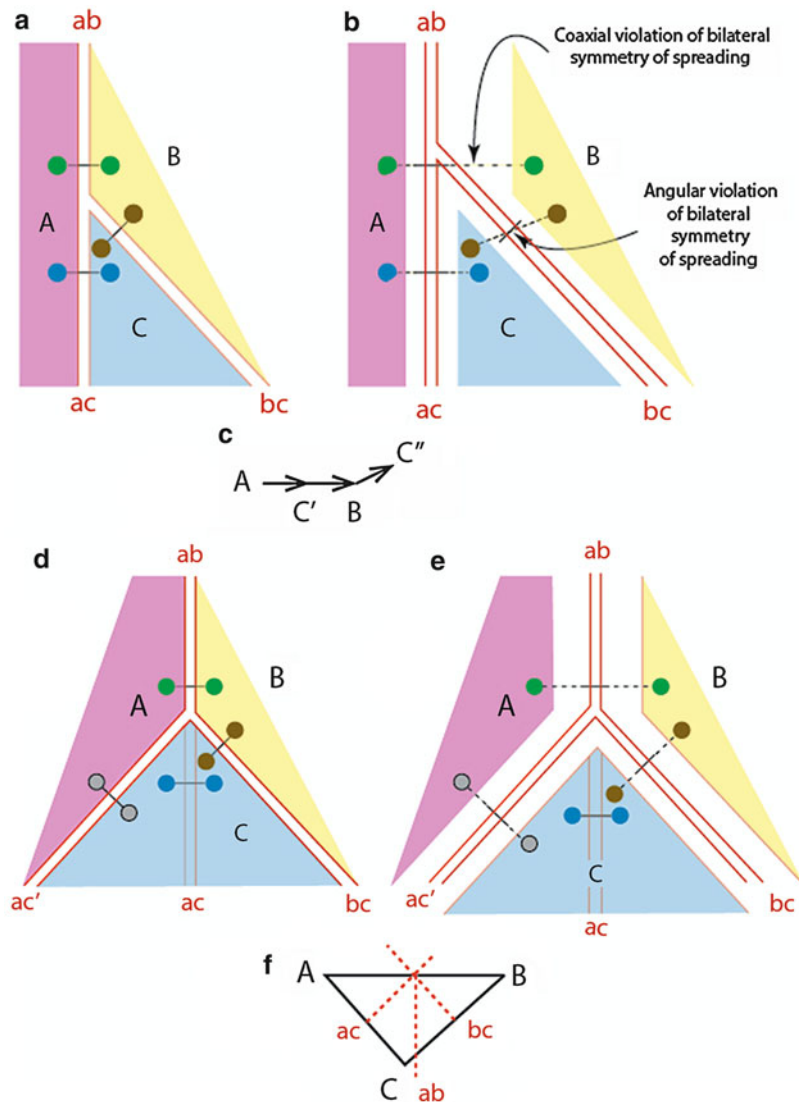
McKenzie and Morgan (1969) discussed the stability conditions of triple junctions using the *velocity space*. To do that, a triangle is formed by using the vectors of relative velocities of the plates meeting at the triple junction. Figure 2 illustrates how the velocity vectors are treated in drawing the necessary triangle: The problem is to determine the relative velocities of three rigid entities with respect to one another around a single point (Figure 2). Imagine a boat B leaving the shore of land L and speeding away along the vector LB on the surface of the sea (since both land and the sea are here assumed fixed with respect to the earth, we can use both for land and the sea the same label L). A man M begins walking along the shore along the vector LM at the instant the boat leaves the shore along the vector LB. What is the relative velocity of the man (M) with respect to the boat (B)? In other words, what is the orientation and the length of the vector MB?

To obtain that we must add the velocities of the man and the boat. However, here is a fine point: the boat moves with respect to land along the vector LB. The velocity of the man also with respect to the land is ML. But we need to fix our reference point *not* to the land but to the boat (or to the man) to obtain the required answer. So we keep M where he is with respect to the origin of the LB vector and move the land L. Hence we add not LB to LM but to LB to ML. But ML is only –LM. So our addition becomes: LB + (–LM) = BM. BM is the velocity of separation of B with respect to M. We could also say that MB is the separation velocity of M with respect to B. In all discussions on plate kinematics, it is of the utmost importance to make sure what reference frame is being adhered to.

To see whether a junction is stable, it is important to find a single point from the viewpoint of which the triple junction does not move (see also Cronin, 1992, but some of the triple junctions he lists simply cannot exist, so there is little point in listing them). Let us take the simple case of the three ridges with inter-ridge separation of 120° meeting

at a triple junction. This is the situation depicted in Figure 1a left side, and the corresponding velocity triangle is shown on the right side. To seek the singularity from the vantage point of which the triple junction does not move, consider that AB represents the relative velocity of the plate B with respect to A. So any point on B moves with respect to the ridge separating the plate A from plate B with a velocity of AB/2. This corresponds to the midpoint of the AB vector. If we now fix a reference frame to the perpendicular bisector of AB, this will be equivalent to hovering over the spreading ridge and moving with it with respect to the reference frames fixed to the plates it separates. If our reference frame is fixed to the bisector, a line, the frame can move up and down the line but not across it. Now if we do it for all the ridges, our bisectors meet at a single point J, called the centroid (McKenzie and Morgan, 1969). If the centroid of any velocity triangle around a triple junction is a point, then that triple junction must be stable, because there is a single point from the vantage point of which that triple junction does not change its shape.

Although McKenzie and Morgan (1969) believed that all orientations of a ridge-ridge-ridge (abbreviated RRR) triple junction are stable, York (1973a) showed that unless the spread of the ridges is greater than 180° around the triple junction, the RRR junctions would be unstable and illustrated this with the example shown in Figure 3. Figure 3a shows an RRR triple junction that is unstable (cf. Figure 3c), if spreading is assumed to be bilaterally symmetric about the ridge axes. Figure 3b shows that if the junction is allowed to evolve, the ridge AB must develop a strong coaxial asymmetry of spreading, i.e., it must accrete more oceanic lithosphere to one of its sides than to the other. Although coaxial asymmetry is known from active spreading centres, it is always very short lived, and all ridges maintain bilaterally symmetric spreading for long periods of time even if this means to jump into the faster-spreading side several times (e.g., Stein et al., 1977; Müller et al., 2008). York (1973a) pointed out that a geometry similar to the Figure 3c, d, illustrating *ridge abandonment*, probably was responsible for the now inactive ridges seen within the Nazca Plate in the southeastern Pacific Ocean. York (1973b; Figure 1) also showed that an RRF junction, which brings together two ridges making an angle of 90° between them and a transform fault, is also stable, thus increasing the number of the triple junction configurations that can be stable under certain specific conditions from 14 to 15.

After the establishment of the stability conditions of all the 16 possible types of triple junctions using velocity triangles, McKenzie and Parker (1974) asked the question whether a similar thing may be done for accelerations instead of velocities. In other words, whether acceleration triangles for triple junctions may be drawn to render useful information about the stability conditions of triple junctions. They pointed out that since, in general, the relative accelerations between plates will not be related to relative velocities, junctions that are stable in *v* space may be unstable in *dv/dt* space. Thus, unless specific conditions


Triple Junctions, Figure 3 (**a**) York's (1973a) unstable RRR junction. (**b**) The same junction after a finite amount of time has elapsed. Note the great amount of coaxial asymmetric spreading imposed on the spreading centre *ab*. (**c**) No velocity triangle can be closed. (**d**) The ridge *ac* is extinguished and a new ridge *ac'* has formed cutting across the former *plate A* and adding the part of it between the new ridge *ac'* and *ac* to *plate C*. (**e**) The new triple junction geometry is stable. The *coloured circles* are markers showing relative displacement between pairs of plates. (**f**) The velocity *triangle* in this case can be closed and indicates a stable triple junction. The symbolism as in Figure 1.

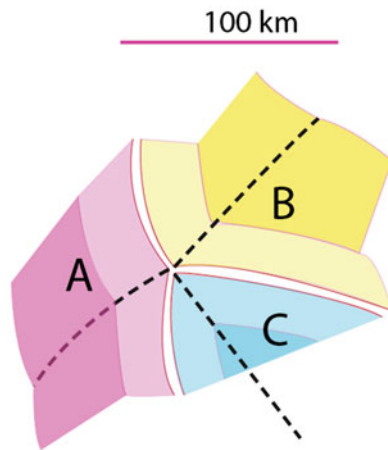
are imposed on $d\boldsymbol{\omega}/dt$, the changes in $\boldsymbol{v}$ space will cause a stable junction to become unstable.

One remarkable result of their study is that if all of the $d\boldsymbol{v}/dt \neq 0$, the paths of the triple junction with respect to the plates are all curved. They indicated that if $_A\boldsymbol{v}_T$ represents the relative motion between the triple junction T and plate A and if $d_A\boldsymbol{v}_T/dt$ is the corresponding acceleration, the important component of the latter is at right angles to $_A\boldsymbol{v}_T$ and McKenzie and Parker (1974) denote it as $(d_A\boldsymbol{v}_T/dt)N$. They point out that the component of $d_A\boldsymbol{v}_T/dt$ parallel with the ridge causes changes in the rate of spreading. The $(d_A\boldsymbol{v}_T/dt)N$ produces a curved path of

the triple junction T with respect to the plate A with curvature $\boldsymbol{\kappa}$ and radius of curvature $\boldsymbol{\rho}$ (Figure 4). The former is obtained by employing the following equation:

$$\boldsymbol{\kappa} = 1/\boldsymbol{\rho} = |\ (d_A\boldsymbol{v}_T/dt)N\ |\ /|_A\boldsymbol{v}_T|^2 \tag{5}$$

$\boldsymbol{\kappa}$ will change with time, unless $d_A\boldsymbol{v}_T/dt \times _A\boldsymbol{v}_T = 0$. One may use the curvature of the ridge axis to obtain the component of the acceleration normal to the vector velocity between the triple junction and the ridge. This is not dependent on whether the spreading is orthogonal to the ridge or not. McKenzie and Parker (1974) further noted that using maps such as the one shown in Figure 4, one

100 km


Triple Junctions, Figure 4 Map of an RRR triple junction among the plates *A*, *B*, and *C* in a plane tangent to the earth at the junction when all of the *dv*/*dt* ≠ 0. Note that in this case the three ridges curve. The symbolism as in Figure 1. The *black dashed line* is the trace of the triple junction on each plate.

could draw an acceleration triangle. All one needs to do is to trace the track of the triple junction T with respect to the three plates and measure the curvature of the ridges. Acton et al. (1988) interpreted such curved magnetic anomalies along the Galapagos Ridge between the Nazca and the Cocos plates as resulting from a change in the velocity (rate and/or direction) of the spreading along a ridge. Since in a rigid plate model, acceleration is needed to change velocity, they might have applied the ideas of McKenzie and Parker (1974), but they do not cite them. McKenzie and Parker (1974) themselves have used the curved anomalies of the Galapagos Ridge, but they were unable to fit the observations to their model because of the insufficiency of the precision of the data at the time. Data such as those presented by Acton et al. (1988) may be used to obtain the accelerations responsible for the changes in spreading velocities. In such situations, one can see how some stable triple junctions may be pushed into unstable geometries during finite plate evolution and might obtain an idea of the driving forces of the plates.

Triple junctions and ridge propagation

Ridge propagation has long been popular since the rise of plate tectonics, because continental splitting has been ascribed to various forms of it from centres of extension caused by diverse mechanisms (e.g., Burke and Dewey, 1973; Bhattacharji and Koide, 1975; McKenzie and Weiss, 1975; Courtillot, 1982), but even before, much had been written on various forms of rift propagation in multifarious contexts. Also, in oceanic areas, in certain cases, one of the two spreading centres joined by a transform fault propagates across the transform fault coevally with the recession of the other, creating complex magnetic

anomaly patterns on the ocean floor (Hey, 1977; Atwater, 1981; McKenzie, 1982). Such propagation processes have various causes:

1. In continents, three-armed rift stars (called rrr junctions formed of intracontinental rifts as opposed to RRR junctions formed of spreading centers: see Burke and Dewey, 1973; Figure 2; Şengör, 1995, 2001; Şengör and Natal'in, 2001) are sometimes connected to one another by the propagation one or more of their arms, and they thus split a continent. Şengör (1995) and Şengör and Natal'in (2001) discussed diverse examples of such connections. The nature of the mechanism of propagation may be gravitational (Şengör, 2001) or any other cause that stretches the lithosphere (Şengör, 1995, 2001; Şengör and Natal'in, 2001) or fluid injection from below (Bhattacharji and Koide, 1975; Casey et al., 2006). Courtillot (1982) discussed a possible geometry of such propagating tips in continental and oceanic areas; although he called the process he described *propagation*, McKenzie (1986) thought *localization* would be a more appropriate appellation. It is however clear that McKenzie's localization is what makes propagation possible in Courtillot's scheme.

2. In the oceans, triple junction evolution leads to rift propagation or *recession* that some authors also term *extinction* or *death*. Recession leads to the formation of *fossil spreading centres* (e.g., Hey, 1977). Zonenshain et al. (1980, esp. Figure 6) first had the idea of placing the velocity triangle directly on top of the geographical triple junction and showed how this geometric construction allows to see at a glance which ridges must propagate and which must recede.

Patriat and Courtillot (1984) followed up Zonenshain et al.'s (1980) idea and pointed out that if the geographical triple junction lies within its own velocity triangle, then all ridges meeting at it propagate toward the interior of the velocity triangle. Figure 5 illustrates the simplest case of an RRR junction with legs spread at 120°. Figure 5a shows the triple junction amidst plates A, B, and C and its velocity triangle as drawn by McKenzie and Morgan (1969; see Figure 1). Figure 5a′ is how Patriat and Courtillot draw it showing that all three ridges, ab, ac, and bc, must propagate. In Figure 5b, the triple junction among the plates A, B, and C is a right triangle. In this case, the ridges *ac* and *bc* propagate, but the ridge ab neither propagates nor recedes. This is an important property of right velocity triangles among three spreading centres. Figure 5c shows that even if we change the triple junction into an RRF junction, it remains stable and again the two previous ridges lengthen. However, in this case the transform fault connecting the ridge *ab* to the triple junction also lengthens without destroying the stability of the triple junction. In the FFR junction depicted in Figure 5d, both ridges *ac* and *ab* neither shorten nor lengthen, but the bc ridge propagates. Although the triple junction shown in Figure 5d has the same isosceles velocity triangle as the triple junction shown in Figure 5e, in 5e all ridges
Triple Junctions, Figure 5 (**a**) An ordinary RRR junction and its equilateral velocity triangle. (**a′**) This figure, after Patriat and Courtillot (1984), shows that in this geometry, all ridges must propagate. The white areas in the ridges show the sections that formed as a result of propagation. (**b**) Another RRR junction, this time with a right velocity triangle. Note that in this case only, two ridges propagate and one does not change its length. (**c**) If the third ridge in Figure 5b is connected to the junction by a transform fault, again two ridges propagate as before, but in this case, the transform fault becomes longer. (**d**) In this configuration of an FFR junction, only the *bc* ridge propagates. The two transform faults also become longer. (**e**) The same isosceles velocity triangle with three ridges meeting at its centroid. In this case, all three ridges propagate similar to the case in Figure 5a′. (**f**) The same situation as in Figure 5d but with an obtuse isosceles velocity triangle. (**f**) The same velocity triangle as in Figure 5f, but here the RRR junction lies outside it. As a consequence, the ridges *ac* and *bc* propagate while *bc* recedes. Symbolism as in Figure 1.

propagate as already discussed in the case of the junction depicted in Figure 5a′, where the special case of an equilateral velocity triangle is shown.

In the RRR junction shown in Figure 5f, only the *bc* ridge propagates. Here the triple junction is coincident with the top of its obtuse isosceles velocity triangle. In Figure 5g, the triangle lies outside the velocity triangle. Here ridges *ac* and *bc* propagate, but the ridge *bc* recedes. Where a triple junction involving only ridges and transform faults lies outside its velocity triangle, at least one ridge recedes.

Patriat and Courtillot (1984) discussed some tectonic effects of the propagation and recession of ridges and lengthening and shortening of transform faults around triple junctions. As transform faults lengthen, they thought that friction between plates will increase, and the evolution of the triple junction will consume more energy. This is not necessarily true, because as they lengthen, the transform fault walls also cool and much lubricating material (serpentinite diapirs, magma) invades the thus opened space facilitating slippage (see "Transform Faults"). They also pointed out that triple junction evolution would
Triple Junctions, Figure 6 (**a**) A TTT junction with its velocity triangle. (**b**) The same triple junction after a finite amount of time has elapsed. Note that the slabs interfere with one another at depth, if they are assumed to be flat, which is unrealistic. (**c**) The *dotted circle* shows the area of slab conflict. (**d**) The *dotted ellipse* shows the volume in which a conical fold must be formed by the slab attached to *plate C*. The slab of *plate B* accommodates itself into that slab. (**e**) 3-D view of the conical fold of the slab of *plate C* and how the slab *of plate B* descends through the opening created by the conical fold of the slab of *plate C*.

influence magma chamber connectivity, which must be true. Some triple junctions generate much magma forming oceanic plateaux atop them (e.g., the Mid-Pacific Mountains).

Triple junctions and the third spatial dimension

Most studies on triple junctions have dealt with their 2-D aspects plus other dimensions like velocity and acceleration spaces. Additional complications in tectonics arise when the third spatial dimension is considered. Figure 6a shows a TTT triple junction amidst plates A, B, and C. The junction connects the subduction zones *ab*, *ac*, and *bc*. Figure 6a shows the initial condition and Figure 6b the situation after the lapse of a finite interval of time. Note that the two subduction zone slabs *ac* and *bc* are attached to the same plate C (Figure 6d). As they bend down to descend into the mantle, a space problem will arise at depth. Moreover, around the triple junction, the descent of the plate B will cause further interference problems among the slabs of the subduction zones *ab*, *ac*, and *bc* (Figure 6c). Interestingly, in this case, the slabs of the plate C will form a conical fold with an axis pointing upward to the triple juction (Figure 6d). The slab of the plate B would have to accomodate itself into the core of this fold as shown in Figure 6e so as not to cause a slab conflict at depth. This geometry might have important implications for the magmatism and the metamorphism of the slab

of the plate B, because that slab may receive volatiles liberated from the slab of the subduction zone *bc* that would help further melt generation. The extensive Neogene to Quaternary volcanics of the Fossa Magna in Japan may well be a result of such a situation. Such significant tectonic effects are to be expected in all triple junctions where more than one subduction zone is involved.

Triple junctions and lithospheric "holes"

When triple junctions occur in non-subductable lithospheric material, they lead to compatibility problems and opening of holes in the lithosphere that express themselves geologically as complex rift basins, which Şengör et al. (1985) called "incompatibility basins."

Consider the triple junction among plates A, B, and C depicted in Figure 7a, which is assumed to be placed entirely in non-subductable continental crust. Its features actually closely correspond to the Karlıova triple junction in eastern Turkey (Şengör, 1979; Şengör et al., 1985), and that is why such triple junctions are herein termed *Karlıova-type*. The boundaries between C and the other two plates are strike-slip faults in Figure 6a. The boundary between A and B is a convergent but a nonconsuming type. Here convergence is turned into convergent strain as depicted by the deformation of the circle placed on it in Figure 7a that turns into an ellipse in Figure 7b.
Triple Junctions, Figure 7 A Karlıova-type triple junction. The *coloured circles* are markers showing displacement across plate boundaries.

Triple Junctions, Figure 8 A Maraş-type triple junction. The *coloured circles* are markers showing displacement across plate boundaries. The *double-headed arrows* show cords connecting some markers to indicate shortening or extension between the markers thus connected.

In Figure 7b, the plate boundary zone between A and B is shortened by 50 %, while plate C remains entirely rigid. Note that a boomerang-shaped hole opens behind the plate C as it is being expelled from the converging jaws of the plates A and B. Within this basin the extension direction changes from E to W in the center of the basin to progressively more northwesterly and southwesterly directions as shown by small arrows in Figure 7b. Correspondingly, the normal faults generated within the basin are expected to have curved map views displaying complex strains.

Another type of incompatibity basin arises at what is herein called the *Maraş-type* triple junctions, after the most prominent and best-studied example around the town of Kahramanmaraş in southern Turkey. Such a junction is shown in Figure 8.

Figure 8a shows the initial situation, where at least plates A and B consist of non-subductable continental material. B and C converge toward A, and this convergence is accommodated by left-lateral strike-slip faulting between A and B. C converges at a slower rate than B, and as a consequence, a hole opens up north of it. In the real case of the Kahramanmaraş triple junction, this basin is the Hatay-Adana-Cilicia basin complex (Şengör et al., 1985). The basin is elongated ENE–WSW, but its direction of opening is almost E–W. By contrast, it shortens in a N–S direction. These directions naturally change as the basin evolves, but here we see all the complexities of a transtensional basin as elaborated by Dewey (2002).

Triple junctions in non-subductable material lead to very great complexities and complex geological histories, but space here fails to elaborate on all.

Conclusions

Triple junctions are critically important elements in the kinematics of plate tectonics. In real life, they give rise to a very complex geological history wherever they occur, where geological events may abruptly overprint each other. McKenzie and Morgan (1969) said that only stable triple junctions allow continuous plate evolution implying that in plate reconstructions, one should allow only such junctions. Dan McKenzie once said that drawing an unstable triple junction would be like drawing a pin on its head. It can only stay at that unstable position for an instant before falling onto the floor to assume a stable position. This is theoretically true, but not in practice. The triple junction among the Japan, the Nankai, and the Izu-Bonin trenches is an unstable FFF junction, but it has been there for the last 60 Ma at least, albeit with small adjustments to the plate velocities around it. Therefore, unstable triple junctions also have their justification in reconstruction of past tectonics of any given area if the data demand them.

However, any reconstruction that does not honour the kinematic and geological requirements of the triple junctions it gives rise to is wrong from the outset.

TSUNAMIS

Jose C. Borrero
eCoast Ltd., Marine Consulting and Research, Raglan, New Zealand

Definition

A *tsunami* (plural, tsunami or tsunamis) is a series of water waves caused by an impulsive disturbance to a body of water. Tsunamis are most commonly caused in the ocean through the deformation of the seafloor during an earthquake or as a result of a submarine landslide. Additional source mechanisms include volcanic eruptions, subaerial landslides, asteroids falling into a body of water, or meteorological forcing (also referred to as "meteo-tsunami"). The word tsunami is Japanese (Kanji: 津波) and translates literally to "harbor wave," due to the fact that this phenomenon was frequently observed in bays and harbors in Japan. Tsunamis are also referred to as "tidal waves" and "seismic sea waves."

Tsunami generation

Tsunamis can generally be categorized as "near field" or "far field" depending on where the majority of its effects occur. A far-field tsunami (also "tele-tsunami" or "trans-oceanic tsunami") is one which causes damage or serious effects at great distances from the source region while the effects of a near-field or "local" tsunami are constrained roughly to the tsunami source region. This term is somewhat ambiguous in that tsunamis with appreciable effects in the far field also produce significant effects in the near field and thus have both near- and far-field components.

Tectonically generated tsunami

Most destructive tsunamis have been caused by thrust earthquakes along subduction zones such as those existing around the Pacific Rim and the Sunda Arc south and west of Indonesia. Notable recent examples include the Pacific tsunamis of 1960 (Chile), 1964 (Alaska), and 2011 (Japan) and the 2004 Indian Ocean tsunami (north Sumatra). Another common tectonic source mechanism is that of the outer-rise earthquake characterized by normal faulting and subsequent large-scale subsidence in the oceanic tectonic plate seaward of a subduction zone trench; the 1933 Sanriku tsunami and 2009 Samoa (South Pacific) tsunami are examples of this type of generation mechanism. Tsunamis have also been caused through strike-slip faulting where one side of the fault is displaced laterally relative to the other, and there is very little vertical deformation of the seabed. However, these types of tsunami may also be associated with additional source mechanisms such as submarine slumps or landslides which contribute to the overall strength of the tsunami and its impact.

Among the subduction zone thrust-type earthquakes exists a special class of events where the resulting tsunami is much larger than would be expected based on the earthquake magnitude alone. Such events have been termed "tsunami earthquakes" (Kanamori, 1972) and are generally characterized by earthquake rupture occurring on the shallower portion of the subduction zone plate interface, a slower rupture velocity and rate of seismic energy release, and a larger sea floor deformation relative to other earthquakes of similar magnitude. Each of these components contributes to an overall larger tsunami, particularly in the near field. Examples of this type of event include Sanriku, Japan, 1896; Nicaragua, 1992; East Java, Indonesia, 1994; West Java Indonesia, 2005; and the Mentawai Islands, Indonesia, 2010.

Landslide-generated tsunami

Tsunami can also be generated by slope failures – commonly referred to as landslides, slumps, slips, or debris flows. Tsunamigenic slope failures can occur either above or below water (i.e., "subaerial" or "submarine"). Tsunami waves are generated as water is displaced; in the case of a subaerial event, as the material crashes on to the water surface or when submarine, as water above the slide is pulled downward in to the void left as the slide material slides downslope. Tsunamigenesis by slope failure is an active and ongoing area of scientific research. The key parameters controlling the height of the initial wave are the slope of the sea bed, the amount of material displaced, the thickness of the slide, the depth at which the slide occurs, the speed at which it fails, and the distance over which the slide material translates (Bardet et al., 2003). Also critical to the study of landslide-generated tsunami is the ability to define the recurrence intervals of such events. This is particularly true for the large-scale flank collapse of volcanic islands, a rare but potentially catastrophic tsunami generator (Ward, 2002).

Perhaps the most famous and extreme example of a landslide-generated tsunami is that which occurred in Lituya Bay in southeastern Alaska on July 9, 1958. In this event, an on-land earthquake along the Fairweather Fault induced a subaerial landslide that displaced some 30 million cubic meters of material which collapsed into the head of Lituya Bay displacing a similar amount of water. The subsequent wave reached a height of 524 m above sea-level proximal to the landslide with wave heights tapering to ~10 m at the mouth of the bay (Miller, 1960). A submarine landslide is believed to be the primary cause of the 1998 Papua New Guinea tsunami which killed more than 2100 people (Synolakis et al., 2002).

Volcanic and other source mechanisms

Tsunamis can occur as the result of a volcanic eruption if the eruptions causes a caldera collapse and results in the displacement of a large volume of water. Additionally, volcanic eruptions and associated earthquakes can produce landslides or other subaerial mass movements which then fall into a body of water causing a wave. The 1883 eruption of Krakatoa in the Sunda Strait between the Islands of Sumatra and Java is the most significant contemporary example of this phenomenon (Winchester, 2005).

Other causes of tsunami or tsunami-like waves include meteorological forcing, i.e., "meteo-tsunami," most commonly through the translation of an area of low atmospheric pressure across a body of water. Since low atmospheric pressure causes a displacement of the water surface, if the translation speed of the pressure anomaly matches the local phase speed of the induced water wave, resonant coupling results in an exponential increase in the water wave height (see Dean and Dalrymple, 1991, p. xx). An example of this effect includes the tsunami-like wave that hit Daytona Beach, Florida, on the night of July 3, 1992 (Sallenger et al., 1995). A final (perhaps literally!) tsunami generation mechanism is that caused by an asteroid impact upon an ocean basin. While no such event is known to have occurred in human history, attempts have been made to quantify the uncertainty of such an occurrence (Chapman and Morrison 1994) and the size of the waves it might generate (Ward and Asphaug, 2000).
Tsunamis, Figure 1 Definition sketch for tsunami inundation and run-up.

Tsunami propagation, inundation, and run-up

Due to the fact that the wavelength (the distance between successive peaks in a series of waves) of most tectonically generated tsunami is usually much greater than the average depth of the ocean basins, they propagate as shallow water waves. An important consequence of this is that the speed of propagation is governed only by the depth of the water through the relationship:

$$c = (gd)^{1/2}$$

where c is the wave speed, g the acceleration due to gravity ($9.8 \ m/s^2$), and d the depth of the water. Taking d as 5,000 m (the average depth of an oceanic basin) yields a tsunami propagation speed of 221 m/s (797 km/h, 495 mi/h). This simple calculation gives rise to the popular maxim that "tsunamis travel at the same speed as a jet airliner." However, as the water depth decreases, so too does the propagation speed, and as a tsunami wave front approaches dry land, it has slowed down considerably relative to its propagation speed in the deep ocean.

It is this slowing of the wave front in shallow water that ultimately leads to the destructive inundation of tsunami waves. Due to their very long wavelengths, the speed of the leading edge of a tsunami wave will approach zero as following sections of the wave are still traveling at full speed. This results in the "train wreck" effect where the advancing wave piles up behind the slower moving wave front. Due to conservation of mass, the water contained in the wave train must increase in height ultimately flooding a coastal area. Depending on the specifics of the tsunami itself and the receiving environment, this flooding can manifest as a rapidly rising water level, similar to a tide (hence the oft-misused moniker "tidal wave"), or it can result in violently breaking waves and destructive high-speed inundation. The terms for tsunami inundation and run-up are defined in Figure 1.

Recent advances in tsunami science

Since the early 1990s there have been significant advances in many aspects of tsunami science and hazard mitigation. This is partially attributable to two tsunamis occurring in 1992. The first, caused by the April 25 Cape Mendocino earthquake at the southern end of the Cascadia subduction zone (CSZ) in Northern California, generated only a small, non-damaging tsunami (~1 m) that affected the coast immediately after. This event was important in that it served as a reminder of the potential for locally generated, near-field tsunamis occurring along the US West Coast and as a reminder of the seismicity of the CSZ, recently identified as a source of very large earthquakes and subsequent tsunamis (Atwater, 1987). This was followed on September 2, 1992 by a M ~7.2 earthquake off the Pacific Coast of Nicaragua. Although the earthquake was relatively small (roughly the same surface wave magnitude of the Cape Mendocino event), it produced a highly localized tsunami with wave heights of up to ~10 m and killed more than 100 people. It was following the Nicaragua tsunami that the modern era of systematic post-tsunami reconnaissance surveys began. This trend has continued since then and has led to a more nuanced and complete understanding of tsunami effects in both the near and far field (Synolakis and Okal, 2005). Around the same time, significant advances in computer hardware made it possible for the first time to begin to accurately simulate the details of tsunami propagation and inundation, and the mid-1990s saw the development of several numerical models designed specifically for this task. In the USA, efforts toward tsunami hazard mitigation also increased in this time frame. In 1997 the US Congress created the National Tsunami Hazard Mitigation Program (NTHMP) which directed the National Oceanic and Atmospheric Administration (NOAA) to develop and lead a program aimed at improving tsunami preparedness in the USA through hazard assessment, warning guidance, and mitigation (Bernard, 1998).

Tsunami deposits and paleo-tsunami studies

The study of tsunami sedimentology has advanced considerably in the past 25 years. Since Atwater's (1987) association between the depositional sand layers on the Pacific Coast of Washington State and the occurrence of great earthquakes and associated tsunamis, more and more researchers have integrated sedimentological analyses into post-tsunami field survey efforts. The resulting database has expanded the understanding of the depositional mechanisms responsible for tsunami deposits and assisted in the identification of tsunami deposits in other parts of the world. Recognizing and identifying tsunami deposits is an important part of paleo-seismological studies since

deposits can be used to determine the magnitude and extent of prehistoric tsunamis or to verify the occurrence of such an event. In the early 2000s deposits resulting from an earthquake and tsunami in 869 AD were identified on the Sendai plain in Japan (Minoura et al., 2001) and suggested that this area was susceptible to large-scale tsunami inundation. This unfortunate reality was confirmed 10 years later as the 2011 Tohoku earthquake created a tsunami, which inundated the same area.

Tsunami in ports and harbors

The tsunamis of 2004 (Sumatra), 2010 (Chile), and 2011 (Japan) affected ports and maritime infrastructure throughout the Indian and Pacific Oceans. In the 40+ years since the last major transoceanic tsunami (the 1960 Chile and 1964 Alaska events), there has been a significant increase in shipping traffic, commerce, and related port development which has drastically increased the risk from tsunami exposure to the maritime sector. The tsunami events mentioned above were notable in that the damaging effects of tsunami-induced currents and the extended duration of tsunami activity were widely reported and quantified in terms of their effect on ports (Lynett et al., 2012; Borrero and Greer, 2012). These events also illustrated how tsunami-induced currents can be damaging and economically disruptive without causing any overland flooding or inundation. This fact suggests that previous hazard mitigation efforts which focused primarily on inundation extent are not sufficient for application to ports and harbors and the activities conducted therein.

Tsunami warning systems

Tsunami warning systems (TWS) are designed to detect tsunamis and issue appropriate warnings. The current TWS are administered through a system of intergovernmental agreements and treaties defining areas of responsibility and operational protocols. In the Pacific Ocean, the Pacific Tsunami Warning Center (PTWC), located in Hawaii, monitors global seismic activity and provides warning for the nations of the Pacific Rim. After the 2004 Indian Ocean tsunami, additional warning systems have been established for the Indian Ocean. Tsunami warning systems are under development in the North Atlantic/Mediterranean and Caribbean Seas.

Existing TWS are comprised of two components: (1) networks of sensors for detecting earthquakes and the tsunami itself and (2) communications infrastructure for the dissemination of the warning messages. Earthquakes detected on seismometers located around the world are used to initiate tsunami watches and warnings, while ocean-based sensors such as the DART® (Deep-ocean Assessment and Reporting of Tsunamis) buoys can directly verify the existence and size of a tsunami (Bernard and Meinig, 2011). The DART tsunameters were first deployed in 1995 and only became operational since the early 2000s. Prior to this, tsunami warnings were based only on the characteristics of earthquakes and monitoring coastal tide gauge networks. Warning

messages are disseminated to the public through a variety of communications channels including radio, fax, telex, SMS, and e-mail. Dedicated communication links have been established for first responders and emergency managers.

Summary

While significant advances have been made in tsunami science and hazard mitigation over recent decades, the work is never done. Tsunamis are not as rare an occurrence globally as we may think; in the past 20 years, there have been at least 29 tsunami events responsible for more than 300,000 deaths worldwide (Table 1). However, on regional or local scales, tsunamis tend to occur only once a generation or less. Furthermore, as Satake and Atwater (2007) recognized, the "great" tsunamis in human history do not conform to expected geological rules of thumb. This unfortunate reality was illustrated again in 2011 with the great Tohoku earthquake and tsunami, which, like the 2004 Indian Ocean event, was not expected along that plate boundary based on historical precedent. If we accept for a moment that hard science might not provide the answers we need in terms of predicting future events, perhaps for the tsunami problem we should not underestimate

the importance of enhancing and expanding efforts in public education to maintain awareness of tsunami hazards over generational timescales.

Turbidity-current deposit; turbidity-flow deposit (Bouma sequence)

Definition

A turbidite is a sedimentary bed deposited by a turbidity current or turbidity flow. It is composed of layered particles that grade upward from coarser to finer sizes and ideally display a (complete or incomplete) Bouma sequence (Bouma, 1962). Mud-dominated turbidites (fine-grained turbidites) may show the sequence detailed by Stow and Shanmugam (1980). The etymology of the term "turbidity current" relates to a turbid flow, which means a flow containing suspended particles.

In a much looser sense, the term turbidite is also used for deposits of other types of density flows that develop a non-cohesive (frictional/granular) behavior. These include deposits of hyperconcentrated flows and concentrated flows displaying divisions of the Lowe sequence (Lowe, 1982). Sensu stricto, a turbidite is the deposit resulting from a turbulent flow.

Deep-sea turbidite systems along ocean margins and, in particular, submarine fans in front of major river mouths host thick successions of turbidites as a major integral component. In addition, individual turbidites cover abyssal plains beyond the limits of turbidite systems or may occur in more shallow marine basins and even continental lakes, wherever gravity processes transport suspended sediment sustained mainly by fluid turbulence (Middleton and Hampton, 1973).

Turbidity currents and related density flows

There are various perspectives appropriate to classify submarine gravity processes as summarized by Mulder (2011). The predominant particle-support mechanism is the most commonly used criterion to classify gravity processes in present-day deep-sea environments (Lowe, 1979; Middleton and Hampton, 1973; Nardin et al., 1979). Four types of particle-support mechanism are usually distinguished: matrix cohesive strength, grain-to-grain collisional interactions, fluid support (excess pore fluid pressure, upward escape of pore water), and turbulent suspension.

The flow processes are best classified employing the rheology (mechanical behavior) of the density flow (Dott, 1963; Mulder and Cochonat, 1996; Shanmugam, 2000). This type of classification is also useful to choose an appropriate numerical model.

Classification relying on flow concentration includes characteristics that are derived from the observation of

deposits (Mulder and Alexander, 2001). It principally takes into account the flow transformation with space and time and its progressive dilution. Because of fluid entrainment, flows may transform from hyperconcentrated to concentrated flow and finally to a turbidity flow.

Finally, much of our knowledge of turbidity-current deposition is inferred from extensive studies of their deposits (Mutti and Ricci Lucchi, 1975; Pickering et al., 1989). This approach is extensively used in research on ancient environments and in the oil industry. It is based on the classification of sedimentary facies and its change along the pathway of the flow.

A turbidity current represents a "particulate density flow." Widely accepted definitions of turbidity currents (Lowe, 1982; Middleton and Hampton, 1973; Sanders, 1965) state that they are sediment gravity flows in which the sediment is supported mainly by the upward component of fluid turbulence. Within such turbulent flows, additional particle-support mechanisms may act near the bed (turbidity current sensu lato). Mulder and Alexander (2001) used the Bagnold limit for full turbulent particle support as a threshold value to define turbidity currents sensu stricto (9 % sediment concentration by volume; Bagnold, 1962).

Based on flow duration and uniformity (Lüthi, 1980), Mulder and Alexander (2001) differentiate between (1) instantaneous surges (lasting over a period of hours to days), (2) longer-duration surge-like flows, and (3) quasi-steady currents (persisting over a period of weeks to months). The distinction between continuously moving currents and shorter-duration flows is important for understanding the nature of its deposits.

Surges are very short-lived flow events that have the form of a traveling, isolated flow head. Surge-like flows are also short lived but comprise a short flow body following the head. Probably, such turbidity flows most often result from flow differentiation through dilution (water entrainment), erosion, and acceleration from a density-flow type with higher sediment concentration (e.g., debris flows, concentrated density flows) created by failures on continental slopes and canyon walls. Quasi-steady turbidity currents typically form where a river discharges into a basin with the bulk density of the effluent (sediment and water) being greater than that of the receiving ambient water, and thus flow continues from the river onto the floor of the receiving shelf and into the deep sea (Mulder and Syvitski, 1995). Such (suspended-load) hyperpycnal turbidity currents are termed quasi-steady, as the flow is supplied by prolonged river flow. These flood-related flows frequently occur in rapidly subsiding basins where steep slopes are present (Mutti et al., 1996).

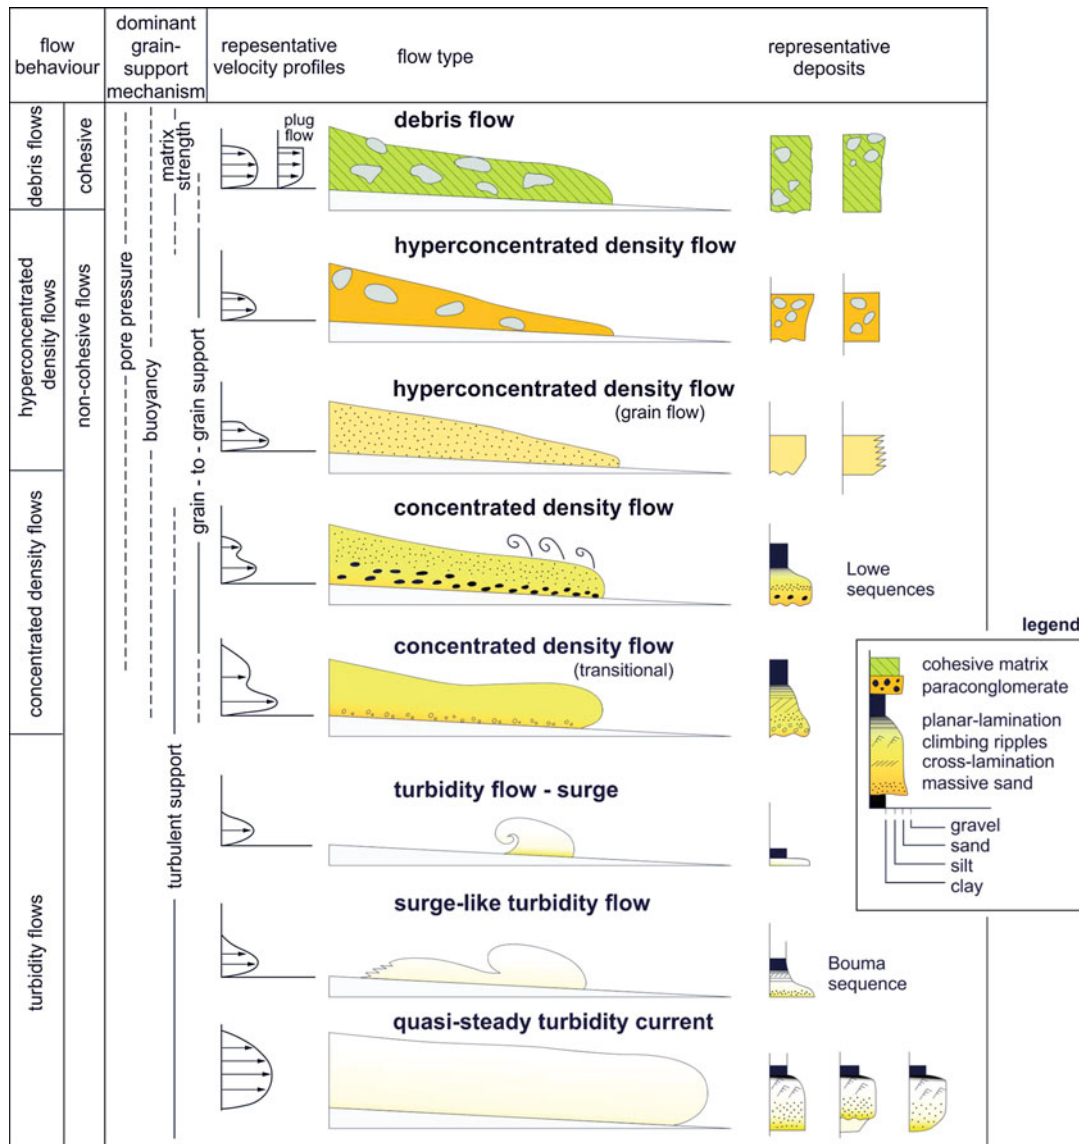
The flow steadiness controls the organization of the resulting deposits (Kneller and Branney, 1995). A surge-like turbidity flow tends to produce classical Bouma sequences, whose detailed characteristics at any one site depend on factors such as flow size, sediment type, and proximity to source. In contrast, a quasi-steady turbidity current, generated by hyperpycnal river effluent, can deposit a negatively graded division capped by positively graded divisions (because of waxing and waning conditions, respectively) and may also include a thick division of uniform character (resulting from prolonged periods of near-steady conditions (Kneller and Branney, 1995).

Any gravity flow may progressively change its character both with distance from the source of the flow and with time at any one point (Fisher, 1983; Shanmugam, 2000). Typically, a slump-generated hyperconcentrated density flow or debris flow is transformed along the transport path into concentrated density flow and finally into turbulent flow. These changed are controlled by parameters related to the flow behavior (internal parameters) such as the rate of fluid entrainment and fine-particle elutriation and by parameters related to the depositional environment such as gradient of the continental slope, lateral confinement by channel levees, and bed roughness.

Flow transformation from a homogeneous sediment failure generates rapidly stratified flows with a strong vertical velocity gradient. During most of its pathway, such a gravity flow remains bipartite, in which the basal part is hyperconcentrated with a laminar regime (or concentrated) and the upper part is more dilute where turbulence progressively develops (Sanders, 1965). A fining-upward vertical grain-size distribution progressively forms only in the most diluted uppermost part of the flow, while the basal part stays ungraded or displays a coarsening-upward grain-size distribution. Successive sediment deposition by such a bipartite flow typically produces a Lowe sequence or parts of it (Lowe, 1982; Figure 1).

Deep-sea turbidite systems

Turbidites are the most common and archetypal deposits forming deep-marine clastic systems at the base of a slope along continental margins – together with related gravity-flow deposits and hemipelagic and pelagic sediments. Reading and Richards (1994) provided a "matrix-shaped" environmental classification of such turbidite systems based essentially on the feeder system and grain size. The nature of the supply system (point-source submarine fan, multiple-source ramp, or linear-source slope apron) regulates the feeder channel stability, the organization of the depositional sequences, and the length/width ratio of the depositional system. Grain size and volume of the sediment supplied (mud rich, mud/sand rich, sand rich, or gravel rich) influence on the slope gradient, the persistence and frequency of flows, the pattern of morphological elements, and the tendency for channels to migrate. Altogether, 12 classes are recognized in depositional systems of deepwater basin margins (Reading and Richards, 1994). The character of these systems reflects a complex interplay between a range of autocyclic and allocyclic controls including sea-level fluctuations, basinal tectonics, and the rate, type, and nature of sediment supply.

Mutti (1985) proposed the efficiency concept, to differentiate between low-efficiency and high-efficiency fan


Turbidites, Figure 1 Diagram illustrating the physical character of subaqueous sedimentary density flows and their deposits (modified from Mulder and Alexander, 2001). Colors indicate sediment composition: *green,* diamictic sediment composition with high proportions of cohesive material (mud); *orange,* sediments with low amounts of cohesive particles; *pastel orange,* predominantly sand-sized sediment composition; *yellow to light yellow,* predominantly sand- to silt-sized sediment composition, displaying vertical trends in grain size and sorting during flow (including variable amounts of cohesive particles) and within the deposit.

systems. High-efficiency fan systems (mud-rich systems) are those where gravity flows are capable of transporting sand over long distances. Low-efficiency fan systems (sand-rich systems), in contrast, are those where gravity flows are not capable of transporting sand over long distances.

Architectural elements of deep-sea turbidite systems

Turbidite systems are best described and interpreted in terms of its architectural elements (Miall, 1985; Pickering et al., 1995; Stow and Mayall, 2000). Firstly defined to describe river systems, architectural elements are the elementary component parts of clastic depositional system which can be delineated by a set of hierarchically grouped bounding surfaces and are classified by its facies (sedimentary, acoustic, and seismic, respectively) and its architectural geometry (3D geometry and orientation). Once these architectural elements are identified, their character and interrelation allow the interpretation of sedimentary processes that formed them. It may help unravel complex depositional histories and understand the growth stages within turbidite systems (Clark and Pickering, 1996).
Turbidites, Figure 2 Turbidite beds of the Carboniferous age at Crackington Haven, Cornwall, United Kingdom. (**a**) Individual beds have sharp basal contacts, are tabular, and can be traced for long distances. Note that the succession is tectonically overturned. Younging direction is to the lower right. (**b**) A complete Bouma sequence is preserved within some of the positively graded sand-mud couplets.

Architectural elements are commonly termed the large-scale building blocks of a "do-it-yourself" depositional system. Both erosional and depositional processes control their formation. Architectural elements of turbidite system typically include canyons, channels and gullies, channel levees and overbank deposits, and various types of lobes, CLTZ (channel-levee transition zone; Wynn et al., 2002), mass-transport complexes, or erosional slide and slump scours (see Mulder, 2011; Stow and Mayall, 2000).

The concept of (architectural) elements in turbidite systems was introduced by Mutti and Normark (1987). These authors established a spatial and temporal hierarchy of five nested orders (turbidite complex, turbidite system, turbidite stage, turbidite substage, and turbidite bed) that allowed to connect between observations at ancient systems in outcrop scale (analysis of sedimentary facies, facies assemblages, and high-resolution stratigraphic correlation) and observations at recent systems by means of geophysical investigations (seismic and acoustic data).

Most turbidite systems in modern oceans are point-source submarine fans fed by a major delta and controlled by mud-dominated supply (Reading and Richards, 1994) although during a sea-level highstand, a substantial number of turbidite systems are fed by coastal drift. Their range extends from 250 km for the Astoria fan, through larger ones like the Mississippi fan (540 km), the Zaire (>800 km), and the Indus fan (1,500 km), to 2800 km for the giant Bengal fan. These turbidite systems display a similar organization into three parts: (1) a canyon, (2) an erosional and then depositional channel bordered with levees becoming progressively thinner and finer grained, and (3) a distal lobe. The Amazon turbidite fan, which has a length of more than 700 km, is a well-documented example (Flood and Damuth, 1987; Lopez, 2001; Figure 2).

Conclusions

The present review shows that turbidite systems cannot be described simply by a few number of parameters, and it is illusory to classify them according to a few number

end-member models. However, most of the data, ideas, and concepts come from a system fed by a siliciclastic source.

Morphology, geometry, architecture, nature of deposits, and transport sedimentary process depend on a large number of parameters acting at different space and time scale: margin and basin type, source of sediment (size and elevation of the drainage basin on continent, nature of its substratum, type of climate), mean slope of the submarine basin, subsidence rate, exhumation, or isostasy rate on the continent. At short time scale, other parameters may be of importance to understand the triggering and deposition of individual gravity-flow beds: structural context and neotectonics (earthquake frequency and magnitude, seepage of fluids), eustatic changes (potential sediment storage on the continent, shelf processes, local bathymetry changes), and climatic changes (erosion, dissolution process and CCD (carbonate compensation depth) variations, vegetal cover on the continent, flood rate and magnitude).

Some of these processes are cyclic (eustatic changes, climate); some are not (earthquakes). A global understanding necessitates a complete reconstruction of paleoenvironment and efficient tools to obtain a proper stratigraphic frame in deep-sea clastic systems.

UNDERWATER ARCHAEOLOGY

Geoffrey N. Bailey
Department of Archaeology, University of York,
York, UK

Synonyms

Continental shelf archaeology; maritime archaeology; nautical archaeology; shipwreck archaeology; submerged landscape archaeology

Definition

Underwater archaeology is the systematic recovery, study, and interpretation of the material remains of human activity that are now located below present sea-level on or under the seabed or below water in inland water bodies such as lakes and rivers.

Introduction

Underwater archaeology covers a wide range of objectives and interests, which fall into two main categories. The first, and the one most commonly recognized, is the study of shipwrecks and other remains of maritime activity, such as harbor walls and port facilities partially or wholly submerged by minor changes of relative sea-level. Here the focus is on recent millennia, from the expansion of seafaring activity in the Bronze Age as much as 5,000 years ago up to the modern era, and on maritime history, particularly the development of seafaring technology and its social and political consequences in terms of trade, mobility, and warfare. "Nautical archaeology" emphasizes the technological aspect of seafaring, and "maritime archaeology" encompasses the social and political dimension (Muckelroy, 1978; Gould, 2000).

The second category comprises the study of the terrestrial landscapes that were occupied by human populations during periods of lower sea-level associated with the glacial periods of the Pleistocene era and which have been drowned by sea-level rise since the last glacial maximum and is variously labeled as submerged landscape archaeology, submerged prehistory, or continental shelf archaeology (Benjamin et al., 2011; Evans et al., 2014). Since modern sea-level was finally established about 6,000 years ago, the focus here is on the earlier time ranges of prehistory; on the reconstruction of the now-submerged landscape – its topography, paleoenvironmental setting, and evidence of prehistoric settlement – and on the social, economic, demographic, and evolutionary consequences of changes in sea-level and paleogeography.

Both categories are concerned with submerged material; the main difference is that the former concentrates on maritime and nautical developments in recent millennia, the latter on the terrestrial features of a more or less extensive and now-submerged lowland landscape that existed during the major glacial episodes of the Pleistocene epoch.

Nevertheless, there is some overlap. For example, the history of seafaring and maritime activity certainly extends much further back than 6,000 years ago. This is demonstrated by evidence for sea crossings at least 12,000 years ago in the Mediterranean and even earlier in the Pacific, the earliest currently accepted example being human entry into Australia and New Guinea at about 50,000 years ago (Anderson et al., 2010). Actual finds of boats from these earlier periods are rare, but an increasing number of wooden dugout canoes have been recovered from prehistoric waterlogged or submerged sediments in Europe, the earliest dated at about 10,000 years (Crumlin-Pedersen, 2010; Cunliffe, 2010).

Conversely, coastal settlements and terrestrial landscape features younger than 6,000 years have been drowned in some parts of the world because of land submergence resulting from recent tectonic or isostatic movements.

Both types of underwater investigation also share a common interest in the technology and logistics of underwater exploration and in stressing the different types and qualities of information that can be obtained from underwater archaeological data compared to data on land. Both of course may involve the study of material on dry land, and practitioners in both fields usually emphasize the desirability of treating underwater work as an extension of archaeological research on land, the two types of activity differing only in their technical requirements.

Geoscientific research has an important role to play in all types of archaeological underwater research, since it is critical to understanding the different processes by which artifacts are variously buried or exposed by marine currents and movements of sediment and the likelihood of long-term preservation or decay. In addition, the exploration of submerged landscapes, and the improved understanding of relative sea-level change that can come from combined archaeological and geological research, opens up areas of mutual scientific interest and collaboration between marine geoscience and archaeology, and this is the main emphasis in what follows.

History

Technological developments have been a key factor. The invention of the aqua lung or SCUBA (Self-Contained Underwater Breathing Apparatus) after the Second World War opened up an era of underwater exploration for thousands of individuals and enthusiasts, and systematic exploration of historical shipwrecks and submerged harbor installations soon followed from the 1950s onwards with the work of pioneers such as George Bass, Honor Frost, and Nicholas Flemming. Military and industrial operations as well as archaeological and scientific questions have stimulated many new technologies, resulting in a modern array of vessels, sonar devices, underwater cameras and vehicles, and technical diving with mixed gases (Bass 1966; Blot, 1996; Delgado, 1998; Ruppé and Barstad, 2002).

Submerged forests with prehistoric archaeological finds were known about in the nineteenth century (Dawkins, 1870), and geologists studying sea-level change in the 1960s recognized the potential archaeological importance of the continental shelf (Emery and Edwards, 1966). Archaeological interest, however, remained limited and intermittent through the later twentieth century. In part this was due to technical and financial obstacles, but more potent inhibitions were the difficulty of locating and identifying target material comprising diffuse scatters of stone tools or potsherds barely distinguishable from the natural background on the seabed and a prevalent belief – still quite widely held – that

Underwater Archaeology, Figure 1 A dugout canoe recovered from the Danish Mesolithic site of Tybrind Vig. Photograph courtesy of Søren Andersen and the Moesgaard Museum.

archaeological material has either not survived, cannot be recovered, or cannot add significant new knowledge.

Pioneering work took place in the 1970s and early 1980s (Gagliano et al., 1982; Masters and Flemming, 1983; Andersen, 1985; Fischer, 1995a), but there was little follow-up. Finds of prehistoric settlements that demonstrated the unusually good quality of preservation in underwater sediments, such as Tybrind Vig, a 6,000-year old site in Denmark with remains of wooden canoes, paddles, and fish weirs (Andersen, 1985, 2011; Figures 1 and 2), and Atlit Yam off the coast of Israel, a 9,000-year old settlement with evidence of farming, fishing, seafaring, and the construction of stone-lined wells (Galili et al., 1993), were regarded as exceptions rather than the norm. Only within the past decade has there been a noticeable acceleration of research, spurred by a growing recognition of the likely importance of coastal regions and marine resources in the earlier stages of human evolution (Erlandson, 2001; Bailey and Milner, 2002; Bailey et al., 2008); by a steady increase in the number of reported underwater finds and a growing realization of how much significant evidence may now be awaiting discovery (Flemming, 1998; Bailey and Flemming, 2008); by the intensification of industrial and commercial activities on the sea floor, which have provided both new opportunities for acquiring archaeological and geologically relevant data, and also an increasing demand for government regulation and management of the underwater heritage, enshrined in the UNESCO convention of 2001 (Flemming, 2004; Gaffney et al. 2007, 2009; Evans et al., 2014); and by the development of new

interdisciplinary and international collaborations and sources of funding (Bailey, Sakellariou et al. 2012).

The archaeological importance of sea-level change and submerged landscapes

The general pattern of changes in global ocean volume with changes in glaciation during the Quaternary period is well known. One well-recognized consequence of low sea-levels is the creation of land bridges that facilitated population movement between continental land masses during the Pleistocene. A more significant consequence of sea-level change is the fact that, for most of human existence on this planet, sea-levels have been lower than present, by depths ranging between −20 m and −120 m for the greater part of the glacial cycle and a modal value of −40 to −60 m. This means that Pleistocene shorelines and extensive coastal regions representing prime territory for human occupation are now mostly submerged and that the apparent explosion of evidence for coastal settlements and maritime activities visible worldwide after about 6,000 years ago, when global sea-level rise at the end of the last glaciation ceased, has more to do with the likely loss of earlier evidence than with some global "revolution" involving social and economic intensification.

These now-submerged coastal regions were also probably the focus of more attractive terrestrial conditions of ecology, food resources, water supplies and local climate,

and higher population densities than their adjacent hinterlands and were likely also major pathways of population movement and cultural interchange. It follows that we are missing some of the most important evidence for the early transformations of human biological and social evolution over the past 2 million years, including evidence relevant to early human dispersal out of Africa; early developments in seafaring, fishing, shell gathering, and sea-mammal hunting; earliest colonization of Australia and the Americas; the first penetration of de-glaciated territory at high latitudes especially in Northwest Europe; the growth of sedentary societies; the earliest dispersal of agricultural economies around coastal basins such as the Mediterranean; and the roots of some of the earliest civilizations such as those of Minoan Crete and Mesopotamia. All these developments took place when sea-level was lower than today; all probably depended to some degree on the resources and opportunities of coastal regions; many of the later developments in this sequence, beginning during the Last Glacial period if not earlier, almost certainly required skills in seafaring and exploitation of marine resources. Most of the evidence must, by definition, be sought in the vicinity of paleocoastlines and must therefore be located underwater (Bailey and Flemming, 2008).

Submerged settlements and landscapes

The discovery and interpretation of prehistoric archaeological evidence cannot be divorced from the reconstruction of the wider physical landscape in which people lived. Geological techniques are essential to reconstruct the likely configuration of topography, drainage channels, lakes, paleoshorelines, and other natural resources, to give precision to the locations which might have been persistently attractive places for human activity and the discard of archaeological material, and to identify the processes that are likely to have preserved, buried, exposed, or destroyed archaeological material before, during, and after inundation. Successful underwater archaeological research increasingly depends on multidisciplinary and multinational collaboration involving archaeologists, marine geologists, geophysicists, sedimentologists, tectonic geomorphologists, oceanographers, and paleoclimatologists.

The initial discovery of submerged archaeological sites usually begins with chance finds by sports divers or by commercial activities on the seabed such as trawler fishing or dredging of marine channels. Dredging operations in Denmark and northern Germany early in the twentieth century first revealed the large quantities of prehistoric artifacts present on the seabed in the western Baltic. Large quantities of ice age fauna such as mammoth tusks and teeth are regularly dredged up by Dutch trawlers working in the North Sea (Glimmerveen et al., 2004), and these catches sometimes include rare finds of Paleolithic stone tools and in one recent case part of a Neanderthal skull (Hublin et al., 2009). On the eastern seaboard of
Underwater Archaeology, Figure 3 A diagrammatic representation, showing the techniques involved in the underwater excavation of Atlit Yam, Israel. After Galili et al. 1993, figure 2. Image supplied by Ehud Galili, courtesy of the Israel Antiquities Authority.

the USA, a mastodon tusk and a bifacially flaked leaf point were recovered from 70 m on the outer shelf in 1970 and languished in a local museum for over 30 years before their significance was recognized. Recent radiocarbon dating of the tusk at 23,000 years BP appears to extend human presence in the Americas by 10,000 years compared to the generally accepted date of earliest colonization (Stanford et al., 2014). The Atlit Yam site in Israel was discovered only by the coincidence of a storm that had temporarily removed the protective cover of sand and a local archaeologist who happened to be diving at that locality. The Cosquer Cave in southern France, with a magnificent gallery of Paleolithic cave art above modern sea-level, is only accessible by a single corridor with an entrance now some 40 m below sea-level, discovered by an intrepid sports diver (Clottes and Courtin, 1996).

Once materials and locations have been found, more systematic work can take place, either in the laboratory or through new work at the original seabed location using remote sensing, coring, and diving. Excavation work on shallow water sites down to depths of 10–20 m is logistically feasible, using SCUBA and normal air mixtures and the adaptation of conventional archaeological techniques, such as trench grids, hand tools, dredges, and sieves, for the processing of large quantities of sediments, and air lifts to take material to the surface (Figure 3). Good examples of such work are the Mesolithic site of Bouldnor Cliff in southern England (Momber, 2011; Momber et al., 2011); Tybrind Vig and other similar sites in Denmark (Fischer, 1997, 2004; Andersen, 1985, 2013; Skaarup and Grøn, 2004), all of Mesolithic date; Mesolithic and Neolithic submerged settlements in the Wismar Bay of northern Germany (Harff et al., 2007; Lübke et al., 2011); and Atlit

Yam in Israel (Galili et al., 1993). Animal and human bones, remains of plant foods, and organic artifacts made from wood and plant fibers are often very well preserved because of burial in anaerobic sediments, providing detailed and well-dated information on paleoenvironment and paleoeconomy.

Sites at greater depth are more difficult to deal with and require divers trained in mixed gas techniques to ensure safe working at depth. Until now, very few examples have been reported other than experimental trials (e.g., Bailey et al., 2007). Other possibilities are the use of coring and dredging, but here the main challenges, in the case of coring, are the processing of sufficient volumes of sediment to locate and recover archaeological materials that may be present in relatively low densities and, in the case of dredging, the difficulties of achieving stratigraphic control. Nevertheless, recovery of cultural material including artifacts has been reported from coring or targeted grab sampling in several parts of the world up to depths of over 50 m below sea-level – on the shelf of the eastern USA (Gagliano et al., 1982), on the Pacific coast of British Columbia (Fedje and Josenhans, 2000), in the North Sea (Long et al., 1986), and in the Black Sea (V. Yanko-Hombach, personal communication, 2010).

Collaboration with industrial operators can be of significant help, especially where government legislation requires mitigation work by companies working on the seabed. In the UK a government tax levied on gravel extraction companies (MALSF – Marine Aggregates Levy Sustainability Fund) provided a multimillion pound (dollar) fund over a period of years that supported important archaeological projects. One was the computer analysis of seismic data provided by the hydrocarbon industry
Underwater Archaeology, Figure 4 Part of the North Sea submerged landscape as reconstructed for the late Pleistocene period from seismic data. Image courtesy of Vince Gaffney and the Visual and Spatial Technology Centre (VISTA), University of Birmingham.

for a sector of the North Sea, which was able to reconstruct a 23,000 km^2 area of the pre-inundation landscape, showing river channels, paleoshorelines, marshes, and hills (Gaffney et al., 2007, 2009; Figure 4). In another case, at the A240 site, also in the North Sea, some 11 miles offshore of the East coast of England, companies processing large quantities of material for gravel extraction recovered Lower Paleolithic bifacial hand axes and cooperated with English Heritage (the government agency responsible for managing the underwater cultural heritage) and a commercial archaeological company to collect more material. Targeted acoustic survey and coring revealed a sequence of sediment-filled paleochannels that could be linked to the hand axe site, providing a date of 350–200,000 for the earliest material and information on the contemporaneous vegetation and environment (Tizzard et al., 2011; Bicket et al., 2014). That such material should have survived several sea-level cycles of inundation is not unique; a similar case of early-dated hand axes has been reported from South Africa (Werz and Flemming, 2001). In the Port of Rotterdam, active industrial collaboration using purpose-built dredges and industrial-scale sediment removal and sieving during the construction of new harbor facilities has resulted in the recovery of Mesolithic stone artifacts and animal-bone material in 17m depth of water (Weerts et al., 2012).

The total number of prehistoric archaeological sites discovered underwater is difficult to know at the present time, since the numbers are increasing all the time, and no systematic audit has yet been completed. But they certainly number in the thousands, including material of all ages from the Lower Paleolithic period (older than 250,000 years) up to the Bronze Age, at all depths from the outer edge of the continental shelf exposed at maximum sea-level regression up to the present-day intertidal zone, and in most continents, with the largest concentrations currently in Europe. At any rate, the number and range of discoveries is such as to refute emphatically the belief that nothing has survived on the seabed or can be recovered.

Purposeful research strategies aimed at discovering new archaeological sites are a much greater challenge than on land. Yet they are vital to the future development of the discipline, which cannot continue to rely on chance discoveries. Divers cannot traverse large areas of the seabed in the same way as with field-walking on land; remote sensing techniques of acoustic and seismic surveys are unlikely to identify archaeological sites unless they are very large and have a very distinctive acoustic signature, e.g., shell mounds, and are in any case expensive to deploy over large areas. Remotely operated vehicles with cameras, and manned submersibles, are other possibilities, but these require large support ships and considerable cost. Whatever the techniques available, it is essential to produce predictive models that can help target the likely location of archaeological material, and these models need to cater for two objectives. The first is the prediction of specific locations in the paleolandscape that were likely attractive places for human activity. The second is an understanding of the processes of landscape erosion or alteration associated with sea-level inundation. Both objectives require geological input, both to reconstruct terrestrial land surfaces and paleoshorelines as they would have existed prior to inundation and to understand the ongoing processes of submarine sedimentation and erosion that may have helped to preserve and make visible archaeological and terrestrial features of the original

landscape. In Denmark, using Anders Fischer's (1995b) "fishing site model," shoreline locations most likely to be good fishing spots were searched by divers. This has resulted in the discovery of many hundreds of new sites and can be adapted for other regions (Benjamin, 2010). In the Gulf of Mexico and the Eastern seaboard of the USA, reconstruction of paleoriver channels and adjacent areas suitable for human settlement, combined with targeted coring and diver exploration, has resulted in successful location of archaeological sites (Faught and Gusick, 2011, Faught, 2014; Gagliano et al., 1982).

Examples of sea-level change

Archaeological settlements are often located at or very close to the ancient shoreline and can provide detailed information on shoreline depth below modern sea-level, chronology, and ecological conditions, all of significant value as sea-level index points. In the Baltic, archaeological data from a chronological sequence of submerged settlements, which underwent progressive inundation during the Holocene, has helped to give precision to the regional relative sea-level curve and the prediction of future shoreline change with continued sinking of the modern Baltic coast (Harff et al., 2007). In the Mediterranean, dates of shoreline features such as Roman fish tanks and loading areas for shipment of quarried stone, which are now submerged, provide sea-level reference points for modeling the complex interaction of tectonic and isostatic displacement (Antonioli et al., 2009; Florido et al., 2011; Furlani et al., 2013). Elsewhere, archaeologically defined problems about early human dispersal are providing the stimulus to more detailed modeling of changes in sea-level and the position of paleoshorelines (Lambeck et al., 2011).

Summary and conclusions

Underwater archaeology comprising the study of shipwrecks has been well established for over half a century. The study of formerly occupied submerged landscapes flooded by sea-level rise at the end of the last glaciation is a newer discipline. Only in the past decade has it become more widely established as a major focus for interdisciplinary research with the marine geosciences, and collaboration with offshore industries, and is opening up a completely new perspective on the contribution of prehistoric maritime activity and coastal settlement to the prehistory of human civilization.

UPWELLING

Colin Summerhayes
Scott Polar Research Institute (SPRI), Cambridge
University, Cambridge, UK

Definition

Geologists have five good reasons for an interest in upwelling currents, which are highly productive and tend to be recorded for posterity through organic enrichment on continental margins. Firstly, massive accumulations of organic-rich sediment eventually form the source rocks for oil. Secondly, these accumulations may contain abundant remains of siliceous organisms like diatoms, providing commercially significant deposits of diatomite. Thirdly, the migration of phosphorus from organic-rich sediments into pore fluids or bottom waters may lead to the formation of phosphorite deposits important to the fertilizer industry. Fourthly, these organic rocks together or separately form part of the signature *triad* of organic-rich black shale, diatomite, and phosphorite that can be used in paleoclimatology as indicators of particular climate conditions including past upwelling (Parrish, 1982; Parrish and Curtis, 1982). And, finally, these rocks provide important clues to the operation of various biogeochemical processes like the carbon cycle, the silica cycle, and the phosphorus cycle.

Understanding the geological effects of upwelling requires familiarity with how upwelling works to affect the biogeochemistry of today's ocean and its relation to the oxygen depletion that may encourage the preservation of sedimentary organic matter. Comprehensive reviews of the nature of upwelling and its geological record can be found in Suess and Thiede (1983) and Thiede and Suess (1983), Summerhayes et al. (1992), Summerhayes et al. (1995a), and Summerhayes et al. (1995b) and are complemented by a review of the productivity of the ocean, past and present, by Berger et al. (1989a).

The winds play an extraordinary role in governing surface ocean properties. When they blow on the ocean surface, they force the surface waters in the same direction. The Earth's rotation deflects both winds and currents to the right in the northern hemisphere and to the left in the southern hemisphere. As pointed out by Swedish oceanographer Vagn Walfrid Ekman (1874–1954) in 1902, surface waters are deflected slightly from the direction of the wind acting upon them. Each layer within the water column deflects the next one down, and deflections continue downward until there is no more vertical transmission of energy. The result is a rotation of flow named the Ekman spiral, which causes the top 100 or so meters of the ocean to move at right angles to the direction of the prevailing wind. This moving layer is the Ekman layer. Its motion, known as Ekman transport, sets up a surface slope rising in the direction of transport. To compensate, cold, nutrient-rich water wells up from below; this is upwelling, referred to by some as Ekman pumping.

Persistent upwelling takes place where high-pressure cells over the ocean in midlatitudes force the winds to blow parallel to the arid coasts of northwest and southwest Africa, northwestern and southwestern America, and northeastern Africa and eastern Arabia, forcing the surface water offshore. Persistent upwelling also occurs in the open ocean, and these two locations are connected in the subsurface. The westerly winds of the Southern Ocean force the Antarctic Circumpolar Current to the east and drive the surface waters north, causing the upwelling of nutrient-rich Circumpolar Deep Water to feed the productive Southern Ocean ecosystem. This cold, northward-moving surface water eventually sinks beneath warmer and less dense surface waters at the Antarctic Convergence, or Polar Front, near 60°S, and spreads out to form the intermediate water layer of the world's oceans at depths of around 800–1,000 m. Somewhat less nutrient-rich Southern Ocean water also sinks at the Subantarctic Front to form Subantarctic Mode Water at depths of 200–300 m. The intermediate and mode water provide the deep source for upwelling water along continental margins, and mode water alone may be responsible for 33–75 % of global ocean productivity between 30°S and 30°N (Berger et al., 1989b; Palter et al., 2010). Persistent upwelling also characterizes the equatorial oceans, where the trade winds blow parallel to the equator, forcing surface waters away to the north and south (Shimmield and Jahnke, 1995). Because of their high productivity, upwelling zones form some of the world's richest fishing grounds. The extraordinary productivity of coastal upwelling may be further stimulated by the supply of iron-rich dust blown offshore from adjacent deserts – iron being a limiting nutrient for ocean productivity. Plumes of dust blowing to the west can commonly be seen in satellite

photographs offshore from the Sahara and the Namib Desert (Summerhayes et al., 1995b). Impersistent and localized wind-driven upwelling also occurs beneath cyclones and anticyclones but for the most part leaves no geological imprint because these are transient phenomena.

Upwelling is also common above the edge of the continental shelf (Summerhayes et al., 1995b; Summerhayes et al., 1995c), where it may be stimulated by vertical mixing induced by the interaction of tides with the change in topography. Hence, it can be found both in areas of wind-driven coastal upwelling, for example, off Namibia, and away from them, for example, at the mouth of the English Channel. Namibia's shelf-edge upwelling is stimulated by wind stress curl, the location of the axis of maximum wind stress along the coast. There, the elevation of the hinterland along the coast forces that axis 200–300 km offshore, more or less over the shelf edge, where the southerly wind stress produces upwelling and divergence seaward of the axis and downwelling and convergence landward of the axis. Different plankton populations are found in the coastal and shelf-edge upwelling centers, because the coastal upwelling taps into nutrient-rich deep waters dragged up across the continental shelf, while the shelf-edge upwelling taps shallower waters with a lower nutrient content. The coastal upwelling waters tend to be rich in silica and support a rich diatom population, while shelf-edge waters tend to be depleted in silica.

Coastal upwelling typically takes place within a coastal current system, such as the California Current, the Humboldt Current (Peru-Chile), the Benguela Current (Namibia and South Africa), or the Somali Current (Somalia and Arabia). Beneath the thermocline in these large-scale systems, there is typically a poleward undercurrent with a core near 350–500 m. Where the continental shelf is deep, as off Namibia, this current may sweep the outer shelf clean of fine-grained recent sediment (Summerhayes et al., 1995b). Upwelling may also occur off the east coasts of ocean basins, for example, off the aptly named Cabo Frio, near Rio de Janeiro, and off Florida, due either to shelf-edge upwelling or to local wind patterns, but is usually less extensive in those locations. Although coastal upwelling might be expected off Western Australia, where winds commonly blow north along the coast, it does not usually occur there. Cold northward-moving water equivalent to the Benguela or Humboldt Currents does occur offshore in the West Australian Current, but at the coast, it is displaced by the warm, south-flowing Leeuwin Current, which is a branch of the Pacific South Equatorial Current and which generates coastal downwelling. In summer, coast-parallel winds induce local countercurrents (Ningaloo and Capes Currents) associated with localized coastal upwelling off Western Australia (Hanson et al., 2005). The West Australian example demonstrates that local ocean dynamics can work against received wisdom regarding the control of upwelling by basin-scale wind patterns.

Upwelling, the oxygen minimum zone, and organic matter accumulation

As plankton die and sink, they consume oxygen, enhancing the depletion of the oceanic oxygen minimum zone that lies between the ocean's oxygenated deep bottom water and its oxygenated surface waters. This zone is significantly depleted in oxygen along those continental margins where productivity is highest. It contains the least oxygen where the mid-depth waters of the ocean are the oldest, in the Pacific Ocean and the Arabian Sea, because sinking organic matter has stripped out oxygen by decomposition in these older water masses over long periods of time. There, the effect of coastal upwelling may be to make the oxygen minimum zone virtually devoid of oxygen – or "anoxic." Any organic remains falling to the seabed in such an environment would be completely preserved, aside from the effects of decomposition by anaerobic bacteria. For these reasons we find exceptionally organic-rich sediment on the continental slopes off Somalia, Arabia, and the eastern seaboard of the Americas, where there is strong upwelling at the surface and strong oxygen depletion at depth.

We tend not to find organic-rich sediments on the continental slopes of the Atlantic, regardless of upwelling, because the mid-depth waters of the Atlantic are relatively young and the oxygen minimum zone as a result is still quite rich in oxygen (Summerhayes, 1983). Nevertheless, there are commonly some residual biological signals of upwelling in the sediments there. For example, there is some organic enrichment on the continental slope of northwest Africa, south of latitude $22°$S, and on the slope off Namibia. In the case of Namibia, this is at least in part because a poleward undercurrent brings oxygen-depleted water south to Namibia and South Africa from the Angola Basin along the upper continental slope (Summerhayes et al., 1995b; Summerhayes et al., 1995c). In the Pacific, ^{14}C studies of bomb carbon show that the extensive oxygen depletion in the oxygen minimum zone off Peru and Chile is driven at least in part by oxygen depletion of a similar subsurface countercurrent that makes its way there from New Zealand via the equator (Toggweiler and Carson, 1995).

For the most part, in the oceans of the Pleistocene and present times, organic enrichment beneath coastal upwelling centers is confined to the sediments of the continental slope, the notable exception being off Namibia where organic-rich sediments accumulate on the unusually deep continental shelf (Summerhayes et al., 1995b; Summerhayes et al., 1995c and references therein). It has commonly been supposed that the impingement of the oxygen minimum zone on the continental slope may account for the widespread occurrence of organic-rich sediments on continental margins. Calvert (1987 and elsewhere) has observed that slope sediments may be enriched because (a) nearer shore, the production of organic matter is high but rates of sedimentation of organic matter are low

because of strong bottom currents on the continental shelf; (b) rates of sedimentation of all components, including organic matter, are high on the continental slope; and (c) further offshore, the rates of sedimentation of organic matter decline. Subsequent studies of the chemistry of pore waters by using cleverly designed oxygen and pH microelectrodes showed that organic matter does degrade more slowly under low-oxygen than high-oxygen conditions, the key to preservation being the duration of exposure to oxygen (Eglinton and Repeta, 2003). High rates of sedimentation on continental slopes do preserve organic matter preferentially, as Calvert suggested, but the impingement on the slope of an oxygen-deficient oxygen minimum zone adds to that preservation, as well as preserving annual laminations that would otherwise be destroyed by benthic organisms through bioturbation (Archer, 2003). Annual laminae are well preserved beneath productive surface upwelling in the anoxic basins of the sea off Southern California (Eglinton and Repeta, 2003).

Not all organic-rich sediments are associated with upwelling – they may form anywhere that the production of organic matter is moderately high, the supply of silt and clay low, and the water depleted in oxygen, for example, at the bottom of basins like today's Black Sea, in the Cariaco Trench of the continental shelf off Venezuela, and in the narrow deep basin of the Gulf of California behind the Baja peninsula.

Black organic-rich sapropels are also found in another closed basin, the Eastern Mediterranean. In Cretaceous times, black, organic-rich sediments were laid down in flooded continental margin basins and on the floor of the deep ocean during oceanic anoxic events (OAEs). They are commonly laminated and may have been laid down under anoxic conditions (for further discussion, see below). They may be associated with upwelling in some places.

Upwelling and phosphorite

Phosphorus is an essential element for life and abundant in the remains of marine plankton, fish bones, and shark teeth. Under appropriate conditions, phosphate-rich fluids can precipitate calcium fluorapatite ($Ca_5(PO_4)_3$ F) otherwise known as francolite. In marine sediments, francolite may also absorb carbonate ions (CO_3^{2-}) to form calcium carbonate-fluorapatite. The fluids can also phosphatize preexisting carbonate deposits (limestones or carbonate ooids). Primary or secondary deposits of phosphate-rich sediment are known as phosphorite, a rock with at least 15–20 % P_2O_5.

It was initially thought that phosphorites were not forming in the modern ocean, but the application of uranium series dating in the 1970s showed that phosphatic minerals are forming today beneath upwelling centers, at the edges of organic-rich mud deposits off Peru (Baturin et al., 1972; Burnett, 1977; Burnett et al., 1980). They have subsequently been found forming in the upwelling centers off Namibia (Thomson et al., 1984; Baturin, 2000), as well as off Baja California, Oman, and eastern Australia (Ruttenberg, 2005). Off Peru, phosphorite forms where conditions begin to become oxidizing. Pore-water gradients of phosphate and fluoride decrease downward in sediments as these ions are incorporated into authigenic carbonate-fluorapatite. The process can occur anywhere but tends to be most common where there is a high rate of supply of organic phosphorus, which is where organic carbon is also supplied, as in upwelling areas (Ruttenberg, 2005). Iron oxyhydroxides are known to play an important intermediate role in the transfer of organic phosphorus to the carbonate-fluorapatite mineral phase.

Phosphate minerals can also accumulate as rounded grains or ooids – sand grain-sized ovoid structures layered like onions in which each layer represents a period of mineral growth. Phosphorite is common as phosphatized limestone outcrops or nodules on the seabed in upwelling zones, for example, off South Africa, Namibia, California, and Morocco, where the phosphatic rocks may occur as rock outcrops or nodules (Burnett and Riggs, 1990). Phosphorite is also widespread on the Blake Plateau east of Florida and on the Chatham Rise east of New Zealand.

The association of submarine phosphorite with upwelling in middle latitudes was pointed out early on by McKelvey (1963). These nodules had been found off the coast of South Africa during the round-the-world oceanographic expedition of *H.M.S. Challenger* (1872–1876) (Murray and Renard, 1891), and a single sample had been dredged from a depth of 600 fathoms (1,097 m) on the continental slope west of the town of Safi, in Morocco, by the *S.S. Dacia*, in 1883, during a survey of the route for a submarine cable from Cadiz to the Canary Islands (Murray and Chumley, 1924). Upper Cretaceous (Maastrichtian) to Middle Eocene (Lutetian) phosphorite was known to be abundant onshore in Morocco and was subsequently found to be abundant on the continental shelf and upper continental slope off Morocco (Summerhayes et al., 1971). These phosphorites are part of a belt of phosphorite-rich deposits formed beneath upwelling currents on the southern margin of the narrow branch of the Tethyan Ocean which separated Europe and Africa in Cretaceous-Eocene times and which extends from western Morocco and the Western Sahara, through Algeria, Tunisia, and Egypt, to Israel, Jordan, and Syria.

Most ancient phosphorites formed as continental margins became flooded, so their control through time was not simply climatic (Cook and McElhinny, 1979); a confluence of different factors was important at different times (Ruttenberg, 2005). Nevertheless, large sustained sites of upwelling seem likely as a necessary condition for the supply of phosphorus.

The last major phosphorite-forming episode in the oceans took place in Miocene times. Miocene glauconitic phosphatic conglomerates are widespread beneath upwelling currents off South Africa, California, eastern New Zealand, and Morocco (e.g., Summerhayes and McArthur, 1990) but do not occur onshore in any of those

places. The California phosphorites are of the same age as the organic- and silica-rich diatomaceous Monterey Formation of California (more on that below).

Upwelling and organic-rich sediments (Pleistocene to present)

Sediments rich in organic matter are common on the continental margins beneath the major coastal upwelling currents (California, Humboldt, Somali, and Benguela). They may typically contain as much as 5–6 % total organic carbon (Corg), equivalent to around 9–10 % nonskeletal organic matter (Corg × 1.8), but higher values prevail in the shallow shelf sediments off Walvis Bay, which contain up to 24 % organic matter (Bremner, 1983). They also commonly contain the remains of siliceous plankton, usually diatoms, which may be fragmented, as on the Namibian continental slope, where the rate of accumulation is modest (Summerhayes et al., 1995b), or whole, as on the Namibian continental shelf where deposition is rapid (Bremner, 1983). There is very little continental shelf off Peru and Chile, so most of the organic matters is dumped directly onto the continental slope there (Reimers and Suess, 1983; Jahnke and Shimmield, 1995). Off southern California, most of the organic matter ends up in the oxygen-poor basins of the California Borderland (Emery, 1960).

It is commonly thought that during glacial times, the equator-to-pole thermal gradient increased, so strengthening global winds and intensifying both upwelling and its associated productivity and, as a consequence, drawing down atmospheric CO_2 (Sarnthein et al., 1988). Under these circumstances, high rates of accumulation of organic matter would be expected on continental slopes in upwelling regions during glacial periods. But the real picture is not that simple, as pointed out, for instance, by Loubere et al. (2003). For example, off northwest Africa, the flux of organic matter rose slowly through Marine Isotope stages 4 and 3 to a maximum in stage 2, the Last Glacial Maximum (LGM) (Shimmield, 1992). There, the coldest surface water temperatures occurred not at the time of maximum ice volume (the LGM) at 21–23 ka but during Heinrich events just before and just after the LGM (Zhao et al., 1995). This cooling reflects not changes in upwelling but the introduction of cold surface water from the north during iceberg outbreaks. We shall see other examples of a divergence from the simplistic thesis that there is a straightforward relationship between productivity, upwelling, and wind strength. In large part, this reflects the advection into upwelling regions, either in surface currents or in oppositely directed undercurrents, of water from adjacent regions with different nutrient and/or oxygen contents.

Deep ocean drilling off northwest Africa indicates tight coupling between increases in African rainfall and decreases in the intensity of coastal upwelling (Adkins et al., 2006; Adkins et al., 2007). For instance, strong upwelling returned at 5.5 ka with the aridity at the end of

the "African humid period," during which the Sahara had been both wet and green. Arid conditions with more upwelling also characterized the cold Younger Dryas period. These data contradict interpretations based on foraminifera and radiolaria (Haslett and Smart, 2006) but make more sense in terms of the observed fluxes of terrigenous material (Adkins et al., 2006; Adkins et al., 2007).

Interpretations of organic enrichment on continental slopes dating back into glacial times also have to consider the role of changing sea-level, which dropped by up to −130 m during the Last Glacial Maximum (LGM). This would have pushed the centers of coastal upwelling seaward from the continental shelf over the continental slope, in addition providing the possibility that erosion of former organic-rich shelf deposits could supply organic matter to the continental slope. Care must thus be taken in interpreting data from continental slope cores, as noted for NW Africa, for example, by Giraud and Paul (2010). They found that during the LGM, the subsurface waters there contained fewer nutrients, thus lowering productivity. The sedimentary record, in contrast, suggested an increase in productivity, which can be explained by the fall in sea-level and a seaward shift in the locus of upwelling.

Upwelling is also evident off southern Portugal. There, signs of heightened productivity (e.g., enhanced Ba content) reflecting pulses of upwelling were found at the transitions between glacial and interglacial periods (Thomson et al., 2000), probably reflecting the reorganization of ocean circulation and wind systems. Abreu et al. (2005) found evidence for upwelling and the associated deposition of organic matter increasing there as the climate deteriorated from the interglacial of Marine Isotope stage 11 (MIS-11) into the following glacial period. Upwelling events introducing colder surface waters could be differentiated from influxes of cold surface water associated with iceberg outbreaks (Heinrich events), by the association of organic matter with the former and characteristic minerals (e.g., dolomite) with the latter (Thomson et al., 1999; Abreu et al., 2005). Iberian margin sediments contain strong precessional signals associated with low-latitude wind-driven processes contributing to dust supply (high at times of precession minima = summer insolation maxima) and upwelling (high at times of precession maxima = summer insolation minima) (Hodell et al., 2013).

Over the continental slope off Namibia over the past 70 ka, sea surface temperatures were coldest and rates of accumulation of organic matter on the continental slope were highest in the interstadial Marine Isotope stage 3 (MIS-3) (Summerhayes et al., 1995b). Temperatures warmed steadily through late stage 3 and stage 2 to the present as the rate of accumulation of organic matter declined. This change occurs together with warming that began close to the Namibian coast just before and during the LGM with the incursion of warm subtropical surface water from the north (Kirst et al., 1999). Evidently, the wind systems were reorganizing and making conditions less favorable for upwelling. Isotope stage 4 was slightly

warmer than MIS-3 (60–24 ka), tended to contain slightly less organic matter, and was associated with abundant terrigenous sediment, probably wind-blown dust, suggesting that winds at this time may have been more offshore than alongshore (Summerhayes, et al., 1995b). Thus, while in toto there was higher productivity off Namibia during glacial times, it did not occur throughout glacial times. The best conditions for upwelling seem to have been focused in stage 3, presumably because winds then were most persistently coast-parallel.

The upwelling signal off Namibia over the past 150 ka fluctuated with a period of around 22,000 years, suggesting primary control by the orbital precession signal, as off Portugal. During stage 3, the precession index and obliquity signal contributed to minimizing insolation, and southerly trade winds were at their strongest as the South Atlantic high-pressure cell shifted north. This pattern led to similar cooling and increased production at that time in the Angola Basin and in the Arabian Sea (Summerhayes et al., 1995b). Comparison of warming and cooling patterns off northwest and southwest Africa shows them to be in antiphase, with warmings in the north correlating with coolings in the south during the Ice Age (Little et al., 1997). This is typical of the seesaw pattern that connects ice core changes in Greenland to those in Antarctica.

Pichevin et al. (2005) used nitrogen isotopes ($\partial^{15}N$) to demonstrate that the upwelling structure off Namibia comprised two cells that decoupled nutrient dynamics on the shelf from those over the continental slope. As elsewhere, the lower slope cores displayed low $\partial^{15}N$ during cold periods and high $\partial^{15}N$ during warm periods, whereas the $\partial^{15}N$ signal of the coastal cell was relatively constant irrespective of wind strength, indicating that nitrate was never depleted in the surface water on the shelf. Over the lower slope, nitrate delivery to the photic zone was driven by the nutrient richness of South Atlantic Central Water, depending on Agulhas inflow, which depended in turn on the position of the Polar Front, rather than on atmospheric forcing.

In the California Current, offshore cores show a close association between cold SSTs and increases in ice volume, but there is only a small cooling associated with the LGM near the coast (Herbert, 2003). While there is some evidence that the coastal upwelling zones off California and Mexico were somewhat less productive during the recent glacial period (Sigman and Haug, 2003), fluctuations in organic carbon off Baja California, Santa Barbara, and Mexico were linked to global climate variability over the past 52 ka (Dean et al., 2006). Concentrations of biogenic proxies are highest in laminated sediments deposited during warm interstadials, including the Holocene, and lowest in bioturbated sediments deposited during cool periods. However, these fluctuations owe much to fluctuations in diluting terrigenous material, and the mass accumulation rate of organic carbon likely varied by no more than a factor of 2 over the past 52 ka (Dean et al., 2006). These variations may relate to changes in the nutrient content of the subsurface waters that form the source for upwelled water. During the last glaciation, the subsurface waters that filled the Santa Barbara Basin had nitrogen isotope ($\partial^{15}N$) values of 6–7 ‰, indicating a better oxygenated (less nutrient-rich) intermediate water mass, while the subsurface waters there today have $\partial^{15}N$ values of 8–9 ‰, indicative of low-oxygen intermediate waters with a higher nutrient content (Emmer and Thunell, 2000). A decrease in nitrogen values indicating a temporary return toward glacial conditions characterized the Younger Dryas at about 12 ka. Hendy et al. (2004) confirm that productivity was not simply linearly related to cold and warm cycles, but reflected the interplay between local winds and the strength and source of the California Undercurrent. For instance, warm conditions were more productive and cool conditions less so during MIS-3; the cold LGM was relatively productive, as was the Bolling-Allerod warm interval, and the cold Younger Dryas was less productive. Warm periods tended to be associated with a more intense oxygen minimum zone that gave rise to laminated sediments (Zheng et al., 2000).

Nitrogen isotopes show much the same picture of change in the northern part of the California Current, off Oregon (Kienast et al., 2002). Low values characterize glacial stages 2 and 4, and high values characterize the Holocene, interstadial stage 3 and the last interglacial (stage 5), when the California Undercurrent was strongest. The source of the nitrogen isotope signal is the oxygen-poor subsurface water of the eastern tropical North Pacific, which advects north into the California Current system via the poleward undercurrent. From the relationship between productivity and the $\partial^{15}N$ signal, Kienast et al. (2002) deduced that upwelling-favorable winds developed first in the NE after the last glaciation then propagated south along the coast. Hence, the response of the California Current and its associated upwelling was regionally diverse.

In the mid-Holocene (8–3 ka), there are indications that upwelling decreased and productivity fell off California, even though sea surface temperatures cooled (Diffenbaugh et al., 2003). This turns out to result from the decline in orbital insolation over the northern hemisphere, which led to a longer and less vigorous mid-Holocene upwelling season in the California Current, with decreased seasonal contrast. The cooling was brought about by the introduction of cooler source waters from the north, not by enhanced upwelling.

Upwelling off Peru was investigated on ODP Leg 112 (Heinze and Wefer, 1992). As off Namibia, Peru has a northward-flowing surface current, the Peru (or Humboldt) Current, beneath which is a southward-flowing Peru Countercurrent (or undercurrent). Sediments are rich in organic matter, except locally where there has been winnowing by the undercurrent, which is associated with slightly higher levels of oxygen than the typical bottom water of the oxygen minimum zone. As in many places, coastal waters cooled significantly during the Last Glacial Maximum, but half of the cooling here appears

largely due to advection of cold water from high latitudes. The rest is due to a mixture of upwelling and uplifting of the pycnocline (Feldberg and Mix, 2003). Cooling began with increased upwelling and then continued as advected cold water arrived in the eastern boundary current. As off California and Mexico (see above), the coastal upwelling was apparently less productive during the LGM than before or since (Sigman and Haug, 2003). Loubere et al. (2003) confirm that productivity was least during cold Marine Isotope stages 2 and 4.

Upwelling off the west coast of South America is less well developed off Chile, where the surface waters belong to the Southern Ocean's high-nutrient, low-chlorophyll regime. Productivity there was significantly less than off Peru (Dezileau et al., 2004). Rain rates of opal and organic carbon there are in phase with the 20 ky precessional cycle, because during southern summer, insolation maxima increased river runoff, supplying large amounts of the limiting nutrient Fe to the coastal ocean, so enhancing productivity. Evidently, changes in upwelling induced by changes in the local wind field may not be the only controls on productivity along coasts where upwelling is prevalent. Mohtadi and Hebbeln (2004) point to latitudinal shirts of the Antarctic Circumpolar Current (ACC) as also being important in providing nutrients for the upwelling system. Close to 33°S, productivity off Chile was higher when the ACC was further north, during the LGM. Continental runoff was a supplementary source of nutrients north of 33°S; there, paleoproductivity values were higher before and after the LGM, when upwelling was stronger.

Off Somalia, in the Arabian Sea, where the Somali Current is driven by the southwest monsoon, sea surface temperatures were low in both the LGM and the Holocene, indicating the persistence of seasonal summer upwelling (Anand et al., 2008). Upwelling was maximal there during transitions between glacial and interglacial stages (e.g., isotope stages 2 to 1 and 15 to 10) (Caulet et al., 1992). It was also maximal, as off Walvis Bay (Summerhayes et al., 1995b), during isotope stage 3 (65–25 ka). At least during the past 60 ky, periods of increased upwelling in the Somalian, Arabian, and Peruvian upwelling systems were synchronous (Caulet et al., 1992).

Budziak et al. (2000) noticed that the organic carbon signal in the western Arabian Sea strongly followed the orbital signal of precession rather than simply changing from glacial to interglacial. Close to the coast, organic carbon values were more abundant in interglacials. Hence, while there is a general precessional control on paleoproductivity across the region, the strengthening of the southwest monsoon winds strengthened coastal upwelling and the supply of organic carbon especially during interglacials (Budziak et al., 2000). Productivity was evidently not driven by precession and associated upwelling alone, but also by changes in the strength of the northeast monsoon winds associated with the development of maximum ice volume in the northern hemisphere, which deepened mixing, so bringing more nutrients to the surface (Budziak et al., 2000).

Tamburini et al. (2003) recognized that productivity off Oman was high due to upwelling during the summer southwest monsoon but noticed that productivity remained high there during the winter northeast monsoon, when coastal upwelling switched off. They attributed the persistence of high productivity over the past 140 ka to the addition of deep mixing induced by the northeast monsoon. Bearing in mind that the northeast monsoonal conditions predominated during recent glacial periods, they surmised that the high productivity of glacial periods (isotope stages 2, 3, and 4) was probably caused by two factors. First, the northeast monsoon introduced more iron-rich dust, and second, wind-driven deep mixing stimulated the vertical supply of phosphorus from sediments to the water column at the top of an intensified oxygen minimum zone. In interglacial phases, by contrast, the coastal upwelling was strong, the winter mixing was diminished, the oxygen minimum zone was less intense, and the vertical supply of phosphorus from that source was cut off.

In the eastern Arabian Sea, off Goa, the sea surface temperature contrast, with more cold water in coastal waters than offshore, was greatest at the LGM, most likely due to increased winter upwelling driven by the NE monsoon along the west coast of India (Budziak et al., 2000; Anand et al., 2008). Productivity there was most abundant during glacial times but collapsed during northern hemisphere cold events (such as North Atlantic Heinrich events) (Singh et al., 2011). Upwelling there is weak today.

In the Southern Ocean, siliceous diatoms and radiolaria abound south of the Polar Front, where they are abundant due to wind-driven upwelling of Circumpolar Deep Water. Changes in their distribution down core show that during the LGM, the Polar Front was located some 7° further north of its present position, indicating a widening of the region subject to upwelling (Gersonde et al., 2005). This latitude also marks the approximate northern boundary of winter sea ice, which covered twice as much sea area then than now. Because of the northward displacement of the circum-Antarctic winds and their associated upwelling, which in turn reflected the growth of the sea ice field around the continent, the Antarctic sector was less productive in glacial times, while the subantarctic sector was more so. These changes are more prominent in the Atlantic and Indian Ocean sectors and less so in the Pacific sector, perhaps because the Pacific sector was the furthest from South American sources of Fe-rich dust that would have stimulated higher productivity.

Upwelling signals in older sediments

Sea surface temperature records from the continental margins of California and Peru show that prior to 3 Ma, the eastern Pacific was warmer during the Pliocene by 3–9 °C compared to today (Dekens et al., 2007). Evidently, the cold upwelling regions characterizing the modern Pacific did not exist in the Pliocene warm period. Even so, the eastern margins were productive, indicating that upwelling of nutrients did occur there. The warmth of

the surface waters is thought to indicate the existence of a deeper, well-ventilated thermocline (i.e., a thicker column of warm water). Cooling toward the temperatures of the Pleistocene and Holocene began about 4 Ma ago, before the onset of northern hemisphere glaciation, presumably representing a gradual decrease in the thickness of the thermocline (Dekens et al., 2007).

California's siliceous and organic-rich Monterey Formation, a Miocene diatom ooze deposit (White et al., 1992), coincides with a substantial global increase in the ratio of $\partial^{13}C$ – which signifies excess trapping of ^{12}C-rich organic matter in sediments (Vincent and Berger, 1985). This was coincident with global cooling as indicated by mid-Miocene $\partial^{18}O$ values, leading Vincent and Berger (1985) to propose that the increased equator-to-pole thermal gradient caused by global cooling strengthened coastal winds that in turn enhanced the coastal upwelling, the productivity, the development of the oxygen minimum zone, and the sedimentation and entrapment of organic matter. Miocene expansion of the oxygen minimum zone in response to increased productivity is also called upon to preserve organic matter on the continental shelf and slope seaward of the California coastal basins (Summerhayes, 1981a), which in turn increased the prospect for the associated formation of phosphorite, as pointed out above. The main organic-rich rocks of the Monterey Formation are Middle to Late Miocene.

Initiation of the Benguela Current at about the same time (Siesser, 1980; Berger et al., 2002) confirms that these increases in upwelling and associated high productivity occurred in response to a global event – presumably the increased extent of the Antarctic ice sheet and associated changes in the circulation of deep water. While Dean et al. (1984) thought that the deposition of silica-rich sediments in the Benguela off Namibia was Late Pliocene-Early Pleistocene, more recently, Diester-Haass et al. (2004) found that organic enrichment began there at 12 Ma (mid-Miocene) and increased significantly (by factors of up to 7–9) at 7–6 Ma (Late Miocene). Oxygen concentrations in the oxygen minimum zone on the continental slope were lowest between 12 and 9 Ma. Diester-Haass et al. (2004) attributed the rise in productivity not to increased upwelling, but rather to ocean-wide increases in nutrient supply and delivery recognizable here and in the western and eastern equatorial Pacific and the Indian Ocean. Heinrich et al. (2011) used analyses of calcareous dinoflagellates to confirm the onset of modern upwelling at 11.8 Ma and to demonstrate pulses of upwelling at 11.5 and 10.5 Ma related to cooling events associated with increases in ice volume in Antarctica and a likely associated increase in southeasterly coastal winds. Permanent establishment of the upwelling regime with a source in Subantarctic Mode Water seems to date to about 10.4 Ma.

An increase in productivity related to an increase in the strength of upwelling in the Benguela Current peaked in the Pliocene, around 3 Ma ago. Data from Ocean Drilling Program 175 (Berger et al., 2002), collected along the entire southwest African margin from Cape Town to Angola, showed that a Namibian diatomaceous silica event in the Late Pliocene-Early Pleistocene covered the entire Namibian margin and that while silica production was in phase with organic matter production between 3 and 2 Ma, the two were out of phase between 2 and 1 Ma. The silica decrease at that time is attributed to gradual exhaustion of the silica supply from the upper ocean (essentially the thermocline) due to its precipitation in diatom-rich sediments. The deposition of organic matter remained high, reflecting a continued supply of nutrients. Evidently, the ecology changed from a productive environment favorable to diatoms to a productive environment unfavorable to them as global cooling continued.

Sampling by deep ocean drilling showed that laminated organic-rich black shales of Cretaceous age were widespread in the deep waters of the Atlantic, in surrounding basins on the continental margin, and in the equatorial Pacific (Schlanger and Jenkyns, 1976). Concentrations of these deposits at certain time intervals led to them becoming described as oceanic anoxic events (OAEs). OAEs recurred at intervals throughout the Cretaceous, and there was one in the Early Jurassic (Toarcian). Each lasted around 0.5–1.0 million years (Jenkyns, 2010). The Cretaceous black shales of the deep North Atlantic were richest in organic matter along the northwest African margin and off northeast Brazil and Guyana. The Atlantic was much smaller at the time, so these deposits were physically much closer together then than they are now. The organic-rich deposits of the margins of northwest Africa and Guyana were characterized by marine organic matter of planktonic origin, while elsewhere over much of the deep North Atlantic deposits of the same age were dominated by terrestrial organic matter, which were less organically enriched (Summerhayes, 1981b).

As with many open ocean sediments, it seemed highly probable that both the organic-rich and organic-poor layers in these cores were deposited either by turbidity currents, giving rise to thin structured *turbidites*, or from near-bottom suspensions of turbid water flowing down from the continental margin and across the basin floor to form *hemipelagic muds* (Summerhayes, 1987). Recent detailed sedimentological studies of black shales from the Cretaceous of both the North Atlantic and the South Atlantic confirm that many of the laminations in these organic-rich deposits are very thin-bedded fine-grained turbidites (Stow and Dean, 1984; Trabucho-Alexandre et al., 2011). The existence of thinly bedded organic-rich turbidite layers confirms that their source areas – the adjacent continental margins – were sites of deposition of organic-rich sediment, most probably originating from upwelling combined with an anoxic oxygen minimum zone impinging on the continental slope. In contrast, the open Atlantic was rather unproductive (Bralower and Thierstein, 1984). The arrival of organic-rich material on the deep Atlantic seabed via bottom currents, and its decay in situ, may have created anoxic conditions near or at the sediment-water interface, so preserving finely laminated structures from destruction by bioturbation.

Kuypers et al. (2002) found that evidence for anoxia in deep bottom waters during the Cenomanian-Turonian black shale event in the deep southern part of the proto-North Atlantic included "the occurrence of molecular fossils of anoxygenic photosynthetic green sulfur bacteria, lack of bioturbation, and high abundance of redox sensitive trace metals indicate sulfidic conditions, periodically reaching up into the photic zone." Indeed these conditions periodically occurred even at very shallow water depths of 15 m or less. However, the lack of change in bottom water conditions at some sites suggested that the increase in burial rates of organic carbon resulted from changes in productivity rather than increased anoxia.

In shallower water deposits of this age, for example, in the basins of Italy, the presence of delicate laminations along with molecular fossils derived from green sulfur bacteria indicates that bottom waters were anoxic and contained free hydrogen sulfide and that these events occurred when sea surface temperatures were exceptionally warm, 32–36 °C in the topics and 25 °C around the poles (Jenkyns, 2008). The global warming of these times "was accompanied by an accelerated hydrological cycle, increased continental weathering, enhanced nutrient discharge to oceans and lakes, intensified upwelling, and an increase in organic productivity" (Jenkyns, 2010). Jarvis et al. (2011) attribute the warming to an enhanced supply of CO_2 from an increase in volcanic degassing associated with emplacement of the Caribbean large igneous province and noted that it was associated with a decrease in oceanic oxygen concentration. Organic enrichment in the Cenomanian-Turonian was thus a function of increased nutrient supply and decreased oceanic oxygenation, which enhanced the usual effects of coastal upwelling.

Samples of Cenomanian-Turonian age were the richest in organic matter in the North Atlantic and surrounding areas, most of it marine and probably originating from continental margin upwelling (Summerhayes, 1981b; Summerhayes, 1987). It seems likely that this regional upwelling was characteristic of the entire Cretaceous. One possible model to explain the unusual enrichment of Cenomanian-Turonian sediments in organic matter across the North Atlantic basin involves the breaking apart of Africa and South America leading to an oceanic connection between the North and South Atlantic that allowed highly saline, oxygen-depleted, and nutrient-rich waters from the south to enter the North Atlantic, accentuating both productivity, through upwelling at the surface, and oxygen depletion and preservation of organic matter at depth (Summerhayes, 1987; Kuypers et al., 2002). The influx of this "new" deep water appears to have caused significant accumulation of organic-rich sediments until the new reserve of nutrients was exhausted or until continued widening of the connection to the south diminished the influx of highly saline bottom water. This event was associated with an exceptionally large positive excursion in $\partial^{13}C$ (Frakes et al., 1992), suggesting a significant increase in the burial of organic matter rich in ^{12}C.

An alternative source for subsurface nutrients in the North Atlantic was the development of an estuarine circulation pattern in which westward-moving nutrient-depleted Atlantic surface waters were replaced at depth by nutrient-rich Pacific waters moving eastward in an undercurrent through the gap between North and South America, which would have made the North Atlantic a nutrient trap (Summerhayes, 1981b; Trabucho-Alexandre et al., 2010; Topper et al., 2011). However, that circulation is likely to have characterized the entire Cretaceous, not just the Cenomanian-Turonian section.

Interestingly, the Cenomanian-Turonian black shale event along the nearby margins of northwest Africa, northeast Brazil, and Guyana was associated not with the sort of cooling one might expect from enhanced coastal upwelling, but with a rise in temperature of about 3 °C that made this the warmest time interval in the mid-Cretaceous (Forster et al., 2007). Forster et al. (2007) speculated that the rise in both temperature and sea-level at this time may have destabilized the water column, enhancing mixing that could have fed nutrients back into the photic zone to stimulate production. However, it still seems highly likely that upwelling currents played an important part in ensuring high productivity on the margins, as demonstrated by numerical models of the Cretaceous climate system (see below).

Hofmann and Wagner (2011) attribute repetitive fluctuations in productivity, ocean redox conditions, and clastic sediment supply on the Demerara Rise off Guyana at this time to shifts in the mean position of the Intertropical Convergence Zone (ITCZ), which connects the large-scale wind field patterns of the two hemispheres. Upwelling was strongest off Guyana, and burial of organic matter most pronounced, when the ITCZ was in its most southerly position, which maximized the impact of the NE trade winds, which fostered upwelling and organic carbon burial off NW Africa and NE Brazil. Fluctuations in the position of the ITCZ are likely to have been orbitally controlled.

Paleoclimate models of upwelling

Given the association of upwelling with the wind, it ought to be possible in principle to map upwelling from maps of paleo-wind direction. In 1977–1978, the Amoco International Oil Company asked Fred Ziegler of the University of Chicago to expand his *Paleogeographic Atlas Project* to apply to continental reconstruction maps the likely circulation patterns of the atmosphere and ocean, so as to determine the probable positions of oceanic upwelling zones that might be associated with the deposition of organic-rich rocks forming petroleum source beds (Ziegler, 1982). Judy Parrish was appointed to supervise that part of the *Atlas* project, and several other oil companies joined the consortium funding Ziegler's team. Parrish's first principle approach to paleoclimate mapping involved plotting on continental reconstruction maps the likely isobars of atmospheric pressure for summer and

winter seasons and deducing from those crude qualitative pressure maps the likely directions of winds and from them the likely locations of wind-driven coastal upwelling currents back through time (Parrish, 1982; Parrish and Curtis, 1982). Parrish and her colleagues carried out this exercise for seven geological periods in the Mesozoic and Cenozoic (Earliest Triassic (Induan), Late-Early Jurassic (Pliensbachian), Latest Jurassic (Volgian), mid-Cretaceous (Cenomanian), Latest Cretaceous (Maastrichtian), mid-Eocene (Lutetian), and mid-Miocene (Vindobonian)) (Parrish and Curtis, 1982) and seven periods in the Paleozoic (Cambrian, Ordovician, Silurian, Devonian, Carboniferous (Mississippian), Carboniferous (Pennsylvanian), Permian) (Parrish et al., 1983). They found a general correlation between the positions of upwelling currents in their model and the actual locations of organic-rich rocks, phosphorites, and chert (representing silica derived from the dissolution of siliceous planktonic skeletons).

Scotese and Summerhayes (1986) quantified Parrish's conceptual and qualitative approach to paleoclimate modeling by applying numerical algorithms to recreate pressure isobars on maps of past continental positions, from which the location of coast-parallel winds – hence coastal upwelling – could be inferred for winter and summer seasons for the Early Triassic (Induan), Early Jurassic (Pliensbachian), Late Jurassic (Volgian), Middle Cretaceous (Cenomanian), Late Cretaceous (Maastrichtian), Middle Eocene (Lutetian), and Middle Miocene (Vindobonian). Taking the next natural step, Eric Barron applied a full-blown general circulation model to the warm world of the mid-Cretaceous and applied an algorithm to determine where upwelling should have taken place based on his model-generated wind directions (Barron, 1986). His maps of where upwelling was likely to have occurred correspond reasonably well with those hindcast by both Parrish and Curtis (1982) and Scotese and Summerhayes (1986). Paleoclimate maps for the Cenomanian-Turonian showed that upwelling should have been well developed then along the margin of northwest Africa and in the narrow gap between northwest Africa and Guyana and NE Brazil, where we find the most marine organic matter (Barron, 1986; Scotese and Summerhayes, 1986).

These modeling approaches are not ends in themselves, but guides to geological thinking. Just because a paleo-upwelling map suggests that upwelling may have characterized a particular continental margin does not mean that the rocks of the upwelling *triad* will be found there. Other requirements include a sedimentary basin, a limited supply of terrestrial silt and clay, a time of transgression, an oxygen minimum zone, and nutrient-enriched subsurface source waters.

Summary and conclusions

Upwelling currents are driven by the wind and increase in strength as the wind does. They bring up nutrients from below, stimulating productivity in surface waters where winds blow parallel to the coast and where winds blow persistently over the open ocean, especially at the equator and around Antarctica. Upwelling became more prominent in the Late Cenozoic as the world cooled and winds strengthened. It was prominent in the Miocene and has continued to the present, fluctuating from stronger in glacial times to weaker in interglacial times, with a tendency to increase at times of transition from glacial to interglacial. Signs of upwelling are found further offshore during times when sea-level was low. The oxygen minimum zone beneath upwelling centers may become significantly depleted in oxygen, permitting more preservation of organic matter; this is less true of well-oxygenated basins like the Atlantic and more true of poorly oxygenated basins like the North Pacific and Arabian Sea. Upwelling led to the deposition of abundant marine organic matter along the margins of northwest Africa and Guyana during the Cenomanian-Turonian, most likely due to an influx of nutrient-rich and oxygen-poor water from the South Atlantic as Africa and South America moved apart. The deep ocean black shales of oceanic anoxic events are not directly related to upwelling, but may contain abundant organic-rich turbidites derived from continental margins beneath upwelling currents. A by-product of decomposition beneath upwelling centers is the release of phosphate to precipitate as calcium carbonate-fluorapatite or to phosphatize preexisting carbonates, which may progress to the point of forming phosphorites. A further by-product is the deposition of sediments rich in the remains of siliceous diatoms, provided that surface waters have not become depleted in silica. Upwelling is thus frequently recognized in the geological record from an association between organic-rich shales or mudstones, diatomite, and phosphorite, the "signature triad." The absence of organic enrichment may not mean that upwelling was absent – it may reflect either low productivity, due to an inadequate supply of nutrients, or low preservation, due to either an abundance of oxygen or the absence of conditions suitable for the accumulation of fine-grained sediment. The richness of productivity associated with upwelling depends as well upon the source of nutrients in the intermediate depth waters of the adjacent ocean. Predictions of upwelling occurrence and organic enrichment based purely on past wind directions are likely to be overly simplistic.

VOLCANISM AND CLIMATE

Olav Eldholm[1] and Millard F. Coffin[2]
[1]Department of Earth Sciences, University of Bergen, Bergen, Norway
[2]Institute for Marine and Antarctic Studies, University of Tasmania, Hobart, TAS, Australia

Introduction

The impact of volcanism on weather and climate is unequivocally documented by temporal correlations in both historical and prehistorical records. Although volcanic events have been traced far back in time, only Quaternary and Holocene records provide the detail and resolution necessary to address many otherwise ambiguous connections. Both observations and modeling suggest inherent relationships among the geosphere, hydrosphere, cryosphere, and atmosphere, setting the stage for various climate responses commonly incorporating complex feedback loop systems and their elusive dependence on proximity to thresholds. Furthermore, both volcanism and climate may trigger secondary phenomena of sometimes catastrophic nature. The cause-and-effect sequence is particularly intriguing, i.e., whether volcanism forces climate or changing climate forces volcanism or if, in fact, either or both can occur in nature. This overview is based on a number of studies that comprehensively address the overall theme (e.g., Cas and Wright, 1987; Sigurdsson, 1999; Robock, 2000; Schmincke, 2004; Oppenheimer, 2011; McGuire, 2012; Cashman and Sparks, 2013; and references therein).

Volcanic impact

Volcanic impact, V_{imp}, and how it affects Earth system, climate, and human society depend on many factors of which timing, duration, and size are key variables. Qualitatively, it may be expressed as

$$V_{imp} \sim f \ (L, \ T, \ M, \ E, \ C, \ S), \qquad (1)$$

where L is the location, in particular relative to major fluid and gas circulation systems; T is the duration; M is the size, for example, given by the volcanic explosivity index (VEI); E is the mode of eruption, i.e., explosive or effusive; C is the ash, gas, and lava composition; and S is the state of societal development. However, relatively large uncertainties in some parameters may preclude assessing volcano-climate relationships at a high confidence level in the geological past. In addition to Eq. 1, the complex relationship of volcanism to environmental change is greatly contingent on the relative abundances of volcanic products (lava, ash, pyroclastics, volatiles, etc.) and their respective physical and chemical properties and on the eruption mode and setting, of which the explosive and effusive eruption processes and submarine and subaerial settings may be considered end-members, respectively.

Short-term volcanic climate forcing is well documented, and even relatively small events may not only cause severe local disturbance and devastation but also have regional and sometimes global impact. Two Icelandic events illustrate such forcing; the 2010 Eyjafjallajökull eruption, which did not have a climatic impact, caused regional havoc on modern air traffic, grounding more than 100,000 flights; the loss to aviation alone has been put at §250 million per day (Gudmundsson et al., 2010; Robock, 2013). The 8-month-long 1783–1784 Laki
Volcanism and Climate, Figure 1 Schematic diagrams showing (**a**) key environmental effects of volcanism, shown in a LIP setting, indicating how eruptions may significantly perturb the Earth system (modified from McCormick et al. (1995) and Coffin et al. (2006)). Note that many present submarine LIPs are formed in subaerial and shallow marine environments. *EX* extrusive. (**b**) The classical chicken-and-egg conundrum. Note that both causal paths may act simultaneously. (**c**) Extent, shown in *red*, and rate of extrusive magma, in *blue*, erupted during formation of the North Atlantic LIP. Adjacent sedimentary basins also commonly contain lava, dike, and volatile expulsion features.

fissure basalt eruption caused a cold spell, thousands of deaths of both humans and animals, and famine also in Europe and beyond (Vasey, 1991). Moreover, the well-monitored 1991 silicic explosive eruption of Pinatubo in the Philippines provides clear evidence for its impact on global temperature, wind, and precipitation patterns. Globally, an average temperature anomaly of $-0.5\ ^{\circ}\mathrm{C}$ is inferred that lasted for about 2 years (McCormick et al., 1995).

Eruptions may trigger secondary phenomena with links to climate as well, specifically by changing or modifying oceanic circulation patterns by forming and destroying marine barriers and gateways. Nonetheless, the greatest impact arises from atmospheric modifications caused by the largest eruptions. Climate forcing is inferred from historic eruptions, but they are dwarfed by some gigantic, cataclysmic effusive and explosive eruptions, from commonly denoted supervolcanoes, at irregular intervals farther back in the geological record. An example is the Toba eruption at $\sim$74 ka (Rampino and Self, 1992). These huge events are relatively rare, approximately two events each 100 kyr since 2 Ma. The most recent one was Taupo in New Zealand, at 26.5 ka ago. Many supervolcanoes are associated with mantle plumes as are the large igneous provinces (LIPs) (Coffin and Eldholm, 1994). Thus, single eruptions of individual volcanoes (e.g., Eyjafjallajökull) and supervolcanoes (e.g., Toba) or cumulative multiple eruptions within a limited time period may force climate change.

Atmosphere processes

Climate is directly linked to the heat budget of the Earth's atmosphere and oceans which is governed by astronomical parameters, solar activity, insolation, and albedo. In turn, both natural and anthropogenic sources and processes modify the budget. Volcanic climate forcing depends largely on the amount and composition of volcanic gas, a minor magma component, injected into the atmosphere. The most important gases are SO_2 and other sulfur compounds and the "greenhouse" gas CO_2 (Figure 1a). In fact, much sulfur gas, in particular SO_2, has a volcanic origin, and present and past volcanic eruptions have had a significant impact on chemical and radiative properties and the energy budget of the atmosphere.

The volcanic record and measurements from space show that eruptions may affect areas far from the source, modifying climate for several years. Their impact depends primarily on the state and composition of the volcanic constituents, the amount of sulfur injected into the stratosphere, and to which atmospheric level the volcanic plume, carrying particulates and gases, extends. In particular, the stratosphere, above $>\sim$10–20 km and lowest at high latitudes, appears sensitive to the physical-chemical properties of volcanic products, affecting the insolation properties and thereby the atmospheric temperature. However, SO_2 and CO_2 modify climate in opposite ways, inducing cooling and warming, respectively. There is much uncertainty about highly variable volcanic CO_2 fluxes and how they affect atmospheric CO_2

concentrations, the role of positive and negative feedbacks, and the intricacies of modeling complex and coupled systems. The quantity of particulates, on the other hand, plays a minor role as they leave the stratosphere in a few months. Moreover, explosive eruptions may also induce changes in atmospheric and oceanic circulation patterns, in precipitation, as well as depletion of the stratospheric ozone layer.

Large events, such as the Toba eruption, may be an efficient mechanism for injecting SO_2 and other sulfur gases into the stratosphere where they interact with atmospheric water vapor yielding a veil of sulfuric acid aerosols that spread globally and affect solar radiation, thus cooling the Earth's lower atmosphere (McCormick et al., 1995). This process is supported by the correlation of eruption events and volcanic sulfate in ice cores (e.g., Abbott and Davies, 2012). Although particulates leave the stratosphere within some months, acid aerosols can persist for several years, spreading out over large parts of the Earth.

Basaltic and trachyandesitic magmas contain far more sulfur than highly differentiated magma, but the eruption rates are commonly too low for stratospheric injection, in contrast to large silicic explosive eruptions that can rapidly inject considerable amounts of SO_2 into the stratosphere. The net amounts depend on the eruption frequency and intensity. Nonetheless, large explosive eruptions, large fissure basalt eruptions, and smaller events of sulfur-rich magma may form ash and aerosol clouds at high altitudes (Self and Rampino, 1988). Although much interest has been directed toward the great silicic explosive eruptions, the Laki eruption and more abundant sulfur in mafic magmas suggest that the atmosphere is also affected by fissure basalt events generating convective plumes reaching the stratosphere, in some cases leading to a wide-ranging "volcanic winter" (Stothers et al., 1986).

The chicken-and-egg conundrum

That volcanism which can drive climate at irregular intervals is documented both by ice cores on Earth and measurements of volatile veils in the stratosphere. On the other hand, observational data also point toward a converse process forcing or modifying the volcanic behavior, i.e., an environmental driver. In fact, changes in lithospheric stress and melt potential and opening of melt pathways appear to govern the process. The postglacial period, in particular, provides evidence for feedbacks of this kind, the most obvious candidate being deformation of the lithosphere by on- and off-loading of large ice sheets (e.g., Maclennan et al., 2002; Schmidt et al., 2013). If eruptions change or modify climate, which in turn has the potential to initiate eruptions, the stage is set for chicken-and-egg scenarios where potential feedback loops and thresholds may yield complex responses (Figure 1b). In fact, only minor external environmental change may be required to trigger a volcanic system that is primed and ready to go.

This setting is typified by two opposite feedback mechanisms (McGuire, 2012). In a cooling world, falling sea-level may result in a positive feedback inducing explosive volcanism that furnishes the stratosphere with SO_2 droplets, thus accelerating cooling, which in turn may lead to new eruptions reinforcing the trend. Conversely, a negative feedback in a warming world with melting ice sheets and rising sea-level may also promote volcanism, also via SO_2 aerosols injected into the stratosphere, resulting in cooling opposing the warming trend.

On the other hand, Huybers and Langmuir (2009) proposed that volcanic events during major climate change inject large amounts of CO_2 into the atmosphere due to enhanced volcanic activity, counteracting the cooling of the SO_2 aerosols. They suggested that the two- to sixfold early Holocene global increase in subaerial volcanism increased atmospheric CO_2 resulting in a positive feedback accelerating warming during deglaciation. Nonetheless, the fact that the amount of CO_2 expelled during most eruptions is small or even insignificant appears to favor that cooling due to emitted SO_2 dominates CO_2-induced warming.

The environmental geosphere driver

As lithospheric stresses change, spatially and/or temporally, the geosphere may deform abruptly or gradually over time. Climate change is an instigator of deformation, principally by water and ice load changes. Data from different regions of active volcanism show enhanced volcanic activity during high rates of sea-level change (McGuire, 2012). Furthermore, removal of large ice masses may induce pressure-release melting and create magma pathways to the surface. The most important observation is that only a small change in loading rate may trigger an eruption, suggesting that the volcano system is approaching a threshold level. A similar, but more elusive, relationship appears to exist between load changes and seismicity.

Early Holocene time offers the opportunity to study lithospheric deformation and volcanic activity in Iceland when a warming climate shifted significant loads from continent (ice) to ocean (water), contributing to the ~130 m sea-level rise since the last glacial maximum at ca. 20 ka. Both data and numerical modeling support intense early Holocene volcanism resulting from glacial unloading of the lithosphere in conjunction with local tectonic features. Warming reduced the ice load on subglacial volcanoes and thereby decreased pressure in the magmatic systems, which encouraged both melting and magma chamber failure, i.e., a climate-volcanism link (Sigmundsson et al., 2010). Thus, mantle melting and magma upwelling are amplified by the pressure reduction due to glacial unloading. We also note that Kutterolf et al. (2013) suggest that circum-Pacific volcanism appears to lag slightly behind the obliquity band of Milankovitch cycles, consistent with a climate link.

Despite incomplete understanding of processes, it appears that deformation of the geosphere within the loaded/unloaded areas and surrounding lithospheric compensation comprises a common denominator for initiating earthquakes, as well as for allowing magma ascent and eruption, yielding volcanism that may contribute to climate change on multiple scales. Thus, the geosphere is a major player in the complex climate system.

The LIP contribution

While LIP formation clearly has affected local and regional environments, its potential global impact is less well understood despite temporal correlations between LIPs and environmental changes (Coffin et al., 2006) that suggest, but do not prove, causal relationships. Detailed studies have tended to focus on the continental flood basalt LIP category due to their relative accessibility, whereas submarine LIPs such as oceanic plateaus and volcanic margins have been less investigated despite their huge dimensions. A primary challenge is to estimate the spatial and temporal budget of volcanism within a given LIP, particularly eruption and emission rates. Some of the largest LIPs appear to have had a protracted history of volcanism from many volcanoes and fissures, but the most massive eruptive period was relatively short lived, possibly 0.5 Ma or less (Figure 1c), producing voluminous basaltic lavas erupted in predominantly subaerial and/or shallow marine environments.

The temporal correlations include eruption of the Siberian flood basalts at 250 Ma, which coincides with the largest biotic extinction in the geological record. During the 145–50 my period, LIPs have been linked to several changes in the global ocean, episodic formation of black shale during oceanic anoxic events being one example. Moreover, the huge submarine basaltic constructions of the North Atlantic LIP have led to suggestions of potential causal links to the early Eocene greenhouse (Eldholm and Thomas, 1993; Svensen et al., 2004; Storey et al., 2007).

A causal link to global climate should consider that (1) voluminous eruptions of basaltic magma release volatiles such as sulfur, chlorine, and fluorine (Figure 1a), and their amounts and relative proportions depend strongly on whether eruptions are subaerial or submarine. (2) The volatiles remain in the troposphere during most basaltic eruptions. However, convective plumes from large single events and the mainly basaltic magma may carry SO_2 and other volatiles into the stratosphere forming a mist of SO_2 aerosol droplets. Self et al. (2005) infer that the Deccan flood basalts emitted gas fluxes of ~1 Gt/year of SO_2 and CO_2 and that the subsequent atmospheric cooling from SO_2 aerosols of only one flood basalt eruption may have been severe, persisting for a decade or more. On the other hand, they considered CO_2-induced warming during an eruption as insignificant. Thus, LIPs may impact the global environment in a manner similar to more silica-rich eruptions, at least at low stratospheric levels at high latitudes. (3) The construction and the subsidence history of submarine LIPs may form barriers and/or open gateways that affect oceanic circulation which in turn may force climate.

Summary

Incontrovertible evidence for causal connections between volcanism and climate extends far back in Earth history. In particular, the link is well established for Holocene time. On the other hand, climate change or major transient climate events may also initiate episodic and protracted volcanism, commonly associated with lithospheric loading and unloading. Both mechanisms document an intimate interplay among the geosphere, hydrosphere, cryosphere, and atmosphere. Cause-and-effect relations incorporate complex feedback loops, not yet fully understood, but which may become increasingly efficient during an environmental threshold situation because active volcanoes are unstable systems quite sensitive to small changes in their external environment. The volcano-climate link may also initiate secondary events, some catastrophic. Depending on the state of societal development, volcanism may at times have inflicted severe climatic strain on human societies affecting food supply, living conditions, and, in cases, migration patterns.

Seafloor Massive Sulfides

Definition

Volcanogenic Massive Sulfides. Accumulations of dominantly sulfide minerals that form at sites of focused hydrothermal discharge on the seafloor. Also refers to a class of ore deposit mined from ancient oceanic crust that is now exposed on land.

Introduction

Volcanogenic massive sulfide (VMS) deposits are mineral accumulations that form on or near the seafloor at sites of high-temperature hydrothermal vent fluid discharge. The deposits are formed by the precipitation of dominantly sulfide minerals around hydrothermal vents (e.g., Black and White Smokers) where high-temperature, metal- and sulfur-rich fluids mix with cold seawater. VMS deposits commonly form along submarine tectonic plate boundaries such as mid-ocean ridges and subduction-relating settings such as volcanic arcs and back-arc basins Although high-temperature "black smoker" chimneys are the most recognizable features, the deposits can take on a variety of forms, from individual chimneys to large mounds that host clusters of active chimneys. At the time of writing, more than 300 sites of high-temperature seafloor hydrothermal systems and related mineral deposits have been found (Figure 1).

Hydrothermal vents, first discovered on the East Pacific Rise spreading center (Francheteau et al., 1979), provided the first direct evidence of the formation of VMS deposits on the modern seafloor. However, the notion of sulfide deposits forming on the seafloor existed among economic geologists long before their discovery. By the late 1970s, many of the details of massive sulfide formation in the submarine environment had already been established from the study of fossil VMS deposits that are hosted in ancient oceanic crust now exposed on land. These ancient deposits have been mined since the time of the ancient Greeks and continue to be an important source for metals such as Cu, Zn, Pb, Au, and Ag. Volcanogenic massive sulfides that are forming on the modern seafloor may represent a

Volcanogenic Massive Sulfides, Figure 1 Global distribution of seafloor hydrothermal systems and related mineral deposits (from Beaulieu, 2013).

significant marine mineral resource for these metals that, unlike their ancient counterparts, have yet to be exploited.

Formation of volcanogenic massive sulfides

Volcanogenic massive sulfide formation is linked to circulation of hydrothermal vent fluids through oceanic crust at volcanically active areas on the seafloor. Large deposits typically consist of a consolidated basal mound of massive sulfide, overlain by hydrothermal crusts, sulfide talus from collapsed black and white smoker chimneys, and metalliferous sediment, and underlain by a metal-bearing subseafloor stockwork (vein and disseminated mineralization) within the underlying crust (Figure 2). The black and white smoker chimneys that often occur on the top and flanks of deposits only represent the uppermost part of a typical deposit and account for only a small fraction of the total amount of sulfide present on the seafloor. Different vents on the same mound are usually fed by the same high-temperature fluids at depth, with the venting temperatures mainly controlled by the degree of subseafloor mixing of the ascending high-temperature (∼350 °C) fluids with local cold (∼2 °C) seawater. When little to no subseafloor fluid mixing occurs, a large proportion of the dissolved metals in the venting fluids are lost to the hydrothermal plume in the overlying water column via high-temperature venting (Figure 2). Fluids that vent at lower temperatures due to subsurface mixing are commonly clear and lack the mineral-rich "black smoke" appearance often seen in high-temperature fluids. In this case, the decreased temperature has resulted in the precipitation of sulfide minerals prior to venting and the accumulation of sulfide material within the sulfide mound or below the seafloor.

The hydrothermal upflow zones below deposits typically contain intensely altered rocks with vertically extensive networks of sulfide veins and disseminated sulfides, referred to as the "stockwork zone" (Figure 2). Stockwork mineralization can contain as much as 30–40 % of the total metal in a deposit, confirming that a large proportion of the metal in the hydrothermal vent fluids never reaches the seafloor. The main alteration minerals are quartz, chlorite, sericite, and illite. In most cases, the alteration causes the rocks surrounding the discharge zone to become insulated, sealing the system against the ingress of seawater and allowing higher-temperature fluids to reach the seafloor without significant mixing with local seawater. Abundant anhydrite is also found within some feeder zones, precipitated from the progressive heating of seawater that is drawn into the mound beneath the hydrothermal vents. Lenses of massive sulfide can form, via subseafloor replacement, within permeable zones in the volcanic substrate, such as interflow breccias, hyaloclastite, or sediments.

The loss of metals to hydrothermal plumes means that the efficiency of metal deposition within deposits is very low in most cases. As a result, special conditions and/or very long periods of hydrothermal upflow are required to form large deposits. Radioisotope ages of hydrothermal

Volcanogenic Massive Sulfides, Figure 2 Cross-section through a typical active volcanogenic massive sulfide mound on the seafloor. As high-temperature hydrothermal fluid ascends to the seafloor, it mixes with local cold seawater, resulting in the precipitation of sulfide minerals and formation of chimneys and mounds on and below the seafloor. *Py* pyrite, *Cpy* chalcopyrite, *Sp* sphalerite, *Po* pyrrhotite, *Gn* galena, *Anh* anhydrite, *Ba* barite.

samples from some deposits, based on uranium-series disequilibrium measurements (e.g., using U/Th and ^{226}Ra/Ba), indicate that tens of thousands of years are required to form the largest accumulations of massive sulfide on the mid-ocean ridges.

Where do VMS deposits form?

Most hydrothermal activity and associated VMS formation are found at plate margins, where a strong spatial and temporal correlation exists between magmatism, seismicity, and high-temperature venting (Figure 1). The divergent plate boundaries include both mid-ocean ridges and intracontinental rifts such as the Red Sea. Convergent plate boundaries, which are characterized by volcanic arcs and back-arc basins that develop as a result of subduction of oceanic plates beneath oceanic crust or continental margins, are host to a smaller but still significant proportion of the known hydrothermal deposits.

On the mid-ocean ridges, the number and distribution of seafloor hydrothermal deposits is roughly proportional to spreading rate. Sulfide accumulations on the fast-spreading ridges tend to be abundant but small; fewer deposits are located on the slow-spreading ridges, but they are commonly larger and more robust. The lack of known vents along many stretches of mid-ocean ridge (e.g., the Polar Regions and the Southern Ocean, Figure 1) mainly reflects the difficulties of marine research at these latitudes. Recent discoveries of hydrothermal plumes and massive sulfide deposits in the high Arctic (Michael et al., 2003) and in Antarctica (e.g., Bransfield Strait) (Klinkhammer et al., 2001) confirm that seafloor hydrothermal activity in remote parts of the oceans is similar to that observed elsewhere. The distribution of deposits along volcanic arcs and back-arcs is largely similar to those along the mid-ocean ridges.

The composition of VMS deposits

The composition of VMS deposits is primarily controlled by the composition of the hydrothermal vent fluids from which they form. Differences in the composition of hydrothermal vent fluids largely reflect variations in the

composition of the underlying volcanic substrates from which the dissolved metals and sulfur in the fluids are leached. Slow- and fast-spreading ridges are generally underlain by mid-ocean ridge basalt (MORB). In contrast, convergent margins are characterized by a range of different crustal thicknesses, heat flow regimes, and magma compositions, depending on the composition and geometry of the converging plates. As a result, the compositions of the volcanic rocks at convergent margins vary from MORB to more felsic lavas (andesite, dacite, and rhyolite), and this leads to major differences in the composition of the hydrothermal vent fluids, the isotopic systematics, and the mineralogy and bulk composition of the sulfide deposits. The composition of VMS deposits can also be influenced by direct magmatic volatile contributions to the hydrothermal fluids, especially in arc and back-arc settings (Yang and Scott, 1996).

The mineralogy of VMS deposits consists of a high-temperature ($\sim$350 °C) mineral assemblage of Cu, Fe, and Zn sulfide minerals including pyrite ($\pm$marcasite), pyrrhotite, chalcopyrite, Fe-rich sphalerite, as well as minor isocubanite and bornite and the sulfate mineral anhydrite (Figure 2). A lower-temperature (<300 °C) mineral assemblage is dominated by pyrite, marcasite, sphalerite, and minor galena and sulfosalts, together with abundant amorphous silica, barite, and minor anhydrite.

A strong mineralogical zonation within VMS deposits reflects the temperature-dependent solubilities of the sulfide minerals in the cooling hydrothermal vent fluids, with high-temperature minerals (e.g., chalcopyrite, pyrrhotite) occupying the core of a deposit and lower-temperature minerals (e.g., pyrite, sphalerite) occurring toward the top and fringes of a deposit. However, detailed examination reveals complex intergrowths, replacements, and recrystallization of the minerals within VMS deposits, resulting from a dynamic and locally complex environment of sulfide precipitation.

The depth at which a deposit forms can also have an effect on composition. At the average depth of known vent sites (2,600 m), most hydrothermal vent fluids at 350 °C are below the boiling temperature of seawater. However, about one third of known seafloor hydrothermal vents occur at depths of less than 1,500 m, where boiling of the fluids is likely to occur. The resulting phase separation can be responsible for important differences in the chemistry of hydrothermal vent fluids at different locations as different elements partition into either the vapor or brine phase, and these have a major impact on the mineralogy and chemistry of the sulfide deposits.

Average metal concentrations of deposits on the mid-ocean ridges are 5.9 wt% Cu, 6.1 wt% Zn, <0.1 wt% Pb, 1.6 ppm Au, and 89 ppm Ag (Table 1). Although anhydrite, barite, and amorphous silica are important constituents, on average Ca, Ba, and SiO2 account for <20 wt% of the samples analyzed. Hydrothermal sulfide deposits in volcanic arc and back-arc settings have elevated Zn, Pb, Au, and Ag concentrations, relative to mid-ocean ridge deposits, reflecting the typically more

Volcanogenic Massive Sulfides, Table 1 Average bulk compositions of 95 VMS deposits by tectonic setting (From Hannington et al., 2010)

Location	(n)	Cu wt%	Zn	Pb	Au ppm	Ag

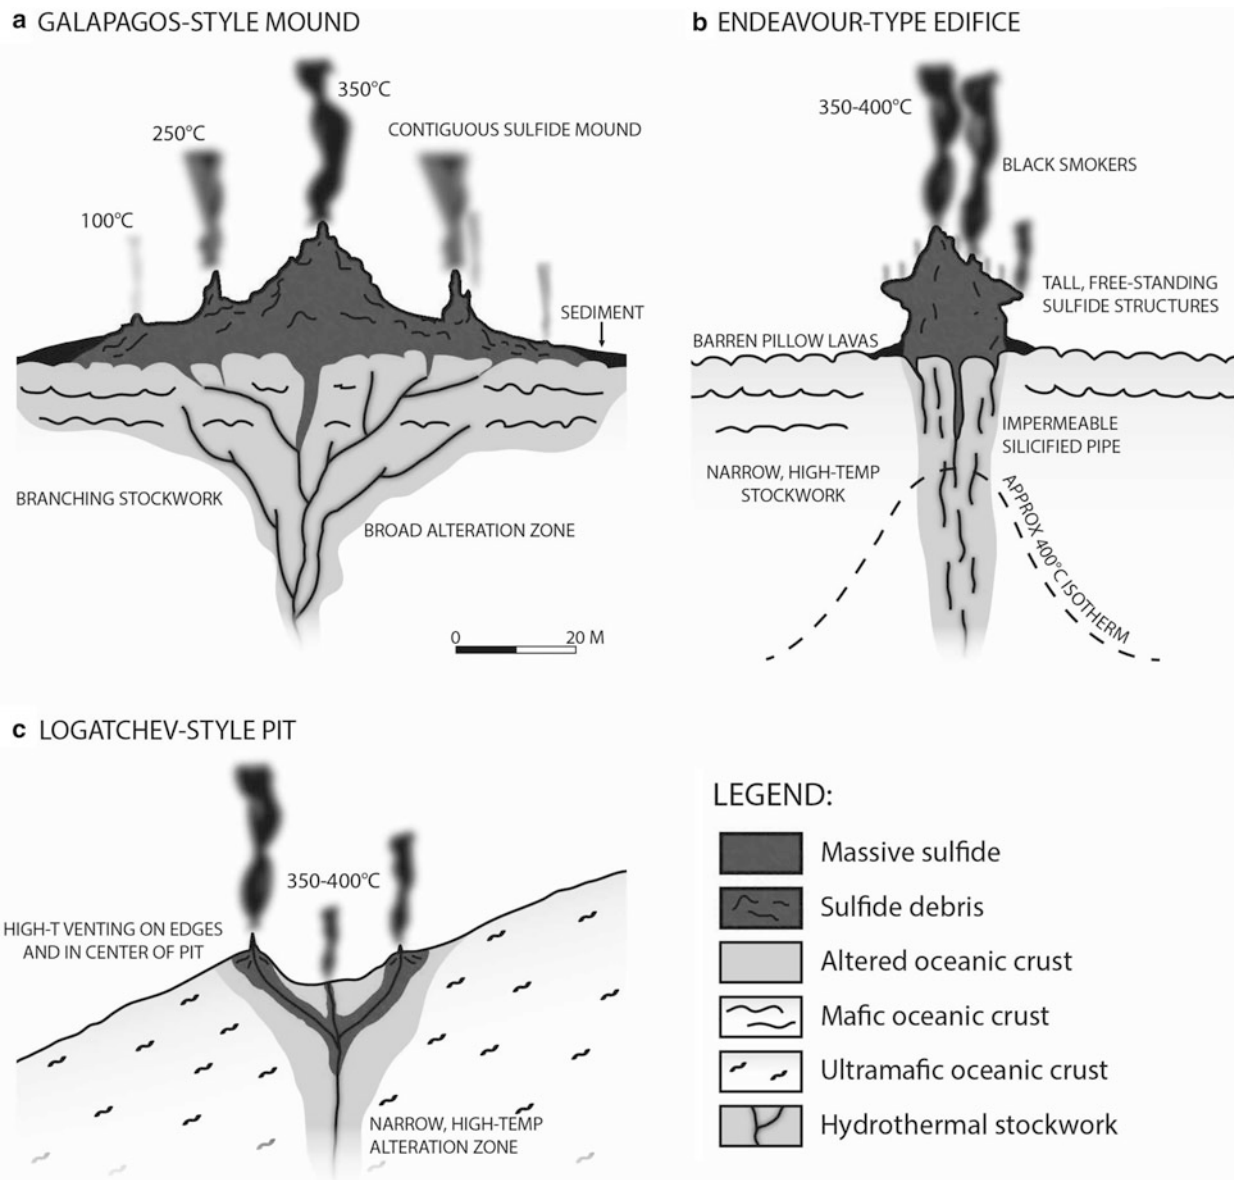
n numbers of samples
[a]Data for the mid-ocean ridges are based on deposits for which there are representative suites of 50 samples or more

evolved magmatic compositions in arc settings and potential magmatic contributions.

Metal distribution within individual deposits is directly linked to the temperature-dependent mineralogical controls described above. For example, Cu is typically enriched in the high-temperature, chalcopyrite-rich zones, whereas Zn and Pb are enriched in the lower-temperature sphalerite- and galena-rich zones (Figure 2). The distribution of trace elements in VMS deposits generally follows similar temperature-controlled distribution, with Co, Se, Bi, and Mo commonly enriched in high-temperature zones within a deposit and Cd, Pb, As, Sb, and Ag enriched in lower-temperature zones.

The size of VMS deposits

Volcanogenic massive sulfide deposits on the seafloor can range from several meters up to 100 s of meters in diameter. The size of a deposit is controlled by a combination of the length of time for which the hydrothermal system is active, the total flux of hydrothermal vent fluids through the system, the concentration of metals and sulfur in the fluids, and the efficiency of deposition (i.e., how much of the mobilized metals is retained within the deposit versus ejected as "smoke" into the overlying hydrothermal plume).

Several distinct deposit morphologies have been recognized. These morphological differences likely reflect the geometry of the hydrothermal upflow and especially the permeability of the crust in the upper few hundred meters below the seafloor (Figure 3). Large-diameter, low-relief mounds (e.g., the TAG site on the Mid-Atlantic Ridge or the Galapagos sulfide mound, in the eastern Pacific) are seafloor manifestations of widespread, branching feeder systems (Figure 3a), whereas tall, free-standing structures (e.g., up to 45 m in height within the Endeavour vent fields on the Juan de Fuca Ridge in the NE Pacific) reflect highly focused, high-temperature upflow (Figure 3b) (Embley et al., 1988; Robigou et al., 1993). Deposits hosted in ultramafic rocks on slow-spreading ridges can form


Volcanogenic Massive Sulfides, Figure 3 Illustration of contrasting volcanogenic massive sulfide deposit morphologies resulting from different permeabilities in the substrate. (**a**) Galapagos-type structures are low-relief mounds with a broad base. (**b**) Endeavour-type structures are steep sided and form over a narrow, restricted upflow zone. (**c**) Logatchev-style pits form in ultramafic settings. Donut-shaped structures have elevated rims consisting of a mixture of sulfide and host rock and host active high-temperature chimneys (modified from Hannington et al., 1995).

low-relief, donut-shaped depressions with elevated rims containing a mixture of sulfide and host rock (Figure 3c). A substrate with high porosity (e.g., volcanic breccias or sediments) may result in a significant amount of sulfide precipitation below the seafloor, forming stratabound sulfide lenses, and only a limited expression of hydrothermal venting at the seafloor.

The largest deposits so far discovered on the seafloor are up to several hundreds of meters in diameter and have total masses on the order of 1–5 million tonnes

(Hannington et al., 2010). Reliable estimates of the total sulfide accumulation in large deposits have been possible in only a few cases where subseafloor drilling has provided information on deposit thicknesses (e.g., the TAG mound on the Mid-Atlantic Ridge, Middle Valley on the Juan de Fuca Ridge, and Solwara I in the Manus Basin), although developments in geophysical methods such as deep-towed magnetics and electromagnetic surveys are providing additional tools for measuring deposit sizes.

The largest deposits are all at least 100,000 years old (Hannington et al., 2010), implying that sustained hydrothermal venting over long periods is required to produce significant accumulations of massive sulfide at the seafloor. Hannington et al. (1998) estimated a growth rate for the main massive sulfide lens (2.7 million tonnes) at the TAG site on the Mid-Atlantic Ridge of about 500–1,000 tonnes/year. Similar growth rates have been estimated for other large deposits on the Mid-Atlantic Ridge (e.g., Logatchev, Ashadze, and Krasnov), based on the maximum ages and estimated tonnages of the deposits.

The relatively smaller sizes of most deposits discovered so far are likely related to the short-lived nature of their heat sources, which include narrow dike injections along the axial zones of the ridges. This is confirmed by uranium-series measurements indicating that hydrothermal discharge at fast-spreading centers is episodic on time scales of only 10–100 years (Lalou et al., 1993). By contrast, the protracted history of hydrothermal venting at places like TAG is a consequence of deep-seated magmatic activity followed by long periods of cooling and release of heat from depth. These deposits are situated in stable structural environments with relatively slow rates of spreading, far from the axis of the ridge. On sedimented ridges, like Middle Valley, long-term heat retention afforded by a thick sediment cover also may contribute to the large sizes of the deposits. Deposits on back-arc spreading ridges are thought to be comparable to deposits on mid-ocean ridges, with a similar relationship between size and spreading rate. Deposits on the summits of arc volcanoes are generally smaller, likely reflecting the small, shallow magma chambers and short-lived, episodic volcanic events that drive circulation (Hannington et al., 2005).

Summary

Volcanogenic massive sulfide deposits form on the seafloor as the result of mixing of hot hydrothermal fluids, rich in dissolved metals and sulfur, with cold seawater as the fluids ascend to the seafloor from deep within the underlying crust. The sulfide minerals that accumulate at these vent sites form spires (chimneys) or mounds that grow and coalesce over time. These sulfide edifices provide a substrate on which the macro- and microfauna that thrive on the hydrothermal fluids for sustenance live. VMS deposits are found along submarine tectonic boundaries, such as mid-ocean ridges, volcanic arcs, and back-arc basins. The deposits are often rich in economically valuable metals such as Cu, Zn, Au, and Ag. Although, at the time of writing, no direct exploitation of VMS deposits from the modern seafloor has occurred, with recent technological developments and elevated metal prices, the desire and feasibility to exploit seafloor

deposits are such that exploitation of these deposits may occur in the near future.

Definition

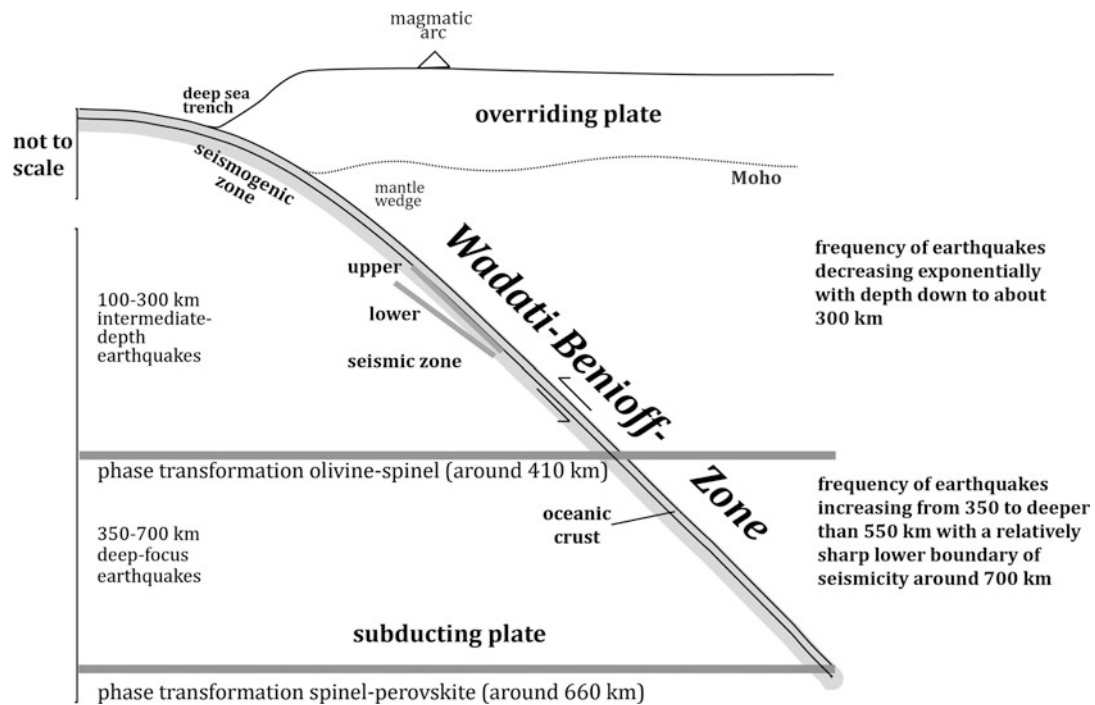
Inclined thin planar zone of seismicity down to depths of about 700 km resulting from processes related to the subduction of an oceanic plate including interaction of descending and overriding plate.

Introduction

About three quarters of all tectonic earthquakes, both along all types of plate boundaries and in various intraplate environments, initiate at shallow depth of less than about 60 km. Among them are the largest earthquakes with M_w larger than 9, which solely occur in the seismogenic zone, the shallow portion of the plate interface in subduction zones. The remaining quarter of tectonic earthquakes occurs in depths deeper than about 60 km and as deep as close to 700 km. These deep earthquakes are nearly exclusively identified along inclined narrow zones of intraplate seismicity within the downgoing oceanic plate in subduction zones, the so-called Wadati-Benioff zones (Figure 1).

Downgoing oceanic slabs exhibit an unusually cold and complex thermal structure with steep temperature gradients to the surrounding lithosphere and uppermost mantle. Therefore, large portions of slabs remain beneath about 600 °C, a temperature, which seems to provide an upper limit for earthquakes to occur (e.g., Emmerson and McKenzie, 2007). Thus, e.g., the age and convergence rate-dependent thermal structure of subduction zones may explain the different cutoff depths of seismicity. However, deep earthquakes are not evenly distributed with depth, but bimodally. They strongly decrease in frequency down to about 300 km and then increase again in number with a maximum around 600-km depth and a relatively sharp lower boundary of their occurrence at about 700 km (Figure 1b). Further, many subduction zones show prominent gaps of deep seismicity. These observations suggest that earthquakes in different depth intervals may be due to different causes (e.g., Rayleigh and Paterson, 1965; Kirby et al., 1991; Kikuchi and Kanamori, 1994; Peacock, 2001; Jung et al., 2004; Kelemen and Hirth, 2007). Although detected in almost every subduction zone by now, deep earthquakes are not evenly distributed spatially. More than 60 % of all earthquakes deeper than 300 km have been recorded in the Tongan subduction zone, where they occur along the entire depth interval (e.g., Frohlich, 2006).

Deep earthquakes seem to be smaller in size than shallow earthquakes. The strongest instrumentally recorded deep earthquakes, the 1994 Bolivia (Kikuchi and Kanamori, 1994) and 2013 Okhotsk (Ye et al., 2013) deep events, had magnitudes of M_w 8.3. Since about 1950, there have only 13 $M_w \geq 7.5$- and three $M_w > 8$-deep seismic events been recorded.

Besides their larger depth, compared to shallow earthquakes, surface waves of deep earthquakes are considerably weaker or even absent, and often they do not have numerous aftershocks. However, stress drop associated with deep earthquakes mostly is considerably higher than for even very large shallow earthquakes (Frohlich, 2006). As deep earthquakes occur at high pressure and temperature, brittle failure most probably is not likely the cause. As the state of stress and ambient pressures and temperatures in the depth intervals of about 60–300 km, where intermediate-depth earthquakes occur, and deeper than about 350 km, where deep-focus earthquakes occur, differ significantly, seismic events in the two depth intervals probably have different causes. In an ongoing hot debate, since some decades, dehydration embrittlement (Rayleigh and Paterson, 1965) and phase transitions (e.g., Kirby


Wadati-Benioff-Zone, Figure 1 Unscaled schematic sketch of the Wadati-Benioff zone illustrating the environment of deep seismicity.

et al., 1991) are most widely discussed as major causes of deep earthquakes. However, stresses in a downgoing oceanic plate are also strongly influenced by bending and unbending. Therefore, these processes also may aid in generating intermediate-depth seismicity (Wang, 2002).

In the following, after a brief historical outline highlighting the important contributions of Kiyoo Wadati and Hugo Benioff to research on deep seismicity, first, the occurrence and potential causes of intermediate-depth earthquakes will be reviewed, followed by a review of deep-focus earthquakes. The Japanese subduction zones (Figure 2a) and Nazca plate subduction beneath South America (Figure 2b) serve as case studies both because Wadati and Benioff focused on these and they exert several of the most important features of Wadati-Benioff zones, South America also being the location of unusually many of the largest instrumentally recorded deep earthquakes. Tonga (Figure 2c), finally, results from fast subduction of the approximately 110-Myr-old Pacific plate and shows patterns of deep seismicity significantly different from those of the other subduction zones.

The historical contribution of Kiyoo Wadati and Hugo Benioff

In the 1920s, the discussion among leading geophysicists was centered on the question of the depth extent of earthquake occurrence and their characteristic seismic waves. Between 1928 and 1935, Kiyoo Wadati, a young scientist working at the Central Meteorological Observatory in Tokyo, published several papers (e.g., Wadati, 1928, 1931) in which he clearly showed the occurrence of earthquakes at all depths down to at least 500 km using the time interval between P- and S-waves arrivals. He then also suggested classifying earthquakes into shallow, intermediate-depth, and deep-focus events in the way this classification is still used today. Further, Wadati noted that deep earthquakes occur along inclined planes and might be related to continental drift (Wadati, 1935) long before plate tectonics was accepted and the presence of subduction zones was confirmed.

Hugo Benioff's main expertise was on the relation between earthquakes and motion along faults; however, using Gutenberg and Richter's seismic catalog, he synthesized the available information on Circum-Pacific deep earthquakes with a focus on South America. From this, he proposed the inclined thin zones of seismicity to represent boundaries between oceanic and continental material with their sharpness resulting from the different densities of these materials (Benioff, 1949). This hypothesis greatly influenced thinking leading to the formulation of the plate tectonics theory and its acceptance (Frohlich, 2006).

Since about the 1970s, the zones of intermediate-depth and deep-focus seismicity have been called Wadati-Benioff zones (WBZ) to acknowledge the important contributions of both scientists to our understanding of deep seismicity and also plate tectonics (Frohlich, 2006).

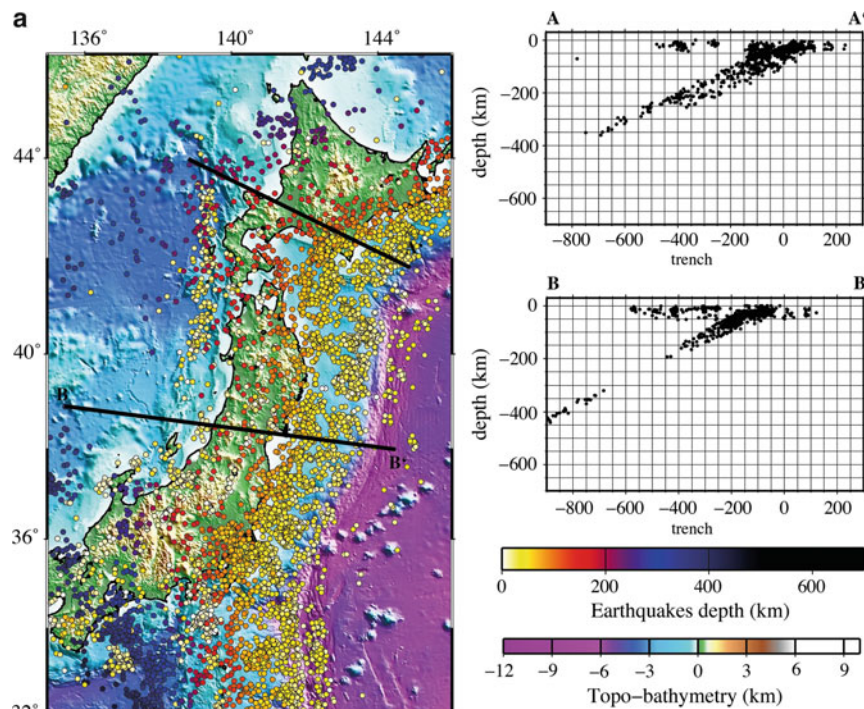
The characteristics and causes of deep earthquakes

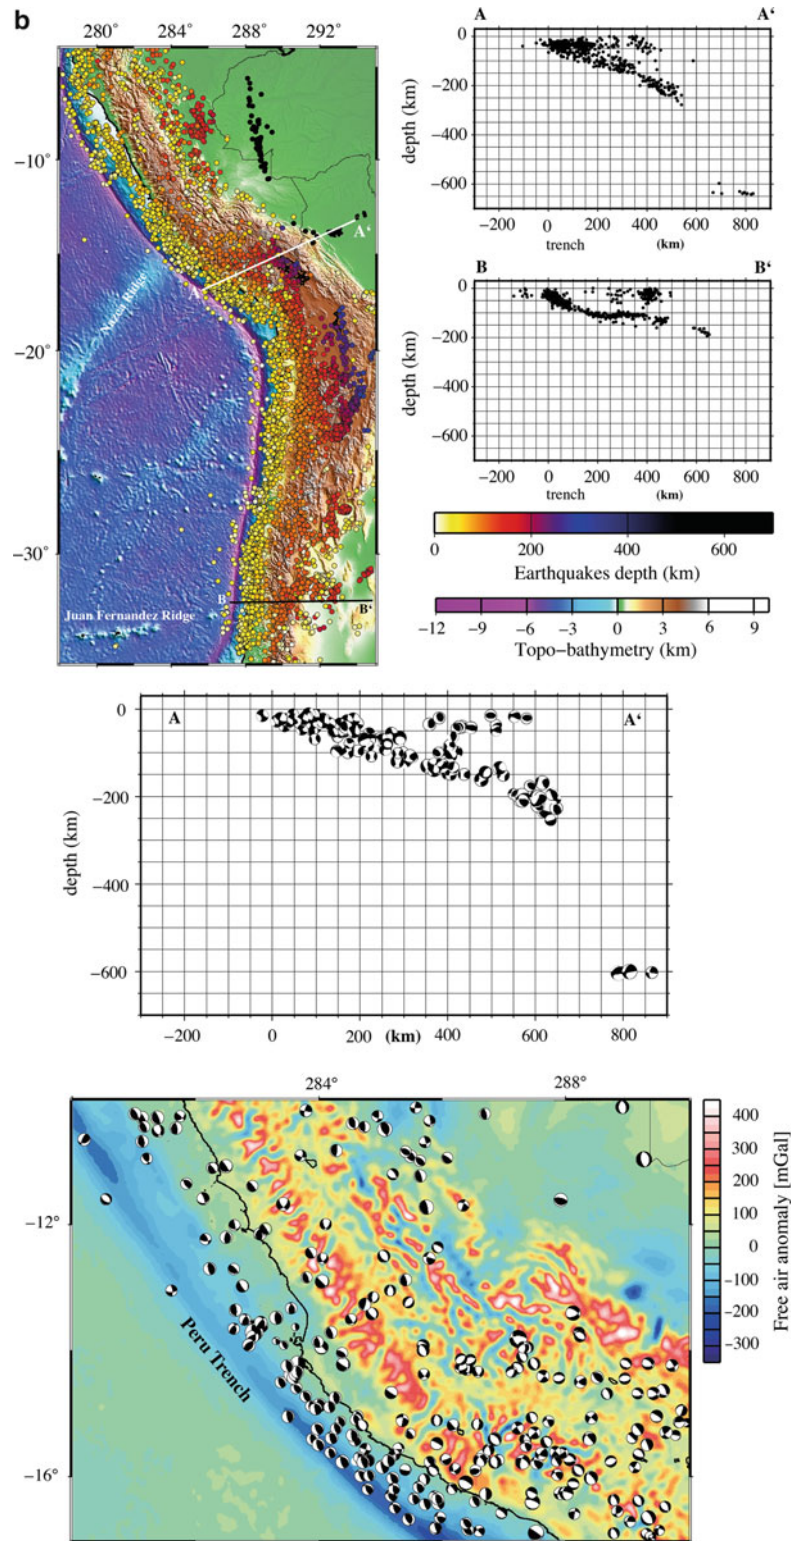
Deep earthquakes with M_w >6 mostly show durations of about 3−10 s and some very large events, like the 1970 M_w 8.1 Colombia earthquake or the 1994 M_w 8.3 Bolivia earthquake, even about half a minute. Rupture velocity mostly is between 0.3 and 0.9 v_s (Frohlich, 2006), inferring that deep earthquakes result from faulting, which, however, cannot resemble brittle failure. Although temperatures within subducting slabs are up to 1,000 K lower than at the same depth outside a slab, thermal models of subduction zones imply that temperatures in the coldest part of the slab in the depth interval, where intermediate-depth earthquakes occur, exceed about 300 °C even in fast-subducting, old slabs such as beneath northern Japan (e.g., Peacock, 2003).

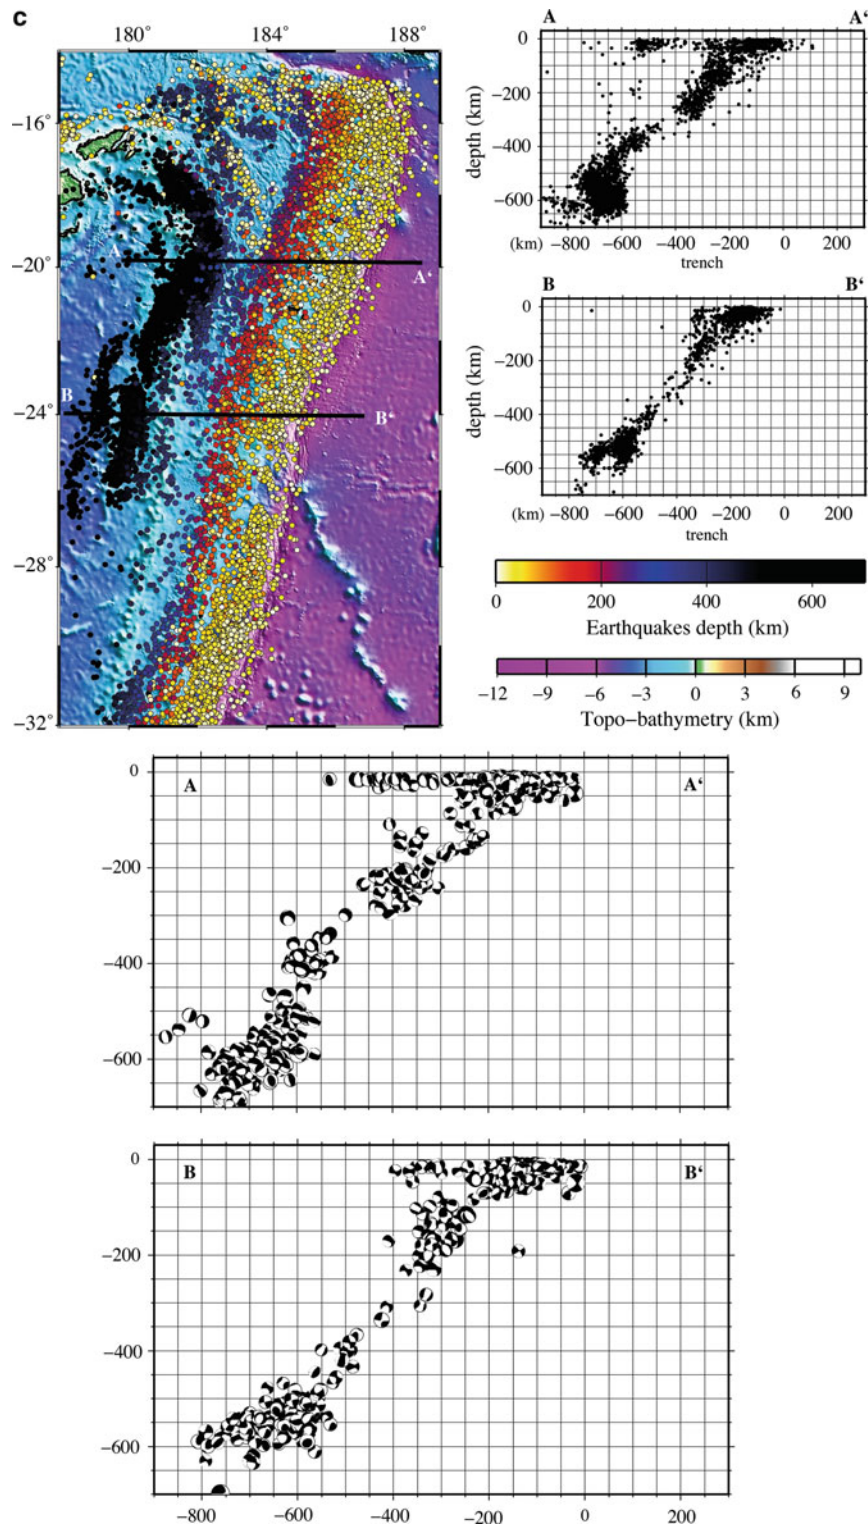
Intermediate-depth earthquakes

A feature of intermediate-depth seismicity is a two-layered WBZ in a depth range from about 60 km to a maximum of approximately 200 km, more and more evidence for which has come especially from local seismic networks, which allow for the necessary precision of hypocenter localization (e.g., Fujita and Kanamori, 1981; Kawakatsu, 1986) since the 1970s, and about 30 years later, it was obvious that at least some segments of most subduction zones exert double seismic zones (DSZ) (Brudzinski et al., 2007). These layers are thin bands of seismicity, the upper one of which with more but smaller seismic events (e.g., Hasegawa et al., 1978) is located within the oceanic crust, whereas the lower one with fewer but larger seismic events (e.g., Fujita and Kanamori, 1981) occurs at variable depths within the uppermost oceanic mantle. Both seismic zones are separated by a seismically quiet layer of about roughly 10−30 km thickness that seems to be a weak function of the age of the descending plate (Brudzinski et al., 2007). The distance between the seismic layers is largest at their shallow end, and mostly both layers converge to the maximum depth extent of a DSZ. Temperatures and stress regimes are different in the upper and lower seismic zone, respectively, with stresses in the upper seismic zone often characterized by a down-dip compression, whereas in the lower one, down-dip tension is observed (Fujita and Kanamori, 1981; Wang, 2002). However, there are double seismic layers exhibiting the same tensional state of stress and related faulting, e.g., beneath the central Andes (Rietbrock and Waldhauser, 2004).

Mechanisms so far discussed for intermediate-depth seismicity mainly can be attributed to two processes: dehydration embrittlement or shear instabilities, e.g., involving thermal runaway or shear heating. Unbending also is suggested to play a role for intermediate-depth seismicity (Wang, 2002; Ranero et al., 2005).

Rayleigh and Paterson already proposed dehydration embrittlement as a potential cause of intermediate-depth


Wadati-Benioff-Zone, Figure 2 (continued)


Wadati-Benioff-Zone, Figure 2 (continued)


Wadati-Benioff-Zone, Figure 2 Maps and profiles illustrating seismicity characteristic for subduction zone segments exhibiting deep earthquakes: (**a**) northern and central Japan, (**b**) South America, and (**c**) Tonga. Profile locations are shown on the maps. Earthquakes hypocenters are from the EHB catalog, focal solutions are from the CMT catalog, and maps have been created using the submap 4.0 tool (Heuret and Lallemand, 2005). Note that focal solutions are only available for a subset of recorded earthquakes.

seismicity in 1965, and since then our understanding of this process has increased considerably through numerous studies (e.g., Jung et al., 2004; Green, 2007; Shiina et al., 2013). Newly created oceanic lithosphere does not have a significant water content which however is required for dehydration reactions to take place, implying that oceanic lithosphere must have been hydrated before it is subducted to where intermediate-depth earthquakes take place. Processes proposed for oceanic lithosphere hydration include faulting at outer rises through which seawater may percolate down to a depth of up to several 10s of km (Peacock, 2001), volatile supply through mantle plumes (Seno and Yamamaka, 1996), or advection in the upper fractured oceanic lithosphere before it enters a subduction zone, which leads to serpentinization along fractures (Wang, 2002). Indeed, evidence for the latter process comes from, e.g., the Nazca plate off northern Chile (Ranero and Sallares, 2004).

Hydrous minerals such as serpentine or antigorite are abundant in slabs at intermediate-depth and thus provide the fluids released through dehydration leading to embrittlement. The first hypotheses of dehydration embrittlement arose from laboratory studies on serpentine (Rayleigh and Paterson, 1965), which, however, has a negative volume change, which would make failure more difficult and thus shear instability would vanish (Jung et al., 2004). The latter workers therefore suggested that antigorite dehydration, which results in fine-grained shear zones under the entire pressure range present at intermediate-depth, is the more probable process causing intermediate-depth seismicity. Water released through dehydration reactions may assist in elevating fluid pressures especially together with the presence of aqueous fluids, which are inferred to be present in some Pacific slabs through unusually high vp/vs ratios (Shiina et al., 2013), thus reducing effective stress and abetting failure.

Viscous creep in thin, i.e., only cm-wide fine-grained shear zones may lead to further weakening a shear zone resulting in further slip. This process of thermal runaway (John et al., 2009) connected with a significant temperature increase of up to a few hundred Ks (Kelemen and Hirth, 2007) including even partial melting (Prieto et al., 2013) provides a failure mechanism without the need of a fluid phase present. However, fluids still may be invoked as previous hydration of the rocks facilitates the formation of fine-grained material prone to later failure (John et al., 2009). Plastic failure of anhydrous, anisotropic peridotite has been suggested as a mechanism to explain lower seismic zone seismicity without the need to invoke former hydration, which may be limited to the uppermost few km beneath the oceanic crust (Ranero et al., 2005); therefore, inferring the uppermost mantle in which the lower seismic zone is located may be dry (Reynard et al., 2010), but this failure then may generate the thin shear zones inevitable for thermal runaway.

Summarizing, observations from various subduction zones reveal that most likely different processes may explain intermediate-depth seismicity in the upper and lower seismic zones. Age and speed of the descending plate, the product of which is the so-called thermal parameter, seem to exert major control on the characteristics of intermediate-depth seismicity, and p-T-paths, i.e., the type of metamorphic reactions a slab is undergoing, the release of water as well as the state of stress when the plate is unbending are suggested to also do so (Abers et al., 2013).

Deep-focus earthquakes

Deep-focus seismicity mainly occurs well beneath the olivine-spinel phase boundary but above the spinel-perovskite boundary (Figure 1). Processes related to the breakdown of metastable olivine (Kirby et al., 1996), the most abundant mineral in the upper mantle, are most widely accepted now to explain deep-focus seismicity (Kirby et al., 1991). If so, slabs should be entirely dehydrated before reaching the depth interval in which deep-focus events occur (Green, 2007).

Deep-focus earthquakes take place in both warm and cold subduction zones, and in both with shallowly dipping slabs and steeply dipping slabs. However, in warm subduction zones like South America rupture velocity, seismic efficiency, and the number of aftershocks are low, whereas they are high in cold subduction zones such as Tonga. Therefore, temperature has been suggested to significantly influencing rupture characteristics (e.g., Tibi et al., 2003).

The increase in seismic moment around 550-km depth may be explained with an equilibrium phase change such as the transformation of garnet to perovskite, which is accompanied by a considerable dehydration (Estabrook, 2004), and therefore possible in a non-dehydrated slab, opposite to what would be required for the breakdown of metastable olivine.

Mechanisms discussed for the largest very deep earthquakes so far recorded, the 1994 637-km-deep Bolivia M_w 8.3 earthquake with a large stress drop of 25–110 MPa, which ruptured along a 30–50 km large subhorizontal plane (Kikuchi and Kanamori, 1994), and the 2013 609-km-deep Okhotsk M_w 8.3 earthquake with a stress drop of about 15 MPa, that had a rupture length of 180 km (Ye et al., 2013) include phase transition triggering but also shear instability. The Bolivia double-couple, highly anisotropic event is inferred to have resulted from volume reduction phase transition of olivine-rich peridotite (Kikuchi and Kanamori, 1994) leading to melting along a very thin (less than a meter) shear zone (Kanamori et al., 1998). This is in line with the slow rupture velocity of only about 1 kms^{-1} and the large stress drop. Rupture of the relatively fast Okhotsk earthquake propagated along two segments in different directions. Olivine to spinel phase transformation seems to be the cause for the NE segment of the rupture, while rupture characteristics to the SSE are better compatible with thermal shear instability (Meng et al., 2014), respectively.

Three case studies: northern Japan, Central Andes, and Tonga

Much of the early research on deep seismicity has been focused on northern Japan and South America, and the seminal contributions of Wadati and Benioff resulted from observations in these subduction zones. Tonga, on the other hand, is the subduction zone, where most deep earthquakes occur, but no event larger than M_w 7.6 was recorded so far. A comparison between these subduction zones reveals their very different characteristics of deep seismicity.

The Japanese Islands were among the first regions equipped with relatively dense seismic networks such that precise location and the estimate of focal mechanisms were already achieved early in the twentieth century. The old Pacific plate and the young Philippine Sea plate are subducting beneath the Japanese Islands at a high and relatively low speed, respectively. Thus, the thermal parameters of the Japanese subduction zones are very different from each other, whereas the release of water from the slabs is relatively uniform regionally (van Keken at al., 2011). Whereas beneath north and central Japan (Figure 2a), there is a pronounced zone of intermediate-depth seismicity, deep-focus seismicity is relatively rare, although present down to about 550 km, beneath the Nankai segment of southwest Japan, intraslab seismicity beneath about 65 km is lacking (e.g., Peacock, 2003). Along the entire Japanese Islands, there are pronounced gaps between intervals of seismicity.

The Nazca plate subducting beneath South America (Figure 2b) has a very variable geometry and exerts three segments with an almost horizontal slab. Oblique convergence and the varying geometry of the Nazca plate lead to a complicated pattern of seismicity (Figure 2b, lower panels). Many seismic events exhibit at least some strike-slip component. Intermediate seismicity occurs persistently from Ecuador to Chile. A double seismic zone identified beneath northern Chile is characterized by an unusually narrow seismically quiet interlayer of only 9-km width (Rietbrock and Waldhauser, 2004), most possibly because of the relative youth of the subducting slab. Contrastingly, the width between both seismic layers identified beneath central Chile approximately where Juan Fernandez Ridge subducts is about 30 km, while the descending Nazca plate is not older than 35 Ma here. This may result from an unusually cold slab relative to its age (Marot et al., 2013), which would hint to the cooling of the upper portion of the Nazca plate lithosphere through advecting seawater as proposed by Wang (2002). The young subducting slab makes South American deep seismicity still somewhat enigmatic: there is close to no seismicity between about 300 and 550 km (Figure 2b), but so far, since earthquakes are recorded instrumentally, more very large very deep events have occurred here than in any other subduction zone.

Despite the high number of deep earthquakes in the cold Tonga subduction zone (Figure 2b), so far no M_w >7.6 deep-focus earthquakes have been recorded here (Frohlich, 2006). Tongan deep earthquakes much more resemble shallow earthquakes than deep earthquakes in other subduction zones. The Tongan slab is dipping significantly steeper than those beneath South America and Japan, and there is a remarkable clustering of earthquakes around 400-km depth. Displayed focal mechanisms (Figure 2c, lower panels) reveal that, whereas most intermediate-depth faults are rupturing subhorizontally, deep-focus seismicity occurs along variously oriented faults implying these are newly generated faults (Warren et al., 2007).

Summary and open questions

Most subduction zones exhibit double seismic layers at an intermediate-depth at least along some of their segments and also deep-focus seismicity. Processes mostly favored for intermediate-depth seismicity include dehydration embrittlement and shear instability, whereas those for deep-focus earthquakes include phase transitions and thermal runaway. This reveals that, although significantly less numerous than shallow earthquakes and restricted to one specific plate-boundary environment, their causes and failure mechanisms are much more variable. This may result from the very different p-T-t- conditions in the oceanic crust and uppermost mantle of descending slabs.

Temperature, faults created through plate bending and unbending, and water, both as aqueous fluids and bound in mineral phases, are thought to exert control on deep seismicity in WBZs. Especially debated is the role of water, as some proposed processes, i.e., thermal runaway or metastable olivine breakdown (Green, 2007; Kelemen and Hirth, 2007), do not require the presence of water. However, other workers have argued for the necessity of the presence of water to explain deep seismicity (e.g., Barcheck et al., 2012), and recent estimates of much higher percentages of water in subducting slabs (Garth and Rietbrock, 2014) hint to its even more prominent role than previously thought.

Definition

Tide influenced coastal zone of the southeastern North
Sea. During low tide, the globally largest coherent system
of sandy to muddy tidal flats emerge between the main-
land and the barrier islands. The Wadden Sea evolved dur-
ing late Holocene transgression and is a high productive
ecosystem with strongly fluctuating environmental condi-
tions. Besides the extended tidal flats, main morphological
units are barrier islands, dunes, ebb tidal deltas, tidal
inlets, tidal channels, salt marshes, and estuaries.

Introduction

The Wadden Sea forms the coastal margin of the southeast-
ern North Sea, a broad and shallow shelf of the passive con-
tinental margin of Northwestern Europe. It extends from
Den Helder (The Netherlands) to Blåvands Huk
(Denmark) (Figure 1) over 490 km. The average width of
the tidal flat area is 5–25 km. Toward the North Sea, the
Wadden Sea is sheltered over long distances by a chain of
barrier islands. Open tidal flats are restricted to the inner part
of the German Bight where high tidal ranges and strong
wave energy prevent the formation of barrier islands. Also,
the larger estuaries and embayments of the rivers Ems, Jade,
Weser, and Elbe are flanked by tidal flats. The Wadden Sea
covers an area of approx. 9,800 km². About half of this
(4,700 km²) is situated in the intertidal environment
represented by sand and mud flats (Common Wadden Sea
Secretariat, 2008). The coherent tidal flats of the Wadden
Sea are known as a conspicuous landscape of global rele-
vance; however, they are part of a worldwide system of bar-
rier islands, tidal flats, and lagoons bordering many coastal
regions in different climatic settings.

Hydrodynamic regime

According to Davis (1964) and Hayes (1979), mean tidal
range and mean wave height are the two principle energy
sources which control depositional coastlines and there-
fore the presence and distribution of barriers. Those parts
of the Wadden Sea coast with barrier islands and
backbarrier tidal flats are typically mesotidal (i.e., tidal
range 1.0–3.5 m sensu Hayes, 1979). As the tidal range
continuously increases toward the inner part of the Ger-
man Bight (Figure 1), low macrotidal conditions (tidal
range > 3.5 m) occur in the larger estuaries of Jade
(3.9 m), Weser (4.2 m), and Elbe (3.7 m) and the open tidal
flats up north to the peninsula of Eiderstedt (3.5 m).

The tides are semidiurnal resulting in an in- and outflow
of 15 km³ of seawater through the tidal inlets during each
tidal cycle, which is half of the entire water volume
(30 km³) of the area. Therefore, the water body of the
Wadden Sea is well mixed.

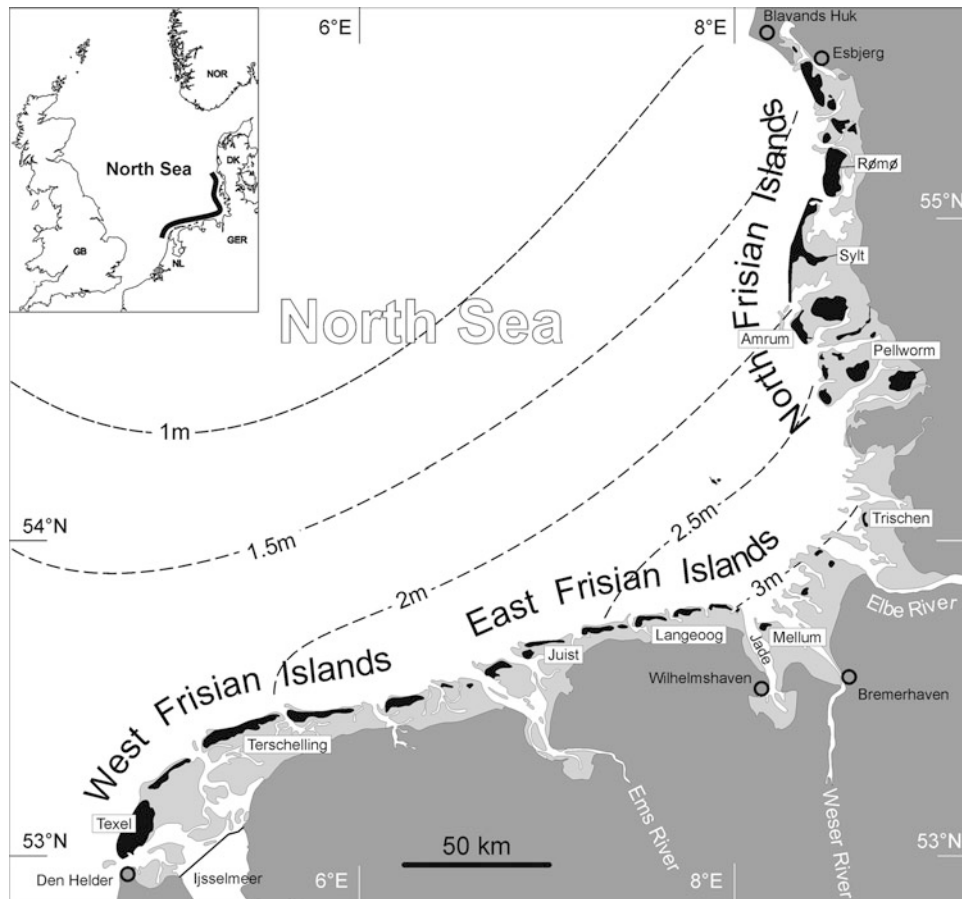
Considering tidal range, wave action, and morphologic
development, the East Frisian Islands reveal high-energy
conditions. Accordingly, the West Frisian Islands and the
Danish Wadden Sea both having considerably lower mean
tidal ranges (1.4 m at Den Helder and 1.5 m at Esbjerg)
(Figure 1) represent the lower energy spectrum of barrier
island systems. Offshore, mean significant wave heights
vary seasonally between 0.5 and 2 m (Bartholdy and
Pejrup, 1994; Dobrynin et al., 2010) but can reach values
of 8–11 m during storm surges.

In high-energy settings (high tidal ranges and/or high
wave impact) ephemeral sand bank islands are developed.
Temporarily, these islands may exhibit a poor salt marsh
and dune vegetation which, however, has not the capacity
to stabilize the islands permanently. The sand bank islands
of the Wadden Sea are highly dynamic and transient sedi-
ment bodies (Wehrmann and Tilch, 2008; Hellwig and
Stock, 2014).

The tidal flats are dissected by a multitude of main and
tributary channels and creeks (Figure 2). Their morphol-
ogy is mainly influenced by tidal currents. The main chan-
nels have mean current velocities of 0.7–1.3 m/s, whereas
only approx. 0.3 m/s are recorded upon the tidal flats
(Krögel, 1997; Gehm et al., 2000). In tidal inlets average
maximum tidal velocities is 1–2 m/s (Bartholdy and
Pejrup, 1994).

Oceanography

The salinity of the water body in the tidal basins ranges
seasonally between 27 and 32, but can vary between
22 and 35 (Becker, 1998; monthly mean Kaiser and Nie-
meyer, 1999). The daily river discharge into the Wadden
Sea is 1.64 × 10⁸ m³. However, no substantial fluvial
input of sediment material into the Wadden Sea occurs
(Bartholdy and Pejrup, 1994; Oost et al., 2012). Mean
water temperature changes from 1 °C in winter to 21 °C
in summers. In long-lasting freezing periods, the
backbarrier zone is covered by drift ice (long-term aver-
age: 19 days per year).

The complex channel systems discharge the tidal basins
during the ebb phase toward the tidal inlets. From the nar-
row and up to 42 m deep incising tidal inlets, the major
channels began to furcate into minor channels and tidal
creeks (Figure 2). The hydrodynamic energy in the chan-
nels is lowest close to the drainage divides separating the
respective tidal basins. Therefore, these parts of the chan-
nels function as sediment traps which results in a pro-
nounced accumulation of mud. In the West and East
Frisian Wadden Sea, semi-consolidated mud beds are
occasionally exposed along deep main channels. They
may be related to former (historic) time periods when the
muddy channel zones (of the watersheds) were located


Wadden Sea, Figure 1 Geographic map of the Wadden Sea. The large coherent system of tidal flats (*bright gray*) is protected toward the open North Sea by a long chain of barrier islands. In the innermost part of the German Bight, which has macrotidal conditions (tidal range > 3.5 m), only small ephemeral sand bank islands and extended open tidal flats occur. *Dashed lines* indicate mean tidal ranges.

in the respective position, i.e., much more westerly than today (Homeier and Luck, 1969). These mud beds reflect the long-term shifting of the backbarrier watersheds toward southeast during the last centuries.

In total, the Wadden Sea consists of 39 tidal basins, of which seven have an estuarine character (Kraft et al., 2011).

Morphodynamics

From sediment trend analysis of the western tidal basins, McLaren et al. (1998) mentioned that some principle processes are similar for each tidal basin and their corresponding tidal inlet/tidal delta system. Inside the tidal basins, the sediment transport is generally directed from the tidal inlets toward the land. The sediment trends follow the branching network of channels and creeks with net accumulation on the tidal flats. Within the tidal basins, the hydrodynamic regime controls the grain size distribution of the siliciclastic sediments. As a general trend the

sediment is fining toward the coast, from sand flats over mixed tidal flats to mud flats (Bartholomä and Flemming, 2007) (Figure 2). In detail, this principle transition in grain size distribution shows a much more complex pattern where the tidal flats are dissected by tidal channel systems (Hertweck, 1994; Flemming and Ziegler, 1995; Hertweck, 1998; Hertweck et al., 2005).

The ebb tidal deltas (Figure 2) are marked by a complex system of transport gyres originating from the deepest channel portion of the tidal inlets. Sediment transport results from both ebb tidal currents and wave action.

Offshore from the barrier islands, an eastward-directed long-shore transport is most obvious in the West and East Frisian Wadden Sea, whereas littoral drift is mostly directed southward in the Nord Frisian and Danish Wadden Sea (Bartholdy and Pejrup, 1994; Zeiler et al., 2000). At each tidal inlet this process is interrupted by the dynamics of the respective tidal basin. Perspectively, the rising sea-level, the loss of accommodation space, and the retrogradational development of sedimentary
Wadden Sea, Figure 2 Main structural elements (morphological units) of the Wadden Sea. The tidal basins are separated by drainage divides. Water exchange between tidal basins and the open North Sea is supported by tidal inlets. The morphodynamic of the exposed beaches of the barrier islands is mainly controlled by wave action and undergoes seasonal modification. Salt marshes mark the transition from marine to terrestrial environment in sheltered positions. Washover fans document local dune erosion during severe storm surges.

facies will subsequently squeeze out the finest sediment particles, i.e., the mud flat facies (Mai and Bartholomä, 2000). However, extended mud flats are widely known from the Holocene sedimentary record of the coastal plain.

Sediment-organism interaction

The entire tidal flats are intensely populated by bivalves (e.g., *Macoma balthica*, *Cerastoderma edule*, *Mya arenaria*) and polychaetes (e.g., *Arenicola marina*, *Heteromastus filiformis*, *Hediste diversicolor*, and the tube-building polychaetes *Lanice conchilega* and *Pygospio elegans*). Another characteristic feature of the central tidal flats are extended mussel beds of *Mytilus edulis*, of which most of them were recently transformed into oyster reefs by bioinvasion of the Pacific oyster *Crassostrea gigas* (Wehrmann et al., 2000). As an ecosystem engineering species, the Pacific oyster has a strong

impact to the Wadden Sea ecosystem causing significant changes in biodiversity. Additionally, by their filter feeding activity they produce enormous amounts of feces and pseudofeces accumulated as muddy organic-rich biodeposits within and around the reefs. As these biodeposits are stabilized by biofilms and microbial mats, they are not in equilibrium with the hydrodynamic regime.

All tidal flats display a similar structural pattern (Hertweck, 1998) as well as a typical distribution of bioturbation (Hertweck, 1994):

(a) Stable platforms with *Lanice conchilega* colonies and frequently with *Crassostrea* reefs or *Mytilus* beds in central position of the platforms.
(b) Sandy tidal flats in the marginal areas undergoing permanent physical reworking; the macrofauna is mostly reduced to the lugworm *Arenicola marina* and subordinately the cockle *Cerastoderma edule*.

(c) Mobile sand bodies in the point bars of channels and at the flanks and spits of the tidal flats which undergo intense reworking and are, therefore, nearly devoid of macrofauna.

At tidal flat margins and spits, which are highly exposed to tidal currents and wave action, sediment bodies are generated indicating intense physical sediment reworking. They consist of fine sand, partly laminated and partly with intercalations of thin mud flasers. Due to the lateral migration of smaller tidal channels and creeks, longitudinal cross-bedding and shell lag deposits are prominent sedimentary structures of tidal flat deposits.

Salt marshes

The salt marshes of the Wadden Sea represent the natural transition between the intertidal flats and the terrestrial environment (Figure 2) where average energy input is low. They are situated above the mean tidal high-water level. Thus, they may frequently be affected by flood events during extraordinary high-water levels and storm surges. Besides the abundant plant community (Dörjes, 1978; Streif, 1990), the salt marshes are also characterized by meandering and multifariously branched channels effecting drainage after extreme high-water events.

Where accretion prevails, the transition from the tidal flats to the salt marshes is marked by a silting-up zone (30–40 cm below the high-water line) which is characterized by the occurrence of the halophyte *Salicornia* sp., a pioneer colonizer stabilizing the sediment by its rootlets. Dense standing stocks of *Salicornia* favor baffling and accumulation of very-fine-grained sediment particles. In the same level, multilayered microbial mats are formed by diatom algae, filamentous green algae, cyanobacteria, and sulfate-reducing bacteria also efficiently stabilizing the sediment surface (Gerdes et al., 1985; Gerdes and Wehrmann, 2008). As these microbial mats with their typical lamination have a high preservation potential, they are a characteristic indicator for the proximate land-sea transition in low-energy environments. The transition from the *Salicornia* zone to the *Puccinellia* zone is situated around the high-water line. All species of the *Puccinellia* zone are genuine halophytes able to tolerate seawater flooding. The topographically highest zone of the salt marsh is the *Festuca* zone which is flooded only during highest spring tides and storm surges. The number of flooding events is less than 100 per year (Streif, 1990).

The sedimentologically most conspicuous feature of the salt marshes are the storm deposits. These are intercalations of silty sand and/or layers of shells and shell debris deposited during storm surges (Bouma, 1963; Hertweck et al., 2005). Flooding of the salt marshes under calm conditions results in the accumulation of muddy sediments.

Dunes

One of the main characteristics of the barrier islands are the dunes, separating the salt marshes of the islands from the shore environment (Figure 2). The dunes are generated at the upper limit of the backshore where sufficient desiccation allows the mobilization of sand by eolian processes.

The organic debris and algal material accumulated at the high-water lines cause a temporary enrichment of nutrients within the sand, resulting in the development of particular plant associations. Primary (embryonic) dunes are generated in leeward position of this pioneer vegetation. They may reach up to 2 m height several months after initial formation. The sediment baffling initiating the formation of primary dunes is caused by *Agropyron junceum* which is highly resistant to sand covering.

In higher parts of the primary dunes *Elymus arenarius* is the second characteristic plant. Both species are characterized by widespread rootlets, thus being highly adapted to sand transport, desiccation, and salt water spray. The fixation of the eolian sand by the plant community causes the formation of secondary dunes ("white dunes") of up to 20 m height. The influence of salt water within the sediment body strongly decreases. Simultaneously, salt water is diluted out of the dunes by precipitation. *Ammophila arenaria* is the characteristic plant species of the white dunes. Deep-anchored roots are a typical adaptation of this species to strong sand transport.

The disappearance of *Elymus arenarius* and *Ammophila arenaria* vegetation on the leeward dunes together with initial soil formation marks the beginning of the tertiary dune development ("gray" and "brown dunes").

Beaches

The upper shoreface and foreshore of the barrier islands are sandy beaches which undergo the hydrodynamic changes of ebb and flood tide but strongly differ to tidal flats. Tidal beaches are situated at the offshore-directed coasts of barrier islands and thus, are fully exposed to onshore winds and waves. During the tidal cycle the effect of wave action continuously undergoes periodical modifications.

Under fair weather conditions two or three coast-parallel ridges are formed in the shallow upper shoreface. These are continuously shifted toward the shore, whereas new ridges are formed at the lower limit of this zone. The same process takes place in the foreshore zone. Depending on the local tidal range, two or three beach ridges alternating with beach runnels occur. The most beachward runnel marks the transition to the backshore. The subparallel beach runnels are some 100 m long and show an extremely acute angle toward the respective waterline (Figure 2). Only at the mouth of a fully emerged runnel a short curved portion is visible effecting discharge in rectangular direction. Thus, the beach ridges and runnels are not parallel structures following the isohypses, but displaying a stepwise pattern along the foreshore zone (Reineck, 1960). The beach ridges are mainly formed by onshore wave action.

The dominating sediments in the beach area and the dune belt are fine-to-medium sands.
Wadden Sea, Figure 3 Geological cross section through the Central Wadden Sea perpendicular to the coastline (modified after Streif (2004) and Bungenstock and Schäfer (2009)). The relief of the early Holocene surface is based on core and seismic data. The narrow sediment wedge of sediments deposited during Holocene transgression represents a fourth-order TST and HST. Marked slowdown in sea-level rise favors the formation and progradation of distinct fen peat horizons. Since land reclamation and dike construction limit retrograde shift of sedimentary facies and gradual fade of the hydrodynamic energy, the finest grain sizes are exported out of the system. This will perspectively cause a depletion of the muddy facies. *MLW* mean low water line, *MHW* mean high-water line.

Holocene evolution of the Wadden Sea and development of the barrier islands

The Wadden Sea is a young sedimentary and ecological system which developed after the last glaciation. Most of the sediment material originates from local reworking of Pleistocene deposits during Holocene transgression, forming the narrow sediment wedge of the Wadden Sea (Figure 3). In the West and East Frisian Wadden Sea, this up to 35 m thick sediment wedge (Streif, 2004) represents fourth-order TST and HST (Bungenstock and Schäfer, 2009). Initially, the rate of sea-level rise was more than 1 m per century but strongly slowed down around 7,500–7,000 year BP (Kiden et al., 2002; Vink et al., 2007). At approx. 8,000–7,500 year BP, the Holocene transgression reached the area where the barrier islands were formed, as evident from ^{14}C datings of reed material (in lagoonal to brackish water deposits from −24 m below chart datum) sampled offshore of Wangerooge Island (Hanisch, 1980). Outcrops of fossil tidal flat deposits, mud beds and salt marshes at beaches, shoreface and offshore areas of the islands point to a shifting of these

islands over their own tidal sediments, i.e., backbarrier areas (Figure 4). It has to be assumed that the West and East Frisian Islands were formed between 6,000 and 5,000 year BP several km offshore from its present position and, therefore, gradually shifted toward southsoutheast during the Holocene transgression. For the last 2,000 years, displacement rates of more than 100 m per century may be stated (Barckhausen, 1969; Streif, 1990). In contrast, the data from the North Frisian Islands Rømø suggested that formation there started around 8,000 year BP (Madsen et al., 2010).

Both, seismic sub-bottom profiling and investigation of long sediment cores revealed a rugged Pleistocene relief below the Holocene deposits which only was preservable if an essential W-E displacement of the tidal inlets can be excluded. According to Streif (1990), the channel bases of the inlets are usually less than 3 km wide, exceptionally 5–6 km. In the coastal area the deep incised paleo-valleys of the rivers Ems, Weser, and Elbe were transformed into estuaries also around 8,000 year BP. During the late Holocene, the sea-level shows several fluctuations

Wadden Sea, Figure 4 Fossil semi-consolidated mud beds outcropping at the offshore exposed beaches of a barrier island at low tide indicates southward (retrograde) shift of the entire Holocene sediment wedge. The mud beds were formerly deposited in sheltered backbarrier environments of the respective island. From historical navigation charts migration rates of more than 100 m per century are documented.

(i.e., stillstand and/or slow down) with multifold progradation of the coastline as indicated by formation of fen peat intercalating the clastic sedimentary sequence (Figure 3).

The formation of the barrier islands of the Wadden Sea mainly results from two contrasting processes. The West and East Frisian Island (except Texel) (Figure 1), the so-called dune islands, were formed by the aquatic and eolian deposition of sandy material, mainly trapped and stabilized by vegetation.

All dune islands originate from shoals having developed by the interaction of hydrodynamic energy and eolian processes. The initial base of the shoals consists of ridges of the Pleistocene moraine landscape submerged by the transgression. The shoals emerging during low tide became more elevated by storm-related accumulation of sand and were, subsequently, flooded only exceptionally. In the leeward area sheltered by these durable shoals, tidal flats could develop favored by the low-energy conditions. Additionally, sand from the offshore exposed beaches of the shoals was mobilized by onshore winds. Thus, primary dunes were formed, subsequently stabilized by plants. During transgression, the barrier islands were shifted toward south passing over their own backbarrier tidal flats (Figure 4). Most of the islands consist of several isolated dune ridges cut by washover fans (Figure 2) which were generated by storm surges.

The North Frisian Islands on the other hand are the remnants of the marsh-like coastal plain (e.g., Pellworm, Nordstrand) or of Tertiary to Pleistocene deposits (e.g., Sylt, Amrum, Föhr), resulting from erosional processes during storm surges (Hoffmann, 2004). Nevertheless, most of the more exposed North Frisian Islands also show the principle sedimentary processes and morphological units of beach and dunes environments.

Summary

The Wadden Sea is a unique coastal landscape of the southeastern North Sea which has evolved during the late Holocene under rising sea-level conditions. Therefore, it is a very young system in terms of geomorphology and ecology. The Wadden Sea is characterized by a coherent system of extended tidal flats, barrier islands, and salt marshes which is one of the largest worldwide. The development of barrier island, which separates the intertidal sandy to muddy flats from the offshore shelf, is linked to two different processes: formation of dunes on supratidal shoals by eolian sediment transport and subsequent stabilization by vegetation (West and East Frisian Islands), and erosion of mainly Pleistocene headlands and/or early Holocene salt marshes (North Frisian Islands), respectively. Water exchange during semidiurnal tide between the tidal basins and the open North Sea is supported by the complex of tidal channels, tidal inlet, and ebb tidal delta.

Definition

Wave motion is the fundamental mode of energy propagation over large distances without substantial deformation or permanent displacement of the medium. Waves organize a part of energy and momentum supplied to the water masses and propagate as coherent motions that rapidly carry the energy to the coasts. Surface gravity waves with periods from about 1 to 25 s are called *ocean waves* below.

Introduction

The most important classes among a variety of wave motions in the ocean (LeBlond and Mysak, 1978) are surface waves and internal waves. The motions in surface waves are concentrated at sea surface, while internal waves (Miropolsky, 2001) propagate along a stratified medium, often along major density jumps in the water column. The basic restoring force for both is gravity and both involve a combination of longitudinal and transverse waves. They can be either progressive or standing and may exhibit all classical properties of waves such as dispersion, reflection, refraction, diffraction, or focusing.

The length of surface waves may range from millimeters (capillary and capillary-gravity waves for which the surface tension is substantial) to many kilometers (tsunamis, seiches, tides, for which the impact of Coriolis force becomes significant). Their periods are from fractions of seconds up to a few days. The presence of coasts substantially modifies large-scale waves such as tides and gives rise for asymmetric and/or coastally trapped waves (e.g., edge waves, Kelvin waves). Energy carried by ocean waves has many implications on beach processes and sediment dynamics, formation of bedforms, and driving of coastal erosion and is an important renewable energy source (Cruz, 2008).

Mathematical description of elementary surface waves

The simplest meaningful way to describe ocean waves is the *first-order*, *small-amplitude*, or *Airy* wave theory, called *linear wave theory*. Although it is based on a number of assumptions and approximations, its outcome replicates the behavior and impact of ocean waves with reasonable accuracy (Dean and Dalrymple, 1991; Craik, 2005; Holthuijsen, 2007).

The linear wave theory addresses nonstationary, inviscid, barotropic, irrotational flow in an incompressible medium. The wave-induced motion of water parcels thus always possesses a *velocity potential* – a function $\phi(x, y, z, t)$, such that velocity components $\vec{u} = (u, v, w)$ can be expressed as its partial derivatives $\vec{u} = (\partial\phi/\partial x, \partial\phi/\partial y, \partial\phi/\partial z)$. Ideal infinite plane (sine or elementary) wave trains correspond to the velocity potential $\phi = ag\omega^{-1} \cosh \kappa(z + d)$ $(\cosh \kappa d)^{-1} \sin(kx + ly - \omega t)$ and produce a moving pattern of undulations $\eta(x, t) = a \cos(kx + ly - \omega t)$. The pattern is characterized by wave amplitude a or height (the vertical distance between the wave trough and crest) $h = 2a$, period T (the time interval between the arrival of two subsequent wave crests) or angular frequency $\omega = 2\pi/T$, and length L (Figure 1). The ratio h/L is called wave steepness. The wave vector $\vec{\kappa} = (k, l)$ represents the direction of wave propagation on the (x, y) plane along *wave rays* (lines normal to wave crests). Its length (wave number) is $\kappa = \left| \vec{\kappa} \right| = 2\pi/L$. For essentially one-dimensional long-crested waves propagating in the x-direction, the y-direction is often ignored by setting $l = 0$.

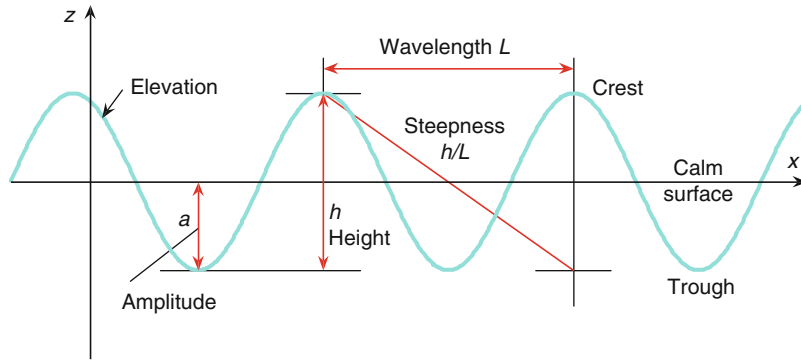
The wave height is arbitrary in the linear theory. The wave number and angular frequency of ocean waves satisfy the dispersion relation $\omega = \sqrt{g\kappa \tanh \kappa d}$, where g is gravity acceleration and d is the water depth.

Motions in the wave

Wave propagation involves three velocities: of water parcels, of wave crests, and of energy. The velocity $\vec{u}$ of water parcels is proportional to the wave amplitude. The maximum (orbital) speed $u_{\max s} = ag\kappa/\omega = ag/c_f$ occurs at the surface. The maximum speed at the ideal bottom is $u_{\max b} = a\sqrt{2g\kappa/\sinh 2\kappa d} = a\omega/\sinh \kappa d$. A bottom boundary layer is formed at the realistic seabed.

The wave *energy* is the energy of water parcels brought into motion by the wave. It is usually expressed as the energy density $E = a^2\rho g/2$ (ρ is the water density) averaged over the entire water column and over a wave period (or over a wavelength). The *phase speed* (also *celerity*, propagation speed of wave crests or any constant-phase point) is $\vec{c}_f = (\omega/k, \omega/l)$ and the *group speed* (propagation speed of energy) is $\vec{c}_g = (\partial\omega/\partial k, \partial\omega/\partial l)$ for any class of small-amplitude waves (Landau and Lifshits, 2000).

The dependence of many surface wave properties on the water depth is governed by the dispersion relation through the function $\tanh \kappa d$. As $\tanh \kappa d \approx 1$ for $\kappa d \geq 3$ and $\tanh \kappa d \approx \kappa d$ for $\kappa d \leq 1/3$ (Figure 2), waves with $L \leq 2\pi d/3 \approx 2d$ (*deepwater waves*) adequately obey the dispersion relation $\omega = \sqrt{g\kappa}$ and waves with $L \geq 6\pi d \approx 20d$ (*shallow-water waves*) satisfactorily conform to the dispersion relation $\omega = \kappa\sqrt{gd}$. Note that this classification relies on the relationship between the wavelength and the water depth rather than the water depth only (Table 1).

Both phase and group speeds for longer waves in deep and finite-depth water exceed that of shorter waves. Ocean waves thus exhibit *normal dispersion*. All shallow-water waves propagate with the same speed in a fixed depth and are *nondispersive*. Very short surface waves (capillary and


Waves, Figure 1 Elementary wave propagating in the *x*-direction. The *z*-axis is traditionally directed upward and $z = 0$ corresponds to the calm water surface.
Waves, Figure 2 The function $\tanh x$.

capillary-gravity waves) possess *anomalous dispersion*: shorter waves propagate faster than longer ones.

Wave energy flux (also called *wave power*) $P = E \vec{c}_g$ is the product of wave energy and its propagation speed. The flux of momentum created by surface wave motion is characterized by *radiation stress tensor* (Longuet-Higgins and Stewart, 1964). For elementary waves propagating along the *x*-axis, the *x*-component of radiation stress is

$$S_{xx} = E\left(\tfrac{1}{2} + \tfrac{2\kappa d}{\sin 2\kappa d}\right) = E\left(2\tfrac{c_g}{c_f} - \tfrac{1}{2}\right).$$

Wave transformation in the nearshore

A surface wave undergoes certain changes when it propagates from the open ocean (of large depth) into the nearshore (of smaller depth). If a wave propagates along a homogeneous (in the *y*-direction) underwater slope, modifications to the wave properties in the process of *shoaling* (during which waves become higher and shorter and thus steeper) are derived from the assumption that the angular frequency and energy flux of the wave remain constant. Changes to the wavelength are dictated by the dispersion relation. The wave height, originally h_0 at a

certain depth and $h_1 = h_0 K_s$ at another location, follows the adaptation of the group speed from c_{g0} to c_{g1} through the shoaling coefficient $K_s = \sqrt{c_{g0}/c_{g1}}$.

A wave propagating obliquely with respect to isobaths experiences *refraction*, i.e., gradual turn in the wave propagation (equivalently, wave vector) direction. This process is quantified through Snell's law $\sin\theta/c_f = \text{const}$ that relates the angle θ between the wave crests and isobaths with the variation in the phase speed. Wave energy usually converges at shoals and headlands (and may be focused at the downwave side of shoals or small islands) and diverges along underwater canyons. Similar processes occur when waves propagate over a sea area that contains spatially variable currents. Additional changes in the wave properties occur in the nearshore owing to wave-bottom interaction and depth-induced breaking.

Reflection of a part of wave energy occurs from steeper slopes. *Standing waves* (called *seiches* in natural water bodies) may be formed when wave energy ideally reflects from a vertical wall. The period of the longest seiche in a basin of constant depth d and with a length L_b is expressed as a particular case of Merian's formula $T_{s0} = 2L_b/\sqrt{gd}$.

Wave *grouping* occurs when two sine waves with almost equal lengths (or periods) propagate in the same direction. Wave *diffraction* is the process of energy and momentum transfer in a direction other than the wave propagation direction, e.g., when a wave propagates through a gap or across an edge of a sheltered domain.

Realistic surface wave systems have much more complex nature than sine waves and exhibit many nonlinear properties (Osborne, 2010). Deepwater waves of considerable amplitude are often described as Stokes waves or using the nonlinear Schrödinger equation. Long waves in shallow domains often obtain a cnoidal shape or become similar to shallow-water solitons described by the Korteweg-de Vries equation.

Ocean waves

Ocean wave fields are traditionally divided into *windseas* (or *seas*, waves that are supported by the same wind that

Waves, Table 1 Phase and group speeds for deepwater, finite-depth, and shallow-water waves

Deep water: $\kappa d \geq 3$ or $L \leq 2d$	Finite depth: $1/3 \leq \kappa d \leq 3$ or $2d \leq L \leq 20d$	Shallow water: $\kappa d \leq 1/3$ or $L \geq 20d$
$c_f = \sqrt{\frac{g}{\kappa}} = 2c_g$	$c_f = \sqrt{\frac{g}{\kappa}\tanh \kappa d}$	$c_g = c_f = \sqrt{gd}$
$c_g = \frac{1}{2}\sqrt{\frac{g}{\kappa}} = \frac{1}{2}c_f$	$c_g = \frac{\omega}{2k}\left(1 + \frac{2kd}{\sinh 2kd}\right) = \frac{c_f}{2}\left(1 + \frac{2kd}{\sinh 2kd}\right)$	

has generated the field) and swell (usually longer waves that have propagated out of the generation area). Windseas are a superposition of many elementary waves with different periods, directions, and heights and are characterized by an extremely complicated shape of water surface. Swell is usually more regular, has well-defined long crests, and resembles propagation of elementary waves.

The analysis of wave heights originally relied on the identification of single waves from the record of surface elevation at a fixed point. For narrow-banded wave systems, the distribution of wave heights is close to a Rayleigh distribution. The distribution of wave periods in offshore conditions is close to a normal distribution (WMO, 1998), while in semi-sheltered domains and at coastal sites, it may be skewed toward shorter waves.

A widely used measure of ocean waves is the *significant wave height*. It has been historically defined as the average height $h_{1/3}$ of one-third of the highest waves (Sverdrup and Munk, 1947). For Rayleigh-distributed waves $h_{1/3} \approx 4.005\sigma$, where σ is the standard deviation of the water surface elevation. Contemporary numerical simulations (Komen et al., 1994) and wave measurement devices define the significant wave height as $h_s = 4\sigma$.

In a Rayleigh-distributed wave system, the probabilities of having waves higher than h_s and $2h_s$ are $e^{-2} \approx 1/7$ and $e^{-8} \approx 1/3000$, respectively. Waves higher than $2h_s$ (sometimes higher than $2.2h_s$) are called *freak* or *rogue waves* (Kharif et al., 2009). They are usually short-living phenomena (Osborne, 2010) but may have much longer lifetime (Peterson et al., 2003) and impact in shallow areas (Nikolkina and Didenkulova, 2012). Their exact prediction is probably not possible, but it is feasible to forecast the areas with enhanced probability of their occurrence (Janssen, 2008).

Wave spectrum and forecast

The practical analysis of ocean waves relies on the assumption that wave fields can be adequately described by their *energy spectrum*. The growth of a windsea usually leads to a wave system with a pronounced single peak at the *peak period*. The condition until which waves grow under a constant wind blowing long time over a large sea area is termed a *fully developed sea*, for which the Pierson-Moskowitz spectrum is an acceptable approximation. The peak period $T_p \approx 0.64u_{10}$ and significant wave height $h_s \approx 0.022u_{10}^2$ of such waves depend only on the wind speed (here u_{10} is the wind speed at a height of 10 m).

The dependence of wave properties on *fetch length L_f* is accounted for in the JONSWAP spectrum (Komen et al., 1994), for which the peak frequency is $\omega_p \approx 22\,[g^2/(u_{10}L_f)]^{1/3}$ and $h_s \approx 0.0005u_{10}\sqrt{L_f}$. These and similar relationships form the basis of *parametric wave models* (WMO, 1998). Contemporary numerical wave models (such as WAM, SWAN, WAVEWATCH, etc.) replicate all major features of wave generation, propagation, interactions, and decay by tracking the evolution of the wave energy spectrum (Komen et al., 1994).

Finite-amplitude and breaking waves

Steep waves ($h/L > 0.17$, Figure 1) may break at any depth, but most of wave breaking is concentrated in the surf zone at the coast. The maximum height limit above which the wave becomes unstable is called *breaking wave height h_b*. Generally it is a function of depth and wavelength. A commonly used assumption in coastal engineering is that waves approaching a natural beach break when their height h_b is about 78 % of the water depth d_b, equivalently, when the *breaking index* $\gamma_b = h_b/d_b \approx 0.78$ (Dean and Dalrymple, 1991; 2002). For strongly reflecting beaches, the breaking index may reach values up to ~1.5, while for domains with horizontal bed, it is in the range of 0.55–0.6. Breaking waves produce plumes of bubbles that may be dispersed in the water column to the depths of $4h_s$ (Thorpe, 1995).

Waves of finite amplitude generate a certain mass transport, estimated as $M = E/c_f$ in Starr (1947). Waves propagating over shallow areas may substantially affect the local water level. Nonbreaking waves produce *wave setdown* $\overline{\eta} = -a^2\kappa/(8\sinh 2\kappa d)$, with a maximum value of $\overline{\eta}_b = -(1/16)\gamma_b h_b$ at the seaward border of the surf zone. The gradual release of cross-shore momentum carried by breaking waves may lead to much higher *wave setup*, theoretically up to $\overline{\eta}_{\max} = (5/16)\gamma_b h_b$. This process may provide 30–60 % of the extreme water levels (Dean and Bender, 2006). On realistic beaches, an acceptable approximation is $\overline{\eta}_{\max} \approx 0.17h_{s10}$, where h_{s10} is the significant wave height at a depth of 10 m (Guza and Thornton, 1987). The release of the alongshore component of momentum contributes to the formation of the alongshore current in the surf zone.

Wave climate and extreme wave heights

The characteristics of the offshore and onshore wave climate vary drastically over different domains of the ocean (Davies, 1980). The largest annual average significant

wave heights (around 4.5 m) apparently occur within the "Roaring Forties" on the southern hemisphere. The highest 100-year return h_s (about 25 m) is likely to occur in the northern Atlantic according to a hindcast based on the ERA-40 reanalysis (Sterl and Caires, 2005). The largest instrumentally measured offshore value of h_s is 18.5 m near Rockall in the North Atlantic (Holliday et al., 2006), whereas $h_s \approx 24$ m and single waves over 32 m have been reported in specific conditions under Typhoon Krosa (Babanin et al., 2011). Extreme wave heights are much smaller in semi-sheltered basins such as the Mediterranean Sea or the Baltic Sea.

Although several variations in wave properties have been identified for different domains of the ocean based on relatively short data sets during the last decades, there is no consensus about the nature of recent changes in the wave climate. The temporal changes in the wave height are likely a part of multi-decadal fluctuations of storminess and seem to exhibit no obvious trend (Weisse and von Storch, 2010). The changes have been most pronounced in semi-sheltered seas where even small variations in the local storm activity may lead to considerable changes in the wave climate (Soomere and Räämet, 2011). Regional variations in the wave direction, changes in the joint occurrence of rough seas and high water levels, and the length of ice cover may have particularly large impact on the intensity of coastal processes in the Arctic and seasonally ice-covered seas.

Conclusions

Although the science of ocean waves is generally a mature field with strong physical foundations and highly developed mathematical gear, it still offers fascinating challenges and reveals the alluring secrets of nature. It has recently been one of few examples in Earth sciences that has opened a principally new research direction into rogue waves in various environments and has contributed into studies of the fundamentals of soliton interactions. The challenges have, however, largely moved from the examination of wave dynamics into the analysis of interaction of waves with various natural and anthropogenic structures. The changing marine environment calls for considerable efforts to understand and quantify the impact of waves in the conditions of rising sea-level and especially in relation with dramatic ice reduction in the Arctic.

WILSON CYCLE

Martin Meschede
Institute of Geography and Geology, Ernst-Moritz-Arndt
University, Greifswald, Germany

Definition

A Wilson cycle describes a large tectonic cycle lasting for more than 100 million years. Such a cycle, named after J. Tuzo Wilson (1908–1993), one of the doyens of plate tectonics, starts with the breakup of a continent and growth of an ocean at a newly formed mid-oceanic rift system. Such oceans may remain limited in size or attain the dimensions of the Atlantic or even Pacific Ocean. Eventually, the ocean closes during continent-continent collision ending the cycle.

Stages of the Wilson cycle

Beginning with the splitting of a so far stable craton (Figure 1a), probably related to a rising mantle plume, the Wilson cycle continues with the formation of a graben system (Figure 1b). The graben is still underlain by continental lithosphere which, however, may be thinned because of extensional tectonics. With ongoing separation of the continental blocks, a new zone of production of oceanic lithosphere in between is formed. This rift zone remains in the middle of the new oceanic basin as a divergent plate boundary (Figure 1c, d). Spreading occurs along the mid-oceanic rift system producing new oceanic lithosphere, while the continents drift apart. The size of the ocean between the continental blocks will determine whether crustal growth by magmatism is large, small, or insignificant. Since young oceanic lithosphere is lighter than older one, a mid-oceanic ridge develops which may surmount the deep sea plains by several kilometers. Oceanic basins may reach widths of several thousand kilometers and depths down to more than 5 km. The transition
Wilson Cycle, Figure 1 Schematic representation of the different stages of a Wilson cycle (modified from Frisch et al., 2011).

from the oceanic basins to the continents is marked by the continental slope. It ends in the shelf area which is part of a passive continental margin dominated by extensional tectonics.

The turnabout in the Wilson cycle from divergent plate movement to continent convergence may be performed by "spontaneous subduction" of old oceanic lithosphere or, in the case of young intermediate oceanic realms, forced by the global plate drift pattern, by "forced subduction." Subduction (Figure 1e) occurs either along continental margins or intraoceanic island arcs. In both cases volcanic arcs develop above the subducting plate. Subduction ends when two continents move against each other and progressively reduce the width of the ocean in between (Figure 1f).

The process of orogeny becomes initiated when a continent-continent collision starts at a convergent plate margin. Continental crust may be thickened to more than 70 km, in comparison to normal continental crust that is 30–40 km thick, when the plates override. Mountain belts form as elongate zones of slightly elevated continental crust. The orogenic process leads to crustal thickening, deformation, and metamorphism (Figure 1g). At the end, the oceanic lithosphere breaks off (slab break off) leading to rapid uplift and increasing mountain formation (Figure 1h). This is called the Alpine-type orogeny in contrast to the Cordilleran-type orogeny, where subduction lasts over long periods with repeated episodes of collision that involve island arcs, oceanic plateaus, and sometimes even microcontinents which are accreted to the convergent plate margin. This orogenic style is exceptionally rich in volcanic and/or plutonic production.

During the final stage of the Wilson cycle, the mountain belt levels out to a normal crustal thickness and a new peneplain is formed. The next cycle can begin when the continental crust gets under extensional stress caused by active or passive rifting induced by warming or a rising mantle plume. The motor of the cyclicity is the subduction process which requires an oceanic basin floored by oceanic crust. This type of crust can be subducted, whereas continental crust cannot. The force of the slab pull is the most powerful force to drag down the oceanic lithosphere.
