ENCYCLOPEDIA OF MARINE GEOSCIENCES

Volume Editors

Jan Harff is Professor of Geosciences and Seafloor Geology at the University of Szczecin, Poland. His previous research focused on sedimentary basin analysis at the Central Institute for Physics of the Earth (ZIPE, subsequently the GeoForschungsZentrum, GFZ), Potsdam, and marine geology at the Leibniz Institute for Baltic Sea Research Warnemünde and the University of Greifswald, Germany. He cooperates, on a permanent basis, with marine research institutes of the Chinese Academy of Sciences, Chinese universities, and the Guangzhou Marine Geological Survey, Guangzhou, China. His research interests concern marine geology in general, sedimentology, coastal geology, paleooceanography, paleoclimatology, mathematical geology, and basin modeling. In addition to having authored and coauthored numerous research papers and having served as editor of other scientific publications, he acted as corresponding editor of *Modeling of Sedimentary Systems* (Springer, 1999) and *The Baltic Sea Basin* (Springer, 2011).

Martin Meschede is Professor of Regional and Structural Geology at the Institute of Geography and Geology, University of Greifswald, Germany. His research interests focus on geodynamic processes at plate margins, subduction, large igneous provinces, exhumation, paleogeography, paleoclimatology, basin evolution, and glacial tectonics. He participated in several marine research expeditions, among these are the Joides Resolution of IODP and a diving cruise with *Shinkai 6500*. Besides a number of scientific publications, he is author and coauthor of several textbooks on plate tectonics, structural geology, and regional geology of Germany.

Sven Petersen is a senior researcher at GEOMAR, Helmholtz Centre for Ocean Research Kiel in Germany. His research focuses on understanding the processes that form and change seafloor hydrothermal systems and associated mineral deposits with time. He participated in more than 30 research cruises to submarine hydrothermal systems in the Pacific, Atlantic, and Indian Oceans. Major aims of his research are to understand their chemical variability, the use of mobile drilling techniques and geophysical methods to investigate their subseafloor extent, as well as the use of autonomous underwater vehicles for their exploration.

Jörn Thiede is the leader of the KÖPPEN-Laboratory of the Institute of Earth Sciences of Saint Petersburg State University. He worked during 1967–1987 at the universities of Aarhus (Denmark), Bergen (Norway), Oregon State University in Corvallis (USA), Oslo (Norway), and Kiel (Germany) and learned to sail the world's oceans to understand their history. Afterward, he pursued the foundation of GEOMAR. In 1997, he joined The Alfred Wegener Institute-Helmholtz Centre for Polar and Marine Research. In 2008, he served at the Geocenter Denmark as well as at UNIS (Longyearbyen/Svalbard) and in 2011 was invited to join the St. Petersburg State University (Russia).

Aims of the Series

The *Encyclopedia of Earth Sciences Series* provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists.

These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students. Go to http://link.springer.com to visit the "Encyclopedia of Earth Sciences Series" online.

About the Series Editor

Professor Charles W. Finkl has edited and/or contributed to more than eight volumes in the *Encyclopedia of Earth Sciences Series*. For the past 25 years, he has been the Executive Director of the Coastal Education and Research Foundation and Editor-in-Chief of the international *Journal of Coastal Research*. In addition to these duties, he is Professor at Florida Atlantic University in Boca Raton, Florida, USA. He is a graduate of the University of Western Australia (Perth) and previously worked for a wholly owned Australian subsidiary of the International Nickel Company of Canada (INCO). During his career, he acquired field experience in Australia, the Caribbean, South America, SW Pacific islands, Southern Africa, Western Europe, and the Pacific Northwest, Midwest, and Southeast USA.

Founding Series Editor

Professor Rhodes W. Fairbridge (deceased) has edited more than 24 Encyclopedias in the *Earth Sciences Series*. During his career, he has worked as a petroleum geologist in the Middle East, been a WWII intelligence officer in the SW Pacific, and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil, and New Guinea. He was Emeritus Professor of Geology at Columbia University and was affiliated with the Goddard Institute for Space Studies.

Dedication

We dedicate the *Encyclopedia of Marine Geosciences* to two scientists: Eugen Seibold and Terry Healy. Eugen Seibold has, directly and indirectly, inspired the four of us and supported our enthusiasm for marine geosciences. While a coauthor of the entry "Marine Geosciences: A Short, Eclectic, and Weighted Historic Account," he passed away in 2013 before the *Encyclopedia of Marine Geosciences* was completed. Terry Healy, a marine scientist from New Zealand, had initiated the *Encyclopedia of Marine Geosciences* project before he passed away in 2010. Terry influenced the geoscience community worldwide by his groundbreaking research in coastal erosion, sedimentation, and hazards (including tsunamis). While Eugen Seibold's contributions represent basic sciences, Terry Healy's address applied aspects of marine sciences. In this sense, the two scientists epitomize our intention for the *Encyclopedia of Marine Geosciences* to bridge the basic and the applied compartments of marine geosciences.

Eugen Seibold (May 11, 1918–October 23, 2013) initiated research on marine geology at the University of Kiel, Germany, with the aim of understanding the fossil depositional environments through the study and comparison of modern sedimentary processes. He realized that marine geology would develop into a fascinating research discipline. He will be remembered as one of the great geoscientists of our time; he was a true man of the *Earth*.

Terry Healy (November 28, 1944–July 20, 2010) was for decades affiliated to the University of Waikato, New Zealand. His special field of research and academic education was the inner shelf oceanography and marine geology, studied on scales from regional to global. Terry Healy's major contribution to marine geosciences involved societal applications of earth science principles.

"*Throughout my professional career I have held to a philosophy of demonstrating in my teaching and research, the importance, relevance, and application of earth science principles to the problems of, and ultimate benefit to, the community.*"

Preface

The globally growing demand for energy and mineral resources, the need for reliable projections of future climate processes, and the necessity for coast protection to mitigate threats and hazards of disasters require a comprehensive understanding of the genesis and structure of the marine geosphere and processes involving it. The "classical" research fields in marine geology are being currently supplemented by the development of more general concepts which strive to integrate marine geophysics, hydrography, climatology, marine biology, and ecology. The term "marine geosciences" has been broadly accepted to serve as an "umbrella" for this new complex field of research and practical solutions in the marine realm.

We have reflected this development by putting together the *Encyclopedia of Marine Geosciences* which appears as a volume of the Encyclopedia in Earth Sciences Series. When collecting entries for the *Encyclopedia of Marine Geosciences*, we intended to provide the current state of knowledge in marine geosciences and to cover their theoretical, applied, and technical aspects. However, as we were working on the Encyclopedia, it became clear to us that one printed volume cannot accommodate all the disciplinary basics of marine geosciences. Therefore, the reader seeking explanation of a specific scientific term is advised to consult not only the list of entries, but also to take a look on the back-of-the-book index. The index can be used as a search engine for text paragraphs in this volume dealing with the words of interest. Because of the complex nature of marine geosciences, we do realize

that some overlap with the "classical" research geosciences fields, already covered by other volumes of the *Encyclopedia in Earth Sciences Series*, must have occurred in the present volume. We did our best to avoid repetitions in this volume and we advise the reader to consult, whenever necessary, other *Encyclopedias in the Earth Science Series* volumes such as *Encyclopedia of Coastal Science*, *Encyclopedia of Geochemistry*, *Encyclopedia of Paleoclimatology and Ancient Environments*, or *Encyclopedia of Sediments and Sedimentary Rocks*.

With this volume, we hope to reach out to a broad audience of users concerned with marine sciences and technology, from students and scholars in academia to engineers in the industry to decision makers in administration and politics.

The editorial team of the *Encyclopedia of Marine Geosciences* reflects the diversity of disciplines covered: Martin Meschede took over responsibility for manuscripts related to plate tectonics, Sven Petersen dealt with those focusing on magmatism, Jörn Thiede was responsible for entries on deep ocean processes, and Jan Harff edited the entries related to ocean margins and associated processes.

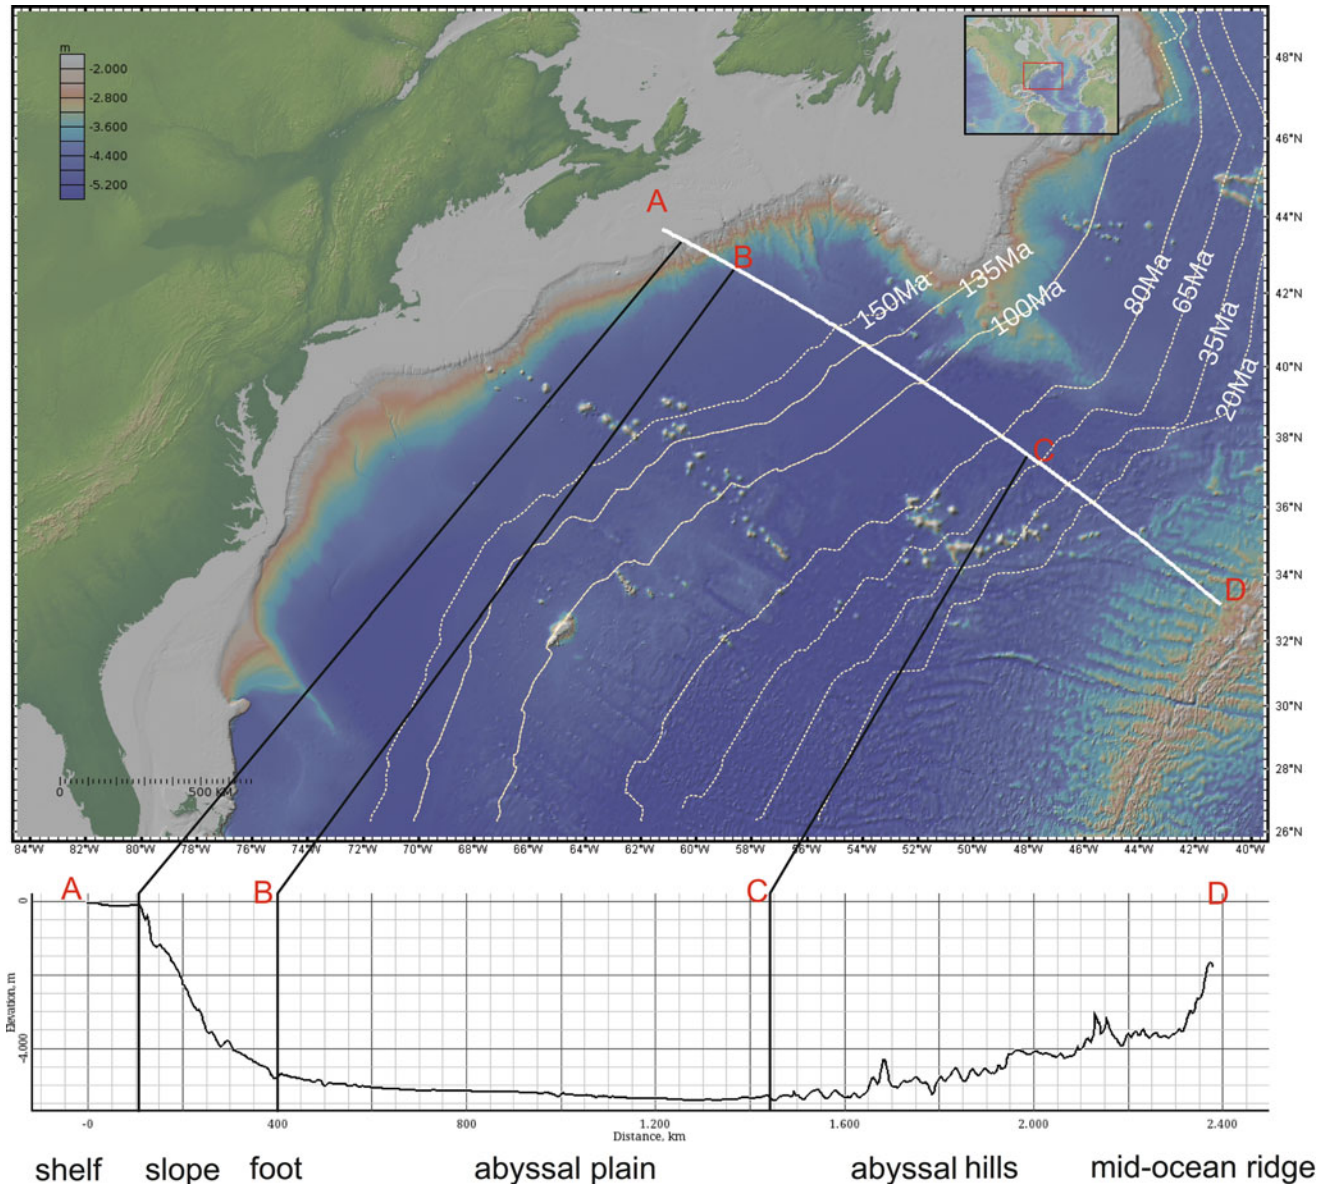
ABYSSAL PLAINS

David Voelker
MARUM-Center for Marine Environmental Sciences,
University of Bremen, Bremen, Germany

Abyssal plains are flat areas of the ocean floor in a water depth between 3,500 and 5,000 with a gradient well below 0.1°. They occupy around 28 % of the global seafloor. The thickness of the sediment cover seldom exceeds 1,000 m, and the sediments consist of fine-grained erosional detritus and biogenic particles. The first global map of seafloor physiography, published by Heezen and Tharp in 1977, illustrated that the bottom of the ocean is bordered by continental margins of variable width and hosts large submarine mountain chains, the mid-ocean ridges. It also illustrated that between the continental margins and mid-ocean ridges, there exist vast flat and almost featureless regions, the so-called abyssal plains (Figure 1). The global seafloor map has been refined in recent years (e.g., by Smith and Sandwell, 1995; Becker et al., 2009), in a way that has allowed to perform quantitative analyses of the global distribution of specific seafloor features (Harris et al., 2014).

Bathymetry
Earth is a sphere with an equatorial radius of 6,378 km and a surface area of $\sim 5.1 \times 10^{14}$ m^2. Roughly 71 % or $\sim 3.58 \times 10^{14}$ m^2 of that surface is covered by oceans. The largest part of the ocean floor is at a depth between 3,500 and 5,000 m (with a mean ocean depth of 3,795 m), in the depth range of abyssal plains. Exceptions from this rule are (1) continental margins and epeiric seas, (2) mid-ocean ridges, (3) seamounts and basaltic plateaus that are shallower, as well as (4) submarine trenches at subduction zones that are deeper. These areas are exceptional because plate collision forces govern the shape of the seafloor (at subduction zone trenches), because they form a transition between continental and oceanic crust (continental margins) or because of atypical structure of the ocean crust (basaltic plateaus and seamounts). Mid-ocean ridges stand out as the crust that is formed at these plate boundaries is young and hot. Cooling of the plate leads to crustal subsidence to abyssal depth within ~ 12 Ma.

Apart from those areas, the seafloor is relatively monotonous in its depth and also very flat. Those regions that typically stretch from the foot of the continental slopes to the mid-ocean ridges have been classified as a specific physiographic entity and termed abyssal plains. The word abyss comes from the Greek word abyssos "bottomless (pool)" indicating the enormous lightless depths, whereas plain refers to the morphological notion of vast monotonously flat areas. Strictly speaking, the term is a kind of contradiction because a plain cannot be bottomless, but it is meant in the same way as its correspondent "deep-sea plain."

The depth distribution of the world oceans is shown in Figure 2 in the form of a hypsometric curve. The curve shows a bimodal distribution with one peak between 0 and 500 m and another broader peak between 3,500 and 6,000 m. This distribution reflects the double nature of the seafloor: around the continents, large areas of the seafloor are actually drowned parts of the continents with a crustal structure that is similar to the crust underlying the continents. The deeper part of the ocean is in contrast underlain by oceanic crust that is formed at mid-ocean ridges in a similar composition on global scale. The lifespan of a portion of oceanic crust from its creation at a spreading center to its destruction at a subduction zone ranges seldom exceeds 120 Ma (Müller et al., 2008).


Abyssal Plains, Figure 1 (**a**) Bathymetric map of the western North Atlantic, showing a broad continental shelf and slope, a prominent abyssal plain (the Hatteras Abyssal Plain), and the Mid-Atlantic Ridge. The map was created with the GeoMapApp (www.geomapapp.org); the underlying bathymetric data were published as Global Multi-Resolution Topography (GMRT) by Ryan et al. (2009). (**b**) shows a depth profile from the continental shelf offshore Newfoundland to the Mid-Atlantic Ridge (*A–D*). In this profile, the continental platform and the continental slope are clearly depicted. Towards the Mid-Atlantic Ridge, the roughness of the seafloor increases with decreasing thickness of the sediment cover. Stippled lines indicate seafloor bedrock age according to Müller et al. (2008).

Over that time span, the ocean floor cools, contracts, and sinks, rapid first and slower later (see "Subsidence of Oceanic Crust"), and this subsidence controls the depth of the largest part of the seafloor.

Abyssal plains grade into the foot regions of continental margins towards the land masses and into areas of increasing topographical roughness towards mid-ocean ridges (Figure 1a, b). In order to delimit this physiographic domain, the International Hydrographic Organization (IHO) agreed upon a definition that includes water depth and the variation in relief over a certain radius (e.g., the variation in relief has to be <300 m over a radius of 25 cells of 30 arc sec). Following this definition, Harris et al. (2014) calculated that globally, abyssal plains make up 27.9 % of the seafloor or 19.8 % of the entire surface of the Earth.

The flatness of abyssal plains is exemplified in Figure 1b. It shows a bathymetric profile of the western North Atlantic Ocean from offshore Newfoundland to
Abyssal Plains, Figure 2 Hypsometric curve of the seafloor of the Atlantic, Pacific, and Indian Oceans. The curve shows the percentage of areas of the seafloor that lie within a certain depth interval and exhibits a bimodal distribution: First maximum lies within the 0–500 m range (continental shelves, *blue bar*), while the largest portion and second maximum lies at water depths between 3,500 and 6,000 m (oceanic seafloor, *red bars*). The second maximum, indicated by *red bars*, also is the typical depth range of abyssal plains. The map is based on the global bathymetric data set of Smith and Sandwell (1995).

the Mid-Atlantic Ridge. The profile across the abyssal plain between points B and C is 1,100 km long. Over this distance, the difference in elevation is 600 m, corresponding to a mean slope gradient of less than 0.04°, similar to shelf areas. In contrast, the continental margins stand out with slope gradients in the range of 1–10° (in places up to 30°). The flanks of the mid-ocean ridges show gradients of 10–20; some seamounts stand out as steep edifices with slopes as steep as 40°. The profile across the abyssal plain between points B and C is 1,100 km long. Over this distance, the difference in elevation is 600 m, corresponding to a mean slope gradient of less than 0.04°. Figure 3 summarizes this information in the form of a slope gradient map.

Sedimentation

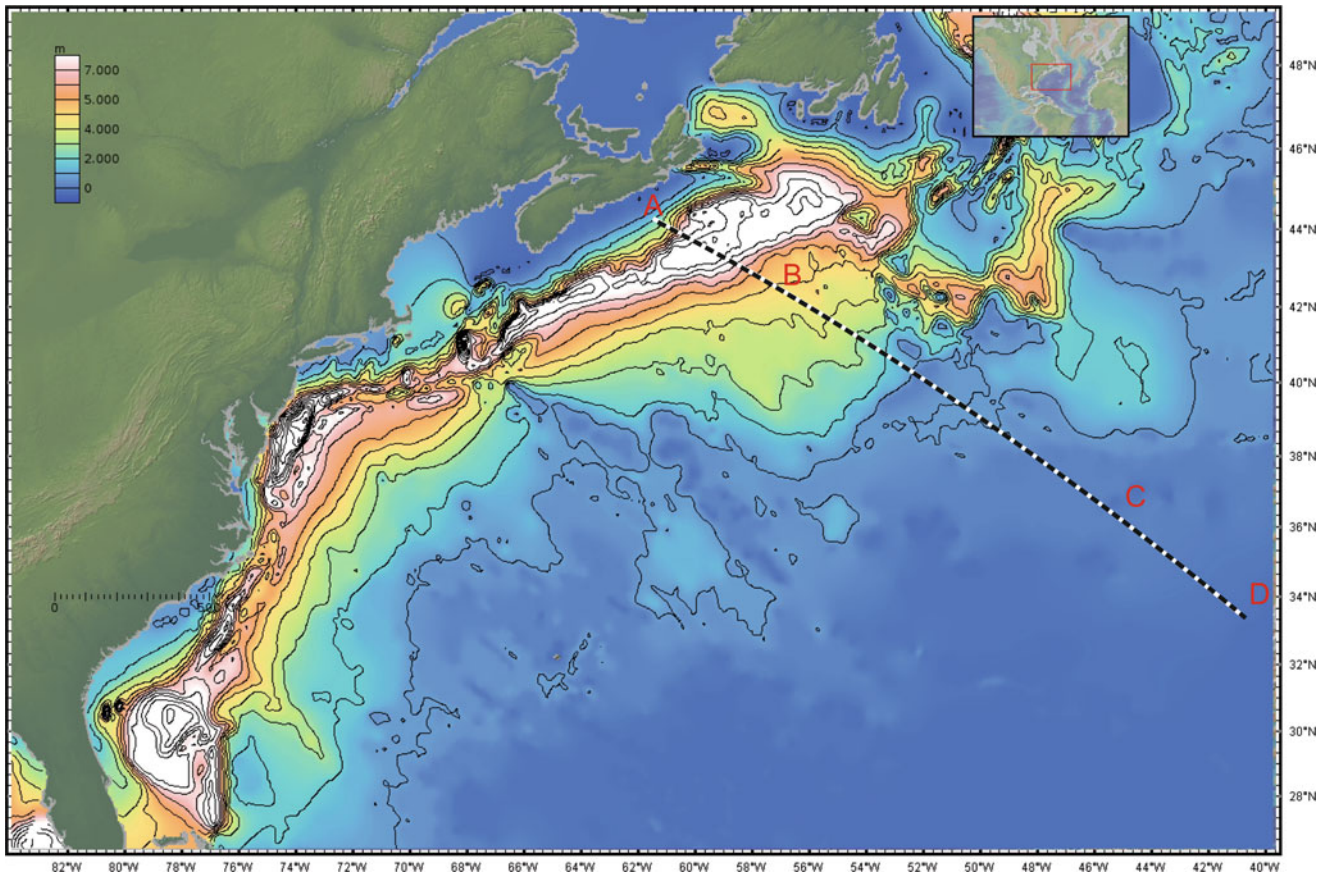
Abyssal plains receive sediments in the form of erosional detritus of the continents and as shell fragments of planktonic animals and algae that live in the upper water column of the open sea. These components form the main constituents of the typical deep-sea or pelagic sediments in varying relative proportions. The growth of the sediment cover in time (the rate of sedimentation) is generally low over abyssal plains (on the order of some cm growth in thickness/ka), as compared to continental margins where sedimentation rates are generally higher by a factor of 100–1,000. Given such low sedimentation rates, on abyssal plain accumulates a sediment cover of some hundred meters. The mean thickness of the sediment cover of abyssal plains is 450 m (Whittaker et al., 2013).

Two reasons account for the comparatively low sedimentation rate: first, the abyssal plains are largely cut off from the main source of sedimentary particles, the erosion of the continents. A large part of sediments that are transported to the sea in rivers are deposited on the shelf regions of the continents during global high stands of the sea-level (when the shelf regions around continents are wide). River-transported sediments surpass this "sediment trap" easily only when rivers directly connect to submarine canyon systems, or when the shelf is narrow, or episodically at sea-level low stands or when turbidites are shaken off. Wind transport of very fine-grained erosional detritus (dust) is an important constituent of abyssal plain sedimentation to the leeward side of arid regions with a constant wind regime (such as offshore the Saharan coast of Western Africa (Morocco, Mauretania)). Erosional detritus of larger grain size (gravel) is brought into the oceans at high latitudes released by melting icebergs (dropstones).

Second, the bioproductivity (density of primary production) of the open seas is low in general (with the exception of zones of equatorial upwelling) because of limited nutrient availability. Low bioproductivity results in little and seasonally variable fallout of shell fragments and organic material from the photic zone. In addition, only a fraction of that export of material from the photic zone ever reaches the seafloor, as the major part gets dissolved or recycled in the water column. This is specifically true for calcareous fragments that become chemically unstable in the deep sea. The water depth underneath of which no calcareous material is preserved in marine sediments is called the carbonate compensation depth (CCD).
Abyssal Plains, Figure 3 Global distribution of abyssal plains and deep-sea basins.

In short, deep-sea sedimentation is sparse and relatively evenly distributed (no local sources), depending mostly on the thin fallout of particles from the photic zone, the so-called pelagic rain of particles, wind transport of dust, and distal turbidites from higher areas. Over time, this kind of sedimentation blankets the oceanic crust and levels its topography resulting in the very smooth and even abyssal plains. The thickness of sediments that rest on the oceanic basement can be mapped in the form of contour lines (isopachs). Global isopach maps (Whittaker et al., 2013) show that the major trend in sediment thickness is from absent close to the mid-ocean ridges where the oceanic crust is young and the distance to the continental sources of sediments is large to some hundred meters close to the foot of continental slopes, where the oceanic crust is oldest and continents are close. This trend is locally overprinted by other effects such as high bioproductivity belts around the equator and bottom current transport of sediments but general to all oceans (Figure 4).

Life in the abyssal plains

New observation systems employed in the last decades give evidence for numerous life forms in the deep sea and on abyssal plains. One of the fundamental conditions for higher life forms, the constant supply of oxygen is provided for by deep ocean currents that are part of the so-called global conveyor belt of ocean currents. Still, life in the abyssal plains meets very specific challenges, because of which sometimes they are termed "ocean deserts," indicating the low diversity and low density of life forms. First, autotrophic (plant) life is impossible in the lightless depth of the oceans. Therefore practically every life form here depends on the "import" of nutrients from the photic (uppermost) zone of the water column in the form of a rain of particles (dead plants and animals, fecal pellets) from above. Second, this rain is very thin over most of the abyssal plains. Only few ocean surface regions (the so-called upwelling zones) have a high primary production and associated food web to produce a constant export of nutrients to the deep sea that can nourish a dense population of animals on the deep seafloor. Third, this rain is variable in time and space. This is exemplified by whale falls. Dead whale bodies that sink to the bottom of the ocean provide food for years for a very specialized group of bacteria and animals. Yet whale falls are so irregular in time and the cadavers are so small in relation to the vast dimensions of abyssal plains that it is a question yet unresolved, how those animals actually find the prey and what they do "in between" the next lucky strike. Fourth, the abyssal plain is covered by relatively soft mud. This is an unfavorable situation for animals that are attached to the ground, preventing them to settle and build colonies. This fact becomes striking when seamounts are considered. Seamounts are solid rock bodies that rise from the abyssal plains. If abyssal plains are termed deserts in terms of biological activity, then seamounts are the oasis.


Abyssal Plains, Figure 4 Sediment thickness (isopach) map of the western North Atlantic, based on a global data set of Whittaker et al. (2013). Towards the American continent, the sediment thickness of the abyssal plain exceeds 1,000 m which partly explains the flatness of that region. Towards the Mid-Atlantic Ridge, sediment thickness decreases while the ruggedness of the ocean floor increases. The depth profile of Figure 1 is superimposed.

ACCRETIONARY WEDGES

Martin Meschede
Institute of Geography and Geology, Ernst-Moritz-Arndt
University, Greifswald, Germany

Synonyms

Accretionary complex; Accretionary prism

Definition

Accretion defines a process at a convergent plate margin above a subduction zone where material of the subducting lower plate is scraped off and transferred to the overriding upper plate. The offscraped material is accumulated in a wedge-shaped stack of sedimentary layers sometimes containing also offscraped material from the oceanic crust of the subducting plate. It is located directly at the boundary between the two converging plates. This region is called the forearc region of the convergent plate boundary (see entry "Morphology Across Convergent Plate Boundaries" and Figure 3 therein, this volume).

Formation

Accretionary wedges essentially develop as compressional fold-and-thrust belts which are composed primarily of oceanic-plate deposits and, in many cases, continentally derived trench-floor sediment from a nearby continental plate (Figure 1). Sometimes scraped-off parts of the subducted oceanic lithosphere are added to the accretionary complex, which then form ophiolitic rocks in the succession of the accreted material.

Accretionary wedges or prisms typically have wedge-shaped cross sections. They are characterized by one of the most complex internal structures of any tectonic element known on Earth caused by imbricate thrusting and folding of the incoming material. Some parts of accretionary wedges are composed of numerous thin rock layers that are repeated by thrust faults (stacking by duplexing); other parts of wedges or even entire wedges are characterized by large-folded and partly brecciated packages of rocks. Frequently they comprise tectonic mélanges that are composed of mixtures of blocks and thrust slices of many rock types (e.g., basalt, sandstone, limestone, chert, graywacke, and others) that are incorporated in a matrix of fine rock material such as shale or serpentinite. The faults and folds, in general, verge toward the subducting plate (Figure 2). However, anticlinal structures that include some landward-verging reverse faults, the so-called backthrusts, are produced, which create tectonic ridges that are expressed as positive morphological structures at subduction zones (Figure 1). Deformation and sedimentation
Accretionary Wedges, Figure 1 3D sketch of an accretionary wedge with fold and thrust structures and their morphological expression in the forearc region with basins and trenches filled with sediments (Modified after Fisher, 1996).
Accretionary Wedges, Figure 2 Schematic section of an accretionary wedge showing its internal structure with frontal and basal accretion and internal deformation caused by contraction and extension (Modified from Cawood et al., 2009). The transparent arrows indicate particle paths within the accretionary wedge during the accretion process.

occur concurrently and incrementally throughout the evolution of the system. The ongoing process causes the most devastating earthquakes on Earth, in some cases of magnitudes more than 9.0 (moment magnitude scale). The earthquakes are concentrated in the seismogenic zone, which in general is situated in the accretionary wedge.

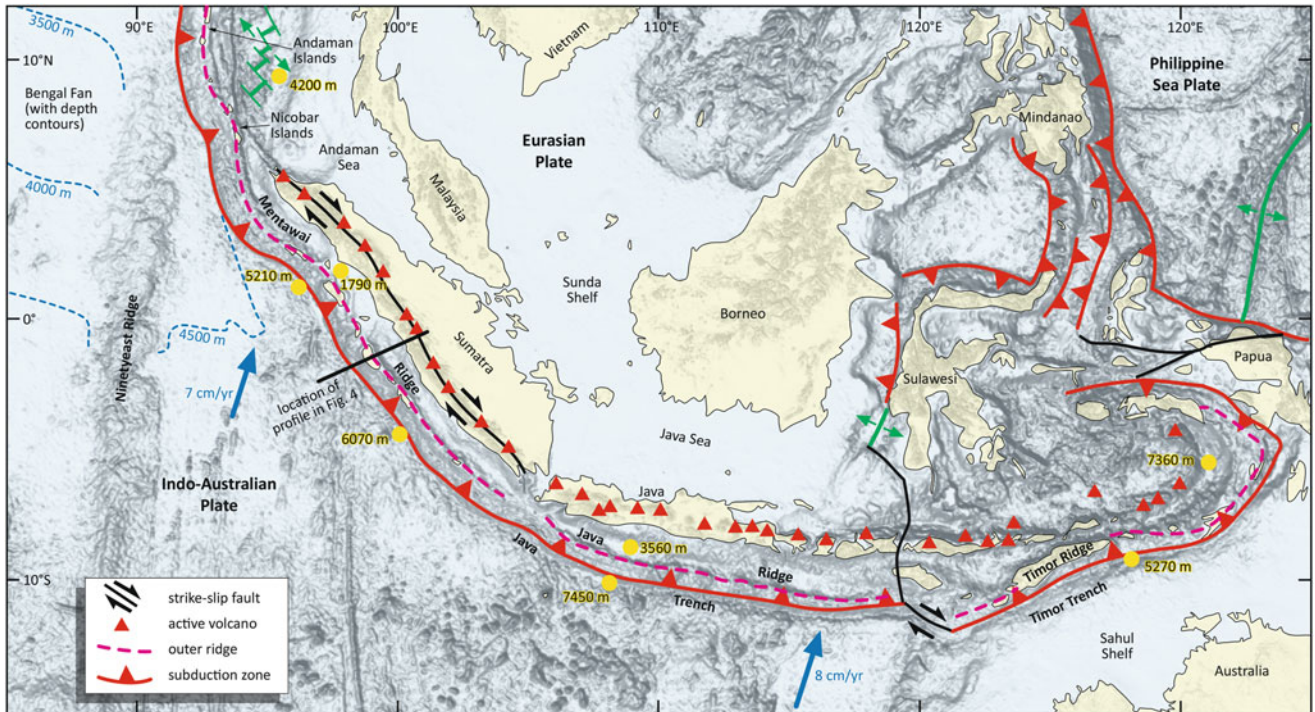
A detachment surface, or décollement, separates the upper part of the accreted section (i.e., zone of offscraping) from material that is underthrust beyond the base of the slope. Above the décollement, scraped-off sediment is transferred to the accretionary prism, and this prism displays a rugged and irregular seafloor morphology governed by numerous tectonic ridges that form by folding and fault dislocation (Figure 1). As the subducting plate transports its sedimentary fill from the trench toward the arc, some portion of the sediment is subducted and transported within the subduction channel down to great depths where it becomes an important factor in the feeding of subduction-related magmas. The remaining portion, or in some cases the entire sedimentary layer and parts of the oceanic crustal basement, can be scraped off forming the accretionary wedge on the upper plate.

An accretionary wedge grows from below. The scraped-off sedimentary layers are stacked and continuously uplifted by renewed underplating from below, a process that results in morphological elevation of the outer ridge. The more material that is scraped off, the higher the elevation of the outer ridge. The process of accretion has been modeled in sandbox experiments so the evolution of the accretionary wedge is well understood (e.g., Gutscher et al., 1996; Dominguez et al., 2000). The underplating process resembles large-scale nappe thrusts in mountain ranges. Previously juxtaposed layers of sediment are stacked during the shortening process, and at each overthrust, older sediments are placed on top of younger ones. The process and sequence of events can

also be viewed from the opposite perspective – younger units are forced below older ones by underthrusting.

Occurrences

About half of the convergent plate boundaries on Earth are dominated by the process of accretion in an accretionary wedge (von Huene and Scholl, 1991), which is the opposite process characterized by subduction erosion (see entry "Subduction Erosion" and Figure 1 therein, this volume). Numerous examples of studies exist that examine accretionary wedges from around the world (e.g., Scholl et al., 1980, Silver and Reed, 1988, Westbrook et al., 1988; Kukowski et al., 2001; Gulick et al., 2004, and others). Large accretionary wedges are represented in southwest Japan, Sumatra, large portions of the Gulf of Oman (Makran subduction zone), in the Lesser Antilles, along the Aleutians, and in smaller areas of western North and South America.

Eight overthrust planes that display repetitions of the sedimentary layers have been drilled at the Vanuatu accretionary wedge in the Southwest Pacific (Ocean Drilling Program, ODP Leg 134; Meschede and Pelletier, 1994). Because the sedimentary layer at the subducting plate has a thickness of slightly more than 100 m, the much larger thickness of the accretionary wedge is a result of intense tectonic stacking. In contrast, south of Japan, where the Philippine Sea Plate subducts beneath the Eurasian Plate, a thick sedimentary layer of more than 1000 m is entering the Nankai subduction zone (Gulick et al., 2004). Here, the décollement zone remains in the sedimentary layer and does not cut through the underlying oceanic crust as is the case in Vanuatu. Approximately the lower third of the sedimentary layer is being subducted and does not contribute to the growth of the accretionary wedge.


Accretionary Wedges, Figure 3 Map showing contrasting plate-tectonic conditions along the Sunda Arc (Modified from Frisch et al., 2011). In front of Sumatra, sediment of the thick Bengal fan are scraped off and incorporated into the accretionary wedge. This causes the outer ridge to emerge from the sea at this location (Mentawai Ridge; see Figure 4). In front of Java, the deep sea trench and the outer ridge are significantly deeper. In front of Australia, the continental crust of the Sahul Shelf is being subducted beneath the Sunda Arc; this causes a particularly strong uplift of the outer ridge (Timor Ridge) and marks the initial stage of orogenesis.
Accretionary Wedges, Figure 4 Example for an accretionary wedge with ridges uplifted above the sea-level (islands of Mentawai and Siberut) and numerous slope basins at the subduction zone off the island of Sumatra (Modified from Frisch et al., 2011).

The Sunda Arc provides an instructive example demonstrating how the shape of the accretionary wedge depends on the amount of sediments transported into the subduction zone (Figure 3). Fed by an enormous monsoon-controlled supply of sedimentary material, the Ganges and Brahmaputra rivers accumulated the huge several-kilometer-thick submarine Bengal fan that extends to the southernmost point of Sumatra. The sedimentary fan rests on the Indo-Australian Plate and is transported toward the NNE where it is being subducted

in the Sunda Arc. Therefore, the deep sea trench along the northwestern part of this island-arc system is mostly masked by the high sedimentation rate, while the outer ridge, built by the tectonic stacking of fan-supplied sediments, is emerged several hundred meters above sea-level. It forms islands such as the Andaman and Nicobar Islands and the Mentawai Ridge in front of Sumatra (Figs. 3 and 4). Farther southwest away from the influence of the Bengal fan and adjacent to Java, the trench is distinctive with depths of almost 7500 m. Accordingly, the outer ridge is not well developed and lies mostly below a water depth of 2000 m.

Along Sumatra, the slope of the accretionary wedge falling from the outer ridge to the deep sea trench typically displays distinctive subdivisions. Here active thrusts produce elongated flat areas and depressions – the so-called slope basins (Figure 4). They are common along the Mentawai Ridge where some are rising above sea-level. During their complex history, these basins served as sediment traps recording the uplift history of the outer ridge. Analyses of the microfauna indicate uplift from deep to shallow water conditions. The youngest sediments contain reefs having formed in very shallow water before uplifting above sea-level (Moore et al., 1980).

ACTIVE CONTINENTAL MARGINS

Serge Lallemand
Geosciences Montpellier, University of Montpellier, Montpellier, France

Synonyms

Convergent boundary; Convergent margin; Destructive margin; Ocean-continent subduction; Oceanic subduction zone; Subduction zone

Definition

An active continental margin refers to the submerged edge of a continent overriding an oceanic lithosphere at a convergent plate boundary by opposition with a passive continental margin which is the remaining scar at the edge of a continent following continental breakup. The term "active" stresses the importance of the tectonic activity (seismicity, volcanism, mountain building) associated with plate convergence along that boundary. Today, people typically refer to a "subduction zone" rather than an "active margin."

Generalities

Active continental margins, i.e., when an oceanic plate subducts beneath a continent, represent about two-thirds of the modern convergent margins. Their cumulated length has been estimated to 45,000 km (Lallemand et al., 2005). Most of them are located in the circum-Pacific (Japan, Kurils, Aleutians, and North, Middle, and South America), Southeast Asia (Ryukyus, Philippines, New Guinea), Indian Ocean (Java, Sumatra, Andaman, Makran), Mediterranean region (Aegea, Calabria), or Antilles. They are generally "active" over tens (Tonga, Mariana) or hundreds (Japan, South America) of millions
Active Continental Margins, Figure 1 Schematic view of an active continental margin after Lallemand et al. (2005).

of years. This longevity has consequences on their internal structure, especially in terms of continental growth by tectonic accretion of oceanic terranes, or by arc magmatism, but also sometimes in terms of continental consumption by tectonic erosion.

Morphology

A continental margin generally extends from the coast down to the abyssal plain (see Figure 1 and entry "Morphology Across Convergent Plate Boundaries"). It typically includes a continental platform gently dipping seaward and a talus with a steeper slope down to the trench. In detail, active continental margins offer a wide spectrum of morphologies from narrow and steep ones (e.g., Porto Rico) to wide and flat ones (e.g., Mediterranean "Ridge" which is a huge evaporitic accretionary wedge). In general, the continental shelves bordering active margins are narrower than those along passive margins. The trench marks the deepest seaward termination of the active continental margin. It coincides with the surface trace of the subduction fault marking the boundary between the converging plates. Its depth generally ranges between 2 and 7 km depending on the age of the subducting plate (young plate like Juan de Fuca – shallow trench) and the amount of trench fill sediment (thick trench fill like Makran – shallow trench).

Birth, life, and death

The discovery of microdiamonds in two billion-year-old rocks in Canada attests to ultrahigh-pressure metamorphism compatible with subduction in the early Proterozoic (Cartigny et al., 2004). The ongoing processes responsible for the sinking of the lithosphere at that time probably differed from those at present since the Earth was hotter than today. For modern subduction zones, Seiya Uyeda, in 1984, has proposed two modes of subduction mechanisms: a forced one (Chilean type) in contrast with a spontaneous one (Mariana type), further used by many authors like Stern and Bloomer (1992). These notions should now be replaced by compressional versus extensional subduction, based on the observation of the dominant strain within the overriding plate and not on the cause of the subduction itself (Heuret and Lallemand, 2005). Indeed, the observation of nascent or young (less than 10 million years old) subduction zones in the western Pacific has shown that all of them result from ongoing collisions and plate boundaries reorganization (Lallemand et al., 2005). None of them can be simply explained by the spontaneous sinking of an old and dense oceanic lithosphere under its own weight. The main driving force for subduction, after it initiates and develops down to a depth of about 200 km, is the slab pull exerted by the excess mass of the slab with respect to the surrounding mantle (Turcotte and Schubert, 1982; Hassani et al., 1997).

Active Continental Margins, Figure 2 Global view of an oceanic subduction zone with an old slab sinking at a high rate in order to get deep earthquakes after Lallemand et al. (2005). The isotherms are deflected along the top of the cold descending slab. Phase changes occur at various temperature/pressure (depth) conditions. This is why they occur at different depths in the slab. Different types of earthquakes (shallow, intermediate, and deep) and stable minerals are described. Variations in the mean density of the slab is indicated in the left column as the main phase transitions occur.

The mantle convection around a subduction mainly results from the dynamics of the plate subduction, not the opposite (Kincaid and Sacks, 1997). Once the subduction process is launched, it becomes stable over millions of years unless an oceanic plateau, an island arc, or a continental block reaches the subduction zone. If this occurs, subduction may stop in the collision zone and jump to another place where a new oceanic subduction may develop (Taiwan, New Guinea, Philippines, Indonesia, etc.). In a few cases, continental subduction prevails for tens of millions of years before plate reorganization (Himalaya, Weissel et al., 1980; Shemenda, 1992).

Tectonic activity
Earthquakes

The subduction process generates large stresses within both converging plates as well as along the subduction interface. Part of the stress is intermittently released seismically (seismic cycle). The largest earthquakes are produced by the so-called subduction earthquakes, i.e., the seismic expression of mega-ruptures along the frictional part of the plate interface, also called "seismogenic zone" (M9.0 2011 Tohoku earthquake, M9.2 2004 Sumatra earthquake, etc.). These particular earthquakes dissipate at least 85 % of the total seismic energy released in the

world (Scholz, 1990). The reason is that the subduction interfaces are the largest faults on Earth (up to several hundred km, even 1,000 + km long) accommodating the largest slips (up to several tens of meters). Kanamori (1977) has shown that the seismic moment for great earthquakes is proportional to the faulted area and the slip on the fault. In addition to the subduction earthquakes, intraplate earthquakes may also occur either in the overriding plate, especially if compressive or extensive stress is transmitted from the subduction zone, or the downgoing plate (commonly called slab when it subducts into the mantle). The intraslab earthquakes include (Figure 2) the flexural earthquakes caused by plate bending near the trench, the intermediate earthquakes (down to about 300 km) resulting from the down-dip stress (often extensional as a result of the slab pull) or the unbending processes necessary to unfold the slab as it penetrates into the mantle, and the deep earthquakes (down to the discontinuity between the upper and lower mantle at 660–670 km). For further details, see also the following entries: "Subduction," "Earthquakes," and "Seismogenic Zone."

Volcanism

Most subduction zones are marked by a volcanic arc located at a distance between 100 and 300 km landward

from the trench and 110 ± 20 km above the subducting slab. Arc magmatism results from the dehydration of the crust and overlying sediment carried by the downgoing oceanic plate. Such dehydration occurs at various depths depending on pressure/temperature conditions, but those occurring below the convective mantle wedge trigger melting and metasomatism of the mantle and subsequent rise of magmas. The explosivity of the volcanism is attributed to the high volatile content in the magma, especially H_2O. Calc-alkaline, potassic calc-alkaline, and shoshonitic series characterize the arc volcanoes lying on continental crust. For further details, see entry "Island Arc Volcanism, Volcanic Arcs."

Terrane collision/accretion and mountain building

Oceanic plates may carry seamounts, plateaus, active or fossil island arcs, and active or fossil spreading centers. Moreover, they may be attached to continents. Thus, it follows logically that during long period of activity of an oceanic subduction, collisions with buoyant features carried by the subducting plate occur. Collisions may be frontal like the Ontong-Java plateau with the Solomon arc or oblique like the Philippine Mobile Belt (Lallemand, 1999). Collisions along active continental margins often give rise to the accretion of crustal slivers (e.g., Izu-Bonin arc accretion in Japan; Tamura et al., 2010) or even large-size exotic terranes of oceanic or continental affinities such as the Caribbean (Antilles) or the Okhotsk (Russia) plateaus, the Panama-Choco (Colombia, Panama) or the Halmahera (Philippines) arcs, and the Qiantang, the Lhasa, or the South China continental blocks (e.g., Lallemand et al., 1998; Taboada et al., 2000; Konstantinovskaia, 2001; Roger et al., 2003; Kroehler et al., 2011). All these accreted blocks contribute to continental growth. When the colliding blocks are large enough, they contribute to mountain building such as the Kunlun Mountain Range north of Tibet or the Eastern Cordillera in Colombia.

Summary

Active continental margins are the most common convergent plate boundaries. They represent one class of subduction zones where an oceanic plate subducts beneath a continental plate. Since their tectonic activity commonly lasts tens of millions of years, they are the locus of continental growth and consumption. Most of the seismic energy is released along these margins. They often concentrate seismic, tsunami, and volcanic hazards.

Definition

Plate tectonics

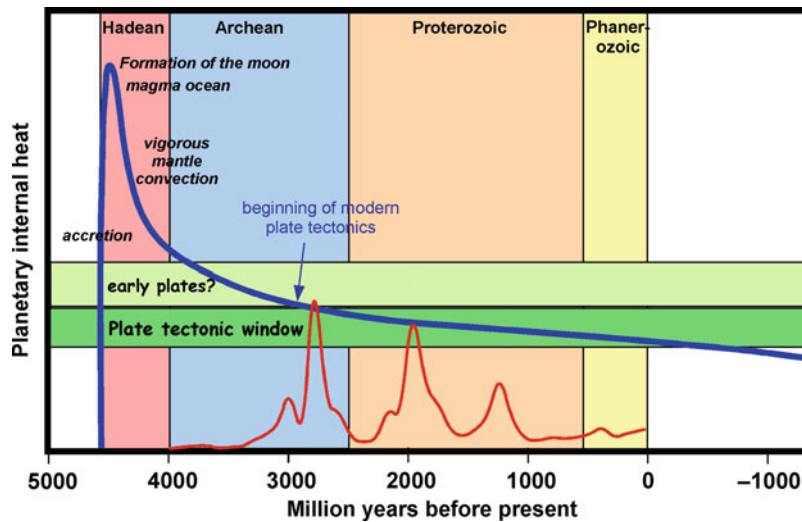
Plate tectonics is a theory which attempts to explain all forms of geological and geophysical observations of the Earth through time in terms of the movement of rigid lithospheric plates that form the upper few tens of kilometers of the Earth. These observations include rock types and their spatial and temporal relationships to each other, their structures and the formation of mountains, the chemical and physical properties of rocks, as well as seismicity, volcanism, and even the distribution of fauna and flora. These lithospheric plates are made up of the crust and the uppermost layers of the mantle (the mantle lithosphere) that are mechanically coupled and can therefore move as a unit on top of convection currents within the mantle. Although moving at rates of only a few centimeters per year, these convection currents explain the movement of continents across the surface over geological time. The crust involved varies from thin ocean crust (around 7 km) to thick continental crust (25–100 km, averaging 35 km). Many plates, such as the South American plate, are topped by extensive tracts of both. When mantle lithosphere is included, some plates may reach total thicknesses of 250 km in the older cores of the continents.

The fact that all geological processes on the modern Earth are thought to be explainable by plate tectonics does not necessarily mean that this was the case for earlier periods in Earth history when the planet was significantly hotter. In deciding whether this was the case, we have a major problem concerning the preservation of rocks from the first half of Earth history. The production and consumption of ocean crust is axiomatic to the operation of plate tectonics, and yet the oldest ocean crust on the Earth's surface today is less than 180 million years old, which is equivalent to only 4 % of the age of the Earth. Linked to this uncertainty is the growth rate of the continental crust, which is thought by most geoscientists to have been gradual or episodic over the 4.57 Ga age of the Earth, with perhaps less than half of it in existence at the end of the Archean period 2,500 myr ago.

History of plate tectonics

The term *plate tectonics* first emerged at the end of the 1960s, following a turbulent decade in which many branches of the geological sciences reorganized their understanding of geological processes to fit this single all-encompassing theory. Its forerunner was continental drift, which followed centuries-old observations such as the similarity of coastline form between Africa and South America, and hypothesized the lateral movement of continents over thousands of kilometers. Continental drift, most commonly associated with the work of Alfred Wegener, remained controversial for several decades owing to the lack of an explanatory mechanism. It received support from the then new science of paleomagnetism in the 1950s, which demonstrated the movement of continents around rotation poles (Runcorn, 1959), but it was the introduction of marine geology and geophysics in the late 1950s that led to the breakthrough. Magnetic stripes were discovered on the ocean floor (Raff and Mason, 1961) and eventually proved to be symmetrically distributed across mid ocean ridges (Pitman and Heirtzler, 1966). The concept of sea-floor spreading was born (Vine and Matthews, 1963), once again linked to rotation around poles that also explained the newly discovered transform faults between ridge segments (Wilson, 1965). However, if sea-floor spreading occurs commonly on a planet of constant size (there were a few who denied this; Carey, 1975), then the ocean crust produced must also disappear again, and this led to the concept of subduction zones (Le Pichon 1968), where sinking ocean crust is delineated by seismically active zones below island arcs (Isacks et al., 1968). Once the mathematical explanation of the rotation of rigid lithospheric plates around poles and the catalog of possible triple junctions was in place (McKenzie and Parker, 1967; McKenzie and Morgan, 1969), all that remained was to fit regional geology including mountains, rifts, and continental margins into the model to explain the geological history of Earth through time (Dickinson, 1970; Dewey and Bird, 1970). For the last 40 years, plate tectonics has been the single complete geological theory into which all geological and geophysical observations are expected to fit.

Mechanisms of plate tectonics

In order to decide whether plate tectonics functioned either differently or even at all early in Earth's history, it is necessary to consider how plate tectonics is thought to work and what characteristics lead us to decide in favor of it. Some of the features described earlier in favor of continental drift, such as the similarity of coastlines between continents, the movement of continents across the surface of the globe, and polar wander curves defined by paleomagnetism, are compatible with plate tectonics but do not require it. The underlying mechanism lies in the distinction between the rigid upper lithosphere and the ability of the asthenosphere below it to flow and requires convection currents in the mantle below the lithosphere. Forces


Ancient Plate Tectonics, Figure 1 Evolution of planetary temperature (*blue line*) indicating entry into the plate tectonic window (*green* box) in the mid Archean from hotter conditions resulting from planetary accretion. Crustal formation in the period labeled "early plates?" may have occurred by melting of the base of thick crust without modern-style subduction. The *red line* indicates major episodes of continental crust formation deduced from the ages of igneous rocks. See text for further explanation.

that act to move the plates are (1) the drag caused by partial coupling of the asthenosphere to the lithospheric plates above it, so that the plates follow the convection movements; (2) phase transformations in the subducting crust and lithosphere, which increase the density of the rocks and therefore cause them to sink through the mantle (known as "slab pull"); and (3) a lateral "ridge push" force imparted by the mountains of the mid ocean ridges where ocean crust is formed; new crust is formed at the top of the ridge and so causes a gravitational force pushing the slightly older crust to both sides. The slab pull force is due mainly to two reactions; the conversion of basalt and gabbro to eclogite (about 20 % denser) in the upper 30–40 km and the transformation of olivine to a high-pressure spinel structure at around 400 km depth (12 % density increase).

For the discussion of whether plate tectonics operated earlier in Earth history, mantle convection will certainly have occurred and volcanism may have been more abundant at any particular time, but the second-phase transformation of the slab pull force will only have functioned if subduction to depths of more than 400 km occurred.

The evolution of temperature in the Earth: the background to global tectonic regimes

Since mantle convection is an essential prerequisite for plate tectonics, and convection will occur once a given threshold is reached (a Rayleigh number of more than 2,380), the state of internal heat of the Earth as a function of time is the deciding factor. The blue curve in Figure 1 shows the approximate expected heat evolution of the Earth. The colored background panels refer to the four Eons, the Hadean before the first preserved rocks,

the Archean until 2,500 Ma, the Proterozoic, and the Phanerozoic, which started with the massive preservation of skeletal fossils at 542 Ma. The blue line begins with the growth of the planet during the accretion of the solar nebula at around 4,567 Ma. At least 85 % of the internal heat of the planet is derived from accretion energy (collisions between small planetary bodies and planetesimals) and the separation of the metallic core: if the moon was formed by a major impact at about 4,500 Ma as considered likely by most scientists (Lee et al., 1997), then this figure is much more than 90 %. The gradual loss of heat after planet formation and the end of collisions is due to two factors: the loss of heat to space due to conduction through the crust and the gradual radiogenic decay of isotopes, particularly K, U, and Th, which decreases with time leading to a flattening of the curve as the parent isotopes become rarer. The green bar shows a postulated "plate tectonic window" (Condie, 1989) in which plate tectonics may operate. Vigorous convection would follow the accretion process and the great loss of heat at this time is unlikely to have allowed the survival and orderly movement of plates. At the other end of the timescale, continued loss of heat and diminishing heat production from radioactive decay will cause the Earth to drop out of the plate tectonic window and form a one-plate planet sometime in the future; the time at which this may happen is not known.

Note that there are many unknowns in the form of the curve and that it should only be taken as a conceptual illustration. Two important unknowns are the rate of decrease after the accretion peak and the degree to which episodic processes may cause humps in the curve (Davies, 1995). The height of the peak is poorly known, but accepting the giant impact model for the origin of the moon (Canup and Asphaug, 2001), the age of the moon at

4,500 Ma must correspond to the existence of a magma ocean in the Earth that may have been hundreds of kilometers thick, resulting in extremely hot conditions near the surface of the early Earth. However, this state may not have lasted for very long, as investigations of the oxygen isotope compositions of the earliest rocks and minerals (zircons) find that they formed in cool conditions in siliceous crustal rocks (that have since been destroyed) near the Earth's surface (Valley et al., 2002). Since the oldest of these zircons are 4,404 Ma (Wilde et al., 2001), there appears to be only 100 million years for the Earth to progress from extremely hot to cool conditions. The other major simplification in the curve is that it represents the whole Earth and implies a gradual, smooth evolution without any episodic or catastrophic developments. This contrasts with the red line superimposed on Figure 1, which shows the rate of production of new continental crust as gauged by the ages of igneous rocks on the same timescale (Hawkesworth and Kemp, 2006). Although there is some discussion as to whether this really indicates ages of crustal growth rather than merely its survival, there appear to be major periods of crustal formation in the late Archean (3,000–2,500 Ma) and in the early Proterozoic (2,000–1,750 Ma), with an additional pulse at around 1,100 Ma. There may have been a similar episodism in plate movements and subduction (O'Neill et al., 2007). These two uncertainties emphasize that the slope of the curve and its exact form are debatable, and therefore, the point marked for entry into the plate tectonic window at around 3,000 Ma can only be approximate, although there is increasing evidence for the onset of modern-style (i.e., steep and deep) plate tectonics at around 3,200 Ma (Shirey and Richardson, 2011; Van Kranendonk, 2011; Dhuime et al., 2012).

The other open question is that if plate tectonics did begin at about this time, then what happened before that? Was there some other form and movement of lithospheric plates that is distinguishable from the modern style (indicated by the light green band in Figure 1; Brown, 2007), or could small plates tip towards each other like ice floes in the Antarctic, or was there a thick lid of crust that was recycled into the mantle by eclogite dripping from its base?

An outline of Archean geology

To adequately assess whether plate tectonics could have operated during the first half of Earth history, it is important not just to ascertain the presence or absence of indicators for plate tectonics but also to explain the Archean geological record. Archean rocks consist of about 80 % high-grade gneisses, mostly summarized as the tonalite-trondhjemite-granodiorite (or TTG) suite, and 20 % greenstone belts with lower metamorphic grade. The gneisses have igneous origins and can be explained by melting of basaltic protolith material (Foley et al., 2002; Rapp et al., 2003). Their deformation often indicates lateral compression, although in some regions, most notably Western

Australia, vertical movements may have been important (Chardon et al., 1996). On the modern Earth, tonalitic melts are formed by melting of basaltic material at subduction zones, and so a subduction environment is the most commonly invoked option to explain them in the Archean. Greenstone belts consist principally of volcanic rocks and sediments wedged between domes of high-grade gneisses. Their most famous constituents are komatiites, which are magnesium-rich mafic volcanics that are almost exclusively Archean in age (Arndt and Nisbet, 1982). However, the majority of volcanics in greenstone belts are more "normal" basaltic to felsic rocks, and not komatiites. The sediments are dominantly texturally immature, whereas shelf sediments such as carbonates and mature sandstones, although present back to 3.5 Ga, are much less common (Eriksson et al., 1994). This would be expected on a planet on which island arc environments and/or volcanic plateaux are common but continents are rare; the first continents would be formed by the amalgamation of island arcs, and all sediments that are preserved would be formed close to these arcs. The rarity of shelf sediments may correspond to the rarity of continents. The relationship between the high-grade gneisses and greenstone belts ought, therefore, to be of paramount interest, but unfortunately, most contacts between them are the locations of later tectonic movements. Examples exist, however, that show basal unconformities, leading to the conclusion that greenstones commonly do not represent ocean crust but were deposited on continents (Bickle et al., 1994; Buick et al., 1995).

There are also changes in rock types towards the end of the Archean; following the peak in continental crust formation at 2.7 Ga (Figure 1), more potassic granites that are typical for later periods in Earth history become most common, often appearing to seal large sections of the newly formed crust together into stable continents. Other rocks remain notably absent – eclogites and blueschists – which are indicators of high-pressure metamorphism at low pressures, and do not appear until around 2,100 Ma.

The characteristics of plate tectonics

From theoretical expectations, we may consider how we can decide if plate tectonics operates on a planet and then deliberate about whether these features are relevant for the early Earth. Table 1 lists the main features by which the operation of either continental drift or plate tectonics can be recognized on the modern Earth. The problem in ascertaining the relevance of plate tectonics for the Archean and Proterozoic Eras is that most of these criteria depend either on geophysical measurements that only provide a picture of the Earth today or on good preservation of rock associations and geological structures. Much of the acceptance and detail of plate tectonics is due to seismological and other geophysical surveys that provide information on all levels of the deep Earth, documenting seismic discontinuities that delineate the size of core and mantle, that the outer core is molten (Fowler, 2005), and

Ancient Plate Tectonics, Table 1 Criteria for continental drift or plate tectonics. Due to the young age of preserved ocean crust, the effects of metamorphism and deformation, and the restriction of geophysics to the present, most evidence for ancient plate tectonics is indirect

Feature	Evidence for	Applicable to Archean?
Geophysical, geomorphological, and geological indicators on the modern Earth		
Matching coastlines	Continental drift	No
Same fauna and flora on different continents	Continental drift	No
Polar wander curves	Continental drift	Maybe, but very limited
Magnetic stripes/reversals	Sea-floor spreading	No
Earthquake zones under arcs	Subduction	No
Seismic tomography	Deep subduction	No
Geological indicators for plate tectonics in the past		
Hadean zircons	Continental crust	Yes
Linear mountain ranges	Continental collision	Yes
Shelf sediments	Continents and their margins	Yes, but restricted
Continental rift rock associations	Continents and lateral movements	Yes, but continents restricted
Large transcurrent faults	Lateral plate movements	Yes, but controversial
Ophiolites	Ocean crust	Yes, but controversial
Geochemical signature of subduction in igneous rocks	Subduction	Yes, but controversial
Arc igneous rock associations	Subduction	Yes, but restricted
Eclogite	Subduction	Yes, but missing at the surface
Blueschist rock belts	Subduction (cold)	Yes, but missing
Sodic granites	Subduction	Yes, but controversial
Paired metamorphic belts	Subduction and collision	Yes, but restricted
Accretionary prisms	Subduction	Yes, but continents restricted

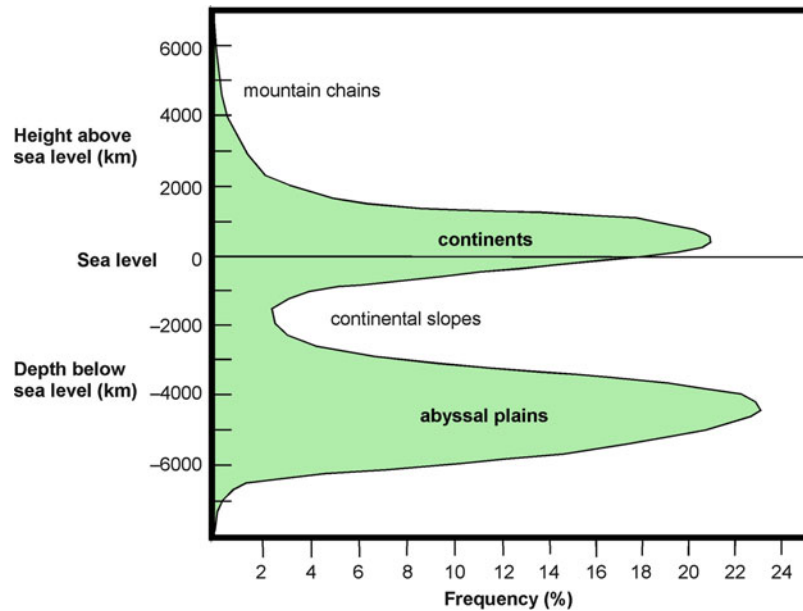
the densities of rocks that constitute these layers (Anderson, 1989).

However, few of the criteria for either continental drift or plate tectonics can be successfully used for the Archean or early Proterozoic, which according to Figure 1 is the time period where plate tectonics is questionable. Of geophysical measurements, seismological records are little more than 100 years old and cannot be carried out in retrospect; only the science of paleomagnetism, which first documented continental drift (Runcorn, 1959), can be used in the distant geological past (Strik et al., 2003), but even here, the accuracy and certainty of interpretations

diminishes as we go back into the Archean and requires coupling to accurate age determinations for earlier times (Evans and Pisarevsky, 2008).

We are left with the indirect geological indicators in the second part of Table 1 that rely on the interpretation of the rock record. A cursory look shows that most of these are potentially applicable, but either their interpretation is to some extent controversial or their application is restricted. This restriction is mostly temporal, meaning that there is a time limit for each before which they cannot be unambiguously recognized. This may be because they did not exist or because of the effects of deformation and metamorphism (the large majority of early Archean rocks have been highly deformed and metamorphosed at medium or high temperatures) or even their complete destruction. Many make a first appearance between 3.3 and 2.6 Ga, but a first appearance must be taken to be a minimum age as they may have existed beforehand but no longer be recognizable. An example of differential preservation is the earliest eclogites, which are evidence for metamorphism of basalts or ocean crust at very high pressures. If we were to restrict our attention to those preserved in collision zones on the continents, then we would conclude that the oldest are younger than 2.9 Ga (Mints et al., 2010), whereas they are common as xenoliths trapped in the mantle lithosphere from 3.3 Ga, where they are interpreted to represent pieces of subducted ocean crust (Jacob, 2004).

The criteria in Table 1 address continental crust, ocean crust, and the subduction process, which raises an important point for discussion of plate tectonics. The hypsometric curve, which shows the distribution of crustal levels above and below sea-level on the Earth, shows a bimodal distribution on the Earth, with most crust around 200 m above or 3–4 km below sea-level (Figure 2). This is equivalent to the distinction between continental and oceanic crust and can be taken to indicate the operation of plate tectonics over several hundreds of millions of years. Before plate tectonics began to function, the term "ocean crust" may have little meaning: there may have been just "crust," broadly of mafic composition, and the huge variety of crustal elevations may not have been present.

The time and rate of formation of the *continental* crust is a controversial topic, but currently most geologists accept episodic formation and accumulation of the continental crust through time (red curve in Figure 1). This would mean that there was less than half the current volume of continental crust until a major phase of production between 3.0 and 2.5 Ga at the close of the Archean. The main controversy lies in the degree to which former continental crust may have been recycled into the mantle (Scholl and von Heune, 2007), such that the alleged crustal formation rate really illustrates the rate of crustal survival. Added to this uncertainty is the high degree of deformation and metamorphism in many Archean rocks, which hampers the interpretation of their formation. The existence of zircons dating from the Hadean


Ancient Plate Tectonics, Figure 2 The hypsometric curve for the Earth today, indicating that most crust is slightly above sea-level (continental crust) or 3–4 km below sea-level (oceanic crust). This bimodality of elevations is a logical consequence of the operation of plate tectonics for several hundred million years.

(4.4–4.0 Ga), although preserved in younger rocks (Wilde et al., 2001), is thought to demonstrate the existence of some siliceous crust at the time, but does that have to be continental crust, or could it be merely siliceous scum on pre-plate tectonic crust? Small sections of felsic crust on large rafts of mafic crust may have been too insignificant volumetrically to prevent wholesale recycling of the crust and its remixing into the mantle.

In terms of structures, plate tectonics results in linear collisional belts of mountains and large strike-slip faults, but taken alone these are indications of lateral crustal movements, but not necessarily plate tectonics. Shelf sediments and rock associations typical of continental rifts are rare until the late Archean, but one cannot expect these before continental crust itself becomes abundant.

The best evidence for ocean crust takes the form of ophiolites, which are rock packages consisting of basalts and gabbros of the ocean crust underlying marine sediments and overlying ultramafic rocks of the uppermost mantle. Opinions differ greatly as to the first appearance of ophiolites; some scientists require the complete package to be present, whereas basalts with an oceanic geochemical signature suffice for others. The first relatively complete ophiolites date from around 2.0 Ga (Scott et al., 1991; Peltonen and Kontinen, 2004), whereas partial ones are claimed for the earliest Archean (de Wit, 1998). Due to the ephemeral nature of ocean crust, it is much more poorly preserved than continental crust, and some sections of mafic crust interpreted as ocean crust may be from the pre-plate tectonic mafic crust. The eclogite xenoliths already mentioned contain clear evidence of having been at the surface and were later returned to the mantle – but by which process? This may not be clear evidence for subduction in the modern plate tectonic style.

Most entries in Table 1 consider the subduction process, as this appears to be the best key to indicating that plate tectonics functioned. All of these either suffer from the preservation problem or are only indirect indictors. The high-pressure, low-temperature metamorphism characteristic of modern subduction produces eclogites and blueschists, and these ideally occur as part of paired metamorphic belts together with low-pressure, high-temperature metamorphism formed at the other side of the subduction suture (Miyashiro, 1961). Blueschists are not known from before 1 Ga (Stern, 2005). However, this time limit addresses large occurrences that can be recognized in the field. Evidence is found for much earlier high-pressure, low-temperature metamorphism as relict features preserved on a microscopic scale in rocks that have been re-equilibrated at lower pressures. These can be used to show that the duality of thermal indicators across subduction sutures can be recognized as far back as 3.26 Ga (Moyen et al., 2006), but at this time the temperature difference between the two sides was considerably smaller than in Phanerozoic times. Before 3.26 Ga, the pair of thermal indicators has not been found, and no relicts for high-pressure, low-temperature metamorphism are known (Brown, 2007; van Kranendonk, 2011).

The most widely used evidence for tectonic settings in old rocks is indirect and concerns the recognition of trace element geochemical signatures reminiscent of modern plate tectonic environments such as island arcs, mid ocean

ridges, oceanic plateaux, and back arc basins (Smithies et al., 2005; Pearce, 2008). However, these are prone to overinterpretation, as they are not foolproof on the modern Earth: for example, continental flood basalts are known to have low-Ti characteristics normally associated with island arc volcanism and calc-alkaline rocks that are characteristic of magmatic arcs above subduction zones also been found in non-subduction settings (e.g., Hooper et al., 2002; Willbold et al., 2009) are known. There is a tendency to engrave interpretations from modern settings onto ancient rocks, although most Archean rocks give mixed signals (Pearce, 2008). But here again, the oldest arc-like greenstones appear to be between 3.2 and 3.1 Ga (Smithies et al., 2005). An additional option is to use rock types characteristic for subduction zones, which include andesites, boninites, shoshonites, and adakites. Most of these become frequent in the late Archean (Condie and Kroner, 2008), whereas adakite is a rock type from modern subduction zones (island arcs and Andean-type subduction beneath continental crust) that is similar to tonalitic and trondhjemitic gneisses that make up large tracts of the Archean continental crust. These are thought to indicate a subduction environment because they do not form in modern plume-related environments (Martin, 1999).

A different type of plate tectonics or no plate tectonics at all?

The Archean rock record consists of small continent-like blocks of high-grade gneisses of broadly tonalitic composition and subordinate greenstone belts that are composed mostly of volcanic rocks and texturally immature sedimentary rocks. These rocks are quite common from 3 Ga onwards, but similar rocks are present from the beginning of the Archean: tonalitic gneisses make up the bulk of the Itsaq complex of western Greenland, dated at 3,800 Ma (Nutman et al., 1999), and supracrustal rocks of similar age occur both here and in northern Quebec (Mloszewska et al., 2012). As we trace them back into the Archean, several of the best plate tectonic indicators, such as paired metamorphic belts, high-pressure, low-temperature metamorphism, and greenstone volcanics with arc-like geochemistry, seem to "pinch out" at about 3.1–3.3 Ga. For the beginning of plate tectonics, no single indicator is as convincing as the testimonial given by the accumulation of these lines of evidence at this time. Even so, the lack of eclogites and blueschists leads some to distinguish between *Proterozoic plate tectonics* (approximately 3,300–700 Ma) and *modern plate tectonics* (after 700 Ma; Brown, 2007). Before 3.3 Ga, we have only a limited number of indicators, but these tell us that TTG magmatism occurred from the beginning of the Archean, although with a tendency for MgO poorer, SiO_2-richer compositions earlier on in time. This possibly indicates a type of shallow subduction, in which the subducting crustal plate directly underlies the overriding plate so that reaction of TTG melts with the mantle wedge could not occur. As time passed and the Earth cooled, subduction to deeper levels occurred and reaction with the mantle became more common.

However, the production of TTG melts does not necessarily denote subduction. The requirement from high-pressure experiments is that these melts must be derived by melting of basalt, but these experiments say nothing about how this basalt reaches its melting conditions. The main competitor hypotheses to subduction for explaining the origin of TTG melts are oceanic plateaux and stagnant lid tectonics. The oceanic plateau model uses the analogy of thickened ocean crust on the modern Earth, which are caused by extra heating from below by mantle plumes, resulting in crust up to 35 km thick (Neal et al., 1997). Thus, formation of some crust as oceanic plateaux could apply to an Archean Earth with plate tectonics, but a major uncertainty in this case becomes the behavior of this thick mafic crust in subduction zones. Can such thick crust be subducted as a unit, or does just part of it return to the mantle and the upper parts accumulate at the surface? In this scenario, the basaltic source rocks for TTG melts are derived from thick piles of volcanics that simply become buried to lower crustal levels because of continued volcanism.

The ocean plateau model is generally thought to work within plate tectonics and does not seem adequate for the early Archean if complete recycling of crust commonly occurred. Here a stagnant lid scenario may be more appropriate, in which the thick crust is not subducted, but the lower levels delaminate and melt back into the mantle. Only the upper sections of crust are preserved, a scenario known as "flake tectonics" (Hoffman and Ranalli, 1988). In the earliest Archean or Hadean, blocks of crust may have tipped like ice flows, thus returning extensive blocks of crust to the mantle without the mechanism of subduction as it occurs on the modern Earth.

It is probable that the large degree of crustal recycling implied by the paucity of surviving crust from the early Archean is incompatible with plate tectonics in its modern form. The transition to plate tectonics may have occurred during the period 3.3–3.1 Ga, followed by an immense increase in the survival of continental crust (Figure 1). The Archean-Proterozoic boundary at 2.5 Ga is the much more publicized major disjuncture in the geological record, but these changes in geological style could only have occurred after abundant continental crust had collected for long periods. The middle Archean may have been a time in which plate tectonics operated on some parts of the Earth, but not on others, and it may have been intermittent (O'Neill et al., 2007).

Summary

Taking multiple indicators into account together, there is good evidence for the operation of plate tectonics on the Earth as far back as 3.3 Ga, but it may have been

a modified form until the late Proterozoic without deep subduction and the production of ultrahigh pressure metamorphic belts. In the early Archean, the production of early SiO_2-rich crust may have been caused by melting at the base of a uniformly thick global crust or oceanic plateaux, with or without subduction as on the modern Earth. In the past few years, the number of lines of evidence for cool conditions at the end of the Hadean is increasing, such as the stable isotope signatures of zircons and the composition of TTG gneisses. The importance and abundance of komatiites and exceptional mantle temperatures in the Archean may have been overestimated in the past.

Definition

A large body of open marine water free of dissolved molecular oxygen and potentially containing dissolved hydrogen sulfide.

Introduction

Today's world oceans are dominated by oxic water masses, except for some marginal basins like the Black Sea, fjords, upwelling areas, and so-called coastal "anoxic dead zones." However, since the formation of oceans on Earth, anoxic (oxygen-free) conditions have occurred frequently in parts of the global ocean, leading to the deposition of organic-rich sediments that subsequently generated oil or gas, the main energy source for our modern civilization. Here we will focus on deep ocean anoxia, their environmental controls, and their geological expressions.

The Proterozoic

Throughout large parts of the Precambrian, the oceans were anoxic. Oxygen-producing photosynthetic organisms like algae were only beginning to evolve, and atmospheric oxygen levels were orders of magnitude lower than at present. Due to this oxygen-poor atmosphere, sulfate was not produced in significant quantities by chemical weathering of magmatic rocks on land, and sulfate concentrations in the early oceans were low. In contrast, dissolved Fe concentrations were very high due to hydrothermal input related to ocean crust formation, reductive weathering on land, and possibly diagenetic Fe release from sediments. These oxygen-free, sulfate-poor but iron-rich (ferruginous) oceans persisted over much of the Proterozoic until the Great Oxidation Event (Canfield, 1998), which initiated the global deposition of banded iron formations (BIFs). When atmospheric oxygen concentrations reached a threshold, the oxidative weathering of sulfide minerals led to the establishment of the marine sulfate pool. Consequently, organic matter degradation by microbial sulfate reduction started to release hydrogen sulfide into the water column. As the dissolved Fe in the water column reacted with hydrogen sulfide to form pyrite, ferruginous conditions were gradually replaced by sulfidic (euxinic) conditions in the marine environment. With increasing atmospheric oxygen, the spatial extent of marine anoxia/euxinia was reduced, only persisting in certain ocean regions (Poulton et al., 2010). While the expansion and duration of Proterozoic deep ocean anoxia were never reached again, there were still periods in the Phanerozoic with widely distributed deep ocean anoxia.

The Phanerozoic

Several intervals of deep ocean anoxia occurred throughout the Phanerozoic (see review by Meyer and Kump, 2008). Their most prominent geological expressions include organic-rich deposits ("black shales") from the Cambrian of China, the Ordovician of North America, the Silurian of North Africa, and the Devonian-Lower Carboniferous of the USA and Europe. Most of these Paleozoic deposits represent shallow marine environments, and synchronous records from the deep oceans are largely missing. In contrast, there is evidence for widespread deepwater anoxia around the Permian-Triassic boundary, coinciding with the most severe extinction event in Earth history (Meyer and Kump, 2008). In the Mesozoic, a number of rather short-termed but severe and widely recognized intervals of ocean anoxia occurred, the so-called oceanic anoxic events (OAEs; Schlanger and Jenkyns, 1976). Although their full global expansion is debated (e.g., Trabucho Alexandre et al., 2010), there is evidence that at least the North Atlantic and Tethys were periodically affected by intense deepwater anoxia to euxinia, whereas comparable records from the Pacific and Indian Oceans are scarce. The Toarcian Oceanic Anoxic Event (T-OAE) and the Cenomanian-Turonian Boundary Event (CTBE or OAE2) are considered to be the most widespread occurrences of Mesozoic marine anoxia (Jenkyns, 2010). The Cenozoic sediment record is comparably poor in black shale-type deposits. Organic-rich sediments related to the Paleocene-Eocene Thermal Maximum (PETM) are mostly limited to shallow marine environments (Cohen et al., 2007). However, the deep Arctic Ocean record shows clear signs of Paleocene and Eocene deepwater anoxia, most likely related to its restricted circulation and stable water column stratification. The most recent witnesses of short-termed deepwater anoxia are Pliocene-Pleistocene sapropels of the Eastern Mediterranean (Emeis et al., 2000; De Lange et al., 2008).

"Modern analogues"

In the modern ocean, there are no true analogues for open marine black shale formation. However, a number of "near-analogue" environments can serve as natural laboratories to study some of the physical, chemical, and biological processes that interacted in past anoxic oceans (Demaison and Moore, 1980). The most prominent example is the Black Sea, Earth's largest permanently euxinic marine basin (Degens and Ross, 1974). It is characterized by moderate primary productivity but strong salinity stratification and a very restricted connection to the Mediterranean. A similarly well-studied but less restricted and less euxinic marine environment is the Cariaco Basin, and also a number of fjords and bays around the world (e.g., Framvaren Fjord, Saanich Inlet, Kau Bay) exhibit multiannual deepwater anoxia to euxinia (Richards, 1965; Tissot and Welte, 1984). Also coastal upwelling areas (e.g., off Namibia, Chile, Peru, Arabian Sea) share common features with past anoxic oceans as they display high seasonal primary productivity, leading to deepwater oxygen consumption and occasional development of sulfidic water masses (Copenhagen, 1953). Over the past decades, the study of geochemically similar but spatially restricted analogues has advanced our understanding of past anoxic oceans. A wide range of geochemical proxies is now at hand to unravel the paleoenvironmental setting from sedimentary archives.

Environmental controls: organic matter export, water column stratification, plate tectonics, and astronomical forcing

Two fundamental environmental parameters are traditionally suggested as drivers of oceanic anoxia: high primary productivity inducing enhanced organic matter export to the seafloor and enhanced organic matter preservation by limited deepwater ventilation, i.e., low oxygen (Demaison and Moore, 1980). Modern end-members of this "productivity versus preservation" debate are the Black Sea, on the one hand (moderate productivity, severe basin restriction, salinity stratification, absence of molecular oxygen below redoxcline), and upwelling areas, on the other hand (full connection to the open ocean, seasonally very high productivity). Recent studies suggest that most black shale deposits do not allow a strict differentiation between organic matter productivity and preservation as dominant cause for organic carbon accumulation and anoxia. Past examples of restricted anoxic basins include the mid-Cretaceous proto-North Atlantic and the Paleogene Arctic Ocean. Past high-productivity regions with anoxic water masses developed in the mid-Cretaceous equatorial Atlantic as nutrients were "trapped" due to specific circulation patterns (Trabucho Alexandre et al., 2010). To create and maintain marine anoxia, a range of important biogeochemical feedback mechanisms needs to be considered. One well-known "anoxia-productivity feedback" is the efficient recycling of phosphate from marine sediments if bottom-water oxygen is strongly depleted (Ingall et al., 1993; Slomp et al., 2004; März et al., 2008). Recycled phosphate can then be reintroduced into the photic zone and sustain high-productivity and organic matter export.

Although the onsets and terminations of widespread ocean anoxia are still debated, they appear to be related to plate tectonics and volcanism (Meyer and Kump, 2008). Astronomical forcing can regulate the intensity of anoxia once favorable conditions have been created (De Lange et al., 2008). Plate tectonic constellations are responsible for the restriction of ocean basins (e.g., the mid-Cretaceous North and South Atlantic), reducing the renewal and oxygenation of deepwater masses (Erbacher et al., 2001). Volcanic activity introduces large amounts of the greenhouse gas CO_2 into the atmosphere, leading to both global warming and enhanced chemical weathering (Turgeon and Creaser, 2008). Warming reduces the oxygen solubility in the oceans and the vertical mixing of its water masses, and chemical weathering

enhances terrestrial nutrient input into the oceans (Adams et al., 2010). Global warming leads to eustatic sea-level rise, concomitant widespread flooding, and an expansion of shelf sea areas. Besides the increased potential for shelf anoxia, these shallow marine areas also trap a large fraction of siliciclastic detritus before it reaches the deep basins. Therefore, organic-rich deepwater deposits are often characterized by reduced terrestrial dilution (Arthur et al., 1988).

Recognizing anoxia in sedimentary archives

As most multicellular organisms (such as benthic foraminifera) require oxygen to survive, anoxic environments are usually strongly deprived in macroscopic life. The sedimentological expressions of this lack of burrowing macrobenthos are finely laminated deposits without any bioturbation.

Both organic and inorganic geochemistry provides a number of proxies to detect anoxia/euxinia in different parts of a water column. For instance, a biomarker to detect euxinic conditions in the photic zone is isorenieratene, an organic pigment exclusively produced by phototrophic green and purple sulfur bacteria (Sinninghe Damsté et al., 1993).

A first-order geochemical approach to reconstruct marine anoxia was the organic carbon to total sulfur (C/S) ratio of Black Sea deposits (Berner, 1984). While normal, oxic marine sediments exhibited C/S ratios around 3, the production of H_2S by organic matter degradation in the Black Sea, and its subsequent precipitation as metal sulfides (mostly pyrite, FeS_2), resulted in C/S ratios <3. A better representation of the C-S-Fe interrelationship is a ternary diagram with the end-members organic C, total S, and reactive Fe, as it allows a distinction between anoxic systems where pyrite formation was limited by H_2S or reactive Fe (Dean and Arthur, 1989).

Under anoxic ferruginous conditions, the sulfate depletion of the water column prevents any enrichment of sedimentary S and hence the recognition of water column anoxia using bulk sedimentary C-S-Fe proxies (Poulton and Canfield, 2011). To distinguish non-sulfidic from sulfidic conditions, a sequential Fe extraction scheme distinguishes between the relative amounts of the Fe pool that can potentially react, or already have reacted, with H_2S (Poulton and Canfield, 2005). In addition to C-S-Fe systematic, the selective removal of sedimentary P relative to organic C under anoxic conditions results in increasing sedimentary C/P ratios under increasingly oxygen-depleted bottom-water conditions (Algeo and Ingall, 2007).

Among the most powerful redox proxies are trace metal enrichments/depletions relative to their lithogenic background contents (Brumsack, 2006). Redox-sensitive metals change their redox states under oxic, suboxic, and anoxic conditions (e.g., Mn, U, V); sulfide-forming metals precipitate sulfide phases/coprecipitate with pyrite if H_2S is available (e.g., Mo, Cd, Zn). While questions remain in our understanding of natural trace metal systematics, several metals have emerged over the years as reliable redox indicators. While Mn tends to be depleted from sediments already under suboxic conditions, Re becomes enriched within sulfidic microenvironments in the sediment. Uranium is enriched if full anoxia is reached in the sediments, while Cd and Zn precipitate as sulfides under weakly sulfidic conditions. Molybdenum requires stronger euxinia in the water column to be transferred to particle-reactive thiomolybdates. The interpretation of trace metal records is complicated by the fact that some of these elements serve as micronutrients and are pre-concentrated via plankton (Böning et al., 2004) before burial. They may as well respond to specific redox conditions in the surface sediment, while others respond to redox changes in the water column. Early diagenetic processes pose another challenge, as trace metals may be redistributed within the sediment, biasing the primary redox record.

Beyond element contents and speciation in marine sediments, the stable isotopic signatures of metals like Mo and Fe are increasingly used as redox indicators (Anbar and Rouxel, 2007). The specific value of Mo isotopes is based on the quantitative removal of Mo from a water column under fully euxinic conditions without any isotope fractionation. Through isotope and mass balance calculations, this ultimately gives the percentage of the global oceanic water mass that was fully euxinic at a given point in time. The stable Fe isotope composition of marine sediments, in conjunction with total Fe enrichment patterns, is controlled by the input of isotopically light Fe from suboxic shelf sediments and the shuttling and distribution of this excess Fe within a suboxic redoxcline. Therefore, the depth of the redoxcline in a water column and the extent of underlying euxinic water masses can be reconstructed (Eckert et al., 2013). However, the full application of these isotope systems as paleo-redox proxies will require a better understanding of these trace metals and their isotopes in the marine environment under a variety of boundary conditions.

Conclusions

Our understanding of anoxic conditions in the oceans has greatly advanced over the past decades. The classic "productivity versus preservation" discussion sparked many of these advances and has motivated scientists to take a closer look at the underlying mechanisms causing, sustaining, and terminating ocean anoxia. This was achieved by combining studies of modern and ancient anoxic marine environments and by working across scientific disciplines. Nowadays, geoscientists can take advantage of a large set of analytical tools and paleoenvironmental proxies that led to a better understanding of, e.g., the causes for the development of anoxic conditions, their effects on organisms, global element cycles and the climate system, duration and spatial extent of anoxia and euxinia, the degree of anoxia or euxinia, and the reasons for their

termination. Still, many questions remain about marine anoxia. Facing a warming ocean and intensifying oxygen depletion in coastal and open oceans, these questions are certainly relevant for the development and understanding of our future ocean.

ASPHALT VOLCANISM

Gerhard Bohrmann
MARUM-Center for Marine Environmental Sciences,
University of Bremen, Bremen, Germany

Definition

Asphalt volcanism is a type of hydrocarbon seepage associated with submarine mounds found in the Gulf of Mexico and the Santa Barbara Basin. The term asphalt volcanism was introduced because of the lavalike appearance of the asphalt flows and several other indications, which resemble magmatic eruptions.

Asphalt seepage versus asphalt volcanism

Although asphalt deposits have been described from several places of the ocean floor, the term asphalt volcanism has been introduced as a novel type of hydrocarbon seepage by MacDonald et al. (2004) after an area of approximately 1 km² solidified asphalt was found on top of one of the Campeche Knolls in the southern Gulf of Mexico. The knoll was subsequently named Chapopote which is the Aztec word for tar. Those knolls in the Gulf of Mexico are clearly associated with salt tectonism which controls the development of hydrocarbon reservoirs and faults that allow oil and gas to escape at the seafloor. Guided by satellite data that showed evidence of persistent oil seepage in the region, the seafloor of Chapopote was mapped and investigated by MacDonald et al. (2004). Visual surveys revealed extensive surface deposits of solidified asphalt and light crude oil, emanating from sites along the southern rim of a crater-like structure in 3.000 m water depth. Some of the asphalt flows were measured to be at least 15 m across and extended far down the slope. In some places the surface appearance of the asphalt deposits was blocky or ropy (Figure 1) similar to pa'hoehoe lava flows of basalt. Furthermore, large areas of the asphalt deposits were colonized by vestimentiferan tubeworms, bacterial mats, and other biological communities. Also discovered alongside the asphalt were locations of sediment/gas hydrate interlayering associated with emanating gas and oil bubbles from the seafloor.

Based on the collected data and observations, MacDonald et al. (2004) postulated repeated, extensive eruptions of molten asphalt under conditions which could destabilize gas hydrates on the seafloor. A violent destabilization of hydrates could contribute to slope failures and mass wasting mapped on Chapopote Knoll, as well as documented on other Campeche Knolls. Based on the idea that the asphalt on Chapopote was molten during extrusion, Hovland et al. (2005) argued for a model that relies on supercritical water being transported vertically upward through a suspected internal conduit within the salt diapir, from near the base of the sedimentary column at perhaps 13 km depth. Organic material including bitumen should have been transported upward together with "hydrothermal-like" components as a hot substance. At the summit of the Chapopote structure, a hot slurry flowed out onto the seafloor where bitumen and asphalt devolatilized rapidly, eventually building up the asphalt volcano's structure.

The Chapopote Knoll was surveyed in greater detail by Brüning et al. (2010) using the MARUM ROV QUEST. The results support the concept that the asphalt deposits on Chapopote originate from seepage of heavy oil with a density slightly greater than water, which leads to remaining petroleum and oil residues on the seafloor. During extrusion of the heavy petroleum, the viscosity increased due to the loss of volatiles, and the heavy petroleum forms the lavalike flow structures along the distance where continuous solidification occurs. The investigations
Asphalt Volcanism, Figure 1 Seafloor images from asphalt flows of Chapopote Knoll/Southern Gulf of Mexico taken by MARUM ROV QUEST. (**a**) Vestimentiferan tubeworms and galatheid crabs colonizing the surface of the asphalt. (**b**) Several asphalt layers of ropy surface piled up above the seafloor.

of Brüning et al. (2010) documented that the asphalt is subject to sequential alteration. While fresh asphalt was gooey, older asphalt appeared fragmented and brittle. Highly altered asphalt was often colonized by further chemosynthetic fauna like mytilid clams and others. The change in the consistency of the asphalts goes along with a change in the geochemical composition and microbial signatures (Schubotz et al., 2011). Besides the unusual asphalt formation, the putative "volcanic structure" is representing a very interesting seepage area which extended our knowledge about the broad spectrum of seafloor venting phenomena.

Beside the Gulf of Mexico, asphalt volcanoes are known from the Santa Barbara Basin, California, in much shallower water depths close to the coast. Seven of those morphological structures were described as extinct asphalt volcanoes by Valentine et al. (2010). Radiocarbon dating of carbonate layers intercalated with the asphalt deposits indicated formation of two of the volcanoes between 44 and 31 kyr ago. Based on quantitative assumptions and the geochemistry of samples taken from the volcanoes, the authors estimated the amount of oil and accompanied methane gas, which are emitted at the sites where the residues of the hydrocarbon seepage (i.e., the asphalt) currently are deposited. Since the amount of greenhouse gas (in this case methane) emissions is not known during former times, the study is of great value to reveal estimates of former seepage rates.

ASTRONOMICAL FREQUENCIES IN PALEOCLIMATES

André Berger
Georges Lemaître Center for Earth and Climate Research, Catholic University of Louvain, Louvain-la-Neuve, Belgium

Definition

The long-term variations of climate display periods characteristic of three astronomical parameters which are the eccentricity (which fixes the shape of the Earth's orbit), obliquity (the tilt of the equatorial plane on the plane of the Earth's orbit around the Sun), and climatic precession (a measure of the distance from the Earth to the Sun at the summer solstice). Their main periods of variations are 400 and 100 kyr for eccentricity, 41 kyr for obliquity, and 23 and 19 kyr for precession.

Introduction

As in the astronomical theory of paleoclimates the glacial-interglacial cycles are of primary interest, this entry focuses on the long-term variations of the astronomical parameters which are involved in the calculation of the energy received by the Earth from the Sun (here called incoming solar radiation or insolation) at time scales of tens to hundreds of thousands of years.

These are the eccentricity, e, obliquity, ε, and climatic precession, $e \sin \widetilde{\omega}$, $\widetilde{\omega}$ being the longitude of the perihelion.

The full spectral characteristics of these astronomical elements and the resulting insolation changes date back only to the 1970s. Although the precessional period of 21,000 years was well known since Adhémar (1842) at least, Milankovitch and his contemporaries did not seem to be much interested in these astronomical periods (Berger, 2012). Milankovitch (1920), like Emiliani (1955) 35 years later, estimated only their mean values by counting the number of peaks from the curves that Milankovitch calculated numerically, leading to about 92,000, 40,000, and 21,000 years for e, ε, and $e \sin \widetilde{\omega}$, respectively. These periods were confirmed 20 years later when Berger (1973) completed his calculation of the long-term variations of precession, obliquity, and eccentricity. Besides its high accuracy over the Quaternary, the Berger calculation provided, for the first time, a full list as well as the origin of the periods characterizing the theoretical expansion of e (with periods of 413,000, 95,000, 123,000, 99,000, 131,000, and 2,305,000 years in decreasing order of the term's amplitudes), of ε (with periods of 41,000, 53,600, and 29,700 years), and of $e \sin \widetilde{\omega}$ (with periods of 23,700, 22,400, 18,900, and 19,200 years) (see Berger, 1978, and for a slightly improved solution Berger and Loutre, 1991). Among these periods, those around 400,000, 2,300,000, and 54,000 and mainly of around 23,000 and 19,000 years
Astronomical Frequencies in Paleoclimates, Figure 1 The Earth (*E*)'s orbit around the Sun (*S*). The astronomical elements are defined in the manuscript. *a* is the semimajor axis of the elliptical orbit and b its semiminor axis, *P* is the perihelion, *A* is the aphelion, *SE* is spring equinox, *SS* is summer solstice, *FE* is fall equinox, *WW* is winter solstice, *SQ* is the perpendicular to the plane of the ecliptic, *S NP* is a parallel to the axis of rotation of the Earth describing the cone of precession, ω is the longitude of the perigee, $\widetilde{\omega}$ is the longitude of the perihelion relative to the moving vernal point γ, λ is the longitude of the Earth in its orbit, υ is the true anomaly, and ε is the obliquity.

were new, their existence not having been previously suspected.

In their science paper, Hays et al. (1976) used a spectral analysis technique which they applied to geological records and to the numerical values of the astronomical parameters calculated by Brouwer and Van Woerkom (1950) and Vernekar (1972) and found also 125,000 and 96,000 years for *e*, 41,000 years for ε, and 23,000 and 19,000 years for precession.

Orbit of the Earth around the Sun and its axis of rotation

The plane of the Earth's elliptical orbit around the Sun is called the ecliptic. The Sun is not located at the center of the ellipse but rather at one of the foci, a fact that was demonstrated in the seventeenth century by the German astronomer Johannes Kepler (1571–1630) whose three laws are:

- Kepler's first law. Each planet moves in an ellipse with the Sun at one focus.
- Kepler's second law. The radius vector from the Sun to any one planet describes equal areas in equal times.
- Kepler's third law. For any two planets, the squares of the periods are proportional to the cubes of the semimajor axes of their orbits.

As the Earth travels counterclockwise around its orbit each year, it is sometimes nearer to and sometimes farther away from the Sun. Today, the Earth reaches the point in its orbital path known as perihelion, the point at which it is the closest to the Sun, on or about 3 January. On or about 4 July, it reaches aphelion, the point farthest from the Sun. At aphelion the distance between the Earth and the Sun, which is in average roughly 150 million kilometers, is about 5 million kilometers greater than it is at perihelion.

Figure 1 displays the various elements of the Earth's orbit. The ellipse drawn through the perihelion, P, the Earth, E, and the aphelion, A, represents the orbit of the Earth around the Sun.

The Earth's eccentricity, *e*, which is a measure of its elliptical shape, is given by $\sqrt{a^2 - b^2}/a$, where *a* is the semimajor axis and *b* the semiminor axis. The vernal point, γ, also called the First Point of Aries, is the position of the Sun in the sky seen from the Earth at the time of the spring equinox, SE, i.e., in Figure 1 when the Earth crosses the celestial equator from the austral to the boreal hemisphere. It is the origin from which the ecliptical longitudes are measured. The winter (ww) and summer (ss) solstices and γ are shown at their present-day positions. In such a heliocentric system, γ is in the direction of the fall equinox, FE. In practice, observations are made from the Earth and the Sun is considered as if it were revolving around the Earth. In such a case, the system of

reference becomes geocentric instead of heliocentric, and the vernal point is in the direction of the spring equinox.

The principal cause of the seasons is not the lack of uniformity of the apparent annual motion of the Sun but rather the tilting of the Earth's axis at an angle, ε, presently $23°27'$ away from a vertical drawn to the plane of the orbit. ε is therefore also the inclination (tilt) of the equator on the ecliptic and is called the obliquity. Seasons occur because the orientation of that axis of rotation remains approximately fixed in space as the Earth revolves about the Sun in 1 year. Each season begins at a particular point in the Earth's orbit. Today these points are reached roughly on 20 or 21 March (spring equinox also called vernal or March equinox), 21 or 22 June (summer solstice also called June solstice), 22 or 23 September (fall equinox also called autumnal or September equinox), and 21 or 22 December (winter solstice also called December solstice). Their respective longitudes differ by a multiple of $90°$ with the longitude at spring equinox being zero by definition.

In the Northern Hemisphere, winter solstice marks the beginning of winter because the North Pole is tipped farthest away from the Sun on that day, making it the shortest day of the year in the entire Northern Hemisphere. Six months later, at summer solstice, the Earth reaches the point at which summer begins in the Northern Hemisphere. At this point, the North Pole is tipped toward the Sun, making the day of the summer solstice the longest day of the year in the Northern Hemisphere. From geometrical consideration, it can be shown that the Sun reaches the zenith at the June-summer solstice at noon of the true solar time (a time similar to the time read on a sundial) at the latitude now of $23°27'$ which defines the tropics of Cancer; it reaches the December-winter solstice at the latitude now of $-23°27'$ which defines the tropics of Capricorn. Between the tropics, the Sun reaches the zenith at noon of the true solar time twice a year. North of the northern polar circle (which latitude is $90° - 23°27' = 66°33'$), at the summer (winter) solstice, the day (night) is 24-h long. At the winter solstice, the Earth is today near perihelion (this approximate coincidence has nothing to do with the beginning of the calendar year).

At the spring and fall equinoxes, the two poles are equidistant from the Sun. On these dates, the number of daylight hours equals the number of hours of darkness at every point on the globe. These two points on the Earth's orbit are therefore known as the equinoxes (the term equinox is indeed derived from the Latin *aequus* (equal) and *nox* (night)). In the Northern Hemisphere, the spring/vernal/March equinox marks the beginning of spring and the fall/autumnal/September equinox the beginning of fall. In the Southern Hemisphere the seasons are reversed.

Orbital elements of a planet

In astronomy, it is usual to define an orbit and the position of the body describing that orbit by six quantities called elements. As shown in Figure 2, three of these elements
Astronomical Frequencies in Paleoclimates, Figure 2 The position of the Earth E around the Sun S given by six quantities called the elements (see the manuscript for definitions). N is the ascending node, γ_0 is the vernal point at the epoch of reference, Ω (the angle $\gamma_0 SN$) is the longitude of the ascending node, ω' (the angle NSP) is the argument of the perihelion P, i is the inclination of the ecliptic on the plane of reference, and v is the true anomaly.

(Ω, ω', i) define the orientation of the orbit with respect to a set of axes, two of them define the size and the shape of the orbit (a and e, respectively), and the sixth, v (with time), defines the position of the body within the orbit at that time. In the case of a planet moving in an elliptical orbit around the Sun, it is convenient to take a set of orthogonal axes in and perpendicular to the plane of reference, xoy, with the origin, o, at the center of the Sun or at the barycenter of the planetary system. The z-axis is taken to be perpendicular to this reference plane, so that the three axes form a right-handed orthogonal coordinate system. The reference point from which the angles are measured is labeled γ_0. As the reference plane is usually chosen to be the ecliptic at a particular fixed date of reference (called the epoch of reference, to distinguish it from any date of the past or the future), γ_0 is, in such a case, the vernal point at the epoch of reference which is taken to be 1950 CE in the Berger calculation. The point where the orbit cuts the reference plane with an increasing z-coordinate is called the ascending node, N; Ω, the longitude of that ascending node, is measured in the reference plane from γ_0; P is the perihelion; ω' is the argument of the perihelion, an angle measured anticlockwise along the orbit from the ascending node; π is the longitude of the perihelion measured from the reference vernal point, γ_0, and is equal to the sum of Ω and ω'; i is the inclination of the orbital plane relative to the fixed reference plane; v is the true anomaly, the angle measured anticlockwise between the perihelion and the Earth's position; and λ is

the longitude of the Earth in its orbit measured from the spring equinox at a specific date. Note that υ and λ fix the Earth on its orbit, respectively, from the perihelion and from the spring equinox at a specific date (Figure 1). In the orbital plane, the distance, r, from the Earth to the Sun, normalized to a, is given by the equation of the ellipse:

$$\rho = \frac{r}{a} = \frac{1 - e^2}{1 + e \cos \upsilon}$$

The perihelion distance is consequently given by $a(1 - e)$ and the aphelion distance by $a(1 + e)$, which leads to the difference between the two being proportional to $2ae$.

Long-term variations of the orbital elements

Due to the mutual attraction of the Sun, the planets, and the Moon, both the orientation and eccentricity of the ecliptic are changing with time. So is the axis of rotation of the Earth and therefore the equator. As a consequence, both the positions of the perihelion and of the vernal point relative to a fixed frame of reference are changing with time. The longitude of the perihelion, $\widetilde{\omega}$, relative to the moving vernal point, γ, is shown in Figure 1. It is equal to $\pi + \psi$, where the annual general precession in longitude, ψ, describes the clockwise absolute motion of γ along the Earth's orbit relative to the fixed stars, and the longitude of the perihelion, π, describes the anticlockwise absolute motion of the perihelion relative to the fixed stars.

To compute the long-term variations of the orbital elements, Newton's law of gravitational attraction is applied to the planetary system. This leads to the Lagrange equations, i.e., a system of equations the number of which is equal to six times the number of planets. These equations provide the time evolution of the six orbital elements of each planet. They relate all the orbital elements of the planets between them together and describe their motion around the Sun. However, these equations possess some inconvenient features for orbits with small eccentricities and inclinations, both of which appearing in the denominators of some terms. It is therefore desirable to use a modified form of these equations by setting:

$$h = e \sin \pi$$
$$k = e \cos \pi$$
$$p = \sin i \sin \Omega$$
$$q = \sin i \cos \Omega$$

If approximations are introduced in the development of the disturbing function (which expresses the mutual attraction of the Sun and the planets), the long-term behavior of h, k, p, q are given by

$$h = \sum_k M_k \sin (g_k t + \beta_k)$$
$$k = \sum_k M_k \cos (g_k t + \beta_k)$$

(1)

$$p = \sum_k N_k \sin (s_k t + \delta_k)$$
$$q = \sum_k N_k \cos (s_k t + \delta_k)$$

(2)

For the Berger (1978) solution, the amplitude M_k and N_k, the mean rates g_k and s_k, and the phases β_k and δ_k were calculated from Bretagnon (1974). Their numerical values are available in Berger (1973 and 1978) and also in Tables 1 and 2 of Berger and Loutre (1990). For the Berger and Loutre (1991) solution, Laskar (1988) was used leading to slightly different values of the orbital elements for periods of time longer than 1 million years (Berger and Loutre, 1992) but not changing our line of argument. Tables 3 and 4 of Berger and Loutre (1991) give the numerical values of the amplitudes, mean rates, and phases in decreasing order of the magnitude of the five most important terms for the two solutions Berger (1978) and Berger and Loutre (1990).

Table 1 provides the periods associated with the five largest amplitudes in decreasing order of magnitude for Eqs. 1 and 2. The values of i for Eq. (1) and j for Eq. (2) are those corresponding to the ordering traditionally used in celestial mechanics. Although there is not a one-to-one relationship between these periods and the individual planets, it can be shown that their origin is, to some extent, associated to one particular planet.

Because of the importance of the mass of Jupiter, the frequency (s_5) associated with that planet is equal to 0. This explains why the spectrum of i is dominated by two periods around 70 kyr and two of about 210 kyr, those characterizing Eq. 2. If the invariable plane (plane perpendicular to the total angular momentum) is taken instead of the ecliptic of the epoch, the term involving s_5 is excluded and the spectrum of the inclination on that plane is dominated by periods of 98, 107, and 1,300 kyr coming from the resonances between the Earth and Mercury, Mars and Venus, and Earth and Mars respectively. The periods of about 100 kyr are close to the periods of 100 kyr of eccentricity but totally different, and they are not associated with the 100 kyr of the geological records (Berger et al., 2005).

Astronomical Frequencies in Paleoclimates, Table 1 Periods related to the frequencies g and s of the most important terms in the series expansion of (e, π) and (i, Ω)

i	Frequencies g		j	Frequencies s	
	Period	Planet		Period	Planet
5	308,043	Jupiter	5		
2	176,420	Venus	3	68,829	Earth
4	72,576	Mars	1	230,977	Mercury
3	75,259	Earth	4	72,732	Mars
1	249,275	Mercury	2	191,404	Venus
			6	49,339	Saturn

Long-term variations of obliquity and precession

After having calculated the motion of the planetary point masses around the Sun, the Poisson equations for the Earth-Moon system were used to compute the long-term variations of two astronomical parameters which, with the eccentricity, play a fundamental role in the long-term seasonal and latitudinal variations of insolation. These two parameters are obliquity, ε and $\widetilde{\omega}$ the longitude of the perihelion relative to the moving vernal point.

Although the hypothesis that the planets attract each other as if the mass of every one of them was concentrated in their respective center of mass is valid for the calculation of the orbital elements, the flattening of the planets has a perceptible effect on their rotation. The Moon's gravitational attraction on the Earth causes two small bulges directed toward the Moon and away from it in the ocean and on the solid Earth. Dissipative processes cause a lag in the tidal response, and a torque is exerted that does not vanish when averaged over an orbital period of the Moon. The consequence of this torque is a change in the Earth's angular momentum or, equivalently, to an increase of the length of the day by about one thousandth of a second in 100 years. At the same time, the bulges slow the Moon down in its orbital motion and lead to an increase in the Earth-Moon distance of the order of a few centimeters per year (400 millions years ago, the length of the day was about 22 h, the year consisted of about 400 days, and the Moon must have been 4 % closer to the Earth).

Viewed by an observer on the Earth near the North Pole, the stars appear to trace out concentric circles, the center of which defines the celestial North Pole, the extension of the Earth's rotational axis in the sky. This celestial North Pole currently lies close to the star Polaris. As already noted by Hipparchus in about 120 BCE, the rotational axis is observed to move slowly and to trace out a cone, clockwise, with a half-angle of about $23.5°$ around the pole of the ecliptic, a motion which takes about 25,700 years to go full circle around the heavens. This steady motion of the rotational axis in space is called the astronomical precession of the Earth (or general precession in longitude). This is due to the inclination of the major axis of the oblate Earth to the ecliptic. Consequently, the net gravitational force on the Earth due to the Sun exerts a torque which attempts to draw the equator into the plane of the ecliptic, but the spinning of the Earth resists this; instead the torque causes motion of the spin axis about the pole of the ecliptic. This observed precession results from the sum of the solar and lunar torques (because of the large mass of the Sun and the proximity of the Moon) plus a rather minor contribution arising from the other planets. In addition, the complex interplay of the solar and lunar orbits induces small oscillations in the secular precessional motion of the rotational axis; these oscillations are known as forced nutations. The principal nutation term arises from a 19-year periodicity in the inclination of the Moon's orbit, but these nutations are not considered in the long-term variations of the astronomical parameters discussed here because of their small magnitude.

These long-term variations of ε and ψ can be expressed analytically as is the case for h, k, p, q:

$$\varepsilon = \varepsilon^* + \sum_i A_i \cos\left(\gamma_i t + \varsigma_i\right) \tag{3}$$

$$\psi = kt + \alpha + \sum_i S_i \sin\left(\xi_i t + \sigma_i\right) \tag{4}$$

ε^* and α are constant of integration and k is the precessional constant. For the Berger (1978) solution, their numerical values are

$$\varepsilon^* = 23°320556$$
$$\alpha = 3°392506$$
$$k = 50''439273$$

The amplitudes, mean rates, and phase of Eqs. 3 and 4 are given in Berger (1978). Some more detailed analytical developments are given in Berger and Loutre (1991) with for the most important terms:

$$\gamma_i = \xi_i = s_j + k$$
$$\varsigma_i = \sigma_i = \delta_j + \alpha$$

Long-term variations of eccentricity, obliquity, and climatic precession

The incoming solar radiation changes from day to day due to the Earth's elliptical motion around the Sun. But there are other changes of interest related to the planetary system and the Sun's interior. In particular, the total solar energy received by the whole Earth over one full year varies, by a very small amount (Berger, 1977; Berger and Loutre, 1994), because the mean Earth-Sun distance varies in relation to changes in the shape of the Earth's orbit around the Sun (the eccentricity, e). The solar output (the so-called solar constant) and the opacity of the interplanetary medium are also changing, but their effects remain difficult to prove at our time scales.

In addition, the seasonal and latitudinal distributions of insolation have also long-term variations which are related to the orbit of the Earth around the Sun and to the inclination of its axis of rotation. These involve three well-identified astronomical parameters (Figure 1): the eccentricity, e; the obliquity, ε; and the climatic precession, $e \sin \widetilde{\omega}$, a measure of the Earth-Sun distance at the summer solstice. $\widetilde{\omega}$, the longitude of the perihelion, is a measure of the angular distance between the perihelion and the vernal equinox that are both in motion. In a geocentric system, the angle ω is the longitude of the perigee and its numerical values are obtained by adding $180°$ to $\widetilde{\omega}$ (Figure 1). The present-day value of e is 0.016. As a consequence, although the Earth's orbit is very close to a circle, the Earth-Sun distance, and consequently the insolation, varies by as much as 3.2 % and 6.4 %, respectively, over

Astronomical Frequencies in Paleoclimates, Table 2 Amplitudes, mean rates, phases, and periods of the five largest amplitude terms in the trigonometrical expansion of climatic precession, obliquity, and eccentricity (BER78 refers to Berger, 1978 and is based upon Bretagnon, 1974 and BER90 refers to Berger and Loutre, 1991 and is based on Laskar, 1988)

4	0.006724	0.005600	13.01334	13.12877	291.6	279.2	99,590	98,715
5	0.005812	0.004759	9.87446	9.92226	126.4	110.1	131,248	130,615

the course of 1 year. The obliquity, which defines our tropical latitudes and polar circles, is presently 23°27′. The longitude of the perihelion is 102°, which confirms that the Northern Hemisphere winter occurs when the Earth is about the closest to the Sun.

The long-term variations of obliquity are given by Eq. 3

$$\varepsilon = \varepsilon^* + \sum_i A_i \cos (\gamma_i t + \varsigma_i)$$

For eccentricity, its analytical development can be calculated from

$$e = \sqrt{(e \sin \widetilde{\omega})^2 + (e \cos \widetilde{\omega})^2} \quad \text{or from}$$

$$\sqrt{(e \sin \pi)^2 + (e \cos \pi)^2}$$

which leads to

$$e = e^* + \sum_i E_i \cos (\lambda_i t + \phi_i) \tag{5}$$

with $e^* = 0.0287069$.

From the definition of $\widetilde{\omega} = \pi + \psi$ and using Eqs. 1, 4, and 5, the climatic precession parameter $e \sin \widetilde{\omega}$ can be expressed into the following trigonometrical expansion as a quasiperiodic function of time:

$$e \sin \widetilde{\omega} = \sum_i P_i \sin (\alpha_i t + \eta_i) \tag{6}$$

The amplitudes P_i, A_i, and E_i; the frequencies α_i, γ_i, and λ_i; and the phases η_i, ς_i, ϕ_i in Eqs. 3, 5, and 6 (Table 2)

have been computed by Berger (1978) and Berger and Loutre (1991). These analytical expansions can be used over 1–2 millions years (Berger and Loutre, 1992), but for more remote times, numerical solutions are necessary (Laskar, 1999).

The sign of the amplitude of terms 3 and 5 in climatic precession and of terms 2 and 3 in eccentricity in column BER78 has been changed relatively to the values given in Berger (1978) in agreement with the change of the phase by 180°. This has been done to allow an easier comparison between the solutions. The five terms given in this table do not allow an accurate computation of the astronomical parameters. More terms are requested. They are available with a computer program in http://www.astr.ucl.ac.be and http://www.elic.ucl.ac.be/modx/elic/index.php?id=83.

Equations 3 and 5 show that ε and e vary quasiperiodically around constant values ε^* (23.32°) and e^* (0.0287). This implies that, in the estimation of the order of magnitude of the terms in insolation formulae where ε and e occur, they may be considered as a constant to a first approximation. On the other hand, in the insolation formulas used to study past and future astronomical forcing of climate, the amplitude of $\sin \widetilde{\omega}$ is modulated by eccentricity in the term $e \sin \widetilde{\omega}$. The envelope of $e \sin \widetilde{\omega}$ is therefore given exactly by e.

Besides their simplicity and practicability for easy computation, Eqs. 3, 5, and 6 and their derivation allow to explain the origin of the main periods associated with the astronomical theory of paleoclimates (for full details see Berger and Loutre, 1990). The periods calculated in

Berger (1978) (but also in Berger and Loutre, 1991) come from the fundamental periods of the orbital elements associated with the g_k in Eq. 1 and s_k in Eq. 2 and from the period of the astronomical precession associated with k.

The main periods of eccentricity in Eq. 5 are 413, 95, 123, 100, and 131 kyr coming, respectively, from the following relationships where the subscripts of g (and s) are the classical ones reported in Table 1:

$$\lambda_1 = g_2 - g_5$$
$$\lambda_2 = g_4 - g_5$$
$$\lambda_3 = g_4 - g_2$$
$$\lambda_4 = g_3 - g_5$$
$$\lambda_5 = g_3 - g_2$$

For obliquity, the main periods are 41 and 54 kyr, coming, respectively, from

$$\gamma_1 = s_3 + k$$
$$\gamma_3 = s_6 + k$$

For climatic precession, the main periods are 23.7, 22.4, 18.98, and 19.16 kyr with

$$\alpha_1 = g_5 + k$$
$$\alpha_2 = g_2 + k$$
$$\alpha_3 = g_4 + k$$
$$\alpha_4 = g_3 + k$$

This leads to conclude that the periods characterizing the expansion of e are nonlinear combinations of the precessional periods and, in particular, that the eccentricity periods close to 100 kyr are originating from the periods close to 23 and 19 kyr in precession:

$$\lambda_1 = \alpha_2 - \alpha_1$$
$$\lambda_2 = \alpha_3 - \alpha_1$$
$$\lambda_3 = \alpha_3 - \alpha_2$$
$$\lambda_4 = \alpha_4 - \alpha_1$$
$$\lambda_5 = \alpha_4 - \alpha_2$$

As a consequence,

$$\lambda_3 = \lambda_2 - \lambda_1$$
$$\lambda_5 = \lambda_4 - \lambda_1$$

which clearly shows that not all the periods of eccentricity are independent. Using the periods associated to the largest amplitude terms in Eqs. 1 and 2, we would conclude that the periods of 413, 95, and 100 kyr are the most fundamental ones (123 and 131 kyr deriving directly from them) with:

- 413 kyr coming from the resonance between Venus and Jupiter
- 95 kyr coming from the resonance between Mars and Jupiter
- 100 kyr coming from the resonance between Earth and Jupiter

For the obliquity, Mars, Earth, and Moon explain the 40-kyr period, Saturn being related to the 54 kyr one. For climatic precession, in addition to the Moon effect, the two periods close to 23 kyr come from Jupiter and Venus and those close to 19 kyr from Mars and Earth.

Instability of the astronomical periods

Over the last few million years, eccentricity varies between 0 and 0.06 with an average period of 95 kyr, being slightly shorter over the future (91 kyr). Correlatively, the line of apses (line through P and A in Figure 1) made a revolution in a fixed reference frame with an average period of 125 kyr but largely varying between 20 and 250 kyr. This dispersion around the average value is related to the existence of very short periods related to the very low values of eccentricity. If these short periods are ignored, the minimum value of the period becomes more realistic (60 kyr).

Figure 3 shows the long-term variations of these three astronomical parameters over the past 400 ka and into the future for the next 100 ka. It shows in particular that the 100-kyr period is not stable in time (Berger et al., 1998), being remarkably shorter over the present day. Actually, the most important theoretical period of eccentricity, 400 kyr, is weak before 1 Ma BP and is particularly strong over the next 400 ka, with the strength of the components in the 100-kyr band changing in the opposite way. It is worth pointing out that this weakening of the 100-kyr period started about 900 ka ago when this period began to appear very strongly in paleoclimate records. This implies that the 100-kyr period found in paleoclimatic records is definitely not linearly related to eccentricity. We are now approaching a minimum of e at the 400-kyr time scale: at 27 ka AP, the Earth's orbit will be circular. Actually, transitions between successive strong 400-kyr cycles (as it is the case now) are characterized by very small eccentricity and short eccentricity cycles with a low amplitude of variation.

For precession, the average period is roughly 21.5 kyr with large dispersion varying between 14 and 30 kyr. At the 400-kyr time scale, the amplitude and frequency modulations are inversely related: when the amplitude of precession is small (large), the period is short (long). It is the reverse at the 100-kyr time scale.

Obliquity varies between 22° and 24°5 with a very stable period of 41 kyr, but there is an amplitude modulation with a time duration of about 1.3 Myr. The spectra of both the amplitude and frequency modulations of obliquity display significant power at 171 and 97 kyr. Although this last might look close to the so-called 100-kyr eccentricity period, they are not related (Mélice et al., 2001). At the 1.3-Myr time scale, a large amplitude corresponds to a short period, the reverse being true at the 170-kyr time scale.

While today the winter solstice occurs near perihelion, at the end of the deglaciation, roughly 10 ka BP, it occurred near aphelion. Moreover, because the length of

BER78
Astronomical Frequencies in Paleoclimates, Figure 3 Long-term variations of eccentricity, climatic precession, obliquity, and insolation at 65°N at the summer solstice from 400 ka BP to 100 ka AP. Time is progressing from *right* to *left* (The data are derived from the formula given in Berger (1978)).

the seasons varies in time according to Kepler's second law, the solstices and equinoxes occur at different calendar dates during the geological past and in the future. Presently in the Northern Hemisphere, the longest seasons are spring (92.8 days) and summer (93.6 days), while autumn (89.8 days) and winter (89 days) are notably shorter. In 1250 CE, spring and summer have had the same length (as did autumn and winter) because the winter solstice occurred at perihelion. About 4,500 years into the future, the Northern Hemisphere spring and winter will have the same short length and consequently summer and fall will be equally long.

Summary and conclusions

The most important periods of the three astronomical parameters which drive the long-term variations of climate are 400 and 100 kyr for eccentricity, 41 kyr for obliquity, and 23 and 19 kyr for precession. Although they are often called Milankovitch periods, they are not originating from his work. For example, the 41-kyr obliquity cycle and the average period of climatic precession, 21 kyr, date from the mid-nineteenth century. Among the properties of these astronomical parameters, some are less known and are stressed here again.

The term climatic precession has been introduced in the 1970s to avoid the too often confusion made at these early times with the astronomical precession.

The first theoretical period of eccentricity, about 400 kyr, and the double precessional peaks, 23 and 19 kyr, were only discovered in the early 1970s and play presently a more and more important role in paleoclimatology. The 400-kyr period is particularly strong over the next 400 kyr, whereas the 100 kyr is very weak. Actually, transitions between successive strong 400-kyr cycles are characterized by very small eccentricity. This is happening now and at 27 ka AP, the Earth's orbit will be circular.

The analytical calculation of the trigonometrical expansions of the astronomical elements shows that the eccentricity periods close to 100 kyr are originating from the periods close to 23 and 19 kyr in precession, and the 400-kyr period is a combination of the two first precessional periods. The periods of eccentricity are therefore not all independent, those of 413, 95, and 100 kyr being the most fundamental ones.

For precession, the average period is roughly 21.5 kyr with a large dispersion varying between 14 and 30 kyr. At the 400-kyr time scale, when the amplitude of precession is small (large), the period is short (long). It is the reverse at the 100-kyr time scale.

Obliquity varies between 22° and 24°5 with a very stable period of 41 kyr, but there is an amplitude modulation with a period of about 1.3 Myr. At this 1.3-Myr time scale, large amplitude corresponds to a short period, the reverse being true at the 170-kyr time scale.

As obliquity and eccentricity vary around constant values ($23.32°$ for obliquity and 0.0287 for eccentricity), these elements may be considered as a constant in a first very rough approximation as compared to the variations of climatic precession. As the amplitude of $e \sin \widetilde{\omega}$ is modulated by eccentricity, the envelope of $e \sin \widetilde{\omega}$ is given exactly by e.

Because the length of the seasons varies in time according to Kepler's second law, the solstices and equinoxes occur at different calendar dates through time. The meteorological seasons are therefore continuously shifting through the astronomical ones and do not correspond to the same configuration of the Earth relative to the Sun.

Definition

An axial summit trough (AST) is a narrow trough or volcanically modified graben that develops at the crest of a midocean ridge and typically is the locus of volcanic and hydrothermal activity.

Introduction

At the summit of magmatically robust midocean ridges (MORs), a narrow trough may develop that marks the location of the divergent plate boundary and is the locus of most magmatic and hydrothermal activity (Macdonald and Fox, 1988). This axial summit trough (AST) is typically less than 500 m in width and 50 m in depth and may be discontinuous along the ridge in terms of its width, depth, strike, and continuity. ASTs are common along fast- and intermediate-spreading rate ridges (e.g., East Pacific Rise, Juan de Fuca Ridge, Galapagos Spreading Center), and magma-rich, inflated portions of the slow-spreading Mid-Atlantic Ridge and Lau Basin back-arc spreading center.
Axial Summit Troughs, Figure 1 Perspective view of the AST at the northern EPR with schematic representation of normal faults between the seafloor and intruding dike (After Soule et al., 2009).

Development of the axial summit trough

The AST is a volcanically modified tectonic graben. The graben forms in response to deformation above magmatic dikes originating at the axial magma lens located 1–3 km beneath the ridge crest (Chadwick and Embley, 1998; Fornari et al., 1998). Models of dike intrusion into a homogeneous elastic medium with physical properties similar to oceanic crust produce horizontal stresses at the seafloor, which reach their maximum at distances from the dike centerline of ~1.5 times the depth to the dike tip (Rubin and Pollard, 1988; Figure 1). Slips along normal faults between these symmetric zones of dilation and the dike tip produce grabens with widths many times greater than depths. The typical depth and width of ASTs on ridges are larger than could be expected for the intrusion of a single 1-m wide dike, the nominal dike width on midocean ridges (Qin and Buck, 2008). Thus, it is assumed that the AST represents accumulated deformation over many dike intrusion cycles. In some instances, an AST may evolve into a much wider (~1–2 km) and deeper (~50–100 m) axial valley by this process (Carbotte et al., 2006; Soule et al., 2009). Other contributions to graben subsidence may include magma withdrawal from subridge melt lenses (Carbotte et al., 2003).

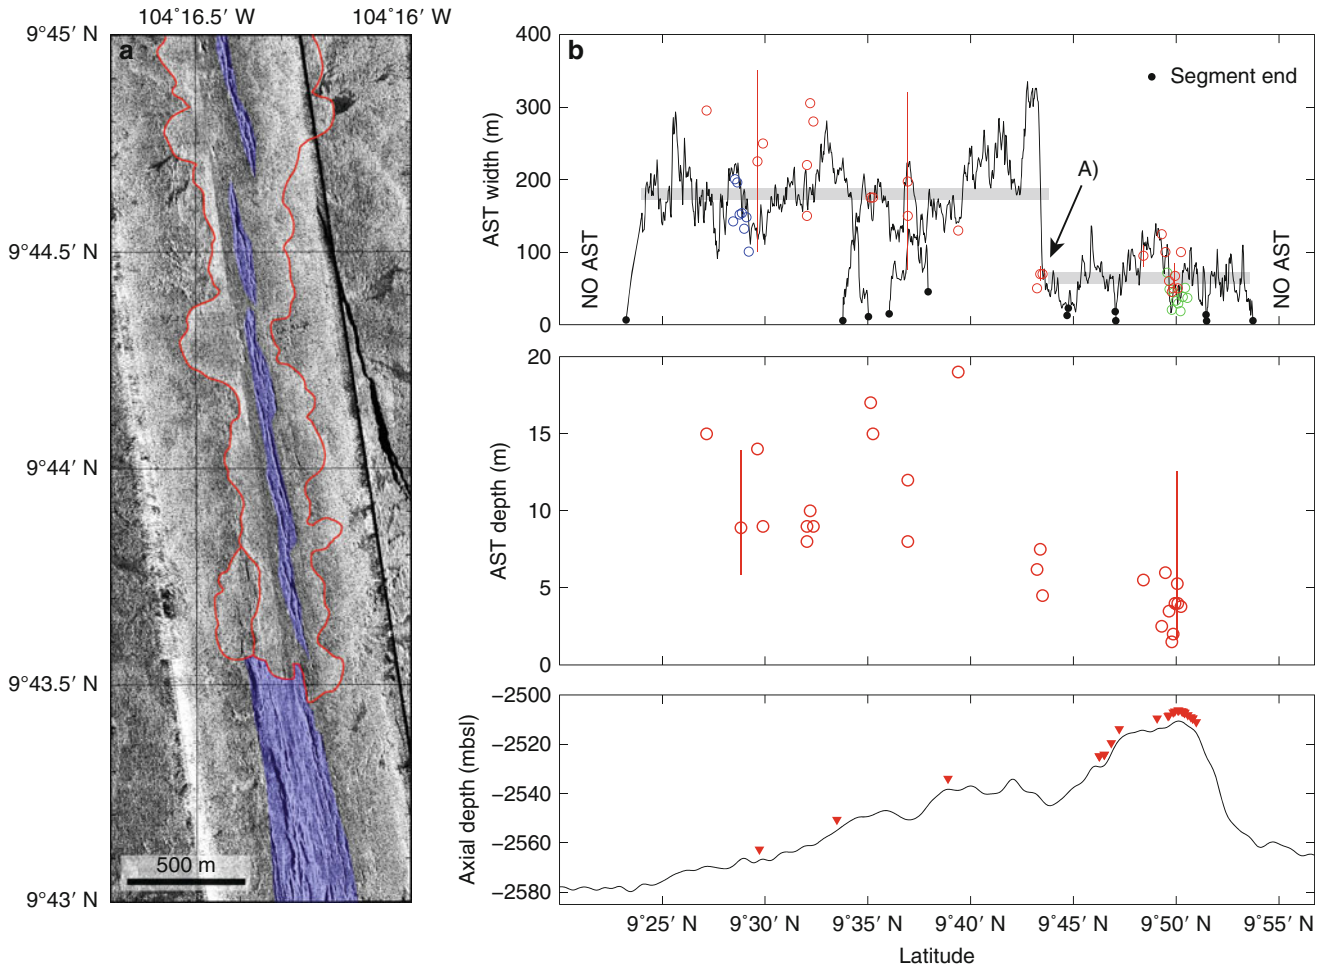
The dimensions of the AST are established by tectonic processes but modified by volcanic processes (Figure 2). Volcanic overprinting during a single eruptive event can range from complete infilling of the AST to minor narrowing and shallowing of the trough based on the style (e.g., low or high eruption rate) and frequency of eruptions (Chadwick and Embley, 1998; Fornari et al., 1998; Soule

et al., 2009). At low eruption rates, pillow lavas can fill the trough and completely obscure the AST. At high eruption rates, lava filling the trough can drain back into eruptive fissures after the eruption has ceased. In the latter case, the solidified upper crust of the lava flow that filled the AST founders and leaves only thin fragmental remnants of the flow on the trough floor (Fornari et al., 1998). Some portions of the upper crust may remain intact, supported by lava pillars – hollow conduits composed of solidified lava – that form between the base and upper surface of the flow (Francheteau et al., 1979; Chadwick and Embley, 1998; Gregg et al., 2000; Chadwick, 2003). This can result in an apparent narrowing of the trough although the open space of the graben remains beneath a thin lid of solidified lava.

In addition to hosting the majority of eruptive fissures, the AST hosts the bulk of hydrothermal vents along the ridge crest. High- and low-temperature hydrothermal venting occurs within the trough, commonly colocated with volcanic fissures as well as along the walls of the AST (e.g., Haymon et al., 1991; Fornari et al., 1998). The association of hydrothermal vents with the AST reflects the location of the graben directly over the shallowest axial melt lenses along the ridge. High permeability in the vertical direction reflects the presence of steeply dipping faults and dikes within what is the weakest and thinnest portion of the ocean crust.

The AST as a record of volcanic-tectonic history

Discontinuities in the AST occur in the form of abrupt changes in the depth and/or width of the trough, physical breaks in the continuity of the trough, or changes in trough orientation. These discontinuities, referred to as devals (deviations in axial linearity) (Langmuir et al., 1986), reflect the finest degree of segmentation of the ridge axis (Macdonald et al., 1988; Haymon et al., 1991; White et al., 2000; Haymon and White, 2004; White et al., 2006) and in many cases correlate with other indicators of segmentation such as lava geochemistry, ridge-crest water depth, presence and continuity of the subridge melt lenses, and volcanic deposition processes (Langmuir et al., 1986; Carbotte et al., 2000; Soule et al., 2007, 2009; Smith et al., 2001).

As an example, the AST along the well-studied EPR between 9 °N and 10 °N varies in width from 20 to 300 m and depth from 2 to 20 m over 60 km of ridge length. The AST is divided into roughly eight segments that range in length from 1 to 25 km. The most pronounced change in AST properties occurs at ~9°44′N, coincident with the onset of significant shoaling in the ridge-crest depth (Figure 3). In addition, this marks the southernmost extent of two recent eruptions in 1991–1992 and 2005–2006. The AST maintains average widths of ~180 and ~75 m to the north and south of this discontinuity, respectively. The greater width and depth of the AST across this discontinuity would suggest that a greater
Axial Summit Troughs, Figure 2 Examples of tectonically defined graben (*white*) overprinted by recent volcanic deposition (*gray*) (Soule et al., 2009).


Axial Summit Troughs, Figure 3 (**a**) Example of AST discontinuity in width (*blue shading*) along the East Pacific Rise (*EPR*) as imaged by 120-kHz side-scan sonar backscatter. The AST narrows north of 9°43.5 due to recent volcanic deposition. (**b**) Compilation of AST properties along the EPR shows that this transition in width (measured from side-scan sonar) persists for tens of kilometers north and south and is consistent with AST depth (measured from towed camera crossings) and ridge-crest depth (measured from ship-based bathymetry) as well as geophysical and geochemical indicators of melt supply (Soule et al., 2009).

proportion of dikes reach the seafloor and erupt to the north resulting in greater magmatic overprinting. This is consistent with a break in the axial magma lens and magma compositions that become more mafic to the north of this discontinuity. Thus, it appears that the AST provides a visible record of the frequency of eruptions, which tend to infill a consistently growing graben.

Summary

The axial summit trough is a common feature along the ridge crest of fast- and intermediate-spreading rate ridges and is present along slower-spreading but magma-rich ridges. The trough forms from deformation due to shallowly intruded dikes, with deformation accumulating over many years, but the graben dimensions are modified by

volcanic deposition from eruptive fissures located within the AST to degrees depending on the frequency and effusion rates of eruptions. The AST, where present, hosts the majority hydrothermal vents along the ridge axis due to its proximity to crustal heat sources (e.g., magma chambers) and anisotropic permeability within the sheeted dikes and tectonically disrupted upper crust. Discontinuities within the AST are coincident with discontinuities in other ridge-crest properties such as depth, axial magma chamber continuity and melt content, and lava geochemistry.

Definition

Axial volcanic ridges (AVRs). Composite volcanic edifices, comprising an elongate, typically spreading-normal orientated topographic high, produced within the inner valleys of mid-ocean ridges, usually those that are slow spreading.

Introduction

The surface expression of volcanic activity is extremely variable at different spreading rates (see "Morphology Across Convergent Plate Boundaries"), as a result of the differing eruption styles associated with each. Axial volcanic ridges (AVRs), sometimes called neo-volcanic

ridges, have been recognized at many slow-spreading Mid-Atlantic Ridge (MAR) spreading segments (e.g., Ballard and Van Andel, 1977; Karson et al., 1987; Smith and Cann, 1992; Parson et al., 1993; Sempere et al., 1993; Lawson et al., 1996; Bideau et al., 1998; Gracia et al., 1998; Navin et al., 1998; Briais et al., 2000; Peirce and Sinha, 2008; Searle et al., 2010) and some ultraslow-spreading segments elsewhere (Mendel et al., 2003). AVRs are elongate, composite volcanoes, typically with a ridge parallel orientation (Figure 1). They vary in size, although are typically a few kilometers wide, are tens of kilometers long, and reach heights of several hundreds of meters above the surrounding seafloor.

AVRs are usually found in the middle of spreading segments and are often associated with hourglass-shaped axial valleys. They may extend all the way from the center of the valley to the base of the bounding axial valley wall faults or be surrounded by areas of flatter seafloor. Where present, an AVR usually represents the largest volume magmatic structure on the segment.

AVR eruption style and volcanic architecture

AVRs themselves are built almost entirely of agglomerations of volcanic hummocks (Smith and Cann, 1990; Yeo et al., 2012), which are circular or subcircular, probably monogenetic, volcanic cones, or domes 50–500 m in diameter with heights of tens to hundreds of meters (Figure 1 inset). Hummocks are constructed of a combination of pillow, elongate pillow, and lobate lavas (see "Submarine Lava Types"), which are erupted from a central vent and flow outwards and down the sides of the hummock. These hummocky structures are responsible for the rough, lumpy surface texture of AVRs in multibeam data (Figure 1). Several hummocks may be produced in one eruption, often, but not always, distributed along an eruptive fissure forming a hummocky lineament on the seafloor (Searle et al., 2010). The feeder dykes for these eruptions are unlikely to be active for more than one eruption as the typical mid-ocean ridge dyke thickness of less than 2 m (Qin and Buck, 2008) is such that it will solidify before the next predicted dyke emplacement (Head et al., 1996). Such predominantly ridge parallel fissure eruptions are thought to be the dominant eruption style on AVRs. The individual hummocks are formed as a result of point focusing down to a number of individual vents that feed discrete, round edifices (Smith and Cann, 1992; Head et al., 1996; Smith and Cann, 1999). Hummocks may coalesce together to form larger hummocky ridges or mounds (Smith and Cann, 1993; Smith et al., 1995; Head et al., 1996; Lawson et al., 1996; Briais et al., 2000), which are similar to large pillow mound eruptions on intermediate-spreading rate ridges (Yeo et al., 2013). Hummocks commonly collapse down the AVR flanks, converting around 12 % of the lavas erupted on the AVR to talus, which probably also form a component of the AVR structure (Yeo et al., 2012). Rare flat-topped seamounts and small areas of smoother lava flows may also form small parts of the AVR structure.
Axial Volcanic Ridges, Figure 1 EM120 bathymetry gridded at 50 m showing the axial volcanic ridge at 45°N on the Mid-Atlantic Ridge as surveyed by Searle et al. (2010). The prominent 22-km-long AVR is shown by the *gray-shaded* area and lies almost parallel to the ridge strike in the center of the hourglass-shaped inner valley. The spreading direction is shown by the *white arrows*. The northern end (north of 45°33) appears more tectonized than the southern end. The rough surface texture is a result of the hummocks that cover its surface. *Inset*: TOBI side-scan mosaic of the hummocky terrain in the area covered by the *dashed box* labeled SS on the main figure (Data is insonified to the north).

The dominant rock type found on AVRs is normal mid-ocean ridge basalt (N-MORB), with variations due to differences in the degree of partial melting or heterogeneities in the source (see "Mid-ocean Ridge Magmatism and Volcanism").

Formation and growth

Melt supply at slow-spreading mid-ocean ridges is irregular in space and time, and, at a typical slow-spreading ridge, melt production is too low to sustain large, steady-state magma chambers anywhere along the segment (Forsyth, 1992; Lin and Morgan, 1992; Sinton and Detrick, 1992; Magde et al., 2000). Therefore at slow- and ultraslow-spreading ridges, volcanism must be episodic. AVRs lie entirely within the Brunhes chron and therefore are difficult to date; however, a number of AVR life cycles as a result of such episodic magmatism have been proposed. Estimates of the lengths of these cycles are highly variable, ranging from several tens of thousands of years (e.g., 10 kyr (Bryan and Moore, 1977), 20 kyr (Sinha et al., 1998), and 25 kyr (Ballard and Van Andel, 1977)) to much longer periods (e.g., 600 kyr (Searle et al., 1998)) on the Mid-Atlantic Ridge and 400 kyr–2.4 Myr on the Southwest Indian Ridge (Mendel et al., 2003). Additionally, where available, the ages measured for AVRs – 10 kyr (Sturm et al., 2000) and ~12 kyr (Searle et al., 2010) – are much younger than the age of the crust calculated based on spreading rate. This, combined with the similarity of estimated ages for lava flows all over an AVR (Yeo and Searle, 2013), suggests that AVRs are the product of episodes of higher than normal volcanic activity.

Such a life cycle is probably comprised of at least one volcanic phase, followed by an amagmatic phase in which the AVR is broken apart and possibly rifted off axis by tectonic activity (Parson et al., 1993; Mendel et al., 2003; Peirce and Sinha, 2008). The length of these various phases and the extent to which rejuvenation may occur during periods of predominantly tectonic extension are poorly constrained. In the extreme, this could, if periods of tectonic extension were insufficient to destroy the AVR between rejuvenation episodes, actually result in an almost steady-state AVR, where a bathymetric high is present nearly all the time, maintained by regular episodic volcanism. However, evidence from the RAMASSES experiment conducted on the Reykjanes Ridge (Sinha et al., 1998) suggests that magma chambers may only exist beneath an AVR on a slow-spreading ridge for around 10 % of the cycle.

Summary

AVRs are large, constructional, volcanic features formed predominantly of volcanic hummocks that are very commonly found on slow- and ultraslow-spreading ridges. They typically lie in the middle of a segment and are the focus of volcanic activity and therefore probably upper crustal construction. Due to the irregular magma supply to slow- and ultraslow-spreading ridges, volcanism on AVRs is almost certainly episodic although the timings and durations of magmatic episodes are currently poorly constrained.

Definition

In the most rudimentary sense, a beach may be considered a shore (see Coasts) covered by sand (e.g., Shepard, 1973), gravel (e.g., Carter and Orford, 1984; Jennings and Shulmeister, 2002), or larger rock fragments (but lacking bare rock surfaces). More specifically, Jackson (1997) defines a beach as a relatively thick and transitory accumulation of loose waterborne materials that are mostly well-sorted sand and pebbles, but contains admixtures of mud, cobbles, boulders, smoothed rock, and shell fragments. The term was originally used in a scientific sense to designate loose waterworn shingle or pebbles on English shores (Johnson, 1919). Today, beaches are defined in a wider geomorphological sense as having subaerial and submarine components that are systematically interrelated. The beach system includes the dry (subaerial) beach, the wet beach (swash or intertidal zone), the surf zone, and the nearshore zone lying beyond the breakers (Short, 2006). Mostly the nearshore zone is defined as the area beginning from the low-water line extending seaward. The surf zone is part of the nearshore zone. The subaerial beach has a gentle seaward slope, typically with a concave profile, and extends from the low-water mark landward to a place where there is a change in material or physiography (such as a dune, bluff, or cliff, or even a seawall) or to the line of permanent vegetation marked by the limit of highest storm waves or surge. If the area beginning from the low-water line is regarded, the profile is not concave when looking to a beach with a certain tidal range. The dry beach is concave, but at low water when including the wet beach, the morphology switches from a concave beach (dry part) to a convex beach (wet part). Nearshore bars and troughs (in the subtidal domain) are often present in the surf zone, but are obscured by waves and surf, as is the always submerged nearshore zone (Short, 2006). Beach morphology refers to the shape of the beach, surf, and nearshore zone. The beach per se contains numerous morphological–processual subunits such as berms, storm ridges (e.g., Zenkovich, 1967; Pethick, 1984; Komar, 1998; Davis and FitzGerald, 2004), cusps, beach face, shoreface (e.g., Swift et al., 1985), plunge step (Davis and Fox, 1971), scarp, etc.

Related features include beach plains, beach ridges, and beachrock. Beach plains are level or gently undulating areas formed by closely spaced successive embankments of wave-deposited materials added to a prograding shoreline (Jackson, 1997). Beach ridges are low mounds of beach or beach-and-dune materials (sand, gravel, shingle) accumulated by waves on the backshore beyond the present limit of storm waves or ordinary tides. Beach ridges are roughly parallel to the shoreline and mark prior positions of an advancing shoreline (Jackson, 1997). Beachrock is a friable to well-cemented sedimentary rock formed in the intertidal zone in a tropical or subtropical region. Beachrock formations, which slope gently seaward on the beach face, consist of sand or gravel (detrital and skeletal) cemented with calcium carbonate.

Etymology and usage

According to Merriam-Webster (1994), the first known use of the term beach was perhaps in 1535. The term beach was used to describe "loose, water-worn pebbles of the seashore," probably from Old English bæce, bece "stream," from Proto-Germanic *bakiz. Extended to loose, pebbly shores (1590s), and in dialect around Sussex and Kent, beach still has the meaning "pebbles worn by the waves." French grève shows the same evolution (http://www.etymonline.com/index.php?term=beach). Thus, early on the term *beach* did not refer to the expanse of sand normally thought of today. Expansion of term to cover the whole shore in the late sixteenth century may have been related to a popular misunderstanding of the "pebbles" connotation of "beach" in phrases such as "walk on the beach" (http://www.word-detective.com/2007/12/strand-beach/).

Geographic occurrence

Beaches are characteristic of almost all coasts where sediments accumulate alongshore. Sandy beaches occur in all latitudes where there are waves, appropriate types of sediments that are available for accumulation, and a favorable littoral geomorphology (e.g., Davies, 1980; Swift et al., 1985; Pilkey, 2003). Long straight beaches tend to occur along gently seaward-sloping continental shelves with abundant sediment supply, whereas curved beaches in coastal embayments are typically associated with steep continental shelves and a limited sediment supply (Masselink et al., 2011). Although most commonly associated with sedimentary coasts such as occur on barrier islands, for example, beach–dune systems may be quite extensive as major coastal features. It is estimated by various researchers that beaches occur along about a third of the world's coastline (Bird, 1984; Bird and Schwartz, 1985; van der Maarel, 1993), depending on the definitions used for compound coasts. Some coasts, for example, may be dominantly cliffy or rocky, but at the same time they contain beaches in front of the cliffs or between rocky promontories (Figure 1). That is to say, beaches may be small disjunctive pocket accumulations along rocky coasts or they may be the dominant coastal type. Australia, for example, has some 11,761 dominant beaches that make up half of the 30,000-km-long coast (Short and Farmer, 2012). Most Australian beaches, like many others throughout the world, are bordered by some kind of natural feature such as a dune field, cliff, headland, rocks, coral reef, or inlet. According to Dolan et al. (1972), 33 % of the North American shoreline is beach, which further breaks down to 23 % barrier-beach islands, 8 % pocket beaches, and 2 % associated with rock headlands. Of the 19,550-km-long shoreline of the contiguous USA, the US Army Corps of Engineers (COE, 1984) estimates that about 76,100 km (i.e., excluding Alaska, Hawaii, Puerto Rico, and US territories) is beach.

Some of the longest beaches in the world include, for example, Brazil's Praia do Cassino Beach (over 250 km

Beach, Figure 1 Carbonate beach on Long Island, Bahamas, showing biogenic carbonate sand derived from shells and coral reef materials that have been comminuted by wave action to form sand-sized grains. Note the soft pink color of the sand seaward of the wetted perimeter. The coral-rich beach sand contains admixtures of species of Foraminifera or forams (microscopic animals with bright red shells), making these pink beaches some of the best in the world. These beaches, bounded by eolianite headlands, occur on the open Atlantic Ocean side of the island and are also well known on Harbour Island near Eleuthera (Photo: C.W. Finkl).

long), India's Cox's Bazar (about 240 km long), Texas' Padre Island (about 210 km long), Australia's Coorong Beach (194 km), New Zealand's Ninety Mile Beach (each about 145 km long), Mexico's Playa Novillero (about 80 km long), and America's Virginia Beach (about 55 km long).

Grain size, shape, chemical composition, and color

Beaches are the product of wave-deposited sediment, but the materials comprising the beach have an almost unlimited range in size, shape, and composition. In practice, however, each beach area has a particular texture and composition with great variation occurring from place to place. Most beaches are sandy (composed predominantly of sand-sized grains, according to the Udden-Wentworth scale), but the term also includes shingle, gravel (pebbles and cobbles), and boulders that are deposited between the upper swash limit and wave base (e.g., Hardisty, 1990; Short and Woodroffe, 2009). Coarse-grained (cobble, boulder) beaches are prevalent in high latitudes and typify many coastal segments in Canada and the southern Baltic Sea coastline, for example, where glacial materials and bedrock are eroded by coastal processes. Coarse-grained beaches and barriers may also occur along many high-energy coasts, as seen along the west coast of North America, and in low latitudes where they are composed of shell or coral fragments (Figure 2).

Very fine-grained (high percentage of silt and clay) beaches may exceptionally occur under specialized conditions where there is an abundance of fine-grained sediments deposited by wave action as, for example, along the Red Sea and in the vicinity of large deltas and estuaries. A well-known example of a muddy coast with a potential for muddy "beaches" (mud flats) is provided by Anthony et al. (2010) for the 1,500-km-long coast of South America between the Amazon and the Orinoco river mouths. Ephemeral mud "beaches" also occur around mud-lump islands of the Mississippi Delta (Morgan et al. 1963). Similar "beaches" occur along the deltaic plains of the Brazos and Colorado rivers of the Texas coast and the eastern shore of Virginia (Davis, 1978).

Beaches tend to be comprised of well-sorted and generally rounded grains. Exceptions include disk, blade, and roller shapes that are so characteristic of gravel beaches where the larger clasts slide over sand and fine gravel (Pilkey et al., 2011). Biogenic beach gravels are also rather common and may comprise the entire beach sediment, as along coral reef beaches, or may be mixed with sand (cf. Figures 1 and 2). The abundance of biogenic debris (shell, algae, coral fragments) on beaches reflects the provenance of materials and the processes acting on the beach to produce a range of irregular shapes such as the pure *Acropora* coral stick beaches (Davis, 1978).

The composition of beach sediments depends on initial materials where terrigenous (or terrestrial, derived from the erosion of other rocks on land), volcanic (directly derived from volcanic activity and volcanic rocks), and biogenic (composed of shells and skeletons of dead marine organisms) lithologies contribute to the clastic pool (Pilkey et al., 2011). Siliciclastic (quartzose) beaches

Beach, Figure 2 Coarse-grained carbonate beach composed of shell hash on Captiva Island, southwest coast of the Florida Peninsula, USA, facing the Gulf of Mexico. Note the cuspate planform of the beach and a series of beach ridges containing shell fragments heaped up by wave action and swash (Photo: C.W. Finkl).

Beach, Figure 3 Siliciclastic beach sands on Amagansett Beach, Long Island, New York, USA, showing a reflective morphodynamic beach state. As swash runs up the steep beach face, it carries sand grains that overtop the berm to the back beach area. Interdigitating swash marks on the berm mark the landward most transport of sand grains that are dominantly quartz but which may contain minor admixtures of biogenic (shell) fragments and organic matter (Photo: C.W. Finkl).

tend to be more common in middle and high latitudes (Figure 3), whereas carbonates (aragonite and calcite) dominate tropical and subtropical zones. Although a small feldspar fraction is usually present in terrigenous sands, those few beaches that are rich in feldspar tend to be close to the source rock from which the feldspar is derived, such as glacial deposits derived from shield (cratonic) areas containing feldspar-rich granites and gneisses. Beach sands derived from granitic source areas sometimes contain heavy minerals (density > 2.9 g cm^3) that tend to be concentrated in the swash zone by the placering effect to form dark-colored streaks that are sorted out from the rest of the lighter-colored grains.

Beach color is determined by grain size and mineralogical composition so that silicates (derived from igneous granitic rocks, metamorphic rocks such as gneisses and schists, and preexisting sandstones) impart a light color to beaches (Figure 3), whereas more mafic compositions imbue black (Figure 4) to dark gray to dark green colors in fragments of fine-grained rocks such as metamorphic slates or volcanic ricks such as andesite and basalt (Pilkey et al., 2011). The inherent color of the beach's grains does not always determine beach color because grains may be stained by iron oxides, tannic acids, or microorganisms that may produce distinctly red, yellow, or green beaches, for example.

Types of beaches

Because beaches occur in all climatic zones, there are some obvious morphological differences related to severe conditions. In very high latitudes, for example, the water is frozen but for a few weeks when beaches may be affected by waves (Davis, 1978) and consequently beach morphology and texture is somewhat different from those in low latitudes. Beaches in arid climates depend almost solely on wave action to provide sediment from the bedrock coast to form a beach. The best developed beaches are associated with low-lying coasts where large quantities of sediment are available. Beach development requires an abundant sediment supply to produce characteristic morphologies and environmental zonations (Masselink et al., 2011).

The term *beach type* refers to the dominant nature of a beach based on tidal, wave, and current regimes, spatio-temporal extent of the nearshore zone, morphodynamics (beach width, shape, and processes) of the surf zone including bars and troughs, and the subaerial beach (Short, 1993). Irrespective of the specific beach type, most beaches contain several morphogenetic zones: (1) the backshore (nearly horizontal to gently landward-sloping area called the berm), (2) inner swash zone (upper limit of swash to the shoreline), (3) surf zone (from the shoreline to where waves break, the breaker zone), (4) nearshore zone (from the breaker zone, commonly with sandbars, to the wave base), and (5) wave base (depth where waves begin to interact with the seabed to transport sand to the beach and seaward to where sand is transported by large waves that cause beach erosion) (Davis, 1978; Short and Woodroffe, 2009). These zones are greatly variable, depending on the processes and materials that affect

Beach, Figure 4 Black sand beach composed of basaltic grains on the south coast of Iceland west of the Dyrhólaey promontory (headland or cape), near Vik. The mafic composition of the basaltic grains does not make the clasts particularly durable, and they are worn down by wave and surge action to finer-grained particles, as seen in the reticulate pattern on this extremely wide berm and beach plain where there are darker-colored coarse-grained ridges and lighter-colored finer-grained flats. This black basaltic beach and beach plain front a large sandur plain (Photo: C.W. Finkl).

beach type. In addition to these major zonations of beach environments, there are numerous smaller, but important, morphological features such as the plunge step (Davis and Fox, 1971), which is a small and commonly subtle shore-parallel depression in the foreshore that is caused by the final plunge of waves as they break for the last time before surging up the beach face (Davis, 1978).

Classification of beaches

Many factors need to be considered in the classification of beaches (e.g., Finkl, 2004) as they are among the most dynamic features on earth, but even so they retain certain overriding characteristics that facilitate generalization and categorization. The overall gradient of the beach and nearshore influences the amount of wave energy that reaches the beach, giving it its configuration. Beach materials, slope, and exposure interact with waves to produce the morphodynamic beach state that is constantly adjusting to new environmental conditions. Although beaches are one of the most dynamic morphosystems on earth (literally changing every day), they exhibit a range of characteristic morphologies that have been intensively studied in Australia. The analysis of Australian beach characteristics and shoreface dynamics (e.g., Short, 1993; Short, 1999) has led to a beach classification system that is now used internationally.

According to the classification scheme for Australian beaches (see discussion in Short and Woodroffe, 2009), there are 15 major beach types that are derived from three major beach systems: wave dominated, tide modified, and tide dominated. An overview of the beaches of Australia, which occupy half the 29,900-km-long coast (including Tasmania), is provided by Short (2006) in his discussion of the roles of waves, sediment, and tide range that contribute to beach type, particularly through the dimensionless fall velocity and relative tide range. Short's comprehensive study of Australian beach types includes descriptions of their regional distribution, together with the occurrence of rip currents, multibar beach systems, and the influence of geological inheritance and marine biota, a natural progression of comprehensive observational collages and models stemming from seminal works (e.g., Wright and Short, 1984) commonly referred to as the "Australian Beach Model" (Short, 2006).

Recognition of the 15 beach types occurring around the Australian coast provides a basis for identifying similar wave–tide–sediment environments throughout the world and classification of many of the world's beaches. Although applied internationally, the Australian Beach Model is not universal because it does not include tide-modified beaches exposed to higher ocean swell and storm seas, resulting in similar though higher-energy beaches, gravel, and cobble beaches (few occur in Australia), nor ice-affected beaches (because they do not occur in Australia). Nevertheless, this system finds wide application throughout the world as, for example, in the classification and study of Florida east coast beaches (e.g., Benedet et al., 2004), eastern Brazil (e.g., Klein

and Menezes, 2001), India (Saravanan et al., 2011), Portugal (e.g., Coelho, Lopes, and Freitas, 2009), France (Sabatier et al., 2009), and so on.

Artificial beaches

When beaches erode along developed shorelines, they are often replenished by sand dredged from offshore and pumped back onto the shore as remediation. Efforts are made to ensure that the dredged sediment closely approximates the nature (size, shape, density, durability, composition, and color) of native beach sands onshore (e.g., Finkl and Walker, 2005). Replenished beaches are engineered to approximate natural morphodynamic beach states so that they perform as sacrificial sand deposits over desired time frames. Some artificial beaches may erode very quickly if impacted by storms and thus fall short of the design life, while others, having greater durability, may exceed the design life, as in the case of Miami Beach, Florida, which has the longest half-life of any renourished beach in America (e.g., Finkl and Walker, 2005). The practice of building artificial beaches, as a soft-engineering shore protection measure, is now so widespread worldwide that many renourished beaches are perceived as natural formations. The practice is, however, not without environmental concerns as borrow sources do not always closely match native beach sands to cause unwanted impacts in the coastal zone (e.g., Bonne, 2010).

Summary

Beaches occur in all latitudes, from tropical to polar regions, and lie on the interface between land and water to form ocean, bay (sound, estuary), and river beaches. They are mostly composed of sand (silicates and carbonates), but there is great compositional and morphological variation between sites. Beaches have great economic and environmental value, serving as tourist destinations and providing habitat as well as buffering impacts from storm waves and surges. Some beaches are artificial, and although their placement is controversial among certain special interest groups, their benefits generally outweigh disadvantages when properly engineered and placed. The morphodynamic classification of beach state finds global application, provides greater understanding of Beach Processes, and contributes to beach safety education programs and surf life saving to reduce public risk.

Definition

The term *beach processes* refers to the collection of processes that are responsible for the formation and maintenance of morphological features and materials that make up all facets of units comprising the beach per se. Because the beach has subaerial and submarine components, processes range from the effects of wind to waves, currents, and tides acting on sediment supply and redistribution to form beach types. Important processes include swash run-up and rundown, overtopping, infiltration into the beachface, step generation, bar formation, cusp development, and so on. Processes and materials interact in a dynamic manner in continual adjustment to changing environmental conditions associated with wind regimes, wave climates, tides, and extreme events such as storm surge and tsunamis.

Introduction

Beaches are complex systems that at first glance appear to be simple enough, sediment piled up along the shore. But, nothing could be farther from the truth as these dynamic systems have historically defied articulation and comprehension because of their continual short-term modification in terms of minutes to hours (e.g., Bascom, 1980; Carter, 1988). High-energy events can induce large-scale beach change that is immediately apparent to an observer. But, even during quiescent periods, the beach is continually changing; literally with every wave grains are moved about the beachface in laminar up- or downrush or by saltation on the berm. Over a longer decadal time frame, some beach materials in tropical and subtropical regions may become indurated by calcium carbonate to form beachrock that in turn provides long-term stability to the beach. Beach processes are similar in general but very different in detail, depending on the ambient energy conditions and materials present. Much is known about beach processes, but some exact modes of formation for some beach features such as beach cusps remain elusive (Guza and Inman, 1975; Komar, 1997; Davidson-Arnott, 2009; Pilkey et al., 2011).

The main agents that affect beaches include waves, tides, currents, and wind (on the dry backbeach area), all of which interact with the sediment to produce distinctive beach morphologies (e.g., Bascom, 1954; Pethick, 1984; Woodroffe, 2002; Davis and FitzGerald, 2004). Breaking waves obviously interact with the sediment, and their position along the beachface depends on tidal ranges and setup or surge. Currents produced by the waves are among the most important processes that change the beach. These important sediment-transporting currents include: (1) combined flow currents, (2) longshore currents, (3) rip currents, and (4) onshore-offshore (cross-shore) currents produced in the swash zone (Davis and FitzGerald, 2004).

Beaches contain noncohesive materials that accumulate in areas affected by wave action along the perimeter of a body of water (whether fresh, brackish, marine, or hypersaline). The material is commonly sand-sized grains

Beach Processes, Figure 1 Dissipative beach along the Oregon coast showing the low-gradient swash that moves up the beachface as laminar flow. Successive incursions of swash move up the beachface as hydraulic jumps until they lose forward momentum and infiltrate into the beach. The high beach groundwater table close to the surface allows swash to run up the beachface for long distances. Pebble and gravel-sized clasts are heaped farther up the beach by storm waves. The backbeach contains coarse-grained lag that has been winnowed by currents when setup temporarily superelevates sea-level during storms (Photo by C.W. Finkl).

(0.06–2.0 mm), but may range through gravel (2–60 mm), cobbles (60–200 mm), and boulders (over 200 mm). Figure 1 shows a gradation in grain size from fine sand on the beachface to cobbles in the backbeach area at the foot of a cliff along the Oregon coast. In very specialized environmental settings, some beaches contain fine-grained materials that are admixed with sand. Intertidal beaches permanently rich in mud (10–20 %) on wave-dominated coasts are, for example, extremely rare because of hydrodynamically controlled nondeposition of mud and lack of substantial nearby mud supplies (Anthony et al., 2011). Mud-rich beaches are generally found associated with high fine-grained discharge deltas such as the Amazon (Anthony and Dolique, 2004) and Mekong (Tamura et al., 2010).

The beach zone is typically subdivided into nearshore, foreshore, and backshore; boundaries between these zones are elastic, responding to cyclic migrations and geo-hydro-meteodynamic events (e.g., Davidson-Arnott, 2009). The nearshore is the submarine part of the beach that lies seaward of the low-tide limit in the region of shoaling waves. The foreshore extends from the low-tide limit to the high-tide upper swash limit that is often marked by a line of flotsam and jetsam. The backshore typically lies landward of the high-tide swash limit and exceptionally lies along the landward limit of storm surge that may include cliffs, dunes, or marshes. The crest of the backshore zone, above the uppermost limit of normal swash, is called the berm. A beach typically has one berm,

but there may be several berms depending on cycles and severity of storminess (e.g., Hardisty, 1990; Short, 1999). The example of the Brazilian beach shown in Figure 2 contains a gently seaward-sloping foreshore, a wide berm, and a narrow backbeach fronting eroded dune fronts.

Study of beach processes

Beach processes are studied in many different ways, as, for example, in the field, in wave tanks, or by numerical simulation on computers (e.g., Hardisty, 1990; Dean and Dalrymple, 2002; Davidson-Arnott, 2005; Dingler, 2005). Whatever approach is used, it is necessary to be cognizant of morphodynamic features such as the cross-shore (equilibrium) profile, presence and interaction of rock alongshore as backbeach cliffs, promontories, beachface beachrock, tidal or subtidal hardgrounds, skerries, or coral reefs offshore. The nature of sedimentary materials that is available for beach processes to act upon, the alongshore supply of sediments, offshore biogenic supply of sediments, and thickness of unconsolidated sediments along the continental shelf are all important parameters that influence beach type (Pilkey et al., 2011). It is also not a matter of presence or absence of any of these features, but the degree to which they are present, or not. With so many cross feedback mechanisms, it is generally not possible to isolate discrete processes that do not interact with other processes or which are modified by different kinds of materials that they act upon.

Beach Processes, Figure 2 Intermediate beach morphotype on the coast of Santa Caterina, Brazil. A wide berm lies landward of a low-tide terrace with poorly developed ridges and runnels. Storm surges have nipped away the front of the backbeach dunes bringing dune sand back into the beach system. The maximum extent of inland penetration of swash is marked by the change in the color of the sand on the berm from darker yellow to cream colored on the backbeach (Photo by C.W. Finkl).

Beaches are thus complex processual systems that require much tenacity and expertise to tease out the secrets of beach formation and modification. In spite of the complexity involved, it is possible to outline some of the main processes that are responsible for major beach features. It is also perhaps worth mentioning at this point that it is not profitable to attempt discussion of beach processes without considering the morphological properties of beach features. The association of process and form (Hardisty, 1990) thus leads to appreciation of beach morphodynamics (e.g., Short, 2006), which includes the interaction between breaking waves, currents, rocky headland or submerged hardgrounds, and the sediments that compose the beach. Beaches are dynamic features where composition, morphology, and orientation are spatiotemporally variable as, for example, in the case of headland bay beaches that rotate between promontories (Klein et al., 2002; Short and Trembanis, 2004).

Small-scale beach processes

Waves and currents sort the sediment and move it alongshore and cross-shore. The concept of a "river of sand" is sometimes promoted, but it is a misnomer because there can be many interruptions to the alongshore sediment flow as in the case of capes, promontories (headlands), submarine canyons, deeply dredged inlets, or other engineering structures such as groins and jetties. Alongshore drift may be predominantly in one direction, but there can be seasonal reversals (e.g., during monsoons) or interruptions due to storms, making the concepts of gross and net

sediment transport viable (Dean and Dalrymple, 2002). As a general rule in sandy environments, coarser materials remain closer to shore, but along high-energy coasts coarse materials may be heaped up on the beachface and berm. Below mobile surface sediments, bedrock platforms or consolidated materials slope gently seaward, serving as a foundation for the beach. Some beach sediments are heaped up on marine benches during storms and because they lie beyond normal waves and tidal cycles, they are referred to as *perched beaches* being the result of special extreme processes.

Beaches exist in a state of dynamic equilibrium with tides and waves. Storm waves tend to move the sand out to deeper water and flatten the beach cross-shore profile while less energetic waves in quiescent periods tend to move sediment shoreward to build up the beach. Some beaches retain sand that is trapped between headlands, while in other settings sand transits the beach by entering in one end and exiting in the other, somewhat in the context of a conveyor belt. The beach therefore exists when processes and materials balance each other over time (e.g., Dean and Dalrymple, 2002; Davis and FitzGerald, 2004).

The surf zone, the most dynamic part of the beach, extends from the breaker zone to the shore (Wright and Short, 1984). Waves theoretically break when the slope of the advancing face is steeper than 1:0.78 but may be closer to 1:1 based on field data. Waves typically start to interact with the seafloor when the water depth is about 75–80 % of the wave height (Bascom, 1980). Frictional

forces then slow the bottom part of the wave while the top continues to move at the same speed, eventually over reaching the slower moving wave base. Waves may break as spilling breakers on low-gradient slopes, as plunging waves on moderate gradients, or as surging waves on steep slopes. Breaking waves transform their potential energy into kinetic energy in the form of broken waves of translation, or wave bores that move shoreward as turbulent white water. Breaking waves dissipate most of their forward-moving energy, which is lost in turbulence. Turbulent flow is an important process because it stirs up large quantities of bottom sediment that will remain in suspension for variable amounts of time depending on the grain size, larger particles settling faster than smaller ones according to Stoke's law and measured in numerous ways in the lab and in the field. This entrained sediment is transported more or less parallel to the shore by the longshore current, which typically reaches from the shoreline through the breaker zone. Under high-energy conditions, breaking storm waves advance across the upper shoreface, sending surge and fast-moving swash up the beachface to erode the berm (Figure 3). Under these conditions when the surf zone temporarily moves shoreward due to increased water depths resulting from surge and setup, beach sands are entrained in cross-shore currents leaving a beach scarp cut into the berm. Beaches equilibrate to a morphodynamic state that is more in balance with quiescent conditions after the storm passes.

Saltation on the berm and backbeach

Once sandy particles are deposited on the berm, wind is the predominant force that moves them inland. Wave-deposited materials are dried by solar radiation, wind, and drainage prior to transport by wind from the berm to backbeach. Wind velocity controls the rate of sand transport, but spatio-temporal variation in sediment deposition depends on beach width (Pethick, 1984; Davidson-Arnott and Law, 1996).

Three main eolian processes transport sediment (Bagnold, 1941). Wind erosion of surface particles on the berm is initiated when air velocities reach about $4.5\,\mathrm{m\,s}^{-1}$. Initial particle movement takes place as a rolling motion, termed traction or creep, where particles as large as small pebbles can be tracted by strong winds. About 20–25 % of wind erosion is by traction. When particles are lifted off the ground, becoming suspended in the air, and then return to the ground surface several centimeters downwind, the process is called saltation (Davis, 1985; Carter, 1988). Saltation on the dry berm accounts for 75–80 % of total sediment transport by wind, with beach sand ultimately ending up in dunes behind the beach (Cf. Figure 2). It provides momentum that drives the other two sand transport modes because when a falling particle strikes the berm surface, part of its impact force is transferred to another particle causing it to become airborne.

Beach Processes, Figure 3 Reflective beach type now adjusting to an intermediate morphotype after the passage of storm conditions along the Florida Atlantic coast near Palm Beach. During the high-energy storm conditions, sand was eroded from the berm forming a new steeper beachface than the more gently sloping one associated with the formerly wider beach. The beach scarp, now a hazard to beachgoers, will slump by uprush undercutting during high tides to form a new more gently seaward-sloping beachface (Photo by C.W. Finkl).

Swash run-up and rundown

When beachfaces are steep, waves can transit the shoreface without breaking, and when the broken wave reaches the base of the wet beach, it collapses and runs up the beachface as swash or uprush in the swash zone (e.g., Davis and FitzGerald, 2004). Under normal or quiescent wave conditions, the laminar-flow uprush stops near the top of the slope, with some of the water infiltrating the surface of the beachface per se and then percolating into the beach until it reaches the water table (Cf. Figure 1). If the water table is close to the surface, the remainder flows back down the beachface as backwash. If the water table does not lie close to the surface, the uprush may completely disappear into the beachface with no back flow. These actions produce a relatively steep seaward-sloping swash zone on the beachface, the slope of which can range from 1° to 20°. If waves approach the beach obliquely, and although sediment in this case is transported in a zigzag pattern across the

Beach Processes, Figure 4 Current ripples along the foreshore on a beach in Long Island Sound near Amagansett, Long Island, New York, USA. Shore-parallel ripples in this intertidal zone are developed on both sides (landward and seaward) of a hardground containing algal overgrowth. A hydraulic jump is visible in the swash seaward of the algae poking through the sand cover. The complexity of these small-scale beach processes is shown by superposition of fine-grained sand in a micro-delta deposited on top of the rippled sand bed, as noted by the lighter color of the sand splay and lack of closely spaced ripples. In addition to physical processes, beaches are modified by biological processes as, for example, seen here with mounds (that look like micro-volcanoes approximately 15 cm in diameter) produced by Atlantic jackknife clams (*Ensis directus*) (Photo by C.W. Finkl).

beachface, the net result is sediment transport in the direction of the waves. As sediment accumulates in a seaward-building swash zone, it constructs a berm, the nearly horizontal to slightly landward-dipping sand surface that merges with the backbeach. This is the so-called dry beach where most people sit or lay down when they go to the beach. The swash zone may contain small-scale features such as beach cusps, spaced about every 20–30 m apart, and which are thought to be produced by edge waves (Guza and Inman, 1975). On intertidal flat-lying parts of the foreshore, swash currents may produce various types of ripples. The ripples shown in Figure 4 are typical of many low-gradient intertidal beaches with fine-grained sediments, as seen on this beach on Long Island, New York, where the ripples formed by progressively dissipating swash currents during a falling tidal sequence.

Sheetwash, runoff channel, and sapping-seepage erosion

Rain-induced beach processes (Otvos, 1999) produce interesting minor features on beaches. Subtle features on sandy beach foreshores include swash grooves (braided scour marks), shore normal, flutes, dendritic rills, rhomboidal microrills, and box canyon valleys. These features are related to a range of processes such as water infiltration (in the infiltration zone) and percolation from the beach (in the effluent zone) at low tide or following a storm

(e.g., Duncan, 1964; Davis, 1985; Komar, 1997), backwash deflection around obstacles (e.g., Otvos, 1964, 1965; Komar, 1997), backwash flow dissipating into the beach and emerging on the foreshore (Higgins, 1984), sheetwash and cross-beach channeled flow (Otvos, 1999), foreshore dissection by headward eroding box canyons and rill channels (Otvos, 1999), etc. Sheetwash, channeled surface flow, and fresh groundwater-driven spring sapping processes produce a wide range of micromorphodynamic features on the beachface and foreshore. Although appearing to be morphologically minor, these processes play an important subsidiary role in seasonal beach degradation and operate on most beaches of the world. These processes are significant in sediment redistribution on coasts with high rainfalls and wide beaches that are backed by permeable bluffs.

Plunge step formation

The plunge step occurs between the base of the foreshore and the top of the shoreface (Davis, 1985). Wave-dominated shorelines often show a sharp break in grain size at the plunge step where coarser clasts tend to accumulate. The plunge step marks a subtle decline in the foreshore profile that is produced by the final plunge (wave break) before a wave runs up the beachface (Pilkey et al., 2011). The last wave break converts potential energy into kinetic energy that is used up in turbulent flow.

Continual wave breaks in the same location alongshore suspends beach sediments that are transported by currents. The continuous turbulent action and cross-shore movement of sand grains creates a sedimentation deficit that produces the small alongshore trough. The penultimate forward movement of the wave thus moves up the beachface as laminar flow, often with several hydraulic jumps as successive waves break and send new swash on top of the preceding swash flow, in piggyback fashion. Bathers entering the surf are often surprised by the presence of the plunge step, especially when the water is murky, because it may be of decimeter scale, the deeper parts of the trough collecting organic debris that is unpleasant to walk through. The plunge step is best developed in low-tidal range beaches with a steep foreshore slope (Davis, 1985), such as commonly seen along Florida Atlantic coast beaches but is also common along gravel beaches. When setup is very high, the plunge step site may transfer up the beachface to the swash berm or even the storm berm. Direct measurement of step morphology is rare on account of the high-energy conditions localized along this zone.

Bar formation and migration

Surf zone currents transport sediment onshore, alongshore, and offshore to build (sand) wave-formed nearshore bars and troughs occupying the surf zone (e.g., Davis, 1985; Komar, 1997; Greenwood, 2005). Wave-formed bars occur as symmetrical or asymmetrical undulations along the upper shoreface profile in intertidal and subtidal environments (Greenwood, 2005). Barred profiles are in general associated with large values of wave steepness and wave height-to-grain size ratios and are associated with waning stages of shoaling and dissipation of wave energy (Wright et al., 1979; Greenwood, 2005). Bar formation has been related to a number of specific hypotheses that involve convergence of sediment transport, viz., (1) breakpoint hypotheses, (2) infragravity wave hypotheses, and (3) self-organization hypotheses. Wave breaking, for example, is thought to induce a seaward transport of sediment that is, respectively, entrained by roller or helical vortices under plunging or spilling breakers (e.g., Zhang, 1994). Alternatively, convergence of sediment at the breakpoint may be related to onshore transport associated with increasing asymmetry and skewness of high-frequency incident waves and offshore transport through setup-induced undertow (e.g., Thornton et al., 1996). Bar frequency of occurrence and geomorphic position may be produced by the interaction of sandy sediments with infragravity waves that are low frequency (greater 30 s period) waves produced by sets of higher and lower waves that are enhanced by wave breaking across the surf zone. These waves can be standing or progressive-produced as a result of energy dissipation during breaking and frequently related to groupiness (Roelvink and Broker, 1993; Reussink, 1998), amplitude modulation of the incident wave field. As a rule, the longer the infragravity wave period, the more widely spaced the bar(s).

Rip currents and channels

Rip currents are narrow, usually fast seaward-flowing currents that penetrate the surf zone, often in a rip channel that flows to deeper water. Rips are a mechanism for returning water back to the sea that piles up alongshore in setup (e.g., Pilkey et al., 2011; Leatherman, 2013). These fast-moving shore-perpendicular currents transport eroded beach sediment seaward to deep water during high seas. These fast-moving cross-shore currents often occur through gaps in offshore bars but are also caused by depressions in the beach, irregular bottom topography, obstructions in the surf zone such as rock outcrops or groins, or longshore currents in circulating cells (e.g., Pilkey et al., 2011). Rip currents, a major hazard to swimmers, are responsible for most beach rescues and drownings (Short, 1999; Leatherman, 2013). Edge waves, a form of infragravity wave (Guza and Inman, 1975; Reussink, 1998), influence the alongshore spacing of rip currents and channels, which are typically 200–300 m apart on open ocean beaches. Bars and troughs that form on the intertidal part of the beach are known as ridges and runnels, with sometimes as many as a dozen or more occurring on intertidal beaches with high tidal ranges. Individual bars may have their own swash zones and dry beach on the crests until they are covered by the rising tide.

Large-scale morphodynamic beach processes

Equilibrium beach (cross-shore) profiles are produced by steady wave forcing during seasonal cycles. Accretionary (summer) and erosional (winter) beach profiles are expressions of seasonal cycles of wave energy, as elucidated in the classic works of Shepard (1950) and Bascom (1954). Accretionary beaches, which are produced by swell waves with a low wave height (generally <1 m) and a period of 8–12 s, produce a wide and well-developed backbeach with a relatively narrow foreshore (e.g., Davis and FitzGerald, 2004).

Large storm events result in a disequilibrium profile where sand may be permanently lost to deep water (Dean and Dalrymple, 2002). Erosional or storm beaches, on the other hand, are temporary morphodynamic states that are characterized by a profile that is generally flat and featureless with a narrow or nonexistent backbeach (Shepard, 1950; Hallermeier, 1981). Most or all of the beach thus occur in the foreshore position (e.g., Davis and FitzGerald, 2004). Due to storms, waves are larger and more energetic in winter than summer. Long periods of stormy weather, such as El Niño winters, erode beaches to the underlying cobbles or bedrock and deposit sand far offshore in deep water, leaving the beach in disequilibrium, as seen, for example, along the California coast. The winter beach is denuded of sand by storm waves, leaving heavier cobbles behind as lag deposits. Wave-cut platforms underlying the mobile sediments are often

exposed during high-energy conditions. Summer wave conditions return sand back to the beach so that the summer beach is covered with a layer of sand that is moved south by alongshore currents and onshore by low-energy wave climate. Other researchers have noted associations between waves, breakers, and beach gradients – the relationship occurring because breaker type is a function of wave characteristics (Pethick, 1984). High values of the surf-scaling factor (e.g., Guza and Inman, 1975) are associated, for example, with wide flat beaches with spilling breakers, while low values are associated with steep narrow beaches and surging breakers (e.g., Wright et al., 1979; Wright et al., 1982). Although the relationship between wave steepness and beach gradient is pronounced, other variables such as the angle of the wave approach (e.g., Sonu and van Beek, 1971) and tides and longshore currents (e.g., Davis, 1985) may also be important.

Morphodynamic beach types

Beach morphotypes range through a sequence of process-form-materials systems between end points marked by low-energy systems with small beach-building waves to high-energy systems with large waves breaking across several hundred meters of surf zone (Wright and Short, 1984). Tides are an additional consideration in beach formation as they range from micro ($<$2 m), meso (2–4 m), macro (4–8 m), to mega tides ($>$8 m). Beaches are divided into the three basic morphodynamic types in order to accommodate tidal ranges, wave heights, and variations in grain size (sand to boulders), viz., wave dominated, tide modified, and tide dominated, based on the relative tide range (RTR) (Short, 2006). This process-based grouping of beach morphotypes, as initially conceived by Wright et al. (1982) and expanded to beaches around the Australian continent by Short (1999, 2006, 2012), provides a basis for cataloguing a range of beach processes associated with beaches in low latitude and mid-latitude. Ice-coast beach processes are not yet comprehensively included in the system. Some essential facets of the morphodynamic classification of beaches are briefly summarized here from Short (2012) and Short and Woodroffe (2009).

Wave-dominated beaches are characterized by a RTR tide range that is less than three times the average wave height (RTR $<$ 3). These beaches occur in three morphodynamic states that are referred to as (1) reflective, (2) intermediate, and (3) dissipative.

Reflective beaches are the result of process-material interactions that are associated with lower waves (H $<$ 0.5 m), longer wave periods, and coarser sediment. As a result of these process-form relationships, all coarse sand and cobble-boulder beaches exhibit a reflective beach state. Reflective beaches contain a relatively steep beachface (5–20°) that reflects backwash. Reflective beach processes do not produce a bar or surf zone.

Intermediate beaches are common along open coasts and are produced by moderate waves (H = 0.5–2.5 m) interacting with fine- to medium-grained sand. These types of beaches are characterized by a surf zone with one or two bars up to 100 m wide. The bar is typically traversed by regularly spaced shore-perpendicular rip channels and currents.

Dissipative beaches are produced by high waves (H $>$ 2.5 m) interacting with fine-grained sand. These morphotypes are characterized by gently seaward-sloping beachfaces with low-gradient swash ($\sim$1°) and 300–500 m wide surf zone that contains at least two bars. Waves sequentially break on the outer bar first and then on inner bars and in the process dissipate their energy as they move through the surf zone.

Tide-modified beaches are characterized by a RTR that lies between 3 and 10, which implies that the tidal range is increasing and/or wave height is decreasing. This morphodynamic beach type usually has a steeply sloping, cusped, and reflective beachface that is developed in coarser-grained sediments to produce a so-called high-tide beach. Tide-modified morphotypes are fronted by a wide, finer-grained, low-gradient, often featureless, intertidal zone (up to 200 m wide), seaward of which lies a low-tide surf zone that may contain bars and rip channels.

Tide-dominated beaches are produced when the RTR lies between 10 and approximately 50, implying high tides and/or very low waves (H $<<$ 0.3 m). These morphotypes are characterized by a low elevation, coarse-grained sediments, irregular, high-tide beach that is fronted by low-gradient ($<<$1°) intertidal sand or mud flats that may be hundreds of meters wide. Beyond an RTR of 50, tidal flats typically prevail.

An additional morphodynamic beach type is associated with a high-tide reflective beachface that is fronted by intertidal rock flats in middle latitudes. In tropical zones, the high-tide beach may be fronted by a fringing coral reef flat. High latitude morphotypes are seasonally exposed to freezing air and water temperatures that lead to the development of sea ice, shoreface ice, and a frozen snow-covered beach (Short and Woodroffe, 2009).

Summary

Although seemingly simple in appearance, beaches are complex systems where many aspects of their formation are incompletely understood. The morphological results of interactions between processes and materials are categorized in a range of processes-based beach types that are easily recognizable on beaches of the world. Beach processes are observed to operate over myriametric (macro-, meso-, micro-) scales and a range of time frames with grains on the beachface changing by the second to some sand bars that may persist for hundreds of years. Complete understanding of how beaches evolve (accrete) and devolve (erode) over time in different kinds of sedimentary environments provides scope for future

studies that involve observation by various means in the field and laboratory.

BED FORMS

Miwa Yokokawa
Laboratory of Geoenvironment, Faculty of Information
Science and Technology, Osaka Institute of Technology,
Osaka, Japan

The term "bedforms" is used for to describe rhythmic topographic features on the surface of granular beds. A wide variety of such features form in response to specific ranges of hydraulic conditions and grain size. Apart from their intrinsic scientific interest, bedforms are important in both geology and engineering. Large subaqueous bedforms can be obstacles to navigation, and their migration can be a threat to submarine structures. Bedforms also play an important role in determining the resistance to flow. Bedforms are also one of the most useful tools available for interpreting ancient sedimentary environments from outcrops.

When unidirectional flow operates on relatively fine-grained sand (less than 0.7 mm), the following bedforms appear in order as flow "strength" is increased: current ripples, dunes, upper-regime plane bed (absence of bedforms), antidunes, and cyclic steps. If the bed material is coarser than 0.7 mm, the ripple regime is replaced by lower-regime plane bed.

Under purely oscillatory flows over fine-grained sediments, small symmetrical regular straight-crested (2D) ripples, less regular 3D ripples, and large 3D ripples appear with increasing oscillatory velocity magnitude. In the case of long-period oscillatory flows, large dome-like mounds with gentle slopes appear; these are known as "hummocky beds." In the case of coarser sediment, ripples tend to stay straight-crested. When the velocity magnitude becomes large, ripples are washed out to plane bed.

When unidirectional flow is superimposed on oscillatory flow, i.e., combined wave-current flow, bedforms change corresponding to the sum of unidirectional flow velocity and oscillatory flow velocity magnitude. When the unidirectional flow velocity is smaller than a threshold, bedforms are the same as those under purely oscillatory flow. When unidirectional flow velocity increases beyond this threshold, bedforms show characteristic rounded crests and asymmetrical profiles. The threshold at which unidirectional flow affects bedform shape decreases with increasing oscillatory period. When the unidirectional component dominates, large, asymmetric dune-like bedforms appear. On the other hand, when the oscillatory component dominates, hummocky beds appear. These bedforms wash out to plane bed at sufficiently high velocities.

Various bed phase diagrams have been proposed to categorize the relationship between bedforms and hydraulic conditions. In order to construct such diagrams, the relevant parameters which govern the relationships must be specified. In general, bed state is a function of seven parameters. Five parameters are common to all cases: grain size, sediment density, fluid density, fluid viscosity, and sediment submerged specific weight. For unidirectional flow, two more parameters, such as flow velocity and flow depth, are needed. For oscillatory flow, two of the following three parameters must be specified: oscillation period, orbital diameter, and maximum orbital velocity. Dimensional analysis allows the seven variables to be grouped into four dimensionless variables. A large body of experimental research on bedforms under unidirectional flows and short-period oscillatory flows is available. Our knowledge of long-period oscillatory flows and multidirectional combinations of combined waves and currents, however, remains limited.

BIOCHRONOLOGY, BIOSTRATIGRAPHY

Felix M. Gradstein
Museum of Natural History, University of Oslo, Oslo,
Norway

Biochronology attempts to organize the fossil record in linear time, using the notion that fossil events and fossil zones are organized according to the irreversible process of evolution.

The key to biochronology and its building blocks is fossil events. A fossil or paleontological event is the presence of a fossil taxon in its time context, derived from its position in a rock sequence. Most commonly used are first appearance and last appearance datums (FAD and LAD). Since the first or last appearance datum may be difficult to recognize or distinguish where specimen numbers dwindle or get obscured by "noise" (like reworking of fossil tests very common with the tiny nannofossils), it can be advantageous to substitute with first and last consistent (or common) appearances. A first or last appearance datum is called consistent when such stratigraphic range

end points are part of an observed continuous stratigraphic range.

If the fossil record encountered in stratigraphic sections that we want to correlate and calibrate in time would be ubiquitous and perfect, i.e., if only time would control the appearance, range, and disappearance of taxa, then biostratigraphy would be a straightforward exercise. The science of biochronology, as developed for the evolutionary first and last occurrence datums of ocean plankton, would be a matter of systematic bookkeeping on a worldwide scale, only constrained by taxonomic deliberations. Unfortunately, the paleontological record is highly imperfect.

Uncertainty factors may be summarized as follows:

1. Quality and quantity of sampling
2. Specimen frequency of fossil taxa
3. Confidence of taxonomic identification
4. Influence of environmental change on the stratigraphic range of taxa
5. Differential rate of taxon evolution in different parts of the world
6. Time lag in migration of taxa, where correlation is over large distances or across major environmental barriers

Hence, biochronology almost always requires careful calibration with independent geomagnetic reversals and stable isotope correlation frameworks.

Biochronology is reaching a pinnacle in the massive fossil event datasets generated with TimeScale Creator software (http://www.tscreator.org). The method and data system confidently link all events in the evolutionary "organic continuum" in an elegant linear time framework, calibrated to Geologic Time Scale 2012 (see Geologic Time Scale). A recent calibration of Cretaceous and Cenozoic planktonic foraminifera and calcareous nannofossils of the temperate to tropical marine realm is by Anthonissen and Ogg (2012). Syntheses for siliceous, organic, and other microfossil biostratigraphy are summarized in the appropriate chapters in *The Geologic Time Scale* (Gradstein et al., 2012), and detailed and updated versions of all stratigraphic scales can be accessed as datasets and graphics at the TimeScale Creator website.

Special mention is made of the detailed and high-resolution (deep time) conodont-foraminifera-ammonoid composite zonation for the Carboniferous, with over 35–40 zones constrained by 36 radiometric dates employed in timescale building for this period (Davydov et al., 2012). Particularly in younger parts of the Carboniferous zonal event, resolution is resolved at a biochronologic scale that provides insight in biota migrations due to the waxing and waning of massive Gondwana supercontinent glaciations.

Summary

Biochronology attempts to order and scale fossil events and fossil ranges in linear time.

BIOGENIC BARIUM

Graham Shimmield
Bigelow Laboratory for Ocean Sciences, East Boothbay, ME, USA

Biogenic barium usually occurs as discrete microcrystals of the refractory mineral, barite ($BaSO_4$). It may be found in the water column (in the tests of both live and dead planktonic species), in benthic foraminifera, in coral skeletons, and in the underlying sediment. The earliest observations of enriched barium (usually identified as barium concentrations exceeding typical shale or sediment concentrations), and attributed to biological processes, are the work of Revelle et al. (1955) working in the equatorial divergence of the Pacific Ocean. Dehairs et al. (1980) and Bishop (1988) showed that barite ($BaSO_4$) was precipitated in decaying suspended marine particulate matter (particularly diatoms) in oceanic waters. Some studies have suggested that biogenic barium may occur in heavy mineral granules functioning as statoliths in statocyst organs and within protozoans such as Xenophyophoria and Loxodes. Biogenic barium distribution and concentration have been studied in benthic foraminifera and corals as a tracer of bottom water nutrients and upwelling, respectively.

Biogenic barium in sediments is often found in water underlying areas of high productivity. Bishop (1988) has studied the barium content of large and small particles in the Gulf Stream, and Schmitz (1987) has illustrated the use of Ba as a tracer of Indian Ocean plate movement beneath the equatorial upwelling zone on a timescale of millions of years. Virtually, all ocean basins display enrichment of biogenic barium where productivity is elevated and with time (paleoproductivity). Shimmield (1992) suggested that barite-secreting organisms may be confined to a rather discrete zone within the coastal upwelling productivity belt, seaward of the shelf break (under a different nutrient regime), and as a consequence shallow-water, organic-rich sediments may receive little biogenic barium, or the sedimentary barite undergoes diagenesis during sulfate reduction (see below). A similar distribution of biogenic barium was noted by Calvert and Price (1983) in their work off Namibia.

The refractory nature of barite was remarked on in the earliest work by Dymond (1981), something he called a

"dissolution residue." The association of biogenic Ba, opal, and biogenic sedimentation has been described by many authors (see reviews in Schmitz, 1987; Gingele et al., 1999). These observations have opened the potential to use biogenic barium downcore distributions as an important proxy for paleoproductivity, given that both organic carbon and opal may suffer from remineralization and dissolution. An important step in quantifying past productivity is to establish the relationship between biogenic barium and organic carbon in sediment traps (Dymond et al., 1992; Francois et al., 1995). Using algorithms developed from empirical observations, downcore variations in biogenic barium flux have been converted to paleo-primary production. This approach has a number of assumptions and potential drawbacks. In particular, it is necessary to calculate the biogenic component of the total barium content in the sediment. This is usually achieved by normalization to lithogenic metals such as aluminum or titanium. There may be additional sources of barium to the sediment from hydrothermal systems or benthic organisms such as xenophyophores. Finally, although barite is very refractory under oxic conditions, during sulfate reduction in anaerobic sediments, barite dissolution may occur.

BIOTURBATION

Gerhard Graf
Institute for Biological Sciences, University of Rostock, Rostock, Germany

Definition

Bioturbation is the mixing and displacement of particles in marine and freshwater sediments caused by benthic fauna mainly during foraging and the construction of burrows. As a result particulate proxies and microfossils such as tests of foraminifera deposited at the seafloor may not be found in the time slice corresponding to its deposition, and the interpretation of the geological record can be hampered. Other effects of animal activity, such as biodeposition and bioresuspension, but also fluid transport will not be considered in this section although they are essential for biogeochemical cycles and are used as subprocesses of bioturbation in recent biological literature (cf. Kristensen et al. 2012).

Measurement and modeling

In geological sciences, mainly natural radioactive tracers like ^{210}Pb, ^{234}Th, or ^{7}Be but also chlorophyll a or stained sand grains have been used for a quantitative description. A basic equation for sediment mixing was provided by Berner (1980).

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x}\left(D_b(x)\frac{\partial C}{\partial x}\right) - \omega\frac{\partial C}{\partial x} \pm R(C, x, t)$$

C = concentration of tracer, t = time, x = depth, D_b = mixing coefficient, ω = burial velocity, R = reaction term for the tracer

It describes particle mixing in analogy to molecular diffusion. This assumption holds true in the case of many animals moving particles in a stochastic way in small steps (local mixing). Statistically this creates a transport of tracers along the concentration gradient, as does the Brownian movement on the molecular level, and can be calculated via Fick's law of diffusion. The mixing coefficient D_b provides a quantitative measure.

Some animals transport food particle directly in one step from the surface to depth, or particles may drop into open burrows. In these cases the diffusion analogy is inadequate, and this advective transport (nonlocal mixing) has to be considered separately, i.e., the step length and frequency of such events have to be determined and to be included into the model, as, for example, in the gallery-diffusion model by Francois et al. (2002).

Order of magnitude

From published data, Boudreau (1994) calculated a world-wide mean mixing depth of 9.8 ± 4.5 cm. It is, however, well documented that animal burrows may reach as deep as 2 m (Thalassinidea). Mixing coefficients D_b may range from 0.0002 to 370 cm^2 years^{-1}. The latter results are

highly dependent on the habitat and the tracers used. The shorter the half-life of the tracer, the higher is D_B. This result is mainly explained by the fact that some animals are highly selective and prefer fresh organic matter.

So far attempts to find general relationships between sediment mixing and biomass or organic carbon content failed, indicating the strong species-specific effect of bioturbation.

Definition

Black and white smokers. Chimney-like edifices composed of mixtures of copper-, iron-, and zinc-sulfide minerals and calcium- and barium-sulfate minerals. They form as very hot (up to ~400 °C or 750 °F) fluids exit very young seafloor and mix with cold seawater, with the high-temperature fluids passing through channels within the edifices into the deep ocean.

Introduction

Black and white smokers are the portions of seafloor hydrothermal vent deposits through which ~200 °C–400 °C hydrothermal fluids travel and exit into the deep ocean, <1,000–5,000 m below sea-level. The hot fluids form as cold seawater percolates down into young, still hot seafloor near the spreading axes of the mid-ocean ridges and spreading centers in back-arc basins; during its transit, the seawater exchanges heat and undergoes chemical reactions with the young oceanic crust. The seawater loses oxygen and sulfate, becomes

more acidic (pH decreases), and becomes enriched in metals (e.g., Fe, Mn, Cu, Zn, Pb) and hydrogen sulfide, and its temperature increases from ~2 °C to >400 °C (German and Von Damm, 2006). The hot fluid is very buoyant (because its density decreases to approximately two-thirds of the original density as it is heated to >400 °C) and rises rapidly to the seafloor, exiting at meter-per-second flow rates (Bischoff and Rosenbauer, 1985; Spiess et al., 1980; see "Hydrothermal Vent Fluids (Seafloor)"). When the hot, metal- and sulfide-rich, oxygen-poor fluid exits and mixes with cold, sulfate-rich, metal-poor seawater, minerals precipitate rapidly as chimney-like edifices and as particles within plumes (with a smokelike appearance) above the edifice – see Figure 1.

Discovery

Venting of hydrothermal fluids from the youngest portions of the seafloor along the mid-ocean ridges was first observed in 1977 along the Galapagos Rift where unusual biological communities were found associated with warm vent fluids (17 °C, much warmer than the surrounding 2 °C seawater); the presence of these warm fluids had been predicted based on measurements of heat flow (see "Marine Heat Flow") and bottom seawater thermal anomalies close to the mid-ocean ridge (Corliss et al., 1979). In 1978, massive sulfide deposits that likely formed from much higher temperature fluids were found near 21°N latitude on the East Pacific Rise about 650 m west of the spreading axis (Francheteau et al., 1979). The first actively venting black and white smokers were subsequently discovered in 1979, along the spreading axis of the East Pacific Rise (Spiess et al., 1980) not far from where the deposits were found a year earlier.

The hot fluids were observed exiting "stacks" or "chimneys" that were 1–5 m tall, composed of copper-, iron-, and zinc-sulfide minerals and the mineral anhydrite (calcium sulfate) (Spiess et al., 1980). The observed black chimneys, or black smokers, resembled organ pipes ≤30 cm in diameter and emitted hot (>350 °C) fluid with dark-colored (black) precipitates suspended within the exiting fluid (Spiess et al., 1980). The white chimneys, or white smokers, were covered with worm tubes (making them light-colored) and emitted cooler (<330 °C) fluids at slower flow rates with light-colored precipitates suspended within exiting waters (Spiess et al., 1980; Haymon and Kastner, 1981).

Formation of black smoker chimneys

Black smoker chimneys form in two stages (Haymon, 1983; Goldfarb et al., 1983): (1) deposition of an anhydrite ($CaSO_4$)-dominated wall as hot, calcium-rich vent fluid mixes turbulently with cold, sulfate- and calcium-rich seawater, followed by (2) deposition of a layer of sulfide minerals against the inner side of the anhydrite layer as the Stage 1 anhydrite wall prevents rapid mixing between the hot fluid flowing inside the chimney and the cold
Black and White Smokers, Figure 1 Hot (347 °C) vent fluid exits multiple black smokers on the chimney edifice "Homer" near 17.5°S latitude on the southern East Pacific Rise (Courtesy Woods Hole Oceanographic Institution; M. Lilley and K. Von Damm chief scientists).

seawater present on the outside of the chimney. Chalcopyrite ($CuFeS_2$) is dominant if temperature is >330 °C and pyrite (FeS_2) and wurtzite ((Zn, Fe)S) occur at lower temperatures. Infiltration of seawater and hydrothermal fluid components across the porous wall also results in the deposition of sulfide and sulfate minerals and silica in the interstices of the wall, which gradually makes the chimney less porous and more metal-rich – see Figure 2. Interaction of fluids and biota on chimney exteriors can also result in the formation of an iron-sulfide-rich outermost layer on the chimney (Juniper et al., 1992).

Rapid formation of the Stage 1 chimney wall (it can form at rates up to 30 cm per day; Goldfarb et al., 1983) is in part a consequence of anhydrite being an unusual mineral that is more soluble at low temperatures than at high temperatures; if seawater is heated to ~150 °C or greater, anhydrite precipitates (Bischoff and Seyfried, 1978). When the very hot vent fluid exits at meter-per-second velocities into seawater, mixtures above ~150 °C will be saturated in anhydrite, with the sulfate coming from seawater and the calcium from both the vent fluid

and seawater (Styrt et al., 1981; Albarède et al., 1981). Metal sulfides and oxides (zinc sulfide, iron sulfide, copper-iron sulfide, manganese oxide, and iron oxide) also precipitate from the vent fluid and vent fluid/seawater mixtures as fine-grained particles. Some of these particles become trapped within and between grains of anhydrite within the Stage 1 chimney walls, giving the anhydrite, which is clear to white in its pure form, a gray to black color (Goldfarb et al., 1983; Haymon, 1983). The remaining particles form a plume of "smoke" above the chimney. Because bottom seawater is denser than the mix of seawater and hydrothermal fluid in the plume, the plume rises a few 100 m above the seafloor to a depth where it is of the same buoyancy as the surrounding ocean water (see "Hydrothermal Plumes").

Once the initial anhydrite-dominated framework is in place, chalcopyrite (or chalcopyrite and pyrite or chalcopyrite and wurtzite for lower temperature black smokers) precipitates on the inner surface of the chimney. Observed young chimney walls are thin, less than a centimeter to a few centimeters, with one side of the wall very hot and one side much colder. The porous chimney wall is subject to steep gradients of temperature and concentrations of elements. As the chimney evolves, the innermost layer thickens (recovery of a chimney known to be only 1 year old had an innermost chalcopyrite layer that was ~1 cm thick; Koski et al., 1994). At the same time that the innermost layer is thickening, aqueous ions, including copper, iron, hydrogen, oxygen, sulfide, sulfate, zinc, sodium, chloride, and magnesium, are transported from areas of high to low concentrations (by diffusion). These elements also are carried by fluids flowing across the wall from areas of high to low pressure (by advection). As a result of these processes, minerals become saturated and precipitate in the pore spaces within the chimney walls, and favorable conditions for microorganisms are established in the outer parts of the chimney walls. In particular, within the chimney walls at temperatures less than ~120 °C, the steep temperature and concentration gradients provide combinations of reducing chemicals from vent fluids (hydrogen, hydrogen sulfide, ferrous iron) and oxidizing chemicals from seawater (oxygen, sulfate, ferric iron) that can be used by microorganisms (bacteria and archaea) as sources of energy (see "Chemosynthetic Life"; Jannasch, 1995). Larger organisms (e.g., alvinellids and paralvinellids; Haymon and Kastner, 1981; Juniper et al., 1992) also reside on the exteriors of chimneys, and their tubes can become incorporated into chimney walls – see Figure 3. As the chimney grows, earlier-formed minerals, as they are exposed to hotter fluids, can be replaced by later-formed minerals.

Formation of white smoker chimneys

The style of mixing between vent fluid and seawater differs in chimneys that emit lower-temperature, white to clear fluids (~200–330 °C). One major reason for this is that the vent fluid is flowing more slowly. Because the

fluid percolates less vigorously through the porous spires, a greater percentage of metal from the fluid precipitates within the deposit instead of being lost to the ocean within particle-laden plumes (e.g., Haymon and Kastner, 1981; Koski et al., 1994). Some of the white smoker chimneys are dominated by zinc- and iron-sulfide minerals, which form both an initial framework and infilling material (Koski et al., 1994 – see Figure 4). Others contain abundant barite and silica, both as initial framework material and as infilling material, with barite then co-precipitating with silica and sulfide minerals (Hannington and Scott, 1988). Many white smokers lack anhydrite, consistent with a lack of entrained seawater as they form. In contrast to black smokers, where flow is rapid through open conduits of >1 cm diameter, flow in white smokers is through narrow, anastomosing conduits that seal over time, commonly diverting flow horizontally (Fouquet et al., 1993; Koski et al., 1994). Beehive structures or diffusers are another type of smoker found at some vent fields. They have a bulbous morphology, interior temperatures only slightly less than for black smoker chimneys, highly porous interiors, and high-temperature (relative to black
Black and White Smokers, Figure 4 *Left image* is of white smoker chimneys (venting 250–300 °C fluids) from the Kremlin area on the TAG active hydrothermal mound at 26°N on the Mid-Atlantic Ridge (Courtesy of Woods Hole Oceanographic Institution; Peter Rona chief scientist); *right image* is a photograph of a slab taken perpendicular to the axis of one of the Kremlin chimneys, composed dominantly of zinc-sulfide – note the absence of large conduits and prevalence of very narrow channelways (courtesy of Woods Hole Oceanographic Institution).

and white smoker chimneys) exteriors (up to 70 °C; Fouquet et al., 1993; Koski et al., 1994). They form from less focused high-temperature fluids that exhibit slower flow rates than those from black smokers; as in white smoker chimneys, some flow is diverted and occurs through sides of these smokers (Fouquet et al., 1993; Koski et al., 1994). Within some vent fields, hot fluids are trapped beneath overhanging ledges, termed flanges; fluids percolate up through the porous flange layers or flow horizontally and "waterfall" upwards over the lip of the flange (Delaney et al., 1992).

Carbonate-rich chimneys

Very different types of chimneys are found at the Lost City vent field, located 15 km from the axis of the Mid-Atlantic Ridge. The Lost City hydrothermal system is hosted in mantle rocks (peridotite and serpentinite – see "Peridotites"), and the venting fluids have a higher pH than seawater, low metal and sulfide concentrations, and low temperature (<100 °C) relative to black smoker and white smoker fluids (Kelley et al., 2005); the very tall spires being deposited from these fluids are composed of calcium carbonate and magnesium hydroxide minerals (calcite and/or aragonite ($CaCO_3$) and brucite ($MgOH_2$)) that are saturated in the high pH, carbonate- and hydroxide-rich fluids.

Summary and conclusions

The morphologies of actively venting seafloor hydrothermal deposits and the composition and appearance of their hydrothermal plumes reflect the compositions of the fluids (hydrothermal fluid and seawater) from which they form, and the styles of flow and mixing of these fluids. "Black smoker" chimneys with conduit diameters of $<2–10$ cm form from very high-temperature ($>330–400$ °C) fluids

that flow at rates of meters per second, and the turbulent mixing that results when this fluid exits into seawater results in the formation of particle-laden plumes reminiscent of black smoke. "White smoker" chimneys form from lower-temperature (~200–330 °C) vent fluids that flow less vigorously through anastomosing narrow conduits that can become blocked resulting in diversion of flow; a greater percentage of metals are trapped and deposited within these chimneys than within black smokers, and they tend to be richer in zinc because of the lower temperatures that result in saturation and precipitation of zinc-sulfide minerals.

Over time, collapse and incorporation of these different types of chimneys and flanges onto and into mounds, and subsequent reworking of this material as hot fluids flow through the mounds, forms larger deposits. These larger deposits (see "Volcanogenic Massive Sulfides" and "Marine Mineral Resources") found along the mid-ocean ridges and along the spreading centers within back-arc basins are analogs for some types of ore deposits found on land (e.g., Cyprus-type massive sulfide ore deposits; Francheteau et al., 1979).

BOTTOM SIMULATING SEISMIC REFLECTORS (BSR)

Jürgen Mienert and Stefan Bünz
Centre for Arctic Gas Hydrate, Environment and
Climate (CAGE), UiT The Arctic University of Norway,
Tromsø, Norway

Definition

A seismic reflection occurring in the upper few hundred meters of marine sediments mimicking the seafloor, cross-cutting sediment layers, and showing a phase reversal is known as a "bottom-simulating reflector." Such a gas hydrate-related BSR originates from a large impedance contrast between a layer of gas-hydrated sediment above and a free gas layer below. A diagenetic-related BSR occurs at the opal-A/opal-CT transition zone, lies often deep and outside the base of the gas hydrate stability zone, shows no phase reversal, and does not always mimic the seafloor.

Introduction

The intent of this article is to describe the two most commonly observed bottom-simulating reflectors (BSRs). The term BSR stems from their principal characteristic that these reflectors mimic the seafloor topography in marine seismic reflection data thereby crosscutting sedimentary strata. BSRs are known to occur in continental margin sediments in regions of gas hydrate and free gas (Shipley et al., 1979) and/or in siliceous ooze (diatoms, radiolaria, silica sponges, silicoflagellates) bearing sedimentary formations (Hein et al., 1978). The largest silica contribution comes from diatoms (Holland and Turekian, 2003), while the largest methane contribution derives from methane-producing Archaea in sub-seafloor sediments (e.g., Kotelnikova, 2002).
Bottom Simulating Seismic Reflectors (BSR), Figure 1 Reflection seismic profile from the mid-Norwegian margin siliceous sedimentary formation showing an example of an opal-A/opal-CT BSR. The BSR and amplitudes are offset by polygonal faults. The origin of BSR 2 is speculative and may be related to transformation from smectite to illite at higher temperatures (Figure is from Berndt et al., 2004, Figure 4).

Diagenesis-related BSR

Siliceous ooze occurs in a wide range of sedimentary basins indicating times of higher ocean productivity, for example, along equatorial, polar, or coastal upwelling regions (Holland and Turekian, 2003). With increasing burial depth, the temperature and pressure increases, resulting in the dissolution of the siliceous skeletons. The dissolution process causes a collapse of the siliceous framework and a geochemical reaction that converts amorphous opal-A into opal-CT (e.g., Hesse, 1989; Knauth, 1994). Deep-sea drilling project studies allowed documenting the chemical, mineralogical, and structural changes occurring during this process with increasing depth (e.g., Hurd and Birdwhistell, 1983). As a consequence of the skeleton dissolution, an interface develops where the opal-CT formation causes an increase in density and compressional-wave velocity and a decrease in porosity and permeability (e.g., Tribble et al., 1992). If the seismic impedance contrast between opal-A (lower density and velocity and higher porosity and permeability) and opal-CT becomes large enough, a seismic reflector with a positive polarity occurs (Figure 1) (Berndt et al., 2004). It is believed that the temperature increase with burial depth is the main parameter controlling the opal-A/opal-CT transition aside from the time since burial, type of surrounding sediment material, and interstitial waters (e.g., Hein et al., 1978). The opal-A/opal-CT diagenesis causes a volume reduction of as much as 30–40 %

(Davies and Cartwright, 2002). Since large areas of siliceous ooze exist in sedimentary formations, a diagenetic BSR (Figure 1) often shows a very large lateral extent, which is uncommon for gas hydrate-/free gas-related BSRs. Moreover, diagenetic BSRs are believed to develop at greater depth below the seafloor, at temperatures (35–50 °C) where hydrate is normally no longer stable (Berndt et al., 2004).

Opal-A/opal-CT BSRs have been reported from many areas containing siliceous sediments such as from the mid-Norwegian margin (e.g., Brekke, 2000; Berndt et al., 2004) (Figure 1). Often, polygonal faults occur in conjunction with diagenetic BSRs as they preferably form in similar types of sediments (Figure 1) (Cartwright and Dewhurst, 1998; Davies and Cartwright, 2002). Polygonal faults show an interruption and vertical offset of continuous reflections leading to short reflection segments. The BSR may be difficult to identify if it runs parallel to the strata, because normally it also does not show a reduced instantaneous frequency (Berndt et al., 2004). The BSR has a strong amplitude, has an apparent polarity that is positive, lies deeper than a gas hydrate-related BSR, and is often interrupted by polygonal faults.

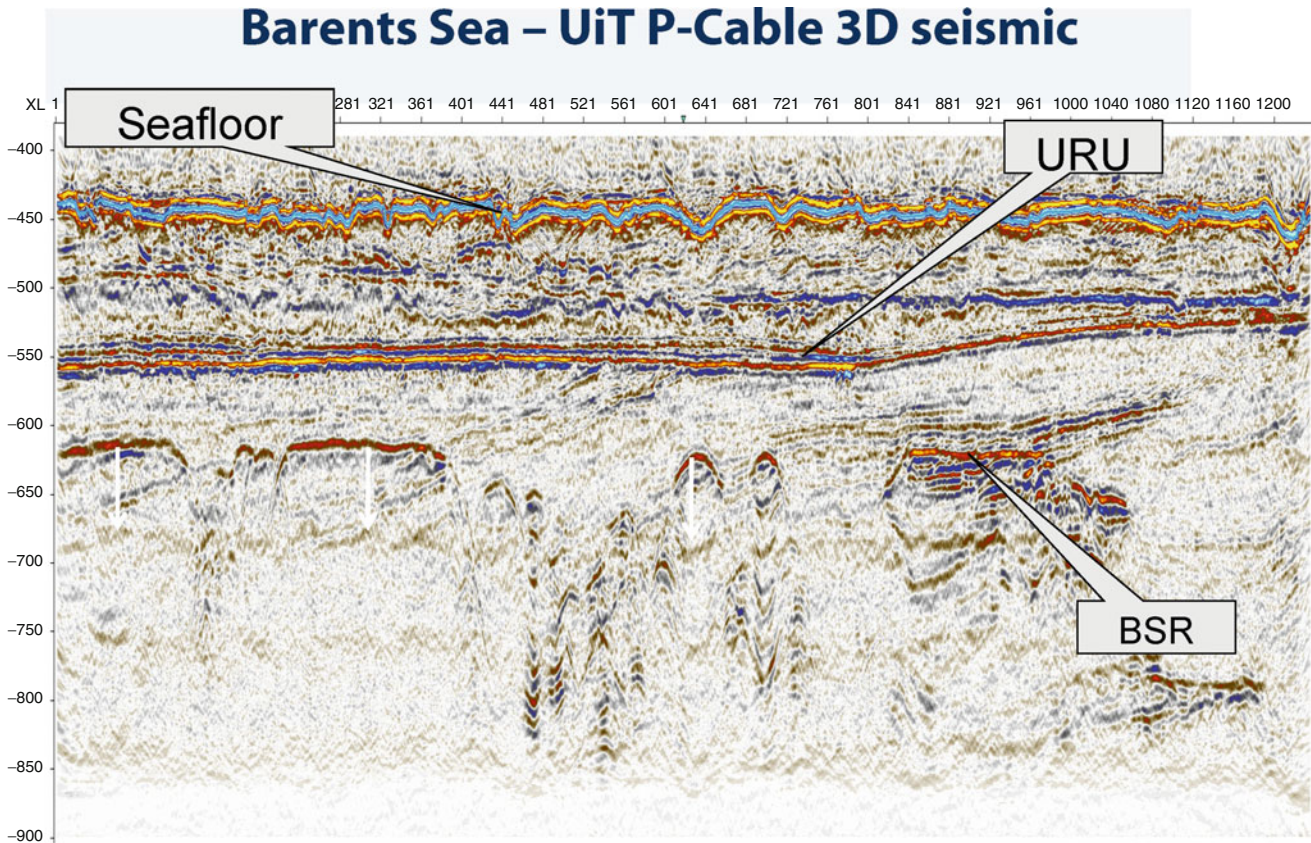
Gas hydrate-related BSR

Gas hydrates occur as an icelike substance composed of water molecules forming a rigid lattice of cages that trap a guest molecule (Sloan, 2003). The predominant guest
Bottom Simulating Seismic Reflectors (BSR), Figure 2 Reflection seismic profile of a hydrate/free gas BSR that follows the sub-bottom depths and coincides with the predicted depth of the base of the gas hydrate stability zone (schematic diagram, *right*). The gas hydrate stability zone is shown as a function of water temperature, pressure, and geothermal gradient.

molecule in the submarine environment is methane, but also hydrates containing high-order hydrocarbons, carbon dioxide, hydrogen sulfide, or other gas may exist. Gas hydrates occur naturally in the pore space of different types of marine sediments, where appropriate high-pressure and low-temperature conditions exist and there is an adequate supply of gas and water (Figure 2) (Kvenvolden, 1993; Rempel and Buffett, 1997; Sloan, 2003). Those requirements confine marine gas hydrates to the upper few hundred meters of the shallow geosphere of continental margins, where biogenic processes produce sufficient amounts of methane gas. The gas hydrate-related BSR detected on marine seismic reflection data commonly corresponds to the base of the gas hydrate stability zone (GHSZ, Figure 2). It is the result of an acoustic impedance contrast between hydrate-bearing sediments (increase in compressional-wave velocity) and free gas trapped in the sediments underneath (decrease in velocity) gas hydrates (Hyndman and Spence, 1992; Bünz et al., 2003). As a consequence, the hydrate-related BSR has reversed polarity (compared to the seafloor reflection) and is often accompanied by high-reflection amplitudes. The gassy sediments beneath the hydrate-bearing sediments also show on the instantaneous frequency attribute as the free gas predominantly attenuates the high-

frequency content of the seismic signal (Berndt et al., 2004).

The BSR shows not always as a reflection proper because gas beneath the hydrated sediments accumulates only in places where rock properties of the host rock have high enough permeability. The seismic reflection shows higher amplitudes preferentially in areas where appreciable amounts of gas accumulate beneath the GHSZ (Figs. 3 and 4). Thus, whether the BSR is a true reflection in its own right on the seismic data is mainly the result of the frequency bandwidth of the acquisition system (Wood et al., 2002). High-frequency seismic acquisition systems often image gas accumulations along layers. The BSR is then identified as the envelope of amplitude increases that crosscuts stratigraphic boundaries (Figs. 2, 3, and 4). The BSR generally lies shallower than a diagenetic BSR, has a smaller areal extent, and might often show in patches over a larger area.

Assumptions on the possible presence of gas hydrate-/free gas-related BSRs along continental margins are based largely on modeling the GHSZ (Figure 2) (Dickens and Quinby-Hunt, 1997; Zatsepina and Buffett, 1998). The modeling and thus the theoretical potential for the existence of a BSR are mainly based on water depth (pressure), seafloor temperature, and the geothermal


Bottom Simulating Seismic Reflectors (BSR), Figure 3 High-resolution 3D P-Cable seismic data showing higher amplitudes beneath the upper regional unconformity (*URU*) in the SW-Barents Sea. This high-amplitude reflection crosscuts sedimentary reflections with reversed polarity and is interpreted as BSR at the base of the GHSZ.
Bottom Simulating Seismic Reflectors (BSR), Figure 4 High-resolution 3D P-Cable seismic data showing higher amplitudes preferentially in areas where appreciable amounts of gas accumulate beneath the GHSZ.

gradient (Figure 2). As these parameters are largely controlled by water depth from the shelf to the deep sea, the methane hydrate BSR shows two pinch-out zones, one at the shallow water depth where pressure becomes too low for hydrates to be stable and one toward the mid-ocean ridge where heat flow becomes too high. Thus, if one describes these two end members, one may still use the terminology BSR but should be clear that the BSR does not parallel the seafloor.

Seismic character of BSRs

BSRs related to hydrate/free gas phase transitions can be distinguished from opal-A/opal-CT phase transitions based on their phase polarity. While diagenetic BSRs have the same positive phase as the seafloor reflection (Figure 1), the hydrate/free gas BSRs show a phase reversal (Figure 2). This reversed polarity is due to the negative impedance contrast between hydrated sediments above (higher density and velocity) and gas-saturated sediments below (Hyndman and Spence, 1992). However, caution is necessary if the phase of the BSR is the only criterion used. Gas trapped beneath a diagenetic BSR may also result in a phase reversal. As a consequence one should use several criteria such as instantaneous frequency, phase reversal, and GHSZ modeling to predict the BSR depth. Frequencies are useful as additional criteria for gas hydrate BSRs. A shift from higher frequencies in the gas

hydrate zone to lower frequencies in the free gas zone (Berndt et al., 2004) beneath the BSR may be used.

Dynamics of BSRs

Both the diagenetic- and the hydrate-related BSR may be used to evaluate the thermal state or reconstruct the thermal development of a sedimentary basin (Grevemeyer and Villinger, 2001; Nouzé et al., 2009). Particularly, the hydrate-related BSR is widely used as a proxy for heat flow in marine sediments. On a small scale, BSR-derived heat flow changes may often be associated with structures that focus warm fluids from deep sediments like mud volcanoes (Depreiter et al., 2005) or chimneys (Rajan et al., 2013). In such instance, the BSR may not mimic the seafloor if lateral variations in heat flow or changes in gas compositions exist. Generally, an increase in heat flow causes a shoaling of a BSR, whereas an increase of higher-order hydrocarbons causes a deepening. Hence, the depth of the BSR may vary greatly as, for example, in the Barents Sea depending on the contribution and thus the amount of thermogenic gases migrating into the GHSZ (Chand et al., 2008; Rajan et al., 2013).

More recently, BSR observations and hydrate stability zone modeling of the upper pinch-out zone on continental margins have been used to assess past and contemporary changes in hydrate stability through warming of ocean bottom water (Vogt and Jung, 2002; Mienert et al., 2005; Biastoch et al., 2011; Ferré et al., 2012; Phrampus and Hornbach, 2012).

Inferred former positions of a BSR are often referred to as paleo-BSR. One of the best examples for a paleo-BSR can be found on the Blake Ridge, approx. 450 km offshore Georgia on the East Coast of the United States (Hornbach et al., 2003). This BSR formed when erosion by strong contour currents on the eastern flank of the Blake Ridge removed the top sediments of a hydrated formation causing an adjustment of the hydrate/free gas boundary by moving it deeper. The free gas layer beneath the former BSR crystallized into a newly formed concentrated layer of hydrates causing both a density and velocity increase. Beneath this paleo-BSR, the new BSR formed with free gas underneath the base of the gas hydrate stability zone (BGHSZ). Though the timing of the readjustment is unknown, it presents one good example for the dynamic behavior (in this case deepening) of a BSR due to erosion of sediments and a drop in seafloor temperature.

Summary and conclusions

Bottom-simulating reflectors (BSRs) occur in a wide range of sediments in the world oceans. Such creation of BSRs involves the existence of free gas and water in the pore space of sediments under low temperature and high pressure, forming hydrates beneath the ocean floor. The depth of the BSR defines the base of the gas hydrate stability zone (BGHSZ) under which free gas accumulates. Free gas becomes trapped beneath the hydrate-charged layer causing a distinct impedance contrast and a seismic

reflection of reversed (negative) polarity if compared to the seafloor. The GHSZ depends on temperature and pressure and to a lesser degree on salinity and gas composition (thermogenic, biogenic). The thickness of the GHSZ decreases toward the upper continental margins (lower pressure) and sedimented ocean ridges (higher temperature). The second type of BSRs concentrates in regions of siliceous ocean sediments. Here, increases in temperature with burial depth result in dissolution of siliceous skeletons, which in turn creates an interface with higher porosity and permeability above and lower values beneath the interface. If the contrast becomes large enough, a seismic reflector occurs but with positive polarity (no phase reversal). As a consequence, diagenetic BSRs occur commonly deeper, show no phase reversal, and exist over large areas at the opal-A/opal-CT interface in ocean sediments.

BOTTOM-BOUNDARY LAYER

Wenyan Zhang
MARUM-Center for Marine Environmental Sciences,
University of Bremen, Bremen, Germany

Definition

In marine geosciences, the bottom boundary layer (BBL) refers to a layer of flow in the immediate vicinity of the solid sea bottom where the effects of viscosity are significant in determining the characteristics of the flow. The BBL was first discovered by Prandtl (1905) in aerodynamics and subsequently applied to other fluids moving on the surface of a solid body.

Starting upwards from the sea bed, the total thickness of the BBL is defined as the distance above the bottom at which the mean flow velocity equals to 0.99 U_∞, where U_∞ is the free-stream velocity of a layer that is in a geostrophic balance overlying the BBL. On top of the geostrophically balanced layer is a surface layer subjected to wind-wave mixing. When both the bottom micro-topography is uniform and the overlying flow is steady, the BBL can be easily quantified from the vertical flow structure. Various ways exist to estimate the thickness δ of the BBL under neutral conditions (e.g., Grant and Madsen, 1986; Nielsen, 1992). In general, the BBL thickness at continental margins is at the order of 5–50 m.

Theoretically the BBL can be classified into three different sub-layers:

(1) A thin inner layer just above the bottom where turbulence is inhibited by the presence of the solid boundary. The flow is controlled by molecular viscosity and the shear stress is consistent with the bottom shear stress.
(2) An outer layer where turbulence shear dominates and viscous shear can be neglected.
(3) A transitional layer where both the viscous shear and the turbulence shear are important.

As the shear stress is almost constant and fulfills Newton's law of viscosity in the inner layer, flow velocity can thus be approximated by a linear form. However, this only applies to a hydraulically smooth bottom where bed roughness is too small to affect the velocity distribution. In hydraulically rough bottom, bed roughness is large enough to produce eddies close to the bottom and the inner layer may not be detectable. Upwards from the inner layer, the importance of molecular viscous decreases and turbulence gradually dominates the flow. Mean flow velocity in this transitional layer obeys the law of the wall and can be

approximated by a logarithmic function. The outer turbulent layer takes up a majority (80–90 %) of the BBL. Flow characteristics of this layer mainly depend on the velocity difference with the external free flow (i.e., velocity defect) and the overall scale of the boundary layer.

Wind waves affect the BBL by imposing a wave boundary layer wherever the water depth is less than half of the wave length. The wave-induced oscillatory water motion is affected by the sea bottom within the wave boundary layer.

However, in a natural continental shelf, any definition of the BBL structure is not straightforward due to the influences of many factors (e.g., density stratification, internal waves, seabed topography). A practical indicator for the BBL is a thermohaline pycnocline observed in the water column (e.g., Stips et al., 1998; Perlin et al., 2005). Just above the sea bottom, there is a homogenous layer of temperature, salinity, and density, which indicates the inner layer and the transitional layer.

BOUMA SEQUENCE

Thierry Mulder[1] and Heiko Hüneke[2]
[1]University of Bordeaux, Talence, France
[2]Institute of Geography and Geology, Ernst Moritz Arndt University, Greifswald, Germany

The Bouma sequence (named after Arnold H. Bouma, 1932–2011) is a characteristic set of sedimentary structures typically preserved within positively graded sand or silt-mud couplets. From base to top, Bouma (1962) differentiated the following intervals above an erosion surface or sharp boundary: (Ta) massive to graded sand, (Tb) plane-parallel laminated sand, (Tc) cross-laminated sand and silt, (Td) parallel-laminated sand to silt, and (Te) laminated to homogeneous mud (Figure 1). Because of nonuniform grain size distribution and flow transformations (Fisher, 1983), the complete sequence is rare. Turbidite beds represent the typical deposit of low-concentration turbidity flows and related non-cohesive density flows.

The Bouma sequence is the first model of sediment-laden gravity flows and represents the first predictive model in sedimentology. It is a facies model of combined suspension fallout and traction deposition by a bipartite density flow (see Mulder, 2011, for details). The successive divisions with typical sedimentary structures display a bottom-to-top decline in energy consistent with the grading.

The basal surface of many turbidites, i.e., the lower bounding surface of Ta, commonly displays erosional features produced by turbulent scouring (Lanteaume et al., 1967).

Turbidity flows commonly develop from stratified density flows with a strong vertical velocity gradient. Within such bipartite flows (basal laminar flow and a top turbulent flow), the high particle concentration of its basal parts hinders suspension fallout (Mulder, 2011). Consequently, a poorly graded Ta division can be interpreted as being deposited from a concentrated-flow basal part. Rapid deposition and resulting unstable initial grain packing are also indicated by the common occurrence of water-escape structures such as dish or pillar structures or dewatering pipes.

The Bouma divisions Tb to Te record the passage of the flow body with a fully turbulent regime and reflect flow deceleration (Walker, 1965). The parallel lamination (Tb division) results from plane-bed transport of sand in the upper flow regime. The ripple cross-lamination (Tc division) reflects settling of sand and silt from suspension while lower-flow-regime current ripples migrate on the seabed. Climbing-ripple cross-lamination and convolute lamination would indicate rapid fallout and short-lived liquefaction, respectively. The Tc division is the most common structure in turbidite beds because ripples are the easiest structures to form for a given grain size and velocity/flow energy.

The uppermost divisions (Td and Te) are mainly products of settling from suspension. The pelitic top (Te division) represents the interaction of ongoing pelagic production with the fine terrigenous particle fallout from the turbulent tail of the flow.

Bouma Sequence, Figure 1 Well-developed Bouma sequence (divisions Ta to Te from base to top) in a turbidite bed of the Carboniferous Crackington Formation at the sea cliff near Crackington Haven, Cornwall, England.

CALCITE COMPENSATION DEPTH (CCD)

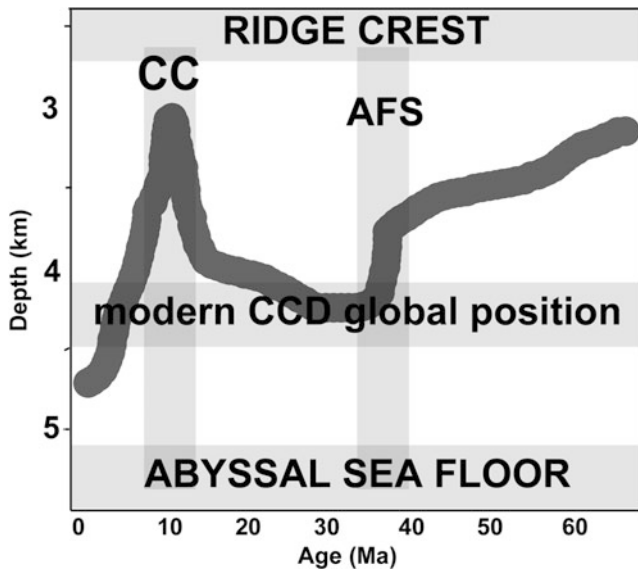
Wolfgang H. Berger
Scripps Institution of Oceanography UCSD, La Jolla,
CA, USA

The carbonate compensation depth (CCD) is the dominant facies boundary on the deep-sea floor. It separates calcareous from noncalcareous sediments, with the calcareous deposits ("carbonate ooze") restricted roughly to the shallower half of the deep-sea floor. The link of the ooze boundary to elevation and the fact that deep-sea calcareous sediments are light gray in color, albeit with a buff tint (Figure 1), have invited comparison to the snow line on land. The ooze consists of calcareous skeletal parts and shells of coccolithophorids and foraminifers (or "nannofossils" and foraminifers). Discoasters (symmetrical ray-bearing nannofossils, Figure 1) are extinct.
Calcite Compensation Depth (CCD), Figure 1 View of calcareous ooze from Ontong Java Plateau, western equatorial Pacific, in a partially opened box core. Contents of calcareous ooze (nannofossils, planktonic foraminifers) to the right (Sources: SIO (box core photo, coccosphere, foraminifers) and Bukry and Bramlette (1969), Leg 1 of DSDP (nannofossils. The discoasters are extinct)).
H.M.S. Challenger.

Calcite Compensation Depth (CCD), Figure 2 The general distribution pattern of deep-sea sediments was first explored by the British Challenger Expedition (1872–1876). Based on samples from that expedition, John Murray postulated elevation-linked facies boundaries between *pteropod ooze* and *globigerina ooze* and between *globigerina ooze* and *red clay*. The latter boundary is now known as the "carbonate compensation depth" or "CCD".

Like snowflakes on land, the skeletal parts and empty shells (produced in surface waters) fall to the seafloor, where they either pile up (at the shallower depths) or dissolve (close to and below the CCD). The CCD was discovered and first described by the naturalist John Murray of the Challenger Expedition (Figure 2).

Several important questions arose in the middle of the twentieth century, with respect to the nature of the CCD (e.g., Bramlette, 1961). The central one concerned the pattern of dissolution: did it start above the CCD, or did it set in, abruptly, at the facies boundary (denoting a change from saturation to undersaturation there)? The answer was provided by Peterson's experiment (Peterson, 1966) and by extensive studies of deep-sea sediments (e.g.,

Berger, 1970a; van Andel et al., 1975; Peterson and Prell, 1985). Dissolution starts well above the CCD; that is, the CCD marks the level where the rate of input of calcareous sediment is balanced by the rate of dissolution. Other questions concerned the position of the CCD, which differs between the Atlantic and Pacific. What processes set the typical depth, why is it regionally different, and why does it change through geologic time? The global mean presumably is a result of a need for balance between total availability of carbonate for deposition and the rate of production by planktonic organisms (the latter being controlled by availability of nutrients, rather than by that of carbonate). Deep circulation greatly affects deviations of the local CCD position from the global mean


Calcite Compensation Depth (CCD), Figure 3 Schematic representation of CCD fluctuations in the South Atlantic (Simplified from Hsü and Wright (1985) and van Andel et al. (1977)). Marine Microfossils
Paleoceanography

(Berger, 1970b). Changes through time (Figure 3) depend on a number of factors, including changes in production of sediment, in rates of dissolution, in deep circulation, and in the sizes of reservoirs containing carbonate and organic carbon. The two most striking CCD events in the Cenozoic (the last 65 million years) are the abrupt appearance of deep-sea carbonate in the earliest Oligocene (the great facies shift at the end of the Eocene) and the "carbonate crash" at the end of the middle Miocene, with the event in the Caribbean leading that of the eastern Pacific by a million years or so. Neither event is fully understood, although there are many propositions regarding possible causes (for review, see Preiss-Daimler, 2011).

CARBON ISOTOPES

Thomas Wagner[1] and Jens O. Herrle[2]
[1]School of Civil Engineering and Geosciences, Newcastle University, Newcastle upon Tyne, UK
[2]Institute of Geosciences, Goethe University Frankfurt, Frankfurt, Germany

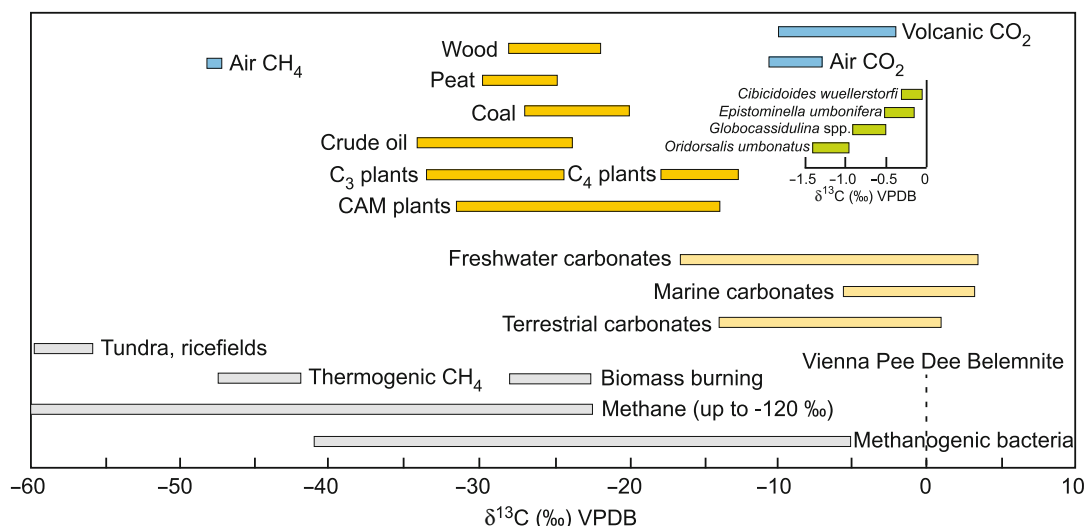
Synonyms

$^{13}C/^{12}C$ isotopes; Carbon isotope stratigraphy; Stable carbon isotopes

Definition

The carbon isotopes with masses ^{12}C and ^{13}C comprise 98.89 % and 1.11 % of the stable carbon on Earth, respectively (Craig, 1953). Because of the low abundances of the rare ^{13}C stable carbon isotope, measurements are expressed as ratios to the more common ^{12}C in a sample ($^{13}C/^{12}C$) and reported in the $\delta^{13}C$ notation relative to the Vienna Pee Dee Belemnite (VPDB) standard in per mil (Coplen, 1996).

Introduction and main applications

The stable carbon isotopes measured on the carbonate and organic carbon fractions in sediments or carbonate tests from planktic and benthic organisms and molecular compounds (biomarkers) isolated from them are classical


Carbon Isotopes, Figure 1 Variations in stable carbon isotope ratios for different organic and inorganic sources in the modern environment and in sediments (modified from Wefer and Berger (1991), Schidlowski and Aharon (1992)).

proxies in marine sciences. The main applications of carbon isotopes in marine and climate sciences are broad including reconstructions of the global carbon cycle in relation to carbon sources and burial, chemostratigraphy, tracing of water masses, and surface water productivity in the modern and past ocean.

Carbon sources

Stable carbon isotopes are widely used geochemical proxy tools to reconstruct changes in the global carbon cycle. Two main carbon reservoirs exist, the reduced biogenic organic carbon reservoir (organic matter) and the oxidized carbonate reservoir, covering a wide range of stable carbon isotopic signatures from below $-100‰$ to around $5‰$, depending on the source of the carbon (Figure 1). Differences in the organic carbon isotopic composition ($\delta^{13}C_{org}$), both at the bulk and the molecular level, are controlled by fractionation during photosynthesis in the marine and the terrestrial biosphere (e.g., Degens et al., 1968). The most negative (light) carbon isotope values are related to microbiologically produced methane (CH_4) measured in, e.g., gas-hydrate-bearing sediments along continental slopes and related carbonate bioherms, marine seep systems, and Arctic permafrost (e.g., Saltzman and Thomas, 2012; Wendler, 2013; and references therein). The organic carbon from terrestrial C3 plants, the most common type of vegetation on Earth, is isotopically less negative with mean $\delta^{13}C_{org}$ values of about $-27‰$. Corresponding $\delta^{13}C_{org}$ values for marine algae scatter around $-21‰$. Terrestrial vegetation from arid climate zones utilizing the C4 and CAM photosynthetic pathway, mainly Savannah grasslands, has mean $\delta^{13}C_{org}$ values of about $-12‰$. The most positive values are from inorganic carbonate precipitates ($\delta^{13}C_{carb}$), which range from about $0‰$ to $5‰$ (e.g., Hoefs, 2009).

Carbon isotopes in shallow seawater

The average dissolved inorganic carbon (DIC) $\delta^{13}C$ of seawater ($\delta^{13}C_{DIC}$) is dynamically coupled to the global carbon cycle via the partitioning of the main carbon reservoirs between the ocean, atmosphere, and terrestrial biosphere. $\delta^{13}C_{DIC}$ is not uniform in the modern ocean nor constant over time (e.g., Sundquist and Visser, 2004). The global seawater $\delta^{13}C_{DIC}$ composition is mainly controlled by two processes: photosynthesis and microbial decay of algal organic matter and physical fractionation during gas exchanges at the air to sea interface (Broecker and Maier-Reimer, 1992). Marine surface water is generally enriched in ^{13}C, because photosynthesis of marine phytoplankton favors the light ^{12}C over the heavy ^{13}C, leading to more negative $\delta^{13}C$ of organic matter ($\delta^{13}C_{org}$) relative to ambient seawater $\delta^{13}C_{DIC}$ (Garlick, 1974). This process is limited by the availability of nutrients, in particular nitrate and phosphate (Broecker and Peng, 1982).

Most marine organisms exhibit $\delta^{13}C$ values in their carbonate shells, which were formed not in full equilibrium relative to ambient seawater (Figure 1). The reason for this is manifold, but metabolic effects, including photosynthetic activity of algal symbionts, growth rate, and carbonate ion concentrations, are critical (McConnaughy, 1989; Rohling and Cook, 1999). These effects, together with species-specific differences, are summarized as "vital effects" (e.g., Wefer and Berger, 1991).

Modern sea surface water $\delta^{13}C_{DIC}$ varies between $+0.7‰$ in the northern Pacific and $+2.5‰$ in the midlatitude Atlantic (Kroopnick, 1985). Remineralization of organic matter and nutrients within thermocline subsurface water recycles isotopically light ^{12}C. Due to upwelling and wind mixing of shallow waters, this light ^{12}C and nutrient-rich subsurface water can be remobilized back into the surface waters, thereby stimulating primary productivity and influencing the carbon isotopic composition of calcareous shells (e.g., Broecker and Peng, 1982).

Tracing of seawater masses, surface water productivity, and ecology

The $\delta^{13}C_{DIC}$ in water is widely used as a tracer for seawater masses (e.g., Ravelo and Hillarie-Marcel, 2007). Although changes in surface water productivity and mixing influence $\delta^{13}C_{DIC}$, other processes, including water mass formation and ocean circulation, determine the $\delta^{13}C_{DIC}$ composition and therefore can be used as tracers for water masses. Deep water captures the $\delta^{13}C$ signature from its surface water sources. North Atlantic Deep Water (NADW) has therefore relatively high $\delta^{13}C$ values (~1.11‰), whereas Antarctic Bottom Water (ABW) is relatively low (~0.4‰), reflecting the major differences in surface water $\delta^{13}C_{DIC}$ in both high-latitude source regions (Kroopnick, 1985). Variations in deep water $\delta^{13}C$ can therefore be used to trace the history of deep water currents. This approach is also referred to as "aging" of deep water (Rohling and Cook, 1999), where the relative age of deep water provides a measure for ocean circulation.

The $\delta^{13}C$ difference between shallow and deep-dwelling planktic foraminifera ($\Delta\delta^{13}C$) provides a well-established proxy for thermocline productivity and the depth of the shallow-water mixed layer (e.g., Wefer et al., 1999). Increasing $\Delta\delta^{13}C$ values reflect more stratified surface water masses, due to increasing contrasts between shallow and deep waters and vice versa. A comparable approach is used to reconstruct productivity via changes in benthic foraminifera $\Delta\delta^{13}C$ of epifaunal and infaunal species (Zahn et al., 1986). Here, the $\delta^{13}C$ differences are mainly controlled by pore water geochemical gradients and the intensity of organic matter degradation, the latter being a function of organic matter supply (flux) to the sea floor (McCorkle et al., 1990). Large $\Delta\delta^{13}C$ values represent less organic matter flux and thus less primary productivity and vice versa. Benthic foraminifera $\Delta\delta^{13}C$ gradients can, however, be biased by the variability in new production of organic matter (fresh phytodetritus), which influences the stable isotope signal. This effect, constrained by variable primary productivity and organic matter fluxes at seasonal time scales, is referred to as the "phytodetritus" or "Mackensen effect" (Mackensen et al., 1993). Furthermore, the carbon and oxygen isotopic composition of calcite tests of planktic foraminifera is used for reconstructing depth habitats and thus the ecology of extant and extinct species (e.g., Pearson et al., 1993).

Chemostratigraphy and carbon isotope excursions (CIE)

The history of the global carbon cycle and climate through time is preserved in the carbon isotope record of marine and terrestrial sediments (Figure 2). The application of organic and inorganic carbon isotope ratios as chemical fingerprints for stratigraphic correlations was pioneered in the late 1970s with the studies of Berger et al. (1978), Weissert et al. (1979), and Scholle and Arthur (1980),

more recently summarized in Weissert et al. (2008), Saltzman and Thomas (2012), and Wendler (2013). The most robust Phanerozoic archives of marine carbon isotope signatures are from individual pristine preserved fossils and bulk carbonate from marine pelagic sediments (e.g., Joachimski and Buggisch, 1993; Veizer et al., 1999; Saltzman and Thomas, 2012; and references therein). Carbon isotope fluctuations of several per mil are also reported from hemipelagic sediments, shallow-water carbonates, and terrestrial sediments. Due to multiple local influences, however, they may differ in their absolute isotope values and ranges from their corresponding pelagic sediment records, complicating their use in stratigraphic correlation across wider areas.

The long-term trend in Earth's climate is interrupted by series of transient events, identified by distinct positive or negative carbon isotope excursions, CIEs (Figure 2). These CIEs, combined with longer trends in the global carbon isotope record, are used in chemostratigraphy to identify chemical events (e.g., Weissert et al., 1998; Zachos et al., 2001), which can be correlated within and across ocean basins and the terrestrial environment (e.g., Gröcke et al., 1999; Herrle et al., 2004). Well-documented examples of CIEs representing major perturbations of the global carbon cycle are reported from, e.g., the Paleogene-Mesozoic greenhouse (Paleocene-Eocene thermal maximum PETM, Cretaceous and Early Jurassic oceanic anoxic events, OAEs, Jenkyns, 2003) and the Paleozoic (Saltzman and Thomas, 2012; Figure 2). Many CIEs coincide with widespread environmental perturbations including severe and short-term global warming (hyperthermal events), ocean acidification and shoaling of the carbonate compensation depth (CCD), enhanced marine organic carbon burial linked to widespread ocean anoxia, major crisis or extinction of biota on land and in the ocean, and sudden shifts in Earth's hydrological cycle and climate. Understanding how the Earth system responded to and recovered from these past extreme events remains a major focal point of Earth sciences, adding to the discussion on anthropogenically induced global warming.

The magnitude and rapidity of CIEs in the Phanerozoic, combined with evidence for massive environmental change, have stimulated intense interdisciplinary research about the underlying trigger and feedback mechanisms. Positive CIEs are reported for multimillion to orbital time-scales and are, among other possible mechanisms (Figure 2), commonly associated with periods of globally enhanced marine carbon burial, leading to the concept of oceanic anoxic events (Schlanger and Jenkyns, 1976; Scholle and Arthur, 1980) and global cooling (e.g., Kuypers et al., 1999). Recent studies, combining geochemical with biotic data and biogeochemical modeling, have shown that global cooling can cause perturbations to marine ecosystems and biogeochemical cycles at scales comparable to those associated with global warming (McAnena et al., 2013). Sharp negative CIEs, either isolated within the chemostratigraphic record or in combination with positive CIEs, have been recorded throughout
Carbon Isotopes, Figure 2 Phanerozoic carbon isotope record and selected global events (*CIEs*) based on Gradstein et al. (2012) and references therein, Caplan and Bustin (1999), Munnecke et al. (2003), Wagner et al. (2007), Korte and Kozur (2010) and McAnena et al. (2013). *PETM* Paleocene-Eocene thermal maximum, *OAE* oceanic anoxic events, *LACS* late Aptian cold snap, *TJB* Triassic-Jurassic boundary, *PT* Perm-Trias event, *HB* Hangenberg event, *LAU* Lau event, *HICE* Hirnantian event, *TOCE* Top of Cambrian Excursion, *SPICE* Steptoean event, *MICE* Mingxinsi event, *AECE* Archaeocyathids event, *SHICE* Shiyantou event, *ZHUCE* Zhujiaqing event.

the Phanerozoic sedimentary record (e.g., Saltzman and Thomas, 2012) and have become a focal point for Earth system research. Negative CIEs have been related to a large number of mechanisms (Figure 2), including rapid dissociation of metastable marine methane hydrate, buildup and release of isotopically "light" carbon in stratified epicontinental seas, thermogenic release of methane related to the placement of volcanic dykes into coal-bearing strata or thermal maturation of other organic-rich sediments, extensive biomass burning, mobilization of labile carbon pools from terrestrial permafrost, ventilation

of marine dissolved organic carbon, and others (for further information on mechanisms, see, e.g., Cohen et al., 2007; deConto et al., 2012).

Conclusions

Stable carbon isotopes are commonly used for a wide range of applications in marine sciences and climate research. Applications include reconstructions of the global carbon cycle including short-term perturbations, chemostratigraphy, and tracing of water masses and surface water productivity in the modern and past ocean.

The development of carbon isotopes at the bulk sediment, foraminifera shell, and compound-specific (molecular) level, especially when combined with complementary evidence on biota, nutrients, ocean chemistry and redox, and modeling, has opened new pathways to unravel the complex interplay between fluctuations of the main carbon pools between the atmosphere, the living biosphere, and carbon buried in the sediments and their interactions with and impact on global climate at multiple temporal and spatial scales.

CARBONATE DISSOLUTION

Leif G. Anderson
Department of Marine Sciences, University of Gothenburg, Gothenburg, Sweden

Definition

Calcium carbonate is a chemical compound with the formula $CaCO_3$. It is the main component of shells of marine organisms. Calcium carbonate can dissolve in seawater to form calcium and hydrogen carbonate ions.

$$CaCO_3 + CO_2 + H_2O \rightarrow Ca^{2+} + 2HCO_3^-$$
Several crystal structures of calcium carbonate are found in the marine environment. The most common crystal structures in the ocean are calcite and aragonite, but also ikaite occurs in cold-water environments.

The crystal structure determines how easy these crystals can dissolve, a property that is expressed as the solubility product, K_{sp},

$$K_{sp} = \left[Ca^{2+} \right] \times \left[HCO_3^{2-} \right]$$

where $[Ca^{2+}]$ and $\left[HCO_3^{2-} \right]$ equal the concentration of these properties in the surrounding media. The value of K_{sp} is dependent on temperature, salinity, and pressure. The temperature (T in K) and salinity (S) dependence of the stoichiometric solubility product was determined by Mucci (1983).

$$\log K_{sp} = (b_0 + b_1 T + b_2/T) \ S^{0.5} + c_0 S + d_0 S^{1.5}$$

The constants for calcite and aragonite are given in Table 1.

Few studies have been made to estimate the pressure effect on K_{sp}. The one most used is by Ingle (1975) who formulated the following expression for calcite based on high-pressure experiments:

$$
\log\left(K_{sp}^p / K_{sp}^1 \right) = \{ (48.8 - 0.53t)(z - 10)/10
$$
$$
+ \left(-5.88 \times 10^{-3} + 0.1845 \times 10^{-3}t \right)(z - 10)^2/100 \} /
$$
$$
188.93 \ (t + 273.15)
$$

where K_{sp}^p is the solubility product at the depth z (meters), K_{sp}^1 is the solubility product at the surface, and t is the in situ temperature in °C.

In order to express if a water is super- or undersaturated, the term saturation state is used, which is expressed as

$$\Omega = \left[Ca^{2+} \right] \times \left[HCO_3^{2-} \right] / K_{sp}$$

Consequently, a Ω value above 1 means that the water is supersaturated, and a value below 1 expresses undersaturation. In the global oceans, most surface waters are supersaturated with the highest degrees in the warm tropical areas. In the waters of the warm-water corals, Ω is typically above 3.

Calcite is the most stable calcium carbonate mineral, with the crystals being trigonal-rhombohedral. Aragonite is the next common mineral with its crystal being orthorhombic. Aragonite is thermodynamically unstable at standard temperature and pressure and tends to alter to calcite on scales of 10^7–10^8 years.

Both calcite and aragonite form naturally in many marine mollusk shells and as the calcareous endoskeleton of warm- and cold-water corals. Often, magnesium is incorporated in the crystal structure by taking the place of the calcium ion. Typically, this will increase the

solubility, i.e., the more percent magnesium a crystal contains, the more soluble it gets.

Ikaite is the mineral name for the hexahydrate of calcium carbonate, $CaCO_3 \cdot 6H_2O$. It is only found in a metastable state and decomposes rapidly once removed from near-freezing water (below 6 °C). It was first discovered in nature in the bottom of the Ikka Fjord in SW Greenland. Here, it is believed to be created when carbonate ion-rich groundwater seeps out and meets the seawater that is rich in calcium ions. During the last 10 years, its occurrence has been found in sea ice, first reported from the Weddell Sea (Dieckmann et al., 2008), and has been observed as grain sizes of hundreds of micrometers.

The solubility of calcite and aragonite is mainly determined by the carbonate ion concentration in the deep ocean as both the salinity and the calcium ion concentration are quite constant. The carbonate ion concentration is impacted by the formation of carbon dioxide through mineralization of sinking organic matter. This also means that the longer the water has been exposed to sinking

organic matter, the higher the carbon dioxide content gets, and the concentration of carbonate ions decreases.

$$CO_2 + H_2O + CO_3^{2-} \rightleftarrows 2HCO_3^-$$

One consequence of this is that the depth at which one finds the water at saturation, i.e., $\Omega = 1$, is deepest in the regions of deepwater formation and shallowest in the regions where the waters have not been in contact with the surface for a long time. This means that the deepest saturation depths are found in the Atlantic Ocean and the shallowest in the Pacific Ocean.

When investigating calcium carbonate in marine sediments, three depth expressions are used. The depth where $\Omega = 1$ is called the calcite (or aragonite) saturation horizon. Deeper than this is the lysocline, which is the horizon where dissolution starts to become noticeable. Finally, we have the carbon compensation depth (CCD) which is defined as the depth where the rain of calcium carbonate is balanced by the rate of dissolution. Operationally, the CCD has been defined as the depth where a fixed content of calcium carbonate (e.g., 10 %) is found in the sediments or alternatively the depth at where the calcium carbonate accumulation rate is 0. A schematic illustration of these three horizons is shown in Figure 1.

Summary or conclusions

The dissolution of metal carbonates is in the ocean mainly depending on the concentration of carbonate ions. In relatively young seawater, the carbonate ion concentration is

Carbonate Dissolution, Table 1 Parameters for the temperature and salinity dependence of the stoichiometric solubility product of calcite and aragonite in seawater

Solid	b_0	$b_1 \, 10^3$	b_2	c_0	$d_0 \, 10^3$
Calcite	−0.77712	2.8426	178.34	−0.07711	4.1249
Aragonite	−0.068393	1.7276	88.135	−0.10018	5.9415

high enough to prevent most crystal forms of calcium carbonate to dissolve. However, carbon dioxide is produced when organic matter sediments out of the photic zone and mineralizes in the deep ocean. The carbon dioxide reacts with the carbonate ion and forms hydrogen carbonate which thus contributes to the dissolution of carbonates. Consequently, the sediments at several km depth of the North Atlantic contain carbonates, while sediments at 1 km in the Pacific Ocean might not.

Carbonate production systems

Definition

Carbonate factories, or production systems, are benthic carbonate associations that show variations in their dominant precipitation mode, mineral composition, and depth range of production as well as growth potential (Schlager, 2000).

Introduction

The term "carbonate factory" was introduced to define the narrow depth zone where tropical reefs and detrital carbonates are produced (e.g., Tucker and Wright, 1990; James and Kendall, 1992; Reading and Levell, 1996). Based on the carbonate factory principle, Schlager (2000) proposed a threefold subdivision of the benthic carbonate production systems, with the planktonic carbonate factory as a fourth system. The latter is traditionally dealt with in the context of paleo-oceanography. The Schlager (2000) carbonate factory concept is based on the style of

carbonate precipitation in aquatic realms: (1) abiotic, (2) biotically induced, or (3) biotically controlled (Lowenstam, 1981). In the latter category, a distinction can be made between sunlight-controlled organisms (phototrophic) and nutrient-controlled organisms (heterotrophic).

Environmental parameters

A series of environmental parameters steer the different modes of carbonate precipitation. The abiotic mode is normally encountered in marine and freshwater aquatic settings, although increasing evidence suggests microbes also play a mediating role in the formation of whitings (e.g., Yates and Robbins, 1998; Thompson, 2000) and ooids (Pacton et al., 2012). The differentiation found in the biotically controlled precipitation mode is directed through a series of environmental factors that drive environmental variations, the most important factors being: (1) light, (2) temperature, (3) nutrients, and (4) salinity. These factors set the boundaries for styles of carbonate precipitation and sediment production profiles but also for sediment production and distribution. As a result, the overall morphological development of the carbonate system relates to the dominance of specific factors:

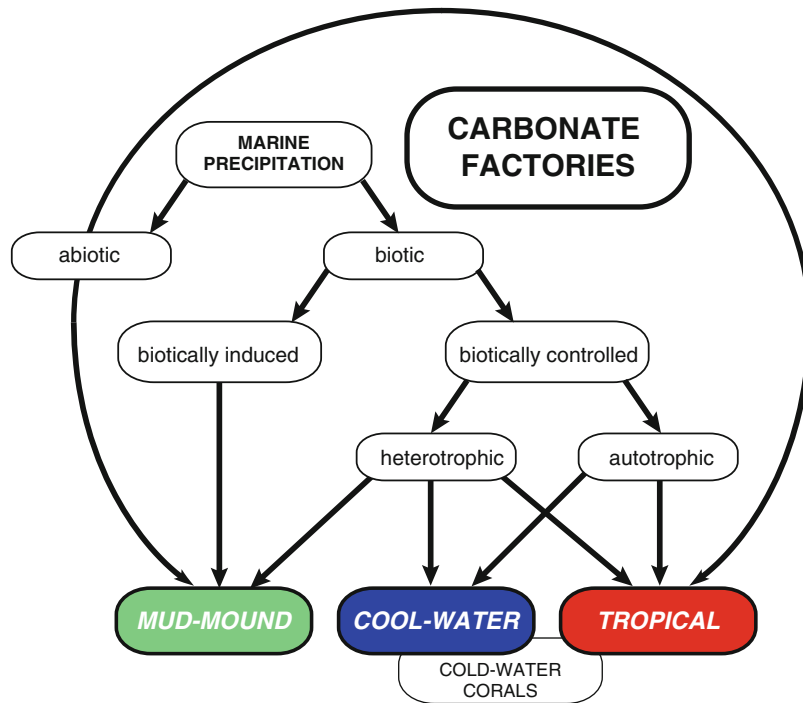
1. Light. This is considered as one of the most important environmental controls. The depth of the photic column, light penetration, varies around the present-day globe with a maximum of almost 150 m for the Pacific atolls (Schlager, 2005).

   The light-saturated zone and euphotic zone not only regulate the growth forms of corals but most importantly the growth rates of the photosynthetic, carbonate-secreting benthos (Schlager, 2003).

2. Temperature. More or less equal to light is temperature, as it regulates the diversity of the biotic association. Each carbonate-secreting species has its own optimum growth window along the temperature scale (Lees, 1975).

   Ocean circulation patterns and latitudinal positions relate to the distribution and occurrence of specific water temperatures and hence determine the distribution of specific organisms across the globe.

3. Nutrients. Nutrient variations play an important role as high nutrient levels reduce calcification rates, but also stimulate the development of filamentous algae, bryozoans, and barnacles (e.g., Halfar et al., 2004, 2006; Reijmer et al., 2012); increase bio-erosion rates (Chazottes et al., 2008); and may hamper coral recruitment (Smith and Buddemeier, 1992; Atkinson et al., 1995).

4. Salinity. Coral communities are tolerant to long-term and short-term salinity variations (Muthiga and Szmant, 1987). The same holds for *Mytilus* shells (Malone and Dodd, 1967) whose calcification rates are not influenced by salinity thresholds. Algal communities exist that have a greater tolerance for high salinities, and they occur in large terminal lakes like


Carbonate Factories, Figure 1 Classification scheme of carbonate factories related to their precipitation modes (see text for details) (modified from Schlager (2003)).

the Great Salt Lake (Stephens, 1990; Harris et al., 2013). Porter et al. (1999) showed, for the Florida Keys coral reef system, that elevated salinities could diminish the negative effects of elevated temperature and conclude that temperature and salinity have opposing effects on coral photosynthesis. In restricted environments, however, biotic diversity might be reduced (Miocene, SE Spain; e.g., Braga and Martin, 1996).

The influence of the aforementioned factors on the growth strategies of skeletal and microbial precipitation and on the formation of non-skeletal particles differs for each component. Various strategies will result in different products at different times. Schlager (2000, 2003, 2005) distinguished three end-members of carbonate sedimentation systems or the so-called carbonate factories. The specific factories possess different sedimentation modes that reflect different growth strategies with different overall geometries, carbonate mineralogy, and grain sizes.

Carbonate factories

The three main factories (Figure 1) that were distinguished are:

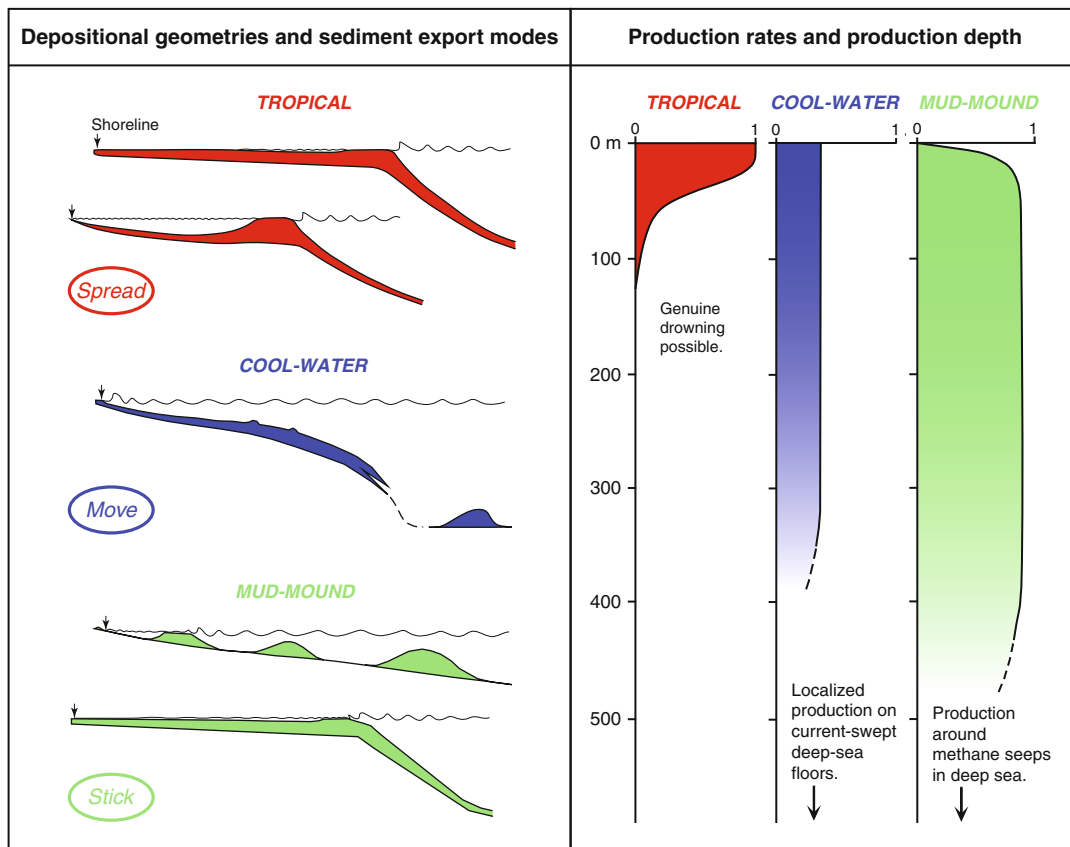
(1) T-factory, in which the T is derived from tropical or "top-of-the-water-column" (Schlager, 2005); (2) the C-factory, in which the C stands for cool-water or controlled precipitation; and (3) the M-factory, in which M represents microbial, micrite, or mud-mound

(Schlager, 2003, 2005). A fourth factory might be distinguished, the cold-water reef systems, which share characteristics with the T-factory through the type of dominant skeletal builder, e.g., scleractinian corals, and with the C-factory type, because of the production-depth profile and the nutrient-steered and light-independent carbonate production mode.

In the *T-factory*, light and water temperature steer the production profiles ensuring high production rates through biota living in the photic zone (Figure 2). The occurrence of this factory is mostly limited to the tropical zone between 30°N and 30°S, with modification through surface currents related to ocean gyres and upwelling areas.

The light and water temperature steered production mode results in a carbonate platform morphology, with a rim, reef barrier, at the edge of the platform (Figure 2).This barrier protects the shallow-water lagoon environments and forms the upper part of the steep slopes surrounding the platform. These slopes are mostly coarse grained and show fast cementation (Grammer et al., 1999).

The major mineralogy here is aragonite explaining the fast cementation rates found on the slopes (Grammer et al., 1999), reef systems, platform interior, and exposed sediments (Dravis, 1996).

This factory is very sensitive to relative changes in sea-level as it is closely tied to the light-saturated zone, and shows a flat top and steep slopes. A relatively small drop


Carbonate Factories, Figure 2 Platform morphologies, production rates, and sediment export mode of the individual carbonate factories (modified from Schlager (2003)).

in sea-level might eliminate most of the sediment production zone. This sedimentation pattern with sea-level-related sharp changes in sediment production is called highstand shedding (e.g., Schlager et al., 1994). One could tag the overall sedimentation pattern as "Spread" as the systems export abundant sediment from shallow-water areas into surrounding basins (Figure 2).

Nutrients and relatively low temperatures steer the biologically controlled production of carbonate sediments in the *C-factory*. In surface waters, the C-factory operates at higher latitudes than the T-factory, northward of 30°N and southward of 30°S. Other realms are upwelling areas and low-temperature waters below the thermocline.

The production profile shows moderate production rates over a large water depth range (Figure 2), so production is not limited to shallow waters (Schlager, 2003). Another characteristic is the open sedimentary system without any shallow-water barriers as found in the other factories. Low cementation rates combined with the absence of a shallow-water barrier result in a sedimentation regime in which waves and currents control sediment transport and redistribution. One could label the overall sedimentation pattern as "Move" as changes in currents and waves result in a shift of the depositional sediment loci. In addition, the

sedimentary response to sea-level changes shows large similarities to that seen in clastic systems (Figure 2).

The *M-factory* is characterized by the microbial-mediated, e.g., bacteria and cyanobacteria, precipitation of mud (Schlager, 2000, 2003). The most prominent features of this factory are the microbial mats, which usually contain several microbial species from various key groups, and their organic EPS (extracellular polymeric substances) matrix steering different organo-mineralization processes. The production profile of this factory shows a fairly steady production rate (Figure 2), which can reach tropical rates (Kenter et al., 2005), within a wide range of environments and water depths. Very characteristic for this factory is the formation of mound buildups, e.g., the Carboniferous of Belgium (Lees and Miller, 1995) and Devonian of Algeria (Wendt et al., 1997), albeit large flat-topped platforms are also very frequent, e.g., the Carboniferous of Kazakhstan (Kenter et al., 2005) and Triassic of the Dolomites (Keim and Schlager, 2001). The production profile shows high production rates down to 500 m water depth or even deeper, e.g., around methane seeps (Figure 2). Production in the shallow-water areas is affected by the waves due to the sensitivity of the biota to these physical processes.

The term "Stick" describes the overall sedimentation pattern very well, because of the ability of the system to glue (through microbial activity) sediments and build sturdy systems (Figure 2).

Relative changes in sea-level do not have a large impact on the production rates of this system as the main sediment production loci are situated on the upper slope, below the wave base, and extend over a fairly extensive water depth range. As a result, the production rates of this system are fairly constant and can be described by slope shedding (Kenter et al., 2005), slope-derived sediment production not being affected by sea-level changes.

As a fourth system, one could add the cold-water coral reefs (CWCR), first described from the Northwestern European margin by Teichert (1958). These systems share the stony corals with the T-factory and the nutrient-dependent growth strategy with the C-factory. Characteristic for this *CWCR-factory* is the dominance of ahermatypic corals, e.g., *Lophelia* and *Madrepora*, in a sedimentary system with very high biodiversity. The nutrient dependency and occurrence throughout a wide range of water depths below the photic zone result in the worldwide distribution of this sedimentary system, with new discoveries being added daily (Correa et al., 2012; Mienis et al., 2012).

Production profiles

The production profiles of the different factories not only reflect the water depths in which the factories reach their optimum growth and sediment production, but also the environmental processes that steer the types and amounts of sediment produced. Various environmental factors drive the development of specific carbonate producing organisms and associated modes of carbonate production, which results in differences in the grain-size spectra produced, as well as dominant carbonate mineralogies. These factors then relate to the efficiency of the system to build sturdy structures, fixing the sediments within depositional realms.

So the different styles of carbonate platform development are related to production profiles and thus the sensitivity of the system as a whole to environmental changes. These differences are very well expressed in the response of the T-, C-, and M-factories to relative changes in sea-level. Sharp contrasts are found in the T-factory, with high production during highstands in sea-level when the flat tops of the platforms are flooded. Sharply reduced production occurs during times when the tops become exposed and sediment production is restricted to small surfaces on the steep platform slopes. In the C-factory, relative changes in sea-level have a minor effect on the overall production rates, but do cause re-sedimentation of sediments during these changes. The M-factory also shows fairly stable sediment production and export rates during sea-level changes, as the main sediment production sites are situated on the upper slope. Minor differences might occur during phases of progradation and aggradation (Della

Porta et al., 2004). The CWCR-factory strongly depends on the steady influx of nutrients either through slope currents or pelagic input. The CWCR-factories along the Irish margin as well as the communities in the Mediterranean show variations in their occurrence related to glacial and interglacial time intervals.

Summary and conclusions

The carbonate factory concept provides a subdivision of marine aquatic benthic carbonate sediment production systems based on their styles of carbonate precipitation. The planktonic carbonate factory is classified as an additional production system. The overall carbonate sediment production for the individual systems (tropical, cool-water, microbial, and cold-water coral reef systems) depends on specific factory-dependent sediment production profiles.

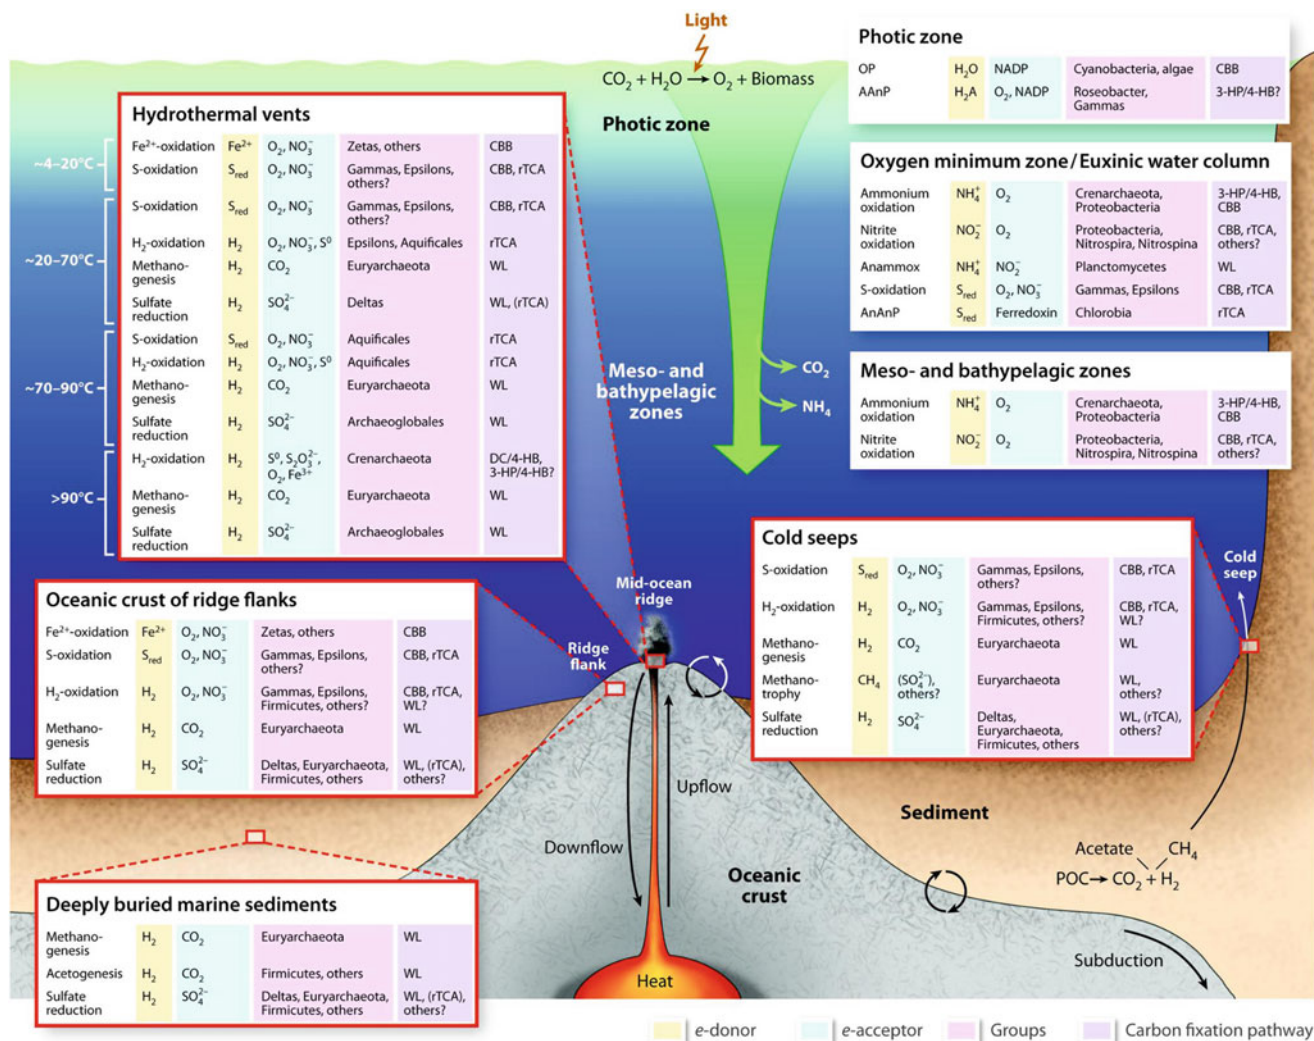
Chemoautotrophy; Chemolithoautotrophy; Chemosynthesis; Life supported by chemosynthesis

Definition

Chemosynthesis is the process that some microbes use to transform CO_2 into organic molecules. Energy to fuel this synthesis is gained from reduction-oxidation (redox) reactions involving inorganic compounds. The process is analogous to photosynthesis. Chemolithoautotrophy is "self-feeding using chemical energy from inorganic sources."

Chemoautotrophic metabolism

It is very likely that the first microbes on Earth able to fix carbon dioxide into organic carbon compounds did so using chemosynthesis (Martin and Russell, 2003). A major requirement of carbon fixation is energy to fuel the conversion process inside the cell. In plants and some microbes, sunlight supplies that energy but other microbes can capture energy from redox reactions mediated inside the cell. Most redox reactions that are key to energy transformation are aerobic using oxygen (either free or bound in another molecule) as the


Chemosynthetic Life, Figure 1 Locations and reactants supporting in carbon fixing processes in the ocean. *Boxes* list the reduction-oxidation reactions and the dominant microbial groups engaged in chemoautotrophy (and photoautotrophy in the upper ocean). The *right column* indicates the biochemical pathway inside the cell involved in creating the organic carbon molecule. *CBB* Calvin-Benson-Bassham cycle, *rTCA* reductive tricarboxylic acid cycle, *WL* reductive acetyl-CoA or Wood-Ljungdahl pathway, *3-HP/4-HB* 3-hydroxypropionate/4-hydroxybutyrate cycle, *DC/4-HB* dicarboxylate/4-hydroxybutyrate cycle (from Hügler and Sievert, 2011).

electron acceptor: sulfur-oxidizing microbes transform hydrogen sulfide to sulfate using oxygen $(H_2S + 2O_2 = SO_4^{2-} + 2H^+)$, while consortia of microbes can use sulfate to oxidize methane, thereby producing sulfide $(CH_4 + SO_4^{2-} = HCO_3^- + HS^- + H_2O)$. Many compounds act as electron donor/acceptor pairs in a wide variety of chemosynthetic reactions (Figure 1). Microbiologists are discovering many energy favorable differences between compounds in which some microbial groups have evolved to mediate the reaction (Hügler and Sievert, 2011). There are also "mixotrophs" that use both organic and inorganic compounds as electron donors or carbon sources. In shallow water, a mixture of photoautotrophy and chemoautotrophy is possible. Aerobic sulfide oxidation is the reaction that yields the highest amount of

energy available to cellular metabolism (McCollom and Shock, 1997). Free energy yield diminishes from O_2 to NO_3^- and NO_2^-, followed by manganese and iron, then SO_4^{2-}, and, lastly, CO_2.

Habitats of chemosynthetic life

Chemosynthesis occurs at interfaces of chemical environments where compounds mingle in disequilibrium (Figure 1). For example, abundant seawater oxygen spontaneously reacts with hydrogen sulfide yet a microbe on an anoxic interface can access both molecules and mediate the reaction inside the cell. Many such settings are fostered by geochemical processes under the seafloor that form emergent fluids rich in reduced compounds

(Tunnicliffe et al., 2003). At hydrothermal vents, high rates of fluid flux form strong gradients of compounds. Within smoker chimneys, zonation of minerals and of microbial diversity reflects a wide array of microhabitats available for chemoautotrophy (Kormas et al., 2006). The geological setting of high temperature rock/water interactions influences the composition of emergent fluids and the resulting microbial community (Amend et al., 2011). Oxidizing habitats on the periphery of vents, and on particulates in hydrothermal plumes, support chemolithoautotrophs that influence metal cycles in the ocean (Holden et al., 2012). Oxidation of reduced minerals within inactive sulfide deposits provides chemical energy to microbes that undergo ecological succession that reflects changing metabolic pathways as the sulfides age (Sylvan et al., 2012). Many similar sources of lithotrophic energy exist in the seafloor, not the least of which includes microbial weathering of basalts (Edwards et al., 2005).

At subduction zones, the pressure of sediment accumulation and mineral dehydration forces fluids upwards through organic matter-rich sediments along faults or bedding planes of the accretionary prism. Seepage that supports chemosynthesis can occur in association with gas hydrate or hydrocarbon deposits and also with brines near salt domes (Tunnicliffe et al., 2003; Levin, 2005). Rising bubbles, carbonate structures, or pockmarks may occur at seeps (Figure 2). Porewater methane generated from organic matter decomposition is the main source of carbon for chemosynthetic processes often through anaerobic oxidation using sulfate oxidation although other reduced compounds (e.g., H_2, NH^{4+}, Fe^{2+}, Mn^{2+}) are also present. The role of microbes in controlling the flux of compounds and behavior of methane reserves is a current interest (Jörgensen and Boetius, 2007).

Chemosynthesis plays an important role in oxygen minimum zones (OMZ) in many enclosed marine basins and in upwelling margins where abundant organic matter sinks into deep water. Microbial decomposition depletes dissolved oxygen often with sulfide and methane forming in and above the seafloor sediments, a feature of increasing concern as oxygen content decreases in the modern ocean (Helm et al., 2011). A complex array of biogeochemical cycles in OMZs reflects the redox reactions that support a diverse chemoautotrophic community.

Another notable site of chemosynthesis is associated with organic remains on the seafloor: large animal carcasses and wood (and sunken organic cargo). Whale skeletons release lipids over many decades creating anoxic conditions from microbial oxidation of organics. In these sulfide-rich bones, microbial chemoautotrophic production supports a community of metazoans for many years (Smith and Baco, 2003).

Microbial diversity and carbon fixation

The diversity of Bacteria and Archaea that use chemoautotrophic pathways continues to grow as new techniques of

Chemosynthetic Life, Figure 2 Representation of multiple habitats. Chemoautotrophy supports diverse animal communities in the deep ocean. White bacterial mats (*lower middle*) are often the first visual indication of reducing conditions. At hydrothermal vents (*upper left*), high biomass of animals develops in a food web dependent on both free-living and symbiotic microbes. Symbioses develop in most of these settings such as endosymbioses in cells of vestimentiferans and clams (*left*) or episymbioses as illustrated in alvinellid polychaetes (*top*) and on the yeti crab claws (*middle*). Various species of clams, mussels, and tubeworms also inhabit cold seeps (background), while highly specific "shipworms" (bivalves) use sunken wood and attract other species. The carcasses of whales (*lower right*) foster another community that includes the "bone-eating worms" depicted (Image credit: Amy Scott-Murray (amy@amyscottmurray.com); use terms under Creative Commons license).

detection emerge. Many microbes remain uncultivated but molecular approaches and genomic techniques to examine functional genes reveal a wide diversity. The Euryarchaeota tend to dominate at vents, especially at higher temperatures, while, among bacterial groups, the epsilonproteobacteria and Aquificales are abundant (Figure 1). Among the alpha- and gammaproteobacteria are the strains that function as symbionts in many animals at reducing habitats such as tubeworms and bivalves (Figure 2). Some microbes form obligate interactions such as the archaeal/bacterial consortia at cold seeps that mediate the anaerobic oxidation of methane with sulfate (Jørgensen and Boetius, 2007). Metabolite exchange among diverse microbes using different redox reactions also occurs in open-ocean low-oxygen zones (Wright et al., 2012). As research explores the metabolic functions expressed by these microbes, discoveries of new biochemical pathways for CO_2 fixation are emerging. In addition

to the classic Calvin-Benson cycle, at least five additional pathways are known (Hügler and Sievert, 2011; Figure 1).

Future directions

Chemosynthesis affects the chemical environment in fluid and rocks. How microbes mediate mineral transformations is a major field of biogeochemical research (Holden et al., 2012). Deep in the subseafloor, the minerals olivine and pyroxene react with water releasing hydrogen in a process called serpentinization. The potential for life in these zones is reflected in uplifted ophiolites where microbes are recorded; the metabolic pathways and consequences of the alkaline habitat are far from understood (Schrenk et al., 2013). Measurement of production rates in most marine-reducing habitats is difficult and especially challenging at hydrothermal vents where strong chemical gradients exist. The degree to which microorganisms are interdependent within a community that adapts a variety of metabolisms to changing chemical conditions is unclear (Sievert and Vetriani, 2012) and suggests that studies need to address the entire metabolome of a chemoautotrophic setting. More accessible are open-ocean hypoxic zones where the complexity of microbial interactions in a cascade of redox reactions is revealed by new genomic approaches. The development of modeling tools (e.g., Amend et al., 2011) to assess bioenergetics of redox/synthesis reactions can help formulate testable ideas of metabolic and microbial diversity in many settings. Relationships of these microbes with eukaryotes and metazoans are complex, often supporting communities with the highest natural biomass of the ocean. Symbiotic associations continue to contribute information on cell-cell signaling and evolutionary patterns. Exploration of deep-sea chemosynthetic habitats has led to many fundamental discoveries in basic life processes and redirected our considerations of the origin of life and life beyond Earth. The potential remains to discover energy sources not linked to processes on or above the seafloor. Exploration, both on the seafloor and in laboratories, continues to challenge our concepts of basic life processes.

CLAY MINERALS

Rüdiger Stein
Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research (AWI), Bremerhaven, Germany

Definition

Clay minerals are hydrous aluminum phyllosilicates. The main representatives are kaolinite, illite, chlorite, and smectite.

Structure and composition

The structure of clay minerals is characterized by alternation of sheets, which yield the layer structure. The composition and configuration of these sheets are different for different clay minerals. There are, however, two basic types of sheets, composing any given clay mineral (Grim, 1962; Bridley and Brown, 1984; Chamley, 1989): (i) tetrahedral sheets with one silicon atom surrounded by four oxygen atoms in a tetrahedral configuration and (ii) octahedral sheets with an aluminum, magnesium, or iron atom surrounded by hydroxyl groups and oxygen in a sixfold coordinated configuration (Figure 1a–d). Alternation of one tetrahedral and one octahedral sheet yields the 1:1 structure, whereas alternation of two tetrahedral sheets with one octahedral sheet results to the 2:1 structure. In most clay minerals, substitution in tetrahedral and octahedral sites creates a charge deficit known as layer charge, which is balanced by potassium, sodium, calcium, or iron and/or hydrated cations. These cations are hosted between the layers in the interlayer space and therefore are called interlayer cations. During hydration, the interlayer cations may cause expansion or swelling of the interlayer space of some clay minerals (e.g., montmorillonite; a member of the smectite family; Figure 1b). In general, clay minerals are classified by the differences in their layered structures, the type of cations in the structure, the magnitude of layer charge, and the type amounts and kinds of exchangeable ions within the interlayers (Meunier, 2005).

Kaolinite is the most important 1:1 clay mineral (Figure 1a), whereas illite and smectites have 2:1 structures composed of two tetrahedral and one octahedral sheet (Figure 1b, d). Chlorite is characterized by a 2:1 structure with an interlayered sheet of brucite (hydroxide interlayer) (Figure 1c). In addition to these main types of clay minerals, there are clay minerals that display a mixed-layered configuration composed of different basic structures and are classified as mixed-layer clay minerals. The most common mixed-layer clay mineral present in marine sediments is illite/smectite (e.g., Fütterer, 2006).

Formation of clay minerals

Clay minerals are the product of physical and chemical weathering of primary, rock-forming aluminum silicates (feldspars, amphiboles, pyroxenes, etc.) and hydrothermal alteration. Different clay minerals are formed under different climate-dependent weathering conditions. Thus, clay minerals determined in surface sediments and sediment cores may provide information on present and past, respectively, weathering conditions and climate of the source areas as well as transport processes of the terrigenous sediments (see examples below and synthesis by Chamley, 1989). The clay minerals illite and chlorite, for example, are common weathering products of igneous and metamorphic rocks. When mobilized during physical weathering, these minerals are typically found in high-latitude marine sediments. Kaolinite, on the other hand,

forms under warm and humid conditions by intensive chemical weathering of feldspars in tropical soils. Thus, kaolinite is often referred to as a low-latitude mineral. Kaolinite, however, is also found in polar regions in sedimentary deposits that were formed either under past warmer and wetter climatic conditions that currently exist or at low latitudes and later displaced northward through plate motion. Derived from the alteration of volcanic rocks, smectite is a good indicator of volcanic sediment sources.

Determination of clay minerals

Clay minerals are commonly determined both accurately and precisely in the <2 μm clay fraction by X-ray powder diffraction (XRD) (Bridley and Brown, 1984; Moore and Reynolds, 1997). For qualitative and semiquantitative estimates of clay mineral composition of marine sediments, the Biscaye method (Biscaye, 1965) is widely used in Marine Geosciences. The method uses oriented samples of the clay fractions prepared by usual sedimentation techniques (Moore and Reynolds, 1997) and subsequent ethylene glycol (EG) solvation and assumes that the sum of the four clay minerals is 100 %.

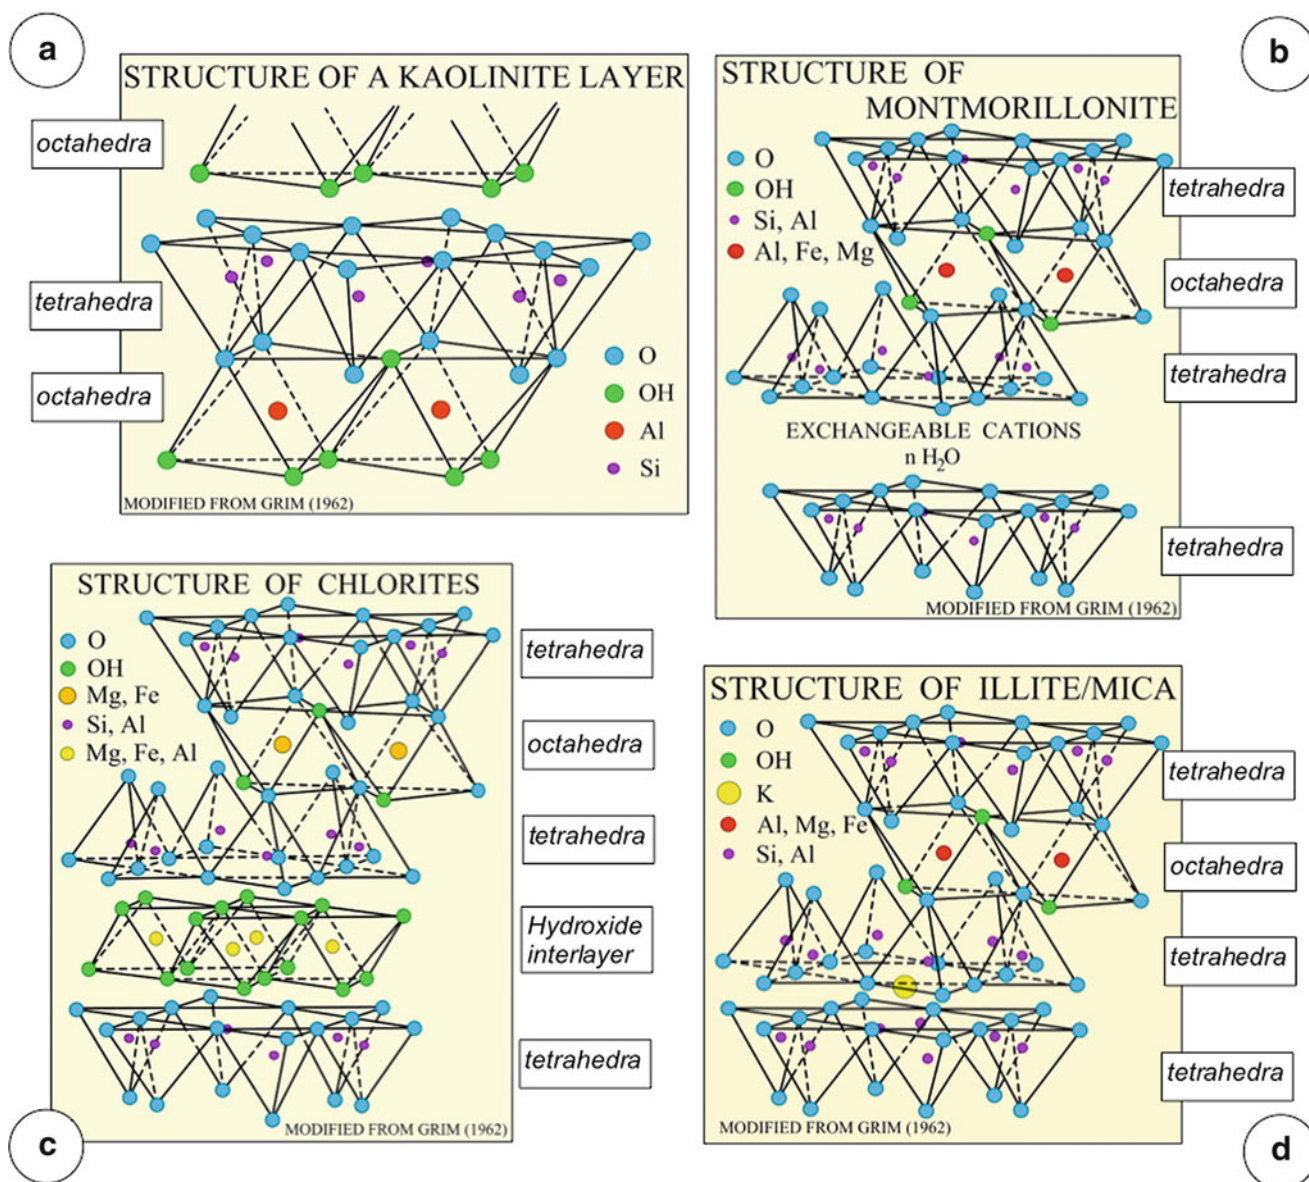
For example the abundance of illite, is given by the following equation:

$$\text{Illite}(\%) = \frac{4I \times 100}{S + 4I + 2K + 2C}$$

where the weighting factors to convert peak areas to relative weight fractions for smectite, illite, kaolinite, and chlorite are 1, 4, 2, and 2, respectively (Biscaye, 1965). For smectite the 17 Å peak, after removal of the chlorite 14 Å peak, and for illite the 10 Å peak are used in the calculations. Kaolinite is distinguished from chlorite from the peaks at 3.57–3.58 Å (kaolinite) to 3.53–3.54 Å (chlorite) peaks using the slow-scan XRD traces. The relative amount of each mineral is estimated from the 7 Å kaolinite-chlorite peak (Biscaye, 1965). Further details about the X-ray diffraction technique and different evaluation approaches can be found in Heath and Pisias (1979), Bridley and Brown (1984), and Moore and Reynolds (1997).

Significance of clay minerals in marine geosciences

In Marine Geosciences, clay minerals represent a major to dominant proportion of fine-grained deep-sea sediments and thus are important proxies for reconstruction of present and past environmental and depositional as well as diagenetic conditions from studies of surface sediments and sediment cores. Some examples are presented and discussed below. For more details the reader is referred to the literature listed at the end.

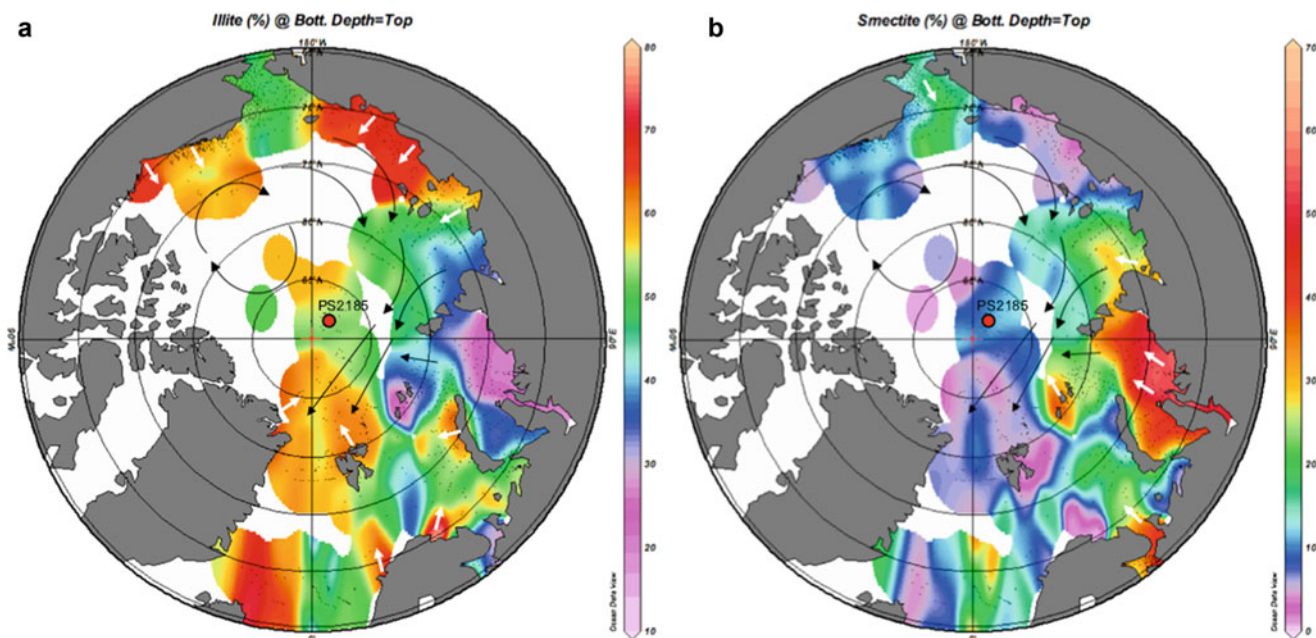
The distribution and abundance of clay minerals within the different ocean basins (e.g., Griffin and Goldberg, 1963; Biscaye, 1965; Venkatarathnam and Biscaye, 1973; Kolla et al., 1976; Heath and Pisias, 1979; Naidu


Clay Minerals, Figure 1 Diagrammatic sketch of kaolinite, montmorillonite, chlorite, and illite/mica (from Poppe et al., 2010: (http://pubs.usgs.gov/of/2001/of01-041/htmldocs/clays/kaogr.htm; Webpage 2010; supplemented)).

et al., 1982; Wahsner et al., 1999; Stein, 2008 among others) as well as the world ocean (Griffin et al., 1968; Rateev et al., 1969; Windom, 1976; Rateev et al., 2008) has been studied thoroughly over the past decades. The distribution patterns of the four main clay minerals have been related to latitudinal climate regimes, weathering conditions, wind regimes, river discharge, and ocean currents. Kaolinite concentrations display prominent maxima in low latitudes characterized by maximum chemical weathering (Figure 2a). Illite reaches maximum values in the mid to higher latitudes, especially in the northern oceans (Figure 2b) surrounded by large land masses, and

is indicative of terrigenous origin and fluvial and eolian supply. Maximum concentrations of chlorite are observed in the high northern and southern latitudes (Figure 2c), i.e., the subpolar regions characterized by predominantly physical weathering processes. Smectite indicative for a volcanic origin displays maximum abundance in the South Pacific (Figure 2d), i.e., a region of intense volcanic activity and low sedimentation rates due to the large distance to the continents and, thus, limited dilution by detrital clay minerals.

Based on the relationship between clay mineral distribution pattern in surface sediments and modern climatic

Clay Minerals, Figure 2 Relative distribution of kaolinite (**a**), illite (**b**), chlorite (**c**), and smectite (**d**) in surface sediments from the world ocean as percentage in the carbonate-free clay fraction <2 μm (from Windom, 1976, color version extracted from Fütterer, 2006).


Clay Minerals, Figure 3 Relative distribution of illite (**a**) and smectite (**b**) in Arctic Ocean surface sediments as percentage in the carbonate-free clay fraction <2 μm (from Stein, 2008). The location of Core PS2185 is shown.

conditions, clay mineral data determined in marine sediment cores were used to reconstruct the paleoceanographic and paleoclimatic changes through time, as shown in numerous studies from different parts of the world ocean (e.g., Janecek and Rea, 1983; Stein and Robert, 1985; Stein, 1985; Ehrmann et al., 1992; Robert and Kennett, 1994; Stein, 2008).

In polar and subpolar regions, with predominantly cold climate at least during Neogene and Quaternary times, physical weathering processes dominate and chemical and diagenetic alterations are negligible. Therefore, the clay mineral association in marine sediments is a valuable indicator to identify origin and transport pathways of terrigenous sediments, and clay mineral data were used to distinguish among the shelf areas by the amounts of smectite, illite, and kaolinite in surface sediments (see Stein, 2008 for review). The Kara Sea is characterized by highest smectite values and the East Siberian Sea with lowest smectite and kaolinite values and highest illite concentrations (Figure 3). The smectite maxima in the Kara Sea result from erosion and weathering of extensive flood basalts of the Putoran Massif of the Siberian Hinterland (Duzhikov and Strunin, 1992; Vyssotski et al., 2006). The Yenisei River with its tributaries drains this area and transports smectite into the Kara Sea. The Central Arctic sediments are characterized by a mixture of these three clay minerals but are distinctly depleted in smectite compared to the Kara and Laptev seas.

In the Arctic Ocean, different processes influence the transport of sediment from the shelves into the deep Arctic Basin. An important mechanism responsible for the clay mineral dispersal pattern is current systems. Clay minerals are extremely fine-grained and therefore can be transported over large distances within the water column. In addition, sediment transport with drifting sea ice is of importance in the Arctic Ocean, and clay minerals might be useful proxies to identify source areas of the sea ice (e.g., Pfirman et al., 1997; Dethleff, 2005).

An example for using clay minerals for reconstruction of paleoenvironments in polar regions, records from Core PS2185 recovered from Lomonosov Ridge/Central Arctic Ocean and representing glacial-interglacial variability of the last 200,000 years BP, is shown in Figure 3 (for location of core see Figure 2). Intervals with increased coarse-grained ice-rafted debris (IRD) were recorded in uppermost MIS 7 to MIS 6 (190–130 ka), upper part of MIS 5 (substage 5.2, about 90–80 ka), near the MIS 5/4 boundary (around 75 ka), and in the late MIS 4/early MIS 3 time interval (65–50 ka), indicating major continental glaciations during those times. Concerning the provenance of the IRD and its variability through time in the Eurasian Arctic, bulk, clay, and heavy-mineral associations of Core PS2185 can be used to identify source areas of the terrigenous (IRD) fractions (e.g., Spielhagen et al., 1997; Behrends et al., 1999; Wahsner et al., 1999; Stein, 2008; and references therein). Here, elevated smectite and kaolinite concentrations as well as high clinopyroxene/amphibole ratios during MIS 6, upper MIS 5, and late MIS 4/early MIS 3, mostly coinciding with IRD maxima (Figure 4), serve as a tracer for an IRD origin from the western Laptev/southeastern Kara Sea/Franz Josef Land and central Barents Sea/Franz Josef Land, respectively. High smectite concentrations, however, do not always coincide with high coarse-fraction

Core PS2185 (Lomonosov Ridge)
Clay Minerals, Figure 4 Summary plots showing coarse-fraction content >63 μm (wt%), detrital carbonate (% of the coarse fraction >500 μm), and kaolinite and smectite (% of clay minerals in the clay fraction <2 μm) (Data from Spielhagen et al., 1997) as well as the clinopyroxene/ amphibole (CPX/Amph) ratio (Data from Behrends, 1999) and quartz content (Data from Vogt, 1997, 2004) in Core PS2185 for the last 240 ka (MIS 7 to MIS 1), using the age model of Spielhagen et al. (2004). Marine isotope stages MIS 1–7 are indicated. In addition, the concentration of planktic foraminifers per gram sediment is shown (Data from Spielhagen et al., 2004). *Green* and *pink* bars indicate sediment source areas in Eurasia and northern Canada, respectively (Figure from Stein (2008)).

content. In some intervals, e.g., in the uppermost and lowermost MIS 5 (5.1 and 5.5), smectite enrichments correlate with very low terrigenous coarse fraction which may suggest transport by sea ice (or currents) rather than icebergs. For more detailed discussion see Stein (2008) and references therein.

Summary and conclusions

Clay minerals, hydrous aluminum silicates which comprise mainly kaolinite, illite, chlorite and smectite, are major to dominant constituents of fine-grained deep-sea sediments. Clay mineral composition of marine sediments may give important information about source areas and transport mechanisms of terrigenous material as well as weathering processes and climate of the source areas. Thus, clay minerals are widely used in Marine Geosciences as proxies for reconstruction of present and past environmental, depositional, and diagenetic conditions from the studies of surface sediments and sediment cores.

COASTAL BIO-GEOCHEMICAL CYCLES

Jing Zhang
State Key Laboratory of Estuarine and Coastal Research, East China Normal University, Shanghai, China

Definition

The "Coastal Biogeochemical Cycles" is dealing with the transformation of chemical speciation of elements (i.e., chemical form and valence) and flow (e.g., flux) of materials between biotic and abiotic compartments of coastal and marine environments (here after the coastal ocean) that is defined by landmass (e.g., continents) on one side and the open ocean on another side. The study of biogeochemical cycles in this domain needs an approach that provides an integrated view of the physical, biological, geological, and chemical aspects of materials in the changing marine environment.

Introduction

Our understanding of the ocean was built up along with the ambition of navigation and exploration of marine resources by human beings that started more than 2000 years ago. The coastal ocean, because of its proximity to the land, is the marine environment that has been extensively explored by our human societies. For instance, about 1,500 years ago, our ancestors from Asia started to reclaim the coastal areas for salt production and for agriculture, and the early history of marine trade in the Middle East can be tracked back to the epoch far before the tenth century.

The modern knowledge of biogeochemical cycles started to be established in the late nineteenth century in Northern Europe where scientists began to determine the chemical composition of seawaters from coastal and open oceans. However, the process studies of the dynamics of the biogeochemical cycles only began in the second half of the twentieth century, benefiting from the technical innovations in clean sample collection in seagoing observations and instrumental analysis in the laboratory, particularly when trace elements were of concern.

Besides, the rapid increase and change of human being activities in the environment are a great challenge for the study of biogeochemical cycles. For instance, the enormous increase in agricultural production after the 1930s–1940s by the application of chemically synthesized fertilizers has considerably modified the seaward fluxes of some macronutrients (i.e., N and P), with a deterioration of adjacent coastal environments, such as eutrophication and hypoxia. More recently, the worldwide dam construction over the watersheds has dramatically reduced the sediment loads to the sea, and in some of the rivers, there has been a reduction of flux of dissolved silicate that induces a change in the phytoplankton community structure (e.g., change in biomass from diatoms to flagellates) with a profound impact on the marine food web.

In this work, we briefly review the major aspects of the coastal biogeochemical cycles and address a number of key issues that affect the biogeochemistry of coastal ocean and link to the health of marine ecosystems and sustainability of their exploitation.

External driving forces

Different from the open ocean, the ecosystems of the coastal environment can be taken as overstressed, because of the combined effects of climate change and anthropogenic perturbations. Although either natural forcing or human being activity can be reasonably characterized with state-of-art observational techniques and simulations, the combined effect of these two categories of driving forces is hardly predictable with our up-to-date knowledge and existing data of ocean sciences. This can be exemplified by the comparison with the interaction of different waves in physics: the interaction of individual waves (e.g., in a pond) is nonlinear mode and can produce a new wave spectrum with different period/frequency and amplification.

The natural driving force of the coastal ocean is related to the global and climate changes, with a number of basin-wide persistent processes and systematic trends, e.g., global warming, the sea-level rise, and ocean acidification, as well as by processes with relatively fast and episodic characters with annual and interannual variability, e.g., tropical cyclones and storms, and change in open boundary circulation (Table 1). It should be kept in mind, however, that studying local and regional

Coastal Bio-geochemical Cycles, Table 1 Characteristics of some of the important driving forces in the biogeochemical cycles of coastal oceans

Driving forces	Temporal and spatial dimensions
Tides (e.g., M_2, S_2, K_1, and O_1)	Semidiurnal, daily, monthly, and seasonal variations at basin scale, particularly in the coastal zone with strong effect of mixing and transportation
Ekman pumping and suction	Related to the wind-induced circulation in low- and midlatitude regions, e.g., monsoon areas, with strong seasonal nature at the mesoscale
Riverine influx and groundwater discharge	Daily and seasonal variations with strong impact from human beings in the watersheds, with change in fluxes of water, sediment, and pollutants
Atmospheric wet and dry depositions	Daily and seasonal variations with significant fingerprints from human emission from upwind side, either from land sector or from the seaside
Incursion of open boundary currents	Seasonally and interannually, with significant character linked to climate variability like ENSO, PDO, NAO, etc. and having an impact on basin-wide scale
Eutrophication	At mesoscale in coastal environment, an ongoing decadal process, usually the phenomena is related to the over-enrichment of nutrients from land sources
Oxygen depletion and hypoxia	Can be local or basin-wide phenomena with seasonal and/or annual persistence with negative impact to the food webs (e.g., in particular benthic organisms)
Reclamation	Usually happens in coastal areas with impacts leading to the loss of habitats because of change in land use for the purpose of economics (e.g., aquaculture and urbanization)
Fishery	Including removal of top predators or even also removal of lower food-web levels and negative effect of by-catch, with a strong "top-down" effect on the ecosystem
Coastal engineerings	Events related to the economic activities of human society, for example, the construction of harbors, oil platforms, and sediment dredging; damage to habitats on land and on the sea bottom

changes has to take into account the effects of distant forcing, i.e., global climate change, the interaction of external forcing and geographic settings can derive a different and sometimes unforeseen driving force at local and/or regional scale. The natural forcings should also include change in atmospheric depositions and riverine influx, however, with consideration of the respective effects of the anthropogenic perturbations. In temperate and high-latitude regions, the recurring seasonal changes and their considerable interannual variability are the most important factors in shaping the biogeochemical cycles of materials.

Since the coastal ocean is adjacent to the continental and/or landmass (e.g., islands), the "biogeochemical cycles" in this region is also modulated by the human being activities in the watersheds and in the ocean-side (LOICZ, 2005). Change in land-use and hydraulic engineering (e.g., damming the river) over the watersheds can dramatically modify the seaward transport of weathering products and pollutants, including riverine flux as well as groundwater discharge and their variability at seasonal and interannual scales. For instance, the terrestrial sediment load has been reduced by more than 50 % and the nutrient fluxes increased by up to twofold for some of the top world rivers over the last several decades (Boesch, 2002; Syvitski et al., 2005). Other examples include the reclamation for arable land in the coastal zone for aquaculture, e.g., shrimp ponds that destroy the wetland, and because of expansion of urbanization, particularly so in the developing countries. The global overfishing problem can have a "top-down" effect on the energy and material flow in ecosystems by removing top predators as well as herbivores thus disturbing interactions in the entire food web (GLOBEC, 1997). Moreover, eutrophication in the coastal environment can exert a negative impact on the ecosystem through "bottom-up" effects that modify macronutrients and their molar ratios and hence alter the community structure of phytoplankton (GEOHAB, 2001).

How and to what extent the natural and anthropogenic forcings interact have a determining effect on the biogeochemical cycles in the coastal ocean, which in turn modulates the structure and function of ecosystems. This is probably why the coastal biogeochemical cycles have significant varying temporal and spatial dimensions and accordingly the research and results often have a case-specific nature.

Machinery of the coastal biogeochemical cycles

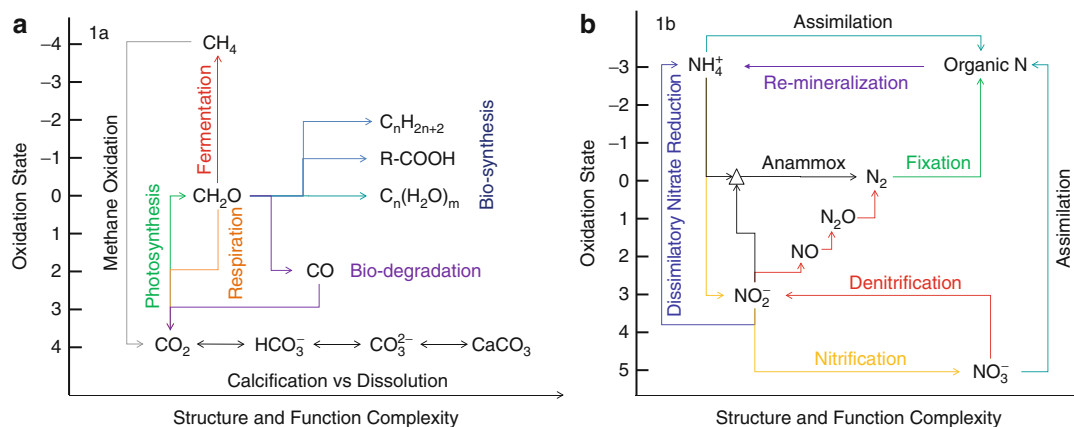
The coastal environment exhibits the transit zone between the landmass and the open ocean where the properties of land and ocean are strongly modulated. Thus, strong gradients exist for hydrographic parameters (i.e., salinity and temperature), chemical properties (e.g., major and trace element concentrations), turbidity and profiles of photosynthetically available radiation, as well as for the composition of organisms.

Dynamics of biogeochemical cycles of the coastal ocean

The coastal biogeochemical cycles incorporate dynamic processes that include the major pathways of chemical elements between biotic and abiotic compartments and variability of source versus sink terms in the euphotic waters, where the tiny phytoplankton and marine algae use the energy from solar radiation to fix carbon dioxide from atmosphere and change it to chemical energy of organisms, releasing oxygen:

$$CO_2 \ + \ H_2O \ \rightarrow CH_2O + O_2$$
where the symbol "CH_2O" stands for a simplified composition of organic matter. This photosynthesis fuels the biogeochemical cycles and energy flow in the entire water column and through the entire food web. Along with photosynthesis, macronutrients such as N, P, Ca, and Si, and about further 30 minor and trace elements such as As, Cd, Co, Cu, Fe, Mn, Mo, Se, V, Zn, etc. that are biologically essential, are also taken up by phytoplankton (Figure 1). Particularly C, N, P, and O_2 are incorporated and remineralized in a relatively fixed molar quota, the so-called Redfield ratio: C:N:P:O = 106:16:1:138 (Redfield et al., 1963; Moral et al., 2003). Chemical elements can be either incorporated as components for soft organic matter or used to form skeletons and cell wall of organisms (GEOTRACES, 2006). Nutrients and trace elements used by the organisms in photosynthesis can be supplied from external sources, like land-source input via rivers and groundwater discharge, atmospheric wet and dry depositions, release through the sediment-water interface, advective transport, and upwellings from open ocean. Generally speaking, all nutrient supply from outside the euphotic zone, which includes nutrients enriched in surface waters during the nongrowth period of phytoplankton, is defined as "new production," which maintains the sustainable food production of ecosystem (e.g., fishery); in contrast phytoplankton uptake of nutrients stemming from remineralization in the food webs of euphotic zone is referred to as "regenerated production" (Dugdale and Goering, 1967).

The organic matter formed in photosynthesis is in part transferred to zooplankton and then through herbivores and carnivores up to the top predators in the food web. Organic matter escaping from water column remineralization sinks eventually to the seafloor as also do inorganic biogenic materials (e.g., carbonate skeletons and silicate shells) that survive dissolution in the water column. The whole journey from the carbon fixation by photosynthesis in surface waters until the organic matter deposition to the sea bottom is referred to as "biological pump" in Global Change Science.

Since the mid-1970s, the significance of microbial loop has been recognized in the ecosystem functioning that complements the traditionally defined "food chain," i.e., phytoplankton via zooplankton to fish, playing an important qualitative and quantitative role in the


Coastal Bio-geochemical Cycles, Figure 1 Oxidation states of chemical elements and relative structure and function complexities of molecules for carbon (**a**) and nitrogen (**b**) in the biogeochemical cycles.

biogeochemical cycles in the ocean. Within the microbial loop, organic matter is used by bacteria in the water column and pore waters to form new biomass that can be grazed by Protozoa, including flagellates and ciliates, which is then fed by zooplankton and linked to the higher trophic levels of the food web. The microbial loop also comprises pico-phytoplankton and autotrophic bacteria (Azam and Malfatti, 2007). In the ocean, functioning of the microbial loop is similar to a filtration system, by selective use of readily decomposed molecules (i.e., labile fraction) of organic matter, leaving the residual fraction being more refractory in nature and thus not readily used by organisms (Hopkinson and Vallino, 2005). The microbial loop in the coastal environment is also fueled with organic matter from the terrestrial sources (e.g., river) and from atmospheric wet (e.g., rainfall) and dry (i.e., aerosols and gases) depositions.

In Figure 2, the major biogenic functional groups that link the biogeochemical cycles with the structure of food web of ecosystems in the coastal ocean are summarized as a conceptual model. Due to the diverse topography and hydrographical forcing, the biogeochemical cycles in shallow coastal seas exhibit considerably stronger spatial and temporal variations when compared to the open ocean. For instance, coastal systems are exposed to tidal forcing and constrained in semi-enclosed basins landward from the coastline or connected to the open ocean through channels/straits between islands, whereas systems affected by the large rivers can extend seaward to the shelf break and even beyond. Thus, horizontal and vertical gradients in hydrographic and chemical forcings induce that biogeochemical cycles have a zonal nature. Briefly, the coastal waters under influence from terrestrial influx can suffer strongly from eutrophication, where photosynthesis (p) can be exceeded by community respiration (r) (i.e., $p - r < 0$), and the ecosystem becomes heterotrophic with occurrence of hypoxia and/or anoxia in near-bottom waters; in the areas closer to the open ocean on the other side, the environment becomes more oligotrophic

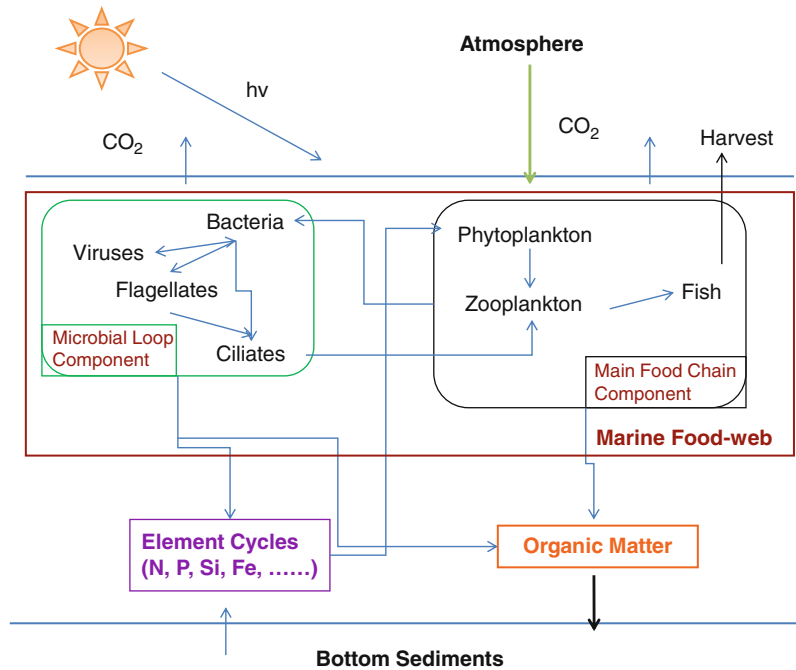
and the photosynthesis is higher than respiration (i.e., $p - r > 0$), and the ecosystem turns to be autotrophic (Bauer and Bianchi, 2011).

Biogeochemical modeling and budgets of the coastal ocean

The quantitative description of coastal biogeochemical cycles integrates our understandings of interactions of chemical species between biotic and abiotic compartments and the dynamic processes of biogeochemistry that regulate the transfer of elements from the sources to the sinks including the fluxes across the boundaries between the coastal ecosystems and adjacent marine and/or land provinces (Figure 3).

The early studies of biogeochemical budgets relied on the application of a "box model," owing to the limitation of available data sets and the lack of the ability of mathematic calculations. In the box model, the system of interest is considered well mixed and at the steady state, that is, the concentration and fluxes of a given chemical species do not change with time, and the principle of energy and/or mass balances can be used to solve the problems; usually the calculation of ordinary differential equation(s) is incorporated.

In the more sophisticated studies, the equations that describe the chemical reactions and/or biogeochemical pathways (i.e., parameterization) are coupled with the 1D to 3D numerical models that simulate the hydrodynamic processes and sedimentary dynamics (e.g., transport of the total suspended matter). The output data can be plotted against timescales, showing the variability in spatial and temporal dimensions. In the numerical simulations, the change of concentration (C) for a volume of water parcel at a given location can be described as

$$\frac{\partial C}{\partial t} = [\text{AdvectionTerm}] + [\text{DiffusionTerm}] + [\text{Source} - \text{Sink}]$$


Coastal Bio-geochemical Cycles, Figure 2 Interlinkages of biogeochemical cycles with traditional food chain and microbial loop in the coastal ocean; collectively they make the food web.
Coastal Bio-geochemical Cycles, Figure 3 Major budgetary pathways for the modeling of coastal biogeochemical cycles, including external forcing terms (i.e., new production) and internal recycle of chemical species (i.e., regenerated production). The extent of seasonal changes is decisive for the spatial and temporal decoupling of new versus regenerated productions, as well as between production and export of organic matter (OM).

The "AdvectionTerm" can be expressed as $-U \cdot \nabla C$, and "DiffusionTerm" by $\nabla \cdot (D \cdot \nabla C)$, where U and D represent the velocity vector and diffusivity tensor, respectively, and $\nabla = i\frac{\partial()}{\partial x} + j\frac{\partial()}{\partial y} + k\frac{\partial()}{\partial z}$, that is, the Hamiltonian. The "Source-Sink" term deals with the chemical reaction(s) that alters the element concentration at molecular level. In the simulations with the 3D model, usually the analytical solutions are not valid anymore; however, the fine and heterogeneous structures of the

system of interest can be analyzed through numerical solutions. Moreover, the model outputs of a numerical simulation can be displayed in a biogeochemical field showing the distribution of species of interest in three dimensions with temporal variability, which can be used for the diagnostic analysis of biogeochemical cycles and perspective scenarios of system behavior in the background of climate change (Sarmiento and Gruber, 2006).

Based on the synthesis of data from the Joint Global Ocean Flux Study (JGOFS Web-site: http//ijgofs.whoi. edu/) in the 1990s, it has been indicated that primary production amounts to 0.5×10^{15} mol year^{-1} of organic carbon for the global continental marginal seas; though continental margins occupy only 5–10 % of ocean surface, ca. 15 % of total primary production of global ocean takes place in the coastal oceans (Chen et al., 2003). Whereas seasonal cycles and interannual to decadal variability in a given latitudinal area are similar in the marginal seas and the open ocean at surface, it should be noted, however, that owing to the proximity to the landmass, the coastal biogeochemical cycles have a stronger character of seasonality as well as interannual variability; the dimensions of spatial nature differ considerably between these two realms, revealed, for example, by the change in biogeochemical budgets (Zhang et al., 2007). For instance, in the coastal region of the tropical East Pacific Ocean, the upwelling affects the dissolved iron profiles in the water column, with elevated *Chl-a* in the wide shelf corresponding to high Fe concentrations in surface waters and depletion of dissolved Fe in the narrow shelf inducing low *Chl-a* values (Bruland et al., 2005).

Feedbacks to the earth system and human society

In the coastal as well as the open oceans, there exist close interactions between biogeochemical cycles and ecosystems from end to end (i.e., from microbial to top predators) (IMBER, 2005), with profound impact on the human society, such as the water quality (GEOHAB, 2001) and fishery (GLOBEC, 1997).

As the coastal ocean covers a transitional area from an often more heterotrophic system with large addition of allochthonous organic matter in coast to a more autotrophic system with dominance of autochthonous organic matter at open boundary, the nearshore waters are usually regarded as a CO_2 source to atmosphere, while the offshore waters become the sink of atmospheric CO_2 (Thomas et al., 2004). Hence coastal and marginal seas can play an important role in the global and oceanic carbon cycles by bridging the land, ocean, and atmospheric carbon reservoirs.

Humans are part of the global ecosystem, and hence the future of human society is affected by the interactions between land, ocean, and atmosphere. Human activities on land have a profound impact on the coastal biogeochemical cycles and thus on the interactions between biogeochemistry and ecosystem from end to end, which can change the composition of material fluxes from the coastal environment to the open ocean and to the atmosphere. This in turn feeds back on the sustainability of human society as well as on the marine life (Bauer and Druffel, 1998; Fasham et al., 2001). For instance, coastal eutrophication can induce a change in phytoplankton community structure (e.g., diatoms relative to dinoflagellates), which in turn affects the food web structure as well as fish-catch through transfer of organic matter and chemical energy between trophic levels. It has been indicated that the emission of some of greenhouse gas species (e.g., CH_4 and N_2O) from the coastal ocean accounts for an important part of global budgets considering its relatively small spatial proportion of world ocean (Bange et al., 2005; Naqvi et al., 2010). The predicted impacts of climate change in the future (e.g., global warming and ocean acidification) have been shown to have irreversible negative impacts on the marine ecosystems in low (e.g., coral reefs) as well as in high latitudes (Hoegh-Guldberg et al., 2007; Arrigo et al., 2008).

Summary and concluding remarks

Coastal biogeochemical cycles exhibit interlinks of different mechanisms that regulate the transfer of chemical elements in the marine ecosystem (e.g., food web) and encompass rapid and complicated processes that bridge the material transport between the various compartments of the Earth system, land, ocean, and atmosphere as well as human society. The external forcing factors on coastal biogeochemical cycles can be either natural or anthropogenic, as well as the combination of these two.

Biogeochemistry in the coastal ocean is composed of cycles of macronutrients and trace elements between biotic and abiotic compartments driven by formation of organic matter fueled by solar energy and the metabolisms (i.e., anabolic and catabolic processes) based on the chemical energy stored in the organisms.

Since the late 1970s, it has been recognized that the microbial loop can be an important component of biogeochemical cycles in the ocean, which is an integral part of the entire food web and affects considerably the pathways of biogeochemical cycles in the coastal ocean. It is known that coastal biogeochemical cycles have strong feedbacks to the atmosphere (e.g., emission of greenhouse gases) as well as the open ocean (e.g., lateral export of particulate and dissolved organic carbon) through change in material fluxes.

COASTAL ENGINEERING

Louise Wallendorf
Hydromechanics Laboratory, United States Naval
Academy, Annapolis, MD, USA

Definition

Coastal Engineering is the civil engineering design of structures to protect or restore a shoreline from the effects of erosion.

Introduction

Coastal engineering was formally recognized as a specialty of civil engineering with the birth of the International Conference of Coastal Engineering in 1950. Informally man has been building structures at the border of the land and sea for centuries; the history and heritage of coastal engineering through 1990 is documented for 15 countries in the world in the hope that the evolution of knowledge can be transferred to future generations (Kraus, 1996). The world population has grown from 2.6 billion in 1950 and to over seven billion in 2014 (United Nations, 2010; NOAA, 2013). In addition, populations are concentrated in coastal watersheds; for example, more than 40 % of cities with populations over 500,000 are located on the world's coastlines (NOAA, 2013). The increased population density and associated shoreline development are interfering with natural coastal processes and ecology.

Coastal engineers are now incorporating design elements that both prevent coastal erosion and create a more natural environment sensitive to the site. Coastal engineers work with biologists, geologists, coastal managers, lawyers, oceanographers, and the local population to create designs.

In order to develop a design to protect infrastructure or restore an eroding shoreline, a coastal engineer must consider the site environment, available tools, customers, and regulations.

Site environment

Before developing a design the project site is investigated. Site characteristics of interest to a coastal engineer are:

- Sediment type (rock, gravel, sand, clay, or muddy soils) and distribution of particle sizes and unit weights are determined. Ideally core samples are taken along the cross section of the shoreline. Sediments are classified by the distribution of particle diameters; clays and muddy soils are treated differently than sand or gravel as their properties are affected by water (Healy et al., 2000).
- Shoreline/beach equilibrium profile – what is the natural profile of the shoreline and are there historical records showing how it has changed over time? Shorelines can be surveyed by LIDAR, aerial photography, and field surveys to determine present conditions.
- Site topography and bathymetry – geographic maps and charts provide general information. Surveys of the land and shallow water areas can show the detailed topography of specific shoreline areas especially when the site is changing rapidly.
- Sediment transport rates and direction – erosion and accretion of shorelines in the site area, predominant wave direction, and currents along with numerical models of the site can contribute to sediment transport rate estimates.
- Coastal inlets – the water flow in and out of inlets to marinas/ports and inland waterways for the coastal population can severely affect the natural sediment processes in an area, and special considerations must be used in their design or presence near a project site (Kraus, 2005)
- Marine habitat – a site can have both native and invasive species of flora and fauna. How can the design enhance the local habitat?
- Hydrodynamics – waves, ship wakes, currents, and low-frequency motions: tides, seiches, and storm surge – regional records of the magnitude, and frequency of atmospheric conditions, winds, waves, and tides exist internationally. Coastal engineers can estimate winds, wave, tide, seiche, and storm water levels from available site data. A major consideration is the wind fetch or maximum distance that the wind blows over the body of water and the angle of incidence to the shoreline. Of particular concern is the prediction of wave run-up and wave overtopping on the shoreline (Jones et al., 2005). Wave run-up is the elevation above the still water on a beach or structural slope due to tide, surge, and wave setup. Wave overtopping is the volumetric rate at which run-up flows over the top or crest of a slope of a beach, dune, or structure. Wave

diffraction, the bending of wave fronts around the ends of coastal structures, must be considered.
- Weather and extreme events – hurricanes/cyclones, tropical storms, earthquakes, and tsunamis – what are the natural hazards in the site area? With increased coastal populations, hazard maps have been developed to show seismic, extreme wind and flooding and wave inundation areas. Has a risk assessment been performed for the site evaluating the vulnerability of the population to the hazards?
- Sea-level rise/subsidence – what is the forecast rate of change of the mean sea-level? The rates of change of sea-level and its causes are continuously documented and updated by scientists (IPCC, 2014).
- Proximity/access to site – road, railway, marina, and ports – how close is the site to major infrastructure? Coastal shorelines naturally fluctuate over time. Is there a room at the site to allow for fluctuation or does the shoreline protection require a stationary profile to protect infrastructure?

Available tools
Design manuals

Design manuals exist to aid the coastal engineer in design (USACE, 2002; CIRIA, 2007). These manuals detail design guidance for all types of coastal structures. Within these manuals, design methodologies are recommended. Simple formulas and techniques based on empirical field data or laboratory model tests are recommended for preliminary design estimates. The engineer must be familiar with the assumptions made in these formulas to evaluate their suitability for a site.

Numerical tools

When there are gaps in environmental site information, numerical models have been developed to predict meteorological and oceanographic conditions, wave run-up, and overtopping. Increasingly climate change/hazard risk models are being developed for project sites. Coastal scientists and engineers must be familiar with how the models operate and the assumptions used to develop them, before applying them to an individual site design.

When field data of weather, oceanographic topography, and bathymetric conditions exists for a location, the time period of data recording should be compared to the proposed life of the structure. Trends can be forecast or extrapolated using both statistics and modeling.

Physical modeling

For large coastal construction projects, physical model testing can be performed on a scaled model of the design. Coastal model testing techniques are provided in detail (Hughes, 1993). Model tests can confirm and enhance numerical predictions. They are also used when the design is too complicated for a numerical model.

Local knowledge

What is the existing local body of knowledge from coastal protection projects near the site? What types of designs have been used over time in the area and in what ways have they succeeded or failed?

Construction resources

What is the availability and cost of both natural and man-made construction materials (soil and beach fill, stone, timber, concrete, steel)? There is a unique set of concrete construction components for shore protection (Reef balls, Core-loc units, Coastal Haven WAD® (Wave Attenuation Device), etc.) which can be used in certain site conditions with design guidance. How long will it take to obtain the materials for construction and what are the transportation costs?

Often specialized construction equipment (dredges, barges, tugs, workboats, divers) is necessary to complete a coastal construction project. Is the equipment required available locally and is there local infrastructure to get it to the site? Are their local contractors with experience with the equipment?

Increasingly coastal projects are completed with the contribution of community volunteers, particularly with landscaping and project monitoring. How can these resources be efficiently combined with the commercial contractors work?

Customer

Coastal engineering projects are initiated by a customer's desire to protect/enhance their coastal property. The customer can be an individual, business, nonprofit, or public entity. The property may be residential, recreational, commercial, or coastal infrastructure (roads, bridges, marinas, ports, railroads). The primary controls are the budget and the proposed life of project and maintenance intervals. What is the customer's permissible level of damage due to an extreme storm/seismic event? How is the project being funded? If public funds are being used, can the economic return to the community from the contribution be justified? The use, the life, the budget, and an acceptable level of risk are balanced in the final design.

Regulation

Every design project is subject to both engineering codes and permitting for zoning and environmental review. Engineers must maintain knowledge of design and construction codes. Permitting is done at the local, regional, and national levels and varies between jurisdictions. As complex as it has become, obtaining permitting for a project has become a special area of legal and policy expertise separate from the engineering. An engineer must continuously communicate and solicit input from all involved parties to insure the coastal project is built to everyone's satisfaction.

Coastal engineering designs

Coastal engineering design solutions can vary from letting nature take its course to any of the following man-made alterations to the shoreline:

Beach fill or nourishment

Beach fill or nourishment is the restoration of a natural beach with sand fill and reconstructed dunes to recreate a historical beach profile. Dunes protect the backshore of the coast in an extreme storm. Models exist to predict two-dimensional coastal erosion due to extreme storm conditions (Kriebel and Dean, 1985). Correct estimates of wave run-up and overtopping are necessary (Jones et al., 2005). Beach fill must be selected that matches the color, weight, median particle diameter, d_{50}, and distribution at the location.

Living shorelines

The concept of "living shorelines" involves the use of native vegetation and low-lying structures to provide shoreline stabilization while attempting to mimic the natural landscape and preserve the intertidal habitat at a site location (Walker et al., 2011). In low-wave energy locations or within estuaries, shoreline marshes can be constructed with toe stabilization provided by rock or timber sills with low crest elevations that provide water exchange, habitat, and protection especially while the vegetation is regrowing. Openings in the sills are provided for wildlife.

Groins

A groin is a low wall or sturdy timber barrier built out into the sea from a beach to check erosion. They are constructed perpendicular or at a slight angle to the shoreline, as shown in Figure 1a. Groins are intended to interrupt the longshore transport and deposit sand adjacent to the structure; sometimes excessive deposition can occur on the updrift and downdrift sides of the groin, so their length and porosity need to be designed carefully.

Breakwaters

Breakwaters are structures designed to provide shelter from the waves and/or manipulate the littoral transport conditions to trap sand in their lee. Breakwaters transform or reduce the height of waves in their lee. They can cause wave setup or an increase in the water level due to the waves trapped behind them. They can be composed of concrete units or layers of rock with varying weights and sizes. Breakwaters can extend at any angle to the shoreline to create a sheltered area depending on wave conditions, as shown in Figure 1b. Rock or concrete breakwaters are constructed with front and back slopes. Rock breakwaters can be composed of a single homogeneous layer of rock or layers of graded rock. A layered breakwater has a central core of finer stone to improve wave transmission. The central core is covered with a level cap and front and back slopes composed of layers of larger heavier stones to

Coastal Engineering, Figure 1 Examples of shoreline protection: (**a**) Bay Ridge Beach, Chesapeake Bay, MD, USA – timber groin and rock berm breakwater system protecting recreational beach and coastal roadway (photo: Louise Wallendorf). (**b**) Shangri-La Center for Islamic Art, Oahu, Hawaii, USA – breakwater creating small boat refuge and beach (photo: Rob Walker). prevent movement of the stone in storm wave conditions. Filter cloth is often used on the base of the foundation to prevent erosion.

Berm breakwaters

Berm breakwaters are detached breakwater constructed in series parallel to the shore, either submerged or with a low elevation above the still water level. Sited at the proper distance offshore and with the correct gaps between them, they can create a salient or widening of the beach directly in their lee. When the salient gets too large, a tombolo is formed; the collected sand connects the beach to the breakwater structure. Generally this type of beach is used to grow and protect the shoreline of a recreational beach; Figure 1a shows a groin and berm breakwater system designed for this purpose. Sand collected in this type of design can serve as a reservoir of material when the beach is eroded during a storm (Dean and Dalyrmple, 2002).

Floating breakwaters

Floating breakwaters have been tested periodically in deeper water sites to provide a portable or low-cost alternate to breakwaters constructed on the seafloor. The keys to a successful floating breakwater design are the structural design of the connections between the units and the moorings.

Seawalls/revetments

Seawalls are vertical walls built to delineate the border between sea and land, in an area where the upland contains infrastructure that requires protection from storm surge and wave overtopping during an extreme storm event. Seawalls are often constructed in regions that have experienced high erosion and have limited or no beachfront. Revetments are sloped surface layers designed to protect the shoreline from erosion from waves and currents. They can be as simple as grass on packed clay, as is in river

levees, or as more complex armored layers of rock or interlocking man-made elements on top of a soil slope. Figure 1c shows a seawall creatively camouflaged as a natural rock along with a rock revetment which is protecting community housing.

Self-closing flood control structures

To prevent damages to large coastal populations when high river or sea water levels can inundate large areas, self-closing flood control structures are designed. The Netherlands has extensive experience in this specialty of coastal engineering with the design and construction of the 13-segment dam and flood barrier system instituted with the Deltaworks plan in 1953. Both the size of the protected population and the community's contribution to a nation's economy must be evaluated and compared to the high cost of this type of protection (Hatheway, 2008).

Setback or relocation

When a community has experienced high damages from multiple extreme coastal events within one generation, a community can choose to relocate structures or infrastructure inland from the shoreline. Hatteras Lighthouse, a historic coastal structure subject to repeated erosion detaching it from the natural North Carolina shoreline, was moved 1.1 km inland (Tice and Knott, 2000). The downtown area of Hilo, HI, was relocated and replaced with a planned tsunami inundation area after the population experienced the tsunamis of 1946 and 1960 (Hwang, 2011).

Summary and conclusions

A good coastal engineer balances the customer's requirements to prevent coastal erosion, using sound science and practical engineering with a sensitivity to coastal ecology.

While the specific techniques used to forecast environmental conditions and develop components of a coastal design are continuously updated (US Army Corps of Engineers, 2002; CIRIA, 2007), a coastal engineer should have a flexible design philosophy balancing the known and unknown scientific data for a site with engineering analysis under an experienced hand (Dean and Dalrymple, 2002).

Synonyms

Bank; Beach; Coastline; Coastal area; Coastal zone; Littoral; Margin; Seaboard; Seacoast; Seashore; Seaside; Shore; Shoreline; Strand

Definition

When used as a noun, the coast is part of the land that is next to or adjoining the shore, a sea, or a large body of water such as an inland sea or lake. The definition of coast depends on the jurisdiction or intended use. When used as "the Coast," it refers to a specific geographic coastal segment such as the Pacific coast of North America or the Dutch coast of the Netherlands or even more restrictively as the Coromandel Coast of southeastern India.

The term *coast* resides in the vernacular as a generic reference to the strip of land adjacent to large water bodies, most commonly the sea. While the term covers a broad sweep between land and water, it at the same time becomes more complicated and convoluted when applied in adjectival form as *coastal* (pertaining to the coast) or conjoined with the suffix *line*, making the term *coastline*, or preceding a noun as in *coastal zone* or *coastal area* (see below). Associated with coast, coastal, and coastline are various nuances, inferences, and interdigitations that come into play depending on the use by geoscientists, engineers, surveyors, lawyers, and resource managers, among others. Some of the legion applications of coast terms and salient types of coasts are indicated in what follows.

Origins of the term, variable meanings, and related usage

The term *coast* is a general expression that, in its simplest sense, refers to the contact between land and water. The origin of the term stems from Middle English *cost*, from Anglo-French *coste*, and from Latin *costa* rib, side, akin to Old Church Slavic *kostĭ* bone, with the first known use in the fourteenth century (Merriam-Webster, 1994). Defined as the land near a shore, it is implied to be more or less equivalent to seashore. Other definitions say "...a strip of land that meets the sea or some other large expanse of water... or which extends from the low tide line inland to the first major change in landform features..." (e.g., Jackson, 1997; Oertel, 2005) or, according to the FAO, "The geographical area of contact between the terrestrial and marine environments, a boundary area of indefinite width, appreciably wider than the shore" (Cullinan, 2006).

A slightly more rigorous definition of the term *coast* involves a relationship with seashore, viz., "A strip of land of indefinite length and width (may be tens of kilometers) that extends from the seashore inland to the first major change in terrain features" (Voigt, 1998). The vernacular related to the concept of coast is often somewhat confusing because the terms are indefinite, imprecisely defined, or partially overlap. In the example abstracted from Jackson (1997), the term *shore* is used to help constrain the definition of coastline, viz., technically the line that forms the boundary between the coast and the shore, the shore being the most seaward part of the coast, but further begs the question regarding the difference between coastline and shoreline. Coast, seaside, coastline, and seashore are all words for the land beside or near to the sea, a river, or a lake.

Although usually associated with the marine realm of oceans, seas, gulfs, and fjords, for example, the term may also be applied to large inland freshwater lakes (e.g., Great Lakes in North America, Lake Baikal in southern Siberia, Lake Tanganyika [an African Great Lake], Lake Balaton in the Transdanubian region of Hungary) and to saline or hypersaline bodies of water such as the Dead Sea in the Middle East, Great Salt Lake in the western United States, the Aral Sea between Kazakhstan and Uzbekistan, and so on. The term coast is also often used in a very general way to refer to some specific geographic region, physiographic feature, or anthropogenic influence as, for example, appreciated by the terms Barbary Coast, Coast Mountains (Canada), Coromandel Coast, Gold Coast, Ivory Coast, rocky coast, reef coast, muddy coast, mountain coast, developed coast, Engineered Coasts (q.v.), and so on.

Coastal zone

The coastal zone is a geographic entity including both terrestrial and submerged areas of the coast, defined legally or administratively for coastal zone management (Cullinan, 2006). According to many definitions, the coastal zone includes parts of landmasses that are under the direct influence of maritime conditions where the weather, wildlife, and soils are obviously different from those of noncoastal areas (Clark, 1996). The coastal zone, in general, is usually obvious to decipher but when freedoms are restricted and legal issues are involved, an administrative definition is needed, and this is where things start to get complicated. Typically, the extent of coastal waters is defined first, and then a strip of shoreland is added to interlock land and sea elements (Clark, 1996). Nicholls and Small (2002), for example, also consider coastal populations and define the coastal zone as the land margin within 100 km of the coastline or less than 100 m above mean low tide, whichever comes first.

The coastal zone can thus be defined in different ways. In most cases, some combination of distance from the coast and elevation is used. The Millennium Ecosystem Assessment (MEA, 2005), for example, used 100 km from the coast as a distance threshold and 50 m as an elevation limit, depending on which was closer to the sea. McGranahan, Balk, and Anderson (2007), on the other hand, used 10 m elevation contiguous with the coast with no distance threshold; this procedure mostly delineated areas closer than 100 km from the sea, but some areas extended farther inland to define the coastal zone.

Coastal area

From an engineering point of view, the term *coastal area* refers to areas of land and sea bordering the shoreline and extending seaward through the breaker zone (CERC, 1966). The coastal area is also a technical term for a geographic entity of land and water affected by the

biological and physical processes of both terrestrial and marine environments. In this sense it is broadly defined for the purpose of natural resources management (Cullinan, 2006). It should be noted that coastal area boundaries change over time without regard to enabling legislation.

Determination of coastline length: the coastline paradox

Application of the term *coast* is conditioned by scale, purpose of the designation, and the audience or user. The so-called coastline paradox states that a coastline does not have a well-defined length because its measurement is scale dependent. Measurements of the length of a coastline behave like a fractal, being different at varying scale intervals. The smaller the scale interval (the shorter in length, the more detailed the measurement), the longer the coastline. This "magnifying" effect occurs because it takes many more shorter scalar lengths to measure the coastline, and consequently, coastline length becomes greater for convoluted coastlines than for relatively smooth ones. Convoluted coastlines tend to obtain for rocky coasts, and determination of coastline length in these situations can be especially problematic. One solution, as proposed by Spagnolo et al. (2008), is the *indentation index*, which is defined as the ratio between the real length of a coast and its Euclidean length. Application of this method involves digitizing the coastline in a GIS platform to test several Euclidean length values on the same coastline, thereby obtaining a different spatial variability of the indentation index with each trial. The best length values that maximize the spatial variability of the indentation index determine an indentation index pattern of high variance and low spatial autocorrelation. This procedure has applicability to some rocky coasts of limited extent but is limited by the scale of operation in a GIS where it would not be practical to determine world rocky coast lengths.

The ten countries with the longest coastlines, regardless of specific coastal types, are listed in Table 1. The data were derived from the World Resources Institute, based on data calculated in 2000 from the World Vector Shoreline, United States Defense Mapping Agency, 1989 (Soluri and Woodson, 1990). The coastline length was retrieved from the World Vector Shoreline database at a scale of 1:250,000. The estimates were calculated in a Geographic Information System (GIS) platform using an underlying database consistent for the entire world. Coastline length was estimated based on the following criteria: (1) use of individual lines that have two or more vertices and/or nodes, (2) length between two vertices was calculated on the surface of a sphere, (3) the lengths of pairs of vertices were summed and aggregated for each individual line, and (4) the lengths of individual lines were summed for each country. Long coastline lengths thus accrued where landmasses were large (i.e., Canada, United States, Russia, and Australia) and for countries that

Coasts, Table 1 Top ten countries with the longest coastline lengths in the world, as abstracted from http://en.wikipedia.org/wiki/List_of_countries_by_length_of_coastline. Coastline lengths were determined at a nominal scale of 1:250,000 as described above

1	Canada	265,523
2	United States	133,312
3	Russia	110,310
4	Indonesia	95,181
5	Chile	78,563
6	Australia	66,530
7	Norway	53,199
8	Philippines	33,900
9	Brazil	33,379
10	Finland	31,119

had convoluted coastlines formed by many islands, peninsular headlands, gulfs, estuaries, and fjords (i.e., Canada [British Columbia, Nunavut, Newfoundland and Labrador], United States [Alaska], Indonesia, Chile, Australia, Norway, Philippines, Brazil, and Finland). Discrepancies in coastline lengths can be illustrated for Australia (number 6 in Table 1), the only one of the top six completely surrounded by water. The coastline length abstracted from Geoscience Australia's GEODATA Coast 100 K 2004 database (2010), for example, gives a total of 59,736 km. Compared to the total length given in Table 1 (66,530 km), there is a difference of 6,794 km, being accounted for by exclusion of thousands of small fringing islands, many of which occur around Tasmania, among other factors. The nature of the measuring conundrum has been reviewed by Galloway and Bahr (1979) for the Australian coastline and it should be noted that this same problem also exists for other countries, where coastline length may be indeterminate but varies consistently with the accuracy of measurement. Galloway and Bahr (1979) illustrate the magnitude of the coastline paradox by the fact that the total length for the mainland, including islands greater than 12 ha, ranges from 24,330 km when measured on 1:2,500,000 maps with a divider intercept of 100–69,630 km when measured on the same 1:250,000 maps with an intercept of 0.1 km. Coastline lengths should thus be taken with a grain of salt, and the reader should be cognizant of the means by which length was measured.

Classification of coasts: types of coasts

To the layman, coasts are thought of in very general terms such as sandy coast, rocky cost, muddy, Mangrove Coasts (q.v.), Reef Coast (q.v.), and so on. Related terms such as *seaside* (especially British English) refer to an area that is by the sea, especially one where people go for a day or a holiday: a trip to the seaside. It is always the seaside, except when it is used before a noun: a seaside resort. The seaside is British English; in American English seaside is only used before a noun. The term coastline broadly

classifies the land along a coast, especially when thinking of its shape or appearance, as, for example, in British Columbia's rugged coastline around Puget Sound. Classification of coast in terms of materials such as sand to a layman refers to a large area of sand on a beach. Although these concepts of coast are useful to laypersons, more rigorous definitions are required for technical applications where scientists and engineers need more detailed information about materials making up the coast (types of rocks and sediments), shape and configuration of landforms along the coast, natural processes operating around the coast (climate, waves, currents), tectonics, sea-level change, coastal-marine ecology, etc.

Organization of different types of coasts into a classification system thus seems simple enough, but as it turns out, the pigeon holing of variants has been elusive (Finkl, 2004). Although it is a natural tendency to try and classify coasts, no universal classification of coasts has yet been put forth. Problems thwarting attempts to classify coasts are legion, but they mostly arise from scalar considerations, the multidimensionality of coasts, and polymorphism that is associated with the concurrence of paleo- and neomorphs along the same coastal segment. The compound nature of coasts often makes it difficult to classify coast according to one type or another, as, for example, when beaches occur seaward of cliffs or as pocket beaches along rocky coasts. Percentage frequencies of occurrence of a particular coastal type may thus overlap if more than one type occurs along a coastal segment, as indicated previously where beaches may occur in front (seaward) of rocky cliffs. Estimates of worldwide coastal types thus differ, and percentage frequency of occurrence overlaps due to the compound nature of many coastal segments. Different types of coasts result from a wide range of processes (e.g., Zenkovich, 1967; Bird, 1985; Fairbridge, 1989; Short, 1999; Woodroffe, 2002) and exhibit distinctive spatial distribution patterns of landforms (e.g., Davies, 1964, 1980) that give character to coastal segments to identify them as sandy, muddy, cliffy, rocky coast, etc.

Previous investigations propose that several salient factors should be taken into account when devising a coastal classification (cf. King, 1966; Davies, 1964, 1980; Bird, 1976; Fairbridge, 1989, 1992; Finkl, 2004): (1) the shape or form (morphology) of the land surface (above and below sea-level), (2) the movement of sea-level relative to the land and vice versa (e.g., change in relative sea-level, RSL), (3) modifying effects of marine processes, (4) climatic influences on process and form, and (5) age and durability of coastal materials. The following examples illustrate the point of proposed terminologies, viz., Atlantic and Pacific type coasts (Suess, 1888); subduction, taphrogenic (rifted), and sediment-loading (alluvial) coasts (Fairbridge, 1992); coastlines of submergence and emergence (Johnson, 1919); primary and secondary coasts (Shepard, 1973); advancing and retreating coasts (Valentin, 1952); soil and unconsolidated coast forms (e.g., cliff, platform, reef); solid and unconsolidated coast materials (e.g., beach, delta, channel, flats, scree/talus)

(Owens, 1994); coasts of plate boundary islands and intra-plate islands (Nunn, 1994); coasts of shelf coral reefs (patch reefs, crescentic reefs, lagoonal reefs, planar reefs) (Hopley, 1988); coast of unvegetated solitary island, vegetated solitary island, multiple islands, and complex low wooded islands (Stoddart and Steers, 1978); reef coasts (fringing reefs, bank reefs, barrier reefs, atolls, ridge reefs, Bahamian reefs) (Guilcher, 1988); beach coast (dissipative, intermediate, reflective beaches) (Short, 1999); Type A coast platforms (e.g., benches (Zenkovitch, 1967), platforms (Trenhaile, 1987), wave-cut terraces (Leet and Judson, 1958), wave-cut platforms (King, 1963)) and Type B coast platforms (e.g., coastal platforms (Guilcher, 1958), marine benches (Cotton, 1963), wave-cut platforms (Short, 1982)); sea cliffs (plunging, composite) (Davis, 1898; Orme, 1962); etc.

All of a sudden the concept of coast becomes very complicated and far-removed from the realm of laypersons as geoscientific terminologies make headway into the literature. The jargon surrounding the term *coast* is necessary because the term, which at first sight seems simple enough, is actually complex. This is because the perception of coast is not only scale dependent but time dependent as well where old and new landforms are juxtaposed along many coasts. An additional classificatory complication is that coasts are dynamic and constantly changing to the point that the study of coastal (coastline) change takes on a wide purview among researchers, especially in regard to identification and evaluation of evident and potential change associated with variations in sea-level (e.g., Bird, 1985; Fairbridge, 1989; Woodroffe, 2002). New technologies associated with remote sensing capabilities now facilitate the recognition and classification of coasts in terms of natural landform features, ecosystems, and processes (e.g., Shaw et al. 2008; Wang et al., 2010; and Klemas, 2011).

Coastal landforms

Landforms and ecosystems often provide specificity to different types of coasts, and it is perhaps useful to indicate some notable examples. The modifier before the noun *coast* (e.g., cliffy coast, sandy coast, mangrove coast, skerry coast) or as a noun by itself to signify a specific kind of coast (e.g., estuary, rocky headland, spit, tombolo) helps project an image of what is being described. There is, however, great variation in scale within a single coast designation as in the example of estuarine coasts where the St. Lawrence Estuary (Canada) is the longest (1,197 km) in the world followed by Chesapeake Bay (United States) (322 km) to very small estuaries along many coasts of the world.

Rocky coasts

Whereas rocky coasts in general make up about 80 % of the world coast length (Emery and Kuhn, 1980), sea cliffs (Figure 1) are distinctive and dramatic forms of rocky coasts that make up about half of the world's coasts, but

Coasts, Figure 1 Example of rocky coast on the eastern shore of Eleuthra Island, Bahamas, showing eolianite cliffs that are undercut at present sea-level to form a notch. Note the height of these sea cliffs (about 30 m) compared to the man standing on top of the cliff (Photo: C.W. Finkl).

there is debate as to the location of the highest sea cliffs depending on the slope of the cliff face and actual free fall distance. The location of the world's highest sea cliffs thus depends on the definition of *cliff*. Kalaupapa, Hawaii (1,010 m high), and the north face of Mitre Peak, Milford Sound, New Zealand, which drops 1,694 meters (Seddon and Dadelszen, 1898), are extreme examples. The average slope of these cliffs is roughly 60 degrees, but a more vertical drop of 1,560 m into the sea occurs at Maujit Qaqarssuasia in the Torssuktak (Tunoq) Fjord (Sound), southeast Greenland (Beckwith, 1989). Considering a truly vertical drop, Mount Thor on Baffin Island in Arctic Canada is among the highest at about 1,370 m for the longest purely vertical drop on Earth (Simon, 2012). These spectacular sea cliffs are tourist attractions around the world for a very specialized kind of coast. Many cliffy coasts have gently sloping seaward ramps (Type A platforms) or subhorizontal surface terminating in a seaward or low-tide scarp (Type B platforms) (Trenhaile, 1987). These shore platforms (wave-cut platforms) often contain shallow pools and are subject to subaerial weathering at low tide. Lithology and structure are important to the types of rocky coasts with volcanic rocks and

Coasts, Figure 2 Sea stack on the northern Oregon coast (United States), which is predominantly a rocky coast with stretches of beach interspersed between rocky headlands (photo: C.W. Finkl).

limestones forming some of the most spectacular and scenic coasts. Many terraces and benches are uplifted above present sea-level, while others are below the water. Sea caves, arches (bridges), and stacks (Figure 2) are additional types of erosional landforms that are characteristic of rocky coasts (Woodroffe, 2002). More subtle forms of rocky coasts are associated with drowned glacial landscapes with drumlins or other glaciated terrains with exposed bedrock to form skerries or partially submerged whalebacks.

Beach and barrier coasts

Beaches (q.v.), which are normally backed by Dunes (q.v.), make up about 70 % of the world's coasts (Bird, 1976) and are well-known types of sedimentary coast. In Australia, where Short and Farmer (2012) report no fewer than 11,761 beaches, dunes back 80 % of the beaches and about 40 % of the coast. Beach sediment is extremely variable in terms of size, shape, color, and chemical

Coasts, Figure 3 Segment of a barrier island along the Florida east coast showing the typical open ocean to mainland shore progression of coastal environments: beach, dunes, back-barrier marshland, lagoon, and mainland. An old inlet (*left* hand side of the photo) is closed off from the ocean by the beach-dune system (photo: C.W. Finkl).

(mineralogical) composition to provide diversity in the appearance of the world's beaches (Pilkey et al., 2011). There are many examples of the world's best beaches, longest beaches, widest beaches, and so on. In the United States, there are about 650 major public recreational beaches, and they have been ranked annually according to fifty criteria since 1991 to determine the top ten beaches (Leatherman, 1997). A range of selected examples of coasts with the longest beaches in the world include Brazil's Praia do Cassino Beach (over 250 km long), India's Cox's Bazar (about 240 km long), Texas' Padre Island (about 210 km long), Australia's Coorong Beach (194 km), New Zealand's Ninety Mile Beach (each about 145 km long), Mexico's Playa Novillero (about 80 km long), and America's Virginia Beach (about 55 km long). Most beaches are sandy (Figure 3), but very fine-grained (high percentage of silt and clay) beaches may occur under specialized conditions where there is an abundance of fine-grained sediments deposited by wave action, as, for example, along the Red Sea and in the vicinity of large deltas and estuaries such as the Bay of Fundy as well as along the northeast coast of South America (Anthony et al., 2010). Coarse-grained (cobble, boulder) beaches are prevalent in high latitudes and typify many coastal segments in Canada, for example, where glacial materials and bedrock are eroded by coastal processes. Cobble beaches and barriers may also occur along many high-energy coasts, as seen along the west coast of North America. Pilkey (2003) estimates that there are about 2,200 barrier coasts (Figure 3) in the world with about 12 % of all

open-ocean coasts fronted by these islands. About 73 % of barrier islands occur in the Northern Hemisphere, with about 25 % of all barrier islands occurring in the United States (Pilkey, 2003).

Muddy (mangrove, deltas, estuaries, marshes, and tidal flats) coasts

Muddy coasts are defined by the SCOR Working Group 106 as "a sedimentary-morphodynamic type characterized by fine-grained sedimentary deposits – predominantly silts and clays – within a coastal sedimentary environment" (Wang and Healy, 2002). These fine-grained sedimentary coasts contain rather flat surfaces that are usually associated with intertidal flats. The term *muddy coast* encompasses a range of physiographic types, viz., tidal flats, enclosed sheltered bay deposits, estuarine drowned river valley deposits, inner deposits in barrier-enclosed lagoons, supra-tidal (storm surge) deposits, swamp marsh and wetland deposits, chenier plains, mud deposits veneering eroded shore platforms, ice-deposited mud veneer, and subtidal littoral mud deposits. The geographic distribution of muddy coasts is a complicated matter, as indicated above by the wide range of conditions under which fine-grained sediment may accumulate along the shore. The largest expanses of muddy coasts are associated with tropical mangroves (Figure 4) or temperate salt marshes (Figure 5) (Flemming, 2002). Tropical mangrove systems (see Mangrove Coast) occupy about 75 % of the world's coasts between 25°N and 25°S (Chapman, 1974).

Coasts, Figure 4 Muddy coast along the southeast Florida shore where red mangroves (*Rhizophora mangle*) grow in carbonate muds in sheltered coves shoreward of barrier islands and keys (photo: C.W. Finkl).

Coasts, Figure 5 Example of a middle latitude coastal marsh on Cape Cod, Massachusetts, showing a tidal creek in the foreground, marsh grasses in photo center, and fringing upland vegetation in the background. Smaller tidal channels may occur throughout the interior of these salt marshes (photo: C.W. Finkl).

Discussions of the geographic distributions of muddy coasts may be found in Bird and Schwartz (1985), Davies (1980), and Flemming (2002) where regional details are provided. A well-known example of a muddy coast is provided by Anthony et al. (2010) for the 1,500 km-long coast of South America between the Amazon and the Orinoco river mouths where this coast is the world's muddiest. This is due to the huge suspended-sediment discharge of the Amazon River ($10^6 \times 754$ t year^{-1} ± 9 %), part of which is transported alongshore as mudbanks.

Reef coasts

Coral reef coasts (see "Reef Coasts"), which contain some of the largest diversity of life in the world, are sometimes referred to as the rainforest of the sea. The three widely recognized coral reef regions include the Indo-Pacific Region, wider Caribbean (including the Bahamas to the north and northeastern coasts of South America), and the Red Sea. Because of restrictive requirements for the growth of coral reef ecosystems (Figure 6), coral reef coasts occur along much of the Central and South Pacific Ocean as far north as Hawaii and southern Japan. Farther
Coasts, Figure 6 Coral reefs along the eastern shore of Long Island, Bahamas, fronting the Atlantic Ocean. This eolianite coast is bordered by nearshore fringing coral reefs and a series of shore-parallel *en echelon* deeper reefs that stair step into deeper waters, each reef tract is separated by interreefal sand flats (photo: C.W. Finkl).

south, coral reef coasts occur around Taiwan, most of Southeast Asia, the islands of the Philippines, and along coasts of the northern half of the Australian continent. Coasts of Indonesia and eastern Africa also contain reefs.

Coral reefs, the largest biological constructions on Earth, occur in many different forms (e.g., barrier [or shelf reefs], fringing, atolls) making up distinctive coasts. Barrier reefs occur along continental, mainland, and island coasts and are separated (not attached) from the land by a lagoon of 10 m or more water depth. One of the largest examples is the Great Barrier Reef, which stretches more than 2,000 km along the northeastern coast of Australia (offshore Queensland) (Woodroffe, 2002). Additional examples of large barrier-type reef coasts include the Belizean Barrier Reef and the Florida Reef Tract. Barrier reefs may also occur on mid-ocean islands, viz., Moorea in French Polynesia, Tahiti, Fiji Islands, and Bahamian Archipelago. Fringing reefs (Kennedy and Woodroffe, 2002) are associated with mainland coasts where there is shallow water between the reef flat and the land or where they are partly attached to the land as seen at Ningaloo Reef along the coast of Western Australia and in the Caribbean, Red Sea, and elsewhere. Atolls contain an annular or irregular reef around a central lagoon that lies above a submerged volcanic peak.

Ice (Polar) coasts

An ice (bordered) coast (so-called cold coast or high-latitude coast) forms where a glacier extends to the sea. Perhaps the most spectacular examples occur in Antarctica where continental glaciers form a wall of ice that is in direct contact with the water. About one-third of Antarctica's coastline (i.e., 11,000 km) is occupied by ice cliffs at the ocean interface (Walker, 2005). Water-terminating glaciers also occur in the form of mountain glaciers that flow down to the sea in fjords, as seen, for example, in Greenland and in nonpolar tidewater areas such as southern Alaska and Chile as well as Ellesmere, Baffin Island, Bylot Island, and Devon Island. A major characteristic of ice coasts is presence of ice shelves, icebergs, and sea ice.

Coastal zone (management)

The term *coastal* refers to regional mosaics of habitats including intertidal habitats (mangroves, marshes, mud flats, rocky shores, sandy beaches), semi-enclosed bodies of water (estuaries, sounds, bays, fjords, fjards, gulfs, seas), benthic habitats (coral reefs, sea grass beds, kelp forests, hard and soft bottoms), and the open waters of the coastal ocean to the seaward limits of the exclusive economic zone (EEZ), i.e., from the head of the tidal waters to the outer limits of the EEZ (Christian and Mazzilli, 2007). This definition was adopted for the study of large-scale regional change for the Global Observing Systems of the United Nations. Because coastal areas (*q.v.*) are particularly sensitive to global change, sentinel ecosystems are used to evaluate terrestrial, wetland, and freshwater ecosystems along the coast.

The coastal zone or coast areas are terms that attempt to better define *coast*. The point of view here is in relation to the legalities of management. Such definitions are required to provide order to human use of the coast, which can be quite deleterious unless properly managed and constrained in this ecologically sensitive environment. The main considerations of coast in this sense relate to landward and seaward boundaries or jurisdictions, usually based on tidal lines. As pointed out by Quadros and Collier (2008), the rigorous and consistent realization of the line of intersection between a nominated tidal datum and the land mass is notoriously difficult. This difficulty in turn creates spatial uncertainty and the potential for conflict.

The location of seaward boundaries shows great variation between countries due to different sets of criteria: (1) political, legal, or administrative criteria, such as the outward limit of the national territorial sea (e.g., New Zealand, France (implicitly), Spain, Singapore), or the boundary between provincial or state jurisdiction and

Coasts, Table 2 Examples of legal seaward boundaries of the coast as defined by the coastal zone or coastal area (Based on Cullinan, 2006)

Costa Rica	Mean sea-level
India	Low tide line
Israel	500 m from mean low tide
New Zealand	12 nautical miles of the territorial sea
Sri Lanka	2 km seaward from the mean low water line
United States	Limit of the three-nautical-mile territorial sea

Coasts, Table 3 Examples of landward boundaries of coastal areas showing the variability of jurisdictional zones based on arbitrary lines and physical features (Based on Cullinan, 2006)

Costa Rica	200 m from mean high tide
Cuba	Limits for each of 6 coastal types
India	Up to 500 m from the high tide line
New Zealand	Line of the mean high water springs, or where this line crosses a river, the lesser of the point situated at 1 km upstream or the point obtained by multiplying the width of the river mouth by 5
Sri Lanka	300 m inland from the mean high water line and 2 km inland measured perpendicular to the straight baseline between the natural entrance points for rivers, streams, lagoons, or other bodies of water connected to the sea permanently or periodically
United States	Inland from the shorelines (not defined) of states "only to the extent necessary to control shorelands, the uses of which have a direct and significant impact on the coastal waters, and to control those geographical areas which are likely to be affected by or vulnerable to sea-level rise"
	Examples include
	California: variable line depending on the issues (since 1977), formerly highest elevation of nearest mountain
	Washington: 200 ft from mean high water mark for regulation purposes (planning controls extend to the inland boundaries of coastal counties)
	Florida, American Samoa, Guam, Northern Mariana Islands: entire state or territory

national jurisdiction (USA); (2) physical landmarks such as shoreline, continental shelf, tidal marks (Costa Rica and India), and depth or isobaths (e.g., China and Indonesia); and (3) a combination of arbitrary distances and physical marks such as an arbitrary oceanward distance in kilometers from a tidal mark (e.g., Brazil, Israel, Sri Lanka).

As appears from comparisons in Table 2, several national coastal area management laws take as the maximum seaward boundary the outer limit of the nation's territorial sea. This is a logical choice since under international law the coastal state exercises full sovereignty over this area, and in most countries the majority of the productive and extractive activities that have an impact on the coast take place within 12 nautical miles of the coast.

There is less uniformity with respect to the landward boundaries of coastal areas in national legislation than the seaward boundaries, as shown in Table 3. Some researchers favor extending the landward boundary of the coast inland to include areas that are influenced by the sea in an ecological sense. This procedure may include an entire watershed, as was done in California. This approach may make sense from an ecological perspective, but it is too unwieldy as a basis for controlling activities such as construction on the coast. Most ICM (Integrated Coastal Management) legislation thus prefers greater legal certainty by stipulating a specified distance inland from a tidal baseline.

Coastal management is not only important but necessary to control access, use, and exploitation of natural resources. About sixty per cent of the world's population already lives in coastal areas, while 65 per cent of cities with populations above 2.5 million are located along the world's coasts (Agenda 21 Staff, 1992). With overpopulated and overdeveloped coasts, there is an urgent need for better understanding of jurisdictions and effective management for sustainability.

Coast and ocean jurisdictions

For purposes of both international and domestic law, the boundary line dividing the land from the ocean is called the *baseline.* The seaward boundary of the exclusive economic zone (EEZ) extends 200 nautical miles from the baseline (based on United Nations Convention on the

Law of the Sea, UNCLOS). The baseline is determined according to principles described in the 1958 United Nations Convention on the Territorial Sea and the Contiguous Zone and the 1982 United Nations Convention on the Law of the Sea (LOS Convention, also UNCLOS) and is normally the low water line along the coast, as marked on charts officially recognized by the coastal nation. In the United States, the definition has been further refined based on federal court decisions; the US baseline is the mean lower low water line along the coast, as shown on official US nautical charts. The baseline is drawn across river mouths and the opening of bays and along the outer points of complex coastlines. Water bodies inland of the baseline – such as bays, estuaries, rivers, and lakes – are considered "internal waters" subject to national sovereignty (U.S. Commission on Ocean Policy). There are, however, problems associated with the baseline concept due to coastal erosion along unstable coasts. By way of one example, as reported by McGlashan, Duck, and Reid (2008), under British property laws, it is possible that a small area of the upper beach (which regularly changes in shape and size on the foreshore) can be owned by adjacent landowners (technically under their control) despite being regularly inundated by the tides, which normally would be thought of as being owned by the Crown.

Summary

Although coasts account for only 10 % of Earth's land surface, they serve as home to two-thirds of the world's human population. As population density and economic activity in the coastal zone increases, pressures on coastal ecosystems increase. Among the most important pressures are habitat conversion, land cover change, pollutant loads, and introduction of invasive species. It is thus relevant and important to have clear concepts of definitions of coast that can be applied in a range of disciplines.

COBALT-RICH MANGANESE CRUSTS

James R. Hein
U.S. Geological Survey, Santa Cruz, CA, USA

Synonyms

Cobalt crusts; Cobalt-rich crusts; Cobalt-rich ferromanganese crusts; Fe–Mn crusts; Ferromanganese crusts; Iron–manganese crusts; Polymetallic crusts

Definition

Layered manganese oxide and iron oxyhydroxide (ferromanganese) deposits formed from direct and very slow precipitation of minerals from seawater onto hard substrates; crusts contain minor but significant concentrations of cobalt, titanium, nickel, platinum, molybdenum, tellurium, zirconium, and other metallic and rare-earth elements sorbed from seawater by the particulate manganese and iron minerals.

Introduction

The existence of iron (Fe)–manganese (Mn) crusts (Figure 1) has been known for more than a century; however, during early explorations, crusts were not distinguished from manganese nodules. It was not until the early 1980s that a research cruise was dedicated to the investigation of Fe–Mn crusts and their resource potential for cobalt (Halbach et al., 1982). From then until the end of the twentieth century, many research cruises were undertaken to study crusts; Hein et al. (2000) summarized much of that work. Although the initial attraction for crusts was their high cobalt (Co) content, they have also been considered to be a potential ore for nickel (Ni) and Mn. Subsequent work has shown that crusts host large quantities of many critical metals needed for high-tech, green-tech, and energy applications (Hein et al., 2013; Hein and Koschinsky, 2014). In addition, because crusts precipitate from seawater layer by layer over millions of years, and therefore represent condensed stratigraphic sections, they have been used to study changes in the global ocean and climates that occurred over the past 70 Ma (e.g., Frank et al., 1999).

Occurrence and distribution

Fe–Mn crusts form pavements on rock surfaces and coat talus (pebbles and cobbles) throughout the global ocean (from Antarctica to the North Pole) where the seabed was kept clear of sediment for millions of years. The crusts obtain thicknesses up to 260 millimeter (mm) and grow (accrete) at rates of generally 1–5 mm per million years. The maximum thickness of crusts on seamounts increases with increasing age of the seamount. Fe–Mn crusts form at water depths of 400–7,000 meters (m) on the flanks of extinct submarine volcanoes (seamounts, guyots), ridges, and plateaus, although crusts of more economic interest occur at depths of about 800–2,500 m because Ni, Co, and Mo contents are higher and crusts are thicker. More than 100,000 seamounts occur in the global ocean, many within the Exclusive Economic Zone (EEZ) of Pacific Island nations (Figure 2). The same volcanism that formed the islands or volcanic edifices below carbonate islands and atolls also formed the submerged seamounts on which crusts grow. Abundant seamounts also occur in many areas beyond national jurisdictions (Figure 2). Fewer seamounts occur in the Atlantic and Indian Oceans, and Fe–Mn crusts there are commonly associated with oceanic spreading centers. Those crusts commonly obtain
Cobalt-rich Manganese Crusts, Figure 1 Fe–Mn crust photographs: (**a**) cross section of a Fe–Mn crust showing growth layers and substrate basalt, from Gorda Ridge, NE Pacific, 1,512 m water depth. (**b**) Fe–Mn crust collected from a seamount in the Marshall Islands EEZ, NW Pacific, water depth 1,780 m; long dimension is about 1 m. (**c**) Seafloor rocks coated by Fe–Mn crust, Horizon Seamount, Johnston Island EEZ, central Pacific, 2,000 m water depth; about 3×4 m of seabed is displayed.

a contribution of Fe or Mn, mostly to the lowermost layers, from hydrothermal sources associated with the spreading centers; this hydrothermal contribution can dilute the metals in crusts of economic interest. Fe–Mn crusts of economic interest occur distant from hydrothermal sources and from continental margins and thus are not associated with direct volcanic, hydrothermal, or river input. Based on these criteria, coupled with the oldest seamounts occurring in the equatorial NW Pacific, the area of greatest economic interest occurs in the equatorial central-NW Pacific (Figure 2), which is called the prime crust zone (PCZ; Hein et al., 2009).

Formation

Mn oxide ($MnO_2 \cdot xH_2O$) and Fe oxyhydroxide (FeO(OH)) are the dominant minerals that compose Fe–Mn crusts, which precipitate from cold seawater onto rock surfaces, called hydrogenetic precipitation. Seawater is the source of Mn, Fe, and all the metals associated with those main components (Table 1). Elements dissolved in seawater are derived predominantly from the continents via rivers and windblown (eolian) dust. The mineral particles delivered to the ocean by those sources dissolve to various degrees in seawater, and the released elements form ionic

and element complexes in seawater. Another source of elements to seawater is hydrothermal venting that occurs along the 89,000 kilometers (km) of oceanic spreading centers and volcanic arcs. However, the continents are the dominant source for all the elements dissolved in seawater except Mn and Fe, which come from hydrothermal input at oceanic spreading centers. Once the elements are dissolved in seawater, a first-order electrochemical model indicates that positively charged ions will sorb onto the surface of the Mn oxide, which has a strong negative surface charge at seawater pH. In contrast, the negative and neutral element complexes in seawater will sorb onto the slightly positively charged surface of Fe oxyhydroxide (Koschinsky and Hein, 2003). Elements may be weakly sorbed, called outer-sphere sorption, or strongly sorbed, called inner-sphere sorption, where covalent bonds usually form that tightly hold the metals to the main Fe and Mn minerals. Many of the metals that are highly enriched in Fe–Mn crusts are oxidized from a mobile state to an immobile state on the surface of the Fe and Mn minerals after inner-sphere absorption (Hein and Koschinsky, 2014). For example, cobalt (Co^{2+}), cerium (Ce^{3+}), and thallium (Tl^+) oxidize to Co^{3+}, Ce^{4+}, and Tl^{3+}, respectively, on the surface of the Mn oxide, and tellurium

Cobalt-rich Manganese Crusts, Figure 2 Map of global distribution of Exclusive Economic Zones (EEZs, *gray shading*), areas beyond national jurisdictions (*dark black blue* to *pale gray blue*), and global permissive areas for cobalt-rich crust development; the central Pacific prime crust zone (*PCZ*) is the zone of greatest economic interest and is enclosed by a *yellow line*; all other areas are marked with a white line; a permissive area does not mean that economic crust deposits will be found in that area. Small occurrences of crusts will occur in other areas. The equator and 180th parallel are marked by *gray lines*.

(Te^{4+}) and platinum (Pt^{2+}) oxidize to Te^{6+} and Pt^{4+} (e.g., Hein and Koschinsky, 2014). Fe–Mn crusts with slower growth rates also have higher concentrations of metals sorbed onto the main mineral phases. Crusts that form in the oxygen-minimum zone (OMZ) have the slowest growth rates and contain the highest concentrations of metals of economic interest. The OMZ is created by upwelling of nutrient-rich waters along the flanks of seamounts, which promotes productivity in surface waters over the seamounts. As the plankton die and sink through the water column, the organic matter oxidizes and depletes the seawater of oxygen, creating the OMZ. In the central Pacific Ocean, the OMZ commonly occurs from about 500 m to 2,000 m water depths.

Composition

Fe–Mn crusts have a simple mineralogy and are composed predominantly of vernadite (Mn oxide) and noncrystalline Fe oxyhydroxide. They contain minor amounts of detrital minerals such as quartz and feldspar derived from weathering of seabed outcrops and blown by winds from the continents. Older layers of thick crusts contain a phosphate mineral called carbonate fluorapatite, which is a secondary mineral that formed long after the Mn and Fe minerals precipitated from seawater.

Fe and Mn occur in subequal amounts (Fe/Mn ~0.7–1.4) in Fe–Mn crusts, and Co, the trace metal of most economic interest, can be up to 2 % but usually averages 0.33–0.67 % by weight (0.1 % = 1,000 parts per million, ppm) for large areas of the global ocean (Table 1); for smaller mine-site size areas (500 km^2), Co can average 0.8 %. Fe–Mn crusts have the highest concentrations of Te compared to other rock types (global mean about 50 ppm); Te is a rare metal that is needed by the solar-cell industry for thin-film photovoltaics and is the best material for converting sunlight into electricity. Fe–Mn crusts are also significantly enriched in bismuth (Bi), molybdenum (Mo), niobium (Nb), nickel (Ni), platinum (Pt),

TREE	2,402	20–43	2,541	12–21	2,454	89–300	1,634	17–75	2,352	115

Modified from Hein et al. (2013) and Hein and Koschinsky (2014)
TREE total rare-earth elements including yttrium

thallium (Tl), thorium (Th), titanium (Ti), vanadium (V), tungsten (W), zinc (Zn), zirconium (Zr), and total rare-earth elements plus yttrium (TREE + Y; Table 1) relative to their average contents in the Earth's lithosphere and in seawater. Thorium is one of the few elements that is more abundant in the Atlantic and Indian Ocean crusts than in PCZ Pacific crusts. On average, Fe–Mn crusts have three times more Co, 10 times more Te, three times more TREEs, and 3–14 times more Pt than manganese nodules. In contrast, nodules contain more Ni and copper (Cu) and significantly more lithium (Li) than crusts, whereas both have about equal amounts of Mo.

Paleoceanography

Growth rates and ages of Fe–Mn crusts were first determined using uranium (U)-series isotope and beryllium (Be) isotope ratios. These two techniques provide reliable ages but are limited by the thickness of crust that they can date, the outer ~2 mm (<500,000 years) using U-series and the outer ~20 mm (<12 Ma) using Be isotopes. Extrapolation of those ages to the base of thicker crusts can result in large errors because of potential changes in growth rates. A new technique compares Fe–Mn crust osmium (Os) isotope ratios to those that define a Cenozoic seawater curve; crusts as old at 70 Ma have been dated using Os isotopes (Klemm et al., 2005). Two

other techniques that have been employed successfully include nannofossil biostratigraphy and paleomagnetic stratigraphy, but both require lengthy sample preparations. In addition, several empirical equations have been developed that estimate growth rates and therefore ages of crusts and can be used if the more accurate isotopic techniques are not available.

Because Fe–Mn crusts occur throughout the ocean basins at a wide range of water depths, they are ideal for paleoceanographic studies. Textural and geochemical changes in Fe–Mn crusts have been related to the history of seamount subsidence, plate tectonic migration of seamounts, primary productivity, changes in the equator-to-pole thermal gradient and associated ocean mixing, and the extent and intensity of the OMZ, among others. Based on temporal changes in trace-metal isotope distributions (such as lead (Pb), neodymium (Nd), hafnium (Hf), and Be), Fe–Mn crusts have been used to reconstruct past circulation patterns of the oceans and erosion rates of the continents on timescales of millions of years (e.g., Frank et al., 1999). Because these elements reflect different sources and different residence times in seawater, they complement each other as tracers of paleoceanographic events for the past 70 Ma. Other metal isotopes in Fe–Mn crusts that have come into play more recently for paleoceanographic studies include Tl, Mo, Fe, and cadmium (Cd).

Resource consideration

A wide array of trace metals (Co, Ni, Ti, Cu), rare metals (Te, Pt, Zr, Nb, W, Bi, Mo, Tl, Th, V), and REEs are sorbed in large quantities onto the Mn and Fe oxides making crusts a potential resource for many metals used in emerging high-tech, green-tech, and energy applications. Such high concentrations of metals are sorbed because of the very slow growth rates, extreme specific surface area (average 325 m^2/cm^3 of crust), and high porosity (average 60 %) of crusts (Hein et al., 2000). The tonnage of Fe–Mn crusts in most areas of the global ocean is poorly known. However, a rough estimate for the PCZ area is about 7,533 million dry tonnes (Hein and Koschinsky, 2014). Using this tonnage estimate, Fe–Mn crusts in the PCZ are calculated to contain about four times more Co, three and a half times more Y, and an incredible nine times more Te than the entire land-based reserve base for those metals; these crusts also contain half the Bi and a third of the Mn that make up the entire land-based reserve base (Hein et al., 2013). The reserve base is defined as land-based deposits that are currently economically viable (reserves), marginally economic, and subeconomic.

There are two technological challenges to overcome before Fe–Mn crust mining can become viable. A deep-towed or autonomous underwater vehicle-mounted instrument must be developed that can measure Fe–Mn crust thicknesses in situ in real time. This measurement gives the tonnage of crusts per square meter of seabed. This is a difficult challenge because there are a great variety of rocks on which crusts grow that have variable physical properties, many of which overlap with those of the crusts. The second technological challenge is developing a mining tool that can remove the Fe–Mn crust from the substrate rock without collecting any substrate rock, to which crusts can be attached tightly to weakly. That separation of crust from substrate will have to be done on an uneven and commonly rough seabed. These challenges will require significant engineering innovations.

Summary

Fe–Mn crusts grow on nearly all rocks exposed at the seabed throughout the global ocean where sediment does not accumulate. Crusts are composed predominantly of Fe and Mn oxide minerals that precipitate from cold seawater and acquire abundant metals and other elements by sorption from seawater. Metals essential to many emerging technologies are enriched in crusts to the extent that they are considered a potential resource for mining in the near future. Four contracts for exploration for crusts have been taken out with the International Seabed Authority, one each by Japan, China, Russia, and Brazil. Fe–Mn crusts also have a unique potential as recorders of oceanographic events that have occurred over the past 70 Ma.

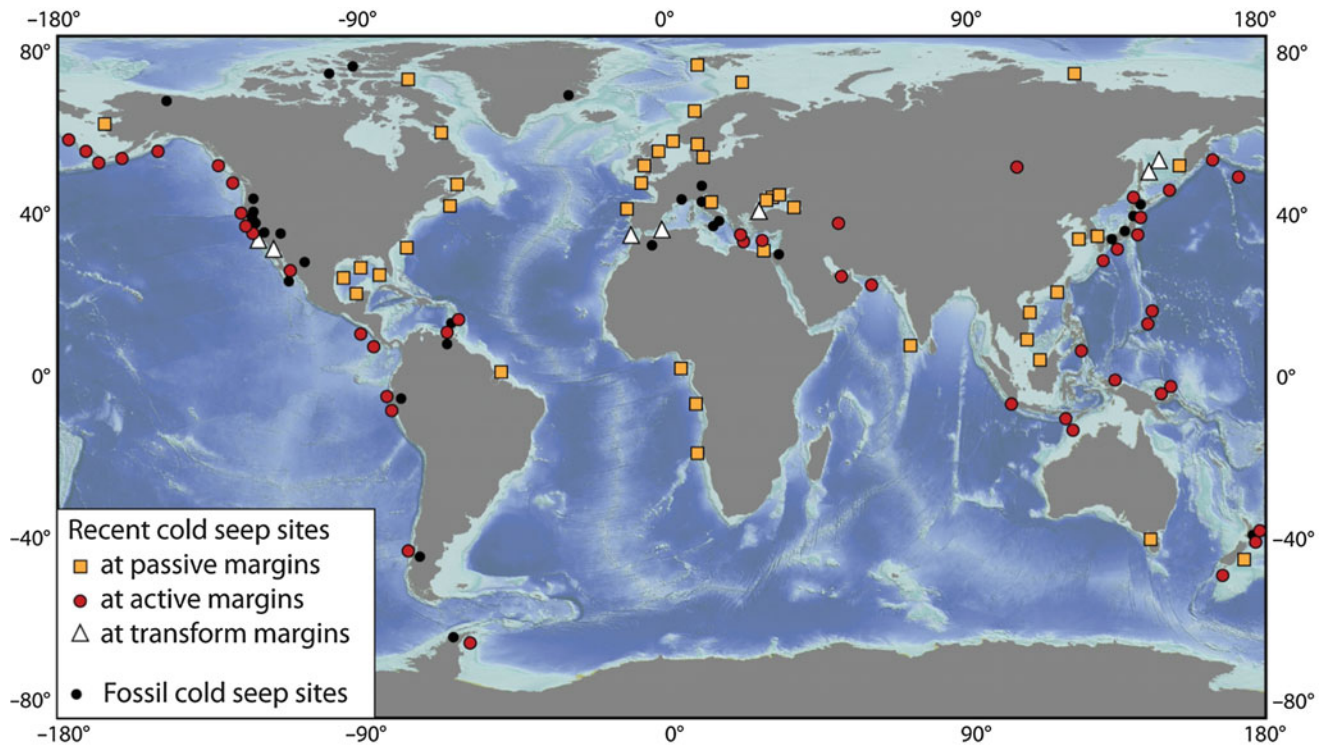
Cold vents; Methane seeps


Cold Seeps, Figure 1 Seep locations at active (recent) locations at passive (*orange squares*) and active (*red circles*) margin sites. Locations along transform faults are denoted by white triangles. Fossil sites are shown by black circles. Seep locations based on compilations from Suess (2010), Campbell (2006) and Römer (2011).

Definition

Cold seepage denotes the emission at the seafloor of deep-sourced fluids enriched in methane and hydrogen sulfide, which support a characteristic biome based on chemosynthetic organisms.

Basic process

Oxygen enters the ocean surface water through contact with the atmosphere. From there, dissolved oxygen is brought to greater depths by sinking and circulation of water masses, so that in the majority of the deep oceans, there is enough oxygen to support aerobic decomposition of organic matter. Against this well-oxygenated hydrosphere, discrete locations on the seafloor experience localized discharge of highly reducing fluids from the underlying sediments and igneous crust. Along continental margins, methane emanates from the sediments at locations known as cold seeps (Figure 1).

At some of the cold seeps, methane emission rates exceed mid-ocean ridge values by more than an order of magnitude. Methane plumes are such a characteristic feature of cold seep areas that dissolved methane in the water column was originally used to prospect for cold seep activity (Heeschen et al., 2005). Acoustic imaging techniques have also been used to identify locations of macroseepage, where methane concentration is so large that it exceeds its solubility and bubble plumes can be observed emanating out of the seafloor (Figure 2). Recent acoustic surveys have led to the discovery and detailed mapping of methane gas plumes along continental margins worldwide (e.g., Westbrook et al., 2009; Faure et al., 2010; Römer et al., 2012).

Source, transport, and fate of methane
Sources

Within continental margin sediments, rapid burial of organic matter tied to a limited supply of oxygen from the overlying seawater results in the development of highly reducing environments that favor methane generation by a group of microorganisms called methanogens (see review by Valentine, 2011). Deeper in the sediment, thermal alteration of organic matter generates methane and higher hydrocarbons within the temperature range of 80–200 °C, which typically occur at burial depths greater than 2 km. The combined action of these two processes leads to high levels of methane, which at high-pressure and low-temperature conditions will combine with water to form a solid structure known as gas hydrates (Sloan and Koh, 2008). Because of the pressure, temperature, and methane concentration needed to form gas hydrate, these deposits are commonly found in continental margin sediments at depths larger than 350 m and are stable to a few hundred of meters in the sediment column, depending on the attendant geothermal gradient.
Cold Seeps, Figure 2 Schematic representation of cold seeps, showing methane generation in the sediments, transport and discharge at the seafloor. Carbonate and barite deposits form at cold seeps. The reducing fluids rich in methane and hydrogen sulfide support complex biomes that include microbial mats, chemosynthetic bivalves and macrofauna. *Arrows* denote relative magnitude of upward methane flux.

Transport

Sediments in continental margins are hydrologically active, but the processes that drive fluid flow vary depending on the tectonic and geologic characteristics of each site (Figure 1).

Convergent margins – The best-studied cold seeps to date are located along margins where continental and oceanic plates converge, such as those found landward of the subduction trenches that rim the Pacific Ocean. Cold seeps in these settings were first reported in the early 1980s by LaVerne Kulm and Erwin Suess along the Oregon-Washington coast (Kulm et al., 1986). To date, cold seepage has been widely studied from Alaska to southern Chile in the Eastern Pacific margin, with similar level of research targeting seeps along the western Pacific offshore Russia, Japan, and New Zealand as well as the Mediterranean and Black Seas. Additional seeps have been reported along convergent margins offshore Makran, Indonesia, and Colombia (review in Suess, 2010).

Pore fluids in the sediments account for as much as 50–70 % of their volume, and these fluids are squeezed out from the sediment by the lateral compression of plate movement. As porosity decreases, the rate of compaction-driven dewatering decreases, and thus water contribution from intergranular and fracture porosity is generally largest within the first ~3–7 km of burial (see review by Saffer and Tobin, 2011). With increasing burial, water is released from hydrous minerals. Common in these systems is the smectite to illite conversion, which occurs at temperatures ranging from 60°C to 200 °C (Colten-Bradley, 1987). Fluid flow in convergent margins appears to control seismogenic behavior, and the extensive research targeting the processes involved in fluid generation has revealed that at ~10–40 km from the trench, fluid sources from smectite and, to a lesser extent, opal dehydration overtake those generated from compaction (Saffer and Tobin, 2011). The excess water accumulates in the pore space, where it creates overpressures that drive flow toward the seafloor. Whether dewatering occurs by compaction, dehydration, or a combination of these processes, water in convergent margins migrates from deep horizons through high-permeability zones such as faults, fractures, or coarse-grained sediment layers.

When methane accumulates as a gas, it can also generate fractures in response to gas overpressures. Gas migration through gas-induced hydrofracture networks or via structural (e.g., faults) and lithologic (e.g., sand horizons) pathways has been documented through acoustic imaging in seismic profiles and by analyses of sediment cores collected under in situ pressure (e.g., Tréhu et al., 2004; Torres et al., 2011).

In *transform margins*, such as the one generated by the lateral movement between the Pacific and the North American plates along the San Andreas fault zone, thick sediment sequences may be exposed by the sideways plate motion along the fault planes (Legg et al., 1989). These cold seeps have received less attention than those in convergent or passive margins. However, a good example of transform-margin seeps is those found along the San Clemente fault, approximately 100 km southwest of San Diego (Torres et al., 2002).

In this transform margin, the turbidite sand layers of the Navy Fan deposits support migration of subsurface fluids, which vent at the locations where the sediment package is cut by fault-induced escarpments. Both methane anomalies in the water column, as well as the presence of chemosynthetic organisms along the fault traces, delineate the zones of active methane venting. Fluid flow in these settings is driven primarily by the development of a hydraulic head and the presence of high-permeability pathways, similar to conditions that drive groundwater flow commonly studied in onshore and offshore aquifers (Torres et al., 2002).

Passive margins are those not marked by a strike-slip fault or a subduction zone. They occur around the Atlantic, Arctic, and western Indian Oceans and define the entire coasts of Africa, Greenland, northern Europe, and Australia. Because of their extensive distribution, the nature of the seeping fluids and mechanisms that control flow are quite large. Mass transport, which is common in these margins, provides an overriding compressional component to the normal faulting regime typical of passive-margin tectonics. In addition, dehydration reactions and gas generation all create overpressures that drive flow. Flow is channeled along highly permeable lithologies, such as ash layers and turbidite sands through normal faulting.

The first cold seep on a passive margin was discovered by Charles Paull along the Florida Escarpment (Paull et al., 1992). Here, groundwater migrates through carbonate aquifers and discharges in the Gulf of Mexico at a depth of 3,200 m. Since then a large number of seep localities have been identified on the northern margin of the gulf. Fluid flow is associated with salt dome intrusions within these (>10 km) thick sediment packages, from which the thermogenic oil and gas accumulations are currently targeted for oil and gas production. In this margin, migration conduits supply hydrocarbon materials that migrate ~6–8 km toward the sediment surface. More recently, cold seeps were discovered along the Mexican margin of the gulf, which are characterized by the presence of thick oil coatings and lavalike asphalt flow structures on the seafloor (McDonald et al., 2004).

Because of the thermogenic nature of these seeps, it is possible to image the naturally created oil slicks at the sea surface, using satellite data. Ian MacDonald and collaborators have analyzed images from space that reveal the presence of oil slicks across the north-central Gulf of Mexico in water depths greater than 1,000 m (McDonald et al., 2000).

Fate of methane and cold seep biomes

If all methane out of the sedimentary reservoir were to reach the atmosphere, this could have significant impact on the Earth's climate, because methane is a strong greenhouse gas. Fortunately, microorganisms consume a very large fraction of the sedimentary methane under anaerobic conditions. If released to the water column, methane is further consumed by aerobic methane oxidation. This combined microbial filter, reviewed by William Reeburgh (2007), is key in regulating methane flux from the sediments to the ocean and potentially the atmosphere.

Within the sediments, a metabolic pathway whereby methane was oxidized by sulfate was originally proposed based on the chemical composition of the pore water (Reeburgh, 1976; Barnes and Goldberg, 1976). This postulate was later confirmed by observations of a microbial consortium that oxidizes methane to bicarbonate while reducing sulfate to hydrogen sulfide (Boetius and Suess, 2004). The hydrogen sulfide generated in this process rises with the ascending fluids to the seafloor, where it is metabolized by *Beggiato*a that aggregate forming the bacterial mats typically found at cold seeps (Figure 2). In these complex ecosystems, there are multiple interactions between microbes and macrobiota that involve symbiosis, heterotrophic nutrition, and geochemical feedbacks. Bivalves (*mytilids, vesicomyids, lucinids,* and *thyasirids*) are nourished by symbiotic bacteria that derive their energy from methane and hydrogen sulfide, and constitute prominent members of cold seep fauna. *Vestimentiferan* tube worms, also common at cold seep locations, extract hydrogen sulfide through their roots, which is also metabolized by symbionts. *Pogonophorans, cladorhizid* sponges, gastropods, shrimp, and crabs are also abundant at some locations (Levin, 2005).

Authigenic minerals

In addition to hosting unique communities, chemical reactions between the highly reduced seeping fluids and the oxidant-rich seawater lead to precipitation of characteristic authigenic minerals. Calcium carbonate ($CaCO_3$) is formed as a by-product of methane oxidation, which provides a bicarbonate source characterized by enrichment in ^{12}C. These methane-derived carbonates are ubiquitous near cold vent sites throughout the globe and constitute a significant carbon sink. The dominant mineral phases are aragonite and high-magnesium calcite (Bohrmann et al., 1998).

Microbially mediated carbonate formations have been observed to rise above the seafloor by up to 90 m in height. In the Cascadia margin, for example, carbonate chemoherms display a pinnacle-shaped morphology with steep flanks and are known to have been active for at least 270 ky (Teichert et al., 2005). Their irregular structure and high porosity reflect vigorous outflow of methane-rich fluids. In anoxic bottom waters, such as those found in the Black Sea, microbial consortia fed by methane bubble emissions at the seafloor support the buildup of towerlike

carbonate structures several meters in height. Other locations of extensive authigenic carbonate formation are found offshore Costa Rica, South China Sea, New Zealand, and in the Gulf of Cadiz (reviewed by Suess, 2010).

Although not as common as the carbonate occurrences, barite ($BaSO_4$) deposits have been observed along structurally controlled sites of cold-fluid seepage in several continental margins. Barite pillars along the San Clemente fault can reach 10 m in height, and similar deposits have been reported on the Sea of Okhotsk. Less massive but distinct barite occurrences have also been reported in the Alaska margin, Monterey Canyon, Peru margin, and the Gulf of Mexico (Torres et al., 2003). The formation of these deposits is intimately linked with the sulfate concentrations, which in the highly reduced environments that characterize cold seeps is depleted at shallow depths within the sediments. At low sulfate, any barite in the sediment will dissolve, leading to high levels of dissolved barium in the upwardly migrating fluids. Upon discharging at the seafloor, barium quickly reacts with seawater sulfate and precipitates in the newly formed barite deposits.

Paleoseeps

The occurrence of carbonates in the geologic record enriched in the light ^{12}C isotope has been commonly attributed to authigenic formation at paleo-methane seeps, which indicate significant methane release from the Proterozoic to the present (Campbell, 2006). The cold seep barite deposits likely constitute the modern analogues to Paleozoic stratiform barite deposits, now being mined in Nevada, Arkansas, Mexico, and South China. These barite deposits represent large-scale submarine methane venting, which could have affected the Paleozoic carbon cycle and perhaps modified ancient climate (Torres et al., 2003).

Summary

Along the ocean margins, sediments experience chemical, microbial, and physical transformations that result in the generation and expulsion of reduced gases and water at the seafloor, in what is known as cold seepage.

Methane is generated by microbial or thermochemical processes in the organic-rich marine sediments. Hydrogen sulfide is a by-product of microbial oxidation of methane under anaerobic conditions. Water is produced at greater depths by dehydration reactions of smectite and to a lesser extent opal. Accumulation of the excess water and gas creates overpressures that can fracture the overlying geological formations and drive fluid flow. Sediment compaction, generation of hydraulic heads, and tectonic compression also act as driving forces for fluids that eventually discharge at the seafloor.

Whereas the majority of life in the deep ocean floor rely upon low levels of sinking organic matter, the chemosynthetic microbial communities at cold seeps take advantage of high fluxes of bioreactive reductants to support unique, oasis-type cold seep biomes in which the density of organisms is several orders of magnitude greater than in the surrounding regions. Authigenic carbonate and barite deposits, which can reach extremely large accumulations, characterize areas of cold seepage and constitute a geologic record of methane discharge at paleo-seep sites.

CONTINENTAL RISE

William W. Hay
Department of Geological Sciences, University of
Colorado at Boulder, Estes Park, CO, USA

Definition

The continental rise is the gently inclined slope between the base of the continental slope and the deep ocean floor.

The expression "continental rise" was first used by Bruce Heezen and Maurice Ewing in their account of the effects of the 1929 Grand Banks earthquake. It was formally defined in 1959 by Heezen et al. in GSA Special Paper 65. The Floors of the Ocean: I, The North Atlantic: "Since we have limited the continental slope to gradients greater than 1:40, we split off this lower portion of the continental margin into a separate province, the continental rise" (p. 19).

In many areas, local morphologic features interfere with the general slopes so that neither the upper nor lower limits of the continental rise are well defined (Figure 1).

The geologic basis for the continental rise

The concept of the continental rise arose in the classic passive margin region of the western North Atlantic. There the continental rise overlies the ocean crust bordering the faulted and fractured continental margin. It is the site where sediment shed from the continent into the deep sea accumulates.

Along active margins where ocean crust is being subducted beneath continental crust, the margin is often marked by an ocean trench; there is no continental rise. However in some areas where there is a great thickness of sediment on the ocean floor entering the subduction zone, or where the supply of sediment from the continent into the subduction zone completely fills the trench, a narrow continental rise may develop.

What controls the configuration of the continental rise

Nature of the crust

Where the continents have broken up, in the Atlantic, Indian, and Arctic oceans, the continental rise overlies the oldest ocean crust. Because the ocean crust subsides with age, this is the region where the differences in elevation between continental and ocean crust are maximal.

Detrital sediment supply

The continental rise is the ultimate site of deposition of sediment eroded off the continents. The current rate of detrital sediment eroded from land and delivered to the sea is estimated to be about 24×10^{12} kg/year. However, the continental shelves can only accommodate about 10 % of this load at high sea-level stands and almost none at sea-level lowstands. This means that most of the detrital sediment load must be passed on to the continental slope, where again accommodation space is very limited, and to the deep sea. The continental rise represents the site of accumulation of most of the sediment eroded off the continental blocks. These conditions have changed over time. The amount of material eroded off the continental blocks depends on topographic relief and changing climatic conditions. The amount of sediment that can accumulate on shelves has decreased with time as subsidence of the shelf areas has slowed. Major erosion of the continental shelves has occurred since the lowering of sea levels associated
Continental Rise, Figure 1 Heezen and Ewing's (1952) diagram of the continental margin off the Grand Banks, showing the times of cable breaks after the 1929 earthquake and debris flow and turbidity current velocities.

with the buildup of Antarctic and then northern hemisphere ice sheets since the end of the Eocene. Once deposited on the continental rise, there is no place else to go for the sediment except further out onto the abyssal plains.

Detrital sediment reaches the continental rise by three mechanisms. First is simply settling through the water column. The oceanic frontal systems separating the brown turbid waters of the continental shelves from the blue waters of the open ocean generally prevent riverine-suspended sediment from being fed into the surface ocean. However, the supply of dust from land is also large, and this settles into the ocean and becomes a part of the rain of pelagic sediment to the deep sea. There is no special supply of dust to the continental rise.

The second mechanism is through turbidity currents. Fresh riverine waters with a significant suspended sediment load have a density greater than seawater and can flow across the shelf and down onto the slope and rise as turbidity currents. Because the density of seawater increases with the depth of these turbidity currents, upon reaching seawater of equal density the turbid flow may mix with the seawater or flow out on a density surface.

The third mechanism is through failures of the sediments of the continental slope as slumps or catastrophic slides into the deep sea. Gradual slumping appears to be a common process where there is a large sediment supply to a steep slope. Landslides from the slope to the deep sea are much more common than had originally been thought. They seem to occur especially in regions where gas clathrates that acted as cement stabilizing the slope decompose as warming of the waters occurs, as during glacial terminations (Bryn et al., 2006). The usual triggering mechanism is thought to be earthquakes, but large storms may also be a cause. Probably half of the sediment in the continental rise reached its present location through mass movements.

The classic study was that of the Grand Banks' Earthquake of 1929 by Heezen and Ewing. Because the slide and subsequent turbidity current cut submarine telegraph cables, their velocities down the continental rise are known, ranging from 50 to 10 knots ($=25.7–10.1$ m/s).

Finally, ocean bottom currents redistribute the sediments of the continental rise.

Carbonate deposition

Carbonate deposition onto the continental rises occurs in two ways. First, the production of shallow water carbonate on banks and atolls far exceeds the rate at which it can be accommodated through subsidence. Most of it is swept off into the deep sea during major storms. Much of that is dissolved by the corrosive waters of the deep sea, but because it may be delivered in large quantities in very short intervals of time, it can accumulate along bank margins (e.g., Bahamas, Maldives). The second source is the rain of carbonate from calcareous nannoplankton, planktonic foraminifera, and pteropods that occurs throughout the oceans. This can be incorporated into the continental rise sediments above the compensation depths for the different mineral phases. The proportions of detrital sediment and pelagic carbonate are an important clue to the relative rates of accumulation from these two sources.

Currents

Originally thought to be a region of very quiet water, the deep sea has been found to be the site of many active currents. Most of these are directly associated with the formation of dense waters that sink into the ocean depths and are redistributed throughout the ocean basins. Their velocities are typically in the range of 0.5–5 cm/s. Flows with the

higher velocities can transport and even erode unconsolidated sediment.

Sea-level

The lowering of sea-level associated with the buildup of Oligocene and Neogene ice sheets has caused erosion of a very large amount of material off the continental shelves and ultimately deposited on the continental rises.

Summary

The continental rise is the gently inclined slope between the base of the continental slope and the deep ocean floor. It overlies the ocean crust bordering the faulted and fractured continental margin. It is the ultimate site of accumulation of sediment shed from the continent into the deep sea. A small amount of sediment reaches the continental rise by settling through the water column. Much of the detrital sediment is brought down by turbidity currents, but a very large amount of the material is delivered through failures of the sediments of the continental slope descending as slumps or catastrophic slides. Deep sea bottom currents move and redistribute the sediments of the continental rise. Sea-level fluctuations associated with the buildup of ice sheets have caused a very large amount of material from the continental shelves and slopes to be deposited on the continental rises.

CONTINENTAL SLOPE

William W. Hay
Department of Geological Sciences, University of Colorado at Boulder, Estes Park, CO, USA

Definition

The first use of the term "slope," referring to the edge of the continental block, appears to have been by Rollin D. Salisbury in his book *Physiography,* published in 1907. "The continental platforms and the ocean basins are topographic features of the first order. The contrast between them is emphasized by the fact that there is almost everywhere a rather steep slope from the one to the other, — a steep descent from the continental platforms to the ocean basins, or looked at from the other point of view, a steep ascent from the ocean basins to the continental platforms" (pp. 5–6). Later in the book, he presented the idea that the junction of the continent and the ocean basin was bordered by a belt that represented a concave-upward part of the seafloor "100–300 miles wide" as indicated in Figure 681: *Map of the world showing in black the portions of the sea bottom which are concave upwards.* The term "continental slope" only appears in the book's index. Although it was obvious Salisbury considered the top of the continental slope to be demarcated by the shelf break, a lower boundary was defined by Heezen et al. (1959) as the point at which the gradient becomes less the 1:40 (about 1°25').

History

The discovery of the continental slope goes back to the time of laying the first telegraph cables across the Atlantic (see SHELF), but the detailed bathymetry of continental margins did not become known until after World War II when the United States and USSR began to make extensive measurements of the seafloor depth using SONAR (Doel et al., 2006).

The geologic basis for the continental slope

It was recognized in the late nineteenth century that the margins between the continents and ocean basins were a fundamental geologic boundary, and in the twentieth century, it became evident that this was due to a fundamental difference between the rocks forming the floors of the continental blocks and ocean basins. However, it was not until the development of the theory of plate tectonics that the nature of the slope became fully understood. There are two kinds of continental slope, one associated with passive continental margins, the other with active margins.

On passive margins, the continental slope overlies the region where the continental margin was thinned by faulting during the process of continental breakup. Along active margins, the continental slope marks the boundary between a subducting oceanic plate and the continental crust on the overriding plate. In some instances, the subducting oceanic plate is physically eroding the continental crust.

What controls the configuration of the continental slope
Crustal thinning

Along classic passive margins, it is the original width of thinning of continental crust by faulting and intrusion of ocean margin basalts, an area with a width typically of 100–300 km. Where the margin coincided with a transform fault, as on the E-W Guinea margin of West Africa, the continental slope can be very narrow and abrupt. Along active margins, where the continent is bordered

by an oceanic trench, the edge of the continent may be undergoing abrasion, and the slope may be very steep.

Detrital sediment supply

As the available accommodation space on the shelf is reduced, detrital sediment may accumulate on the continental slope. Although initially unconsolidated, it may be held in place by the cementing effect of gas hydrates, especially where significant amounts of organic carbon are present. However, sea-level fluctuations and currents may destabilize slope sediments and landslide scars are common.

Carbonate deposition

The production of carbonate occurs in shallow water, but even minor sea-level fluctuations will expose the original aragonitic sediment to fresh water and cause its conversion to well-cemented calcite or dolomite. As crustal subsidence occurs, carbonate banks may build upward very rapidly, and the marginal slopes may be almost vertical.

Waves

Today, other than tsunamis, wave action has little effect on slope deposits as they are below wave base of even long swell. However, during glacial sea-level lowstands, when the ocean surface was near the shelf breaks, waves actively eroded the upper part of the continental slope.

Currents

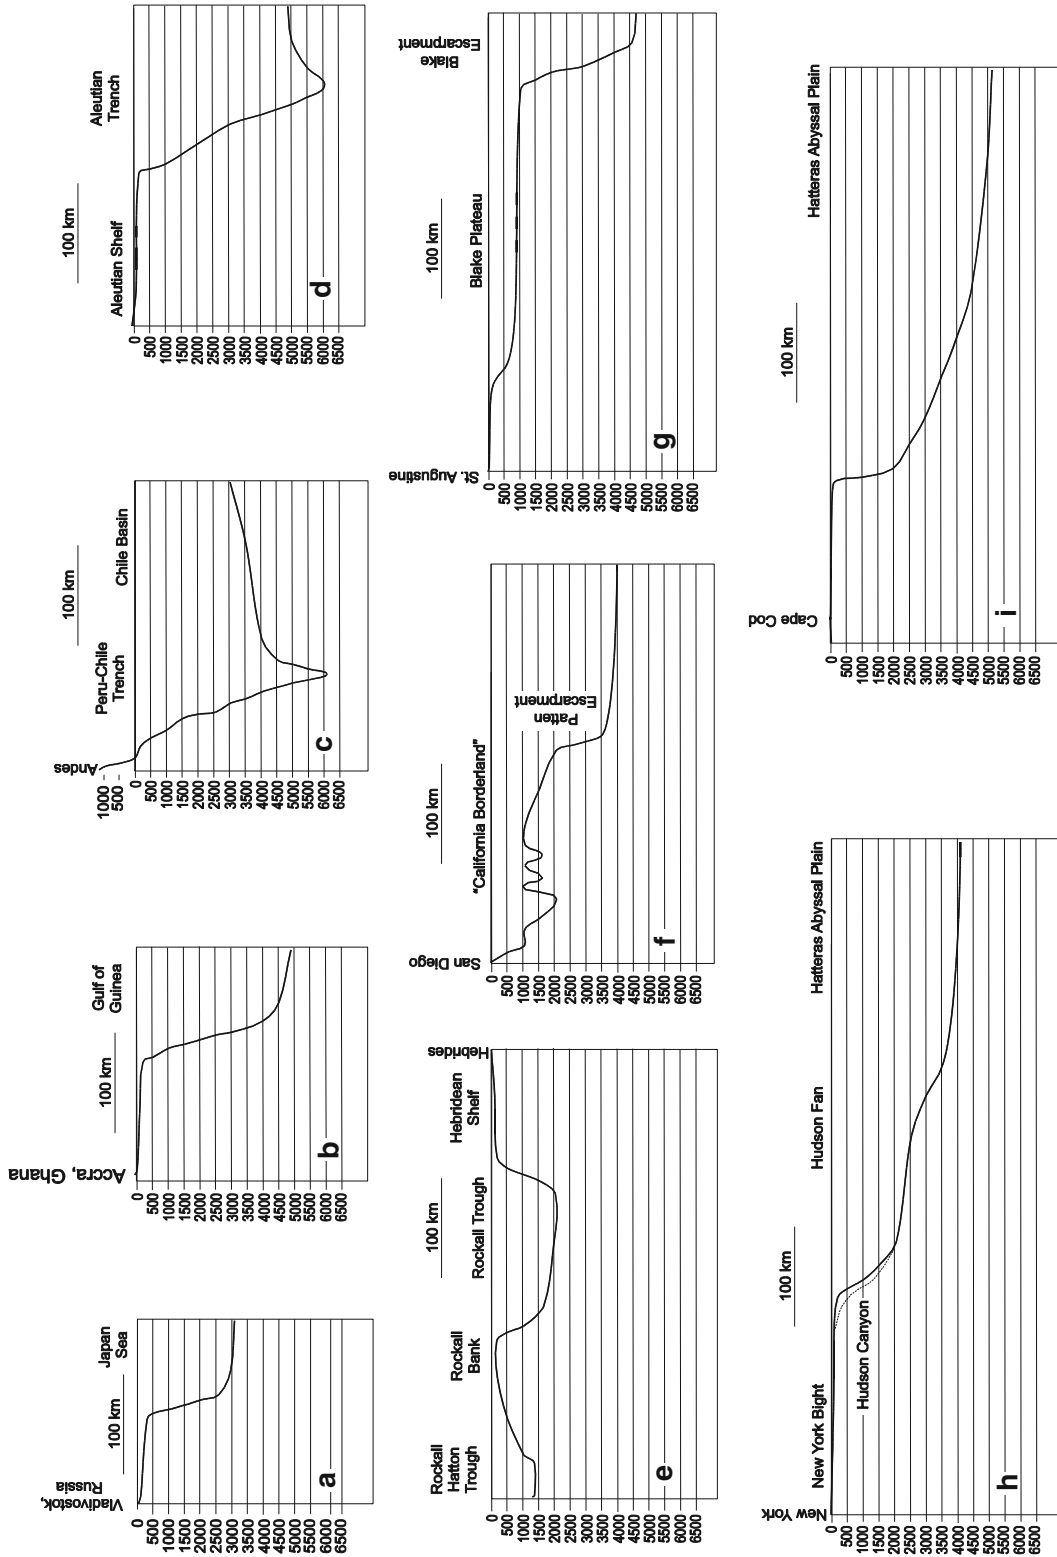
Many continental slopes are sculpted by contour currents flowing along them. These currents have velocities of up to 40 cm/s and can easily erode and move sediment. They generally flow in a direction opposite to the surface gyres. Along the western margins of the ocean basins, the currents of the tropical-subtropical surface gyres (e.g., Gulf Stream, Kuroshio) are narrow and deep and can sculpt the upper parts of the continental slopes.

Sea-level

The large sea-level fluctuations associated with the development of high latitude ice sheets lowers the surface of the ocean to the top of the continental slope. During lowstands, rivers may cut into the edge of the continental shelf and carve canyons in the upper part of the continental slope. Their turbid waters can then flow down the slope and their sediment load deposited on the lower slope and continental rise.

Mass wasting

In many areas the continental slope is at the maximum angle of repose for sediments, and very large mass wasting events often triggered by earthquakes can occur. One of the largest was the three Storegga Slides on the Norwegian margin (Bondevik et al., 2005; Haflidason et al., 2005). Their heads were at the edge of the continental shelf (Storegga is Norwegian for "the Great Edge"). The landslides occurred along 290 km of the continental margin

with an estimated volume of 3,500 km^3 of debris. The last of the slides occurred about 6,100 BCE and generated a large tsunami, over 20 m high in Northern Scotland.


Continental slope profiles

While the continental slope forms the steeper part of the transition from the shelf to the ocean basin, the profiles differ greatly from place to place as shown in Figures 1 and 2.

Figure 1a shows the steep slope south of Vladivostok into the Japan Sea which occupies a pull-apart basin behind the Japanese archipelago. Figure 1b shows one of the steepest slopes along the edge of a continent, near Accra, Ghana, where the continent-ocean transition is along a transform fault. Figures 1c and d show two very tall, steep continental slopes on active margins associated with oceanic trenches. Figure 1c shows that on the western South American margin at 25°S, from the Andes into the Peru-Chile Trench; note that a continental shelf is lacking. Figure 1d shows the transition from the eastern Aleutians across a shelf into the Aleutian trench. Figure 1e is an E-W section from the Hebrides across the shelf with a slope into Rockall Trough and then up again onto Rockall Bank, a continental fragment. This is the area in which the term "continental shelf" was first used. Figures 1f and g show two continental margins with "borderlands." Figure 1f shows the complex bathymetry of the Southern California Borderland with ridges and basins terminating oceanward in a steep escarpment. Figure 1g is an E-W section off northern Florida showing the transition from the shelf down a slope onto the broad Blake Plateau and finally down a steep slope into the western Atlantic Basin. Figures 1h and i are profiles along the classic passive margin of the northeastern United States. Figure 1h is a NW-SE transect from Cape Cod into the deep Atlantic with a very steep upper slope and a classic concave-upward lower slope and rise. It is evident that there is no distinctive morphological feature that separates the slope from the rise. Figure 1i shows the broad shelf of the New York Bight, the slope, the Hudson Submarine Fan, and the transition onto the Hatteras Abyssal Plain. The trace of the Hudson Canyon is indicated by a dashed line.

Figure 2a shows a typical Antarctic profile, with a broad deep shelf generally sloping toward the ice-laden continent, and a relatively gentle slope into the deep ocean. Figure 2b is an W-E section from the Gulf of Mexico across south Florida to the Great Bahama Bank, all carbonate terrains. Off western Florida, the shelf is very broad and ends at a steep escarpment into the depths of the Gulf of Mexico basin. The shelf off Miami is very narrow, and the slope down into the Florida Strait is interrupted by the Pourtalés Terrace. The slope up to the Bahama Banks is almost vertical and swept clean of sediment by the Florida Current/Gulf Stream.

Figure 2c shows the transition from continent to ocean basin along an N-S section from the Ganges-Brahmaputra Delta into the Bay of Bengal. This is the most gradual

Continental Slope, Figure 1 Continental slope profiles on active and passive margins based on GEBCO (1984) charts.
Continental Slope, Figure 2 Profiles of some unusual continental margins based on GEBCO (1984) charts.

transition on Earth, reflecting the huge supply of sediment from the erosion of the Himalaya. The trace of the canyon cut during sea-level lowstands is indicated as a dashed line.

Summary

The continental slope is the steep part of the transition from continent to ocean basin. However, the form of the transition is highly variable from place to place. The "classic" transition is that of the passive continental margin off the northeastern border of the United States, with a steep slope starting at the shelf break and a concave-upward profile. Continental slopes on active margins may descend directly from the shoreline into an oceanic trench. The complexity of the continental breakup process has resulted in a variety of forms of continental slope, many with interruptions that differ from the classic profile.

Bottom-current deposit

Definition

Contourites are the sediments deposited or significantly affected by the action of bottom currents (Stow et al., 2002a; Rebesco, 2005; Stow and Faugères, 2008). They comprise a group of essentially deepwater facies, typically formed below 300 m water depth under the influence of semipermanent currents (Stow et al., 2008).

Bottom currents

Any semipermanent water current that affects the seafloor by resuspending, transporting, and/or controlling the deposition of sediments may be called a bottom current (Rebesco et al., 2008; Stow et al., 2008). They are persistent features within specific regions of the ocean basin (detailed below), more or less continuously affecting the pattern of sedimentation over periods of hundreds to up to millions of years.

In modern oceans, contourites are formed mainly under the influence of bottom currents driven by the major

thermohaline and wind-induced circulation systems (Faugères and Stow, 2008). In addition, bottom currents can operate as part of upwelling and downwelling currents, up- and down-canyon currents, internal tides and waves, and seafloor polishing and spillover (see Faugères and Stow, 2008; Shanmugam, 2008; and references therein). These processes produce rather isolated contourite facies commonly interbedded with other deep-sea sediments.

Bottom currents are predominantly unidirectional subsurface currents controlled by the ocean-basin configuration. When their flow direction largely parallels the submarine topography, they are called contour currents. Although bottom currents show a quasi-steady flow, they are highly variable in location, direction, and velocity over relatively short time scales (hours to months). Deepwater tidal effects, seasonal changes in water mass properties, and laterally migrating eddies modulate the velocity of the main bottom-current flow and even flow reversals may occur (Shanmugam, 2008).

The mean velocity of a bottom current and its ability to redistribute sediment are controlled by the Coriolis force and by the topography of the ocean basin (Stow et al., 2002a; Faugères and Mulder, 2011). Stow et al. (2008) differentiate between (i) low-velocity flows (mean velocity <10 cm s^{-1}), which typically move as a broad sluggish water body over low-gradient slopes and abyssal plains; (ii) intermediate-velocity flows (10–30 cm s^{-1}), which become intensified over steeper slopes and around topographic obstacles; and (iii) high-velocity flows (>30 cm s^{-1}), which are constricted and accelerated in narrow passages and over shallow sills. Flow velocities may exceed 100 cm s^{-1} where the flow is particularly constricted, such as through gateways on the deep-sea floor and within shallower straits, where flow velocities in excess of 200 cm s^{-1} have been recorded (Stow et al., 2002a).

Episodic downslope flows, which are not in equilibrium conditions with the oceanic water masses, do not represent bottom currents; for example, turbidity currents are short-lived (in the range of hours to months) and dense (more heavily loaded with suspended sedimentary particles) currents driven by gravity.

Contourite drifts

Bottom current-induced erosion and redeposition produce large-scale accumulations of sediment termed contourite drifts, which may be part of an even larger contourite depositional system, comprising several related drifts and associated erosional elements (Faugères et al., 1993; Stow et al., 2002b; Rebesco, 2005; Faugères and Stow, 2008). Contourite drifts were first described in the North Atlantic Ocean, where they were called "outer ridges" or "sediment drifts" (e.g., McCave and Tucholke, 1986). Present at most of modern continental margins, they are as frequent as deep-sea turbidite systems, occurring anywhere from the abyssal seafloor to slope settings. Sediment bodies deposited on the uppermost part of the

continental slope and across the outer shelf edge are named "shallow-water contourite drifts."

Contourite drifts range in size from about 100 km^2 (small patch drifts) to larger than 100,000 km^2 (giant elongated drifts) and occasionally even approaching 1,000,000 km^2 (abyssal sheet drifts). They may form a positive relief of up to 2,000 m height. Larger contourite drifts may record long-term continuity of deposition of over several millions of years, resulting in the accumulation of several hundreds of meters of contourite sediments. Contourite drifts are mainly composed of the sediments deposited by bottom currents, but they may also enclose associated deepwater sediments, particularly pelagites, hemipelagites, and glaciomarine sediments, as well as being locally intercalated with turbidites and other density-flow deposits. They are often closely associated with erosional areas that display coeval current-induced winnowing of the seafloor, sediment bypassing, and the formation of coarser-grained (gravel-lag) contourites (Stow et al., 2008).

The principal types of contourite drifts that have been identified include sheeted, elongate-mounded, channel-related, confined, infill, and mixed systems (McCave and Tucholke, 1986; Faugères et al., 1999; Stow et al., 2002a; Rebesco, 2005). Case studies can be found in Stow and Faugères (1993, 1998), Stow et al. (2002c), Viana and Rebesco (2007), and Rebesco and Camerlenghi (2008). The classification summarized below (Figure 1) is based on a combination of criteria, such as drift distribution (i.e., location) and morphology, and furthermore illustrates the drift development in the context of a particular hydrological background (Faugères and Stow, 2008; Faugères and Mulder, 2011):

(1) Contourite-sheeted drifts accumulate over a broad area with very low relief and form a sediment body of more or less constant thickness. They represent relatively slow rates of deposition of fine-grained contourites (Stow et al., 2008). Extensive, impressive fields of sediment waves may cover their surface. Abyssal-sheeted drifts can extend across large basin plains with deposits of up to a few hundreds of meters thick, while slope-sheeted drifts are plastered against the continental margin and cover smaller areas.

(2) Mounded drifts show an elevated relief with thicker accumulation over a narrower, elongate region. They represent relatively enhanced rates of deposition of fine- to medium-grained contourites, commonly focused into slope-parallel, elongate sediment bodies over moderate to large areas of the deep seafloor (Stow et al., 2008). Along one or both lateral margins of mounded drifts, the flow tends to be markedly intensified, in many cases causing distinct zones that experience intermitted erosion and bypassing (contourite channels, moats, and marginal valleys).

(3) Elongate-mounded drifts are the archetypical contourite accumulations because of their distinctly mounded and elongated geometry. Giant elongated

Contourites, Figure 1 Different types of contourite drifts (based on classifications of McCave and Tucholke, 1986; Faugères et al., 1993, 1999; Stow et al., 2002a), showing the general drift geometry and the trend of migration-aggradation (*triple black arrow*), as well as inferred *bottom*-current pathways (*broken-line black arrow*) (Redrawn and modified from Faugères and Mulder, 2011). Position of the main *bottom*-current flow (highest velocities) is indicated by *dashed* contour lines and *blue* color.

drifts are well recognizable as being of contourite origin, and they are the most spectacular because of their size (dimensions ranging from a few tens of kilometers to over 1,000 km). They are characterized by

length–width ratios varying from 2:1 to 10:1 and thicknesses reaching several hundreds of meters. Elongate-mounded drifts have been documented anywhere from the outer shelf and upper slope down to

the abyssal plains. McCave and Tucholke (1986) identified plastered, separated, and detached elongate-mounded drifts.

(4) Drifts related to deep channels or other oceanic passages (gateways, seaways, gaps, and straits), where the bottom currents are constricted and flow velocities are substantially increased, occur as axial and lateral patch drifts (either mounded or sheet form). Within the channel, the localized deposition of finer-grained contourite facies is closely related to significant erosion of the passage seafloor, widespread sediment bypassing, and the formation of coarse-grained lag deposits. Near the channel exit region, where the flow is expanded and decelerated, sheetlike contourite fans form, typically with a downflow decrease in contourite grain size. The channel-related patch drifts are typically small, a few kilometers in diameter, and up to 150 m thick. The contourite fans are much larger cone-shaped accumulations, up to 100 km or more in radius and 300 m in thickness.

(5) Confined contourite drifts are characterized by an elongate-mounded geometry aligned parallel to the axis of a relatively small confining basin. A significant feature is the presence of distinct moats along both sides of the drift, suggesting that the fairly slow contour current is confined on both margins or that it develops into some kind of circulatory pattern within the basin (Faugères and Stow, 2008).

(6) Mixed drift systems are those that involve significant interaction of *along-slope* bottom currents with other depositional processes in the buildup of the drift body. These drifts include substantial deepwater facies deposited either by episodic *downslope* processes (e.g., turbidites, debrites, and hyperpycnites) or by continuous *vertical* settling (e.g., pelagites, hemipelagites, periplatform carbonates, ice-rafted debris). The regular contourite-drift morphologies may be markedly modified by significant downslope sediment transport, and vice versa, bottom currents crossing deep-sea turbidite systems may induce a lateral shift of the channel-levee complexes. Mulder et al. (2008) outline the variable aspects of these alternating and interacting processes and the resulting drift geometries.

Contourite sediment facies

Depending on the flow characteristics and on local sediment sources, a large variety of contourite facies occurs in modern oceans (Stow et al., 1996, 2002a; Stow and Faugères, 2008). The grain size of contourites varies from fine muds, through silts and sands, to sand and gravel-lag components. The composition of the sediment can be terrigenous siliciclastic, biogenic (calcareous and siliceous), volcaniclastic, and chemogenic (manganiferous, phosphatic). Biogenic components typically comprise whole tests or shell fragments of foraminiferas, radiolarians, diatoms, spicules, and coccoliths. The different grain-size fractions and diverse materials are often poorly sorted mixtures. The rare contourite deposits identified in the fossil record are mainly carbonate-rich contourites (Hüneke and Stow, 2008; e.g. Hüneke 2013).

It is the bottom-current velocity that mainly governs the depositional processes and resulting sediment facies (Faugères and Mulder, 2011). Low-velocity flows allow vertical setting of fine-grained suspended particles from the nepheloid layer, whereas intermediate-velocity flows induce more bed load transport and deposition of silt and sand. High-velocity flows can affect still larger grain sizes and generate large-scale winnowing and erosion, resulting in coarse-grained lag deposits. Dissolution and authigenesis can accompany the current-induced processes, generating very low sedimentation rates and sediment bypassing.

The large variety of contourite facies typically displays (a) abundant bioturbational sedimentary structures, (b) bad preservation of hydrodynamic sedimentary structures, and (c) an irregular vertical variation in grain size. Burrowing animals intensely colonize contourite sediments due to their low accumulation rates and to the generally well-oxygenated (cold) water masses prevailing during bottom-current-induced deposition. Several types of ichnofabrics can be distinguished, depending on the prevailing current intensity (Wetzel et al., 2008). Hydrodynamic (small-scale) sedimentary structures are scarce or completely lacking, being obliterated by the permanent bioturbation, except when the sedimentation rate exceeds the bioturbation rate (Martin-Chivelet et al., 2008). Consequently, the vertical variation in grain size and sediment facies, which typically displays a repeated superposition of coarsening-upward and fining-upward units, may be difficult to recognize.

The facies model for contourites typifies the vertical grain-size variation of a standard mud-silt-sand contourite sequence, which results from variation in contour-current velocity (Faugères et al., 1984; Stow et al., 2002a; Stow and Faugères, 2008). A complete sequence of any particle composition consists of five principal divisions: (C1) lower muddy contourite division, (C2) lower mottled silty contourite division, (C3) middle sandy contourite division, (C4) upper mottled silty contourite division, and (C5) upper muddy contourite division. Traction structures, including rare cross-lamination, are more evident in the coarse silts and sands than in finer-grained facies. There may be an indistinct and discontinuous parallel lamination, and lenses of coarser materials may occur in all intervals.

The centimeter- to decimeter-thick successions of the standard sequence may be truncated. In that case, some divisions are missing, and erosional-sharp contacts or nondeposition surfaces are present between the facies units (typically at division C3). In fact, partial sequences

of different thickness are at least as common as the full sequence. The complete absence of certain divisions can be related to an increase in bottom-current velocity, resulting in a prolonged phase of nondeposition and/or erosion. Consequently, gravel-lag deposits, manganiferous horizons, and phosphatized hardgrounds can be produced.

The standard contourite sequence is interpreted to reflect at least sub-regular periodicity in mean bottom-current velocity (and/or in variation in sediment supply), related to climate variation or other external factors. Based on modern age data, Stow et al. (2002a) calculate approximate sequence periodicities for a variety of marginal drifts of terrigenous to mixed composition (Gulf of Cadiz, Rockall Margin, West Shetlands, and Norwegian Margin). In each case, they obtained a periodicity of between 5,000 and 20,000 years (Stow and Faugères, 2008).

Summary

Contourites are generally not easily recognized because of the lack of unambiguous diagnostic criteria. Their deposition involves multiphase entrainment of sedimentary particles and long-distance transport and furthermore depends on the interaction among the depositional processes induced by the various types of bottom currents operating in the deep sea. Hydrodynamic sedimentary structures are usually obliterated by coeval, permanent bioturbational mottling. Therefore, a composite triple-stage approach is recommended for the identification of sediments deposited by bottom currents (Stow et al., 1998). The analysis must include small-scale criteria (sedimentary facies and sequences), medium-scale criteria (drift geometry and internal architecture, facies distribution and trends, bottom-current activity, unconformities), and large-scale criteria (oceanographic features and continental reconstruction, basin configuration, drift location) in order to unambiguously identify a contourite.

CONVERGENCE TEXTURE OF SEISMIC REFLECTORS

Christopher George St. Clement Kendall
Earth and Ocean Sciences, University of South Carolina, Columbia, SC, USA

Depositional and erosional bounding surfaces define sedimentary sequences, systems tracts, and parasequences (see section on the topics of Sedimentary Sequence in the encyclopedia). They match surfaces that coincide with the convergence and termination of seismic reflectors but are best displayed in outcrops and are often easily identified in well logs and cores.

In seismic reflection data the convergence and termination patterns and their continuity are used to identify sequence stratigraphic surfaces. On seismic data the most prominent of these surfaces are subaerial unconformities marking sequence boundaries (SB) eroded during sea-level fall (Sloss et al., 1949) and time-equivalent submarine correlative conformities (SB-CC) (Hunt and Tucker, 1992; Posamentier et al., 1988; Figure 1).

SB and geometries of sediment fill as they respond to changes in relative sea-level

- An upper sequence boundary:
  - Toplap: termination of strata against an overlying surface, as the result of nondeposition and/or minor erosion
    - Truncation: removal by erosion (often after subsequent tilting; representing the most reliable top-discordant criterion of a sequence boundary) or with a channel termination against erosional surface
- A lower sequence boundary:
  - Onlap – A base-discordant relationship in which initially horizontal strata progressively terminate against an initially inclined surface or in which initially inclined strata terminate progressively updip against a surface of greater initial inclination.
  - Downlap: a relationship in which seismic reflections of inclined strata terminate downdip against an inclined or horizontal surface. Examples of downlap surfaces include a top basin-floor fan surface, a top slope fan surface, and a maximum flooding surface.

Subsequent deformation of the sedimentary section can make onlap indistinguishable from downlap, so in this case the term baselap is used; in contrast offlap refers to en echelon progradation of (outward building) strata often expressed in seismic and other data.

NB: *Visit the SEPM STRATA website* (http://www.sepmstrata.org/) *for explanations of the sequence stratigraphic terminology used here, which is linked to pop-up boxes containing information that clarify the understanding and use of this discipline of stratigraphy.*

Formation of ocean crust

Definition

Crustal Accretion. Formation of ocean crust at mid-ocean
ridges, by a combination of magmatic, tectonic, and
hydrothermal processes.

Introduction

Since the early 1970s, the classical model of a uniformly
layered ocean crust, with from top to bottom basaltic lava
flows, basaltic sheeted dikes, and gabbros, known as the
"Penrose" model (Anonymous, 1972), has considerably
evolved, with complementary contributions from
ophiolite studies, seafloor geology, marine geophysics,
and scientific ocean drilling. At the global scale, there is
substantial variability of the mid-ocean ridge morphology
and hence of crustal architecture. This results from various
modes of accretion that are controlled by magma supply to
the ridge, which itself primarily depends on the spreading
rate. This article briefly describes the current end-member
models for crustal accretion at fast-spreading
(>~80 mm/year) and slow-spreading (<~40 mm/year)
ridges.

## Fast-spreading ridges: a nearly continuous magma chamber

At fast-spreading (and part of intermediate-spreading)
ridges, the ocean crust is assumed to be relatively simple
and continuously layered, in accordance with the "Pen-
rose" model, as a result from the presence of nearly contin-
uous and steady-state axial magma chamber, along the
axis. Most of the first models for mid-ocean ridge magma
chambers, in the 1970s and early 1980s, proposed rather
large magma bodies, ~10–20 km large across the ridge
axis and ~4 km thick at the axis, lying below the sheeted
dike complex (e.g., Cann, 1974; Pallister and Hopson,
1981). Using thermal constraints, Sleep (1975) proposed
that most of the chamber was filled with magmatic mush
and that melt-rich magma would be limited to the top,
below the sheeted dikes. This prediction was confirmed
about 10 years later, with the first seismic reflection
images of an axial magma chamber beneath the Valu Fa
Ridge in the Lau Basin (Morton and Sleep, 1985) and
beneath the East Pacific Rise (e.g., Hale et al., 1982;
Detrick et al., 1987; Kent et al., 1994). This shallow and
thin magma lens then became a key element of all models
for accretion at fast-spreading ridges. Details of the rela-
tionships between the morphologic segmentation of the
ridge, the along-axis variability (depth and melt content)

of the magma lens, volcanic activity, lava chemistry, and
hydrothermal cooling in the upper crust are discussed in
many studies published over the last three decades (e.g.,
Macdonald et al., 1988; Hooft et al., 1997; Singh et al,
1998; Goss et al., 2010; Carbotte et al., 2013; Xu et al.,
2014). In intact fast-spread crust, the deepest stratigraphic
level reached by drilling is the transition zone between the
sheeted dike complex and the gabbros of the lower crust,
in the ODP (Ocean Drilling Program) Hole 1256D on
the Cocos Plate (Wilson et al., 2006; Teagle et al., 2012;
Ildefonse et al., 2014). This zone, also described in
ophiolites (e.g., Gillis, 2008; France et al., 2009), marks
the thermal boundary layer between the magmatic and
hydrothermal systems at the ridge axis. It displays a com-
plex petrological record of the interplay between tempo-
rally and spatially intercalated magmatic, hydrothermal,
partially melting, and metamorphic processes.

Below the axial magma lens is a seismically attenuated
domain, which is believed to correspond to a melt-poor
magmatic mush (e.g., Sinton and Detrick, 1992; Dunn
et al., 2000). Two competing models are proposed for
building the lower, gabbroic crust in this domain. The
"gabbro glacier" models (e.g., Henstock et al., 1993;
Phipps Morgan and Chen, 1993; Figure 1a) postulate that
the entire lower crust is formed by the flow of mushy
material downward and outward from the single, shallow
axial magma lens. In contrast, "sheeted sill models,"
largely based on observations made in the Oman ophiolite
(e.g., Kelemen et al., 1997; Figure 1b), involve in situ for-
mation of the lower crust by sill intrusions. Boudier
et al. (1996) proposed a combination of these two
end-members. Deep, lower crustal seismic reflectors,
interpreted as magma sills accreting the lower igneous
crust, have now been imaged below the axial magma lens
at the Juan de Fuca Ridge (Canales et al., 2009) and at the
East Pacific Rise (Marjanović et al., 2014). Accretion
models can be used for predicting contrasted vertical
trends of chemical composition, deformation, and alter-
ation in the gabbroic crust, which still remain to be fully
tested in ophiolites and by deep drilling in intact fast-
spread crust (e.g., Teagle et al., 2012; Ildefonse et al.,
2014). While the gabbro glacier model does not require
deep hydrothermal circulation close to the axis, the latter
is needed to sustain a sheeted sill model (Figure 1b; e.g.,
Maclennan et al., 2005). The IODP (Integrated Ocean
Drilling Program) Expedition 345 recovered, for the first
time, significant sections of layered gabbros from
disrupted lower crust exposed at Hess Deep in the equato-
rial Eastern Pacific (Gillis et al., 2014), where young
(~1 Ma) lower fast-spread crust is tectonically exposed
at the tip of the Cocos-Nazca rift.

Slow-spreading ridges: a variable, composite crust

In contrast to fast-spread crust, ocean crust created at
slow- and ultraslow-spreading ridges is spatially heteroge-
neous, both along and across the ridge axis. Along parts of
slow-spreading ridges (e.g., the centers of ridge segments
Crustal Accretion, Figure 1 Sketches of end-member crustal accretion models (modified from Kelemen et al., 1997). (**a**) Gabbro glacier model. (**b**) Sheeted sill model of in situ formation of the lower crust by on-axis sill intrusions.
Crustal Accretion, Figure 2 (**a**) Simplified, interpreted, axis-parallel section through slow-spread crust (modified from Cannat et al., 1995). (**b**) Sketch of crustal accretion controlled by detachment faulting (modified from Escartín and Canales, 2011).

in the northern Atlantic), magmatic processes dominate. Seismic imaging has revealed an axial magma chamber beneath the Lucky Strike Volcano (37°18′N) at the Mid-Atlantic Ridge (Singh et al., 2006), similar to that imaged along fast-spreading ridges but limited in space to 7 km along the axis. The architecture of slow-spread crust typically changes along axis toward segment ends, where it is more heterogeneous, with a mixture of

serpentinized mantle peridotite and gabbroic intrusions locally capped by lavas with or without intervening sheeted dikes (e.g., Cannat, 1993; Figure 2a). This lateral and vertical variability of slow-spread crust has been well documented through ophiolite studies, seafloor geological studies, geophysical surveys, and scientific ocean drilling expeditions (e.g., Karson et al., 1987; Dick, 1989; Cannat et al., 1995; Canales et al., 2000; Kelemen et al., 2007; Blackman et al., 2011; Sauter et al., 2013; Ildefonse et al., 2014; Lagabrielle et al., 2015). In this type of crust, tectonics play a key role in crustal construction, through detachment faulting (e.g., Escartín and Canales, 2011; Figure 2b), which dominates the style of accretion over ~50 % of the Mid-Atlantic Ridge between 12.5°N and 35°N (Escartín et al., 2008). Long-living (~1–2 Ma) detachment faults cap domal features, known as "oceanic core complexes" or "megamullions," where gabbroic rocks, serpentinites, and fault-related material (e.g., talc-amphibole schists) are typically sampled (e.g., Cann et al., 1997; Tucholke et al., 1998; Escartín et al., 2003; Ildefonse et al., 2007; MacLeod et al., 2009; Dick et al., 2010). The magma-poor end-member for this style of accretion is expressed at the ultraslow-spreading South-west Indian Ridge by the nonvolcanic "smooth seafloor," where almost exclusively serpentinized mantle peridotites are sampled (Cannat et al., 2006; Sauter et al., 2013). Details of the detachment-controlled accretion mode remain poorly constrained. In oceanic core complexes, drill cores document a complex interplay between magmatism, faulting, and hydrothermal cooling, which is yet to be fully resolved (e.g., Blackman et al., 2011; McCaig and Harris, 2012; Ildefonse et al., 2014).

CUMULATES

Jürgen Koepke
Institute of Mineralogy, Leibniz University Hannover,
Hannover, Germany

Cumulate is a name for plutonic rocks which were formed either by the process of accumulation of crystals (crystal settling) or by direct crystallization (in situ crystallization) in a magma chamber. Since "cumulate" is clearly a genetic term, it should not be used as rock name (qv. "Gabbro," and the chapter on rock classification of gabbroic rocks therein), but can be used as additional qualifier, in order to express that rocks were formed by a distinct process within a magma chamber.

For the oceanic crust, this term is directly related to the accretion of oceanic gabbros, forming the lower part of the oceanic crust (layer 3; qv. "seismic layers"). The corresponding magma chambers are located directly under the spreading centers of mid-ocean ridges or back-arc systems (qv. "axial magma chamber"). Here, primitive MORB (mid-oceanic ridge basalt; qv. "Mid-ocean Ridge Magmatism and Volcanism") melts differentiate by fractionation of mainly olivine, plagioclase, and clinopyroxene, which may accumulate at the floor of the magma chamber to form a dense crystal mush, resulting in the oceanic gabbros after cooling. Thus, the vast majority of oceanic gabbros can be regarded as cumulate rocks, formed by the process of crystal sedimentation in axial magma chambers.

Traditionally, the term cumulate was used for layered intrusions on continents (e.g., Skaergaard Layered Intrusion, Greenland; Rum Layered Suite, Scotland). Based on the work of Wager et al. (1960), a scheme of textures for cumulate formation was introduced which has been a major contribution to the understanding of igneous textures. Reviews on that are given by Shelly (1993) or Hunter (1996). "Cumulus phases" or "cumulus crystals" are those phases which are accumulated (sedimented) in a magma chamber, while the liquid around is called "intercumulus" liquid. "Adcumulate" textures represent an accumulation of crystals from which the intercumulus liquid was pressed out, possibly driven by compaction. The cumulate phases occupy the entire volume of the rock, resulting in crystals with subhedral to anhedral shapes which are defined by the jointly merged boundaries of adjacent crystals. "Orthocumulate" textures represent accumulated crystals around which a more evolved intercumulus liquid crystallized often resulting in typical poikilitic growth, meaning that relatively large, late crystallized minerals enclose earlier, smaller crystals.

However, the detailed cumulate terminology as established by Wager et al. (1960) is generally not applied to oceanic gabbros, due to several reasons. First, the terms are rather specific, often with a strong genetic aspect, which makes its application to oceanic gabbros difficult, since the mechanisms by which the lower, gabbroic crust forms are poorly constrained (qv. "crustal accretion"; "gabbro"). Moreover, primary textures may be obscured by later strain which may result in magmatic foliation (especially in gabbros from fast-spreading systems) or in crystal-plastic deformation (especially in gabbros from slow-spreading systems). Thus, for the petrographic characterization of oceanic gabbros, common petrographic description terms for mineral structures and rock textures are commonly used. For example, the record of crystallization of a late, evolved melt in the interstices of earlier crystallized minerals, producing minerals like amphibole, oxide, orthopyroxene, apatite, and zircon occurring in many gabbros from slow-spreading ridges (qv. "gabbro"), can simply be described as "late assemblages crystallized interstitially," instead of using a term like "orthocumulate" or "mesocumulate" which might be appropriate in some cases.

CURIE TEMPERATURE

Hans-Jürgen Götze
Institute of Geosciences, Christian-Albrechts-University Kiel, Kiel, Germany

In a physical sense the Curie temperature (CT or T_c) is defined as the temperature that marks the reversible phase crossing of ferromagnetic or ferrimagnetic materials in its high paramagnetic temperature form:

- Above the CT, spontaneous or directed magnetization disappears from crystal domains.
- Below the CT, magnetic materials get magnetic behavior back, i.e., the spontaneous magnetization and magnetic domains without any effect of an external magnetic field.

Therefore, CT is a material-specific temperature, above which magnetic properties of matter, solids, or rocks will change. Also remanence of magnetized ferromagnets is removed above CT (Blakely, 1995).

"CT" is named in honor of the eminent French Physicist *Pierre Curie* (1859–1906), who was a pioneer in crystallography, magnetism, piezoelectricity, and radioactivity and won the Nobel Prize in Physics in 1903.

A certain level in the Earth's crust is called "Curie depth" in which temperatures are so high that the Curie temperature is reached. In the continental crust this temperature is usually achieved at about 20 km depth, while in the oceanic crust, the Curie temperature lies, depending on temperature, pressure, and rock properties, at greater depths.

When rocks are in a ferromagnetic state, exposure to a magnetic field can align their atoms and create an attraction. If the field is taken away, the magnetism remains, as the material has a form of "memory." This can be used to make permanent magnets and demonstrate a variety of interesting physical phenomena. Paramagnetic materials, however, require the maintenance of an external magnetic field to remain magnetized. At the Curie temperature, the heat agitates the atoms inside the material so much that they cannot align, and it loses its magnetism. At Curie temperature rocks lose their spontaneous magnetization (e.g., 580 °C for magnetite; 769 °C for iron (Fe);

1,400 °C for Cobalt (Co); 631 °C for Nickel (Ni); e.g., Buschow, 2001; Bouligand et al., 2009).

This can have important implications. In geology, for example, high temperatures can occur in lightning strikes and volcanic eruptions and are capable of causing the properties of minerals in the Earth's crust to change. Observers looking at magnetic minerals need to consider their history and what may have influenced them. One can map the depth to the Curie temperature isotherm from *magnetic anomalies* in an attempt to provide a measure of crustal temperatures. Such methods are based on the estimation of the depth to the bottom of magnetic sources, which is assumed to correspond to the temperature at which rocks lose their spontaneous magnetization (see above). Therefore, depths to the bottom of magnetic sources show several features correlated well with prominent heat-flow anomalies. Bouligand et al. (2009) used a method based on the spectral analysis of magnetic anomalies. It incorporates a representation where magnetization has a fractal distribution defined by three independent parameters: the depths to the top and bottom of magnetic sources and a fractal parameter related to the geology. The Curie temperature has also practical implications in marine geosciences. For instance, the oceanic crust can be altered by high-temperature fluids related to hydrothermal processes, thereby losing its magnetization. The resulting magnetic lows in basaltic crust can be used to detect fossil zones of hydrothermal upflow and associated volcanogenic massive sulfides (Zhu et al., 2010).

As a practical example the table below (after Bouligand et al., 2009) shows heat-flow values, depths to the Curie temperature isotherm, and the Moho depth and expected basal depth of magnetic sources for an area in the Western United States. For comparison, results from survey in the South China Sea and the Caribbean are included in the table.

Area	Heat flow (mW/m²)	Curie depth (km)	Moho depth (km)	Basal depth (km)
Great Basin (typical values)	75–95	17–23	25–35	17–23
High Cascades	~100	~16	~45	~16
West Cascades	40–50	41–63	~45	41–45
Great Valley	25–55	36–250	~35	~35
Colorado Plateau	~60	~32	40–50	~32
Eastern Caribbean (Arnaiz-Rodríguez and Nuris, 2013)	40–80	23	20	
South China Sea (Li et al., 2010)	~80	12–22	<15

Not to be confused with electrical current; Ocean currents; Water flow

Definition

Currents are large-scale (mainly horizontal) translational motions of seawater, as opposed to the wave motions where water particles perform periodic back-and-forth excursions relative to the state of rest. Ocean currents can flow at great distances; they carry seawater and its inherent properties (heat and salt content, dissolved and particulate matter, etc.) from one region to another.

Ocean currents are expressed in terms of horizontal velocity (m/s) of fluid motion as a function of space and time, given either by the velocity vector components or by the direction and speed of the current. This is the Eulerian description of currents. Current velocity components are often presented as (eastward) zonal current and (northward) meridional current. When using the current presentation by flow direction, zero direction has been agreed for the current flowing to the north; the direction angle is further counted positive in clockwise rotation. In Lagrangian description of currents, trajectories of fluid particles are followed over time.

Development of observation techniques

The first ancient tracks of ocean currents were obtained by investigating the ship logs. As an example, historical cross-Atlantic voyages discovered regions of very strong currents like Gulf Stream, where the sailing of ships was slowed down or speeded up (depending on the sailing direction) because "the currents are more powerful than the wind"; the first Gulf Stream map was drawn in the 1770s by Benjamin Franklin. Drift data of objects floating on the sea surface (boats, message bottles, etc.) carry information about an object-dependent combination of currents, waves, and wind in creating the drag forces.

Modern current-tracking drifters as Lagrangian observing platforms have specially designed drogues to minimize the wind and wave effects on the surface; the drifters are satellite tracked (e.g., WOCE-SVP), and the recorded data are transferred over satellite communication links to the shore stations. Currents and stratification of deeper ocean layers are effectively observed using the profiling ARGO drifters, which move most of the time, neutrally buoyant in deep layers at about 1,000-m depth, but rise periodically to the sea surface for the profile measurement and data communication.

Direct water flow measurements at fixed locations are technically complicated. The flowmeter needs to be fixed in the dynamic ocean environment; or alternatively, the sensor motions due to waves and currents need to be determined with high precision. Since the flow field is usually fluctuating, averaging of current data over time is important. The earliest mechanical rotor-based current meter capable of recording direction and speed from an anchored ship on different depths has been introduced in the 1890s by John Elliott Pillsbury. Vagn Walfrid Ekman introduced in the 1930s reliable current meter design which included mechanical averaging of speed and direction data. This instrument was in service until the 1960s, when Ivar Aanderaa introduced modern electronically recording current meters. Although concepts for acoustic current measurement methods were elaborated already before the 1950s, reliable technologies for replacement of mechanical rotor-dependent speed counters with acoustic point sensors were developed by Neil Brown at the end of the 1970s. A breakthrough of current measurements was the introduction of acoustic Doppler current profilers (ADCP) in the 1980s that allow self-recording measurements of full current profiles from the instruments mounted either on the bottom or on the moving ship.

Complementary to the direct current measurements, indirect dynamic method based on charting of the density fields has been widely used since the beginning of the 1900s to identify the main large-scale current patterns. The method is based on geostrophic relations. Relative currents of one vertical level in reference to another level can be easily calculated from temperature and salinity profiles. Historically absolute currents were calculated with the assumption that deep levels around 1,500-m depth were motionless. In the recent decades, satellite-based altimeters measure sea-level topography (determines the pressure gradients at the sea surface) with high precision; therefore pressure gradients forming the geostrophic currents throughout the water column can be calculated also with high accuracy.

In the coastal areas, near-shore currents, including the tidal streams, can be well detected by modern coastal maritime radars with advanced signal processing algorithms.

Further details of current observing methods can be found in the books by Emery and Thomson (2001) and Talley et al. (2011).

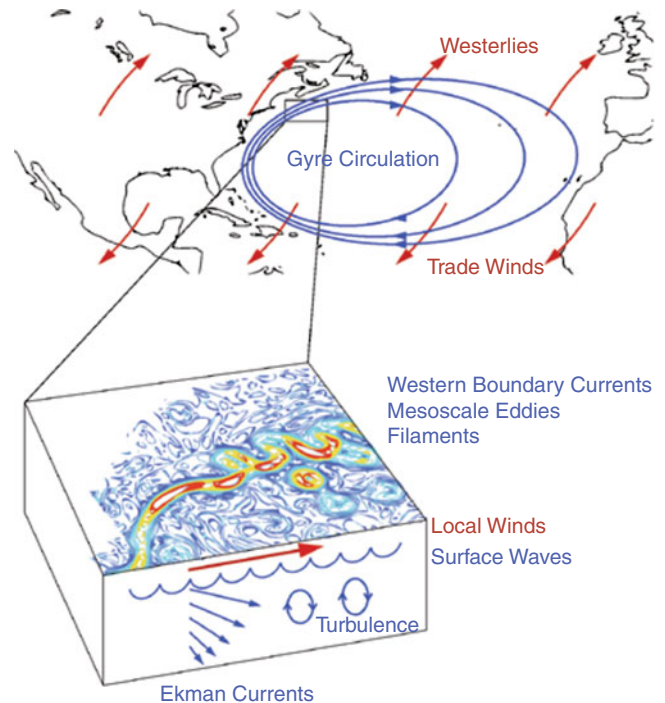
Basic theoretical concepts

Motions of seawater follow the laws of hydrodynamics written in partial differential equations. The flows are generated mainly by the pressure gradients, forming due to the gravity and acting through the whole water column, and by the frictional forces acting on the sea surface due to the wind stress. The balance of forces (momentum) follows Newton's Second Law for the continuum fluid in the system of partial differential equations: the sum of forces due to the gravity, pressure gradients, and friction per unit mass is equal to the acceleration of the water parcel. Acceleration consists from local time rate of momentum velocity change (absent for stationary flows), nonlinear momentum advection per unit mass (can be omitted for small flow speeds and/or curvature), and Coriolis acceleration (can be omitted for short-period motions).

Coriolis acceleration appears due to the rotation of the Earth and deflects in the Northern (Southern) Hemisphere the currents to the right (left) from the original direction. Its magnitude is described by the product of Coriolis parameter with the current speed in rotated, perpendicular direction. Coriolis parameter is zero at the equator and reaches twice the Earth's angular speed on the poles.

In an idealized case of boundless ocean and vanishing horizontal flow variations, the wind stress acting on the sea surface and frictional drag of the underlying layers are balanced by the Coriolis force. This flow is called "Ekman spiral," according to the theoretical work by Vagn Walfrid Ekman published in 1905. In such conditions, the surface drift currents are deflected by 45° to the right (left) from the wind direction in the Northern (Southern) Hemisphere. When going deeper from the surface, the flow speed decays exponentially, but the direction deflects further in linear dependence from the depth. At the Ekman depth (depends on the turbulent viscosity and Coriolis parameter), usually from a few tens of meters to hundred meter, the drift currents become negligibly small. Total water transport in the upper layer (Ekman transport) is perpendicular to the wind direction.

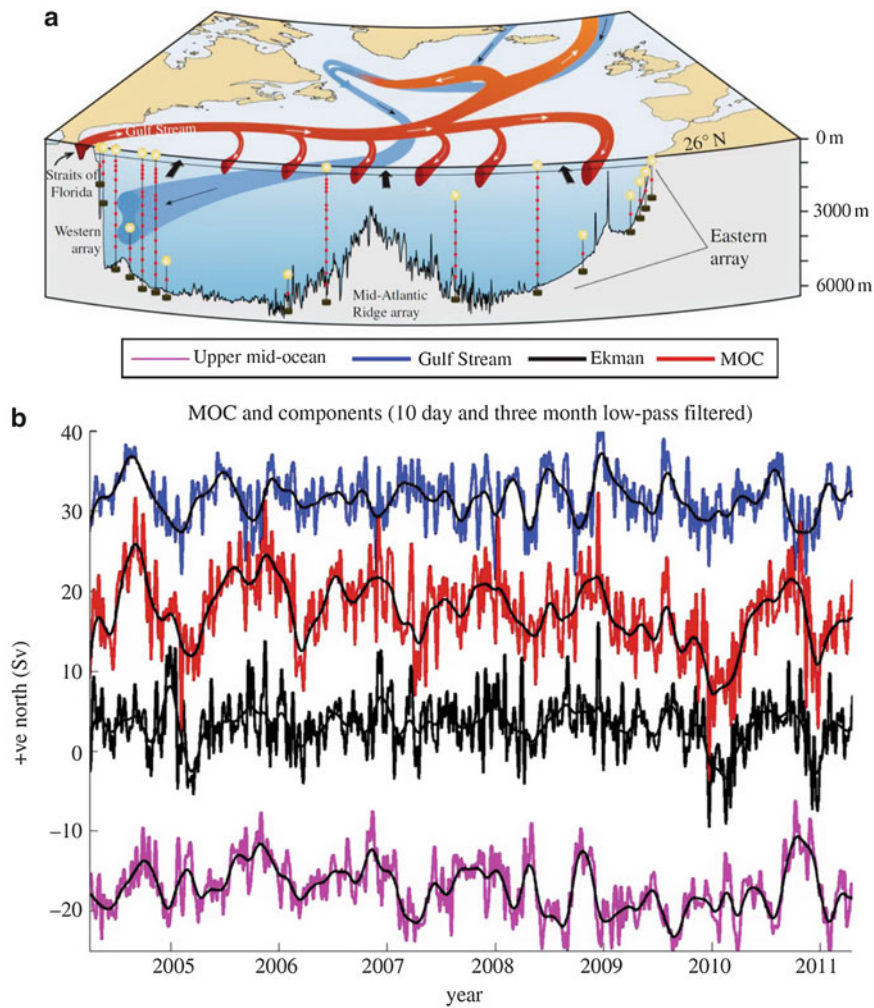
Besides the momentum equations, the flow must follow also the continuity equation. In a simple explanation, when the currents are converging in horizontal direction relative to the bottom, then isopycnals (surfaces of constant water density) and sea-level will rise; in case of diverging currents, the vertical motion is of opposite direction. When the wind blows parallel to the coast, then Ekman transport is offshore or onshore, depending on the wind direction. Ocean waters are usually stratified; warm surface waters are separated from deeper colder



Currents, Figure 1 Schematic of the hierarchy of near-surface currents focused on the Gulf Stream region in the Northern Atlantic Ocean. The gyre circulation consists of a broad eastern component and a narrow, fast, western boundary current (*WBC*). The WBC is enlarged to highlight the mesoscale (100 km and larger) features and the submesoscale eddies, filaments, and turbulence. Global winds drive basin circulation, while local winds force local Ekman currents, surface waves, and turbulence (Dohan and Maximenko, 2010).

waters by a thermocline where temperature drops rapidly. By the continuity arguments, offshore Ekman transport causes upwelling of cold and nutrient-rich deeper waters to the sea surface; downwelling occurs in case of onshore Ekman transport.

The pressure gradients are formed by sea surface topography and spatial variations in water density; the pressure at actual point can be usually calculated by hydrostatic relation. Ocean currents are quite well described by the geostrophic relations where the pressure gradient force is balanced by the Coriolis force. Geostrophic flow is directed along the lines of constant pressure (isobars) in a direction that looking from the higher pressure toward lower pressure, the flow is directed perpendicularly to the right (left) on the Northern (Southern) Hemisphere.

Tilting of sea surface and isopycnals is easily formed by horizontally diverging or converging flows due to the continuity; pressure gradients formed by the flow in such a way have feedback to the flow itself in the momentum equations. As a result, different wave motions are created. In the time scale of days to months, planetary and/or topographic Rossby waves appear. These waves are nearly in the geostrophic balance like are also the mesoscale eddies which have typical size of the order of baroclinic Rossby


Currents, Figure 2 (**a**) Schematic of Northern Atlantic circulation with the rapid monitoring array at 26°N. From http://www.noc.soton.ac.uk/rapidmoc/. (**b**) Gulf Stream (*blue curves*), meridional overturning circulation (MOC; *red curves*), Ekman (*black curves*) and upper mid-ocean (*purple curves*) transports (10 days and 3 months, low-pass filtered) April 2004 to March 2011 as measured by the rapid array. Transports are in Sverdrups (1 Sv = 10^6 m^3 s^{-1}). From http://www.noc.soton.ac.uk/rapidmoc/ (Bryden et al., 2012).

deformation radius (a length measure derived from the depth, stratification strength, and Coriolis parameter). Eddies are mainly generated by the instability of large-scale currents, and these motions follow the law of potential vorticity conservation that counts variations of Coriolis parameter with latitude (beta effect) and depth variation (topographic effect). Vorticity balance as derived in special cases by Sverdrup and Stommel explains also existence of strong narrow-band currents near the western coasts of the oceans: Gulf Stream in the Atlantic, Kuroshio in the Pacific, etc.

Surface and deep currents in the ocean

Surface currents in the ocean follow the global wind patterns, forming the basin-wide gyres with stronger western boundary currents. Many descriptions of surface currents can be found in the literature (e.g., Talley et al., 2011). Modern views have been created with the help of remote sensing and numerical modeling. We refer to the recent paper by Dohan and Maximenko (2010), from where we have adopted the schematic of circulation in the Northern Atlantic (Figure 1). In the Southern Hemisphere, the continents do not cut the ocean flow path; Antarctic Circumpolar Current flows clockwise through all the oceans and provides the global link of water masses of different oceans.

When warm surface waters move toward the polar regions, they cool down. As the water density increases, the waters sink toward greater depths and can move toward tropical regions. Sinking waters are modified by freshwater flux. When the latter exceeds some critical level, the "new" water in the polar region may not be dense

enough for sinking; then blocking of warm surface currents may occur. This abyssal flow is also called thermohaline circulation. The overall water parcel cycle through all the oceans – along the thermohaline conveyor belt – takes about 1,000 years.

Changing ocean currents

Ocean circulation varies on interannual and decadal scales, as seen from the observations from long-term arrays installed in different parts of the ocean. An example of water transport variations in different layers of the Northern Atlantic is presented in Figure 2 (Bryden et al., 2012). Such variations have impact to weather patterns and climate, fluxes of dissolved and particular matter, ocean productivity, fish resources, etc.

Conclusions

Currents are large-scale translational motions of seawater. Surface currents in the ocean follow the global wind patterns, forming the basin-wide gyres with stronger western boundary currents. When warm surface waters move toward the polar regions, they cool down. As the water density increases, the waters sink toward greater depths and can move back toward tropical regions. This abyssal flow is also called thermohaline circulation. Ocean circulation varies on interannual and decadal scales, having

impact to weather patterns and climate, fluxes of dissolved and particular matter, ocean productivity, and fish resources.

DATA

Michael Diepenbroek
MARUM-Center for Marine Environmental Sciences,
University of Bremen, Bremen, Germany

Data are an integral part of geo-scientific work. Full and open access to data is a good scientific practice. It allows for the verification of research findings and is a prerequisite for large-scale and complex research approaches. The management of data covers the entire life cycle of research data from field or real-time data acquisition to long-term archiving and publication as well as analysis and reuse of these data. Reliable usage of data implies that accuracy, consistency, and authenticity of data are maintained and assured during ingest, archiving, and dissemination (data integrity). The Open Archival Information System (OAIS) provides a corresponding reference model.

Production and preparation of data includes control and assessment of data quality (QA/QC), documentation of lineage and process steps, as well as harmonization of data and metadata according to international standards, whereby the heterogeneity of data types and used methods imposes a particular challenge. To ensure the consistency of data and metadata, most of the different science fields maintain specific metadata standards. Consistency is supported by development and usage of common ontologies and vocabularies.

Within data centers, ingest and archiving of data are mostly based on well-defined procedures and supported through corresponding software frameworks and editorial systems operated by professional data managers. The technical development allows storage of data at nearly any scale and complexity. Relational Database Management Systems (RDBMS) are mostly used as storage back ends. Other technologies like the Resource Description Framework (RDF) are available for contextual data such as ontologies.

Increasingly important is the publication of archived data. The publication process involves persistent identification of data (e.g., through Digital Object Identifier – DOI), registration (e.g., using DataCite), license protection, and cataloguing. In this way, data are citable, can be cross-referenced with literature, and are thus part of the scholarly publishing system.

For long-term archiving and publication, a multitude of good quality data centers covering the whole range of earth and environmental sciences are available. Prominent are the data holdings of space agencies (e.g., NASA, ESA), the World Meteorological Organization Information System (WIS), data centers linked to the genome community (EMBL-EBI, GenBank), the Global Biodiversity Information Facility (GBIF), the International Oceanographic Data and Information Exchange (IODE), and multidisciplinary data centers like PANGAEA (Diepenbroek et al., 2002). A long-standing nongovernmental organization comprising many of these facilities is the World Data System (WDS) of the International Council for Science (ICSU). The WDS is certifying and monitoring their members on the base of international standards and policies thus ensuring high quality of supplied data and services.

Data centers are part of the globally evolving information infrastructures. Efficient usage of data from a network of providers requires a high level of data consistency as well as interoperable and generally available added value services for data integration and analysis. Technically, a multitude of content and interoperability standards, as well as warehouse, cloud, and other systems, are available for this purpose. Integration of multidisciplinary data raises particular new research opportunities.

DEEP BIOSPHERE

Axel Schippers
Federal Institute for Geosciences and Natural Resources, Hannover, Germany

Synonyms

Deep subseafloor biosphere; Deep subsurface biosphere

Definition

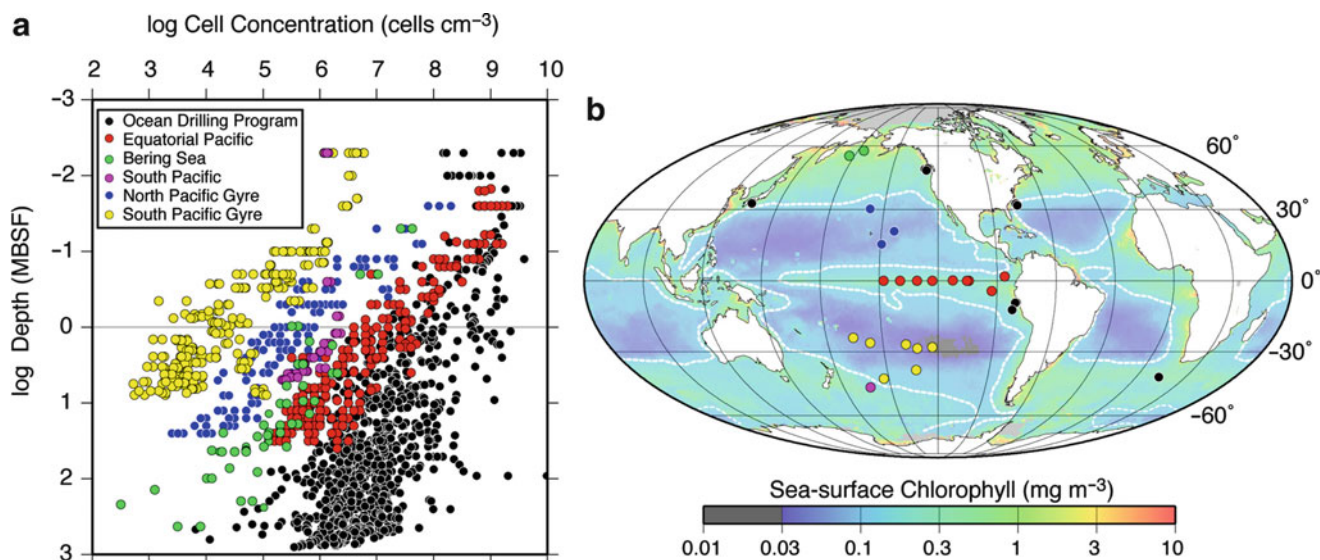
Deep biosphere. Jørgensen and Boetius (2007) define the seafloor as the top meter layer of the seabed that is bioturbated by animals and porous ocean crust that is penetrated by seawater, whereas the deep subsurface, which harbors the deep biosphere, comprises the sediment and rock that is deeper than 1 m below the seafloor (mbsf).

Introduction

The Earth's deep biosphere includes a variety of subsurface habitats, such as mines and deep aquifer systems in the continental realm and sediments and igneous rock in the marine realm. The terrestrial deep subsurface biosphere has been studied in various geological formations (e.g., Gold, 1992; Pedersen, 1993, 1997; Stevens and McKinley, 1995; Amy and Haldeman, 1997; Chapelle et al., 2002; Moser et al., 2003; Lin et al., 2006; Fry et al., 2009; Borgonie et al., 2011; Breuker et al., 2011; Itävaara et al., 2011; Edwards et al., 2012) but is not in the scope of this entry. Jørgensen and Boetius (2007) and Edwards et al. (2012) defined the seafloor as the top meter layer of the seabed that is bioturbated by animals and porous ocean crust that is penetrated by seawater, whereas the deep subsurface, which harbors the deep biosphere, comprises the sediment and rock that is deeper than 1 m below the seafloor. Several review papers have been published about the marine deep biosphere (Jørgensen, 2000; Parkes et al., 2000; Parkes and Wellsbury, 2004; Teske, 2005; Teske, 2006a; Teske, 2006b; Jørgensen et al., 2006; Jørgensen and Boetius, 2007; Fry et al., 2008; Mascarelli, 2009; Schrenk et al., 2010; Edwards et al., 2012; Hoehler and Jørgensen, 2013; Lever, 2013; Orcutt et al., 2013a; Teske et al., 2013; Parkes et al., 2014). This entry gives an overview about the marine deep biosphere in deeply buried sediments and in the ocean crust considering the deep biosphere biomass, the predominant microorganisms and their diversity and activity, as well as implications for biogeochemistry. The marine deep biosphere has been explored at various ocean sites mainly within the framework of the Ocean Drilling Program (ODP) and the Integrated Ocean Drilling Program (IODP).

The deep biosphere in marine sediments
Biomass

Organic carbon from marine primary production is usually the energy source feeding the deep biosphere. Only about 1 % of the total marine primary production of organic carbon is available for deep-sea sediment microorganisms (Hedges, 1992). For the largest part of the ocean seafloor, the organic carbon amount available on the ocean seafloor from sedimentation is on average 1 g of carbon per m^2 per year (Jahnke and Jackson, 1992). Most of the organic carbon is degraded within the top 1-m sediment, and the organic carbon content in the deep subsurface comprises approximately 0.1–1 % of sediment by dry weight (Jørgensen and Boetius, 2007). In deep sediments with extremely low organic carbon flux, radiolysis of water may provide hydrogen and thus an energy source for autotrophic microorganisms independent of photosynthesis (Jørgensen and D'Hondt, 2006; D'Hondt et al., 2009).

A fundamental question in deep biosphere research is its size or the biomass of living cells. This topic was first comprehensively addressed by the research group of Parkes et al. (1994, 2000). For counting of microbial cells under a fluorescence microscope, the cells in a sediment sample were stained with the DNA-intercalating dye acridine orange, and the number of total cells counted is given as acridine orange direct counts (AODC). Using this method for building up an AODC database, the first report about an existence of a deep biosphere in several hundred meters deeply buried sediments was published (Parkes et al., 1994). Studies of contamination potential have demonstrated that it is possible to obtain core samples without outside contamination (Smith et al., 2000), and the enumeration of prokaryotes is now a standard protocol onboard the IODP drillships JOIDES Resolution (Lever et al., 2006) and Chikyu (Yanagawa et al., 2013). The total number of prokaryotes (*Bacteria* and *Archaea*) in the subsurface sediments decreases with sediment depth mainly because it is controlled by the organic carbon content of the sediment as it is the main microbial substrate (Parkes et al., 2000; D'Hondt et al., 2004; Roussel et al., 2008). This data was then further extrapolated to calculate a global biomass of the deep biosphere, and it was estimated that marine sediments harbor over half of all prokaryotic cells on Earth (Whitman et al., 1998). However, these estimates were mainly derived from organic carbon-rich, meso- to eutrophic sediments from continental margins and/or upwelling areas. A recent study included organic carbon-lean, oligotrophic subsurface sediments which contain much less cells and showed that the total cell counts varied between ocean sites by ca. five orders of magnitude (Figure 1; Kallmeyer et al., 2012). They estimated Earth's total number of microbes and living biomass to be 50–78 % and 10–45 %, respectively, lower


Deep Biosphere, Figure 1 Subseafloor sedimentary cell counts (From Kallmeyer et al., 2012): (**a**) cell counts versus depth (mbsf) for various ocean sites. (**b**) Site locations overlain on a map of time-averaged sea surface chlorophyll (chl-a; Gregg et al., 2005).

than estimates by Whitman et al. (1998). Therefore, Kallmeyer et al. (2012) estimated the values for the global biomass in marine sediments to be now 2.9×10^{29} cells, corresponding to 4.1 petagram (Pg) C and ~0.6 % of Earth's total living biomass. The total microbial abundance in subseafloor sediments (2.9×10^{29} cells) is now similar to the estimates for the total number of prokaryotes in seawater (1.2×10^{29}) and in soil (2.6×10^{29}).

Kallmeyer et al. (2012) were able to count very low cell numbers by using a protocol in which the cells were counted after being detached from the sediment particles which allowed a concentration of more cells on a filter (Kallmeyer et al., 2008). For cell staining the brighter fluorescent dye SYBR Green was used instead of acridine orange. SYBR Green is nowadays more frequently used for total cell counting in sediments than any other dye (Figure 2; Weinbauer et al., 1998; Engelen et al., 2008; Morono et al., 2009; Schippers et al., 2010, 2012). Total cell counts do not provide information about the viability of the cells and their taxonomy. Using the cellular ribosomal RNA-targeting molecular technique catalyzed reporter deposition-fluorescence in situ hybridization (CARD-FISH or FISH), the first direct quantification of living cells – defined by the presence of ribosomes – was provided for deep sediment samples from the equatorial Pacific and the Peru margin (ODP Leg 201, Schippers et al., 2005; Teske, 2005; Biddle et al., 2006). A striking finding was that a large fraction of the subseafloor prokaryotes is alive, even in very old (16 Ma) and deep (>400 mbsf) sediments (Schippers et al., 2005). However, critical for a successful application of CARD-FISH or FISH seems to be the cell permeabilization protocol (Lloyd et al., 2013b).

Microbial activity and biogeochemistry in deep subsurface sediments

Results of the ODP program demonstrated that subseafloor microbial communities are active in biogeochemical cycling (e.g., Parkes et al., 2000). Within sediments and on rock surfaces, bacteria interact with minerals, thus catalyzing dissolution, precipitation, and other surface reactions that have been traditionally viewed as abiotic (Parkes et al., 2007, 2011). Pore water data from a large number of Deep Sea Drilling Project (DSDP) and ODP sites (e.g., Whelan et al., 1986; Kastner et al., 1990; Borowski et al., 1997; D'Hondt et al., 2004), in particular, decreases in sulfate and increases in methane, and the presence of hydrogen sulfide has long been identified by geochemists as manifestations of deep microbial activity. More recently, also stable sulfur isotope measurements have shown to reflect the activity of deep biosphere sulfate-reducing microbial communities (Wortmann et al., 2001). Anaerobic processes, in particular sulfate, Fe(III), and Mn(IV) reduction and methanogenesis, characterize subsurface marine sediments (D'Hondt et al., 2004; Schippers et al., 2010). In continental margin sediments, bacterial sulfate reduction can be responsible for 50 % or more of the organic matter degradation (Jørgensen, 1982; Ferdelman et al., 1999; Fossing et al., 2000). Consequently, sulfate-reducing bacteria (SRB) are among the most numerous microorganisms (Sahm et al., 1999; Ravenschlag et al., 2000; Schippers et al., 2010, 2012). From deep sediment layers in the Pacific Ocean, sulfate-reducing bacteria (SRB) have been enriched with different organic compounds at different temperatures (Barnes et al., 1998), and a novel barophilic sulfate-reducing bacterium, *Desulfovibrio profundus*, has
Deep Biosphere, Figure 2 Staining of cells in marine sediment samples with the DNA-intercalating fluorescent dyes DAPI (cells in bright *blue*, top) and SYBR Green (cells in *green*, bottom).

been isolated (Bale et al., 1997). Furthermore, a consortium of *Archaea* and sulfate-reducing bacteria catalyzes anaerobic methane oxidation, an important process in marine sediments regulating the sedimentary flux of methane to the ocean water column (Hoehler et al., 1994; Boetius et al., 2000; Jørgensen and Boetius, 2007; Milucka et al., 2012). In deeper sediments, where sulfate becomes depleted, bacterial methanogenesis and acetogenesis become quantitatively more important (Parkes et al., 2000; Heuer et al., 2009; Lever et al., 2010). Direct evidence for sulfate reduction and methanogenic activity comes from radiotracer experiments performed on sediments from various ODP Legs (Cragg et al., 1996; Parkes et al., 2000, 2005; Hoehler and Jørgensen, 2013).

Organic-lean, oligotrophic, and oxic sediments, with penetration of molecular oxygen to several meters, host oxygen-respiring prokaryotes, which likely dominate organic carbon oxidation (Røy et al., 2012; Ziebis et al.,

2012; Orcutt et al., 2013b). In such sediments radiolysis of water may provide hydrogen, and thus an energy source for autotrophic microorganisms independent of photosynthesis (Jørgensen and D'Hondt, 2006; D'Hondt et al., 2009).

Microbial cells in deeply buried marine sediments catabolize 10^4–10^6-fold more slowly than model organisms in nutrient-rich cultures, representing turnover biomass on timescales of centuries to millennia rather than hours to days, and subsist with energy fluxes that are 1,000-fold lower than the typical culture-based estimates of maintenance requirements (Hoehler and Jørgensen, 2013). Furthermore, it has been demonstrated that the microbial communities and their activities change at sediment interfaces over geological times (Coolen et al., 2002; Inagaki et al., 2003; Parkes et al., 2005; Schippers et al., 2012). For example, bacterial populations in subseafloor sediments from the Sea of Okhotsk, composed of pelagic clays with several volcanic ash layers containing fine pumice grains, were approximately two to ten times larger in the ash layers than those in the clays (Inagaki et al., 2003).

Microbial diversity and quantification in deep subsurface sediments

The biomass of the deep subsurface biosphere comprises the three domains of life *Archaea*, *Bacteria*, and *Eukarya*, as well as spores and viruses (Schippers et al., 2005, 2012; Edgcomb et al., 2011; Lomstein et al., 2012; Breuker et al., 2013; Engelhardt et al., 2013; Orsi et al., 2013a; Ciobanu et al., 2014). Total cell numbers alone do not provide information about the microbial diversity and the physiology of the microorganisms that are critical to understanding deep biosphere biogeochemical processes. It is important to ask what types of microorganisms are present and in what abundance and which of these microorganisms are truly active (i.e., not dormant) and participating in deep sedimentary geochemical processes. In the early days of deep biosphere research, classical cultivation techniques were applied, while nowadays molecular techniques are more frequently used (see below).

Using classical cultivation techniques, i.e., the most probable number (MPN) cultivation method, various physiological types of microorganisms have been enriched from deep sediments and their numbers determined (Cragg et al., 1990, 1996; Barnes et al., 1998; Parkes et al., 2000, 2009; D'Hondt et al., 2004; Biddle et al., 2005; Batzke et al., 2007). These types include aerobic ammonifiers, nitrate reducers, fermentative anaerobic heterotrophs, sulfate reducers, methanogens, acetogens, and anaerobic hexadecane oxidizers. MPN population counts ranged from 0 to 10^5 cells/cm^3 and generally decreased with increasing depth. Most of the prokaryotes in natural environments do not grow on standard laboratory media since the complex conditions of the natural habitat are difficult to reproduce. Thus, generally less than 0.6 % of the total cell numbers in deep sediments were

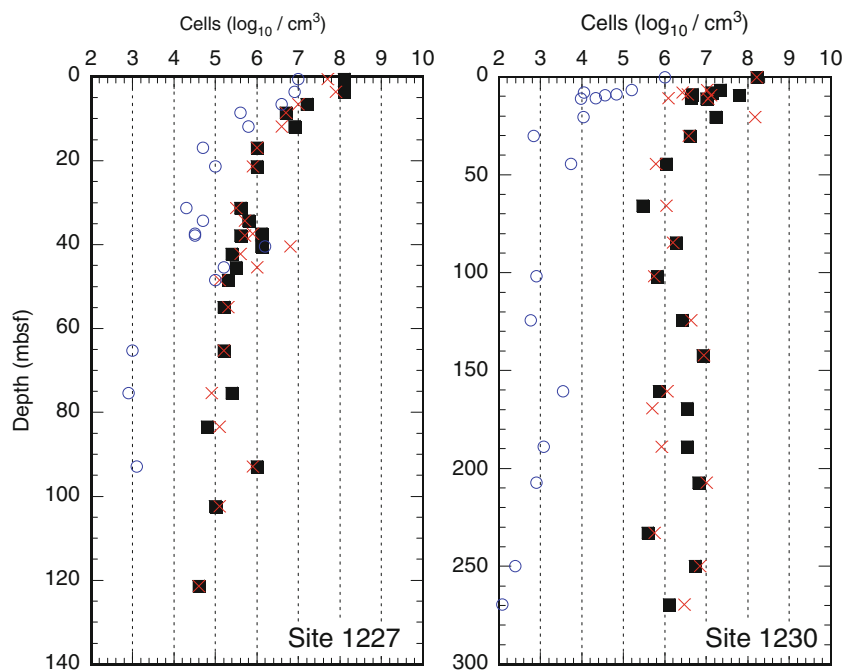
detected via cultivation (Cragg et al., 1990, 1996; Barnes et al., 1998; Parkes et al., 2000). Bacteria have been enriched and isolated with different organic compounds at different temperatures (Bale et al., 1997; Barnes et al., 1998; Inagaki et al., 2003; Mikucki et al., 2003; Toffin et al., 2004, 2005; Biddle et al., 2005; Lee et al., 2005; Kobayashi et al., 2008; Parkes et al., 2009). Isolates belonged to the alpha-, gamma-, deltaproteobacteria, Firmicutes, Actinobacteria, and Bacteroidetes (D'Hondt et al., 2004; Batzke et al., 2007). For example, a barophilic sulfate-reducing bacterium, *Desulfovibrio profundus* (Bale et al., 1997), and a methanogenic archaeum, *Methanoculleus submarinus*, have been isolated from deep marine sediments that contain methane hydrates (Mikucki et al., 2003). Cultivation and isolation of microorganisms is still the only way to get novel organisms from the environment; to study the properties for the description of new species, understanding their role in the environment; and to use them for biotechnological applications. However, molecular methods provide a more comprehensive picture about the diversity and abundance of microbial communities in the environment.

In recent years, nucleic acid-based techniques (i.e., DNA and RNA extraction, PCR amplification, and sequencing) have been developed to identify subsurface microorganisms without cultivation. Most of these techniques make it possible to phylogenetically identify specific groups of microorganisms and can highlight microbial diversity and detect new sequences. The analyses of 16S rRNA gene sequences showed that microbial communities of deep marine sediments harbor members of distinct, uncultured bacterial and archaeal phylogenetic lineages (Teske, 2006a; Teske, 2006b; Biddle et al., 2008; Teske and Sørensen, 2008; Fry et al., 2008; Durbin and Teske, 2012; Kubo et al., 2012; Orsi et al., 2013b). Among the *Bacteria*, 16S rRNA gene sequences belonging to the JS-1 group and the *Chloroflexi* were frequently found (Webster et al., 2004, 2007, 2011; Blazejak and Schippers, 2010). Typical groups for the *Archaea* include the Marine Benthic Group B (MBG-B), a deeply branching phylum-level lineage; the Miscellaneous Crenarchaeotal Group (MCG), a frequently detected crenarchaeotal lineage with high intragroup diversity; the South African Gold Mine Euryarchaeotal Group (SAGMEG); and the Marine Benthic Group D (MBG-D), an euryarchaeotal group affiliated with the *Thermoplasmatales* (Durbin and Teske, 2012). The metabolic capabilities of these uncultivated organisms have started to be explored using metagenomic approaches (Biddle et al., 2008, 2011; Rinke et al., 2013; Wasmund et al., 2014). For example, recent metagenomic data indicate that uncultured archaea such as MCG and MBG-D may have a role in protein remineralization in anoxic marine sediments (Lloyd et al., 2013a). The microbial ecology of the deep biosphere has been mainly studied in organic-rich, meso- to eutrophic sediments, and relatively few studies focused on organic carbon-lean, oligotrophic subsurface sediments (Inagaki et al., 2001; Sørensen et al., 2004; Nunoura et al., 2009; Roussel

et al., 2009; Durbin and Teske, 2011; Breuker and Schippers, 2013). Since oligotrophic sediments exhibit specific archaeal diversity patterns, the organic carbon content is obviously extremely relevant for the natural selection of distinct *Archaea* (Durbin and Teske, 2012). However, the organic carbon concentration is not a directly proportional index of the sediment trophic state, as substrate availability and organic carbon residence time can vary between sediments with similar organic carbon contents (Durbin and Teske, 2012). Consequently, Durbin and Teske also defined other parameters such as the sedimentation rate, the penetration depth of electron acceptors such as sulfate, and the ammonium concentration to characterize the trophic state of sediments.

Sulfate reduction and methanogenesis are relevant biogeochemical processes in deeply buried sediments (e.g., D'Hondt et al., 2004). However, sulfate-reducing *Bacteria* or methanogenic *Archaea*, which are frequently found in near-surface sediments, were rarely detected in deep sediments (Parkes et al., 2005; Biddle et al., 2006; Inagaki et al., 2006; Teske, 2005; Teske, 2006a; Teske, 2006b; Webster et al., 2006; Fry et al., 2008; Teske and Sørensen, 2008). In addition to 16S rRNA genes, sulfate reducers and methanogens have been detected and quantified via their functional genes encoding dissimilatory sulfite reductase (*dsr*), adenosine 5′-phosphosulfate reductase (*apr*), and methyl-coenzyme M reductase (*mcr*), respectively (Parkes et al., 2005; Schippers and Neretin, 2006; Webster et al., 2006, 2009; Wilms et al., 2007; Engelen et al., 2008; Nunoura et al., 2009; Blazejak and Schippers, 2011; Breuker et al., 2013; Lever, 2013; Ciobanu et al., 2014).

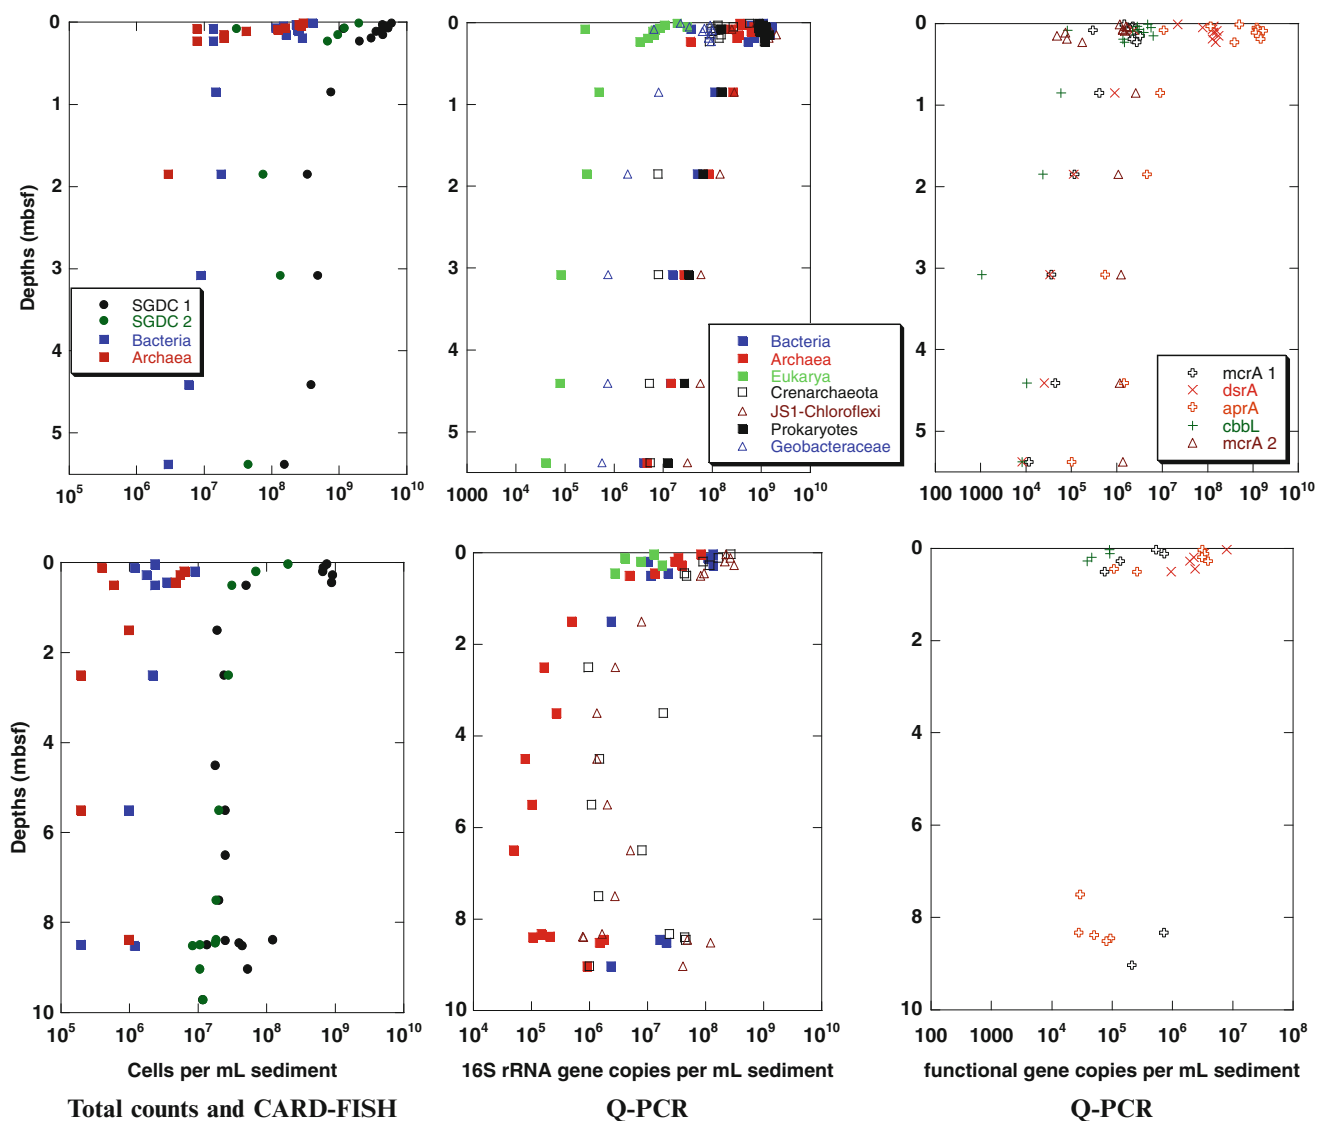
As mentioned above CARD-FISH (and FISH) has been applied for the quantification of living *Bacteria* and *Archaea* in deeply buried subsurface sediments. Another technique with high sensitivity is quantitative real-time polymerase chain reaction (qPCR). It has been used frequently for the enumeration of phylogenetic 16S rRNA genes as well as functional genes coding for enzymes particularly involved in biogeochemical processes. qPCR is based on the online fluorescence detection of PCR products and allows the rapid detection and quantification of gene sequences without the need for labor-intensive post-PCR processing (Heid et al., 1996). For application, DNA is quantitatively extracted from sediment samples, purified, and specifically amplified with a thermocycler using sequence-specific fluorescently labeled probes. There are different formats of the used probes, but the most common are sequence-specific TaqMan probes (Heid et al., 1996) and the intercalating nonspecific SYBR Green dye (Wittwer et al., 1997). The detection limit of the method depends on the target of interest, sample purity, PCR conditions, and other factors but theoretically allows to detect a single DNA molecule (Lockey et al., 1998). Additionally to DNA, RNA can be quantified after application of an additional reverse transcription step.

A quantification of particular prokaryotic groups (i.e., *Bacteria* and *Archaea*) in deep subsurface sediments has


Deep Biosphere, Figure 3 Depth profiles of total prokaryotes (*squares*), *Bacteria* (*crosses*), and *Archaea* (*circles*) determined by qPCR for two Peru continental margin sites (ODP Leg 201; from Schippers et al., 2005).

been done by qPCR in several studies (Figures 3 and 4; Inagaki et al., 2003; Schippers et al., 2005; Inagaki et al., 2006; Schippers and Neretin, 2006; Wilms et al., 2007; Engelen et al., 2008; Nunoura et al., 2009; Webster et al., 2009; Schippers et al., 2010, 2012; Breuker et al., 2013; Breuker and Schippers, 2013; Ciobanu et al., 2014). Eukaryotic 18S rRNA genes were orders of magnitude less abundant than prokaryotic 16S rRNA genes (Schippers and Neretin, 2006; Schippers et al., 2010, 2012; Ciobanu et al., 2014). Published qPCR data on the abundance of *Bacteria* and *Archaea* of several sediment studies show that the ratio of *Archaea* versus *Bacteria* seems to be variable depending on the type of sediment (Table 1; Breuker and Schippers, 2013; Breuker et al., 2013) and/or the qPCR protocols applied in different laboratories (Lloyd et al., 2013b). Using qPCR, an almost equal abundance of *Bacteria* and *Archaea* has been found for the Porcupine Seabight (IODP Exp. 307; Webster et al., 2009), the northeast Pacific ridge flank (IODP Exp. 301; Engelen et al., 2008), Sumatra forearc basins (Schippers et al., 2010), and sediments of the Black Sea and the Benguela upwelling system of the Atlantic coast of Namibia (Figure 4; Schippers et al., 2012). By contrast, *Bacteria* dominated other sediments such as the Sea of Okhotsk (Inagaki et al., 2003), the Gulf of Mexico (IODP Exp. 308; Nunoura et al., 2009), the Peru continental margin, and the equatorial Pacific sediments (Figure 3; ODP Leg 201; Schippers et al., 2005; Inagaki et al., 2006), as well as gas hydrate-bearing sediments from the Cascadia margin (ODP Leg 204; Inagaki et al., 2006) as

well as very deep sediments of the Canterbury basin (IODP Exp. 317; Ciobanu et al., 2014). These data on the abundance of *Bacteria* and *Archaea* in deeply buried marine sediments originate from qPCR analysis of rather organic carbon-rich, eutrophic sediments. There, *Bacteria* either dominated or an overall equal portion of *Bacteria* and *Archaea* were determined in all qPCR studies. *Archaea* dominated only clearly in the oligotrophic (total organic carbon ~0.15 ± 0.07 %) and oxic sediments from the North Pond area in 7 Ma western flank of the Mid-Atlantic Ridge 23°N (Breuker and Schippers, 2013). It is not understood which factors control the *Bacteria*/ *Archaea* ratio but likely the organic carbon content is an important factor. In addition, a potential underestimation of *Archaea* depending on the applied qPCR protocols has to be considered in future studies (Lloyd et al., 2013b).

The data for the Peru continental margin and the equatorial Pacific sediments (ODP Leg 201) as well as gas hydrate-bearing sediments from the Cascadia margin (ODP Leg 204) gave conflicting results depending on the quantification method. Nucleic acid-based methods (CARD-FISH and qPCR) showed as mentioned above a dominance of *Bacteria* (Schippers et al., 2005; Schippers and Neretin, 2006; Inagaki et al., 2006), while the analysis of intact polar lipids (IPL) of prokaryotic cell membranes determined *Archaea* as major prokaryotes in deeply buried sediments (Biddle et al., 2006; Lipp et al., 2008). These conflicting results may be explained by a potential underestimation of qPCR-determined *Archaea* (Lloyd et al., 2013b) but more likely by a different preservation


Deep Biosphere, Figure 4 Sediment samples from Benguela upwelling system (station 3, *top*) and from the Black Sea (stations 22, *bottom*; from Schippers et al., 2012). Total cell counts obtained with two different methods (SGDC1 after Weinbauer et al., 1998, SGDC2 after Kallmeyer et al., 2008) and CARD-FISH numbers for *Bacteria* and *Archaea* (*left*); qPCR quantification of 16S rRNA genes of *Prokaryotes*, *Bacteria*, *Archaea*, *Eukarya*, *Crenarchaeota*, *Geobacteraceae*, and JS-1-*Chloroflexi* (*middle*); and the functional genes *mcrA* 1 and 2, *dsrA*, *aprA*, and *cbbL* (*right*).

of DNA and IPL in deeply buried sediments (e.g., stabilized on clay surfaces or organic matter; Coolen et al., 2006; Inagaki and Nealson, 2006; Schippers and Neretin, 2006). The preservation of archaeal IPL biomarkers in marine sediments has been confirmed based on experimental and modeling approaches (Schouten et al., 2010; Logemann et al., 2011; Xie et al., 2013). These indicate that due to their different chemical nature, a faster degradation of ester-bound bacterial than of ether-bound archaeal IPLs leads to an increasing proportion of archaeal IPL with sediment depth. The fossilized archaeal IPLs mainly derived from sedimented *Archaea* from the water column were masking the much smaller pool of IPLs from

living cells in the sediments. As a consequence, the published IPL data do not reflect the abundance of living *Archaea*, and the conclusion that *Archaea* are dominant in deeply buried sediments is therefore questionable (Lipp et al., 2008; Xie et al., 2013).

Life in the ocean crust

Some recent review papers give an overview about life in the ocean crust (Edwards et al., 2005, 2012; Schrenk et al., 2010; Orcutt et al., 2011). Nearly 70 % of the Earth's surface is covered by ocean crust of which the major part is covered by sediments. The marine deep biosphere in the

ocean crust has been less intensively studied than that in subsurface sediments. Unlike sediments in which organic carbon, derived from photosynthesis in the oceans, is the major energy source for microbial life, inorganic processes in the ocean crusts likely provide the main energy for the rock-hosted deep biosphere.

Prokaryotic cell abundances on seafloor-exposed basalts are three to four orders of magnitude greater than in overlying deep-sea water. Microbiological analyses of basaltic lavas revealed that the basalt-hosted biosphere harbor is a substantial community of phylogenetically and physiologically diverse microorganisms. This community is dominated by *Bacteria* and comprises at least 16 different taxonomic groups, including all subdivisions of the proteobacteria (Santelli et al., 2008). As energy source for these microorganisms, the alteration of basalt, in particular the oxidation of reduced iron and sulfur in the basalt, has been suggested (Bach and Edwards, 2003). Evidence for this suggestion comes from textural observations in altered glass of oceanic pillow basalts (Fisk et al., 1998), the fact that iron-oxidizing bacteria can live on basalt glass and increase basalt-weathering rates (Edwards et al., 2004) and that microbial biomass and community composition correlate with the age and alteration state of seafloor basalts (Santelli et al., 2009). As a competing hypothesis, iron- and manganese-oxidizing bacteria living as biofilms on basalt rock are rather fed by material from hydrothermal venting than by basalt-weathering processes explaining the formation of iron-manganese crusts on basalt surfaces (Templeton et al., 2009).

Support for microbial life in ocean crust came from the microbial analyses of borehole fluids (reviewed in Edwards et al., 2012). For example, ribosomal RNA gene sequence data of 65 °C fluids from a 300-m-deep borehole indicated the presence of diverse *Bacteria* and *Archaea*, including gene clones of varying degrees of relatedness to known nitrate reducers (with ammonia production), thermophilic sulfate reducers, and thermophilic fermentative heterotrophs, all consistent with the fluid chemistry (Cowen et al., 2003).

Evidence for microbial carbon and sulfur cycling in deeply buried ridge-flank basalts has been recently given by the presence of functional genes of methane-cycling and sulfate-reducing microorganisms, their successful cultivation, as well as signatures of carbon and sulfur stable isotopes in the drilled basalt core. Hydrogen-producing abiotic serpentinization reactions have been discussed to be relevant for providing the energy for these microorganisms (Lever et al., 2013).

In the deepest gabbroic layer of ocean crust, a low diversity of proteobacterial lineages was observed. These were related to *Bacteria* from hydrocarbon-dominated environments and to known hydrocarbon degraders. Archaeal 16S rRNA genes were not detected; however, the functional gene *mcr* of methanogens was detected as well as functional genes coding for enzymes involved in nitrate, sulfate, and metal reduction, carbon and nitrogen fixation, and ammonium, methane, and toluene oxidation (Mason et al., 2010). Since hydrocarbons were detected in the same borehole, probably originating from abiotic serpentinization reactions, the microbial community is

likely fed by hydrocarbons formed independently of photosynthesis in the ocean (Mason et al., 2010).

The size of the biomass in oceanic crust is unknown. Ocean crust shall harbor the largest aquifer on Earth (Fisher and Becker, 2000), which may transport molecular oxygen and nitrate for basalt-weathering reactions (Expedition 329 Scientists, 2011; Ziebis et al., 2012; Orcutt et al., 2013b). This provides an enormous porous space and chemical redox gradients as energy source for a potentially huge deep biosphere. It has been suggested based on model estimates that the size of the biomass of the deep biosphere in oceanic crust is at least as big as that in marine sediments (Heberling et al., 2010). Future research will reveal this estimate.

Conclusions

The marine deep biosphere has been explored at various ocean sites mainly within the framework of the Ocean Drilling Program (ODP) and the Integrated Ocean Drilling Program (IODP). The deep biosphere in the ocean crust has been less intensively studied than that in subsurface marine sediments. Unlike sediments in which organic carbon, derived from photosynthesis in the oceans, is the major energy source for microbial life, inorganic processes in the ocean crusts likely provide the main energy for the rock-hosted deep biosphere. The size of the biomass in oceanic crust is unknown. Kallmeyer et al. (2012) estimated the values for the global biomass in marine sediments being now 2.9×10^{29} cells, corresponding to 4.1 petagram (Pg) C and ~0.6 % of Earth's total living biomass. The total microbial abundance in subseafloor sediments (2.9×10^{29} cells) is now similar to the estimates for the total number of prokaryotes in seawater (1.2×10^{29}) and in soil (2.6×10^{29}). The biomass of the deep subsurface comprises the three domains of life *Archaea*, *Bacteria*, and *Eukarya*, as well as spores and viruses. The analyses of 16S rRNA gene sequences showed that microbial communities of deep marine sediments harbor members of distinct, uncultured bacterial and archaeal phylogenetic lineages. Living cells, microbial activity, and the impact of the deep biosphere for biogeochemical processes have been demonstrated.

Synonyms
Single-point-sourced turbidite system; Submarine fan

Definition
The term "deep-sea fan" has been coined by Normark (1970) to describe modern turbidite systems with a point source that typically display a fan-shaped outline. This morphological analysis was based on the Pleistocene Californian fans San Lucas and Astoria. Mutti and Ricci Lucchi (1972) used a similar model to describe the fan-shaped facies association of Cretaceous and Tertiary turbidite systems in the Apennines and Spanish Pyrenees.

The depositional system
Models that are more recent try to make a synthesis between morphology, sedimentary processes, depositional environment, and sedimentary facies (Walker, 1978; Mutti, 1979; Barnes and Normark, 1985). They include control factors such as sedimentary source, tectonic context, and eustatic changes.

The term "turbidite system" was thus preferentially used to embrace all deepwater clastic depositional systems. The environmental model of Reading and Richards (1994) includes (a) submarine fans controlled by single-point-sourced supply, (b) submarine ramps displaying multiple-point-sourced delivery, and (c) slope aprons with line-sourced supply. Based on the lithology, mud-rich, mud-/sand-rich, sand-rich, or gravel-rich systems are differentiated.

Mud-rich submarine fans are the typical turbidite systems of modern passive continental margins. The largest fans (10^5–10^6 km^2) are the Bengal, Indus, Amazon, Mississippi, and Zaire fans. Much of the clastic material of these high-efficiency, open-ocean fans is typically supplied during floods from major rivers.

The modern mud-rich submarine fans are subdivided into canyon, channel-levee, and lobe complexes. The canyon usually largely incises the continental slope and shelf, sometimes up to river mouth. On the continental rise, it opens on a channel-levee complex including several generations of stacked channel-levees. The channel is usually meandering and aggradational and bordered with bird wing-shaped (in a transversal cross section) levees built above the fan surface. Levees progressively diminish in height and grain size and pass into lobes extending in the abyssal plain. Lobes are first channeled and become unchanneled with increasing distance.

Today, classification of deep-sea turbidite systems has been officially abandoned (Walker, 1992).

Sedimentologists prefer the "do-it-yourself" toolbox using the architectural element concept (Miall, 1985).

DEEP-SEA SEDIMENTS

Mitchell Lyle
College of Earth, Ocean, and Atmospheric Sciences, Oregon State University, Corvallis, OR, USA

Synonyms
Pelagic sediments

Definition
The term "deep-sea sediments" or the interchangeable term "pelagic sediments" refers to sediments that deposit

Deep-sea Sediments, Figure 1 Sediment thickness in the world's oceans (Whittaker et al., 2013; http://www.ngdc.noaa.gov/mgg/sedthick). The thickest sediments (*beige*) are along continental margins where turbidites accumulate. The thinnest sediments (*dark blue*) are on areas far from land or on zero age crust along the mid-ocean ridges where there has not been time for sediments to accumulate.

slowly in the abyssal ocean beyond the continental margins.

What are deep-sea sediments?

Deep-sea sediments typically have sedimentation rates less than 30 m/10^6 years, and rates as low 0.1 m/10^6 years have been reported. The slow sedimentation rates and unusual sediment compositions reflect the low fluxes of aluminosilicates eroded from continents. The terrigenous material that does deposit is often windblown dust. Other solids produced through biological activity, through hydrothermal leaching of basalts, or even by earth's bombardment by meteorites can make up large fractions of a deep-sea sediment deposit.

Not all sediments in the deep ocean are deep-sea sediments depositing slowly. A significant portion of the deep ocean is filled by turbidites, which are gravity flow deposits that typically originate from the continental margins. These sediments will be discussed briefly in section "Turbidites and Hemipelagic Sediment Components" but are really extensions of continental margin sedimentation.

Typically, the total sediment accumulation in the deep sea that is on basalt crust is less than 250 m (Figure 1; Whittaker et al., 2013). For most ocean regions, sediment production is small compared to erosion of mountains and river transport. Because of plate tectonics, there is little time to accumulate a thick sediment pile because the ocean crust is young – the seafloor is totally resurfaced in about

160 million years. Thickest accumulations outside of the turbidite regimes are on older shallower crust or underneath zones of high biological productivity. Sediments are thicker under regions of high productivity because the $CaCO_3$ and SiO_2 tests of plankton are a major deep-sea sediment component (section "Biogenic Sediment Components") and in shallow plateaus because there is better preservation (section "Seafloor Processes Affecting Deep-Sea Sediment Composition: Dissolution, Early Diagenesis, and Sediment Movement"; Berger, 1970).

Why study deep-sea sediments?

Deep-sea sediments are the main means to study environmental change within the marine world. Because they accumulate slowly but steadily, analysis of sediment cores can provide environmental records that span millions of years. Components of deep-sea sediments record changes in ocean temperature and salinity and track the growth and decay of ice sheets. They can be used to track the change of winds and aridity on continents in response to climate cycles. They are also used to study ocean biogeochemical cycles and how they are changed by natural variation in weathering or greenhouse gas emissions. The strong imprint of Milankovitch solar insolation cycles in the sediments is an important indication of the sensitivity of the earth and oceans to minor changes in climate drivers (Hays et al., 1976; Hodell et al., 2001; Lisiecki and Raymo, 2005).

Regions with coherent sedimentation patterns within the oceans are extremely large compared with those on land. Patterns of change in the oceans can thus be elucidated from relatively few sediment cores. Large regions in the oceans have similar environmental conditions (e.g., temperature, nutrients, and salinity), and most of the ocean basins are being covered with a continual rain of sediment. Deep-sea sediment regimes are also large because they reflect the relative size of the depositional processes, whether it is the region underneath continental dust plumes or regions with coherent production of planktonic hard parts. On land, the primary variables (precipitation, temperature, seasonality) vary on a much smaller scale and thus must be sampled more densely. Terrestrial basins that systematically collect sediments are also more rare than in the oceans.

Geophysical and geologic study of deep-sea sediments

Marine geologists have difficulty accessing deep-sea sediments, because the average ocean depth is ~3,800 m and recovery of ocean bottom samples is technically challenging and time consuming. While sampling is hard, geophysical methods that use acoustic pulses are much easier to perform at sea than on land. Sound propagates well through water and it is much easier to produce and receive an acoustic pulse through the ocean than through the land surface. Marine geologists are much more dependent on geophysical methods than continental geologists.

Marine geologists use acoustic methods to map the topography of the seafloor (echo sounding or multibeam bathymetry) and to map sediment layers beneath the seafloor (reflection seismology). Multibeam mapping uses acoustic technology to emit a focused array of acoustic pulses and uses the time for each pulse to return to calculate ocean floor depths in a swath perpendicular to the ship. The travel time data (time for the echo to hit the bottom and return) can be converted into a topographic map of the seafloor by using measured ocean sound velocity to convert from time to depth (e.g., Caress and Chayes, 1996; Mosher, 2011). An example of the resultant map is shown at the top of Figure 2, a survey around the IODP drill site U1335 (Expedition 320/321 Scientists, 2010).

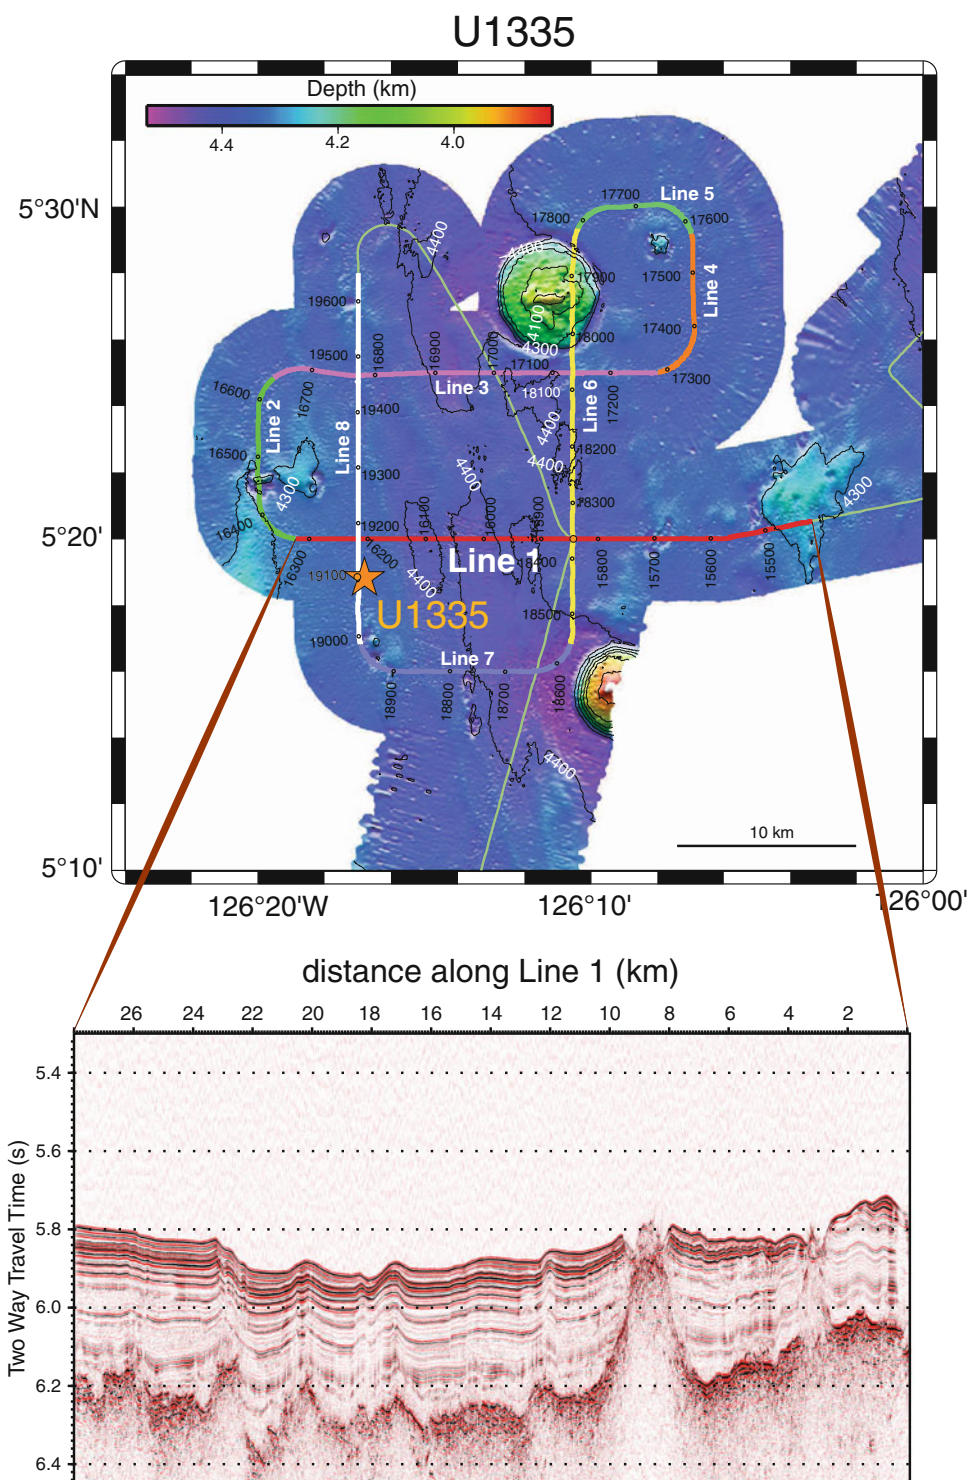
Seismic reflection measures the time for an echo to be reflected back from sediment layers. The echoes occur where sediment density and/or acoustic velocity change and are typically caused by a change of sediment lithology. Rarely, acoustic interference causes composite echoes from closely spaced beds (Mayer, 1979). The echoes from sediment layers produce a cross section of sediment deposition through the sediments (Figure 2 bottom; Mayer et al., 1986). The combination of swath mapping and seismic reflection allows marine geologists to interpret how sediments have accumulated, allowing them to understand the long-term development of a marine sediment sequence (e.g., Sacchetti et al., 2013; Brothers et al., 2013).

Such information has limited use without ground truth from sediment samples. Marine geologists use a variety of techniques to sample near-surface sediments by lowering coring devices to the seafloor on a wire rope. Where the ocean is greater than 3 km deep, it takes 2–6 h to lower a corer to the bottom, collect a sample, and bring it back to the ship. Sediment cores taken by wireline range in length from 0.3 m to about 20 m long, sufficient to study relatively recent geologic events. Because of the effort needed to collect these cores, the sediment cores are archived in core repositories around the world (e.g., Lamont-Doherty Earth Observatory core repository, http://www.ldeo.columbia.edu/core-repository/collections). Locations of many of these geologic samples can be plotted using the online mapping and database tool GeoMapApp (http://www.geomapapp.org/).

While wireline coring can collect near-surface sediments, drilling technology must be used to sample the entire sediment column and the ocean crust (Duce et al., 2011). The time needed to sample the entire sediment column may take days or weeks, depending on the thickness of the sediments and the care taken to recover a full sediment column for scientific analysis. Once recovered, the drilled sediment column can be correlated to the seismic reflection profile to identify and date specific seismic reflection horizons. With dated seismic horizons, it is possible to study regional variations in sedimentation by using seismic reflection profiles (Mayer et al., 1986; Tominaga et al., 2011).
Types of deep-sea sediments

Tens of thousands of archived deep-sea sediment samples have made it possible to map different types of sediments, linked to regional environmental conditions (Menard, 1964; Lisitzin, 1972; Dymond, 1981). Deep-sea sediments are often classified by the source of their major components. For example, sediments consisting of ferromanganese oxyhydroxides precipitated from mid-ocean ridge hydrothermal plumes are referred to as hydrothermal sediments.

Based upon a source definition, there are four major classes of deep-sea sediment components: (a) *terrigenous* sediments, aluminosilicates from the continents, divided into *hemipelagic* (water-transported continental debris) and *aeolian* (windblown dust); (b) *biogenic* sediments, primarily calcareous or siliceous hard parts of organisms; (c) *hydrothermal* sediments, derived from mid-ocean ridge hot springs; and (d) *authigenic* sediments, precipitated directly out of seawater. Most deep-sea sediments are mixtures of the different components. For example, hemipelagic sediments will also have a small percentage of biogenic-sourced plankton tests.

The sediment types have typical sedimentation rates, reflecting their relative supply to the pelagic environment (Figure 3). Sedimentation rates are plotted against sediment C_{org} content because the amount of C_{org} is a primary indicator of the rate of primary productivity in the surface


Deep-sea Sediments, Figure 2 An example of a swath map bathymetry map (*top*) and a seismic reflection profile (*bottom*) from a site survey for IODP Site U1335, in the central tropical Pacific Ocean (Expedition 320/321 Scientists, 2010). The bathymetric map shows areas of current scour near seamounts and areas of disturbed sediment along Line 1. The seismic reflection profile along Line 1 shows that the sediment disturbances found by the swath map survey are where small seamounts still stick up through the sediment column. The parallel seismic horizons in the seismic reflection profile mark changes in lithology. In the tropical Pacific, these normally result from changes in sediment $CaCO_3$ content (Mayer et al., 1986).

Deep-sea Sediments, Figure 3 Ranges of sedimentation rates versus organic carbon content for different types of deep-sea sediments. Highest sedimentation rates and C_{org} contents are found in hemipelagic sediments, because of high terrigenous sediment deposition and high biological productivity along continental margins. Authigenic sediments have the lowest rates of deposition and low C_{org} % because the rate of precipitation of these oxides from seawater is so slow.

waters and the intensity of early diagenesis (chemical and physical changes as sediment is converted to rock; section "Seafloor Processes Affecting Deep-Sea Sediment Composition: Dissolution, Early Diagenesis, and Sediment Movement") depends upon C_{org} degradation.

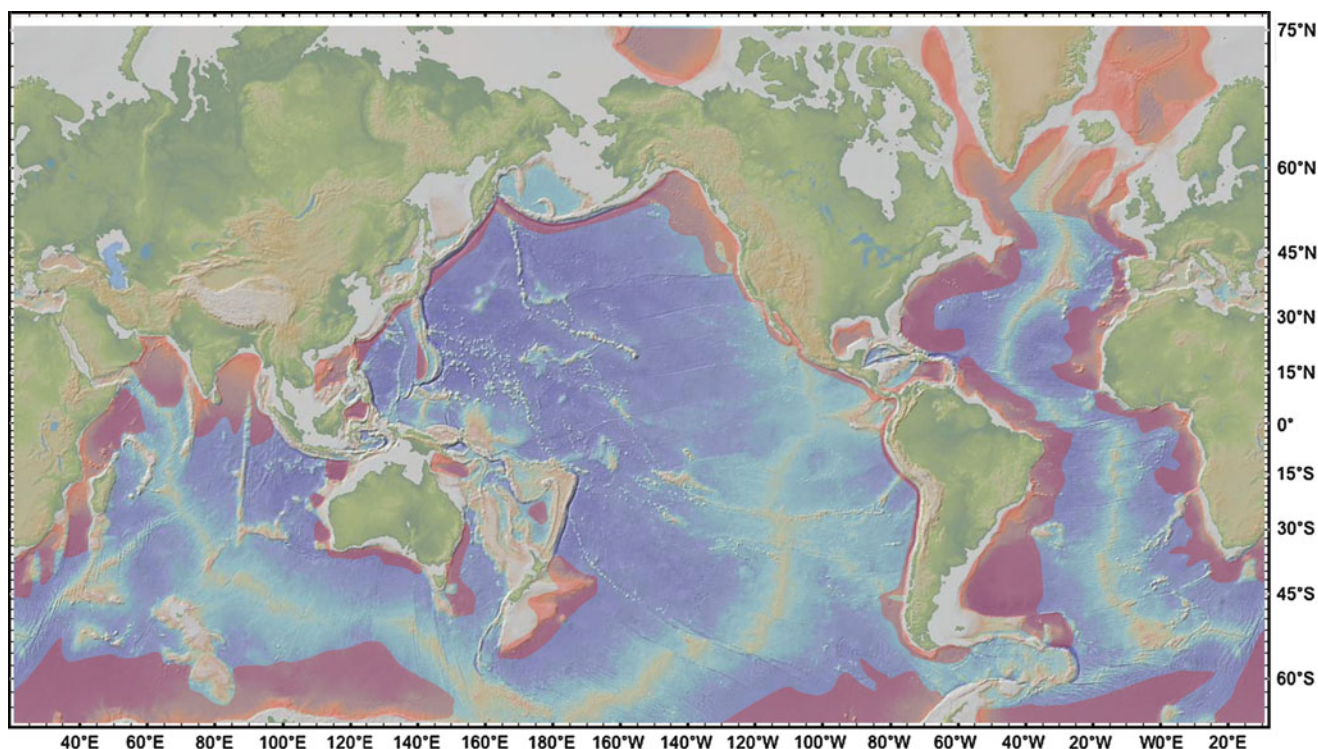
Turbidites and hemipelagic sediment components

The most abundant deep-sea sediments are terrigenous sediments derived from rivers or glaciers and which may temporarily reside on continental shelves before being deposited on abyssal plains. Turbidites are terrigenous in origin but not considered pelagic sediments. They are rapidly deposited from turbidity currents, relatively thick sediment-water slurries that flow down from continental shelves into the adjacent deep ocean. They are a type of continental margin sediment that happens to lie on the deep-ocean floor.

Turbidite-filled abyssal plains are common along continental margins (Figure 4) and are most commonly associated with passive continental margins, e.g., most of the Atlantic Basin, especially where there is high flux of sediments carried to continental margins by rivers or glaciers. Turbidites mostly fill basins at the toe of continental margins, and because they are deposited from dense sediment suspensions, they tend to ignore topography and form a

relatively flat deposit surrounding existing ridges or other upraised topography. An example of turbidite deposition can be found on the right-hand side of Figure 5, nearest to the North American continent. Figure 5 shows a seismic reflection profile across the Gorda Ridge, a slow-spreading mid-ocean ridge near the California-Oregon border.

Hemipelagic sediments, in contrast to turbidites, are fine-grained clay sediments that fall out of the water column and drape over the seafloor topography (Damuth, 1977; Gorsline et al., 1984). The sediment drape across topography can be found on the higher topography on Figure 5. Ocean crust is being formed at the Gorda Ridge axis and is transported east and west from the ridge axis. As the crust moves, it gradually gets covered with a thick layer of fine-grained sediment. Sediment at 2203z on Figure 5, for example, is about 150 m thick and is on crust about two million years old, indicating an average sedimentation rate of 70–80 m/10^6 years.

The fine-grained sediments that make up hemipelagic sediments originate from turbid plumes from rivers or from resuspension of fine-grained shelf sediments by internal waves or storms. The fine-grained sediments are then carried by currents and eventually deposited (Karlin, 1980; Krissek, 1984; Biscaye et al., 1988).


Deep-sea Sediments, Figure 4 *Red* shading shows locations of turbidite abyssal plains and deep-sea fans in the world ocean, assigned by using GeoMapApp (http://www.geomapapp.org/) to identify areas of flat topography near continental margins and to access geo-referenced analog seismic reflection data. Within the abyssal plain region, one often finds fine-grained hemipelagic sediments draping over higher topography above turbidite deposition. Largest turbidite plains are associated with passive continental margins and large river drainages.

Sediment composition can be used to track average current flow along the continental margins and how sediments move from the rivers to the deep sea. Krissek (1984), for example, estimated that 50–90 % of the river sediment flux to the Oregon/northern California margin escaped to deposit in the deep sea.

The Atlantic Ocean has a higher percentage of its total floor covered by turbidites than other ocean basins because it is surrounded by passive continental margins where continental sediment accumulates. The Pacific Ocean has a much higher percentage of its basin covered with deep-sea sediments because the sediment load from rivers is smaller and because much of the sediment is trapped in ocean trenches or back-arc basins. The Indian Ocean is home to two major deep-sea fans associated with sediments draining from the continental collision of Asia and India (Clift and Gaedicke, 2002; Bastia et al., 2010).

Aeolian and volcanic ash sediment components

Windblown dust is an important terrigenous component in slowly accumulating sediments of the deep sea, downstream from major dust sources on land (Figure 6; Rea, 1994; Mahowald et al., 1999, 2006). Not only is dust important as a sediment component, but dust deposition can also be critical to deliver micronutrients like Fe to the oceans (Martin 1990; Maher et al., 2010). Dust originates from the arid regions of the earth, found near 30° N or S of the equator. Most dust is produced from regions that are periodically wet rather than the hyperarid centers of deserts where there is not enough precipitation to weather the rocks quickly (Rea, 1994).

Windblown dust is a major component of deep-sea sediments where other sources are rare, e.g., the northwest Pacific Ocean (Figure 6). In the North Pacific, ocean crust is old and deep, and biogenic sediments dissolve before burial (see section "Seafloor Processes Affecting Deep-Sea Sediment Composition: Dissolution, Early Diagenesis, and Sediment Movement"). There is little left after dissolution except dust and the fraction that precipitates from seawater (*authigenic* sediments, section "Authigenic and Cosmogenic Sediment Components and Ferromanganese Nodules"). The highest dust flux into the oceans is from North African and Middle Eastern dust sources into the Arabian Sea and from North Africa westward into the subtropical Atlantic Ocean (Figure 6). Because these regions also have high biogenic sediment flux, the sediments are not as distinctly aeolian as sediments from the North Pacific.

Lowest dust fluxes are in the South Pacific, where the lowest sedimentation rates in the world ocean are also
Deep-sea Sediments, Figure 5 Seismic reflection profile across the Gorda Ridge, near the California-Oregon border. The location of the profile is shown on the inset map. The first reflection is the reflection from the seafloor, while the dark reflection is the echo from basaltic basement. Depth scale is in two-way travel time, where 1 s is equivalent to 750 m depth in water. Turbidite sediments (*right side*) fill in topography and typically have horizontal layering. Hemipelagic sediments are fine-grained continental sediments carried out in the water column and drape upon the topography. New ocean crust at a mid-ocean ridge is typically bare, but sediments thicken away from the mid-ocean ridge as the crust ages and there is time for sediments to deposit. Seismic profile is from cruise EW9413, from the UTIG seismic database (http://www.ig.utexas.edu/sdc/cruise.php?cruiseIn=ew9413). Processing: band-pass filter, 20–450 Hz, 1 s AGC.

found (Rea et al., 2006). Typically, dust fluxes into the Southern Hemisphere oceans are 1–2 orders of magnitude lower than those in the North Pacific (Rea, 1994). In the Southern Hemisphere, there are only two major dust sources, one in South America and one in Australia (Figure 6). In contrast, there are extensive northern arid regions, including northern Africa, Asia, and North America.

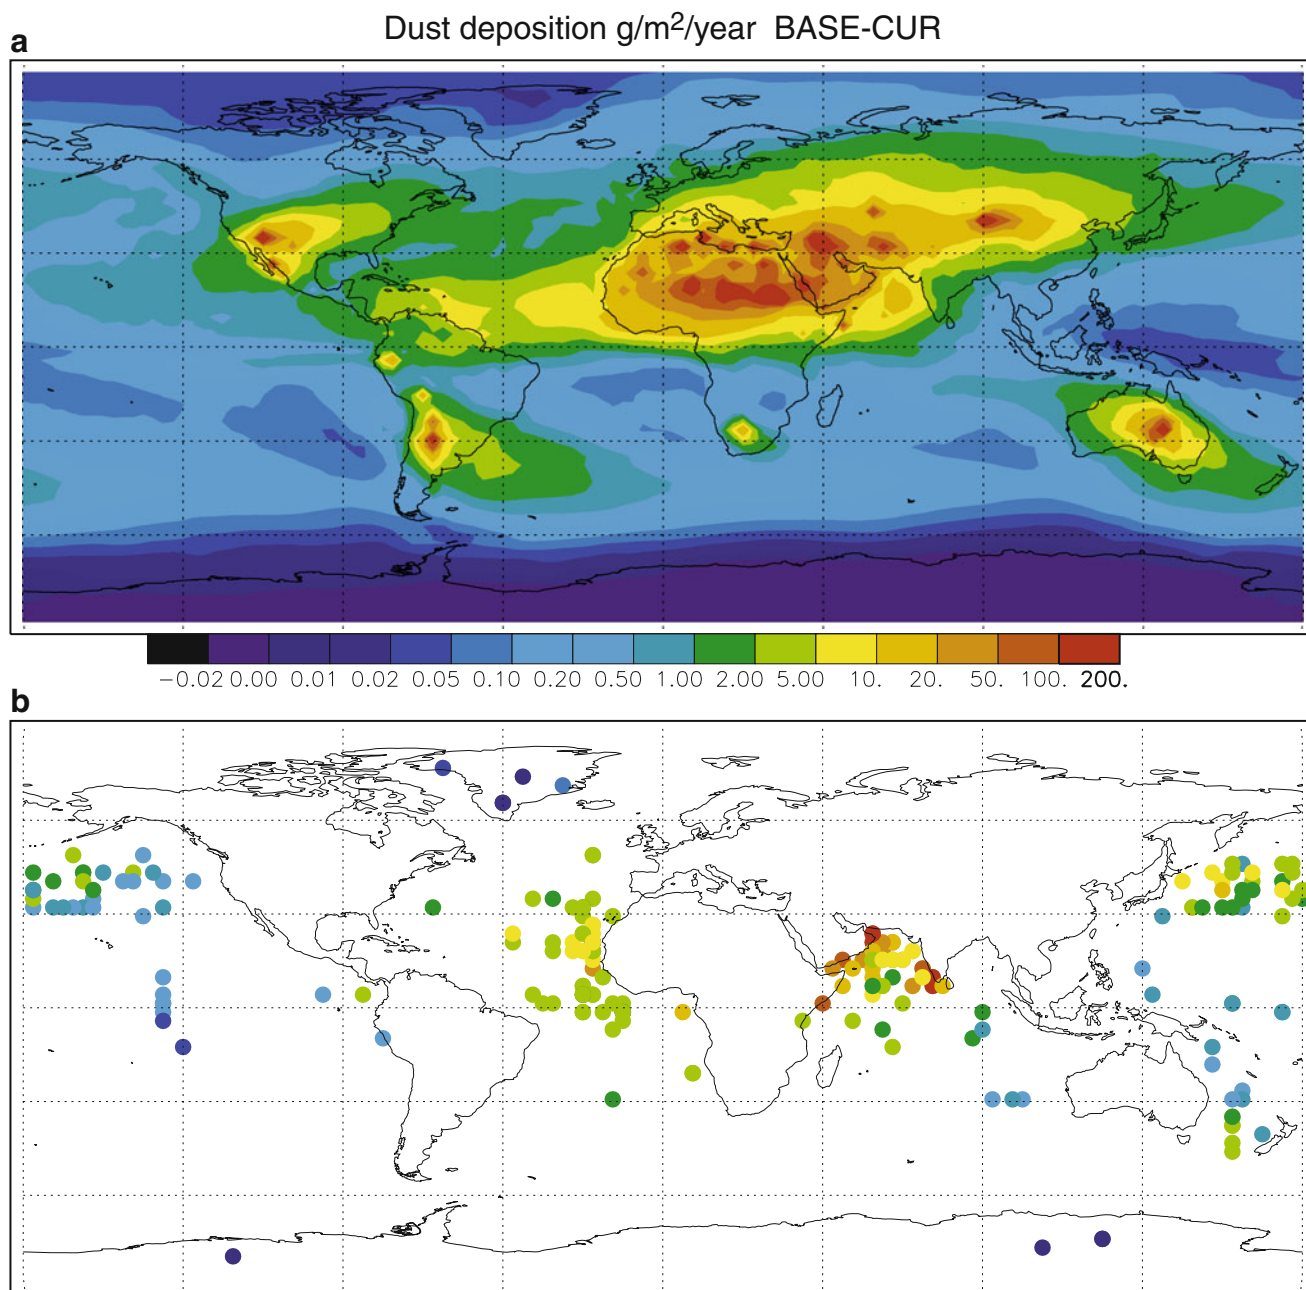
Volcanic ash is also a significant air-transported sediment component that can be found a surprisingly long distance from explosive volcanoes (Scheidegger et al., 1980; Olivarez et al., 1991). It also can be a significant source of Fe to the oceans (Duggen et al., 2010). Volcanic ash is most often recognized as discrete coarse layers of volcanic glass (e.g., Drexler et al., 1980), but dispersed ash can also be found using its distinctive chemical composition (Finney et al., 1988; Olivarez et al., 1991).

Biogenic sediment components

Biogenic sediments are primarily composed of mineralized hard parts produced by a variety of marine organisms. They also include organic remains (the C_{org} fraction) and elements like Ba that precipitate within C_{org}-rich particle rain as it falls from the euphotic zone to the seafloor (Griffith and Paytan, 2012). In shallow water, corals and calcareous algae are major producers of biogenic sediments, but in the pelagic realm, the production of mineral tests by protist plankton is the major source of this deep-

sea sediment component (Kennett, 1982). Production by plankton is often large enough to produce sediment accumulations that are essentially pure biogenic tests (Berger, 1973; Burckle and Cirilli, 1987; Lyle et al., 2010).

Biogenic sediments are divided into siliceous and calcareous oozes based on the composition of the plankton test. Tests are made of either biogenic SiO_2 (biogenic opal or biogenic silica) or biogenic $CaCO_3$ (biogenic carbonate). Both phytoplankton and zooplankton contribute to biogenic sediment production (Lipps, 1993). Single-celled photosynthetic algae are a major source of both biogenic silica (diatoms, with a minor contribution by silicoflagellates) and biogenic carbonate (coccolithophorids). The larger zooplankton tests are also significant fractions of biogenic sediment: foraminifera produce sand-sized tests of biogenic carbonate, whereas radiolaria produce silt- to fine-sand-sized tests of biogenic silica.

Biogenic carbonates are commonly used for paleoceanographic reconstructions because the tests of foraminifera are large enough to be easily separated from sediments for analysis. The chemistry of the test gives quantitative data about the environmental conditions at the time they were formed (e.g., Dekens et al., 2007). The preserved microfossil assemblages (census of different species preserved in a layer) can also be used to infer environmental conditions (e.g., Le and Shackleton, 1994) because plankton species live within characteristic


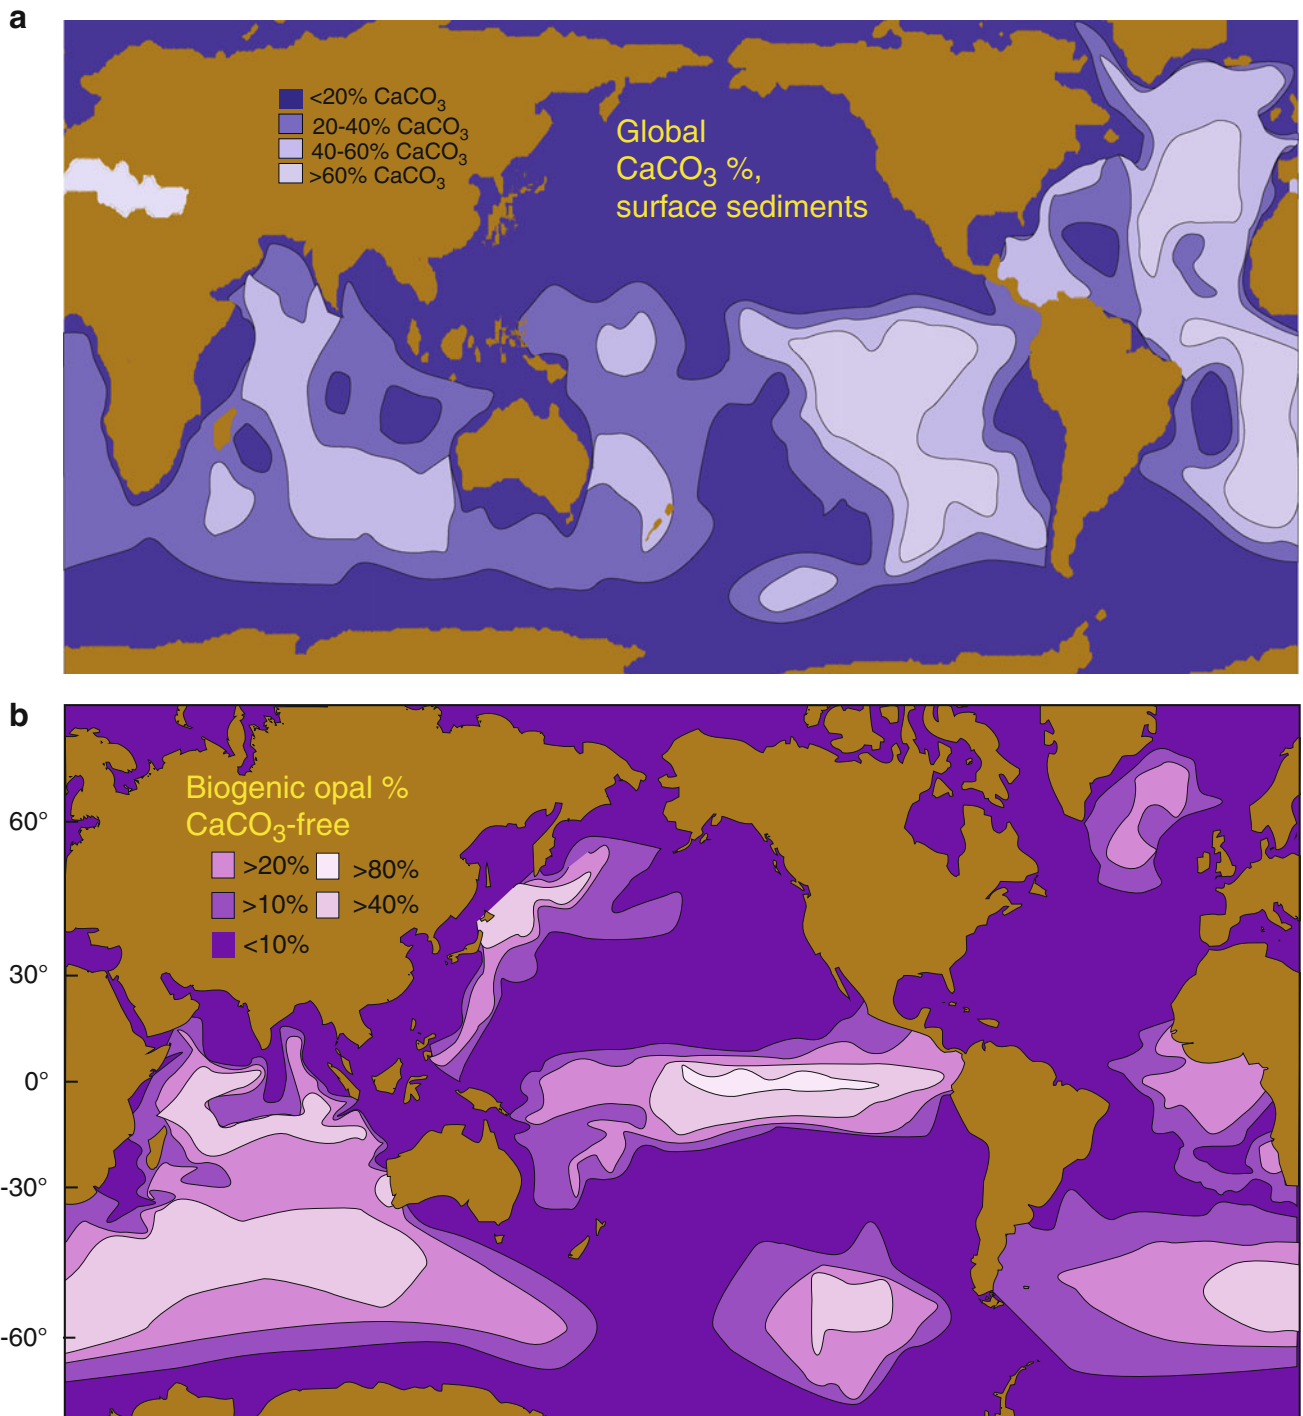
Deep-sea Sediments, Figure 6 Modeled modern global dust deposition compared to measured Holocene dust mass accumulation rates (MAR) in sediment cores from DIRTMAP (From Mahowald et al. (2006)). The highest dust deposition into the oceans is in the northern tropical Atlantic and the Arabian Sea. Extremely low dust fluxes are found in the Southern Hemisphere because there are few sources for dust.

environmental conditions. Equations can be made to relate the amount of each assemblage from a past time to the environmental conditions at that time. The assemblage techniques can be used to assess past ocean temperatures, e.g., CLIMAP project members (1976).

Pelagic sediments rich in biogenic components can be mapped by their opal and carbonate content (Figure 7;

Archer, 1996, Leinen et al., 1986). $CaCO_3$ is prominent in the Atlantic Ocean, because the ocean chemistry in the basin leads to better preservation (section "Seafloor Processes Affecting Deep-Sea Sediment Composition: Dissolution, Early Diagenesis, and Sediment Movement"). In the Pacific Ocean, biogenic sediments are primarily found in the south Pacific because the crust is shallower

a

b


Deep-sea Sediments, Figure 7 (**a**) Distribution of CaCO$_3$ in the world ocean after Archer (1996). The highest carbonate contents are in the Atlantic and in the Southern Hemisphere. The North Pacific is too deep to preserve CaCO$_3$. (**b**) Distribution of biogenic opal on a carbonate-free basis (as a percentage of the noncarbonate sediment fraction) from Leinen et al. (1986). Equatorial Pacific sediments are rich in both biogenic opal and CaCO$_3$, while sediments near the Antarctic polar front are typically diatom-rich.

and above the calcite compensation depth (CCD). Because CaCO$_3$ solubility is pressure dependent, the CCD represents where all CaCO$_3$ dissolves and none has been preserved. CaCO$_3$ will not accumulate in the oldest and deepest parts of the ocean basin like the North Pacific, even though plankton produce CaCO$_3$ and it rains to the seafloor (e.g., Zaric et al., 2005). High production of CaCO$_3$ occurs in pelagic, moderately strong upwelling regimes, especially

in the tropics (Figure 7a). Because the CCD represents the difference between production and dissolution, high $CaCO_3$ production forces down the CCD under the equatorial upwelling region resulting in higher $CaCO_3$ content in equatorial sediments (van Andel and Moore, 1974).

Biogenic opal distribution in Figure 7b is presented on a carbonate-free basis, as a percentage of the noncarbonate fraction of the sediments. Because biogenic opal is undersaturated in ocean waters, it only accumulates where sedimentation rates are reasonably high. For the most part, opal is an important but secondary biogenic sediment component in the pelagic regime. However, diatom oozes can be found where upwelling brings nutrient-rich waters to the euphotic zone and high diatom production results. Diatom oozes are characteristic of the Southern Ocean, for example (Burckle and Cirilli, 1987). A zone rich in radiolarian opal has often been noted along the north edge of the equatorial Pacific upwelling zone, but this primarily represents the outcropping of Eocene and older biogenic radiolarian oozes (Riedel, 1967). Eocene radiolarian oozes result from a shallow CCD prior to 34 million years ago and conditions favorable to radiolarian production of biogenic opal. Some researchers have proposed that the rich deposits of Eocene biogenic opal were caused by elevated dissolved Si in the oceans delivered by a very active silica weathering cycle, but Moore et al. (2008) showed that, at least in the equatorial Pacific, biogenic opal burial was no greater in the Eocene than the Holocene. Additional Si inputs to the oceans are not needed to produce the ooze deposits.

Both C_{org} and Ba are also biogenic sediment components. Near continental margins, C_{org} sediment contents are typically 1–2 % and occasionally can reach as high as ~20 % where hydrodynamically light sediments are deposited near coastal upwelling zones (Müller and Suess, 1979). In most of the pelagic realm, however, C_{org} contents are less than 0.25 % (Pedersen and Calvert, 1990). C_{org} burial is enhanced where primary productivity and sedimentation rates are high and secondarily where bottom water oxygen contents are low (Pedersen and Calvert, 1990). Enhanced C_{org} burial strongly affects the subseafloor redox environment and causes mobilization of some elements as well as enhanced burial of others (section "Seafloor Processes Affecting Deep-Sea Sediment Composition: Dissolution, Early Diagenesis, and Sediment Movement"; Froelich et al., 1979; Calvert and Pedersen, 1993; Morford and Emerson, 1999). Preservation of C_{org} has changed with time, and C_{org} is more poorly preserved when Earth climates were warm, perhaps because heterotrophs have higher metabolic demand under warm conditions (Olivarez Lyle and Lyle, 2006).

Ba is enriched in biogenic sediments as well as in hydrothermal sediments (Griffith and Paytan, 2012). As the remains of plankton fall through the water column, barite ($BaSO_4$) precipitates in microenvironments within the falling debris (Dehairs et al., 1980; Griffith and Paytan, 2012). Biogenic Ba is the most consistently preserved of the biogenic sediment components in deep-sea sediments. In the Holocene, less than 5 % of the C_{org} particulate rain is typically buried in deep-sea sediments, versus 5–10 % of biogenic opal, and 30 % biogenic Ba (Dymond et al., 1992; Dymond and Lyle, 1994). $CaCO_3$ has highly variable preservation depending on water depth and ocean chemistry. Where biogenic sediments are severely dissolved after deposition, a barite ($BaSO_4$) residue can be the last remaining marker of biogenic deposition (Dymond, 1981). Barite is preserved in well-oxygenated sediments but will dissolve under sulfate-reducing conditions and can be remobilized (Torres et al., 2002).

Hydrothermal sediment components

The mid-ocean ridges are a world-circling volcanic mountain chain, creating ~3 km^2 of new hot basalt crust each year (Williams and von Herzen, 1974). Hot springs that cool the crust are ubiquitous along mid-ocean ridges, form rich environments for benthic life (Kelley et al., 2002), and form distinctive sediments that precipitate around the vents and are dispersed in hydrothermal plumes. Unusual sediment composition found on all mid-ocean ridges led to the hypothesis that hydrothermal systems must be common in the oceans (Boström and Peterson, 1966, 1969).

Near hydrothermal vents, where large-scale precipitation of minerals from solution results from mixing with normal ocean water, massive sulfide deposits and oxidized remains of massive sulfides and other minerals are found (Haymon, 2005). Proximal hydrothermal deposits can be highly varied because of the variability of temperature and mixing conditions. The deposits themselves are scattered and uncommon because active vent fields are small relative to the total ridge length and are spaced ~20–50 km apart along the ridge crest (Baker and Urabe, 1996).

Farther away from the actual vents, hydrothermal plumes consist of particles with much more uniform composition. The plumes distribute particles rich in amorphous Fe-Mn oxyhydroxides and poor in Al that form the hydrothermal sediment component (Boström and Peterson, 1969; Dymond, 1981). Hydrothermal sediments are most apparent in the South Pacific along the East Pacific Rise, partly because little besides biogenic carbonates deposit there and partly because highest ocean crustal formation occurs there. As the hydrothermal plume material drifts away from mid-ocean ridges, the Fe-Mn oxyhydroxide particles scavenge other elements from seawater, like P and the rare earth elements, and form a significant sink for these elements (Wheat et al., 1996; Ruhlin and Owen, 1986). Downcore variation in the rate that hydrothermal sediments accumulate has been used to track changes in hydrothermal activity through time. Lyle et al. (1987) showed that hydrothermal activity at the East Pacific Rise increased dramatically during ridge reorganizations, presumably because fracturing allowed significantly better seawater access to hot rock.

Authigenic and cosmogenic sediment components and ferromanganese nodules

A fraction of deep-sea sediments are transition metal-rich oxyhydroxides precipitated directly from seawater, referred to as the authigenic or hydrogenous sediment component (Goldberg, 1954). "Authigenic" has also been used to refer to aluminosilicate minerals that are formed as other unstable components dissolve within deep-sea sediments, e.g., authigenic smectite clays (Cole and Shaw, 1983) or authigenic phillipsite (Stonecipher, 1976; Bernat and Church, 1978). However, this is more properly considered early diagenesis (section "Seafloor Processes Affecting Deep-Sea Sediment Composition: Dissolution, Early Diagenesis, and Sediment Movement").

The authigenic ferromanganese oxyhydroxides are only a significant sediment component when sedimentation rates are very low, because of the low concentrations of transition metals in seawater and slow precipitation rates. Ferromanganese nodules, an authigenic concretion, typically have growth rates of $1–10$ mm/10^6 years, for example, versus typical sedimentation rates in the surrounding sediments that are ~1,000 times faster (Heath, 1981; Dymond et al., 1984).

Authigenic oxyhydroxides include both ferromanganese nodules and the dispersed ferromanganese oxyhydroxides in sediments. Ferromanganese nodules are large concretions of Fe-Mn oxyhydroxides ranging in size from about 0.5 to 10 cm (Figure 8) and are found in all low-sedimentation-rate ocean basins (Glasby, 2006). Typical authigenic oxyhydroxides contain nearly equal amounts of Fe and Mn, unlike hydrothermal plume sediments which have Fe:Mn weight ratios near 3.5 (Dymond, 1981). More

Mn is in the authigenic fraction because Mn has a longer residence time than Fe in the oceans, and because Mn is preferentially reduced and remobilized from continental margin sediments (Lyle, 1981). High concentrations of co-precipitated transition metals such as Co, Ni, and Cu have made ferromanganese nodules a potentially attractive mining target, although only trial mining has yet been carried out (Glasby, 2006). Detailed chemical analyses of tops and bottoms of nodules have shown that the chemistry and even growth rates of ferromanganese nodules have been influenced by significant interactions with the sediments (Dymond et al., 1984). The side of the nodule buried within sediments is enriched in Mn, Ni, and Cu and has a faster growth rate than the top of the nodule exposed to seawater. Lyle et al. (1984) suggested that metals sorbed on sediment grains provide the additional source of metals to nodule bottoms.

In very slowly accumulating sediments, it is possible to separate out a cosmogenic sediment component of small meteorite grains that have slowly accumulated (Kyte, 2002). The amount of cosmogenic debris is estimated by measuring elements or isotopes that are highly enriched in meteorites like Ir or ^{3}He. There have been rare large meteor impact layers, like the Cretaceous/Paleogene event that caused the extinction of dinosaurs, but for the most part, there has been a relatively constant background deposition through time (Kyte, 2002). Assuming a constant cosmogenic deposition rate, it is possible to estimate sedimentation rates in cores since the sedimentation rate will be inversely proportional to the concentration of the cosmogenic debris (Marcantonio et al., 1996).

Deep-sea Sediments, Figure 8 Ferromanganese nodule collected at the top of a sediment core taken from the Southwest Pacific gyre in 2005 (R/V Melville TUIM-03 expedition). Ferromanganese nodules are very common in this region. The nodule is nearly the same diameter as the coring device (~10 cm).

Seafloor processes affecting deep-sea sediment composition: dissolution, early diagenesis, and sediment movement

Particles that have fallen through the water column are transformed before they become sediment. Unstable, mainly biogenic, components dissolve, new minerals are formed by early diagenesis, and particles may be fractionated and moved about by seafloor currents before burial.

The composition of deep-sea sediments is strongly affected by dissolution of particles at the seafloor and by early diagenesis. There is a significant flux of biogenic debris to the seafloor even in low-productivity regions like ocean gyres, but most of the particulate rain that lands on the seafloor dissolves or degrades before burial. For example, at 40°N in the Pacific Ocean, 1.8 g/cm^2/kyr of CaCO$_3$ and a similar amount of biogenic opal flux were measured in a sediment trap at 5,016 m (Honda et al., 2002), but only clays are found in sediments below because of dissolution at the seafloor. Nevertheless, elements scavenged on the surface of biogenic particles that rain to the seafloor may be carried to the seafloor and buried (Balistrieri et al., 1981; Fischer et al., 1986).

Sediment dissolution and the carbonate compensation depth

Biogenic silica must be buried relatively quickly to prevent dissolution, since all ocean waters are undersaturated with respect to biogenic opal (Ragueneau et al., 2000). Slowly accumulating sediments do not preserve biogenic opal.

The solubility of calcite increases with increasing pressure, decreasing temperature, and decreasing dissolved carbonate ion, $[CO_3]^=$ (Boudreau et al., 2010). Deep-ocean water temperature is low and relatively constant, but pressure causes the calcite solubility product constant to double between 2,000 and 5,000 m water depth (Boudreau et al., 2010). Deeper parts of the ocean lack $CaCO_3$ because of elevated $CaCO_3$ dissolution. The calcite compensation depth (CCD) is defined as the depth where the rate of dissolution matches the $CaCO_3$ particulate rain, and all $CaCO_3$ is dissolved before burial. Since the CCD depends upon both production and dissolution, the CCD has changed as environmental conditions have changed (Figure 9; Pälike and Expedition 320/321 Shipboard Scientists, 2012).

Shallow ocean waters are supersaturated with respect to $CaCO_3$, but there is a depth, referred to as the lysocline, where the increasing effects of $CaCO_3$ dissolution become apparent, e.g., the depth below which dissolution-susceptible foraminifera rapidly disappear. This depth occasionally matches the depth where undersaturation occurs, but it may also show where the cumulative effects of dissolution are easily measured. The lysocline and CCD are at different depths in different ocean basins because they experience different levels of $CaCO_3$ production and because the different basins have different deep water $[CO_3]^=$ levels. In the Atlantic, the lysocline ranges from 4 to 5 km deep, and the CCD is 5–6 km deep (Figure 7; Biscaye et al., 1976). In contrast, the Pacific Ocean lysocline ranges from <3 to 4 km deep, and the CCD is typically about 4,500 m deep (Berger et al., 1976). The Atlantic has much better $CaCO_3$ preservation than the Pacific or Indian Ocean because deep waters in the basin are flushed by high $[CO_3]^=$ water North Atlantic Deep Water sourced from the North Atlantic surface ocean rather than from lower $[CO_3]^=$ water sourced from the Antarctic.

Early diagenesis

The chemical environment within sediments is significantly different from that of the abyssal ocean, so that some minerals will dissolve and new minerals can form. The changes are referred to as early diagenesis. Oxidation of organic matter is a major driver of early diagenesis, leading to reduction and remobilization of Fe and Mn and the formation of oxide-rich surface sediment layers (Froelich et al., 1979; Finney et al., 1988). Other early diagenetic reactions include the formation of calcite overgrowths on foraminifera and formation of diagenetic dolomite ($CaMgCO_3$). Diagenetic calcite overgrowths can severely affect the chemical composition of foraminiferal tests and thus cause major errors in proxy estimates of past temperatures and other properties (e.g., Pearson et al., 2001).

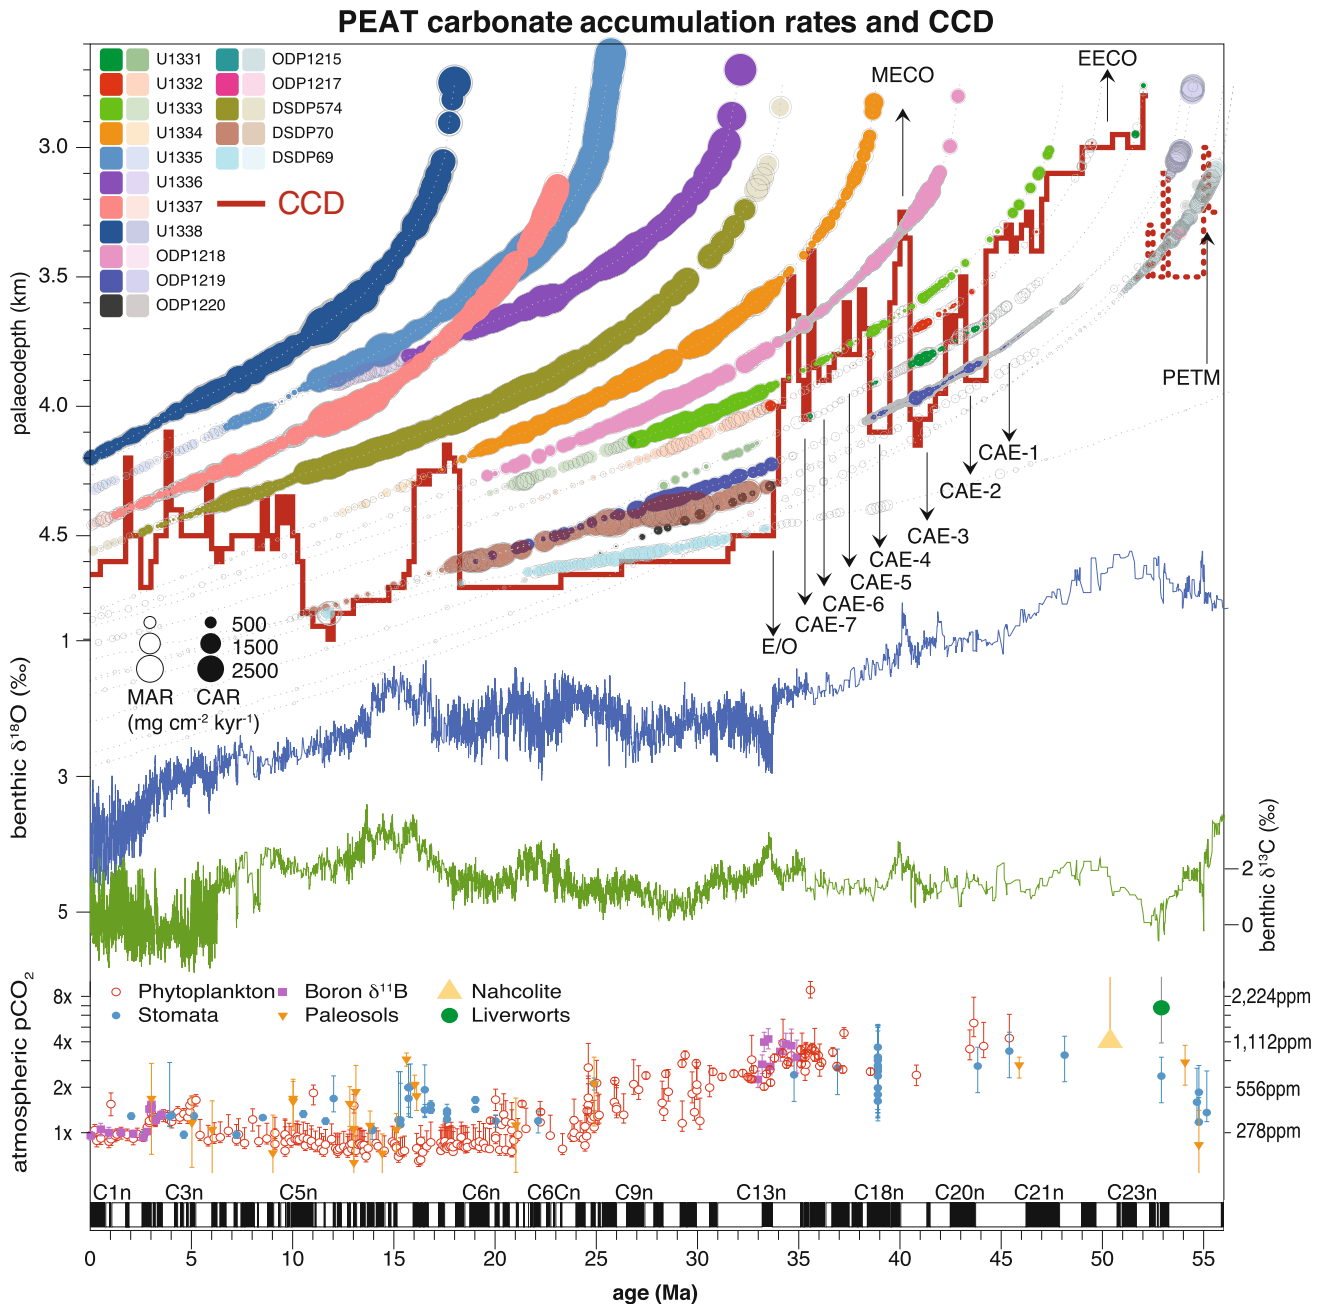
Near-bottom sediment movement and sediment focusing

The cycle of elements to the seafloor is further complicated by near-seafloor particle dynamics. The particle rain from surface waters can fall to the seafloor but then be resuspended back into the lower water column before final incorporation into sediments (McCave, 2010). In the abyssal realm, Walsh et al. (1988) found that there was a "rebound" sediment flux caught in sediment traps up to 500 m above the bottom. Chemical analysis of the near-bottom sediment traps showed that the additional flux is intermediate in composition between particle rain and the surface sediment, suggesting that the recycled particulate flux includes degrading particles resuspended before they were completely incorporated into the sediment.

During the resuspension process, currents and tides can cause sediments to be transported laterally, and sediments will preferentially fill in low topography. Over time, in depositional environments, the infill will tend to flatten seafloor topography because sedimentation rates are higher in abyssal valleys (Tominaga et al., 2011). The amount of drape versus sediment infill appears to depend upon topography and rate of sedimentation. The high topography of the slow-spreading mid-Atlantic Ridge results in bare ridges with little sediment drape and much basin infill (Ruddiman, 1972). In contrast, the subdued abyssal hill topography in the tropical Pacific results in high amounts of sediment drape and only small differences between sediment cover on abyssal hills versus valleys (Tominaga et al., 2011). As can be seen in Figure 2, seafloor topography still mimics the topography of basaltic basement, even though the sediment column is many times thicker than the original basement topography.

Summary and conclusions

Deep-sea sediments deposit slowly and are distinctive chemically from typical terrestrial or continental margin sediments. Because such a small fraction of clays is deposited in the deep ocean compared to continental margins, deep-sea sediments can have large fractions of biogenic debris or metal oxides precipitated from hydrothermal plumes or directly from seawater. Deep-sea sediments also steadily accumulate, making them an excellent archive of Earth's environmental change.

Acknowledgments


Deep-sea Sediments, Figure 9 Changes in the equatorial Pacific CCD (carbonate compensation depth) for the last 50 million years, from Pälike and Expedition 320/321 Shipboard Scientists (2012). The *red line* marks the depth of the CCD over time, while the bubbles mark CaCO₃ mass accumulation rate plotted versus paleodepth of different drill sites from the equatorial Pacific. A shallow CCD means that there is little CaCO₃ preserved in the sediments. The major change in CCD occurs at about 34 million years ago (the Eocene-Oligocene boundary), where the CCD permanently drops by about 1 km. Also shown are the benthic oxygen isotope profile (*blue*), an indicator for temperature and ice volume, the carbon isotope profile (*green*), and a compilation of estimates for atmospheric CO₂.

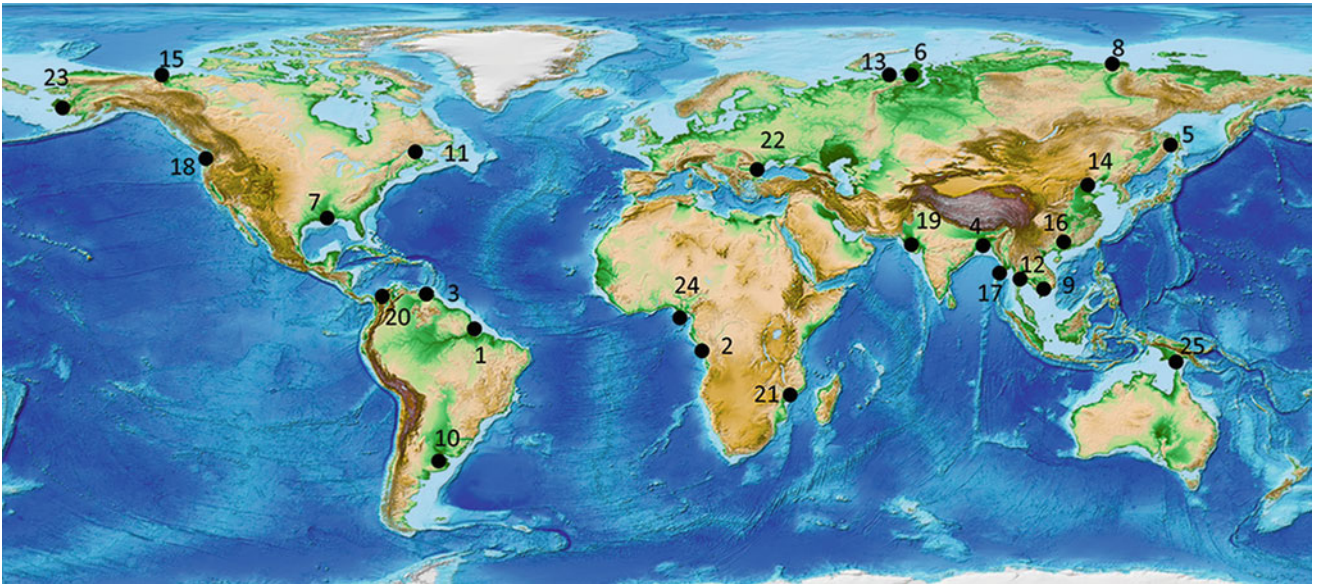
River-mouth deposits

Definition

As defined by Moore and Asquith ([1971](#)), a delta is the subaerial and submerged contiguous sediment mass deposited in a body of water (ocean or lake) primarily by the action of a river. Wright ([1985](#)) added that deltas included secondary riverine-derived deposits that had been reworked and molded by waves, currents, or tides.

The term *delta*, for the sedimentary accumulation at a river mouth, was coined by the Greek historian Herodotus who in the fifth century recognized a similarity in shape of the Greek letter Δ to the tract of land at the mouth of the Nile River (*The Histories*, 450–420 AD). Although the distinctive morphology is lacking in many river-mouth land tracts, the term has become accepted to describe both the geographical region near a river mouth and the sedimentary package deposited by fluvial processes into a depositional basin. Although sediment delivery to a delta is by a fluvial system, the dynamic interaction of riverine and ocean processes controls morphologic, stratigraphic, and sedimentologic variability of deltaic environments. Deltaic environments exist throughout the world and have been widely recognized in the sedimentary rock record. Buried deltaic sandstones are associated with reservoir rocks containing many of the world's major natural gas and oil resources (Morse, [1994](#)). Modern deltas have abundant food sources derived from diverse flora and fauna, extensive cultivable land, and navigable waterways reaching from the coast to interiors of continents. Thus, these settings became the centers of numerous formative cultures and today are the home to some of the densest populations in the world. It is estimated that approximately 61 % of the world's population live on deltas and that percentage continues to grow (Bianchi and Allison, [2009](#)). Deltaic systems are also recognized as important carbon sinks due to burial of vegetative detritus coming down rivers as well as phytoplankton blooms spawned by nutrient-rich waters. Thus, the progradation or erosional reworking and retreat of deltas affects the carbon budget and climate change.

Globally, deltas are found on all continents and in all climates (Figure [1](#)). In a general sense, the locations of deltas are similar, at the terminus of a catchment basin that provides sediment load into an ocean, gulf, lagoon, estuary, or lake. Although a delta may form regardless of the size of the fluvial system or receiving basin, some tectonic settings are more conducive than others to the development of major deltaic landscapes. Using the Inman and Nordstrom ([1971](#)) tectonic classification of coasts, trailing-edge coasts typically have the largest drainage basins followed by marginal-sea coasts, and the smallest are common to leading-edge coasts. Of the 58 major river systems in the world with drainage areas greater than 10^5 km^2, 56.9 % occur on trailing-edge coasts, 34.5 %


Deltas, Figure 1 Map showing the global distribution of the 25 largest sediment discharge rivers (refer to Table 1). These rivers roughly coincide with the major deltas of the world. Note that most of these river systems are located along trailing-edge coastlines close to the equator (modified from Coleman and Prior, 1980). Background image from ETOPO7, NOAA database.

along marginal-sea coasts, and 8.6 % on collision (leading-edge) coasts.

Trailing-edge coasts provide a geologic setting favorable to delta development because of their tectonic stability and geologically old, low-relict terrains with extensive river systems that provide an abundant supply of sediment. Moreover, trailing-edge coasts often border broad continental shelves, which provide shallow-water platforms for the formation of deltas. Marginal-sea coasts typically provide relatively low-energy settings with many trailing coast characteristics that are conducive to delta development. Mountainous and immature drainage systems of tectonically active, leading-edge coasts (Pacific coast of South America) with small catchment basins and low sediment supply generally limit the likelihood of extensive deltaic deposition. However, it is the mountains of tectonically active coastal margins (e.g., Andes) or former coastal margins and present subduction zones (Himalayas) that can supply vast amounts of sediment to trailing-edge margin deltas (e.g., Amazon and Ganges-Brahmaputra, respectively). Figure 1 shows the locations and Table 1 lists the sizes of the world's 25 largest deltaic systems, according to McKee (2005) and Meade (1996).

Delta types and formation

Previous summaries of the world's deltas have focused primarily on the major large deltas (e.g., Coleman and Wright, 1975). A review of the recent literature on Late Quaternary deltaic systems reveals that deltas can be classified into four basic types depending on sea-level position (highstand or lowstand) and sediment supply (high or low)

(Kindinger, 1988; Boyd et al., 1989; Nichol et al., 1996). The four basic types of deltas include: (1) lacustrine, (2) bayhead (or lagoonal), (3) continental shelf, and (4) continental margin. In a geomorphic and evolutionary sense, these four types of deltas represent end members and transitional forms describe many deltas. For example, during a sufficiently long sea-level stillstand, a lacustrine deltaic system having an adequate sediment supply and wave and tidal setting could evolve into a continental shelf margin deltaic system through progradation.

Lacustrine deltas

A lacustrine delta consists of sedimentary deposits located landward of the coast or paralic zone within an inland lake or small inland sea. In these cases, the environmental setting is typically a shallow-water basin with a low-energy regime. Along the Gulf of Mexico, the best example of a lacustrine delta is the Grand Lake delta within the Atchafalaya drainage basin of south-central Louisiana. At the start of the nineteenth century, Grand Lake, within the Atchafalaya basin, was a shallow, low-energy lake (Tye and Coleman, 1989). However, by the 1950s a large lacustrine delta had filled this lake and started conveying its sediment load into the Atchafalaya Bay. This rapid infilling largely resulted from the progressively increasing Mississippi River flow into the Atchafalaya basin (van Heerden and Roberts, 1988). Historically, if left uncontrolled, the Mississippi River would have avulsed from its modern course into the Gulf of Mexico past New Orleans to the Atchafalaya course located farther west. Other lacustrine delta examples include deltas in

Deltas, Table 1 Top 25 largest rivers based on freshwater and sediment discharges (modified from McKee, 2005, after Milliman and Meade, 1983; Meade, 1996)

River	Sediment discharge (10^6 t year^{-1})	Sediment discharge rank	Water discharge (10^9 m^3 year^{-1})	Water discharge rank	Drainage basin area (10^6 km^2)

Lake Geneva and Lake Constance (Switzerland) (Müller, 1966; Reineck and Singh, 1973) and Lake Ayakum Delta, Tibet (Figure 2).

Bayhead/lagoonal deltas

Bayhead/lagoonal deltas are located in the upper reaches of the coastal zone. In many cases they represent an evolutionary step from a lacustrine delta during a sea-level stillstand or withdrawal, which allows the delta to build into coastal environments. Bayhead-delta settings are typically protected by barrier-island systems or remnants of preexisting antecedent topography, resulting in a low-energy environment. Examples of bayhead deltas are found within the northern part of Mobile Bay (USA, Alabama; Kindinger et al., 1994), Trinity Bay and San Antonio Bay (USA, Texas; McEwen, 1969; Donaldson et al., 1970; van Heerden and Roberts, 1988), and Merrymeeting Bay, Maine (Fenster et al., 2005). One of the largest bayhead deltas in the world exists in the Rio de la Plata at the border between northern Argentina and

Uruguay where the Parana and Uruguay Rivers have combined to build a bayhead delta 280 km long and 40 km wide.

Continental shelf deltas

Continental shelf deltas develop during prolonged sea-level stillstands and a moderate sea-level fall. Trailing-edge or marginal-sea continental shelf deltas typically are characterized by an abundant sediment supply, and their geomorphology reflects the wave and tidal conditions in which they develop. Examples of continental shelf deltas include those associated with rivers of the Lena along the Russian Siberian coast (Figure 3), the Mississippi in Louisiana (USA) (Figure 4), the Ebro in Spain, the Colville in Alaska (USA) (Frazier, 1967; Maldonado, 1975; Naidu and Mowatt, 1975; Alonso et al., 1990), the Ganges-Brahmaputra (Goodbred and Kuehl, 2000), and those along the East China Sea (Zhou et al., 2014).

Deltas, Figure 2 Lake Ayakum Delta in Tibet (Astronaut photograph ISS027-E-16922, acquired on 25 April 2011).

Continental shelf margin deltas

Continental shelf margin deltas are typically most well developed during sea-level lowstands or formed by rivers with large sediment loads during prolonged sea-level stillstands. The majority of shelf margin deltas in the recent geologic record have developed during falling sea-level or sea-level lowstand conditions as river valleys lengthen, incise across subaerially exposed continental shelf sediments, and discharge their sedimentary load at the shelf margin (Suter, 1994). With sufficient sediment load or during lowstand conditions, these deltas continue to build seaward, creating an apron of deltaic sediment along the shelf edge that extends the preexisting continental margin into deeper basinal waters. Numerous lowstand shelf margin deltas, as listed above, formed during the Late Pleistocene sea-level fall and lowstand culminating at approximately 18,000 year BP. Some specific examples include those found seaward of the Rio Grande and the Mississippi River deltas (Morton and Price, 1987; Suter et al., 1987; Suter, 1994). Sufficiently large rivers carrying substantial sediment loads may also construct shelf margin delta deposits during sea-level highstand conditions. The main stem of the modern Mississippi River delta represented by the "bird-foot" delta is an example of a shelf margin highstand delta (Boyd et al., 1989).

Delta components

The delta plain contains a subaerial and subaqueous zone where sediments are discharged from the alluvial valley and accumulate in the receiving basin (Figure 5).
Deltas, Figure 3 Lena Delta (from: earthobservatory.nasa.gov).

Typically, a delta plain is subdivided into an upper delta plain and a lower delta plain, each of which is characterized by different vegetation, morphology, and depositional processes (Reineck and Singh, 1973; Coleman, 1981; Elliot, 1986).

Deltas, Figure 4 Mississippi bird-foot delta in Louisiana, USA (from: http://eoimages.gsfc.nasa.gov).

Upper delta plain Many of the features of the upper delta plain are inherited from its alluvial valley. In the upper delta plain, deposition is primarily fluvial as the main stem of the river leaves the alluvial valley discharging sediment onto the upper delta plain. The vegetative landscape of the upper delta plain is a freshwater environment, generally beyond the influence of marine incursions created by the tidal regime of the receiving basin. The major landform includes distributary channels with their subaerial natural levees, point bars, and crevasse splays, as well as interdistributary environments characterized by low-lying swampy areas.

Lower delta plain The lower delta plain is low relief and characterized by tidal incursion and greater sedimentation compared to the upper delta plain. Elevations of the natural levees are relatively low, producing frequent overbank flooding, which results in channel crevassing and avulsion. Distributary shifting is a common dynamic process, resulting in a complex pattern of multi-aged distributary channels in various stages of evolution (Figure 5). The lower delta plain contains active and abandoned distributary channels leading to different stages of regression and transgression within a single delta complex (Penland et al., 1988). Because the lower delta plain is a transitional
Deltas, Figure 5 Schematic diagram showing the primary physiographic components and depositional environment of a delta (modified from Coleman and Prior, 1980).

environment influenced by freshwater fluvial and saline marine waters, the vegetative landscape generally contains species tolerant of both brackish and saline water. For example, the lower modern Mississippi River delta is characterized by *Phragmites australis*, an invasive species that tolerates fluctuating salinities, river stage, and storms (White, 1993). The resiliency of this plant community is largely responsible for stabilizing deltaic deposits and greatly reducing erosion and reworking during frequent hurricane impacts. Mangroves serve a similar function in low-latitude deltas, such as Ganges-Brahmaputra.

Subaqueous delta plain This is the shallow, seaward sloping part of the delta that is characterized by sedimentation at the ends of distributary channels and the reworking of these deposits onshore and laterally by waves and tides. The subaqueous delta plain forms a broad apron of interfingering deltaic and marine sediments that transitions seaward into continental shelf sediments. Major components of the subaqueous delta plain consist of distributary bar mouth sands incised by channels bordered by subaqueous levees. Seaward of this region is an area of increasingly finer-grained sediments and less marine reworking as the depositional environment transitions from distributary bar mouth sand to sandy silt of the delta front and finally to the silty clay of the prodelta. At some deltas where progradation has reached at or close to the shelf edge, sediment from distributaries is conveyed directly into submarine canyons (e.g., Indus Goodbred and Kuehl, 2000; Giosan et al., 2006; Ganges-Brahmaputra).

Deltaic sediments

In general, deltaic sedimentary lithosomes contain a coarsening upward sequence that reflects seaward progradation of the delta into its receiving basin. At any given time, there is typically a well-developed fining grain size pattern extending seaward from the subaerial to subaqueous portions of a delta. The relatively coarsest-grained material is deposited proximal to the river mouth where transport competence is highest, whereas the finest-grained material is carried farther seaward and deposited in more distal locations. Thus, as sediments are delivered to the receiving basin from the river mouth, they accumulate in a subaqueous, fine-grained depositional zone referred to as the *prodelta*. The prodelta forms the platform across which the delta progrades and subsequently aggrades. The prodelta sedimentary package is a widespread laterally continuous interval composed primarily of the finest sediment fraction transported by the fluvial and ocean system. Thus, the overall finest sediment is found at the base of the prodelta sequence and the whole sequence coarsens upward. Bioturbation of prodelta sediments is a function of the rate of deposition.

The delta front is located between the fine-grained prodelta deposition and the landward, coarser-grained distributary mouth deposits of a progradational deltaic system. The relatively coarser-grained sediment of the delta front generally consists of interbedded clays, silts, and sands. This zone is dominated by the interaction of fluvial and marine processes, resulting in sand-rich accumulations landward of the advancing prodelta that are commonly a result of high-stage fluvial discharge or storm reworking. They are usually highly bioturbated. The delta front also represents a zone of transition between deposits representative of progradation and aggradation.

In a progradational deltaic sequence, distributary channel deposits overlie the relatively finer-grained delta front and prodelta deposits. The framework of distributary channels consists of distributary mouth bars overlain and bordered by natural levee deposits. Distributary mouth bar deposits are primarily subaqueous deposits that grade laterally into relatively finer-grained deposits; locally, mouth bar deposits may contain fine-grained beds within the generally sandy matrix of the mouth bar. The presence of fine-grained deposits represents deposition during low-stage conditions when current velocities are relatively weak. During high-stage flood conditions, natural levees can be overtopped and breached creating crevasse splays. These splays occur within the distributary network and provide conduits for sediment dispersal into interdistributary bays. Crevasse splays are one of the major landform processes in riverine-dominated deltas (e.g., Mississippi) contrasting to the preponderance of beach ridges at wave-dominated deltas (e.g., Ebro, Danube). However, crevassing can produce loss of stream power downstream of the cut due to loss of flow, leading to decreased channel competency and sedimentation within the channel. A case study in South Pass, one of the Mississippi River distributaries, in Louisiana, USA, reported that lateral flow loss from crevassing, including flow into a relict distributary channel, diminished stream power significantly such that South Pass aggraded immediately downstream (Clark et al., 2013).

Interdistributary bay and marsh sediments are generally as volumetrically significant as prodelta sediments. The interdistributary area is a low-energy depositional environment and less dynamic than areas of the delta plain characterized by multiple channels, channel bifurcations, and channel avulsions. Interdistributary deposits characteristically consist of fining upward deposits consisting of clay-rich bay sediments overlain by organic-rich marsh deposits. This fine-grained depositional environment is punctuated by sandy depositional events associated with overbank flooding and crevasse splay events. Channels within the crevasse splay also create elongated sand deposits.

Delta processes

Deltas develop when sediment-laden river water decelerates upon entering a receiving basin and sediment transport competence of the river is lost. Consequently, the interplay between fluvial and river-mouth processes constitutes an important controlling factor in the nature of deltaic

deposition (Bates, 1953). Fluvial processes are particularly important in deltaic environments where wave and tide regimes are less important. In such environments the primary riverine factors, influencing the nature of deltaic deposition, are river discharge, sediment load, and textural character of the sediment. Generally, the primary forces controlling the character of deltaic sedimentation are (1) the riverine effluent inertia and diffusion, (2) friction between the sediment load and the floor of the receiving basin, and (3) density contrasts between the effluent and the receiving basin waters (Bates, 1953; Wright, 1977; Orton and Reading, 1993).

Homopycnal conditions Homopycnal flow describes flow conditions where the density contrast between riverine and basinal waters is small. Discharge patterns are influenced primarily by inertia of the riverine water, which allows the effluent to radially spread into the receiving basin. As a result of deltaic progradation, fine-grained bottomset sediments are overlain by relatively coarser-grained topset beds and river-mouth bar deposits, creating a coarsening upward depositional sequence common to deltaic systems. Gilbert (1885) first described this type of deltaic system associated with the paleo-lakes of the western USA; hence, they are termed Gilbert-type deltas.

Hyperpycnal conditions Hyperpycnal conditions occur when the riverine discharge is denser than the waters of the receiving basin. Consequently, the sediment-laden effluent moves along the floor of the receiving basin as a density current. This type of discharge condition is rare and typically restricted to deltaic systems rich in silt and coarse-grained sediments discharging into freshwater lakes, such as the Rhone River entering Lake Geneva in Switzerland and Bella Coola fjord delta of British Columbia (Kostashcuk, 1985). Although not common, hyperpycnal conditions may exist in some deltas for short periods during early spring, when river water temperatures are appreciably lower than those in the receiving basin, contributing to the formation of density currents. This is usually a seasonal phenomenon associated with spring and summer meltwater discharges from glaciers.

Hypopycnal conditions Hypopycnal discharge conditions occur when riverine inflow is less dense than the waters of the receiving basin, a condition commonly present where rivers debouch into marine waters. Most of the world's deltas form under hypopycnal conditions. In hypopycnal settings, as the riverine inflow enters the receiving basin, it undergoes spreading and expansion facilitating turbulent mixing resulting in the deposition of the sediment load. Finer-grained sediments are transported distally into the receiving basin (prodelta) as the freshwater sediment plume disperses above relatively more dense basinal waters. The relatively coarser-grained sediments are deposited in close proximity to the river mouth (distributary mouth bars and delta front). In shallow-water hypopycnal discharge conditions, friction between the receiving basin bottom and the riverine leads to multiple bifurcations of the distributary system. Conversely, in deepwater during hypopycnal discharge conditions, buoyancy dominates during the dispersal of the effluent, producing elongated distributaries such as those present at the modern Mississippi River depocenter (Suter, 1994).

Channel processes

Deltas grow by utilizing their distributary channel networks through a series of successive bifurcations, whereby a channel splits into two. Bifurcations are caused by sediment deposition at the mouths of distributary channels resulting in flow around a bar. Each bifurcation can be stable, whereby both channels receive the same flow, or unstable, where one channel receives greater flow than the other. At each bifurcation, sedimentation produces a distributary mouth bar that eventually becomes subaerial, thereby stabilizing the channel position. With each successive bifurcation, channels become smaller in both width and depth as they approach the delta front. In a study of 11 deltas worldwide, Edmonds and Slingerland (2007) found that channel widths decrease nonlinearly with bifurcation order, suggesting that across the delta there is continuous reduction in channel geometry. However, this should not be interpreted as loss of stream power, because deltas can maintain channel efficiency such that their ability to transport sediment downstream remains unaltered. A case study by Esposito et al. (2013) showed that the loss in dimensions with each bifurcation is met with an increase in water surface slope, resulting in unchanged velocity in the channels. This evolution can be significant in the delta growth cycle, because efficient channels can extend via depositional processes throughout the change in stage of the river (Esposito et al., 2013) or can extend during low flow conditions by incising through the delta front. Shaw and Mohrig (2014) reported that the channels of the Wax Lake Delta in Louisiana, USA, have extended seaward primarily through channel incision during low flow conditions, rather than solely by deposition.

Delta morphology

Although sediment delivery to a delta is via a fluvial system, it is ultimately the dynamic interaction of riverine and marine basinal processes that control the morphologic, sedimentologic, and stratigraphic variability of a deltaic accumulation. Water depth and basinal configuration, tidal range, wave climate, and coastal currents are the primary basinal processes that control delta morphology. The dynamics of these processes and complex interaction between them lead to a highly variable array of deltaic configurations (Coleman and Wright, 1975).

One of the first and simplest attempts to describe deltaic variability as a function of processes depicts the morphology of river deltas as a function of sediment influx and
Deltas, Figure 6 Schematic diagram showing the variation in deltaic geomorphology as a function of the relative influences of fluvial and marine processes (from Fisher et al., 1969).

marine processes such as waves and longshore currents (Fisher et al., 1969; Figure 6). The tidal regime of the receiving basin was not considered in the formulation of this model. Fundamentally, this model describes the processes leading to deltaic deposition as constructive or destructive (Davis, 1983). Deltas dominantly influenced by the nearshore wave climate are termed destructional, characteristically cuspate shaped with poorly developed distributaries, such as well-developed strand plains of the Sao Francisco delta in Brazil. Intermediate between destructional and constructional forms is the lobate-shaped delta, typified by the Niger delta of Africa. Lobate deltas possess well-developed distributary networks and a smooth coastal outline. Deltas that are strongly influenced by sediment deposition are essentially constructional and are characterized by distinctive elongate distributaries. An example of this type of delta is the modern "bird-foot" depocenter of the Mississippi River (Figure 4).

In the 1970s, a process-response approach to understanding morphologic variability of deltas incorporated features of the constructional/destructional approach but also considered the effects of the receiving basin tidal regime. In Galloway's (1975) scheme, a variety of previously documented delta morphologies (e.g., Fisher et al., 1969; Wright and Coleman, 1973) were classified within the framework of a ternary diagram that differentiated delta morphology as a function of sediment input, wave energy flux, and tidal energy flux (Figure 7).

End member deltas (Figure 7) dominated by sediment input are supplied by a large well-developed drainage system, capable of transporting large volumes of sediment to the deltaic coast. Distributary switching is an important process, resulting in highly constructive elongate to lobate deltas with straight to sinuous active and abandoned channels. The bulk composition of the sediment supply is muddy to mixed, and the framework facies include

Deltas, Figure 7 Ternary classifications of deltas on the basis of dominate processes and the resulting morphology (after Galloway, 1975).

distributary mouth bar, channel-fill sands, and delta-margin sand sheets (Table 2).

Wave-dominated cuspate and lobate deltas are usually characterized by small sediment discharge relative to the volume of sediment reworking by wave energy. The high-wave-energy regime leads to winnowing of fine-grained sediments leaving behind a relatively coarser-grained sediment fraction. Consequently, the bulk composition of wave-dominated deltas is typically sandy. The primary distributary channels are meandering, and the framework facies are coastal barrier and beach-ridge sands (Table 2).

**Deltas, Table 2** Characteristics of different delta types

Characteristics	Fluvial dominated	Wave dominated	Tide dominated
Geomorphology	Elongate to lobate	Arcuate	Estuarine to irregular
Channels	Straight to sinuous distributaries	Meandering	
distributaries	Flaring straight to sinuous distributaries		
Sediments	Muddy to mixed	Sandy	Variable
Framework facies	Distributary mouth bar and channel-fill sands, delta-margin sand sheet	Coastal barrier and beach-ridge sands	Estuary fill and tidal sand ridges
Framework geometry	Parallels depositional slope	Parallels	
depositional strike	Parallels depositional slope		

Tide-dominated deltas are shaped by onshore-offshore sediment transport caused by reversing tidal currents. They occur primarily in funnel-shaped, macro-tidal embayments, such as the Kuskokwim Delta in the Alaskan Bering Sea or the mouth of the Elbe River in the German Bight. Fine-grained sediment that enters the embayment is deposited offshore and along the borders of the estuary forming broad tidal flats transitioning into wetland areas (2–10s km wide) (Table 2). Riverine-derived coarse sediment is transported offshore, reworked by tidal currents, and deposited as linear sand shoals, also called tidal ridges. These features are usually subtidal with a relief of several meters, greater than 0.5 km wide, and 5–20 km in length. It appears that under very high sediment discharge conditions, such as at the mouth of the Fly River in Papua New Guinea, elongated channel-parallel islands have developed that are up to 60 km long and 5–10 km wide (Canestrelli et al., 2010).

A fundamental sedimentologic difference between wave- and tide-dominated deltas is that tide-dominated systems formed sand bodies oriented shore normal, whereas wave-dominated deltas contain sand bodies trending parallel to shore. The bulk of sand contained within river-dominated deltas is associated with distributary channels, and thus, these sand bodies are sinuous and oriented normal to oblique to shore (Rich, 1923).

Modern deltas

Formation, sea-level, and sedimentation Most of the world's deltas began forming 6–8,000 years ago (Figure 8; Stanley and Warne, 1997) during a period when
Deltas, Figure 8 Graph showing the time of formation for latest Quaternary deltaic systems and ages of deltaic archaeological sites in relation to deceleration in the rate of sea-level rise following the late Wisconsin sea-level lowstand (ages (*triangles*) from Stanley and Warne, 1997; sea-level curve (*solid line*) from Fairbanks, 1989, derived from radiocarbon dates from Barbados (*open circles*) and other Caribbean sites (*closed circles*)).

the rate of sea-level rise began to slow (Ibanez et al., 2014; Maselli and Trincardi, 2013). During this initial period, estuaries filled with sediment and were gradually transformed into prograding deltaic shorelines. In the present regime of accelerating sea-level rise, the survival of deltas is related to their ability to accrete vertically through overbank flooding, crevassing, and distributary switching. Because these sedimentary systems are composed of varying percentages of mud, they are susceptible to compaction and subsidence, which creates additional accommodation space and need for additional sediment to maintain their areal footprint. In a study of basal marsh peats, Tornqvist et al. (2008) showed that Mississippi delta subsidence was primarily due to compaction of Holocene muds. Contrastingly, Goodbred and Kuehl (2000) suggested that subsidence of the Ganges-Brahmaputra Delta was primarily a product of tectonics and not compaction. Given the proximity of the Indian-Eurasian plate collision, this condition is not surprising.

Deltas and human impacts Deltaic settings continue to play an important role in global society. As mentioned earlier, deltaic environments served as the culture hearth for early civilizations throughout the world because of their tremendous variety of food resources such as fish and wildlife. Moreover, the rich alluvial soils of deltaic landscapes allowed for the establishment of bountiful crops vital to the establishment and expansion of early cultures (Stanley and Warne, 1997). The historic impact of human development on delta evolution is revealed in a comprehensive study of European deltas by Maselli and Trincardi (2013). They showed that the Ebro, Rhone, Po, and Danube deltas underwent rapid progradation during the Roman Empire as a result of widespread deforestation and extensive agricultural use of the land, leading to greater sediment contribution to rivers and delta growth. They also reported widespread delta erosion and shoreline retreat coincided with the collapse of the Roman Empire in 400 AD when lands were reforested leading to lower sediment influx to rivers. A second period of broad delta erosion was caused by extensive dam building between 1960–1990 (Maselli and Trincardi, 2013). Similar comprehensive studies and findings have also been reported for the Mississippi River delta (Kessel, 2003; Tweel and Turner, 2012) and Ebro (Guillen and Palanques, 1997).

The extent of delta erosion on a global scale is summarized in a thoughtful paper by Giosan et al., 2014. They show that dam construction, levee building, and other human impacts have led to a drastic reduction in sediment conveyance to many of the world's largest deltas including the Nile, Indus, Mississippi, Danube, Yangtze, and Rhone with sediment loads having decreased by 60–98 % during the past century. They state that most of the world's largest and moderately sized deltas have experienced significant erosion and are predicted to succumb to rising sea-level during the next century, as they do not receive sufficient sediment to maintain their elevation and areal extent (Giosan et al., 2014). The demise of deltaic lands can be hastened by subsidence brought on by the subsurface withdrawal of hydrocarbons (e.g., Mississippi; Morton and Bernier, 2010) or water (e.g., Po; Teatini et al., 2011). A detailed analysis by Blum and Roberts (2009) of the Mississippi River sediment load indicates that the amount of sediment coming down the river is vastly inadequate to maintain the existing delta plain above sea-level, and therefore, they predict that most of the delta will drown by 2100. Contributing to erosion and drowning, it also should be noted that 11 of the largest 25 deltas are impacted by hurricanes (cyclones, typhoons) (Bianchi and Allison, 2009) and that 85 % of the world's largest deltas have experienced severe flooding during the last two centuries (Syvitski et al., 2009).

The partial solution to erosion and the eventual drowning of deltas will require a multiple-faceted approach undoing certain human alterations and implementing new ones. For example, dam removal will allow sediment behind dams to be transported to the coast, reestablishing natural sediment conveyance systems. Since 1912, 1,150 dams have been removed along American rivers, including 51 dams in 2013 (American Rivers, 2013). Other solutions to delta land loss might involve: (1) initiating crevasse splays in the lower delta plain, (2) creating channel diversions to fill large open water areas (e.g., Atchafalaya delta formation, Mississippi delta), or (3) diverting the entire river flow to form new distributary delta lobes.

Summary and conclusions

Deltas are sedimentary deposits that exist at the mouths of rivers and whose morphology and facies architecture are a product of riverine sediment discharge (type and load) and processes within the receiving basin, including waves, tides, storms, and tectonic regime. Modern deltas began forming 6–8,000 years ago coincident with a slowing in the rate of SLR when river-derived sediment filled estuaries producing shoreline progradation. Riverine-dominated deltas are characterized by elongate sandy distributary deposits with intervening muddy bays and wetlands; wave-dominated deltas tend to be cuspate to lobate in shape having numerous prograding chenier/beach ridges; tide-dominated deltas are characterized by funnel-shaped embayments with linear islands and/or subtidal sand shoals and onshore mud flats and wetlands. Deltas of the world are under siege due to their overall low-lying elevation and high rates of relative SLR brought on by subsidence and accelerating global SLR. In addition, dams have drastically reduced sediment contribution to most deltas, leading to widespread shoreline erosion. The fact that deltas coincide with dense human population centers means that they are particularly susceptibility to RSLR, especially because many deltas are impacted by periodic cyclones and severe flooding.

DEPLETED MANTLE

Andreas Stracke
Westphalian Wilhelms-University, Institute of
Mineralogy, Münster, Germany

Definition

Depleted mantle: The depleted mantle is the part of Earth's mantle from which basaltic melt has been extracted in one or multiple melting events at, for example, mid-ocean ridges, hot spots, or island arcs. Elements that do not fit into the crystal lattice of mantle minerals, the so-called incompatible elements, are preferentially incorporated into the melt and thus removed from the mantle, leaving the latter *depleted* with respect to these elements. This residual depleted mantle amounts to anywhere between 30 % and 100 % of Earth's mantle.

Basic facts about Earth's mantle

Earth's mantle extends from the core-mantle boundary at 2900 km depth, the Gutenberg discontinuity, to the base of Earth's crust, the Mohorovičić discontinuity. With about two-thirds of Earth's mass, the mantle is the largest silicate reservoir of our planet. Earth's most abundant elements, O, Mg, Si, Fe, Ca, and Al are the main constituents of Earth's mantle (Palme and O'Neill, 2014). The mantle is mostly peridotitic in composition, with varying mineral assemblage that adapts to the large range of pressure-temperature conditions in the mantle. At upper mantle pressures, a typical mantle peridotite with a density of 3300 kg per m^3 is made up of about 55 % olivine, 35 % ortho- and clinopyroxene, and 5–10 % Al-bearing phase such as plagioclase, spinel, or garnet. At the core-mantle boundary, the mantle is mostly composed of the high-pressure minerals perovskite and ferropericlase and has a density of about 5600 kg per m^3.

Although the mantle is solid over its entire depth range, it convects in response to density gradients between Earth's cold surface and hot interior. Thermal mantle convection is the primary agent of cooling of the Earth and transports hot mantle from the deep interior into shallower

regions. At mid-ocean ridges, shallow mantle rises passively in response to plate spreading and melts partially through adiabatic decompression. The latter process generates the oceanic crust at mid-ocean ridges and is responsible for about 80 % of Earth's volcanism. At hot spots, where hot buoyant mantle rises from the deeper mantle, some melting occurs because temperatures exceed those of the ambient shallow mantle. At island arcs, basaltic and andesitic crust is generated by fluid-induced melting of the mantle wedge overlying the subducted slab. The newly generated basaltic crust is eventually subducted at convergent plate margins, establishing a large-scale plate tectonic cycle of ocean crust generation and its return into the mantle. In this way, the mantle has evolved continuously since the onset of plate tectonics.

Formation and evolution of the "depleted" mantle

During partial mantle melting at mid-ocean ridges, hot spots, and island arcs, elements that do not fit into the crystal lattices of mantle minerals, the so-called incompatible elements (e.g., Cs, Rb, Ba, Th, U, Nb, Ta, K, Sr, Zr, Pb, Hf, Ti, and rare earth elements), are extracted preferentially from the mantle and incorporated into the newly formed basaltic crust. Left behind is a residual mantle whose mineralogical and chemical composition has changed by melting at shallow depths (usually <100 km depth), that is, it has become *depleted* in incompatible elements. This residual mantle is therefore referred to as the "depleted mantle."

The depleted mantle (DM) has undergone a complex geological evolution. Depleted mantle that has formed at mid-ocean ridges, hot spots, or island arcs is transported with the overlying oceanic crust and eventually subducted at convergent plate margins. Although part of the oceanic crust, consisting of igneous rocks and their sedimentary cover, is removed during subduction, most of the oceanic crust is recycled back into the mantle. Once introduced into the deeper mantle, the subducted oceanic crust and mantle become stretched and intermingled by mantle convection. In this way, crustal material that is enriched in incompatible elements is reincorporated into the DM. These processes counteract depletion by melt extraction and re-enrich the DM in incompatible elements.

Over geologic time, the DM is thus expected to have evolved into an assemblage of materials that is mineralogically and chemically heterogeneous, consisting of variably depleted peridotitic mantle and some remnants of recycled crustal rocks (e.g., van Keken et al., 2014). Owing to the different composition, size, and distribution of its individual components (e.g., residual peridotitic mantle, oceanic crust, continental crust, and marine sediment), the DM is heterogeneous on a range of scales, from the 1000-km scale of ocean basins (Dupré and Allègre, 1983; Hart, 1984) down to the cm scale of single hand specimens. Each individual component of the DM can also vary compositionally: the composition of the residual peridotitic mantle varies because of differing degrees of depletion (melt extraction) or refertilization (metasomatism) (e.g., Johnson et al., 1990; Bodinier and Godard, 2014). Crustal components (oceanic crust, continental crust, and marine sediment) are compositionally variable as a result of different conditions of formation (e.g., Plank, 2014; Rudnick and Gao, 2014; White and Klein, 2014) and varying extents of hydrothermal alteration (e.g., Staudigel, 2014) and modification during subduction (e.g., Bebout, 2014; Ryan and Chauvel, 2014).

Composition of the depleted mantle

Direct investigation of mantle composition is a complicated task because mantle rocks are rarely exposed at the surface. Mantle peridotites are sporadically found on the ocean floor, in ophiolite complexes and peridotite massifs on the continents, and as xenoliths in lavas (e.g., Bodinier and Godard, 2014). Fragments of the DM recovered from the ocean floor, abyssal peridotites, are often highly altered through interaction with extracted melt and seawater. Peridotites from ophiolites, peridotite massifs, and mantle xenoliths are also generally affected by melt-rock interaction (metasomatism) and weathering and are sometimes metamorphosed (Bodinier and Godard, 2014). Owing to their scarcity, small scale, and prevalent modification by secondary processes (metamorphism, metasomatism, alteration), it is difficult to derive a representative composition of the DM by direct investigation of the available mantle samples. Current estimates of average DM composition (Salters and Stracke, 2004; Workman and Hart, 2005) are therefore mostly indirectly inferred from mantle-derived melts: basalts generated at mid-ocean ridges (MORB).

Mantle melting integrates over different components of the DM, and one strategy of constraining DM composition is to use compositional parameters that are invariant in MORB (Salters and Stracke, 2004; Workman and Hart, 2005). MORBs, however, have highly heterogeneous chemical compositions (Hofmann, 2014; Arevalo and McDonough, 2010; Jenner and O'Neill, 2012; Gale et al., 2013) that reflect the different conditions during melting and the compositional diversity of their DM source. Estimates of DM composition thus span a range of compositions, mirroring the compositional variability observed in MORB. In detail, there may be a systematic bias between MORB and the DM because some components melt preferentially and may thus become overrepresented in the melt (MORB) relative to their mantle source, the DM (Stracke, 2012).

Although estimating the composition of the DM is thus complex, current estimates should adequately account for the compositional range of the DM. Even more difficult than estimating its composition is assessing the proportion of the DM relative to the total mantle. Current estimates are based mainly on geochemical mass balances or "box" models and range anywhere from 30 % to 100 % (e.g., Allègre et al., 1983; Boyet and Carlson, 2006; DePaolo, 1980; Hofmann, 1988; Jacobsen and

Wasserburg, 1979; O'Nions et al., 1979; Zindler and Hart, 1986). Constraining which fraction of the mantle corresponds to DM hence remains a considerable challenge.

The composition and relative proportion of DM, however, are key parameters for inferring Earth's bulk composition, for assessing global geochemical cycles, and for understanding the compositional evolution and differentiation of our planet and will thus continue to be a focus of geoscience research.

Summary

The depleted mantle forms by partial melting of the upper mantle at mid-ocean ridges and hot spots. Partial melting "depletes" the residual mantle in incompatible elements and preferentially incorporates them into the generated melt. Hence mantle from which basaltic melt has been extracted in one or multiple melting events is defined as "depleted mantle." The large-scale plate tectonic cycle of mantle melting, ocean crust generation, and subsequent subduction at convergent margins forms the backbone of silicate Earth evolution. Knowledge of the composition and mass fraction of the depleted mantle is therefore key for assessing global geochemical cycles and for understanding the compositional evolution and differentiation of our planet.

DIATOMS

Arto Miettinen
Norwegian Polar Institute, Fram Centre, Tromsø, Norway

Definition

Diatoms are single-celled, eukaryotic, photosynthetic algae of the class Bacillariophyceae.

Introduction

Diatoms are microscopic (usually 2–200 μm) algae characterized by a compound silica cell wall, called a frustule composed of two interlocking thecae, each of which consists of a valve and a series of girdle bands. Diatoms are the most species-rich group of algae (more than 200 genera and up to 100,000 species) and are found in almost every aquatic environment. The diatom taxonomy is based on the shape and ornamentation of the valves including a variety of pores, processes, ribs, spines, marginal ridges, elevations, and other distinguishable features. Both planktonic and benthic forms exist. Further details of diatom biology can be found in, e.g., Round et al. (1990) and Not et al. (2012).

Diatoms play a significant role in global climate via the global carbon cycle. They constitute the major part of phytoplankton and are major primary producers in the oceans producing as much as 40 % of the annual organic carbon in the ocean. They also contribute a major fraction of the downward flux of particulate organic carbon and, thus, a major fraction of the export of CO_2 to deep seawater (Hopkinson et al. 2011).

In the oceans, diatoms occur from the tropics to the poles, but are most abundant in polar to temperate, nutrient-rich regions, where silicic acid is not a limiting factor. Sea surface temperature (SST), sea-ice conditions, light and nutrient levels, stability of the surface water layer, and grazing are the most important factors determining the distribution and abundance of diatoms in the ocean surface waters. Diatoms live in the photic zone in the uppermost surface waters (commonly 0–50 m, max. 200 m), because they are dependent on light for photosynthesis. Therefore, mostly planktonic species occur in the open ocean and benthic species occur only in the nearshore environments.

Diatom applications

Di/atoms are used extensively in paleoenvironmental studies, especially in paleoceanography and paleolimnology. For example, diatoms have proved to be an excellent paleoclimatic tool for SST reconstructions in the Nordic Seas and the North Atlantic. Diatoms are good paleoindicators as they are a species-rich group of algae and living diatoms have specific tolerances to temperature, salinity and pH levels, and other environmental parameters. The high diversity of diatoms makes them particularly useful in high-latitude oceans where calcareous microfossils are often poorly preserved. Therefore, diatoms are one of the foremost tools available in the biostratigraphic studies and paleoclimatic reconstructions. In this entry, modern diatom-based reconstruction methods and topical results are summarized from the North Atlantic region.

Diatom biostratigraphy

Fossil diatom records reveal that the first diatoms, radial centrics, appeared in the Jurassic, multipolar centrics in the Early Cretaceous, pennates in the Late Cretaceous, and the first raphid pennates at 55 Ma in the Paleogene (Not et al. 2012). Since diatom species have undergone rapid evolution through the Cenozoic, it is possible to establish a diatom biostratigraphy for the North Atlantic; eight Pleistocene diatom datum events were identified and tied to the oxygen isotope record and paleomagnetic stratigraphy in studies on sites ODP 919 and ODP 983 (Koç and Flower 1998; Koç et al. 1999) in the subpolar North Atlantic:

- The first occurrence (FO) of *Pseudoeunotia doliolus* at 1.89 Ma
- The FO of *Proboscia curvirostris* at 1.53 Ma
- The FO of *Neodenticula seminae* at 1.25 Ma
- The last occurrence (LO) of *Neodenticula seminae* at 0.84 Ma
- The LO of *Nitzschia fossilis* at 0.68 Ma
- The LO of *Nitzschia reinholdii* at 0.6 Ma
- The LO of *Proboscia curvirostris* and *Thalassiosira jouseae* at 0.3 Ma

This biostratigraphy can be updated by the ninth event, "the second occurrence (SO) of *Neodenticula seminae* in the 1990s." *N. seminae* is a marine planktonic diatom which belongs to the modern assemblage of the subarctic North Pacific and its high-latitude marginal seas. The FO of *N. seminae* in the North Atlantic is an indicator of the cooling, which started at 1.26 Ma, leading to the transition from the dominance of 41 ka cycles in the climate record to the dominance of 100 ka cycles and intensified Northern Hemisphere glaciations (Koç et al. 1999). Conditions in the North Atlantic were too warm for subarctic *N. seminae* before 1.26 Ma, after which conditions cooled to subarctic environment favorable for the species. *N. seminae* thrived in the North Atlantic until conditions turned too severe with perennial sea-ice cover leading to the disappearance of the species at 0.84 Ma (Koç et al. 1999). After an absence of more than 0.8 Ma, *N. seminae* reappeared in the Labrador Sea in the late 1990s (Reid et al. 2007) and was found for the first time in the northern Nordic Seas with a widespread modern distribution in the mid-2000s (Miettinen

et al. 2013). The introduction of *N. seminae* in the Nordic Seas can be associated with an increased influence of Pacific waters via the Arctic, probably due to diminished Arctic sea ice and/or changed ocean circulation in the Arctic Ocean. This might suggest the initiation of a unique climatic transition of the scale seen during the mid-Pleistocene transition though now the appearance may indicate a transition to warmer conditions (Miettinen et al. 2013).

Diatom-based sea-ice reconstructions

Sea ice has a prominent effect on climate and thus paleo-sea-ice reconstructions are important for climate modeling and for setting the recent sea-ice variability into a geological context. For the sea-ice reconstructions, three diatom-based methods are available.

The qualitative method is based on the statistically (Imbrie-Kipp method and a Q-mode factor analysis) defined occurrence of diatom assemblages according to their relation to modern surface hydrography (Andersen et al. 2004). The dominant marine diatom species in the specific sea-ice assemblage are *Fragilariopsis cylindrus*, *F. oceanica*, *Bacterosira bathyomphala*, *Thalassiosira hyalina*, *T. nordenskioeldii*, and resting spores of *T. gravida* (Koç-Karpuz and Schrader 1990). For example, the sea-ice cover of the Nordic Seas for the last 14,000 years was reconstructed by this method (Koç et al. 1993). In addition to the previous marine assemblage, some brackish-water diatom species indicating sea ice occur in the Arctic, such as *Melosira arctica* (Boetius et al. 2013 and references therein).

The transfer function for May sea-ice cover is based on diatoms preserved in surface sediment samples from the North Atlantic and the associated modern sea-ice concentrations, using the maximum likelihood method (Justwan and Koç 2008). The results attained by this method are comparable to the ones obtained by other paleo-proxies (e.g., dinoflagellates) indicating the reliability of this new technique for the quantitative reconstruction of May sea ice. The method has been used, e.g., for sea-ice reconstruction from the Norwegian Sea showing a marked decrease in May sea-ice concentration at the transition between the Younger Dryas and the Holocene (Justwan and Koç 2008).

Recently, the highly branched isoprenoid lipid, IP_{25}, is an approach based on long carbon chains produced by diatoms living in association with seasonal sea ice (Belt et al. 2007). IP_{25} has emerged as a potential sea-ice-specific proxy for the past sea-ice cover as it seems to reliably reconstruct trends in observed sea-ice concentrations (Weckström et al. 2013).

Diatom-based sea surface temperature (SST) reconstructions

Diatom SST transfer functions

Diatom-based quantitative SST reconstructions from the North Atlantic have been generated using data sets consisting of modern diatom assemblages of the surface sediment samples and modern SST data from the North Atlantic (e.g., Andersen et al. 2004; Jiang et al. 2005; Miller and Chapman 2013) and the transfer function methods, such as weighted averaging partial least square (WA-PLS; ter Braak and Juggins 1993), Imbrie-Kipp transfer function method (IKM; Imbrie and Kipp 1971), maximum likelihood (ML), the modern analog technique (MAT; Hutson 1980), and the artificial neural network approach (ANN; Malmgren and Nordlund 1997).

Recently, Miettinen et al. (unpublished) expanded the most commonly used diatom SST calibration data set of 139 surface sediment samples with 52 diatom species (Andersen et al. 2004) to 184 surface samples and refined the SST equation. This new WA-PLS diatom transfer function has a root mean square error (RMSE) of 0.8 °C, a coefficient of determination between observed and inferred values (r^2) of 0.96, and a maximum bias of 0.6 °C. These statistical criteria indicate that diatoms show good analogue relations to modern oceanic conditions and are linearly related to SST.

The WA-PLS method is a commonly used transfer function method for SST reconstructions because it shows the best statistical fit between observed SST and estimated SST through the temperature range of modern calibration data. The reconstructions indicate summer temperatures; as for diatom transfer functions, August SST gives the best match (Berner et al. 2008). The WA-PLS method can be regarded as the unimodal-based equivalent of multiple linear regression, i.e., a diatom species has an optimal abundance along the environmental gradient being investigated. The method uses several components in the final transfer function. These components are selected to maximize the covariance between the environmental variables to be reconstructed to improve predictive power of the method (ter Braak and Juggins 1993).

Late Holocene SSTs in the North Atlantic and the Nordic seas

Recently, several quantitative high-resolution SST reconstructions have been generated from the North Atlantic in order to investigate the variability of the SST pattern, the surface currents, and the forcing factors behind the variability. For example, the most recent high-resolution diatom August SST records show persistent opposite climate trends toward warming in the subpolar North Atlantic (Miettinen et al. 2011, 2012) and cooling in the Norwegian Sea (Berner et al. 2011) during the late Holocene (Figure 1). An apparent tendency to coherent antiphased SST variations between the regions is also revealed for the multicentennial time scales implying an SST seesaw between the northern subpolar North Atlantic and the Norwegian Sea (Miettinen et al. 2012). This seesaw might have had a strong effect on two major climate anomalies in northwest Europe during the past millennium: the Medieval Warm Period (MWP) and the Little Ice Age (LIA).
Diatoms, Figure 1 Sea surface temperature records (aSST) from the subpolar North Atlantic (core Rapid 21-COM) and the Norwegian Sea (core CR948/2011) for the last 2,800 years (adapted from Miettinen et al. 2012). *Stippled lines* refer to linear trends of the aSST records.

During the MWP, warming of the sea surface in the Norwegian Sea occurred in parallel with cooling in the northern subpolar North Atlantic, whereas the opposite pattern emerged during the LIA. Coupled changes in SST between the subpolar North Atlantic and the Norwegian Sea indicate common driving forces behind the observed variability. The emerging spatial pattern of changes resembles the one predicted by modeling studies and is associated with rapid changes in the regimes of the North Atlantic overturning circulation (AMOC) (Hofer et al. 2011). The observed aSST seesaw between the subpolar North Atlantic and the Norwegian Sea could be a surface expression of the variability of the eastern and western branches of the AMOC with a possible amplification through atmospheric feedback (the North Atlantic Oscillation, NAO).

In the subpolar North Atlantic, the last 200 years represent the warmest SST period of the late Holocene. The last

three decades since the 1970s show a strong decadal SST variability with several years among the warmest of the record but also the coldest years since the 1820s. These cold years correspond with the documented great salinity anomalies in the North Atlantic suggesting that the fluxes of cold, low-salinity waters from the Arctic have been increased recently. Furthermore, August SST and the August NAO index (Luterbacher et al. 2002) show similar but reversed multidecadal-scale variability indicating a close coupling between the oceanic and atmospheric patterns corresponding with the general NAO/SST pattern in the North Atlantic (Wanner et al. 2001; Miettinen et al. 2011).

Summary and conclusions

In marine geosciences, diatoms are one of the foremost micropaleontological tools available for biostratigraphic,

paleoceanographic, and climatic studies. Their high sensitivity to surface ocean conditions makes them invaluable especially for the quantitative reconstructions of SST, sea ice, sea-ice margin, distribution of surface water masses, variability of the surface currents, and ocean–atmosphere interactions. Although quantitative reconstructions are the topical methods, highly valuable environmental data can be extracted from the diatom stratigraphic data as the statistical errors are always minimized in the qualitative data.

The diatom research has progressively concentrated on high-resolution studies and reconstructions providing the most useful data for the climate research; the numerical SST reconstructions are routinely archived into the scientific databases (e.g., NOAA) with open access to the scientific community. In extending the record of climate variability beyond the era of instrumental measurements, diatom records help to infer information about the mechanisms, forcing factors, and spatial and temporal ranges of climate variations.

Definition

Dinoflagellates (Greek, **διvη**, *dino*, "whirl" and Latin *flagellum*, "whip, scourge") are unicellular protists that have two distinctive flagella during at least part of their life cycle.

Introduction

Dinoflagellates are a biologically complex group of protists that comprise planktonic, meroplanktonic, and benthic species. They have different modes of nutrition making it difficult to attribute the group as a whole to animals or plants. Some species produce toxins that impact human health through consumption of contaminated seafood or water or aerosol exposure (Hackett et al., 2004). Toxic algae blooms are increasingly documented over the past decades (http://oceanservice.noaa.gov/hazards/hab) and may have a considerable economic impact. Extensive blooms of dinoflagellates may cause a coloration of water known as red tide. Some species are an important source of bioluminescence (Hackett et al., 2004). Since it has been finally accepted more than 50 years ago that the fossil hystrichospheres in Mesozoic and Cenozoic sediments are cysts of dinoflagellates (e.g., Dale, 1983), dinoflagellate cysts have become important in stratigraphy and understanding past environments.

General characteristics

Dinoflagellates (*c*. 2 to 2,000 μm) are primarily unicellular eukaryotes but some species are colonial, and chain formation is common (Taylor et al., 2008). Organisms are assigned to the division Dinoflagellata (kingdom Alveolata) based on possession of one or more of a suite of characters including an amphiesma, two dissimilar flagella, and a unique type of nucleus (Taylor, 1987). The amphiesma is the complex outer region of the cell wall, usually containing a single layer of flattened vesicles. These amphiesmal vesicles may contain thecal plates usually composed of cellulose (thecate or armored forms). Six basic types of tabulation, i.e., arrangement of amphiesmal vesicles, are known (Fensome et al., 1993). Dinoflagellates without thecal plates are called athecate, naked, or unarmored.

A distinctive flagellar apparatus consisting of a coiled transverse flagellum within a cingular groove and a posterior flagellum within a sulcal groove enables a spiral motion and to move freely in the water column (Taylor, 1987). Swimming speeds range from centimeters to a few meters per hour. Vertical migration is a result of endogenous rhythms. This motility permits to optimize position in the euphotic zone to a limited extent to take full advantage of light and nutrients and avoids sinking under very stable water conditions.

The unique type of nucleus, the dinokaryon, is characterized by chromosomes that remain condensed between cell divisions, and a lack of histones. Dinoflagellates may have special vacuole-like structures of unknown function called pusules (usually two per cell). The accessory pigment peridinin that enables energy transfer may be present in photosynthetic cells.

Ecology of dinoflagellates

Dinoflagellates live in all aquatic environments and have been observed both in snow and sea ice (Taylor et al., 2008). They are most abundant in shallow marine settings but also occur in fully oceanic environments. The biogeographic distribution is primarily determined by temperature, and the same species occur within similar climatic zones in both hemispheres. True endemism is rare, and some species have a bipolar distribution. More than 2,300 species have been described (Gómez, 2012) of which more than 180 are marine benthic (Hoppenrath et al., 2014) and 350 freshwater species (Mertens et al., 2012).

Dinoflagellates have diverse feeding mechanisms and utilize various modes of nutrition: they may be phototrophic, heterotrophic, and mixotrophic and may be free living, endosymbionts, or parasites (Jeong et al., 2010). Most species are probably mixotrophic or heterotrophic feeding on diverse preys such as bacteria, picoeukaryotes, nanoflagellates, diatoms, other dinoflagellates, heterotrophic protists, and metazoans or ingest particulate matter or dissolved substances. They are important in planktonic marine food webs since they may have both a considerable grazing impact on natural populations and are excellent prey for mixotrophic protists and metazoans. Together with diatoms and coccolithophores, dinoflagellates are among the most prominent marine primary producers today, thus playing an important role in the global carbon cycle.

Dinoflagellate cysts (dinocysts)

Dinoflagellates may form different types of cysts during various stages of their complex life cycle that involve asexual and sexual and motile and nonmotile stages (Taylor, 1987). Resting cysts represent a dormant stage in which normal life processes are greatly reduced. They are part of the sexual reproduction cycle (hypnozygotes) but may also be formed asexually (Kremp, 2013). Vegetative cysts are metabolically and/or reproductively active nonmotile cells. Temporary cysts are formed asexually as a result of adverse conditions. Digestion cysts that form after feeding are rare. Dale (1983) suggests that resting cysts may have three possible functions: protection, propagation, and dispersion. The latter may be extremely effective in introducing viable dinocysts into new geographic areas via transport in ships' ballast water (Taylor et al., 2008). Resting cysts may remain viable in sediments for centuries (Ribeiro et al., 2011).

Formation of resting cysts is a complex process and may be induced by various biotic and abiotic factors but is often related to peak abundances of the vegetative cells occurring at various times of the year (e.g., Matthiessen et al., 2005). After a mandatory dormancy period of variable length, excystment is triggered by different environmental factors. The cytoplast excysts through an opening in the cell wall, the archeopyle, which is an important feature for taxonomic definition of cyst genera. Only a minority of living dinoflagellates produce resting cysts (less than 20 %, Head, 1996). Establishing cyst-theca relations are complicated by the fact that a single dinoflagellate species may produce cyst morphotypes attributable to different cyst species (Rochon et al., 2009).

Fossil record of dinoflagellates

Dinoflagellates are preserved in the fossil record predominantly through their resting cysts. Micropaleontologists mainly focus on organic-walled cysts (i.e., consisting of a refractory biomacromolecule called dinosporin, Fensome et al., 1993) but calcified cysts are increasingly recognized in tropical to temperate environments (Zonneveld et al., 2005). Siliceous skeletons are rare. Taphonomic processes that alter dinocyst assemblages while sinking through the water column are relatively little known (Matthiessen et al., 2005), but species-selective aerobic degradation at the seafloor is an important process (Zonneveld et al., 2008).

Fossil cysts first occurred in the Triassic with a subsequent major radiation from late Triassic to mid-Jurassic, but molecular biomarkers indicate that ancestors of dinoflagellates originated in the Proterozoic (Hackett et al., 2004). Species diversity was highest in the Cretaceous declining throughout the Cenozoic and followed the global sea-level record with high diversity corresponding to intervals of high sea-level and large shelf seas (Pross and Brinkhuis, 2005). To date more than 4,000 fossil cyst species have been described.

Separate classification schemes have been developed by biologists and paleontologists for living dinoflagellates and fossil cysts before their natural relationship was discovered. Therefore, the resting cysts are often attributed to a different genus and species than their motile stage. Due to their nutritional strategies, dinoflagellates have been handled under the International Code either of Botanical or Zoological Nomenclature. Based on morphological characteristics, a phylogenetic classification at suprageneric level including both extant and fossil vegetative cells and cysts has been proposed by Fensome et al. (1993). Cyst species are generally described based on morphology, but molecular genetic studies become increasingly important to unravel the intricate phylogenetic relationship between taxa difficult to distinguish by morphology (Matsuoka and Head, 2013 and references therein). The database dinoflaJ2 comprises the classification of fossil and living dinoflagellates down to the generic rank; an index of fossil dinoflagellates at generic, specific, and intraspecific rank; and the references of original descriptions (Fensome et al., 2008b).

Ecology of extant dinoflagellate cysts

Like dinoflagellates, their cysts are found in all aquatic environments and occur even in regions with a seasonal sea-ice cover (e.g., Dale, 1996; Matthiessen et al., 2005; Mertens et al., 2012; Zonneveld et al., 2013). In general, diversity is highest in shallow marine settings (continental shelf and rise) and decreases toward the poles as a function of annual mean sea-surface temperature (Chen et al., 2011). Apart from changes in assemblage composition in relation to environmental gradients, cyst morphology (e.g., process morphology and length) may be affected by environmental stress such as temperature and salinity variability (Dale, 1996; Rochon et al., 2009; Jansson et al., 2014). The assemblage composition generally depends on both water mass properties and surface water circulation pattern. Application of multivariate ordination methods (canonical correspondence, detrended correspondence, and regression analysis) on regional and global data sets confirms a relationship to different physical (e.g., mean annual and seasonal surface temperature, salinity, upwelling intensity, sea-ice cover), biological (e.g., chlorophyll-a concentration, primary productivity), and chemical (e.g., phosphate, nitrate, and bottom water oxygen concentration) water mass properties. Ecological preferences are relatively well defined for a number of extant species (Zonneveld et al., 2013). The sensitivity for nutrient availability makes them ideal to identify areas of high productivity such as polynyas and upwelling regions and also of human-induced pollution and eutrophication if these signals can be differentiated from climate change (Dale, 2009). Biogeographic distributions of assemblages on regional and hemispheric scale have been widely used to develop transfer functions (using primarily the modern analogue technique) in order to quantitatively reconstruct sea-surface temperature and salinity,

seasonal extent of sea-ice cover, and primary productivity in Quaternary sediments (e.g., de Vernal and Marret, 2007; de Vernal et al., 2007; Bonnet et al., 2012).

Paleoecology of extinct dinoflagellate cysts

Dinocysts are increasingly used for paleoenvironmental reconstructions (Pross and Brinkhuis, 2005) but the definition of ecological preferences of extinct species remains a challenge. Various combinations of actuopaleontological, empirical, and statistical approaches including comparison with the morphology and ecology of co-occurring extant genera and species, the identification of latitudinal and onshore-offshore gradients from paleobiogeographic data, the interpretation of statistical analyses (e.g., correspondence analysis) on dinocyst distribution in relation to independent paleoenvironmental information, and the relation between dinocyst assemblages and geochemical proxies for water mass properties may yield qualitative and quantitative ecological information on, e.g., temperature, salinity, onshore-offshore gradients, bottom water oxygenation, and productivity (e.g., Versteegh and Zonneveld, 1994; Pross and Brinkhuis, 2005; De Schepper et al., 2011; Bijl et al., 2011; Masure et al., 2013; Schreck and Matthiessen, 2013). These ecological parameters are qualitatively known for some extinct species, groups of taxa or complexes of genera (e.g., Pross and Brinkhuis, 2005), and the correlation of species abundance to geochemical proxies (e.g., Mg/Ca temperatures on co-occurring planktonic foraminifera, De Schepper et al., 2011) is promising for providing quantitative data.

Biostratigraphy

Since the middle of the twentieth century, palynostratigraphy has emerged as a routine tool in both hydrocarbon exploration and academic research in Mesozoic and Cenozoic sediments, and numerous biostratigraphic zonations have been erected for Triassic to Neogene sediments (Stover et al., 1996). Dinocysts typically exhibit high abundances in neritic settings; thus, the derived stratigraphic information is complementary to that obtained from typically more offshore groups such as planktonic foraminifers, coccolithophores, and radiolarians (Pross and Brinkhuis, 2005). Significant progress has been made during the past four decades of scientific ocean drilling (DSDP, ODP, IODP) by assessing stratigraphic ranges against independent chronostratigraphic information. Recently, the focus is slowly moving from defining new zonations toward calibrating bioevents to the geological time scale on both regional (De Schepper and Head, 2008; Fensome et al., 2008a; Schreck et al., 2012) and global scales (Williams et al., 2004). This avoids the inherent problem of zonations that zones named after the same species may have different age ranges. However, few studies illustrate that dinocyst bioevents are rarely synchronous worldwide, and low-, mid-, and high-latitude bioevents should be distinguished to account for the observed latitudinal control on species ranges. Nonetheless, some bioevents are useful on regional and/or supraregional scale and enable stratigraphic correlations between different basins in the mid- and high latitudes (Schreck et al., 2012).

Conclusions

In recent years, biological and paleontological studies have provided a wealth of new information relevant for the application of recent and fossil dinocysts in marine geosciences. However, our knowledge of their ecology is still biased to coastal and shelf environments, and many open ocean regions such as the Pacific yet remain largely unexplored. The phylogenetic relationship to the motile form of many extant species is unknown, and molecular genetic studies will be particularly useful to address the long-standing question whether a single dinoflagellate species forms different cyst species. In the geological record, dinocysts are of eminent importance for paleoenvironmental interpretation and biostratigraphy in high latitudes where preservation of calcareous and biosiliceous microfossils is poor, but data from lower latitudes are required to inevitably improve independent age calibration of bioevents. This will also provide new data on the temporal and spatial distribution of fossil dinocysts, which together with calibration of species abundances to geochemical proxies for, e.g., surface temperature, will lead to a better understanding of cyst paleoecology.

DRIVING FORCES: SLAB PULL, RIDGE PUSH

Carolina Lithgow-Bertelloni
Department of Earth Sciences, University College
London, London, UK

Definition

Plate Driving Forces: The forces that drive the motions of tectonic plates at the surface.

Slab Pull: The force exerted by the weight of the subducted slab on the plate it is attached to.

Ridge Push: The pressure exerted by the excess height of the mid-ocean ridge.

Introduction

The history of the development of plate tectonics is centrally tied to the question of what drives plate motions. This has been the case since the failure of Wegener's ideas about polflucht to explain continental drift to the seminal papers by Elsasser (1969), Solomon and Sleep (1974), and Forsyth and Uyeda (1975) on slab pull and ridge push. This contribution cannot possibly review all the seminal and historical publications that led to the establishment of the terms and concepts of *slab pull* and *ridge push* as major plate driving forces; instead, it gives a brief historical introduction and then focuses on modern views of the plate-mantle system and what remains to be understood.

Historical overview

Beginning studies on plate driving forces all used parameterizations of forces acting at plate boundaries (e.g., Solomon and Sleep, 1974; Harper, 1975; Forsyth and Uyeda, 1975; Chapple and Tullis, 1977). This choice was partly out of necessity and partly a historical remnant of the development of plate tectonics with a contraposition of surface and interior. The perspective necessarily was a geological one, focusing on what could be seen and observed. Seminal early work focused on mantle convection and showed that the top thermal boundary layer of the convecting system could have plate-like properties and velocities (Turcotte and Oxburgh, 1967). This division between studies of plate driving forces from the plate or mantle perspective remains today. Early studies were partly influenced by the need to explain the apparent contradiction between a fluid, weak mantle, and transmitting stresses to strong plates, a corollary to Harold Jeffreys' objections to continental drift. These were the days before global seismic tomography (Dziewonski et al., 1977) and there was an understandable reluctance to correlate deep and unseen mantle structure with the surface. The existence of a low-velocity zone (the asthenosphere), which coincided (Anderson, 2007) with a very weak, very low-viscosity region, furthered the notion that stresses from mantle convection could not be transmitted to the lithosphere and effectively decoupled plates from the mantle. All return flow generated by the subduction of slabs was limited to convection in the asthenosphere (Forsyth and Uyeda, 1975). As global tomographic models emerged (Dziewonski et al., 1977), the suggestion that global geoid anomalies were correlated with past subduction (Chase and Sprowl, 1983) opened the door for studies that linked interior flow and surface motions. These ideas culminated in the classic papers of Hager and O'Connell (1981) on plate motions and driving forces in the context of mantle flow. The clear correlation between the long-wavelength pattern of subduction, mantle flow, and the geoid (Richards and Engebretson, 1992) further motivated the link between convection and the interior, leading to integrated studies of mantle flow to predict plate motions incorporating ever larger complexity in rheology and boundary conditions (Ricard and Vigny, 1989; Lithgow-Bertelloni and Richards, 1995; Becker and O'Connell, 2001; Conrad and Lithgow-Bertelloni, 2002; Becker, 2006; Stadler et al., 2010; van Summeren et al., 2012).

Basic principles

Plate driving forces in the traditional formulation are driving and resisting forces acting at the edges and the base of lithospheric plates, balanced so that there is no-net torque on any given plate or the lithosphere as a whole (Solomon and Sleep, 1974). In other words, plates are in dynamical equilibrium. The assumption of no-net torque is justified by the high viscosity of mantle and lithosphere, precluding acceleration and inertial forces. The balance of forces is best illustrated in the formulation of Forsyth and Uyeda (1975) shown in Figure 1. The main driving forces are slab pull (F_{SP}) and ridge push (F_{RP}), and forces like mantle drag (F_{DF} and F_{CD}) can both oppose and drive plate motions. Suction (F_{SU}), first identified by Elsasser (1971), pulls the overriding plate toward the trench. There are significant resisting forces, slab resistance (F_{SR}), transform resistance (F_{TF}), and collisional resistance (F_{CR}). For the sake of brevity, we only focus on slab pull and ridge push.

Slab pull is defined as $F_{SP} = \Delta\rho g \sin\theta V_s$ where $\Delta\rho$ is the density contrast between the slab and the surrounding mantle, g the gravitational acceleration, θ is the dip angle of the slab, and V_S the volume of the slab. The slab pulls
Driving Forces: Slab Pull, Ridge Push, Figure 1 Cartoon of plate driving forces illustrating the parameterization of forces at the edges and base of the plates (reproduced from Forsyth and Uyeda (1975)).

on the plate and is resisted by viscous drag along the interface (F_{SR}). This definition implies a strong slab capable of transmitting stresses to the plate and therefore acting as a stress guide (Elsasser, 1969).

Ridge push is induced by the pressure gradient at the ridge crest due to its higher elevation with respect to the surrounding oceanic lithosphere. It is approximately given by $\Delta P = 1/2\, g(\rho_o - \rho_w)l$ where ρ_O and ρ_W are the densities of the oceanic lithosphere and water, respectively, and l the elevation of the ridge (McKenzie, 1972). It acts at the plate boundary and is resisted by mantle drag (F_{DF}) and transform resistance (F_{TF}).

Mantle drag (F_{DF}) is the shear exerted by the flowing mantle at the base of the lithosphere and considered as largely opposing plate motions as the plate drags across the surface of the mantle.

Minor forces such as collisional resistance also act to impede plate motions. Explicitly parameterizing these forces is a way to account for the differences in composition and rheology of the continental crust (Meade and Conrad, 2008).

These basic definitions of the force balance acting on the plates view the plate-mantle system as largely decoupled. This view is strongly prevalent in the geological and tectonophysics community. Many modern studies focus on individual plates and forces at the edges of plates (Coblentz et al., 1998; Bird, 1998; Govers and Meijer, 2001, among many others). In geodynamics, there is a different point of departure. Plates are not seen as rafts on a convecting fluid mantle and hence decoupled; instead, plates are mantle convection (Bercovici, 2003). In this view, plates and the mantle are inextricably linked and the same thing as plates represent the upper thermal boundary layer of the convecting system. In this framework, the only relevant physical force driving plate motions is gravity acting on lateral density variations, and the only resisting forces are viscoelastic stresses. Plate velocities are the result of the integration of the net shear tractions induced by mantle flow acting on the base of the lithosphere. The net tractions are those resulting from the driving buoyancy as well as the resistance-induced viscous flow in the mantle from plates moving at the surface. Therefore, net tractions can be both in the direction of plate motions or against it and any other direction. It is the integral of these tractions over the area of the plate that generates the plate velocity vector. This is already clear when comparing textbook estimates of slab pull (10^{13} N/m) and ridge push (10^{12} N/m) with the gravitational body force of the top thermal boundary layer of the mantle convecting system (Turcotte and Schubert, 2014).

The difficulty lies not in understanding the individual balance of driving and resisting forces but how to physically understand the interplay between the buoyancy and rheology in light of our incomplete knowledge of both: specifically, (a) complete catalog and understanding of the energy sources available to generate buoyancy (e.g., radioactive decay, cooling from the core, crustal composition) and (b) the rheology of mantle and plates. The latter, the ignorance of rheology as a function of composition, volatile content, stress, deformation, temperature, and pressure, is the most serious obstacle to a full theory of mantle convection and plate tectonics.

In this light, force balancing on individual plates by a catalog of forces acting at the edge is one way to parameterize the strength of plates, the rheology of plate boundaries, and the available buoyancy.

State of current knowledge

The importance of rheology for plates, plate boundaries, and slabs in generating realistic plate tectonics is illustrated by Stadler et al. (2010) and Alisic et al. (2012). These studies match plate motions globally and locally in the no-net-rotation reference frame with very high-resolution simulations that incorporate lithospheric thickening, upper-mantle slab temperature profiles defined by seismicity, and lower-mantle buoyancy from seismic tomography and complex nonlinear rheologies. The inclusion of nonlinear rheology and variations in rheology at the plate boundary are important for matching other observables, such as the state of stress of the slab defined by deep earthquakes. The buoyancy of the slab remains the most important driving factor, but the details of the rheology of the plate boundary, slab, and mantle are critical for matching plate velocities and defining the slab-plate coupling.

At present, the slab pull force is understood as the weight of the slab exerting a pulling stress on the plate it is attached to. The buoyancy of the slab induces flow, but the slab is strong enough to support its own weight and transmit all the stresses to its attached plate, in other words act as a stress guide (Elsasser, 1969). However, once the slab gets into the lower mantle and warms up in a more viscous lower mantle, it is no longer able to support its own weight and is supported by viscous stresses in the mantle (Conrad and Lithgow-Bertelloni, 2002; Stadler et al., 2010). This view reconciles a mantle convection view of plate driving forces with the more traditional approach of Forsyth and Uyeda (1975), where the slab pull force pulls at the edge of the slab and is resisted by viscous drag along the slab interface.

Ridge push is just another source of buoyancy acting over the entire surface area of oceanic plates. It arises from the cooling and thickening of the oceanic lithosphere as it ages (Lister, 1975). At the ridge or for young oceanic lithosphere ($<20–30$ My), the density contrast with respect to the mantle is negative and no flow is induced. This driving force is again balanced by viscous stresses acting at the bottom of the oceanic lithospheric plates.

The magnitude of individual forces depends on the tectonics of each plate and the local viscosity structure. Globally, the ratio of forces due to the excess buoyancy of slabs including those in the lower mantle (slab pull) and those due to lithospheric thickening (ridge push) is 70–80 % to 30–20 % (Lithgow-Bertelloni and Richards, 1995; Becker and O'Connell, 2001).

The effect of lateral variations in viscosity, deep continental roots, and parameterized slab strength (van Summeren et al., 2012) shows that the effect of roots is minimal and does not affect plate driving forces substantially, but the presence of a laterally varying asthenosphere is critical and slab buoyancy and strength (slab pull) remain the most important contribution to the force budget. Locally, however, the tractions exerted by large-scale mantle upwellings can contribute significantly to the force balance of individual plates (Lithgow-Bertelloni and Silver, 1998).

Summary and conclusions

The plate-mantle system is one and indivisible. Plates are part of mantle convection and interact with all parts of the mantle through their buoyancy and rheology. The classic view of plates decoupled from the mantle by a very low-viscosity asthenospheric layer does not conform to the present understanding. While the presence of the asthenosphere is critical to making plates and matching plate velocities (Tackley, 2000; Richards et al., 2001), it does not preclude interaction with the deeper mantle as far as the core-mantle boundary. The terms slab pull and ridge push are parameterizations of the buoyancy and strength of plates and slabs. Matching plate motions and the state of stress of plates and slabs is critically dependent on the rheology of the plates, slab, and mantle as well as the plate boundary, which remains the most uncertain physical property affecting the plate-mantle system.

DUNES

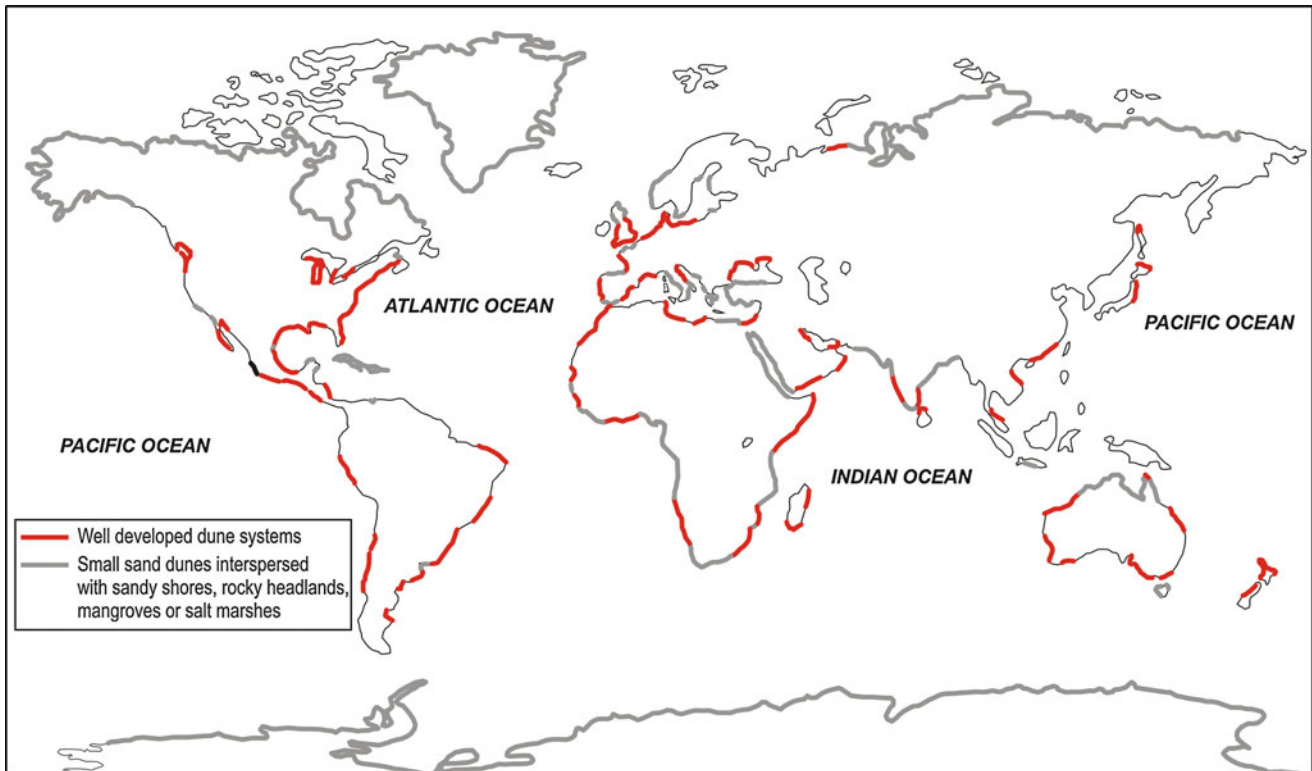
Sara Muñoz-Vallés and Jesús Cambrollé
Department of Plant Biology and Ecology, University of Sevilla, Seville, Spain

Definition

Dunes are sedimentary landforms originated by Aeolian processes. More than simple accumulations of loose sand, dunes show particular shapes with defined windward and slip face slopes and an internal laminated structure due to their formation dynamics of sand deposition. Adequate supplies of well-sorted sands and winds capable of moving these sands for at least part of the year are required to their formation, both in coastal and continental areas. In the case of continental dunes, availability of sandy sediments originated by desertification in emerged lacustrine deposits or due to alteration of rocks can provide considerable sandy supplies. Under arid or semiarid climate conditions, where vegetation is sparse or absent, such deposits are mobilized by wind, resulting in the origination and development of dune fields such as the existing in the Sahara, Arabian, Australian, Kalahari, or Mohave deserts (García Mora, 2000). In the case of coastal dunes, they are relatively complex phenomena that form at the interface of terrestrial, oceanic, and atmospheric systems, where the influence from the sea and the vegetation cover are relevant factors to their formation and development. In addition, due to the joint action of tides and wind-driven currents, submarine sand dunes are also originated in continental shelves (Le Bot and Trentesaux, 2004), while the existence of sandy bed material in rivers also promotes the formation of fluvial sand dunes (Carling et al., 2000).

This entry focuses on coastal dunes as sedimentary landforms and ecosystem and describes their occurrence, typology, formation dynamics, and main ecological traits. In addition, some information about environmental services and conservation is included.

Occurrence of coastal dunes

Coastal dunes are distributed worldwide, from polar to tropical latitudes, comprising very diverse climates and biomes, but covering a really limited global area (Figure 1). They mainly develop in association with dissipative coasts dominated by marine winds, with an ample supply of loose, sand-sized sediment (i.e., continental shores, sandy barriers and spits), but they also occur on lake and estuary shorelines (Carter, 1988; Martínez et al., 2004). Coastal dunes present a large variety of forms (see the subsection "Dune Typology" in this entry) and dimensions (they range in size from less than 1 m to several kilometers) related with spatial and temporal variations in sediment supply and wind regime (Hesp, 2004; Martínez et al., 2004; Pye and Tsoar, 2009). For instance, dunes in geographical areas such as Australia show greater developments and sizes due to the enormous volumes of sand supply from the continental shelf, in contrast with areas from USA or Europe, where dune systems show in general smaller sizes and longitudinal developments due to the action of the littoral drift currents (Sanjaume et al., 2011). On the other hand, dune fields migrating obliquely onshore to onshore (not alongshore), in very general terms, are more common in the tropics and adjacent humid subtropics than in temperate areas, where tabular dune fields are more common (Hesp, 2004).


Dunes, Figure 1 Worldwide distribution of coastal dunes (Adapted from Martínez et al., 2004).

Dunes typology

The different factors involved in the formation and development of coastal dunes result in a wide variety of forms and dimensions. During the last decades, different authors have proposed diverse dune classifications based on different criteria (e.g., morphogenetic, geometric, morphoecological) (see Sanjaume et al., 2011), since the study of sand dunes is a multidisciplinary matter, carried out by researchers from different science branches such as physical (e.g., engineering, physics), life (ecology, botany, zoology), or earth (geomorphology, sedimentology, hydrology) sciences (Pye and Tsoar, 2009).

In general, the most widely spread and applied coastal dune classification has been based on morphogenetic criteria, sometimes considering vegetation traits. Here we summarize the most common dune types found in coastal environments (based on the descriptions by Goldsmith, 1985; Hesp, 2002; Pye and Tsoar, 2009; otherwise cited):

- **Embryo dunes**: also named *shadow dunes*; they are the most elementary and small coastal dunes that form in the wind shadows of clumps of vegetation or other small obstacles to sand transport by the wind. Sometimes, the term *shadow dune* is used to name the smaller forms, with decimetrical or centimetrical lengths.
- **Foredunes**: dune ridges that run parallel to the shore, more or less perpendicular to the prevailing wind. Foredunes are usually developed from several former *embryo dunes* that grow and coalesce to form an incipient *foredune*, corresponding to a higher evolutionary dune stage (see the subsection "Dune Formation" in this entry).
- **Transverse dunes**: alignments or longitudinal ridges with a gentle slope in the windward face but more pronounced in the slip face, more or less parallel to the coastline and always arranged perpendicular to the prevailing wind that originates them. It includes other types of dunes if they are arranged perpendicular to the prevailing winds, such as foredunes, barchans, parabolic, or precipitation dunes.
- **Barchans**: dunes with crescent shape and wings developed downwind.
- **Parabolic dunes**: relatively stable, U-shaped dunes with lateral lobes anchored by vegetation and the crest migrating downwind.
- **Reversing dunes**: a special type of transverse dune, showing similar slopes both in the windward and slip faces due to winds acting in opposite directions.
- **Transgressive or precipitation dunes**: mobile dunes with high dynamism and absence of vegetation cover due to high burial rates, which rush on the existing tree line and may become a burial hazard for roads and towns.
- **Climbing dunes**: dunes originated by a sand-laden wind or a migratory dune that bump into a topographic barrier – a hill or a cliff – and climb it totally or partially.

- **Cliff-top dunes**: *climbing dunes* that have remained at the top of a cliff due to erosion, usually disconnected from the original source of sand. *Falling dunes* are *cliff-top dunes* that are provided with excess of sand supply so that the dunes keep moving down the side of the cliff lee.
- **Echo dunes**: elongated mounds with a more or less linear ridge, generated near a subvertical topographic barrier and parallel to this barrier.
- **Wrap-around dunes**: dunes that surround the barrier and their shape is adapted to the obstacle. *Nebkha* – or *nabkha,* also named *hummock* or *coppice dune* – is a particular type formed in and around clumps of grass, herbs, bushes, etc. (Figure 2).

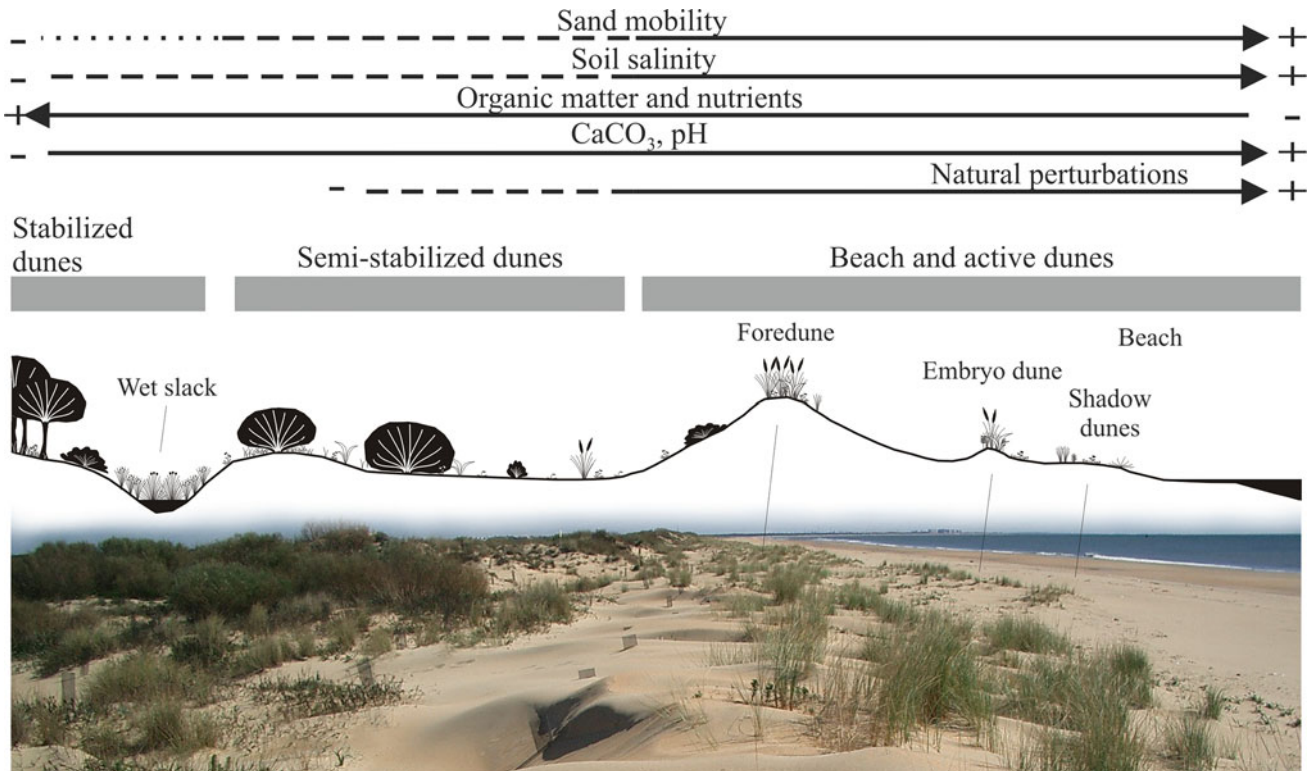
Other classifications are based on biological, ecological, and morphological traits, where different dune areas are related with different habitats colonized by characteristic plant species in each case, which often coincide with particular geomorphological situations. Corresponding to different stages of dune maturity and/or evolution, *white* (carbonate rich sands due to shell content) and *yellow* (siliceous sand) *dunes* are referred to mobile dunes with scarce or null vegetation cover, where sand surface is clearly visible, while *grey dunes* are referred to dunes that are semistabilized and stabilized (fixed) with vegetation (mainly grass), where a major organic matter content in the soil would provide a darker color to the sands (Sanjaume et al., 2011). On the other hand, the dune classification carried out by Cooper (1967) is based on factors driving the dune genetics and development, and it can be sometimes related with the dune conservation status and vulnerability. It groups dunes according to factors such as the sediment exchange with the beach: *primary dunes* derive directly from the beach sand transported by the wind and maintain an active sediment exchange with the beach while *secondary dunes* are derived from the erosion of *primary dunes.*

Dune formation

The origination and development of coastal dunes are determined by a complex interaction of factors, the main ones being wind velocity and direction, sand supply availability, influence from marine processes, moisture content, vegetation, and topography of the beach and its adjacent continental zone (Ranwell, 1972; Klijn, 1990; Hesp, 2002; Sanjaume et al., 2011). Coastal dunes are originated when the amount of sand that reaches the beach from the sea is greater than the amount that the beach loses, for instance, by erosion during storms, and this sand surplus is transported inland by the wind toward a dry zone of the beach, out of the reach of normal waves and tides (Olson, 1997).

Once the sand is deposited in a wide and dry enough area of the beach, a selection of grain sizes occurs in relation to the wind intensity and grain traits. Four types of Aeolian transport of particles take place: very coarse sand (1–2 mm diameter) and granules (2–4 mm) are rolled or slid forward (**traction** or *creep*) and generally remain in the beach and absorb part of the wind transport energy. On the other hand, very fine grains (silt and clay) that have not been washed away by waves during the transport of beach sediments tend to be carried upward in turbulent eddies (**suspension**) and finally winnowed out of the beach and dune. As a result, middle size-range grains consisting mostly of fine to coarse sand, ranging, respectively, from 0.125 to 0.25 mm (fine sand), 0.25–0.5 mm (medium sand), and 0.5–1 mm diameter (coarse sand) remain to the formation and development of the dunes. These sand grains are transported by wind by *saltation* or by *reptation*. During **saltation**, the sand grains are lifted up into the air and describe a parabolic trajectory for a short distance before falling back to the surface. During **reptation**, particles on the ground may set in motion at wind velocities lower than those required to move them by wind alone, due to collisions with grains that are already in motion by saltation (Bagnold, 1941; Olson, 1997). This transport by wind takes place almost entirely within 0.5 m of the ground surface, with nearly 90 % of this movement within 2.5 cm of the surface (Bagnold, 1941).

Dune formation begins with the deposition of sand transported by the onshore winds, to the lee of the roughness elements by reverse flows. It is therefore necessary to set some obstacles in the beach surface, natural or artificial, such as vegetation, pebbles and stones, shells, marine debris, or some irregularities existing out of the reach of waves and tides (Ranwell, 1972; Olson, 1997). More usually, tidal litter initiates sand accumulation at the top of the backshore. This is firstly colonized by annual plant species and subsequently by perennial grasses capable of growing up through sand accretion, forming *shadow dunes*, *mounds,* and *nebkhas*. Although other inert obstacles are capable of producing sand deposition, these incipient dunes are not able to grow once the obstacle is buried. The development of *embryo dunes* and their transformation from ephemeral to permanent features is therefore favored by vegetation establishment and succession (Ranwell, 1972; Hesp, 2002). Scattered embryo dunes may coalesce to form a continuous band parallel with the strandline and would grow upward and in width to form a *foredune*. In situations of high availability of sand supply, the resulting morphology is consistent with a series of parallel foredunes of increased age from seaward to landward, separated by interdune depressions or *slacks* (Figure 3). Otherwise, a foredune regression and a dune topography dominated by washovers would occur.

Rates of beach-dune sediment exchange (particularly the balance between the beach and frontal dune sediment budgets) strongly influence the frontal dune development and morphology. In this regard, Hesp (1988) differed 5 foredune types (Fa – Fe), corresponding to gradual situations associated to the loss of vegetation cover and foredune disintegration. Under conditions of positive balance of beach sediment supply, the formation of the coastal dune continues until a reduction in sand supply
Dunes, Figure 2 Dune morphologies (*arrows* indicates wind direction): (**a**) *Shadow dunes, embryo dune,* and *foredune* in Isla Cristina Coast, Huelva (Spain); (**b**) *Barchans* in Jericoacoara Beach, Ceara State (Brazil); (**c**) *Parabolic dune* (also named *blowout*) in Doñana National Park (Spain); (**d**) *Parabolic dunes* near Foxton Beach, North Island (New Zealand); (**e**) *Transgressive* (also *climbing*) *dune* in Bolonia dune Natural Monument, Cádiz (Spain); (**f**) *Transgressive dune field* in Myall Lakes National Park (Australia); (**g**) *Cliff-top dunes* in El Asperillo Cliff Natural Monument, Doñana Natural Park (Spain); (**h**) *Hummocks* (also named *nebkhas* or *coppice dunes*) in Valdevaqueros dune Natural Monument, Cádiz (Spain) (Images **a–g** have been extracted from Google Earth, 2014).


Dunes, Figure 3 Main environmental gradients on coastal dunes (adapted from Carter, 1988; Brown and McLachlan, 1990; Muñoz-Vallés, non published data).

occurs, due to a change in the beach sedimentary balance, from prograding to erosive, or to the formation of new seaward embryo dunes (Hesp and Martínez, 2007). Therefore, the frontal dunes will either grow vertically to their maximum height and then erode moving landwards (e.g., in beaches with narrow backshore and prevailing and intense enough winds on the shore) or prograde seawards through the development of new embryo dunes and foredune ridges (in beaches with broad and high backshore levels and moderate onshore winds). Under generally negative balance of beach sediment supply, embryo dunes will not form and the foredune will undergo net erosion. In extreme circumstances, the foredune will become disrupted by blowouts, leading to the development of transgressive sand sheets and dunes (Ranwell, 1972; Hesp, 2002).

Dunes as ecosystems

Coastal dunes support unique and complex ecosystems of high ecological value. They represent a harsh environment for the survival of many living beings; hence, species of sand flora and fauna are specifically adapted to such stressful conditions, mainly related to sand properties, sedimentary dynamics, the proximity to the sea, and the influence of wind (Ranwell, 1972; Chapman, 1976; Carter, 1988; Maun, 2009). One of the main traits that make these ecosystems so particular is the nature of the

substrate, i.e., sands, onto which the biocenosis is developed. Apart from its mobility (burial, but also bypassing and erosion), fine to coarse siliceous sands that commonly comprise the dunes are characterized by a considerable pore size, which confers these substrates a free drainage and a pursuant low capacity to retain water or nutrients, such as phosphorous, nitrogen, or potassium (Maun, 2009). Severe leaching often occurs, which leads to substantial losses of nutrient and organic matter in the soil. This leads to a general low vegetation coverage, which is related to high air and soil temperatures and light intensities in low and medium latitudes. In addition, this characteristic low plant abundance is usually unable to develop a real soil, and only a partially formed surface horizon (*arenosol*), with poor levels of humus, is noticeable in the more mature stages of the dune development. On the other hand, the influence of the sea determines a series of environmental and biological gradients from the shoreline and landwards (Figure 3). In this regard, factors such as incidence of *salt spray*, wind and sand blasting and saltwater flooding (in the strandline), tend to decrease or disappear inland while nutrient concentration, sands stability, vegetation cover, and, in general, the ecosystem maturity increase (Ranwell, 1972; Carter, 1988; Doody, 2012). In this regard, coastal dunes have served scientific research on ecological succession through dune age gradients (*chronosequences*), and some of these studies have

relevantly contributed to the elaboration of ecological theories and to a major understanding of the general functioning of ecosystems (e.g., Cowles, 1899; Clements, 1916; Salisbury, 1922; Olson, 1958; Yarranton and Morrison, 1974).

A characteristic vegetation type including unique species with specific adaptations to the harsh environmental conditions establishes on coastal dunes (Ranwell, 1972; Maun, 2009). Such vegetation shows a wide distribution through different climatic and geographic areas, both at the species level (particularly those established on the beach and active dunes) and at the genus level or their growth forms, so these ecosystems have relatively similar vegetation worldwide in temperate latitudes (Doing, 1985). Coastal dunes also support a high number of rare and endemic species (Martínez et al., 1993; Heslenfeld et al., 2004). Other plants from inland ecosystems, ruderal, and/or alien species may be also present, mainly associated with the degradation status of the dune. Vegetation is closely related to the sediment dynamics and geomorphological processes of the dune, and a continuous interaction is maintained between both elements (Ranwell, 1972; Hesp, 2002). On the other hand, the environmental gradients previously referred determine the establishment of the different plant species, particularly in the youngest areas, nearest to the sea, while biological interactions (mainly positive for the interacting species, although they may be also negative) play a relevant role in determining the structure and composition of vegetation, particularly in more stabilized and mature situations of the dune, toward the inland areas (Lichter, 1998; Maun, 1998). As a result, vegetation becomes ordered in bands from the strandline and landward, more or less parallel to the coastline and originating a particular type of landscape composed of a mosaic of habitats, both in dune systems developed on continental coasts, spits, or barrier islands.

Environmental services and conservation of coastal dunes

Coastal dune systems are not only relevant from the geomorphological, geological, or ecological point of view. They also have a recognized historical, archaeological, scenic, cultural, and socioeconomic interest (Nordstrom et al., 2000; Heslenfeld et al., 2004; Martínez et al., 2004; van der Meulen et al., 2004). In addition, they provide us with different direct and indirect benefits and resources (which are known as *environmental services*), acting as zones for livestock grazing, agriculture, sand exploitation for construction purposes and water extraction, or for human settlement, urban development, tourism, and recreational use (Carter, 1988; van der Meulen and Salman, 1996; Williams et al., 1997; Kutiel et al., 1999; Baeyens and Martínez, 2004; Heslenfeld et al., 2004). Furthermore, coastal dune systems play a relevant role as natural barriers that preserve other inland natural areas and human settlements by buffering the effects of storm waves, tides, and wind and preventing groundwater salinization by intrusion of sea water, among others (Carter, 1988; Hesp, 2000; Kidd, 2001; Gómez-Pina et al., 2002).

Nevertheless, due to an excessive exploitation of the resources and services they offer, the human demographic expansion and the relatively recent urban, engineering and industrial development, many coastal dune systems are being seriously degraded at present, some of them irreversibly altered and lost (Carter, 1988; Heslenfeld et al., 2004; Doody, 2012). Only in Europe, it is estimated that around 25 % of the coastal dune surface has been lost since 1900, while around 55 % of the remaining surface has lost its natural character, and approximately 85 % of the currently existing dunes are endangered (Heslenfeld et al., 2004). Among the main damages that coastal dunes suffer are the net loss or fragmentation of natural habitats, loss of landscape scenic quality, alteration of soil and aquifers, water and air pollution, hazards for endangered species, global biodiversity decline, and increase of the ecosystem vulnerability. On the other hand, the anthropogenic habitat degradation and destruction (mainly associated to urban development and tourism), dune stabilization and eutrophication, expansion of invasive species, and the effects of global warming and the progressive sea-level rise are identified as the main current threats to coastal dunes (Carter, 1988; Kutiel et al., 1999; Nordstrom et al., 2000; Heslenfeld et al., 2004; Martínez et al., 2004; Doody, 2012; Muñoz-Vallés and Cambrollé, 2013).

Currently, many coastal dunes are being protected under regional, national, and international initiatives, devoting a great effort in the conservation, management, and restoration of such ecosystem from different disciplines and government levels, in pursuit of a sustainable development that takes into account both the ecosystem health and the use of their services (Doody, 2012).

Summary

Coastal dunes are Aeolian landforms that form at the interface of terrestrial, oceanic, and atmospheric systems, mainly associated with dissipative coasts dominated by marine winds with an ample supply of well-sorted sands and occurring on ocean, lake, and estuary shorelines. Distributed worldwide, they comprise very diverse climates and biomes and present a large variety of forms and dimensions related with sediment supply and wind regime, where vegetation plays a relevant role. The influence of the sea determines a series of environmental and biological gradients from the shoreline and landwards. The harsh environment characterized by the scarcity of water and nutrients, substrate mobility and sand burial, incidence of salt spray and sand blasting, high air and soil temperatures and light intensities in low and medium latitudes, and saltwater flooding in the strandline determines the establishment of species of singular sand flora and fauna that are specifically adapted to such stressful conditions.

Coastal dune systems have a recognized geomorphological, geological, ecological, historical, archaeological, scenic, cultural, and socioeconomic interest and provide us with different direct and indirect benefits and resources including their role as natural barriers that buffer the effects of storms, sea, and wind. Nevertheless, they cover a really limited global area that is largely endangered at present, mainly due to human direct and indirect impacts. This has led to the development of initiatives and efforts focused on dune conservation, management, and restoration from different disciplines and government levels.

Definition

Mineral particles, mainly composed of clay and quartz, are emitted from arid regions of the continents. The presence of these nonspherical particles in the atmosphere influences the radiative budget of the Earth. Mainly under the form of pulsed events, much of this mineral material enters the open ocean with high spatial and temporal variability. Following a settling of the largest particles during transport, dust deposition on the ocean surface consists mostly of particles of a few microns in size. These particles bring to the ocean surface new nutrients (e.g., phosphorus) and metals (e.g., iron) that are essential to life, impacting marine biogeochemistry and thus ocean uptake of carbon dioxide and deep-sea sedimentation.

The fate of dust in the ocean

Despite observations and references to dust events dating back to ancient times, such as "blood rain" or "red rain" (e.g., in *Homer's Iliad*), the significance of desert dust and its emission, transport in the atmosphere, and deposition in large areas of the ocean has been demonstrated only very recently. We know now that dust particles emitted in the atmosphere and deposited at the surface of the ocean (Table 1) do impact the global climate as they influence the radiative budget of the Earth (e.g., Miller and Tegen, 1998), the marine biogeochemistry in various areas of the ocean (e.g., Martin et al., 1991; Jickells et al., 2005), and the sedimentation in the deep ocean (e.g., Windom, 1975; Lisitzin, 2011). However, the linkage of dust to ocean productivity and climate is far from being fully understood (Schulz et al., 2012).

Emissions: Today, the major regional sources are concentrated in a broad "dust belt" (Prospero et al., 2002) in the northern hemisphere (Table 1, Figure 1a). The chemical composition of desert dust aerosol particles reflects that of the average Earth surface rocks with a dominance of SiO_2 (~60 %) and Al_2O_3 (10–16 %) resulting from the dominance of quartz and clay minerals (Goudie and Middleton, 2006). From estimates of mass concentrations, desert dust and sea spray aerosol are the largest aerosol contributions on a global scale (Jickells et al., 2005; Andreae and Rosenfeld, 2008).

Dust transport: Vertical and horizontal scales of dust transport from arid areas are clearly defined (Lisitzin, 2011). Local transport includes movements of sand and gravel by rolling and saltation over the desert surface within 0–10 km from the source. Regional transport (10–1,000 km) occurs at heights of 5–7 km (to the cloud top and above). Finer particles (silt and clay) are transported over longer distances. The long-range global transport (more than 1,000 km) may occur during the emission of finer-grained pelitic material above the in-cloud scavenging height (5–7 km). Mineral crustal particles in the atmosphere have a mean size around 2 μm (diameter range 0.1–10 μm), and the largest particles fall out quickly during their long-range transport (thousands of kilometers, e.g., Ginoux et al., 2001). Together with lithogenic particles, biogenic components and nutrients, black carbon, and different pollutants enter the dust load transported to the ocean from industrial centers and areas of biomass burning, for example, from Southeast Asia (e.g., Chin et al., 2007; Guieu et al., 2010; Lisitzin, 2011). This mixing with, for example, anthropogenic acids (such as HNO_3) between emission and deposition regions may result in deposition of dust enriched in nitrogen (Geng et al., 2009).

Deposition: One of the main characteristics of dust deposition is its very high spatial and temporal variability (e.g., Jickells et al., 2005). A few, intense events may account for the bulk of the annual deposition (e.g., Loÿe-Pilot and Martin, 1996). The largest contribution is from arid North Africa (58 % of the total emissions, Table 1), which feeds large areas of the North Atlantic where high deposition dust fluxes occur. Saharan dust has also strong deposition in regional seas such as the Mediterranean Sea (Guerzoni et al., 1999). Deposition occurs as wet or dry

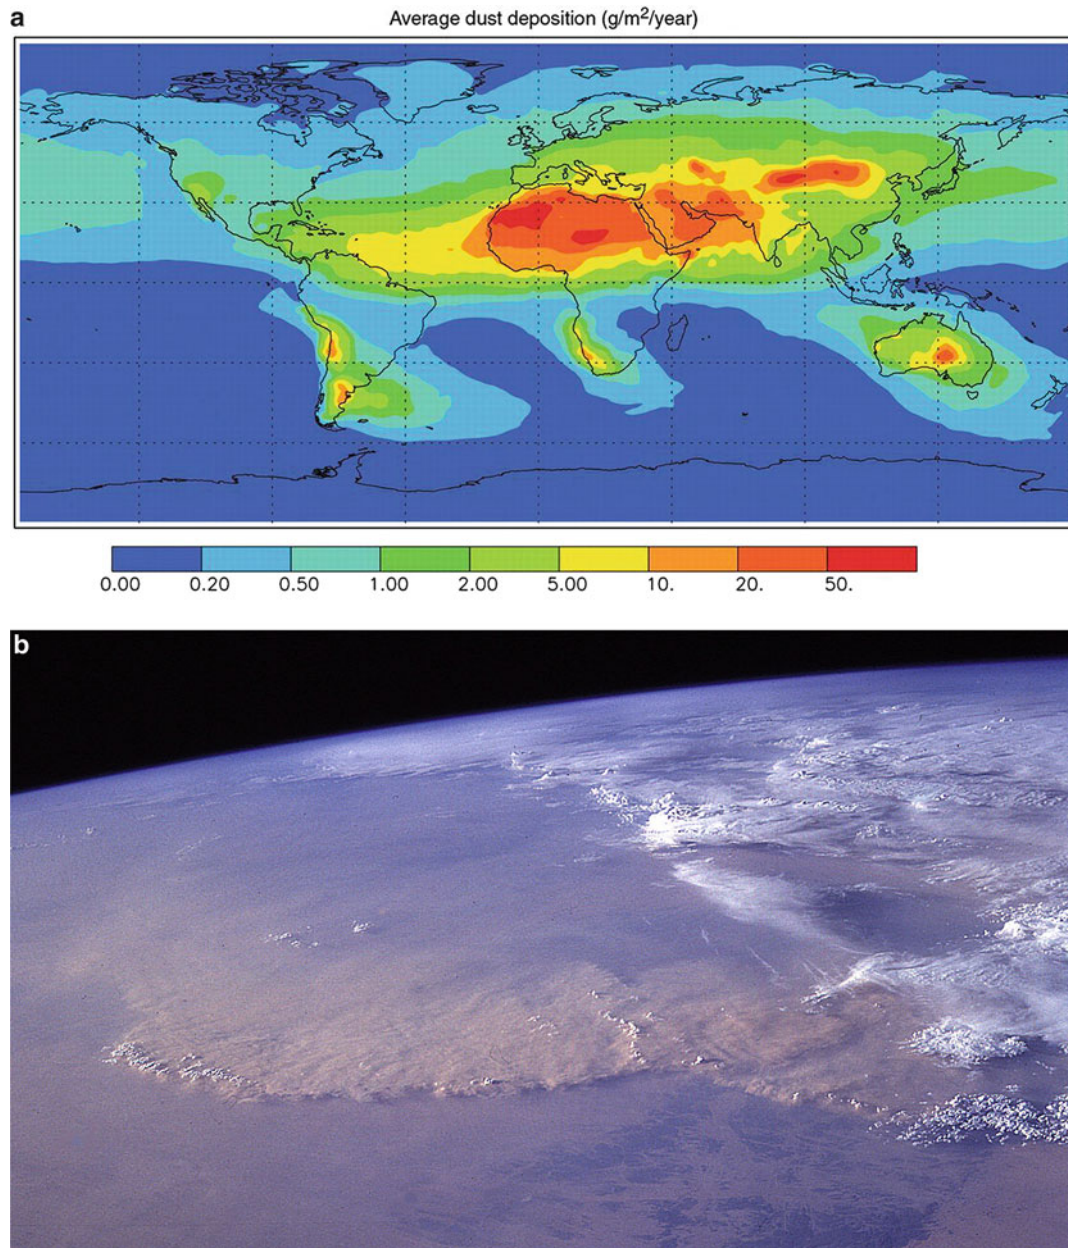
deposition. Our knowledge on this partitioning both from models and observation is still quite fragmented (Mahowald et al., 2005). The few observationally based estimates suggest that wet deposition is more important than dry deposition over ocean regions (Hand et al., 2004), although observations are limited in both space and time.

Variability of the emissions/deposition in geological history and present time: Desert dust emission being very sensitive to climate, dust deposition is not constant over time. For example, during glacial periods, dust deposition rates were three to four times higher globally (Rea, 1994; Kohfeld and Harrison, 2001) and 2–20 times higher at high latitude (e.g., Fisher, 1979; Petit et al., 1990; Steffensen, 1997) compared to interglacial periods. Dust deposition varied by a factor of 4 regionally in the later part of the twentieth century (Prospero and Lamb, 2003) and doubled in the twentieth century over much, but not the entire globe (Mahowald et al., 2010).

Contribution to ocean sedimentation: The regions where "arid marine (oceanic) sedimentation" occurs are located in the tropical zone and cover the same climatic zones as arid continental regions. The arid oceanic regions – where evaporation is higher than atmospheric precipitation – account for about one third of the modern ocean surface. They are by far larger than the total area of arid continental sedimentogenesis (Lisitzin, 1996; Lisitzin, 2011). In North Atlantic, Pacific, and Indian Ocean deep-sea sediments, dust particles account for up to 10–50 % or more of the noncarbonate fraction (e.g., Chavagnac et al., 2008; Lisitzin, 2011). The sedimentation rate in these areas is very low (<1 mm/1,000 year). Red clays and other abyssal sediments contain fine detrital quartz (diameter <1 μm). Volcanic ashes that are

transformed to authigenic minerals (phillipsite, montmorillonite, clinoptilolite, etc.) play an important role in Pacific Ocean sediments, suggesting the influence of a tectonic factor, i.e., active margins (Lisitzin, 2011). Using sediment traps, studies of airborne dust settling in the water column (e.g., Romero et al., 1999; Lee et al., 2009; Brust and Waniek, 2010; Ternon et al., 2010) attempted to link the atmospheric dust input with interior ocean processes while also providing data for selected time intervals. It was demonstrated that the lithogenic particle flux in sediment traps differs seasonally and interannually with no systematic variations between lithogenic and biogenic flux. In the Mediterranean Sea, Ternon et al. (2010) revealed a series of "lithogenic events" (corresponding to both high particulate organic carbon (POC) and high lithogenic marine fluxes), likely resulting from interactions between lithogenic particles and dissolved organic matter present at the time of deposition. Such strong and rapid POC exports are thus not directly related to a fertilization effect (Bressac and Guieu, 2013) but rather mediated by aggregation processes and dust ballasting, which can account for ~45 % of the total annual POC export following an extreme dust event (Ternon et al., 2010).

Dust and the ocean biogeochemistry: This link has been mostly explored in iron-limited, high-nutrient low-chlorophyll (HNLC) regions (i.e., Boyd et al., 2007) after John Martin formulated his "iron hypothesis" linking stimulation of new production and atmospheric CO_2 drawdown during the last glacial maximum to higher atmospheric dust iron inputs at that time. Although a number of in situ mesoscale experiments and microcosm and mesocosm approaches since the 1990s have improved our understanding of the actual role of dust input in ocean


Dust in the Ocean, Figure 1 (**a**) Map of average dust deposition (g m^{-2} year^{-1}) to the world oceans (Jickells et al., 2005) showing the "dust belt" in the northern hemisphere (reproduced by permission of *Science*). (**b**) Desert dust emission over several 100 km^2 in the Sahara Desert. A portion of the particles produced eventually reaches the ocean surface (leading to complex biogeochemical processes) and then the seafloor where they contribute to deep-sea sedimentation. biogeochemistry, our knowledge of the impact of dust deposition on the biogeochemistry of different areas of the ocean is still fragmented (de Leeuw et al., 2014). Dust dissolution experiments have shown the potential of dust to release nutrients such as phosphorus (e.g., Ridame and Guieu, 2002) and iron (e.g., Baker and Croot, 2010). Large dust deposition events may also be a sink for dissolved iron in the surface ocean via scavenging processes occurring during the sinking of the particles. The importance of this scavenging depends on the iron-binding capacity of seawater where the deposition occurs (Wagener et al., 2010). The impact on biota varies and depends on the trophic status of the regions affected by the deposition. In high-nutrient low-chlorophyll (HNLC)

regions where phytoplankton growth is limited by the availability of iron, additional iron supply from dust will directly affect primary production and species composition (de Baar et al., 2005; Boyd et al., 2007). In oligotrophic regions limited and/or co-limited by nitrogen, phosphorus, and iron availability, the impact of dust (providing both P and Fe) will stimulate nitrogen fixation organisms (Mills et al., 2004). Enrichment of dust in anthropogenic nitrogen (see above) can stimulate biological activity when the dust deposition relieves both P and N limitation and co-limitation (Ridame et al., 2013). Toxic elements such as Cu contained in transported dust can also negatively impact phytoplankton (Paytan et al., 2009). Different phytoplankton groups show differential responses to dust addition (e.g., Paytan et al., 2009; Giovagnetti et al., 2013). Heterotrophic bacteria are stimulated also by dust inputs in oligotrophic regions such as the Mediterranean Sea (Pulido-Villena et al., 2008). The dominant response (bacterial production vs. primary production) has been shown to be dependent on the degree of oligotrophy, with heterotrophic bacteria having a superior ability to take up nutrients under ultraoligotrophic conditions (Marañón et al., 2010). Such a competition for the additional nutrients between heterotrophic bacteria and phytoplankton will result in opposite effects on CO_2 drawdown, in particulate organic carbon export, and thus on the carbon budget (Marañón et al., 2010; Guieu et al., 2014).

Conclusions

Recent studies on the continental sources of dust aerosol production, transport, and deposition in the ocean increased the understanding of the importance of long-range transport of dust. The dust consists of fine (mostly less than 2 µm) particles originating mainly in the arid tropical and subtropical regions extending into the oceans and is similar in composition to deep-sea (pelagic) red clays. The total contribution of dust sedimentation is almost equal to the net influx of the riverine terrigenous material to the pelagic zones of the ocean (Windom, 1975; Lisitzin, 2011). By bringing to the ocean surface iron and other essential nutrients, dust creates an impact on the ocean's biogeochemistry, affecting carbon fixation, respiration, and nitrogen fixation, depending on the ongoing limitation and co-limitation where the deposition occurs (Moore et al., 2013). A number of important issues, relevant to the International Surface Ocean-Lower Atmosphere Study (SOLAS) research community, have recently been raised to better link atmospheric deposition of nutrients, ocean productivity, and feedbacks to climate (Law et al., 2013). In this complex picture, dust is nodal, in particular because of the dominant role of strong-pulse events in atmospheric deposition (Guieu et al., 2014). A better understanding of these links is crucial to accurately represent the present role of atmospheric deposition of new nutrients and particles in marine biogeochemical models and to be able to predict its evolution in a context of global and anthropogenic changes.

Seismic event

Definition
The term earthquake describes ground shaking and radiation of seismic energy, which is caused, e.g., by slip on a fault, magmatic activity, or cavity collapse.

Introduction
Earthquakes are events of seismic ground shaking caused, e.g., by the release of elastic stress accumulated along a previously locked fault zone (Figure 1), by magmatic activity, or by the collapse of caves. Further, human activity such as mining and hydrocarbon exploitation, underground nuclear explosions, geothermal fluid injection, or rapid water level changes in dam lakes may cause earthquakes. Mostly, stress release occurs suddenly and unpredicted. In the case of large earthquakes, ground shaking may be considerable and cause devastation and fatalities.

By far the most earthquakes, about 90 % of all natural seismic events, are of tectonic origin, and in the following sections only these will be dealt with. Earthquakes caused by magmatic or human activity have characteristics different from those of tectonic events and therefore in most cases can be identified by experienced scientists.

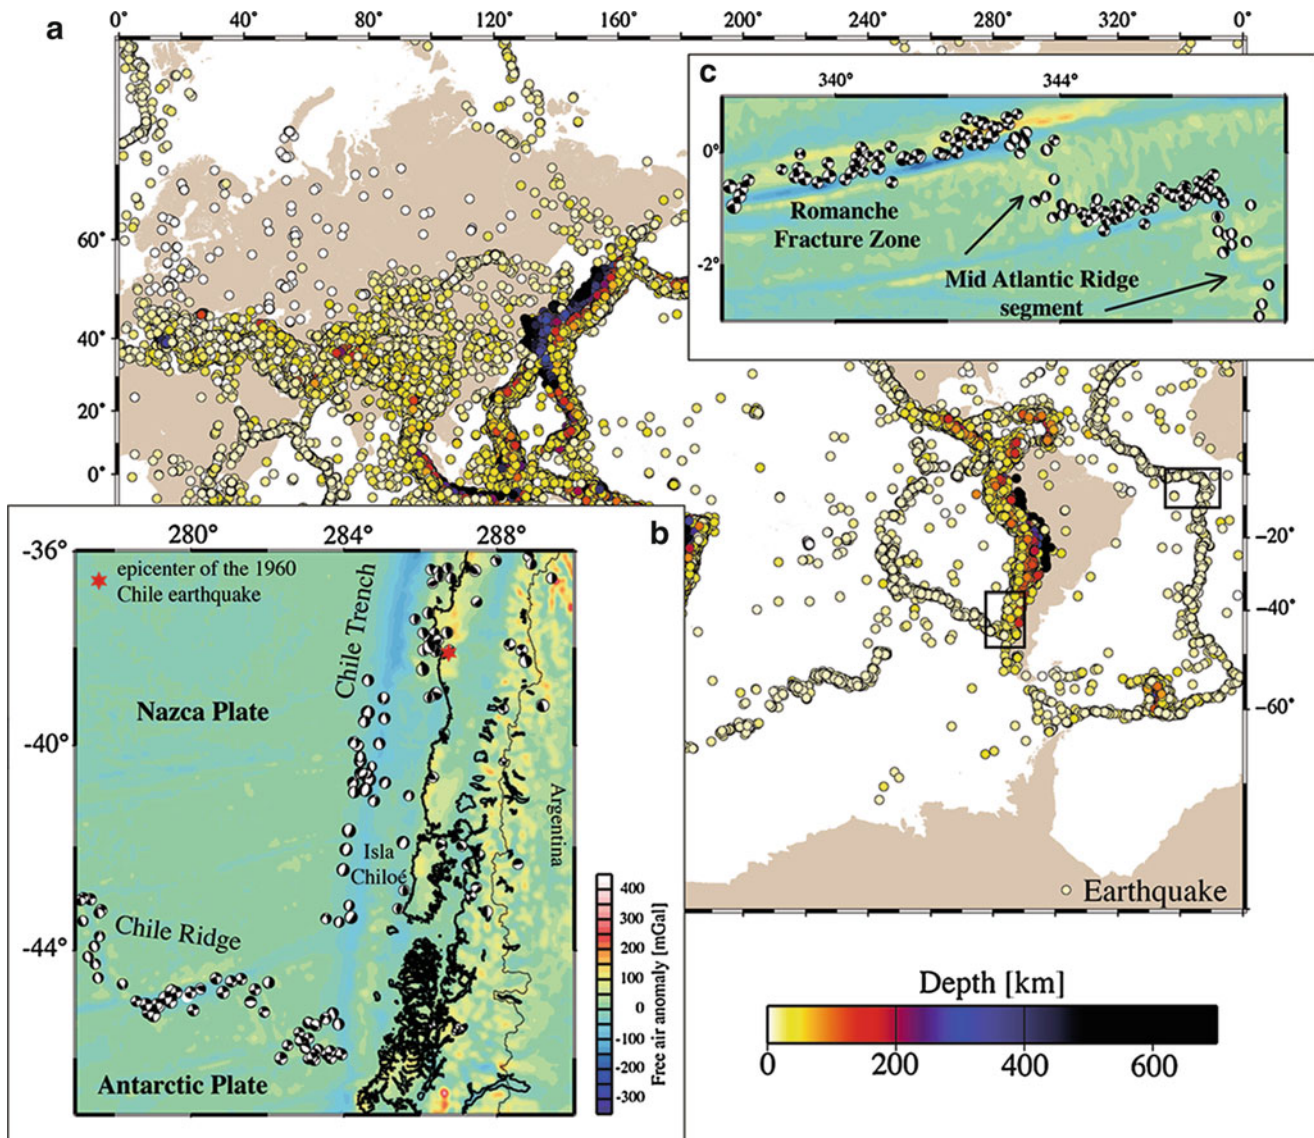
Before instruments were developed to detect and record ground motion related to earthquakes, knowledge about earthquakes having occurred only came from human observations and reporting. Therefore, historically only earthquakes sufficiently large to be felt by humans were identified. Instrumentally it is possible to detect very small earthquakes, which remain unfelt. The basic principle of a seismometer (from the Greek "seismos," quake, and "meter," measure), as it was firstly invented by J. Milne (1850–1913) in 1882, is a sensor that detects and amplifies ground vibration, which may be recorded as a seismogram either in a directly visible form or is converted to an analogue or digital electronic signal before display (Figure 1b).

Generation, travel, and recording of seismic waves
Faulting and earthquakes mechanisms
Tectonic earthquakes are related to motion along faults occurring in either the three basic (Figure 1c) or mixed types of faults. These reflect the variable orientations of the principal axes of stress with respect to the horizontal plane. When motion on the fault occurs as a pure up or down slip in the slip direction of the fault plane, then it is called a dip-slip fault. In case of upward motion this corresponds to a thrust or reverse fault, and when the motion is downward to a normal fault. In case of horizontal motion, parallel to the strike of the fault, this is called a strike-slip fault. Thrust faulting, normal faulting, strike-slip faulting, or any combination of them will occur on a fault, depending on whether the stress regime in the corresponding region is compressional, extensional or in a state of shear, and on how the usually preexisting fault strike and dip are oriented with respect to the direction of maximum compression and tension.

Faulting within the Earth occurs under high confining pressure. At depth, the minimum tensional stress corresponds to the maximum compressional stress, and vice versa.

Failure or faulting in case of brittle deformation, respectively, occurs on the plane of maximum shear stress. After
Earthquakes, Figure 1 (**a**) Hypocenter position and rupture propagation along a fault. The epicenter is directly located above the hypocenter from where the rupture initiates. (**b**) Seismogram of a near earthquake recorded by the Thuringian Seismic Network (TSN) in central Germany at a distance of about 15 km. P marks the first arrival of longitudinal P-waves, S marks the first arrival of transversely oscillating S-waves. (**c**) Three basic types of tectonic faults and illustration (beach balls) of the related focal mechanisms derived from the azimuth- and distance-dependent P-wave first motion polarity pattern. + refers to compressional first motions, − refers to extensional first motions. See text for more explanation and Figure 2b, c for examples of focal solutions.

a fault has been initiated, further motion is controlled by friction along the fault planes. In the fifteenth century, Leonardo da Vinci experimentally discovered the two main laws of friction and also observed that rough surfaces exert higher friction than smooth ones (Scholz, 2002). However, this knowledge remained largely forgotten until in 1699, Amontons described the two main laws of friction, namely that frictional force is independent of the size of the surface in contact but is proportional to normal load.

As friction along faults is often unstable, slip usually occurs rapidly as a rupture dynamically propagating along a fault surface, leading to sudden motion that generates seismic waves. Thus, seismicity is the short-timescale phenomenon of brittle tectonics, whereas faulting is its long-timescale expression. As faults move through


Earthquakes, Figure 2 Global seismicity: (**a**) earthquake location of ≥5 earthquakes from 1978 to 2012 (data from USGS website). Earthquake occurrence mirrors plate boundaries as the region of highest seismicity, but significant earthquakes also occur in the interior of plates (map generated using the Submap-tool 4.0 described in Heuret and Lallemand, 2005). (**b**) Focal solutions for a region around the Chile triple junction. (**c**) Focal solutions for a segment of the Mid-Atlantic Ridge.

repeated earthquakes, their record of faulting mirrors the history of past seismicity (Scholz, 2002).

Shear stress builds up on a locked fault as a result of tectonic motions, until the failure stress is reached, and the accumulated stress is completely, or mostly partially, relieved in a seismic event. Most earthquakes are associated with recurring displacements on preexisting faults. During an earthquake the accumulated elastic energy is released by physical displacement of the ground. In the case of shallow earthquakes, this rupture most often propagates along the fault at velocities of about 75–95 % of that of shear waves (S-waves) (Kanamori and Brodsky, 2004) and generates seismic waves that propagate through

surrounding rocks and the entire Earth. However, minor fractions of the stored energy may be dissipated as heat by friction on the fault.

As the presence of overpressured fluid reduces friction, and therefore rock strength, fluids may play an important role in faulting and therefore also in earthquake processes (e.g., Hickman et al., 1995 and articles therein). There is worldwide evidence for fluid driven seismicity for all types of tectonic earthquakes; important examples are the Parkfield earthquake along the San Andreas Fault zone, swarm earthquakes, or megathrust events in the seismogenic zone of subduction zones.

Seismic waves

Elastic seismic energy released during an earthquake travels away from the hypocenter as body waves through the Earth and also, as a result of wave interference near the Earth's surface, as surface waves. On the seismic timescale, usually deciseconds up to almost 1 h for the longest free oscillations of the whole planet, the Earth behaves as an elastic body.

Compressional or P-waves (P for primary) propagate by stretching and contracting the medium parallel to the direction the wave travels through the entire Earth, whereas in the case of shear or S-waves (S for secondary), swinging is perpendicular to the direction of propagation. Shear waves cannot travel through fluids. The fact that already in early world-wide records of P- and S-waves after the great 1897 magnitude 8.1 Assam earthquake no direct S-waves were found that had traveled through the Earth's center led Dixon Oldham (1858–1936) to infer the existence of an Earth core and to conclude that it was liquid. This, however, relates only to the outer core, as the existence of a solid inner core was later proved by Inge Lehmann (1888–1993) in 1936.

Seismic P-waves travel at sound velocities of about 1.5 km per second in water and faster, i.e., several km per second, in most rocks. In sedimentary rocks, P-waves are as fast as between about 1.5 and 6 km per second, whereas in crystalline, igneous, and metamorphic crustal rocks they usually are faster, between about 4 and 7 km per second, and in the uppermost mantle around 8 km per second. In highly porous rocks or loose sediments, seismic velocities often are similar to those in water or even lower. S-waves travel about 1.7 times more slowly than P-waves. The velocity ratio between P- and S-waves depends, e.g., on fluid content and therefore differs slightly between various tectonic settings and in the presence of significant amounts of fluid or major fluid motion. Therefore, it can be used to study the role of fluids for earthquake processes (e.g., Schurr et al., 2003; Eberhart-Phillips et al., 2008).

There are also two types of surface waves, Rayleigh waves (LR) and Love waves (LQ). While Rayleigh waves swing in the vertical plane with particles moving along a retrograde ellipse, particle motion of Love-waves is horizontal and transverse to the travel direction. Love waves are the fastest surface waves and travel with velocities close to the subsurface velocity of S-waves, whereas Rayleigh waves travel slightly slower, with about 90 % of the shear wave velocity. Although surface waves generated by crustal earthquakes are associated with generally larger amplitudes of ground motion than body waves, their periods are also significantly longer (see Figure 1b). Therefore, in the local distance of several tens to hundred kilometers, the largest destructions are usually associated with shear waves and Love waves, and not with true surface waves.

Seismic waves are reflected and refracted at lithological, rheological, diagenetic, or other boundaries with a contrast in acoustic impedance, i.e., the product of seismic velocity and density. Besides reflection and refraction, seismic waves can also undergo conversion, e.g., from a P- to an S-wave, and vice versa. Thus, the body waves P and S originating from the earthquake source will be split in many phases, due to the interaction with many velocity discontinuities and inhomogeneities along their way through the subsurface and the deeper parts of the Earth's interior. These different phases usually arrive along different and sometimes rather complicated travel paths at different times at a distant seismograph. The different wave onsets can be identified one after the other; however, one has to keep in mind that the arrival of some theoretically possible but weaker later waves may be masked through the coda of other, earlier waves. Because of damping and geometric spreading, but also focusing effects due to the complicated velocity structure and inhomogeneities of the subsurface and the deep interior of the Earth, the amplitudes of P- and S-waves vary with distance from their source in a complicated way despite the overall tendency to decay with distance. Besides this the amplitude ratio between P- and S-waves also depends on the angle at which their seismic rays leave the source (Aki and Richards, 2002).

Seismic records and fault plane solutions

High precision modern seismographs most basically consisting of an inertial pendulum mass and auxiliary electronic transducers and amplifiers record ground motion, which may be as low as less than 10^{-10} m for a magnitude 2 earthquake and as large as 10 cm in case of a large seismic event. Because of the small size of most earthquake signals, these need to be amplified. This is commonly done by attaching a coil to the mass that moves through the magnetic field of a magnet attached to the frame of the instrument, thus transducing the mechanical movement into an equivalent electronic signal, which can be then amplified and converted into a digital signal. Further, highly accurate synchronized timing between the seismic records at many stations is crucial for precisely locating seismic sources. Whereas older instruments had provided only analogue records on slowly moving paper, modern seismometers provide digital records in high temporal resolution.

Seismic records may be used to identify the focal mechanism of the earthquake and to reconstruct motion along a seismic fault. The oldest and simplest way is to compare P-wave first-motion polarity recorded for a given event by several seismic stations that lie in different directions and at different distances from the focus. Consider motion along a dipping fault such that the material above the fault, the so-called hanging-wall, moves upwards. Then, this material is subject to compression and the region beneath the fault undergoes dilatation, i.e., extension. With the compensatory downward motion of the region beneath the fault, there will be two regions of compression and extension, separated by the fault plane and an auxiliary

plane orthogonal to it (Figure 1b). A positive (+; upward) P-wave first motion observed in vertical component records corresponds to a push away from the hypocenter and thus to a seismic ray that has left the source in an extensional quadrant, and vice versa an observed dilatational first motion (−; downward) to a compressional segment in the source volume. Thus, by plotting the azimuth of the station to the hypocenter and its distance together with the polarity of first motion (dark shaded area for compression, light colored areas for dilatational first motions, cf. Figure 1c) on a stereogram, the two orthogonal great circle lines that separate best the + − and –polarity data points can be considered as the fault plane and its orthogonal auxiliary plane, from which both the strike and dip of these planes but also the slip direction can be derived. However, which of these two planes relates to the acting fault plane cannot be inferred from polarity readings alone but requires additional amplitude and frequency observations or independent field evidence. Moreover, existing faults constitute planes of weakness that may be reactivated in stress fields that are not optimally oriented to the direction of maximum pressure and tension in the source area, and as frictional strength of faults is less than the stress necessary to form them, inferring the real stress-field orientation and the size of the deviatoric stresses from the orientation of active faults or earthquake focal mechanism is also ambiguous without additional information (Scholz, 2002).

The accuracy of the estimation of both the hypocenter and the focal plane of an earthquake depends on the number of records studied from stations in different directions and distances to the hypocenter. Therefore, since the beginning of the twentieth century, global and local, permanent and temporary seismic networks have been installed. This need made seismology play an important role in leading the way for open data distribution. Nowadays, the scientific community does not only share seismograms, but more and more permits also open access in real time to digital recordings from stations worldwide via the Internet.

Earthquake size and frequency

Earthquakes size and frequency of occurrence are unevenly distributed in space and time, with small events being much more common than the larger ones.

Earthquake size is both estimated in a qualitative way based on observations like the amount of damage, felt shaking or vibrating glasses, rattling doors, etc., and in a more objective instrumentally measured quantitative way in order to get a measure of seismic moment released or seismic wave energy radiated by the seismic source independent on the distance of observations. The classification of earthquake shaking effects is done by means of intensity scales, and that of the size of seismic sources by magnitude scales, respectively.

There exist several intensity scales, among them the Modified Mercalli (MM) scale, which is mainly used in

Earthquakes, Table 1 Modified Mercalli intensity scale (After Stein and Wysession, 2003; Turcotte and Schubert, 2014)

I	Usually not felt at all
II	Just a few people felt the earthquake, mainly on upper floors of buildings
III	Lamps and similar objects swing, vibrations like from a passing truck
IV	Glasses in a cupboard and windows clink, felt by many indoors
V	Felt by nearly everyone with people sleeping mostly always waking up
VI	Glassware and windows break, felt by all
VII	People have difficulties to stand upright, minor damage
VIII	Branches break from trees and many buildings partially collapse
IX	Most people panic, cracks occur in the ground, solid buildings partially collapse
X	Landslides occur, large buildings fall completely, rails bend
XI	Few buildings remain standing, bridges destroyed
XII	Complete damage, objects thrown in the air

the USA, and the European Macroseismic Scale (EMS). Common to these scales is the definition of 12 degrees through which increasing amounts of felt ground-shaking-related phenomena and the degree of devastation is described. Although these degrees and their description are based on human observation and judgement, and thus are somewhat subjective, the proper application of intensity scales yields reasonable results how to take into account, e.g., different percentages of damage or different amounts of vulnerability. Table 1 is intended to provide an idea of the character of each intensity degree, but is far from the detailed description of the MM or EMS (for more details see, e.g., modern textbooks on geophysics like Fowler, 2005, or Clauser, 2014, and references therein). Moreover, macroseismic studies are the only way to estimate not only the size but also the epicenter and depth of historical earthquakes, which occurred prior to the instrumental record. Therefore, the evaluation of epicentral intensity and location of preinstrumental earthquakes yields not only important data for more reliable long-term seismic hazard estimates but related seismic intensity distribution maps for assessing differences in vulnerability and seismic risk of settlement areas exposed to earthquake shaking. Still older paleoearthquakes, which took place before any human reporting can be identified through, e.g., tsunami deposits, sand intrusions, fallen stalagmites, and other co-called seismites (Goldfinger, 2011). If dated, the area, which was affected by the same earthquake, can be used to estimate its size. However, mostly, only major and great earthquakes can be detected in these ways. If several paleoearthquakes were identified and dated, e.g., through isotopic methods, in the same area, recurrence intervals can be estimated (e.g., Cisternas et al., 2005).

In order to describe the size of an earthquake in a physically more meaningful way, modern magnitudes are calculated from instrumental measurements of either the

Earthquakes, Table 2 Earthquake parameters (After Stein and Wysession, 2003; Turcotte and Schubert, 2014). Magnitude does not refer to a specific magnitude

Size	Magnitude	Rupture length	Annual number	Distance up to which the earthquake is felt [km]	Energy released (10^{15} J/year)
Great	≥ 8	> 200 km	1	> 600	0–1000
Major	7–7.9	70 km	18	400	100
Strong	6–6.9	20 km	120	220	30
Moderate	5–5.9	ca. 3 km	800	150	5
Light	4–4.9		6,000	80	1
Minor	3–3.9		50,000	15	0.2
Micro	0–2.9		Many thousands per day, mostly not detected	0	

scalar seismic moment M_0, a tensorial property related to fault area, slip vector, and shear modulus (e.g., Hanks and Kanamori, 1979; Scholz, 2002) or of the radiated energy E_s by integration of the squared P-wave velocity records (e.g., Choy and Boatwright, 1995). The latter is suggested to be superior to traditional seismic energy estimates from empirical Gutenberg–Richter magnitude–energy relationships (e.g., Gutenberg and Richter, 1956). However, also these modern moment (M_w) and energy magnitudes (M_e) are semiempirical as they have been scaled to the empirical 20 s M_s surface-wave magnitude and the classical empirical relationship log $E_s = 1.5\ M_s$ + 4.8 according to Richter and Gutenberg.

The scalar seismic moment M_0 is a relation between shear modulus μ, rupture area A, and average displacement D ($M_0 = \mu A D$). It is a static measure of earthquake size, but does not say anything about, e.g., rupture velocity or stress drop, which strongly control the energy radiated by an earthquake of a given seismic moment. Therefore, M_0 is only a rough average estimate of the released seismic energy and thus the moment magnitude M_w ($M_w = 2/3\ \log_{10} M_0 - 6.0$ with M_0 in Nm; cf. Fowler, 2005) is less well suited for a realistic assessment of the seismic shaking hazard than the energy magnitude M_e ($M_e = 2/3\ \log_{10} E_s - 2.9$; e.g., Choy and Boatwright, 1995). However, both modern magnitudes should be used complementary, as they are related to different properties of the source in order to achieve a reliable assessment of important issues related to earthquakes such as hazard or fault maturity. Table 2 intends to provide a brief overview of some earthquake parameters and terms discussed without referring to a specific magnitude.

Large earthquakes occur rarely, but release most seismic energy, e.g., 27 % of the entire seismic energy released between 1904 and 1986 was that released during the M_w 9.5 Valdivia, Chile (Figure 2), earthquake, the largest earthquake recorded so far instrumentally. The number of earthquakes occurring in a certain period of time is a function of their size (Table 2). This is expressed in the logarithmic frequency–magnitude relationship (log $N = a - bM$ with N being the number of earthquakes with

a magnitude greater than M occurring in a certain time span, a being the intercept, and b the slope). Richter and Gutenberg first introduced this relationship in 1954.

Global occurrence of earthquakes

The majority of tectonic earthquakes occur in the Earth's crust with 95 % of the global seismic moment released along plate boundaries (Scholz, 2002) with convergent margins and continental collision zones exhibiting largest seismic events (Figure 2). Large, often destructive earthquakes also occur in plate interiors, however with a much lower frequency. Also here, earthquakes seem to cluster in certain regions. Earthquakes with hypocenters deeper than some tens of kilometers almost only are found along the Wadati-Benioff zones (see Wadati-Benioff-Zone) of subduction zones.

A typical displacement in a very large earthquake is 10 m. If the relative velocity across a plate boundary would be 50 mm per year, it would take 200 years to accumulate this displacement. Large earthquakes at subduction zones and major transform faults such as the San Andreas recur in about such periods of time. Since regular displacements do not need to be accommodated in plate interiors, the period of time between major intraplate earthquakes is much longer (Turcotte and Schubert, 2014).

Tectonic earthquakes in the shallow brittle part of the crust and along the seismogenic zone of convergent plate boundaries mainly are caused when stress accumulated along a locked fault exceeds rock strength. As rock strength is dependent on the tectonic regime, stresses necessary to generate earthquakes may differ in different tectonic environments such as compressional or tensile tectonic regimes (Scholz, 2002). However, independent of the tectonic regime, shallow earthquakes seem to be limited by the brittle behavior of rock and do not seem to occur at temperatures exceeding about 600 °C (McKenzie et al., 2005). However, in subduction zones, earthquakes occur down to depths of more than 600 km, asking for other potential mechanisms causing those deep earthquakes (see Wadati-Benioff-Zone).

Unusual earthquakes

Immediately after a large earthquake, the so-called main shock, usually, many smaller events, the so-called aftershocks, occur in the same region, i.e., along parts of the fault plane that had ruptured before. This seismic activity often decays over some weeks or months, depending on the size of the main earthquake.

If seismic activity is observed over weeks or months, but without any major event, this is called an earthquake swarm. Further, there are also unusual types of seismic events like those causing a tsunami larger than expected from their magnitude (Okal and Newman, 2001). Since about 15 years, another type of seismic events, called slow slip events, has been identified along certain plate boundaries.

Earthquake swarms

Earthquake swarms are periods of seismic activity of more or less equal size without dominating events, an abrupt onset and ending of the seismic activity. Individual magnitudes scarcely exceeding three or four, which are occurring over weeks or months in a certain region limited in space (e.g., Scholz, 2002; Hainzl et al., 2012). Earthquake swarms usually consist of several hundreds to several thousands detected individual events. Often, they start and cease with gradually increasing and decreasing magnitudes, respectively. Whereas earthquake swarms were first mainly detected in volcanic regions, they now have been identified in nearly all seismotectonic settings, such as subduction zones close to the seismogenic thrust, transform faults, or intraplate regions (Holtkamp and Brudzinski, 2011; Hainzl et al., 2012). B-values of earthquake swarms often are between 1.5 and 2, and therefore considerably larger than those obtained from global or regional earthquake data sets (Scholz, 2002; Holtkamp and Brudzinski, 2011). Fluids have been proposed to play an important role for earthquake swarms, e.g., pore pressure changes or magma transport. Further, earthquake swarms may be potentially related to slow slip events.

Slow earthquakes

Recently, a special type of release of seismic energy has been identified from GPS records in several subduction zones around the Pacific, like Cascadia offshore the USA and Canada west coast (Dragert et al., 2001) or Hikurangi offshore the east coast of New Zealand's north island (Wallace et al., 2012). Well-studied regions with SSEs recurring in relatively regular intervals, like Cascadia or Hikurangi show that these events may nucleate at very shallow depths, about 5–6 km beneath the seafloor, but also at depths of 30–40 km indicating they can occur in very different thermal regimes. Several types of slow earthquakes are known, e.g., tremors, slow slip events, or very low-frequency earthquakes. Mostly, they seem to occur in subduction zones with a young downgoing plate, but have also been detected beneath the San Andreas fault system (Beroza and Ide, 2011).

It seems that fluids are invoked in their occurrence, possibly at very high fluid pressures. However, SSEs' mechanisms so far are largely not understood (Schwartz and Rokosky, 2007). An important role of Love waves also has been hypothesized. Slow earthquakes seem to occur episodically, often quite frequent, with recurrence times of only a few years or even less at the same location and typically show durations of hours to several months. Slow earthquakes cannot be detected with seismometers and so far only have been identified from geodetic (GPS) records. Slip caused by slow earthquakes suggests that usually their size is comparable to that of usual earthquakes with magnitudes around 6–6.5.

Seismic hazard

Most seismic hazard is related to major and great earthquakes, as one magnitude >8 earthquake releases more energy than all other earthquakes during an entire year. It describes the probability of a certain level of ground shaking caused by recurring earthquakes (Shedlock et al., 2000; Stein and Wysession, 2003).

Damage caused by an earthquake mainly is the consequence of ground acceleration, which describes the amount of shaking or strong motion, and is used as a measure for seismic risk. Other hazardous phenomena occurring in relation to earthquakes are, e.g., slumping in regions of steep slope, liquefaction, or tsunamis (see Wadati-Benioff-Zone).

The size of an earthquake does not necessarily directly relate to damage and fatalities caused by it as the depth of the hypocenter, and consequently ground motion as well as bedrock in the region affected by an earthquake largely control destruction. When nonconsolidated, water-saturated sand, which is typical, e.g., for river estuaries or shores, is repeatedly shaken, especially at resonance period, e.g., during ground motion caused by a large earthquake, it may behave like a liquid, i.e., it completely looses its shear strength and therefore no longer is able to carry, e.g., buildings. As a consequence of this liquefaction, buildings may sink several meters and become severely damaged, like during the 1906 San Francisco, 1964 Alaska, 2010 Canterbury, or 2011 Christchurch earthquakes (Quigley et al., 2013). Strike-slip earthquakes seem to be especially prone to a high degree of damage relative to their magnitudes as their hypocenters usually are quite shallow. If sediments redistributed by liquefaction keep their geotechnical properties, they may be indicative of paleoearthquakes (Green et al., 2005).

Therefore, globally, seismic hazard differs considerably between different tectonic settings and to a large degree mirrors the distribution of brittle strain rate, i.e., deformation (Triep and Sykes, 1997). To quantify seismic hazard, data of historical and instrumentally recorded earthquakes, their source characteristics, and related strong ground motions have been compiled to compute global seismic hazard and assign a level of seismic hazard to every location worldwide (Giardini et al., 1999).

EL NIÑO (SOUTHERN OSCILLATION)

Janina Körper
Institute of Meteorology, Free University of Berlin,
Berlin, Germany

Synonyms

El Niño-Southern Oscillation (ENSO) warm event

Antonym

La Niña

The term El Niño (Spanish for "the Child Christ") was initially used by Peruvian fishermen to describe a warm-water current that periodically flows along the coast of Ecuador and Perú about Christmas time. It is an oscillation associated with the unusually large basin-wide warmings of the eastern tropical Pacific Ocean that occur every few years (about 2–7 years) and change the local and regional ecology and have global impacts. The oceanic event is connected to the atmospheric component termed "Southern Oscillation." The coupled atmosphere-ocean phenomenon is collectively known as the El Niño-Southern Oscillation (ENSO). While El Niño refers to the warm phase of ENSO, La Niña (Spanish for "the girl") refers to the cold phase of ENSO. See Trenberth (1997) for a review on definitions of El Niño.

An initial positive sea surface temperature (SST) anomaly intensifies due to a positive feedback first hypothesized by Bjerknes (1969). The anomaly reduces the east-west SST gradient, which leads to reduced equatorial westerlies of the Walker circulation and inherent weakening of equatorial upwelling. This reinforces the positive SST anomaly. To explain the determination of an El Niño event and its quasiperiodic reoccurrence, two mechanisms are still discussed. ENSO is explained by either a self-sustained, naturally oscillatory mode of the coupled ocean atmosphere system or a stable mode triggered by stochastic forcing. See Wang and Fiedler (2007) and Wang et al. (2012) for a review of these mechanisms.

There are two types of El Niño that differ with respect to their spatial structure, evolution, underlying mechanisms, and their global impacts. The eastern-Pacific type is characterized by SST anomalies centered in the eastern Pacific cold tongue region. The SST anomalies of the central-Pacific type, also referred to as date line El Niño or warm pool El Niño, are centered near the International Date Line (Wang et al., 2012).

ENERGY RESOURCES

Dieter Franke and Christoph Gaedicke
Federal Institute for Geosciences and Natural Resources, Hannover, Germany

Definition

Energy resources. Energy resources are used to satisfy the energy consumption of the global economy. Energy in general is the capacity of a system to perform work. The unit for measurement of this scalar physical quantity is the joule. A resource is defined as a source of supply or support that is ready to use if or when it is needed. Energy derived directly from a natural resource is called primary energy, i.e., burning coal for heating or collecting solar energy with solar cells to generate electricity. When primary energy is transferred into another form of energy, i.e., burning coal in a power plant to generate electric power, this energy is called secondary energy.

Energy resources are generally divided into (1) renewable energy sources and (2) fossil energy resources. The renewable sources are continually replenished from sunlight, wind, rain, water, waves, tides, geothermal heat, and biomass. Fossil energy resources consist of coal, uranium, natural gas, and oil. The most important *offshore* energy resources are oil and gas. Renewable offshore energy is mainly derived from wind, waves, and tides.

Introduction

Energy resources from offshore areas are of increasing importance. This is valid for both renewable and fossil energy resources: On the one hand, new exploration methods and technical innovations enlarge the volumes and accessible areas for the exploitation of fossil energy resources. On the other hand, technological advancements and the increasing efficiency in using the renewable energy resources, combined with the benefits of mass production and market competition, are continuously improving the competitiveness of renewable technologies.

World primary energy consumption grew by more than 40 % over the past 20 years and is likely to grow by a similar amount over the next decades. The world's most important energy resource is oil. With an annual worldwide consumption of about 34 billion (10^9) barrels, it accounts for more than 30 % of the world's primary energy consumption. The global oil supply is continuously growing and rose to up to 90 million barrels/day in 2011, but further growth is uncertain. In fact there is considerable controversy about the date when the maximum rate of oil production is reached. Without doubt the amount of oil on earth is limited. However, there is an ongoing discussion about the percentage that has already been extracted and mainly about the date when a further increase in production will no longer be possible ("peak oil"). Peak oil must not be confused with oil depletion. Even when reaching the point of maximum production, there will be continuous oil supply on high levels; only

a further increase in production from thereon is not possible. Optimistic scenarios suggest that additional reserves can be obtained by a more effective oil recovery from producing fields, the usage of unconventional resources, and that significant additional oil – and also natural gas – is found in the frontier areas of the Arctic and the deepwater areas of the continental margins. It is not only the geology and reservoir performance that defines if the targeted resources are exploited, it also depends on future demand and prices, the availability of new technologies, the infrastructure, environmental issues, and political and regulatory considerations. The impact of carbon dioxide on the climate may result in efforts to limit the extensive use of coal, oil, and natural gas.

At present, renewable energy represents only a minor percentage of global primary energy consumption, but it is growing very rapidly. Renewable energy costs continue to drop as a result of technological innovation and mass production. A main driving force to expand the use of renewable energy is its relatively low impact on climate and on the environment.

Offshore renewable energy

In order to decrease emissions of carbon dioxide into the atmosphere, serious efforts are undertaken to develop renewable energy sources.

Offshore wind farms boast some advantages in comparison to onshore installations: the wind blows more constantly most of the time, and the demands on "land" use are less competitive offshore. Technical challenges include the foundations of the wind turbines installed in shallow water. This requires detailed information of the sediment distribution not only on the surface but also some tens of meters below the seafloor, where peat horizons or shallow gas may occur. Sediment movement may restrict the foundations of wind turbines. Many shallow areas of the sea are important habitats for the reproduction of marine mammals, fishes, and benthic invertebrates. These biological communities are not only disturbed during the construction but also may be perturbed during operation.

As the number of offshore wind turbines installed in the marine realm increases, integrating them into the existing power supply structures will become increasingly important. While the present total capacity of offshore wind farms is in the megawatt range, plans call for much larger offshore units. A substantial increase in the amount of wind power will have to be integrated into national and international electricity grids. The next step in offshore wind farming will lead to installation in deeper and more remote areas far away from the coast. Since the wind blows more strongly and comparatively smaller areas are needed, electricity generation with wind turbines out at sea is particularly attractive. The organizational and technological requirements are however significantly higher than on land, i.e., great distances to the coast, ocean depths of up to 40 m, and the harsh sea climate with humid, salty air, strong temperature fluctuations, severe storms, squalls, and high wave loads (see Ocean Margin Systems).

The development of wave power devices is still in progress and so far only prototypes are being tested at sea. With the recent worldwide growth in interest in renewables, wave energy may also become more important. Wave power devices harness the continuous energy of waves to generate electricity. These may be installed at the shoreline, nearshore, or offshore. Tidal power plants convert the potential energy or the power of currents between low and high tide into electricity. The major advantage of this renewable energy is that tides are more predictable than other renewable energy sources. However, regions with sufficiently high tidal ranges or flow velocities are limited. Further technological improvements are necessary to bring production costs of tidal energy down to competitive levels.

Other ocean energy sources that are at present not widely used include ocean thermal energy, making use of the small temperature difference between deep and shallow water, salinity gradient energy which becomes available from the difference in the salt concentration between seawater and river water, and the energy of marine currents.

Fossil energy resources

The most important offshore energy resources are oil and gas. Given the huge onshore resources, coal and uranium are not expected to be produced in the coming decades from offshore areas.

Petroleum classifications, reserves, and resources

Oil and gas are trapped in subsurface geological structures and the volumes cannot be physically examined or inspected. Regional estimates are based on data that provide indirect evidence of the scale of the resource base. Classification usually starts with a petroleum play, which is a concept to recognize patterns in petroleum occurrence that can help to predict the results of future exploration. Plays are characterized by the presence or prediction of source rocks, reservoirs, and seals. Hydrocarbon generation in sedimentary basins (see Marine Sedimentary Basins) is controlled by the source rock, its lithology, facies, distribution, and organic content and by the tectonic evolution of the basin. The amount of organic matter in the source rock depends on the production and input of organic matter during sedimentation (see Paleoceanography) but also on preservation or degradation during diagenesis. The increasing heat and pressure during subsidence and continuing sedimentation control the generation of hydrocarbons in the source rock, while porosity and permeability control the migration of hydrocarbons from the source rock into a reservoir. The potentiality of sedimentary basins thus depends also on subsidence, burial, and physical conditions such as pressure and heat flow. Porous structures for accumulations and seals

trapping the generated hydrocarbons are prerequisites for petroleum reservoirs.

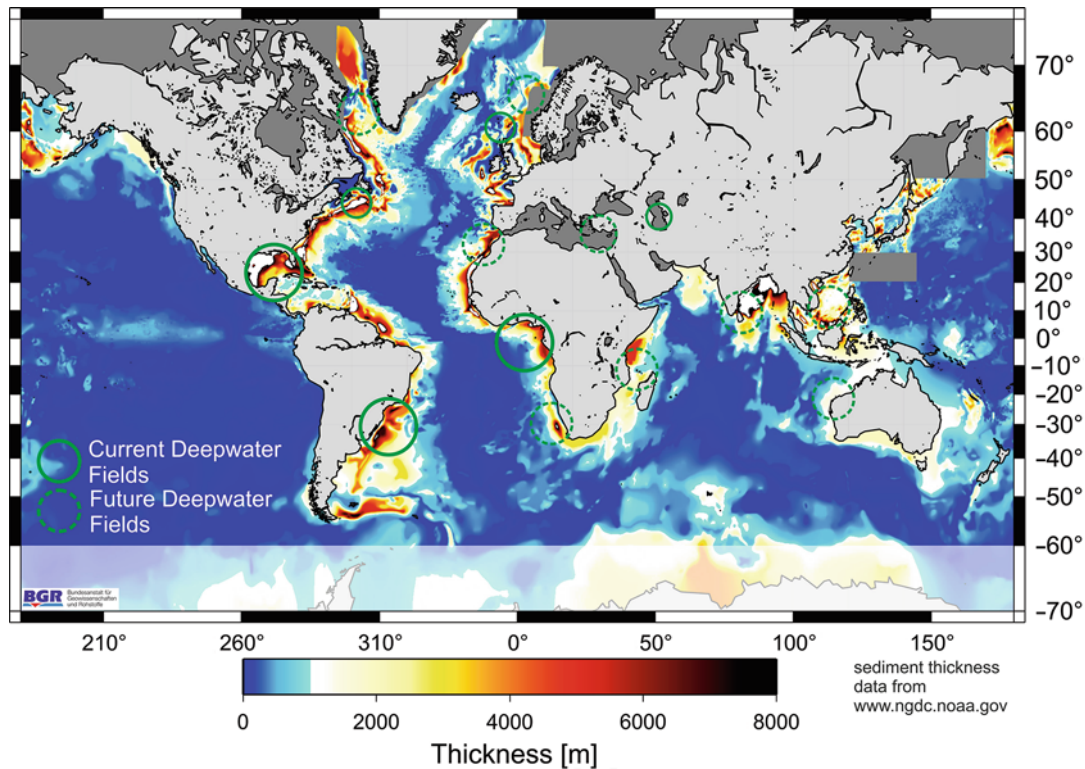
The amount of the producible and usable energy resources in a specific setting depends on the geological conditions of the deposits, the state of the scientific and technical knowledge, the technological potential of development and production, as well as the economic and political requirements. Correspondingly, the intentions and methods used to assess the amounts of energy resources considerably vary. There is one general distinction that applies to all energy resource statistics: the distinction between those energy resources whose exploitation is regarded as proven (reserves) and those energy resources whose existence is only assumed or whose production is currently not considered economically feasible (resources) (Andruleit et al., 2013). *Oil and gas reserves* are defined as the volumes that have been accurately recorded and can be commercially recovered in the future using the current technical possibilities. *Resources* are those amounts of oil and gas which have been geologically proven, but which at the present time cannot be economically recovered, and the amounts which have not been proven, but which can be expected for geological reasons in the concerned area. There is a dynamic boundary between resources and reserves and, e.g., variations in the price or technical advances will convert resources to reserves and vice versa.

There is no common definition to subdivide oil and gas into *conventional and unconventional occurrences*. Probably most commonly classified are conventional occurrences as the ones which can be exploited by standard exploration and production methods. According to this definition, the development and use of unconventional occurrences requires alternative technologies. Aspects of economic efficiency, or whether the individual deposit is already used for production, are not considered in this definition. However, once an alternative technology becomes established, earlier unconventional resources may be classified as conventional.

Giant oil and gas fields (those with 79,000,000 m^3 (500 million barrels) of ultimately recoverable oil or gas equivalent) account for about 40 % of the world's petroleum reserves (Halbouty, 2001). The majority of the world's giant oil and gas fields exist in two characteristic tectonic settings – passive continental margin and rift structures – highlighting the potential impact of future offshore resources. Passive continental margins are the outcome of a "successful rift" which resulted in continental separation and the formation of new oceanic crust, while in failed rifts, extension terminated at some stage during the evolution to leave an aborted rift (see "Plate Tectonics").

Offshore petroleum exploration and production
Evolution of offshore petroleum exploration
Offshore drilling for oil in seawater began off the US West Coast, just south of Santa Barbara, California, as early as 1896. Significant offshore exploration, however, only started in the middle of the twentieth century. In the Gulf of Mexico, off the Louisiana coast, the first productive wells were installed in the 1940s. However, water depth was still far less than 100 m. 1947 is commonly used as the year defining the initiation of offshore drilling beyond the sight of land. From then on, exploration also began in the Caspian Sea, the Persian Gulf, the Arabian Sea off India, and the North Sea. Some discoveries were made in China and Australia. Exploration peaked in 1982 when nearly 200 new fields were discovered. In 1986, the first deepwater field (>1,500 m) was discovered in the Gulf of Mexico (Mensa gas field). Based on the dominant discovery pattern of the 1990s, the deep water became the primary new exploration target for petroleum companies (Esser, 2001). Several new discoveries were made up until the twenty-first century, but the number of new discoveries never again reached the high numbers of 1982. In 2000, when the oil price dropped to about 12$/barrel, almost all coastal countries bordering passive continental margins were involved in deepwater exploration. Until this time, offshore exploration had been concentrated in shallow waters. Only about 40 production rigs were installed in waters exceeding 500 m depth, accounting for about 3 % of global oil production. More than 2000 new discoveries were made since that time, the most important being in the Gulf of Mexico, offshore Brazil, Iraq, and Australia. Global deepwater production has more than tripled since 2000, and in 2010, about 10 % of the global oil production came from deepwater wells. The fact that more than 50 % of newly discovered reserves are found in deep waters over the last few years indicates that the proportion of deepwater oil and gas production will grow further in the near future.

Deepwater petroleum
There is a wide range of definitions for deep water. The most widespread definition refers to water depths greater than 500 m. That is about the depth at which traditional development platforms cannot be implemented. Deepwater exploration came along with major improvements of exploration and production methods. Major challenges include 3-D seismic data acquisition (see Technology in Marine Geosciences) and advanced seismic processing integrated with interpretation workstations capable of handling and visualizing large 3-D volumes, the use of seismic amplitudes for hydrocarbon and reservoir prediction, methodologies for basin analysis and predictive stratigraphy (see Deep-sea Sediments), and drilling and logging tools (dynamically positioned drill ships, automated pipe handling systems, horizontal drilling and well completions, and subsea systems).

Offshore oil production represents about one-third of present world oil output. Globally, there are more than 150 major deepwater fields that have the potential to come on-stream over the next few years. Drilling activity has particularly increased in the "golden triangle" of Brazil,


Energy Resources, Figure 1 Sediment thickness exceeding 1 km along the continental margins (data from ngdc.nooa.gov). Present (*solid*) and future (*dashed*) deepwater fields are indicated by *green* circles. Drilling activity has particularly increased in the "golden triangle" of Brazil, the Gulf of Mexico, and West Africa, but in the future, many more potentially productive areas are expected.

the Gulf of Mexico, and West Africa (Figure 1). The exact size of the hydrocarbon resources at the continental margins is unknown, but recent estimates indicate there could be as much as 3.8 billion barrels of oil and 609 billion (10^9) cubic meters of natural gas in the eastern Gulf of Mexico alone (Hughes and Kinnersley, 2010). Of particular interest are basins with evaporite deposits, especially those with pre-salt oil and gas accumulations. In Brazil, almost 20 billion barrels of oil equivalent were reported discovered in subsalt Cretaceous deposits.

Exploration and production in the Arctic realm

Exploration and production of oil and gas in the Arctic realm has been taking place for several decades. At present, the activities focus on northern Alaska, the Barents Sea, and on West Siberia. The Prudhoe Bay and Kuparuk fields in Alaska and the Urengoy field in the Russian Federation are prime examples of the giant field potential of the region. The first Arctic offshore oil platform is located in the Pechora Sea, in the southeastern Barents Sea. Production with the first ice-resistant platform "Prirazlomnaya" started in 2014.

The Canadian Arctic has been intensively explored over the past decades and more than 100 wells have been drilled. Despite considerable gas potential, the economic risks and the complex geology resulted in no production

so far. Offshore Greenland is considered by some researchers as the region with the largest undiscovered resources. In both East and West Greenland, a couple of exploration licenses have been sold, but so far there is no known noteworthy discovery, and there is no production at the moment. The land and sea areas of the north of the European continent mainly belong to the exclusive economic zone of Norway and Russia (Figure 2). The first licenses for oil and gas exploration in the Norwegian Barents Sea were awarded in 1980, leading to the discovery of the Snøhvit gas field in 1984. In recent years, several oil discoveries were made in the Norwegian sector of the Barents Sea. On the Russian side, seismic surveying started in the 1970s, leading to the discovery of giant fields like Shtokmanovskoye (estimated to hold 3.8 trillion m^3 of recoverable gas), as well as Ledovoye and Ludovskoye. Further south in the Pechora Sea, many smaller fields were identified. More than 100 wells have been drilled in total, and the current assessment is that there is some 42,000–50,000 million barrels of oil equivalents in the Barents Sea, some 80 % of this on the Russian side. In the Kara Sea, to the east of Novaya Zemlya, Russians have discovered two other giant gas fields, Leningradskoye and Rusanovskye. Oil production in Russia shows a continuous increase. In 2005, it reached some 110 million barrels/day, and since then Russia was able to expand
Energy Resources, Figure 2 Geography and bathymetry of the Arctic region. Major sedimentary basins with hydrocarbon potential (*red shaded*) are located within the exclusive economic zones of the Arctic countries. The sedimentary basins with hydrocarbon potential are commonly located in less than 500 m water depth (modified after Grantz et al. 2011).

its oil production still further. Oil reserve figures indicate that Russia can be one of the world's key oil producers for at least the next 40 years.

Among the greatest uncertainties in future energy supply and a subject of considerable environmental concern is the amount of oil and gas yet to be found in the Arctic (Gautier et al. 2009). Further research and a better understanding of the complex geological configuration of the Arctic is a prerequisite for reliable estimates of petroleum resources. However, the geological conditions for petroleum generation are favorable in the Arctic realm (Figure 2). A large majority of the undiscovered petroleum resources are expected to be found on the shallow Arctic shelves, well within the 200 nm exclusive economic zones of the countries bordering the Arctic Ocean. As the Arctic becomes more accessible, interest in its potential resources is increasing – but as well the public concern for the environmental consequences of petroleum exploration and production. When it becomes necessary to drill in harsh and sensitive environments such as the Arctic region, the costs of producing oil and gas are very high. However, interest for petroleum exploration is enhanced by estimates about how much oil and gas could be found in the Arctic region. The most reliable results in forecasting offshore large fields are obtained when the geological

environment of a well-studied region onshore is extrapolated to the adjacent shelf area. By using a probabilistic geology-based methodology, the United States Geological Survey has assessed the entire area north of the Arctic Circle and concluded that about 30 % of the world's undiscovered gas and 13 % of the world's undiscovered oil may be found there, mostly offshore under less than 500 m of water (Gautier et al., 2009).This assertion of undiscovered Arctic reserves of 90 billion barrels of oil, 47 trillion (10^{12}) m^3 of natural gas, and 44 billion barrels of natural gas liquids (NGLs) still remains unproven. But there is no doubt that the resources are substantial in a global context, and there is consensus that some ¾ of these are expected to be natural gas.

Environmental impact of offshore petroleum production

The production of natural resources is inherently associated with environmental risks. Minor oil spills are quite common during oil production. On the other hand, there are natural oil and gas seeps all over the ocean seafloor. There is not a single oil field in the world that would be completely leak-proof. In the Gulf of Mexico, naturally seeping oil partly reaches the sea surface but is mainly deposited on the seafloor. This enables the growth of three

kinds of naturally occurring oil-consuming bacteria: sulfate-reducing bacteria and acid-producing bacteria are anaerobic, while general bacteria are aerobic. These bacteria act to remove oil from an ecosystem, and their biomass tends to replace other populations in the food chain.

Most marine oil spills are the result of accidents during transportation; however, deep-sea accidents during production or exploration activities also occur. Although they are rare, they may have a significant impact on the environment, such as the accident with the Deepwater Horizon platform in 2010. Spilt oil penetrates the plumage of birds and the fur of mammals, reducing its insulating ability and making them more vulnerable to temperature fluctuations and much less buoyant in the water. Cleanup and recovery from an oil spill is difficult and depends upon many factors including the type of oil spilled, the temperature of the water, weather condition, and the types of shorelines and beaches involved.

The worst oil spills recorded in history include the crude oil carrier Amoco Cadiz accident in 1978, about 5 km off the coast of Brittany, France. The vessel contained 1857 barrels of crude oil when it ran aground. Severe weather resulted in the complete breakup of the vessel and the entire cargo was spilled into the sea. The fuel oil was swept onto the French shoreline, and the total extent of the spill includes more than 300 km of coastline, where the oil penetrated the sand on several beaches to a depth of half a meter. The resultant environmental impact was massive due to delayed cleanup operations owing to rough seas. In 1979, the Ixtoc I exploration well in the Gulf of Mexico suffered a blowout in waters 50 m deep. Due to a loss of hydrostatic pressure, the drilling rig lost mud circulation. Without the counterpressure from the circulating mud, the pressure in the oil reservoir forced oil up the well resulting in a disastrous blowout. Large quantities of oil and gas reached the surface and caught fire. The fire and the eventual collapse of the drilling rig caused damage to the underlying foundations of the well structures, which led to significant amounts of oil leaking into the Gulf. The incident led to the loss of 84,500 barrels of oil that spread to beaches. The water contamination directly affected food fish and octopus species. In early 1991, a disastrous environmental impact resulted from the war in Kuwait. The retreating Iraqi military forces set 700 oil wells on fire in Kuwait. This severely affected the Gulf economy and environment and destroyed several tankers and terminals that resulted in the loss of close to 8.5 million barrels of oil each day. One of the most devastating manmade environmental disasters occurred in 1989. The Exxon Valdez, an oil tanker that was carrying about 200,000 m^3 of oil, hit Prince William Sound's Bligh Reef on the south coast of Alaska and released 42,000–120,000 m^3 of crude oil into the sea. An inaccessible location made it difficult to deploy rescue and clean up operations quickly. The oil spilled retains its toxicity to this day putting a large amount of marine life and vegetation at risk. In 2009 an oil and gas leak occurred in the Montara well in the Timor Sea, off the northern coast of Western Australia in shallow waters. The oil spill was released following a blowout and continued leaking for 74 days. The oil leak could have been as high as 2,000 barrels. BP's Deepwater Horizon explosion in 2010 killed 11 people and injured several others, as well as resulted in a severe oil spill. The oil spill flowed for 3 months and spewed out 5.8 million barrels of crude oil. The spill is considered one of the worst accidents in US history and caused grave damage to the surrounding wildlife and biosphere, putting at risk many endangered species. The Gulf's fishing and tourism industry were also seriously affected. A 6-month offshore drilling moratorium below 150 m of water was enforced.

The Arctic area with its cold climate and waters represents a particularly vulnerable environment with respect to wildlife, biodiversity, fisheries, and nature. Environmental regulations in the Arctic realm are typically stricter than further south. Accidents analogous to BP's Deepwater Horizon disaster in the Gulf of Mexico are expected to have a much stronger impact on the highly sensitive Arctic environment. The risk resulting from transportation at sea has been shown quite plainly from the accident of the Exxon Valdez tanker in 1989 in offshore southern Alaska. There is already a risk of oil spills from the increased oil tanker traffic, and there are additional concerns raised by the increased petroleum exploration and production activities. The conditions in Arctic environments are less favorable for removing oil spills than in moderate or warm climate conditions. The water temperature is close to zero degrees Celsius, slowing down microbial processes and reducing the dissolution and evaporation of oil compounds. Because oil-degrading microbes are usually found in environmental samples, including relatively pristine Arctic environments, it is likely that the potential for oil degradation is already present in the ocean around Northern Greenland, but it is not known how fast and to what extent the degraders will respond to increased oil concentrations in waters and sediments. A better understanding of the potential of the indigenous microbial communities to react to naturally or accidentally spilled hydrocarbons is necessary to delineate risks and develop possible measures for remediation in the future.

Future targets for the petroleum exploration

One of the open questions is how much oil and gas will be discovered in previously unexplored offshore areas. Potential targets include shallow shelf areas that in the past were not accessible, because of, e.g., the harsh environmental conditions in the Arctic, unconventional resources, and deepwater areas (see Regional Marine Geology). In well-explored basins (see Marine Sedimentary Basins), further deepwater exploration will probably include more giant gas discoveries in relation to oil giants and a move to deposits in deeper water along passive continental margins (Chakhmakhchev and Rushworth, 2010).

The deep water is where many of the largest finds of recent times have been made – but also poses challenges,
Energy Resources, Figure 3 Schematic sketch of the end-member extremes of continental margins. *Top*: The magma-poor margin is defined by a wide area of highly attenuated continental crust where the upper crust is deformed by deep-reaching listric faults that may sole out on a common detachment surface, the proximal margin. In the distal margin, the listric faults may cut across the entire crust leading to a detachment at the Mohorovičić (MOHO) discontinuity. Further seaward, extensional allochthons may be situated on exhumed mantle before relatively thin oceanic crust is reached. *Middle*: Volcanic rifted margins show a comparatively narrow proximal margin with considerable crustal thinning over a short distance, thick wedges of syn-rift volcanic flows manifest in seismic reflection data as seaward dipping reflectors (SDRs), and a wide high-velocity (Vp > 7.3 km/s) lower-crust seaward of the continental rifted margin. The oceanic crust is comparatively thick at these margins, especially close to the continent-ocean transition. *Bottom*: Currently not in the focus are hydrocarbons in forearc basins at active margins. These basins develop along active continental margin by the subsidence induced by the subducted oceanic crust.

as seen at BP's Deepwater Horizon disaster. Besides subsalt plays, advances in deep water have been made in exploiting stratigraphic traps, deltas, thrust structures, and carbonate reservoirs. Exploration success often is driven by a better understanding of the geology. Our present knowledge about the structure and architecture of passive continental margins (see Regional Marine Geology) is mainly derived from the interpretation of seismic data, supported by other geophysical data (see Technology in Marine Geosciences), and at times controlled by

drilling. Such interpretation underpins exploration concepts, and future exploration is expected to be challenged by the maturation of conceptual models.

There are two end-member extremes of passive rifted margins: (1) magma-poor rifted margins and (2) volcanic rifted margins (Whitmarsh et al., 2001; Menzies et al., 2002; Franke, 2013; Peron-Pinvidic et al., 2013). Magma-poor rifted margins typically evolve along wide rifts that may be divided into a proximal and a distal part (Figure 3). The proximal margin is characterized by

high-angle listric faults related to fault-bounded rift basins, while the distal margin is characterized by extremely thinned continental crust that is potentially separated from the oceanic crust by a domain of exhumed subcontinental mantle. The boundary between the two domains is at the point where listric faults cut across the entire crust reaching the mantle (see Lithosphere: Structure and Composition). In the proximal margin, typically a detachment is interpreted between the brittle upper crust and the mantle, while at the distal margin, brittle upper crust and upper mantle are separated by only a thin lower crustal layer or are juxtaposed (Figure 3). This leads to coupling and the development of a detachment at the crust-mantle boundary, allowing the exhumation of the mantle further seaward.

Volcanic rifted margins are characterized by up to 15 km thick wedges of volcanic flows (see "Intraplate Magmatism") (Hinz, 1981; Mutter et al., 1982), manifested in multichannel seismic reflection data as seaward dipping reflectors (SDRs), and high-velocity (Vp > 7.3 km/s) lower-crust seaward of the rifted continental margin (Figure 3). Because thinning of the continental crust typically occurs over a comparably short distance (50–100 km), the continent-ocean transition is abrupt and located in the vicinity of the SDRs (Figure 3). Various models place the continent-ocean transition, and thus the seaward limit of the presence of potential rift basins, at the seaward edge, in the center of, or at the landward edge of the seaward dipping reflectors. The effusive magmatism of volcanic margins and the corresponding lavas represented by the seaward dipping reflections obscure the seismic images of potential underlying fault blocks that undoubtedly accompanied the rifting. The major challenge will be a better imaging of sub-basalt structures to understand the complexity in the rift development, the heat flow history, and hydrocarbon maturation and thus to identify prospective plays (Skogseid, 2001).

Forearc basins (see Subduction) are only by way of an exception in the focus of petroleum companies. Such basins are located at almost all convergent continental margins between the deep-sea trench and the magmatic arc (Figure 3). Active margins stretch for a total length of some 44,000 km (von Huene and Scholl, 1991), mainly around the Pacific Ocean, but also along the Indonesian Island Arc, in the Caribbean, the Mediterranean, and the Arabian Sea. The widespread occurrence of this basin type makes it worth reviewing its hydrocarbon potential. Forearc basins may overlie either continental crust or accreted rocks that became attached to the continental plate during the collision of the involved plates. Commonly, forearc basins are bounded seaward by an outer-arc high that is part of the accretionary prism. The tectonic evolution of forearc basins is mainly controlled by the subduction of an oceanic plate. Important factors controlling the basin dynamics are convergence rate, lateral movements of the bending axis, dip angle of the oceanic plate, obliquity of convergence, roughness and sedimentary cover of the oceanic crust, and the sedimentary input of

the landward magmatic arc and continent. Forearc basins typically show an elongated shape, extending parallel to the trench-arc system. Their width commonly ranges between 25 and 125 km, but their length may reach 500 km. Forearc basins are widespread; however, their hydrocarbon potential is believed to be low. This is due to generally low heat flow and the complicated structural history with long-lasting and usually ongoing tectonic activity affecting the basins, mainly terrigenous sediment input from the volcanic arc, and thus the questionable presence of prolific source rocks. Nevertheless, a tectonic basin classification alone is not sufficient to evaluate the petroleum potential of a sedimentary basin. The heat flow values of forearc basins range between 20 and 45 mW/m^2, with a typical value of 40 mW/m^2 (Dickinson 1995). In contrast, passive margins typically exhibit a heat flow between 30 and 50 mW/m^2, or even more in cases of forced fluid flow. Relatively cold oceanic crust is subducted at continental margins, and this reduces the heat flow beneath the forearc basin. Heat flow is typically further reduced by high sediment input from the volcanic arc and the adjacent continent.

Natural gas hydrate is an unconventional energy resource that is currently unexploited. Gas hydrate is a potentially vast source of hydrocarbon energy; the dissociation of 1 m^3 of gas hydrate can release 164 m^3 of gas. Gas hydrates occur under conditions of high pressure and low temperature and are abundantly found in marine environments and the permafrost environments of polar regions. However, the exact volumes are unknown and it is unclear how the gas may be produced. Some estimation predict that the carbon bound in gas hydrates is twice as high as in all other recoverable and non-recoverable energy resources such as oil, gas, and coal (Kvenvolden, 1993). Not only gas hydrates, but also the free gases trapped below the hydrates can be seen as potential energy sources.

Example: Simeulue forearc basin of the Sunda Arc, Indonesia

The Sumatra-Java area is part of the Sunda Arc (see Subduction) that stretches from the Andaman Sea in the northwest to the Banda Sea in the east. Along the Sunda Arc, the Indo-Australian Plate subducts under the Eurasian Plate. The western Indonesian forearc basins extend for more than 1,800 km from northwest of Aceh to southwest Java. The width of the basins varies from less than 70 km to the south of the Sunda Strait to about 120 km to the west of northern Sumatra. The basins form a strongly subsiding belt between the elevated Sumatra Paleozoic-Mesozoic arc massif cropping out along Sumatra and Java and the rising outer-arc high (Berglar et al., 2010).

The Simeulue forearc basin extends between Simeulue Island and northern Sumatra. It matches all features of a typical forearc basin (e.g., low heat flow, tectonic setting controlled by subduction). It is a frontier shallow shelf area with few wells and no wells in the basin center:

therefore it is studied using geophysical data and geological surface samples. Multichannel seismic data show bright spots above potential hydrocarbon reservoirs in carbonate buildups. Amplitude versus offset analysis indicates the presence of gas, and surface geochemical prospecting indicates thermal hydrocarbon generation. Heat flow in the Simeulue Basin ranges between 37 and 74 mW/m^2, as deduced from 1-D petroleum system modeling. Two possible source rocks (Eocene and Early-Middle Miocene; see Geological Time Scale) were assigned for 3-D petroleum system modeling in the Simeulue Basin. Due to a similar pre-Miocene geological evolution in the present-day back-arc and the forearc, it can be assumed that the back-arc source rocks also occur in the forearc.

Modeling based on two heat flow scenarios (40 and 60 mW/m^2) reveals that oil and gas generation is possible within and below the main depocenters of the central and southern Simeulue basin (Lutz et al., 2011). Deep burial (>6 km) of source rocks can compensate for low heat flow. This is an example of a prolific forearc basin and highlights the necessity to carefully evaluate the hydrocarbon potential of each basin individually.

Example: gas hydrates: an unconventional energy resource

Gas hydrates are drawing attention because of their contribution to geological hazards, to climate change, and because of their potential as a future energy supply. From the stability diagrams and the phase boundary of methane hydrate, it can be deduced that elevated pressure and reduced temperatures are necessary for the formation of gas hydrates. Additionally, sufficiently high concentrations of gases are essential. These conditions limit the occurrence of gas hydrates to marine environments (sediments of continental slopes, rises, and in the deep seas) and to permafrost environments (sediments in the Arctic region and in continental ice sheets). At continental margins, the formation of gas hydrates is primarily controlled by the sedimentation rate and the organic matter content. Therefore, the gases involved in the gas hydrates are mostly of biogenic origin. Gas hydrates in permafrost regions can also be the result of the migration of gases from deeper hydrocarbon reservoirs into the Gas Hydrate Stability Zone (Kvenvolden, 1993).

Most of the marine gas hydrates are detected based on the occurrence of bottom simulating reflectors (BSRs) in reflection seismic data. The BSR indicates the base of the Gas Hydrate Stability Zone and mirrors the seafloor. A BSR marks the phase boundary between free gas in the deeper sediments and the gas hydrates of the stability zone, which is determined by temperature, pressure, gas composition, and pore water salinity. Therefore, BSRs are not restricted to layer boundaries and may thus intersect them. In reflection seismic data, a BSR is generated by the inversion in the P-wave velocity from the hydrates to unconsolidated sediments. However, although the BSR is often cited as evidence of gas hydrates, the magnitude of the BSR amplitudes primarily depends on the amount of free gas below the BSR. There are examples of BSRs with no associated gas hydrates, or BSRs within the Gas Hydrate Stability Zone. Nevertheless, the existence of gas hydrates in sediments decreases, or even hinders the further migration of gases, so that in marine sediments, the highest concentration of the gas hydrates is generally just above the BSRs (Dillon and Max, 1998).

Much research is still needed to determine the geological and economic feasibility of extracting gas hydrates. Also the environmental implications of gas hydrate exploration must be considered thoroughly for safe and environmentally friendly exploration. Until now, the exploration of gas hydrates has not been successful due to the complex technical requirements for economic extraction, despite existing offshore and onshore know-how from the oil and gas industry. This is because, in contrast to conventional gas deposits, gas hydrate reservoirs react largely unpredictably to changes in physical and chemical environmental parameters. Therefore, better understanding of the reservoir behavior of gas hydrates is required before significant commercial exploration could take place. However, even if only a small fraction of the estimated gas hydrates could be produced, the resource could be very important (Collet, 2000).

Potential options for the recovery of gas hydrates are based on changing the factors that control their phase stability. This can be achieved by three principal methods. Producing the free gas below the Gas Hydrate Stability Zone reduces the local pressure so that some of the gas hydrates at the base of the Gas Hydrate Stability Zone dissociates and can be produced (depressurization). In the case of thermal stimulation, the dissociation of gas hydrates is achieved by increasing the temperature either by heating or by injecting warm surface water into the Gas Hydrate Stability Zone. Injection of inhibitors such as methanol into the gas hydrate-containing sediments changes the chemical composition so that some of the gas hydrates dissociate and release gas.

Summary

Energy resources from marine environments are of increasing importance. This is valid for both renewable and fossil energy resources: renewable energy represents at present only a minor percentage of global primary energy consumption but is growing very rapidly. Natural oil and gas are the most important offshore energy resources. Information concerning the amount of the producible and usable oil and gas resources depends on the geological conditions of the deposits, the state of the scientific and technical knowledge, the technological potential of the development, and production as well as on the economic and political requirements.

Offshore and deepwater petroleum exploration and exploration in the Arctic are ongoing since decades. At present drilling activity has particularly increased in the

"golden triangle" of Brazil, the Gulf of Mexico, and West Africa. The greatest potential of undiscovered oil and gas is assumed in deepwater settings at continental margins and in the Arctic realm.

While it is believed that renewable energy has minor environmental impact, the production of oil and gas resources inherently comes along with a risk for the environment. Best practice regulations are necessary to reduce risks in the future.

ENGINEERED COASTS

H. Jesse Walker
Department of Geography and Anthropology, Louisiana State University, Baton Rouge, LA, USA

Definition

Engineered coasts, as used in this essay, refer to all coastal zones that have consciously modified by humans from their natural state. Emphasized are those that have been reclaimed, converted into ports, urban, and recreational

H. Jesse Walker is deceased.

centers, and those protected from atmospheric and ocean-ographic processes.

Introduction

Although humans did not originate in a coastal environment, once they "discovered" it, they entered an ecological niche that contained numerous opportunities and challenges. However, long before humans arrived on the scene, the coastal zone's gross character had been established by the constructive and destructive forces that accompanied the movement of Earth's several migrating plates, forces that are still occurring and that may cause havoc with human endeavors and often tax the expertise of coastal engineers. With the more localized actions of wave, current, tide, wind, glacier, biota, and sea-level change occurring along the world's 10^6 km long coastline (Bird and Schwartz, 1985), numerous highly varied forms developed. These forms, which are not necessarily mutually exclusive, include barrier islands, beaches, cliffs, coral reefs, deltas, dunes, estuaries and lagoons, mangrove swamps, marshes, and mudflats, among others. Because of location, structure, configuration, and composition, some coastal types are more amenable to human utilization and modification than others.

Occupational history and coastal impact

Although humans came in contact with the oceanic shores of Africa, Europe, and Asia and even Australia quite early, it was not until near the end of the Pleistocene that they moved into the Americas. It was not long thereafter that most of the world's habitable coastal zones were occupied even if sparsely. Morphological impact was mainly limited to the construction of middens while exploiting the zone's biological resources.

With the coming of agriculture, deltas were colonized, political organizations founded, and trade utilizing coastal locations developed. As trade expanded, coastal cities prospered. This trend continued to such an extent that today some 60 % of the world's population is coastal as are two-thirds of the world's largest cities (Viles and Spencer, 1995). Further, the pressures exerted by such concentrations are resulting in a coastal zone that is being humanly modified more rapidly than at any time in the past.

Recognizing that not all human modification is direct or even intentional, the discussion that follows, nonetheless, places emphasis on those changes that are engineered, namely, reclamation, harbors and ports, shoreline protection, and soft engineering.

From tide pools to polders

Just who was the first coastal engineer is unknown. However, if engineering includes all conscious modification of the environment, then he or she might have been the person who first rearranged boulders along a rocky shore in order to aid in harvesting tidal pools. The objective was to enhance food supply, an objective that has dominated much of coastal engineering. Such a simple structure that takes advantage of tides and waves has evolved into concrete tidal ponds in which the Japanese cultivate abalone, rock-bound *loko* (fish ponds) in aboriginal Hawaii, and solar salt pans in many countries around the world (Walker, 2002). Although only a few of the Hawaiian fish ponds are in use today, their structures still mark the shore line, and, for the most part, solar salt production has expanded from small pans to very large fields in France, Korea, Italy, the USA (Ver Plank, 1958), and elsewhere.

The structures associated with such endeavors capitalized on the physical and chemical processes of the near-shore waters. In contrast, as Chapman noted, "...reclamation usually signifies exclusion of marine or estuarine waters from littoral or riparian lands..." (1982, 514). Such exclusion can be achieved by raising the level of the land or by damming and then draining the area being reclaimed. Both practices have a long history. In China, a well-documented history of the Shijiang (Pearl River) delta traces reclamation through hundreds of years and for scores of kilometers. By 1950, it had more than 1,300 km of dykes and levees. Reclamation has been so extensive in China that more than half of its mudflats have disappeared (Halvany, 2009). Similar projects have been undertaken elsewhere. In Korea a plan, which is still ongoing, called for reclaiming 7,270 km² of tidal flat and shallow water areas.

Although reclamation has been mainly in the name of agriculture and mariculture, other objectives are gaining in importance. For example, in Singapore, it is being done in the name of industry, urban renewal, shipping, recreation, housing, and transportation with each reflecting its own engineering challenges (Walker and McGraw, 2010).

A somewhat different but more "sophisticated" (according to Volker, 1982, 2) type of reclamation is that generally known as *poldering*. Volker defines polder as a "...reclaimed level area having a naturally high water-table but where the surface and groundwater levels can be controlled" (1982, 2). Low-lying coastal areas, coastal marshes, and tidal embayments have all been polderized. Because polders are isolated from surrounding water bodies, elaborate drainage systems are necessary and excess water must be transferred through sluice gates or by pumps – achieved in part, and especially in the past, by picturesque Dutch windmills. The key to poldering is the dyke that surrounds the reclaimed land (Figure 1a). There is some question as to whether the first dykes in the Netherlands were defensive structures aimed at protecting the *terpen* (dwelling mounds) from floods or offensive structures that helped create new land (Harris, 1957). Whereas poldering is usually associated with the Netherlands, it is a practice that probably goes back at least 6,000 years. In more modern times (often with the help of Dutch engineers), it has been used in countries such as the USA, Venezuela, Colombia, India, Vietnam, and Russia.

Harbors and ports

When sailors began to ply the seas, they used irregularities in the shoreline as harbors. Eventually they were modified converting them into ports. The Mediterranean, with its very irregular shorelines, became extensively used by various trading and warring cultures such as the Minoans, Phoenicians, Greeks, and Romans. The Phoenicians, for example, had more than 75 ports between the Atlantic Ocean and the Black Sea (Sarton, 1960).

Although port development in the so-called Dark Ages and for a few centuries after was limited, during the periods of exploration/discovery/colonization and industrialization, ports increased in number and complexity (Figure 1b) and today are common along most of the coastlines of the world. Their number, size, and complexity vary with many factors including the nature of the coastline, location, population, and function.

Because natural harbors are rare along some coasts, ports are constructed by enclosing open ocean areas with offshore breakwaters and in some locales by dredging behind natural coastal barriers. Another type of modern facility is the deep-water mooring buoy from which pipelines transfer materials to onshore facilities. Ports are classified in a variety of ways, e.g., by size, location, and function. The World Port Index (NGIA, 2012) divides ports into eight types including those on rivers, lakes, and canals as well as on ocean shorelines. Of the eight types, the largest number falls in the coastal breakwater

category, suggesting extensive shoreline engineering (Figure 1b). The WPI, which provides information on only 3,700 ports worldwide, excludes many, mostly small fishing ports. For example, Japan, with a coastal length of about 30,000 km, has more than 4,000, 28 % listed as commercial and 72 % as fishing ports (Shapiro, 1984). The WPI lists only 292 for Japan.

The structures that are found in ports include piers, docks, warehouses, and other support facilities. The type and number of which vary greatly from port to port depending mainly on their function.

Shoreline protection

"The need for coastal protection only becomes evident as human activities become established…and fixed structures and buildings are constructed…" (Gourlay, 1996, 12). Once humans began to fill the coast with dwellings, roads, industries, and other infrastructure elements, they often found themselves at odds with nature. According to Horikawa, beach erosion is "…one of the largest world problems from the perspective of land preservation" (1978, 327), and Bird (1996) adds emphasis by noting that 75 % of the world's beaches are in retreat. Human reaction to coastal erosion has mostly been "stabilized" so that today artificial structures dominate extensive sections of the world's shorelines.

This "hard" or "static" engineering approach centers around structures that are fixed in position and that have durability. They include those that are land/sea interface structures such as seawalls, bulkheads, and revetments. The seawall is the one "…most generally regarded by the public as representing the best form" (French, 2001, 51). Designed to separate land from sea, it in essence becomes an artificial cliff. Some, like the one along a typhoon-prone area on the Pacific coast of Japan, are more than 12 m high. Japan's coastline, much of which is also threatened by tsunami, has more than 8,000 km of dykes and seawalls.

Breakwaters, designed to eliminate or reduce wave action, are used to protect the shore behind or adjacent to them. Most early breakwaters were attached to the shore, especially in connection with harbors. Today they are also constructed off shore. They are especially abundant in Italy and Japan. In the USA, along the southern coast of California, detached breakwater construction began in 1899 and eventually extended along 14 km of shoreline (U.S. Army, 1977). Other hard structures include jetties and groins (Figure 1c). They are nonparallel structures designed to protect river entrances from silting (jetties) and to trap long-shore drift and combat shore erosion (groins).

The materials of which such structures are made are highly varied. Natural rock as rubble and riprap was the traditional material, although timber, steel piling, and, more recently, manufactured armor blocks are also used. The first fabricated armor unit was a simple concrete block that served as a substitute for natural boulders. In 1950 the French designed an interlocking unit called "tetrapod" which subsequently led to numerous designs including dolos (South Africa), akmon (the Netherlands), trumpets (Spain), and more than 30 others in Japan with such names, when translated from the Japanese, as spindle, turtle, and igloo (Walker, 1988).

The extent and character of an engineered shoreline varies greatly from one country or locale to another and depends not only on the nature of the coast itself but also on how humans, with their varied population densities, histories, cultural preferences, and technological expertise, have adapted to it. For example, less than 2 % of Finland, with its hard-rock, rebounding coast, is bordered by artificial structures, whereas more than 85 % of the coastline of Belgium is so bordered.

Soft engineering

Hard engineering has been the most common method of combating coastal erosion despite the fact that it is expensive and often unsightly and frequently aggravates erosion. Recently, a technique that is more compatible with natural processes has been utilized. Basically, it is the replenishment of the sand that has been removed from a beach by erosion. The first example of such an engineering feat may have been the creation of a beach in Turkey with sand shipped from Egypt more than 2,000 years ago for Cleopatra (El-Sammak and Tucker, 2002). Today, that beach (on the island of Sedir) is a popular tourist destination but one with very strict preservation restrictions.

Beach nourishment, proposed in the United States in 1916, was done sparingly for decades; the first large scale beach nourishment in Europe was at Norderney, Germany, in 1951. Beach nourishment mainly elevates the beach and advances the shoreline, thereby increasing its effectiveness against erosion and, of course, its desirability for recreation. Sediment sources for beach nourishment projects are varied including from offshore; transport is by truck, bulldozer, dredge, and pipeline (Finkl and Walker, 2002). Durability also varies; effectiveness averages between 5 and 10 years, although some, such as Miami Beach, Florida, last much longer.

Another soft structural procedure is the construction of dunes which serve as barriers to wave action, locales for vegetative growth, and reservoirs of sand during storms (National Research Council, 1990).

Other types of engineered coasts

Although reclamation, ports, and shoreline protection dominate coastal engineering, there are other modifications that have altered the natural coastal zone. Some examples include the construction of highways and railways along the top, the bottom, and on the slopes of cliffy coasts; the creation of flood gates as on the Thames, in Venice lagoon, and in the Netherlands; the damming of straits creating fresh water bodies as in Hong Kong; the construction of offshore islands for drilling platforms as in the Beaufort and Kara Seas; and the construction of

marine parks in a number of countries. Marinas are a specialized type of port that takes many forms primarily dedicated to recreation. Recently the concept has been expanded with the use of Belgian and Dutch contractors in the construction of a 5.72^2 km residential and recreational complex in the form of a palm off the shore of Kuwait (Figure 1d).

Summary, conclusions, and the future

The time between when humans first utilized the varied resources of the coastal zone and when they first consciously began its modification (engineering) consumed most of human history. However, once such modification began, change progressed rapidly. Today, coastal reclamation projects dominate many coastal sites, ports are numerous in coastal countries, and protective structures front many shorelines. Further, urban waterfronts which reflect a great variety of modern-day activities – industry, commerce, housing, recreation – also demonstrate the complexity of modern-day engineered coasts.

Although most coastal engineering has been in support of such normal endeavors, much of it is in response to catastrophic events – e.g., landslides, hurricanes and typhoons, earthquakes, and tsunami. Recent examples include the hurricane/flooding reconstructions from Katrina in New Orleans and Sandy in the northeastern United States and the reconstructions resulting from the tsunamis in Southeast Asia and Japan. The style of engineering in response to coastal disasters also has a cultural component that differs among countries (Bijker, 2007).

Because this summary paper about coastal engineering has only been able to touch on selected characteristics of the topic, it is recommended that the reader consult other, more definitive, treatments such as Artificial Structures and Shorelines (Walker, 1988) and, especially, History and Heritage of Coastal Engineering (Kraus, 1996). The Artificial Structures volume demonstrates how coastal engineers have impacted the shorelines of 48 countries around the world, whereas the History and Heritage volume provides detailed and well-illustrated histories of coastal engineering for 15 major countries.

Engineering and coastal modification in the future will continue to evolve as environmental conditions such as sea-level and storminess change, as technology develops, and as the attitudes of humans vis-à-vis the coastal zone modify. The recent acceptance of the importance of coastal wetlands impact on reclamation and the trend toward soft engineering are but two examples.

EPICENTER, HYPOCENTER

Nina Kukowski
Institute of Geosciences, Friedrich-Schiller-University, Jena, Germany

Synonyms
Focus (hypocenter)

Definition
The *hypocenter* of an earthquake is the subsurface location at which energy stored along a locked fault is first released. The *epicenter* is that location at the surface, which is closest to the hypocenter.

During an earthquake, rupture propagates from the hypocenter to both sides along the originally locked fault (see "Earthquakes," Figure 1). The hypocenter is directly located beneath the epicenter, and the distance or depth of the hypocenter, respectively, is the focal depth. Seismic waves initially propagate spherically away from the hypocenter and will be reflected and refracted at, e.g., the boundaries of geological layers, which show a contrast in impedance, which is the product of seismic velocity and rock density. This leads to complicated travel paths of seismic waves arriving at seismic stations.

One of the most important inverse problems of seismology is to find the hypocenter, i.e., the location, where the earthquake nucleates, from the arrival times of the different seismic waves at seismic stations (Stein and Wysession, 2003). Whereas the distance to the epicenter, the epicentral distance (Lowrie, 2007), can be estimated from the time difference of the arrivals of p- and s-waves at one seismic station, to localize the epicenter, distances determined from three stations are necessary, from which it can be found through triangulation. As Earth's velocity structure is not homogenous, there will be an error in the epicenter estimate, which will be quite small, if data from many seismic stations are available and if these stations are not too far away.

Focal depth can range from close to the surface of the Earth to several hundred kilometers depth (see "Earthquakes," and "Wadati-Benioff-Zone"). It can be estimated from the epicentral distance and the distance traveled by the direct wave. Again, combining estimates from several seismic stations improves the accuracy of determining focal depth.

In case of shallow earthquakes, the epicenter usually also is within the area of greatest damage. However, in case of deeper earthquakes, when rupture is propagating all along the fault to the surface, damage usually is greatest where the fault reaches the surface. This is especially true for seismogenic zone (see "Seismogenic Zone") earthquakes along subduction zones (see "Subduction"), which can reach the largest magnitudes observed. For such seismic events, the seismogenic fault often reaches the seafloor, which may lead to destructive tsunamis (see "Tsunamis").

EROSION-HIATUSES

William W. Hay
Department of Geological Sciences, University of Colorado at Boulder, Estes Park, CO, USA

Definition
Erosion is the processes whereby the detritus and solutes resulting from the weathering of sediments and rock are transported to a site of deposition. *Hiatus* derives from the Latin, meaning a gap in something. In its geological sense, a *hiatus* represents either a cessation in deposition of sediments, resulting in an interval during which no strata form, or an erosional surface within the stratigraphic sequence representing a gap in the rock record.

History
Prior to the introduction of the ideas of seafloor spreading and plate tectonics, documented by the recovery of long sequences of ocean basin sediments by the Deep Sea Drilling Project (DSDP) in the late 1960s and 1970s, it was thought that the deep sea was the repository of an essentially undisturbed monotonous but continuous multibillion-year record of Earth history. It was thought that sedimentation had been slow but continuous in a
Erosion-Hiatuses, Figure 1 Moore and Heath's (1977) compilation of the proportion of surviving stratigraphic sections for the Cenozoic (*solid line*), a decay curve assuming an erosion factor of 0.07 %/my (*dashed curve*) and a plot of ocean bottom water temperatures based on oxygen isotopes in benthic foraminifera after Savin (1977) (*dotted line*), with temperature scales reflecting the changing oxygen isotope ratios in response to the buildup of ice on land.

sluggish environment that had always been cold. The first estimates of the velocities of currents in the deep sea came in the 1950s through analysis on the data collected by the German "Meteor" expedition of 1925–1927, revealing that current velocities of the deep western boundary currents ranged between 2 and 18 cm/s.

It was only after the recovery of extensive sediment cores by the DSDP that it became evident that the record was one not only of changing conditions over the past 180 million years, but that there were many gaps in the record caused by erosion and redeposition by bottom currents. As sonic swath mapping of the seafloor proceeded, it was realized that there are many bottom features, such as sediment drifts, sand sheets, dunes, gravel bars, and scour marks that reflect the activity of bottom currents.

The overall pattern of deep-sea erosion and deposition

Moore and Heath (1977) compiled data on the amount of the sampled chronostratigraphic section preserved in cores taken during the first 32 legs (313 sites) of the DSDP.

It was evident that there were many gaps in the record and that the missing parts of the record increased with age. This was an expression of the phenomenon that had been discovered a few years earlier by James Gilluly based on studies of the age distribution of sediments on the continents: that younger sediments are largely the product of erosion and redeposition of older sediments. A much more complete discussion of the distribution of hiatuses in deep-sea sediments, both in time and space, was presented by Moore et al. (1978). The first 32 legs of the DSDP were close to being a random sample of the sediments on the deep ocean floor. Subsequently the selection of sites for sediment drilling and coring was adjusted to prefer areas where loss of section due to hiatuses would be minimal.

It was evident that the widely held assumption that the deep sea was the ultimate repository of sedimentary material and was unaffected by the erosion characteristic of the land, continental shelf, and slope was incorrect (Figure 1).

A modern interpretation of the data would be that the initiation of intensive bottom water formation as a result
Erosion-Hiatuses, Figure 2 Relation between seawater flow velocity and erosion and deposition of sediments with some major current-generated bottom features (after Brown et al. 1993).

of global cooling caused erosion and redeposition of unconsolidated sediments on the deep ocean floor. Because the deep ocean waters are corrosive to the $CaCO_3$ skeletal materials of oceanic plankton, their erosion and resuspension often resulted dissolution, destroying the fossil record of their reworking into younger sediments.

Erosion, suspension, transport, and deposition of sediment on the ocean floor

Figure 2 shows the relation between current flow velocity and sediment grain size in terms of erosion, transport, and deposition of unconsolidated sediment.

It has become evident that ocean bottom waters are everywhere in motion. Velocities of the order of 2 cm/s are common, but significant variations are introduced by the tides and eddies. These can result in "benthic storms" when flow velocities reach 20 cm/s or more. Local flow velocities are controlled by the bottom roughness and topography. The currents suspend, scour, transport, and redeposit sediment, leaving hiatuses in the geologic record.

Extent of hiatuses

Hiatuses can be recognized as unconformities in seismic profiles. Figure 3 shows interpretation of a profile in the Atlantic off Florida by Vail et al. (1980). Unconformities are common and extensive. This is a region that is affected by the north to south-flowing western boundary current of the North Atlantic Basin.

Summary

Erosion, once thought to be rare or impossible in the deep sea, has turned out to be a common phenomenon. It produces hiatuses (gaps in the record of geologic time) in the stratigraphic record. Ocean bottom current velocities vary with time but can exceed 20 cm/s and easily erode and transport bottom sediment either as suspended load or along the bottom by traction. Carbonate skeletal elements of nannoplankton and foraminifera, eroded and suspended in the water column, are subject to dissolution by ocean deep waters so that reworked fossils are relatively rare.
Erosion-Hiatuses, Figure 3 Unconformities (hiatuses) in the Blake Outer Ridge region of the western North Atlantic (Vail et al. 1980). Unconformities are marked as heavy lines. Numbers associated with them are estimates of the ages of the sediment below the unconformity.

Definition
According to the definition given by Cameron and Pritchard (1963), an estuary is a semi-enclosed coastal body of water which has a free connection with the open sea and within which seawater is measurably diluted with freshwater derived from land drainage. This definition applies to the so-called classical (positive) estuaries of the Earth's temperate latitudes in which freshwater input is the main driver of the long-term circulation. Freshwater inflow establishes longitudinal density gradients resulting in long-term surface outflow and net inflow underneath. In some arid basins, called inverse (negative) estuaries, where evaporation exceeds the sum of precipitation and runoff, the loss of freshwater becomes a main force shaping long-term circulation and the development of longitudinal density gradients, in analogy to classical estuaries (Valle-Levinson, 2010).

Introduction
Estuaries constitute unique ecosystems influenced by freshwater input and tide currents which establish the estuarine circulation often called the gravitational circulation. This steady-state circulation may be modified by tidal currents, the Earth's rotation, atmospheric forcing, topographic features, and river discharge (MacCready and Geyer, 2010; Geyer and MacCready, 2014). The water circulation controls many estuarine processes and phenomena. One of peculiar features in estuaries is the occurrence of turbidity maxima in the area of interface of fresh- and salt waters. These zones of high suspended sediment concentrations influence primary production, contaminant flushing, fish migration, and dredging (Mitchell et al., 1998). Estuaries are regions extensively exploited by man since they serve as locations for ports, urban and industry development, sewage discharge systems, recreational areas, farming, as well as fishing and hunting grounds (Wolanski and McLusky, 2012). It should be kept in mind, however, that any pollutant in an estuary, i.e., pollution loading, oil spills, thermal discharges, coastal dredging, and offshore drilling, may significantly affect its environment.

Origin of estuaries
Considering their geological origin, estuaries are divided into four types (Pritchard, 1967; Valle-Levinson, 2010):

- **Drowned river valleys (coastal plain estuaries)**: originally rivers, formed as a result of the Pleistocene increase in sea-level, typically funnel shaped, several kilometers wide, and shallow (of about 10 m depth) with large width/depth discrepancy. The salinity decreases steadily from about 30 ‰ (at the mouth) to about 0.1 ‰ (at the head). In this type of estuary the stretch of the freshwater river above the upper limit of intrusion of sea-derived salt is still subject to tidal action. Examples of drowned river valleys are Chesapeake Bay, Delaware Bay, and the Elbe Estuary.
- **Fjords**: located in high-latitude regions, where glaciation has been a major factor in shaping the land, characterized by an elongated, deep channels with steep sides and a sill. The sill is related to a moraine of either a currently active glacier or an extinct glacier. Fjords are typical in Scandinavia, Greenland, and Antarctica as well as in New Zealand, Canada, and Patagonia.
- **Bar-built estuaries**: formed when offshore barrier sand islands and sandpits build above sea-level and extend between headlands in a chain, broken by one or more inlets, usually shallow, oriented parallel to the coast. In these estuaries the circulation is provided by the wind, as tides are considerably choked and the river discharge is of low volume. Bar-built estuaries are found in northern Mexico or in southern Portugal.
- **Tectonic estuaries**: formed by earthquakes or by the Earth's crust fractures and creases that generated faults in regions adjacent to the ocean, typically developed after sinking a part of the crust and forming a hollow basin. An example of this type of estuary is San Francisco Bay.

Water balance of estuaries
In terms of water balance estuaries may be classified according to Pritchard (1952) as:

- **Positive estuaries**: in which freshwater input from rivers, rainfall, groundwater, and ice melting exceeds evaporation. The longitudinal density gradient drives a net volume outflow to the ocean; surface outflow is stronger than near-bottom inflow.
- **Inverse (negative) estuaries**: in which evaporation exceeds the combined sources of freshwater. They show stronger surface inflow than near-bottom outflow.
- **Neutral estuaries**: in which evaporation and freshwater input are in balance.

With the exceptions of lagoons in arid or semiarid regions, most estuaries are positive. As reported by Valle-Levinson et al. (2001), some estuaries could change

seasonally from one type to another (e.g., they are positive during rainy seasons, whereas negative during dry periods). The estuary during the neutral stadium represents a temporal transition between positive and negative stages (Kjerfve, 1989).

Salinity vertical structure and mixing processes

Estuaries may be divided based on the vertical stratification and the extent of lateral homogeneity (Bowden, 1967; Pritchard, 1989). According to Valle-Levinson (2010), this classification includes:

- **Salt-wedge estuary**: caused by weak tidal forcing and large river discharge, the tidally averaged salinity profiles show the sharp pycnocline, with mean flow dominated by outflow throughout most of the water column and weak inflow in a near-bottom layer; mixing between fresh- and salt waters is negligible (e.g., the Mississippi River, Ebro River, Rio de la Plata).
- **Strongly stratified (fjord-type) estuaries**: formed as a result of moderate to large river discharge and weak to moderate tidal forcing. The tidally averaged salinity profiles have a well-developed pycnocline with weak vertical variations above and below it. The inflow is weak because of weak mixing with freshwater and weak horizontal density gradients. An example of this type of estuary is the almost tideless Baltic Sea.
- **Weakly (partially) stratified estuaries**: resulted from moderate to strong tidal forcing and weak to moderate river discharge. A weak pycnocline or continuous stratification from surface to bottom, except near the bottom mixed layer, is observed. Stronger tidal currents induce mixing between fresh- and salt waters (e.g., Chesapeake Bay, Delaware Bay, James River).
- **Well-mixed estuaries**: produced by strong tidal forcing and weak river discharge, in which mean salinity profiles are practically uniform and mean flows are unidirectional with depth. In wide estuaries inflow may develop on one side across the estuary and outflow on the other side (e.g., the lower Chesapeake Bay in early autumn).

Estuaries would tend to shift from strongly stratified to well mixed with (a) decreasing river flow, (b) increasing tidal velocities, (c) increasing width, and (d) decreasing depth (Pritchard, 1989). They respond to consecutive tidal cycles, meteorological forcing, and topographic features. For instance, the Hudson River Estuary changes from highly stratified during neap tides to weakly stratified during spring tides (Valle-Levinson, 2010).

Principal forcing variables

The tidal velocity and the freshwater flow constitute the basis of the prognostic approach to classification of estuaries. Geyer and MacCready (2014) mapped the estuarine parameter space using two nondimensional parameters Fr_f and M, where Fr_f is the freshwater Froude number, the net velocity due to river flow scaled by the maximum
Estuary, Estuarine Hydrodynamics, Figure 1 Scheme of gravitational circulation in a partially mixed estuary.

possible frontal propagation speed, with a tidal Froude number as the other axis (Geyer, 2010) and M is the mixing number which is based on the ratio of the tidal timescale to the vertical mixing timescale (Geyer and MacCready, 2014). Estuaries with similar hydrodynamic conditions would be expected to appear at the similar place in the Fr_f-M parameter space. They are depicted as not points in the parameter space but rectangles owing to the spring-neap variations in tidal velocity as well as changes in river discharge and variations in depth. Salt-wedge estuaries such as the Mississippi and the Ebro River (with higher values of the Fr_f number) are near the top of the Fr_f-M space. Partially mixed estuaries fall in the middle (e.g., the Hudson and the James Rivers). Fjords appear in the lower-left corner, whereas well-mixed estuaries (the M number higher than 1) appear in the lower-right part of the estuarine parameter space.

Estuarine hydrodynamics

Currents in the most common partially stratified estuaries are primarily induced by density and elevation differences between fresh- and salt waters. They establish two-layer gravitational circulation, which is maintained by dynamic balance between advective and diffusive processes. Primarily less dense freshwater has a tendency to remain in the surface layer of estuary (Figure 1). However, due to the impact of tide and wind, a vertical exchange between fresh and salt layers takes place. That process explains the existence of longitudinal and vertical salinity gradients in the estuary (Kjerfve, 1989). The time-average pressure surfaces tilt seaward in less dense surface layer forcing a net outflow of freshwater. In the bottom layer they tilt upstream, driving the salty and dense water toward land. At a certain depth in mid-water column, the pressure surfaces become horizontal and a level of no net motion is observed. The net outflow from the estuary can have a much greater volume than the river discharge as it carries some of the seawater back toward the sea.

Tidal straining is one of effects forcing water circulation within estuaries and refers to variations in stratification that may not reach the well-mixed limit (MacCready and Geyer, 2010). Due to the convective instability of
Estuary, Estuarine Hydrodynamics, Figure 2 Scheme of inverse estuarine circulation.

the near-bottom flow at the flood tide, the vertical velocity profile is much more uniform at the flood than at the ebb tide. As a consequence, velocity profiles are bottom intensified during flood and surface intensified during ebb (Burchard and Baumert, 1998). Burchand and Hetland (2010) revealed that tidal straining is the governing process in generating estuarine circulation for periodically stratified estuaries. The process may not only be driven by tidal asymmetries resulting from horizontal buoyancy gradients but from other asymmetric process as well (e.g., wind straining). Tidal straining is the main mechanism for generation of estuarine turbidity maxima.

Spring-neap modulation of tidal forcing has been found in many estuaries. In these estuaries during neap tides, potential energy input due to straining by the mean gravitational circulation exceeds the buoyancy flux due to tidal mixing and results in increase in stratification (Geyer and MacCready, 2014).

Lateral flows in estuaries are usually much smaller than the dominant tidal currents directed along the channel (Lerczak and Geyer, 2004). In many systems differential advection drives secondary flows, with the exception in the vicinity of channel beds where flow curvature is the main factor (Chant, 2010). The Coriolis acceleration is the next important forcing variable influencing the estuarine secondary circulation. Lerczak and Geyer (2004) found that the lateral flow tends to be stronger during flood than ebb tides. Moreover, Scully et al. (2009) demonstrated that tidal rectification of lateral advection may act as a driving force for the residual estuarine circulation.

In some enclosed water bodies located in arid or semiarid regions, inverse current system may emulate as a result of negligible river discharge and low precipitation but high evaporation. In those negative estuaries, the high evaporation rates cause increase in salinity and density of a surface layer, which sinks deeper into the ocean (Figure 2). Then it outflows seaward at the near-bottom layer, while less dense ocean water inflows landward as a surface layer. Reverse estuaries present the longitudinal density gradient of the opposite sign as compared with positive estuaries, i.e., water density increases landward (Valle-Levinson, 2010). Examples of reverse estuaries

are the Bay of Guaymas in Mexico in the late spring (Valle-Levinson et al., 2001) or Shark Bay in Australia (Hetzel et al., 2013). In some estuaries with freshwater input from rivers but very small, during hot and dry season strong evaporation may cause the occurrence of salt plug near the river mouth. That salinity maximum zone serves as a buffer between the fresh to brackish waters and the offshore waters. That phenomenon was recorded, i.e., in the South Alligator River or the Escape River in Australia (Wolanski, 1986).

Investigations of estuarine processes

Initially the processes taking place in estuaries were mainly investigated during field experiments. Since the 1950s estuarine modeling has emerged, starting from studies by Ketchum (1951) and Stommel (1951). Subsequently, mathematical models describing mixing and circulation in estuaries have been devised by, i.e., Stommel and Farmer (1952), Pritchard (1952), and Hansen and Rattray (1965). In the recent years the extended capacity of numerical models allowed to simulate physical processes in estuaries with a high accuracy. Burchard et al. (2004) applied General Estuarine Transport Model (GETM) for simulating dynamics of the estuarine turbidity maxima in the Elbe Estuary. The GETM was also successfully applied for studying the water dynamics in the Baltic Sea (Holtermann et al., 2014). Scully et al. (2009) explored the mechanisms driving the estuarine circulation in the Hudson River Estuary utilizing the Regional Ocean Modeling System (ROMS). An estuarine and coastal version of Princeton Ocean Model was efficacious for the simulations of water circulation in the Delaware Bay (Schmalz, 2009), the Hudson Estuary (Hellweger et al., 2004), or the tideless Oder Estuary in the Baltic Sea (Kowalewska-Kalkowska and Kowalewski, 2006). The recent study by Burchard et al. (2011) allowed to quantify the contribution of the gravitational circulation, tidal straining, advectively driven circulation, and horizontal mixing circulation to longitudinal and lateral residual circulation in tidally energetic estuaries.

Summary

Estuaries are complex systems, with nonlinear crosscoupling and feedback between the circulation and density structure (Geyer and MacCready, 2014). The water circulation within them is controlled by river discharge, tidal currents, the Earth's rotation, atmospheric forcing, and bathymetry impacts. The classifications of estuarine systems show the great diversity in their regimes. Many estuaries cross boundaries between different estuarine types as a result of the numerous processes. Recent advances in the understanding of estuarine circulation allowed to decompose the residual estuarine circulation and study the contributions from various processes taking place in tidally energetic estuaries (Burchard et al., 2011).

Estuaries, extensively exploited by man, need careful management and continuous monitoring of environmental

processes occurring there (Wolanski and McLusky, 2012). The nowadays research is based on the joint applications of field measurements and advanced numerical models. It is expected that gained knowledge will prevent the deterioration of the estuarine natural environments and preserve them as biodiverse-rich and healthy marine ecosystems for future generations.

EUSTASY

Reinhard Dietrich
Institute of Planetary Geodesy, Technical University of Dresden, Dresden, Germany

A volume change of the global ocean divided by the area of the global ocean is called eustatic effect. The eustatic effect is one number representing the average value of global sea-level change (Pugh, 1987, p. 460; Emery and

Aubrey, 1991, p. 165). It may be caused by mass exchange between land and sea (built up or melting of continental ice and snow, changes in hydrological conditions on land) or by a density change (temperature, salinity) of the ocean water. The latter one is also called steric effect.

If the contribution of land ice is considered only, the resulting effect is called glacial eustasy. However, the built up or melting of ice masses will never result in a uniform sea-level change. Here, the changes of the gravity field due to the mass changes ("geoid effect") and the response of the solid earth due to changing mass loads ("glacio-isostatic adjustment") have to be considered as well.

For the time period 1993–2010, a value of 2.8 ± 0.5 mm/year for the eustatic effect has been determined (IPCC, 2013). The main contributions come from thermal expansion (1.1 mm/year), glaciers and ice caps (0.76 mm/year), and ice sheets (0.8 mm/year).

EVENTS

William W. Hay
Department of Geological Sciences, University of Colorado at Boulder, Estes Park, CO, USA

Definition

Events are relatively short-lived phenomena recorded in the geologic record by depositional, erosional, or geochemical features. They may be of local significance (e.g., a storm deposit (tempestite), debris flow, submarine landslide, tsunami deposit) or more extensive (e.g., a volcanic ash deposit, changes in the distribution of fossil species, changes in ocean water properties such as anoxia reflected by sapropels) or even global (eustatic sea-level changes, variations in isotopic ratios, changes in seawater composition).

Major events in ocean history

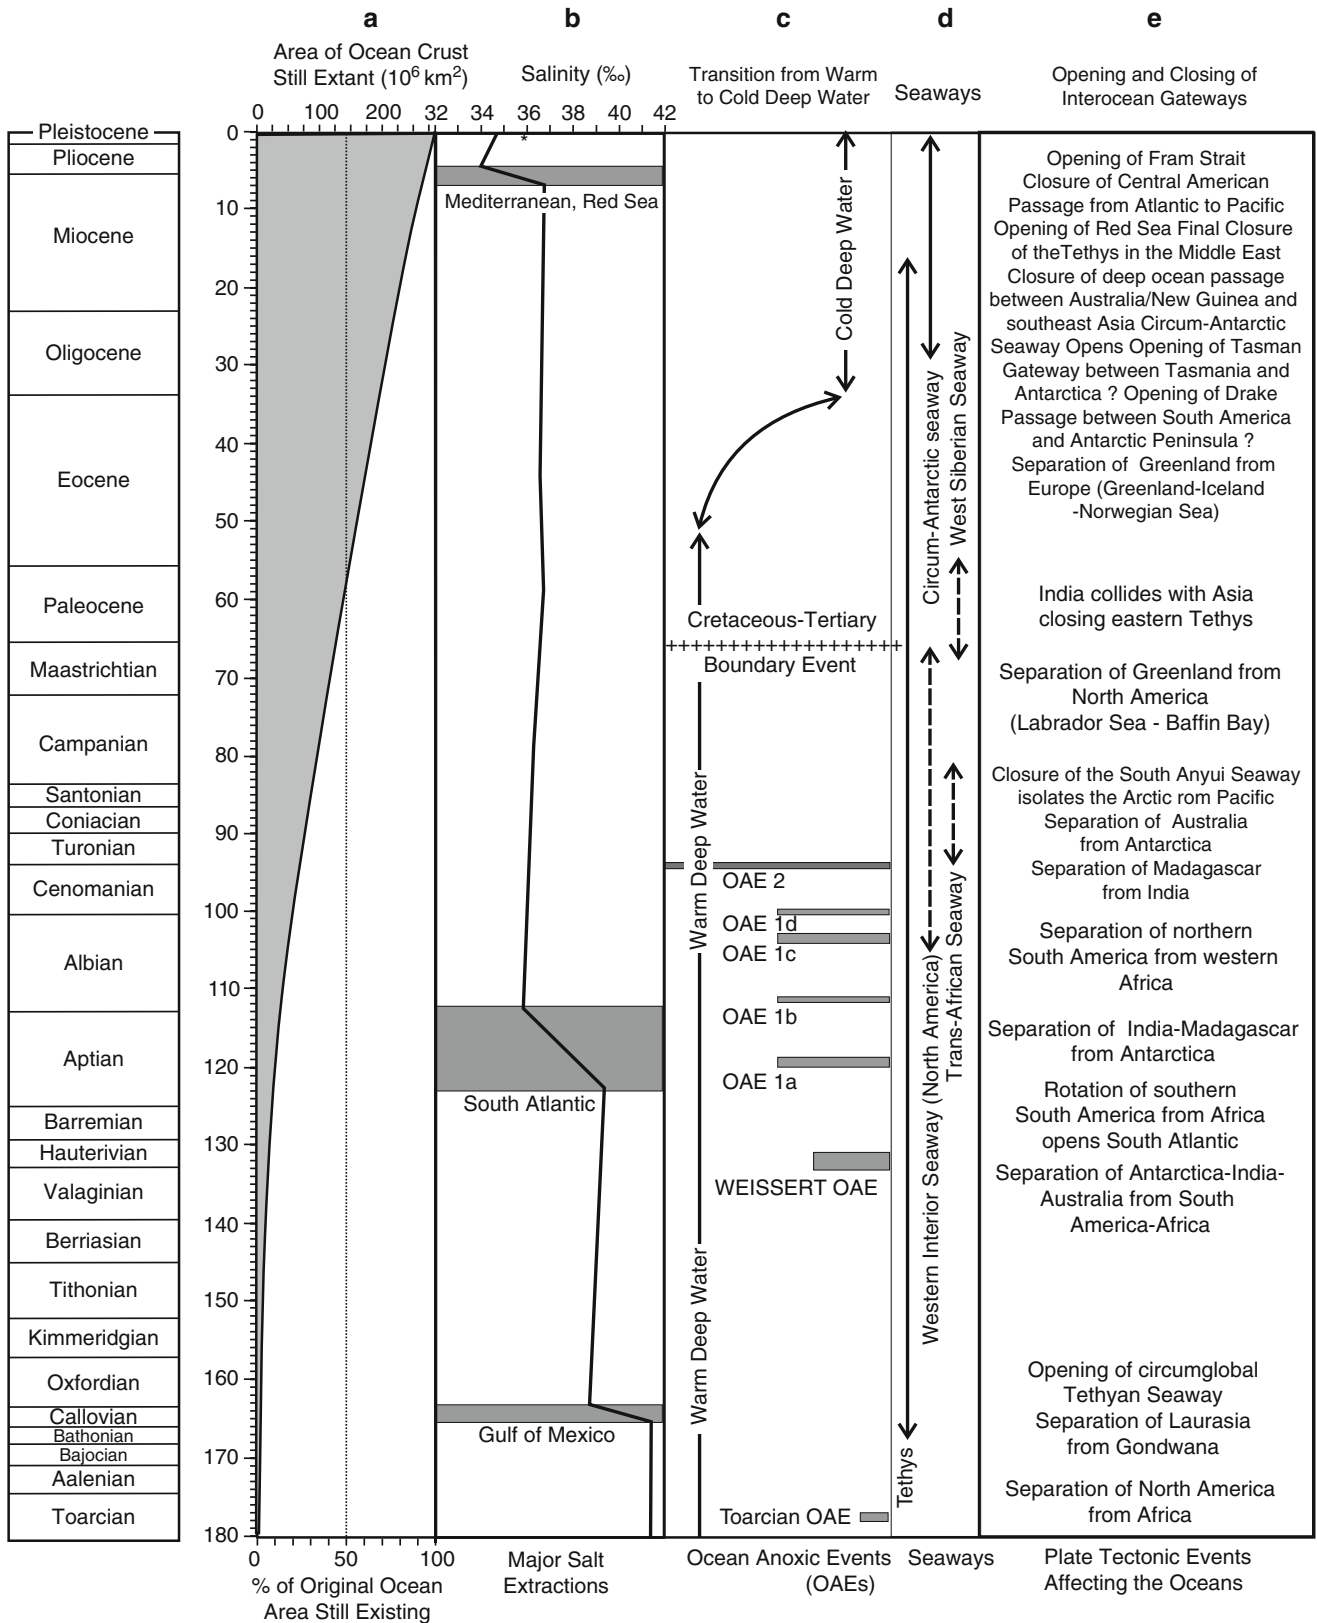
Knowledge of the history of the oceans depends in part on how much of the ocean floor is still available for an examination. As shown in Figure 1a, only half of the ocean crust with its sediment that existed 180 million years ago is still present. The oldest fragment of the ocean crust in the ocean basins is between 180 and 200 million years old, but other bits of the older ocean crust are preserved as ophiolites in mountain ranges. Subduction and consequent loss of the geologic record primarily affect the Pacific and Indian Oceans. Subduction in the Atlantic Ocean basins is limited to the eastern peripheries of the Caribbean and Scotia Plates.

The salinity of the ocean has generally declined during the Phanerozoic as salt has been removed to form evaporite deposits. Erosion of older evaporites on the continental blocks slowly returns salt to the ocean, but overall, the trend has been toward freshening of the ocean. Salinities in the Precambrian are thought to have been generally above 50 ‰. During the Paleozoic, they were of the order of 48 ‰ to 42 ‰. Figure 1b shows major salt extractions and changes in the average ocean salinity since 180 Ma.

The breakup of Pangaea produced several isolated deep basins on ocean crust, particularly the opening Gulf of Mexico and southern South Atlantic, that accumulated large amounts of salt, and each significantly reduced ocean salinity. The deposition of salt in the isolated Mediterranean and Red Sea basins and the Persian Gulf lowered salinity to its modern value of about 34.72 ‰. The evaporites in these deposits on ocean crust will not return to the ocean until continental collisions or other plate tectonic processes bring them back above sea-level. The buildup of ice on land during the Pleistocene glacials increased ocean salinity to as high as 35.90 ‰, indicated by the asterisk at the top of the figure.

Ocean anoxic events (OAEs), shown in Figure 1c, were episodes of extensive anoxia in the intermediate and/or deep ocean. Most of these are known only from the Tethys and North Atlantic, as indicated by the width of the gray bars in the figure. Durations of these events, as estimated by Erba (2004) but here expressed in millions of years, were as follows: the Toarcian OAE – ?1? myr, Weissert OAE – 2 myr, OAE 1a – 1.250 myr, OAE 1b 0.046 myr, OAE 1c – 1 myr, OAE 1 day – 0.3 myr, and OAE 2 (the Bonarelli event) – 0.3–0.4 myr. Each of the OAEs occurred during very warm greenhouse conditions.

During the Cretaceous and Paleocene, the ocean's deep waters were warm, containing only about half as much dissolved oxygen as cold deep waters. This was undoubtedly one of the factors contributing to the development of OAEs.

Also indicated in Figure 1c is the Cretaceous-Tertiary boundary event, probably caused by the impact of an asteroid in Yucatan. The global effect of this event is marked in the ocean by the extinction of most calcareous nannoplankton and planktonic foraminifera. The recovery of the diversity in the plankton took several million years.


Events, Figure 1 Major events in the history of the oceans since 180 Ma.

A major shift in circumglobal circulation occurred in the mid-to late Tertiary. From about 165 to 8 Ma, circumglobal ocean circulation was possible through the Tethys, located about 20–30° north of the equator. However, the Tethys consisted of many basins separated by swells, both of which were constantly changing, affecting the width and depth of shallow water passages. Connections at depth were even more variable, and it is possible that a deep passage through the entire Tethys never existed. As the Tethys closed, circumglobal circulation shifted to the high latitudes of the Southern Hemisphere. A continuous path for circulation around the Antarctic continent became possible with the opening of the Drake Passage and Tasman Gateway during the Eocene.

Seaways across the continental blocks were associated with the high sea levels of the Cretaceous. These are shown as dotted lines in Figure 1d. The Western Interior Seaway of North America connected the Gulf of Mexico with the Arctic Ocean, but probably had an arm via the present Hudson Bay region across Greenland to northern Europe. Finally, during the middle of the Cretaceous, a seaway extended across Africa from the northern South Atlantic to the Mediterranean. In the latest Cretaceous and early Tertiary, a very shallow seaway extended across western Siberia periodically connecting the Tethys with the Arctic.

A shallow seaway from the North Atlantic to the Arctic between Greenland and Europe (not shown in Figure 1d) existed from the time of the separation of North America and Africa until spreading began to separate Greenland from Europe to form the Greenland-Iceland-Norwegian (GIN) Sea. However, a deep connection between the Arctic and North Atlantic is blocked by the Greenland-Iceland-Scotland Ridge.

The opening and closing of major interconnections between the ocean basins are shown in Figure 1e. Although very important over the long term, these were gradual "events" that occurred over intervals of a few million years. Opening passageways were initially shallow and became deeper with time, just as closures initially restricted deep water circulation and ended by shutting off surface circulation.

Summary

Events are episodes of change recorded by depositional, erosional, or geochemical features. They may be only local or regional in extent or global, reflecting significant trends in ocean evolution.

EXPLOSIVE VOLCANISM IN THE DEEP SEA

Christoph Helo
Institute of Geosciences, Johannes Gutenberg-University Mainz, Mainz, Germany

Definition

Explosive eruption	Eruption characterized by magma fragmentation at the vent, producing pyroclasts.
Effusive eruption	Extrusion of magma as lava flow.
Explosive Volcanism in the Deep Sea, Figure 1 Explosive deep-sea eruption at West Mata, Lau back-arc basin. (**a**) Strong active degassing and pyroclasts formation. Field of view is ~2.5 m. (**b**), (**c**) Magma bubble bursts, in (**b**) visibly accompanied by effusion of degassed lava (white arrow). (**b**) Field of view is ~1.25 m; (**c**) base of bubble is ~0.5–0.8 m (Resing et al. (2011), adapted by permission from *Macmillan Publishers Ltd*: Nature Geoscience, *copyright* (2011)).

Pyroclast	Rock or glass fragment expelled from volcanic vent during the eruption.
Volcaniclast	Nongenetic term for any fragment of volcanic origin.
Magma	Multiphase system containing silicate melt $\pm$ crystals $\pm$ bubbles.
Melt, silicate	Liquid phase of a molten rock.
Volatile	Chemical compound of the melt that can form a free gas phase (mostly water, carbon dioxide, and sulfur, minor chlorine and fluorine).
Solubility	Maximum concentration of a volatile phase dissolvable in the melt; decreases strongly with declining pressure.
Exsolution	Formation of a free magmatic gas phase (commonly as bubbles), as the volatile concentration exceeds solubility.

Introduction

Within the past decades, it has been realized that volcanoes in the deep sea (i.e., water depths in excess of a few hundreds of meter) compare in their general spectrum of eruption styles to those on land and explosive activity is common to both environments (Figure 1). Either setting covers the full compositional width from basaltic to rhyolitic. The seafloor is volcanically the most active place on Earth (roughly 75 % output volume of terrestrial volcanism), with mid-ocean ridge basalts (MORB) accounting for most of the eruptive output. While explosive eruptions of rhyolitic volcanoes in the deep sea may reveal themselves prominently by so-called floating pumices (buoyant, highly porous pyroclasts), ongoing basaltic eruptions commonly remain undetected as monitoring of the deep sea is still sparse and technically challenging.

Our current understanding of deep-sea volcanism is vitally owed to indirect information sources: (1) ophiolite sequences and other uplifted blocks of ancient seafloor (e.g., Moores et al., 1984; Staudigel and Schmincke, 1984), (2) dredging and ocean drilling of the ocean seafloor (e.g., Fox and Hezeen, 1965), and (3) tedious mapping and sampling using underwater vehicles (cf. Yoerger et al, 2007; Rubin et al., 2012). The abundance of fine-grained volcaniclastic material in addition to lava flows was recognized early on. Initial models on the formation of volcaniclastites at water depths below 500 m focused largely on nonexplosive mechanisms (Fisher and Schmincke, 1984), mainly lava granulation due to cooling contraction and spalling of glassy lava rinds (Schmincke et al., 1978; Bonatti and Harrison, 1988).

Clastic deposits from what is more recently interpreted as basaltic *pyroclastic* eruptions have been recovered from all major oceanic settings: mid-ocean ridge (MOR), subduction arc, back-arc basin, and intraplate environments. Although explosive eruptions seem volumetrically minor compared to their effusive counterparts, in particular along MOR (Clague et al., 2009a), they too bear implications on the behavior of volatile phases within magmatic reservoirs and likely impact on the properties and evolution of the volcanic edifices. (This chapter focuses on basaltic volcanoes, due to their vast abundance on the seafloor. Key to their general eruption behavior is the low viscosity of basaltic magmas, opposing to the high viscosity common to rhyolitic systems.)

Classification and terminology of eruption styles and products

Explosive subaerial eruptions are often classified as one type of either steady activity, ranging from low-energy
Explosive Volcanism in the Deep Sea, Figure 2 Known locations of basaltic explosive volcanism in the deep sea: (*1a*) Juan de Fuca Ridge, Axial Volcano and Vance Seamounts, (*1b*) Gorda Ridge and President Jackson Seamounts, (*2*) Taney Seamounts and Ben Seamount, (*3a, b*) East Pacific Rise, (*4*) Seamount Six, (*5*) Hawaii, (*6*) Gakkel Ridge, (*7*) Mid-Atlantic Ridge south of the Azores, (*8*) Sumisu basin, Izu-Bonin back-arc, (*9*) NW Rota-1, Mariana arc, (*10*) W-Mata, Lau back-arc basin. See text for references.

Hawaiian fire fountains to violent *ultra-Plinian* eruptions, or transient activity classified as *Strombolian* to *Vulcanian*. Discrete, short-lived burst events are characteristic for the latter, whereas steady eruptions display sustained ejection of fragmented magma-gas mixtures. Principally, the same categories can be applied to submarine explosive activity (Head and Wilson, 2003).

Explosive activity of basaltic low-viscosity systems is generally driven by expanding magmatic gas bubbles *(magmatic eruption)*. When ground or seawater is mingled with the magma prior to the eruption, rapid water-steam expansion drives extremely violent *phreato-* or *hydromagmatic* activity (cf. White et al., 2003). However, the vigorousness of phreatomagmatic events ceases rapidly at water depths beyond 100 m and should be strongly suppressed in the deep sea (Zimanowski and Büttner, 2003).

Magma fragmentation is at last responsible for the formation of the clasts observed in primary deposits. Fragmentation maybe magmatic, that is, due to the expansion of magmatic gas bubbles, caused by water-magma interaction or both. In either case, the term *pyroclastic* applies. (Various, slightly different definitions exists for the terminology of eruption products and deposits (cf., Fisher and Schmincke, 1984; Cas and Wright, 1987; White and Houghton, 2006).) More specifically, particles maybe referred to as *hydroclastic* if derived from the second mechanism. This does not equate to the term *hyaloclastic* that typically bears connotation to effusive activity when flowing lava is quenched in contact with water.

Occurrence

Pyroclastic deposits and explosive activity is documented at various MOR in the Pacific and Atlantic Ocean, near-ridge seamounts and intraplate seamounts on the Pacific Plate, as well as the Izu-Bonin-Mariana arc and Lau back-arc basin, Western Pacific Ocean (Figure 2) (e.g., Gill et al., 1990; Fouquet et al., 1998; Maicher et al., 2000; White et al., 2003 and chapters within; Davis and Clague, 2006; Chadwick, 2008; Sohn et al., 2008; Clague et al., 2009a and references within; Resing et al., 2011). This distribution of eruption sites is most certain strongly biased by, if not purely reflecting the pattern of scientific sampling surveys. In fact, the presence of pyroclastic fragments appears to be ubiquitous at most MOR (Clague et al., 2009a). MOR known for widespread pyroclastic deposits include the *East Pacific Rise*, the *Juan de Fuca Ridge*, the *Gorda Ridge*, the central *Mid-Atlantic Ridge*, and the *Gakkel Ridge*.

Explosive activity is thus documented, (1) over nearly the entire depth range of the worldwide MOR system, (2) for a wide array of spreading rates, and (3) for the entire range of MORB geochemical compositions. Individual eruptions at MOR are thought to be small in volume, depositing only a thin cover of pyroclasts onto the adjacent lava flows (Sohn et al., 2008).

More prominent pyroclastic deposits or clastic sections containing abundant pyroclastic fragments are known for many near-ridge seamounts. These often host one or multiple calderas (collapse craters) at their summit and volcaniclastic sections are frequently found as lithified
Explosive Volcanism in the Deep Sea, Figure 3 Common morphologies of basaltic deep-sea pyroclasts. (**a**) Angular fragments, (**b**) Limu o Pele, (**c**) Pele's hair, and (**d**) clasts with tube vesicles. Typical order of abundance: (**a**) > (**b**) >> (**c**), (**d**). Samples collected during dives T1009 and T1010 on Axial Seamount, by D. Clague at Monterey Bay Aquarium Research Institute.

units exposed within the caldera wall. Well-studied examples include the *Vance Seamount chain*, west of the Juan de Fuca ridge; the *President Jackson Seamounts*, west of the Gorda ridge; or *Seamount Six*, east to the Northern East Pacific Rise. The intraplate seamount *Loihi*, Hawaii, exhibits unconsolidated volcaniclastic sequences of several meters thickness, derived from Strombolian and Hawaiian activity (Clague et al., 2003a; Schipper et al., 2010). For wide parts of the deposits, the accumulation was found to be fairly rapid at an average rate of 0.37 cm/year (Clague, 2009).

Along the subduction zone of the Western Pacific Plate, submarine explosive activity is known for the Izu-Bonin-Mariana arc and the Lau back-arc basin. Explosive submarine activity in this setting has been recognized as early as 1990 (Gill et al., 1990) and directly observed at *NW Rota-1*, Mariana arc (Chadwick, 2008), and *West Mata*, Lau Basin (Resing et al., 2011) – the first deep-sea eruptions ever to be witnessed by eye. Detailed mapping of the morphology and structure of the volcanic terrain and deposits in the Lau back-arc basin suggests pyroclastic eruptions to be a prevalent phenomenon in this environment rather than the exception.

Eruption products

Produced fragments are often glassy and of low microlite content due to fast quenching. A core of morphological characteristics is common to many pyroclastic glasses in the deep sea and can be used for a rough subdivision as illustrated in Figure 3.

1. *Angular, blocky* clasts (Figure 3a), with sharp edges. This is the most abundant form, at MOR typically dense, and stronger vesiculated in seamount deposits. The dense character may appear counterintuitive for explosively derived deposits, but is consistent with the inferred eruption conditions (see below).
2. *Limu o Pele* (Figure 3b). Thin rapidly quenched melt films, largely described as broken bubble walls. They come in manifold morphologies, ranging from platy to bended and complexly folded varieties, with thicknesses usually between 10 and 200 μm. Limu o Pele is typically seen as a characteristic clast form indicative of explosive activity of low-viscosity magmas.
3. A minor component of fragments may be present as fluidal forms like *Pele's hair* or small *ribbons* (Figure 3c).

4. Fragments with prominent *tubular vesicles* loosely resembling tube pumice (Figure 3d).
5. Various *lithics* ranging from basaltic rock clasts to mineral fragments from a hydrothermal stockwerk may occur.

Deep-sea pyroclastic deposits are in tendency finer grained than subaerial Strombolian deposits. Although larger fragments and spatter are known, grain sizes typically range between <63 μm and 2–4 mm. This is diagnostic of increased fragmentation efficiency.

General eruption mechanism

Although much if not most about the nature of explosive submarine eruptions is still puzzling, a general and simplistic view may be described by the following: Hydromagmatic activity is largely ruled out as the main force to trigger fragmentation and formation of pyroclastic deposits, in particular as the violence of water-magma interaction diminishes with increasing water pressure (cf. Zimanowski and Büttner, 2003). Instead the volcaniclastic record is often considered to represent explosive volcanic activity and magma fragmentation driven primarily by exsolved magmatic gas. Further fragmentation due to rapid quenching upon contact with seawater is thought to reduce the primary clast size (Potuzak et al., 2008; Helo et al., 2013).

At MOR, pyroclastic eruptions are widely envisioned to occur as Strombolian bubble bursts accompanying effusive activity. In exceptional cases, more energetic eruptions and fragmentation levels deeper within the conduit seem possible. The extent of pyroclastic discharge has been proposed to depend broadly on the rise rate of the magma within the conduit. Sheet lavas forming under high extrusion rates have been associated with intensive formation of pyroclastic fragments, whereas the opposite appears to hold true for the slow extrusion of pillow lavas. Direct observations at *NW Rota-1* and *W-Mata* (Figure 1) have confirmed both the transient eruption character, i.e., discrete eruption pulses, and the coeval occurrence of explosive and effusive activity. The eruptive events at *NW Rota-1* were Strombolian in style and characterized by the repeated ascent of gas-rich pockets. This gave rise to a cycle of individual eruptive bursts sustained for several minutes with short response intervals (Chadwick et al., 2008). Explosive activity on *W-Mata* ranges from lava fountaining to bubble bursting and vigorous active degassing. Its eruptions produced a variety of Limu o Pele and Pele's hair (Clague et al., 2009b).

After fragmentation, pyroclasts may be entrained into an eruption plume that mainly rises by thermal buoyancy (Deardorff et al., 2011). Constraints on how effective the entrainment of clasts into a rising plume aids to their dispersal are still poor. Field observations and modeling suggest that small Limu o Pele might advect up to few hundreds of meters within buoyant plumes and can be dispersed up to a few kilometers from the vent (e.g., Barreyre et al., 2011).

Role of magmatic volatiles

The principle role of volatiles is to form gas bubbles that drive the eruption and ultimately cause fragmentation. Formation of bubbles typically happens when magma rises from deep, high-pressure levels to shallow, low-pressure levels. Since volatile solubility decreases as pressure is reduced, the concentration of one or more volatile compounds will at some point exceed the solubility and starts to exsolve.

At MOR, CO_2 is the crucial volatile to drive explosive eruptions (Clague et al., 2003b; Helo et al., 2011; Pontbriand et al., 2012). Due to its low solubility (e.g., Dixon et al., 1995; Newman and Lowenstern, 2002; Papale et al., 2006; Witham et al., 2012), it starts exsolving from the magma at early stages during the ascent from the mantle into a shallow magmatic reservoir. This situation is broadly analogous to subaerial volcanoes. When the magma eventually starts to erupt from the shallow reservoir, the two cases differ. Under subaerial pressure condition, vigorous exsolution of various volatiles and fast bubble growth is characteristic for this stage, while high ambient water pressure at the seafloor hampers syn-eruptive CO_2 and H_2O exsolution (Shaw et al., 2010; Helo et al., 2011). Eruptions are then merely driven by gas bubbles that formed in the magmatic reservoir prior to the onset of eruption. This is the key to resolve the apparent paradox of dense pyroclasts forming during explosive activity: at the onset of eruption, the free gas phase already present becomes concentrated in larger potentially coalesced bubbles rising in the conduit, with the interstitial melt remaining fairly dense as only marginal amounts of new bubbles grow at this point. In the pyroclastic record, the interstitial dense melt is then represented by angular clasts, while Limu o Pele fragments represent remnants of the larger pockets of bubbles. The bulk vesicularity (effectively the large bubbles) becomes thereby completely obscured in the deposits.

Magmatic H_2O is considerably more soluble in basaltic melts (cf. Moore, 2008) than CO_2. Exsolution of H_2O therefore requires very low pressure and/or a high amount of H_2O dissolved in the magma. Consequently magmatic H_2O qualifies as a driving force for submarine explosive eruptions merely at volcanic settings with sufficiently high concentrations of dissolved H_2O (e.g., Schipper et al., 2010).

The initial volatile budget of many deep-sea volcanic systems, in particular MOR, may be too low or just adequate to drive efficiently explosive activity at the given water depth (Head and Wilson, 2003; Shaw et al., 2010). This obstacle is solved effectively when magmatic foam collapse models are invoked (e.g., Vergniolle and Jaupart, 1990). Magmatic gas that exsolves from magma arriving in the reservoir progressively accumulates at the top section of the magma body. This way, a high degree of vesicularity can build up, culminate in a sudden collapse of the foam, and trigger explosive activity. Hence, the capacity to erupt explosively becomes less dependent on the intrinsic

volatile content but rather on the potential to sequester gas bubbles within the shallow reservoir. Such mechanisms have been argued for to facilitate deep-sea explosive activity, specifically at MOR systems (e.g., Clague et al., 2009a; Helo et al., 2011; Pontbriand et al., 2012).

Concluding remarks

Deep-sea volcanoes in all principle oceanic settings display the capability to erupt explosively. Volcanism in this environment is therefore more vigorous than previously thought. Notably, this includes MOR, the most volatile-poor, but in total the most productive volcanoes on Earth. Many of the observed features and relationships that led to our current concept of explosive deep-sea volcanism are still based on a limited number of cases, and much remains unknown about the nature of submarine explosive eruptions and the phenomenon is still enigmatic.

EXPORT PRODUCTION

Introduction

Export production (EP) is the fraction of organic carbon formed by primary production in the photic zone (photosynthesis) that is not degraded before it sinks below 100–150 m. Typically, EP is measured in units of carbon due to its importance for the ocean's biological carbon pump. Under steady-state conditions and on longer time-scales (years), EP is assumed to be in proportion to the part of primary production that is fed by upwelled nitrate (Eppley and Peterson, 1979), named new production (Dugdale and Goering, 1967). A fraction of EP is then transferred to the deeper ocean (below 1,000 m) and only less than 1 % of the primary produced organic carbon is finally stored in the sediment. This transfer of organic matter from surface waters to the deep sea is known as the biological pump (Neuer et al., 2014). The final sequestration of organic carbon in the sediments, which stores CO_2 from the upper ocean and atmosphere over longer timescales ($>1,000$ years), is controlled by the strength of the biological pump.

Primary production, export production, and deep ocean flux

EP generally mirrors surface distribution of phytoplankton standing stock and primary production. Usually, this fraction is below 25 % but can be higher in coastal upwelling systems and areas with pulsed production such as the polar environments. Primary production and export production are low in the so-called ocean deserts such as the great oligotrophic gyres. Often sediment traps are used to measure flux and flux attenuation in the deeper water column. Typically, the flux attenuation is described by a power function with high attenuation at shallow depths (Suess, 1980).

Aggregation, marine snow, and fecal pellets

Particles of a few μm in size are not able to sink and constitute the sediment. Therefore, the EP (export flux) mainly consists of larger particles that are formed in the surface waters by physical and biological processes such as coagulation and collision (marine snow) and feeding activity by zooplankton (fecal pellets). Marine snow and fecal pellets consist of organic matter from living and dead organisms and of mineral particles produced both biogenic and non-biogenic. The minerals act as ballast for larger particles and may enhance their settling velocities (Iversen and Ploug, 2010), which have an important influence on the strength of the biological pump.

Sediment traps

Sediment traps collect sinking particles over time and area at a certain water depth, mostly around 1,000 m. The collected material is used to estimate vertical fluxes of organic carbon and other components such as carbonate, biogenic opal, or minerals (Buesseler et al., 2007). Sediment traps can be anchored to the seafloor and have multiple time-controlled collectors to reveal annual patterns of particle sedimentation/flux with a temporal resolution of a few weeks. Alternatively, sediment traps can also drift freely with the water body. These drifting traps sample sinking particles in the upper few hundred meters (export production/flux) over hours to days. Recently, drifting traps have been equipped with gels to collect intact marine snow particles or fecal pellets. Often these particles fall apart when collected with conventional sediment traps.

FAULT-PLANE SOLUTIONS OF EARTHQUAKES

Wolfgang Frisch
Department of Geosciences, University of Tübingen,
Tübingen, Germany

Definition

Earthquakes are caused by ruptures (faults) in solid rock with instantaneous movement, during which seismic body waves are emanated by elastic rebound. By evaluation of the seismic waves, the focus (location) of the earthquake, the spatial orientation of the fault plane, and the mode of movement can be determined. The result is called "fault-plane solution."

Fault-plane solutions

The orientation of planes of movement at plate boundaries or within any block of solid rock can be deduced from earthquake data. In the case of an earthquake triggered at a fault plane, the two blocks move by creating an instantaneous offset up to several meters. This results in the generation of the two types of seismic body waves. Primary (P-) waves oscillate in the longitudinal direction of propagation. They are faster than secondary (S-) waves that oscillate transversally. If all of the seismic data from a given earthquake collected around the Earth are put into a diagram, four quadrants and the two separating planes (Figure 1) can be determined with their spatial orientation. In the two quadrants that are in the direction of movement of each block, the first motion of the primary waves is away from the earthquake focus, and an observer on the Earth's surface first receives a push; the wave starts with a compressive movement (compressive first motion shown as black quadrants in Figure 1). First motion in the other two quadrants, shown in white, is in the opposite direction; it starts with a tension and is dilatational. Each of these motions is registered by seismographs.

One of the separating planes represents the slip plane generated by the earthquake; the other one is an aiding plane that has no use in nature. However, initially it is not possible to decide which one of these two planes was the slip plane (Figure 2). Commonly, this can be deduced from geological observations if the approximate orientation of a fracture zone is known. On the other hand, careful analysis of seismic data generated by the aftershock activity following every large earthquake provides the opportunity to identify the slip plane because of the shift of the seismic centers. If the slip plane is known, the sense of movement is easily detected (Figure 2). Direction of movement in the slip plane is orthogonal to the aiding plane. A process similar to that used for analyzing P-waves can also be used for the analysis of S-waves.

Conclusions

Using this method, which is called fault-plane solution, the orientation of a slip plane and the sense of movement can be determined with high accuracy. Fault-plane solutions allow for a reconstruction of plate boundaries and their movement patterns. The analysis of earthquake first motion data impressively confirmed the concept of three different types of plate boundaries.
Fault-Plane Solutions of Earthquakes, Figure 1 Principle of fault-plane solutions of an earthquake hypocenter. The fault plane of the earthquake (orthogonal to the paper plane) and an orthogonal virtual aiding plane define four quadrants. First motions of the primary waves oscillating in the propagation direction and expressed by vertical motions in the soil indicate the sense of movement of the blocks displaced during the earthquake. Seismograms subdivide two quadrants with compressive and two quadrants with dilatative first motion.
Fault-Plane Solutions of Earthquakes, Figure 2 Ambiguity of fault-plane solutions illustrated by an earthquake that produces an overthrust. Illustration is a schematic vertical section through the Earth.

Copenhagen, Denmark

Definition

Fjords are defined as deep, elongated arms of the sea that have been (or are presently being) excavated or modified by land-based glaciers (Syvitski et al., 1987).

Summary

The term "fjord" has its origin in the Old Norse word "fjorthr" which also included freshwater lakes. However, according to above definition, we will deal here exclusively with deep, semi-enclosed coastal inlets that generally are long relative to their width. Globally, almost all fjords are found at higher latitude, i.e., north of 43° and south of 42°. The longest (>200 km) fjords are Scoresby Sund, East Greenland, and Sognefjord in Norway. The inland termination and seaward opening of the fjord are referred to as head and mouth, respectively. Fjord topography is often characterized by one or more submarine sills representing relict moraines or bedrock ridges. Sediments from fjord basins may provide high-resolution records of both marine and terrestrial environmental changes (Gilbert, 2000), with maximum accumulation rates amounting to more than 1 m per year (Syvitski and Farrow, 1989). Sedimentation patterns in the fjord are controlled by glacial and fluvial conditions, topography, sea-level, and hydrography of coastal waters (Syvitski et al., 1987). Usually, an estuarine circulation regime with a

saline, occasionally poorly oxygenated deep layer and a low-salinity surface layer marks the hydrography. In fjords where a tidewater glacier is present, turbid meltwater from beneath the glacier rises as a plume into the surface layer, where flocculation of silt and clay particles leads to settling of these fine-grained particles contributing to the bulk mass of the fjord deposits (Mugford and Dowdeswell, 2011). Lamination may occur due to the effect of seasonal melting on the depositional process. These fine-grained sediments do, however, often display intervals with coarser ice-rafted debris which may reflect changes in iceberg calving activity of the local glacier (Andresen et al., 2012). A common feature of fjord basins with a high sediment input is a wide variety of slope failures along side-wall margins or basement highs and frequent occurrence of turbidites and mass-flow deposits in the adjacent basin. This slope instability implies a potential geohazard risk in the form of a local tsunami.

Synonyms

Benthic foraminifera; Benthic foraminifers; Informally benthic forams

Definition

Benthic foraminifera are unicellular, aquatic (marine and brackish) eukaryotic organisms. They are benthic bottom dwellers characterized by high diversity and abundance. In benthic foraminifera, the cytoplasmic body is encased in organic or mineralized test (shell), which provides a fossil record (Cambrian to recent). Due to the presence of the test, benthic foraminifera are useful indicators of past and present-day environmental changes. Foraminiferal shells consist of single or multiple chambers interconnected with each other by a channel, called *foramen*, which gives the name to the entire Foraminifera group.

Introduction

One of the first findings on benthic foraminifera dates back to the seventeenth century, and a drawing by Antonie van Leeuwenhoek of a specimen nowadays recognized as the genus *Elphidium*. Following numerous studies by, e.g., A. d'Orbigny (1826), H.B. Brady, J.A Cushman and A. R. Loeblich, and Jr. H. Tappan made a substantial contribution to foraminiferal research (Sen Gupta, 1999a). These and subsequent investigations resulted in benthic foraminiferal classification system consisting of 16 orders, Allogromiida, Astrorhizida, Litoulida, Trochamminida, Textulariida, Fusulinida, Miliolida, Carterinida, Spirillinida, Lagenida, Rotaliida, Buliminida, Globigerinida, Involutinida, Robertinida, and Silicoloculinida (Loeblich and Tappan, 1988), which have been recently placed in 3 to 4 major classes (Pawlowski et al., 2013; Mikhalevich, 2013). Based on shell morphology, about 5 000 modern and 40 000 fossil species are described (Sen Gupta, 1999). Recent molecular studies reveal a much higher genetic diversity due to numerous cryptic species and genetically distinctive phylotypes (Pawlowski et al., 2014).

Morphology and taxonomy

Foraminifera belong to the kingdom Protista because their body consists of a single cell filled with cytoplasm. Cellular structures include mitochondria, vacuoles, and nuclei placed in a cytoplasmic body and encased in a shell (test). Foraminiferal shells can be calcareous
Foraminifers (Benthic), Figure 1 Scanning electronic microscope images of selected benthic foraminifera: 1, *Reophax sp.* with a shell of *Cassidulina laevigata* (arrow); 2, *Elphidium excavatum*; 3, *Lagena sulcata*; 4, *Bolivinellina pseudopunctata*; 5, *Melonis barleeanus*, 6a,b, *Ammonia* sp. (a, spiral side; b, umbilical side); 7, *Eggerelloides scaber*; 8, *Pyrgo williamsoni*.

(precipitated $CaCO_3$), arenaceous (built of sediment particles), or organic (made of tectin).

Calcareous forms (Figure 1: 2–6, 8) are the most abundant, due to their greater diversity and better potential for preservation. The calcareous test wall is divided into two main types: porcellaneous (e.g., suborder Miliolina), which are milky to white in color, translucent to opaque under light, and with no pores (Figure 1: 8), and hyaline (e.g., Rotaliina), which are transparent with a glassy, shiny appearance and always contain pores (Figure 1: 2, 4–6) (Murray, 1979).

Agglutinated forms (e.g., order Astrorhizida) have an organic membrane to which they glue foreign particles – mineral grains (e.g., quartz, rutile), volcanic ash, or biogenic debris (e.g., sponge spicules, foraminifera, diatoms, coccoliths) with an organic and/or calcareous cement (Kuhnt et al., 2005; Thomsen and Rasmussen, 2008). Test surfaces are smooth to very rough and often irregular (Figure 1: 1, 7) and brownish in color and may be brittle and fragile, causing difficulties in taxonomic identification of some species (Schröder, 1988).

The organic-walled foraminifera (e.g., order Allogromida) secrete an organic membrane made of tectin. Their soft and elastic body readily changes in shape but has low or no fossilization potential.

Test size depends largely on environmental conditions prevailing during growth and ranges from < 0.01 mm in very small individuals to several centimeters (in tropical latitudes). Larger benthic foraminifera (e.g., *Nummulites gizehensis*) are often disc-shaped, contain many chambers and can grow up to 15 cm, being still a single-celled organism.

The generally accepted classification of benthic foraminifera is based on characteristic test morphologies (morphotypes). While more recent molecular studies have added greater detail to taxonomic classifications (e.g., Pawlowski et al., 2013), we focus on the morphological aspects here.

Enormous diversity of test appearance allows foraminiferal classification from the order, family, or genus level to the species level, frequently including several morphotypes. Tests of benthic foraminifera consisting of a single chamber are called *unilocular* (Figure 1: 3); of two chambers, *bilocular*; or of several chambers, *multilocular* (Figure 1: 2, 4–8). While unilocular species grow by increasing the single chamber size, multilocular individuals grow by adding new chambers. The addition of new chambers usually occurs according to a well-defined pattern: uniserial, whereby chambers are added linearly (e.g., *Reophax*); biserial (Figure 1: 4) or triserial (Figure 1: 7), where chambers are added in two or three

parallel series (e.g., *Bolivina* or *Eggerelloides*); and coiled (e.g., *Elphidium, Ammonia*). Coiling also follows strict patterns as each chamber is added in a spiral – either planispiral when chambers are added along a single plane (e.g., *Haynesina, Elphidium*) (Figure 1: 2, 5) or trochospiral when chambers spiral along more than one plane, up into a spire (e.g., *Ammonia, Trochammina)* (Figure 1: 6a, b).

The aperture (opening in the shell) can assume a variety of shapes, positions, and forms and may include additional structures such as teeth, tubercles, and flaps.

Taxonomically important are also other shell features such as the shell margin (e.g., keeled or rounded) and surface ornamentation (e.g., bosses, costae, ridges, sutures). For more detailed descriptions of shell morphology, see Boltovskoy and Wright (1976) and Haynes (1981).

Biology
Pseudopodia: The foraminiferal shell functions as protection for the soft internal body. Cell interaction with the external environment occurs via extensions of cytoplasm called *granuloreticulopodia (pseudopodia)*, which extend from the test through the aperture. Granuloreticulopodia branch, creating a network around the test, and carry out many of the fundamental biological functions in foraminifera. They take part in growth, reproduction, respiration, metabolism, test construction, locomotion, feeding, and protection.

Trophic relationships: Benthic foraminifera have various feeding strategies including symbiosis (e.g., *Alveolinidae*), parasitism (e.g., *Hyrrokkin sarcophaga*), suspension, and deposit feeding (e.g., *Ammotium cassis, Elphidium* spp.) (Pawlowski, 2012). Foraminiferal diets may include diatoms, dinoflagellates, macroalgae, organic detritus, and bacteria. Some species are carnivorous and ingest small copepods, shrimp larvae, and even other foraminifera (cannibalism). For some, the sediment surface provides a sufficient amount of nourishment, while other species dig into the sediment to find food. During feeding, pseudopodia build a feeding cyst surrounding the shell and provide a safe space for extra- or intracellular digestion (Murray, 1979). Pseudopodia often collect food and transport it toward the aperture and inside the cell. In addition, some carnivorous species use pseudopodia to catch prey and/or keep it in the net (e.g., *Astrammina rara*).

Locomotion: Some benthic foraminifera live attached to the seabed by extending pseudopodia to anchor themselves to pebbles, macrophytes, mussel shells, or worm tubes, thereby avoiding displacement by water masses. Pseudopodia are also used to burrow into the sediments to avoid predation or destruction and to change location to find better food sources.

Growth and Reproduction: During growth, pseudopodia build a growing cyst, outlining a new chamber frame and creating the base for calcification in calcareous group and for gathering and attaching foreign particles to in agglutinated group (Haynes, 1981). Benthic species follow a great variety of reproductive models, among which a

life cycle with two (sexual and asexual) generations is well understood and described (Goldstein, 1999).

Ecology and geographic distribution
Though benthic foraminifera mainly occur in marine habitats, some families (e.g., Allogromidae and Lagenidae) have been reported in freshwater or even terrestrial environments (Pawlowski, 2012). Benthic foraminifera interact with other components of meio- and macrofauna and are influenced by a combination of abiotic and biotic factors. Abiotic factors include temperature, salinity, currents, light, dissolved oxygen, nutrients, pH, trace elements, and substrate. Interaction with other organisms, e.g., competition for space and food, symbiosis, grazing, and parasitism, constitutes biotic factors (Murray, 2006). Some species are more sensitive to ecological factors and prefer narrow factor ranges, while others have wider tolerance limits (Murray, 1991).

On the global scale, water depth, temperature, and salinity are, perhaps, the leading factors determining distribution, diversity, and abundance of benthic foraminifera (Boltovskoy and Wright, 1976).

The distribution of foraminifera within the water column is controlled by seawater saturation with respect to $CaCO_3$. Occurrence of calcareous assemblages at deepsea settings depends on the carbonate compensation depth (CCD). The CCD in the central Pacific occurs between 4000–5000 m, while in the Atlantic Ocean, it lies deeper at around 5000–6000 m (Boltovskoy and Wright, 1976). Thus, ocean depths located above the CCD are characterized by a highly diverse and rich calcareous benthic fauna. However, with increasing water depth, calcareous foraminifera decrease in abundance and disappear. Simultaneously, an increase in proportion of agglutinated and organic-walled taxa takes place. Surface ocean waters are generally saturated with $CaCO_3$; however, lower temperatures and higher atmospheric CO_2 may cause $CaCO_3$ dissolution in shallow areas at high latitudes, resulting in rich agglutinated and organic-walled assemblages. Consequently, sediments from the Antarctic shelf (e.g., Weddell and Ross Sea) where the CCD lies at 400-500 m water depth are carbonate impoverished. However, there are a few calcareous species adapted to such extreme conditions, e.g., *Nuttallides umboniferus* (Murray, 2006).

Salinity is of great importance to foraminifera in general. While planktonic species are more sensitive to salinity changes, most benthic foraminifera have broad salinity tolerance ranges. Fully marine conditions (30–40 psu) favor many benthic species and promote their reproduction, survival, and growth. Therefore, open oceans have rich and well-preserved benthic foraminiferal assemblages. In environments with salinities <30 psu, foraminiferal reproduction decreases (Bradshaw, 1955; Bradshaw, 1957) and tests have thinner walls, often loose ornamentation, and become reduced in size or deformed (e.g., Almogi-Labin et al., 1992; Stouff et al., 1999; Polovodova and Schönfeld, 2008).

Coastal habitats with brackish waters often host benthic foraminiferal species from the agglutinated *Trochammina*, *Jadammina*, and *Miliammina* and calcareous *Elphidium*, *Miliolidae*, and *Ammonia* genera (Boersma et al., 1998). In the brackish Baltic Sea, carbonate preservation is limited and foraminiferal assemblages are largely dominated by the calcareous *Elphidium* and *Ammonia* and agglutinated *Miliammina*, *Trochammina*, and *Reophax* genera. Intertidal-subtidal lagoons and estuaries often host foraminifera adapted to extreme daily salinity fluctuations from 35 to 0.5 psu (Murray, 2006). In the Mediterranean Sea, during dry seasons brackish lagoons become hypersaline but still hold foraminiferal species, which tolerate salinities of >45 psu (Murray, 2006).

Substrate determines foraminiferal microhabitats, and, based on substrate preferences, benthic foraminifera can be epifaunal (e.g., *Cibicidoides wuellerstorfi*) and shallow to deep infaunal (e.g., *Melonis barleeanum, Uvigerina peregrina, Globobulimina affinis, Chilostomella ovoidea*). Epifaunal species live at the sediment surface, while shallow and deep infaunal taxa dwell at 2–4 cm and below 4 cm in the sediments, respectively (Gooday, 2001).

Shell geochemistry

Calcareous benthic foraminifera incorporate aspects of the chemical elements prevailing in seawater as they precipitate their shells. Hence, these organisms record environmental information – being preserved as fossils serves as a signal carrier for climate and ocean changes taking place during their life cycle. This makes foraminifera important *paleoproxies* (indicators of past changes).

The pioneering work of Cesare Emiliani, using stable oxygen isotopes from planktonic foraminifera as a proxy for temperature change, fundamentally changed our view on past climates (Emiliani, 1955). This paleothermometer can be applied to benthic foraminifera: depending on bottom water temperatures and glacial-interglacial cycles, benthic foraminifera incorporate more or less ^{16}O or ^{18}O into their shells, in much the same way as planktonic species in the upper water column. Changes in $^{18}O/^{16}O$ ratios have been widely considered as indices of climate cycles during the Pleistocene and Quaternary (Ravelo and Hillaire-Marcel, 2007). Oxygen isotopic records also mirror ice volume fluctuations and, hence, allow estimation of past sea-level changes (Mix and Ruddiman, 1984; Shackleton, 1987). The application of oxygen isotopes improved our understanding of glacial-interglacial stages in the North Atlantic during the Pleistocene (Shackleton et al., 1988).

Another approach increasingly used in paleoclimate studies is magnesium/calcium ratios measured in foraminiferal shells. The Mg/Ca is used as a paleotemperature proxy and can be used to constrain the salinity and temperature components of the oxygen isotope records with respect to seawater (Kristjansdottir et al., 2007). The Mg/Ca ratios measured on benthic foraminifera proved

glacial-interglacial temperature shifts in the deep ocean during the Quaternary, as well as deep water mass temperature oscillations (Martin et al., 2002). Additionally, other trace element ratios (Cd/Ca and Ba/Ca) in benthic foraminiferal shells can be analysed to study seawater nutrient content (Lea, 1999).

Conclusions

Benthic foraminifera are an important component of marine habitats. Due to their high fossilization potential, worldwide occurrence, high abundances, high reproduction rates and rapid response to environmental changes, benthic foraminifera are used in numerous studies from biostratigraphy and reconstructions of past climate, ocean and sea-level changes, to bio-monitoring and ocean acidification (Horton et al., 1999; Murray, 2006; Schönfeld et al., 2012; Haynert et al., 2012; Dolven et al., 2013). The uniformitarian principle "the present is a key to the past" has been widely applied in paleoenvironmental interpretations based on foraminiferal assemblages, with reference to their present ecological preferences. These marine organisms show enormous potential - providing interdisciplinary knowledge linking biology, geosciences and industry. This potential will undoubtedly expand to other subjects in years to come.

Synonyms

Planktic foraminifers; Planktonic foraminifera; Planktonic foraminifers

Definition

Planktonic foraminifers (from the Latin "foramen," hole or orifice, and "ferre," to bear) are exclusively marine, open-ocean, single-celled, eukaryotic protists that secrete a multichambered calcitic shell. The group comprises 45–50 living morphospecies, but the actual number of genetically different forms is probably much higher. They inhabit all latitudes, chiefly above 100 m water depth. Planktonic foraminifers are very important in the biogeochemistry of calcite in the oceans. Their rich fossil record
Foraminifers (Planktonic), Figure 1 Examples of representative foraminiferal morphospecies. Notice that *Globigerina falconensis*, *Orbulina universa*, *Globigerinoides ruber*, *Globigerinoides conglobatus*, and *Sphaeroidinella dehiscens* are spinose species (like *Globigerinoides sacculifer*), but spines are usually absent in specimens retrieved from bottom sediments (like most of those figured here). Scale bar equals 50 μm. *G. sacculifer* is from Bé (1968); all others are from Kemle-von Mücke and Hemleben (1999).

is widely used for stratigraphic and paleoenvironmental studies.

Shell and cell

All planktonic foraminifers build shells (up to 1.5 mm, mean around 0.3 mm in size) composed of mostly more or less globular chambers arranged in a streptospiral (where each chamber is half a whorl), planispiral (coiled in a single horizontal plane), trochospiral (helical), or, very rarely, triserial coil. An exception is the genus *Orbulina*, which builds a complete sphere around a small trochospiral test which may be resorbed prior to gametogenesis (Figure 1). Biserial arrangement of chambers is present in some fossil species. The shell is made of calcium carbonate (CO_3Ca) with hexagonal crystals (calcite), usually formed by the addition of lamellae separated by organic material. The outer lamella of successive chambers may also cover previous chambers, in which case, the wall of earlier parts of the test becomes considerably thicker. In most species, prior to gametogenesis the test is covered with a more or less continuous additional calcite layer with coarse crystalline structure. Calcite comprises around 80–90 % of the shell material, the remaining being represented by $MgCO_3$, $FeCO_3$, SiO_2, Sr, and several amino acids (Boltovskoy and Wright, 1976; Hemleben et al., 1989). The shell wall comprises poreless areas (such as the keel), but most of it is perforated by pores, which are obliterated by an organic, sometimes porous, layer in living specimens. In some species the shell surface may bear pustules or a cancellate, honeycomb-like, ornamentation. Spinose species have long calcitic spines, circular, triangular, or three bladed in cross section, which are shed during gametogenesis.

The cytoplasm typically fills all shell chambers (occasionally the last chamber may be only partly filled) and also extends as a thin layer covering the shell surface, where it forms a dense array of very thin filopodia or reticulopodia. This outer layer may be foamy ("bubble capsule"), or finely reticulate, or smooth and sheathlike.

Organelles present in the cytoplasm comprise a single nucleus (usually in one of the inner chambers, with granular nucleoplasm and strands of chromatin and heterochromatin), small mitochondria, peroxisomes (involved in the synthesis of carbohydrates and metabolism of waste products), endoplasmic reticulum, Golgi complex, vacuoles (digestive, waste, etc.), and fibrillar bodies (which probably aid in flotation) (Hemleben et al., 1989). In addition to these, the cytoplasm contains various inclusions, such as lipid droplets and pigment granules.

Reproduction and growth

As opposed to benthic species, which show a range of reproductive modes, in planktonic foraminifers, the only process that has been observed to date is the release of thousands of very small (3–5 μm), free-swimming, biflagellate "swarmers," which fuse producing a zygote. Subsequently, this zygote grows into an adult individual (Hemleben et al., 1989).

Most of the spinose, symbiont-bearing species, as well as some non-spinose ones have a life span of 2–4 weeks and a lunar or semilunar cycle, reproducing at either full moon or new moon, while other non-spinose forms, in particular the deeper-living ones, seem to follow a yearly cycle (Kemle-von Mücke and Hemleben, 1999).

All planktonic Foraminifera perform ontogenetic vertical migrations. The deep-living species reproduce in

surface waters and then migrate to layers as deep as 1,000 m or more (Hemleben et al., 1989). Surface-dwelling species reproduce in the pycnocline or chlorophyll maximum layer, and the offspring migrate to more surficial waters.

Growth of the shell starts with a small spherical chamber ("proloculum") and the subsequent addition of progressively larger chambers around it (roughly at the rate of one chamber every 48 h; Hemleben et al., 1989). Successive stages (five, according to Brummer et al. (1987)) are characterized by marked morphological changes, including inflation of chambers, development of pores, and development of spine collars, ridges, secondary apertures, etc. Prior to reproduction, the shell wall thickens, spines are shed, and internal septa may disappear.

Trophic relationships

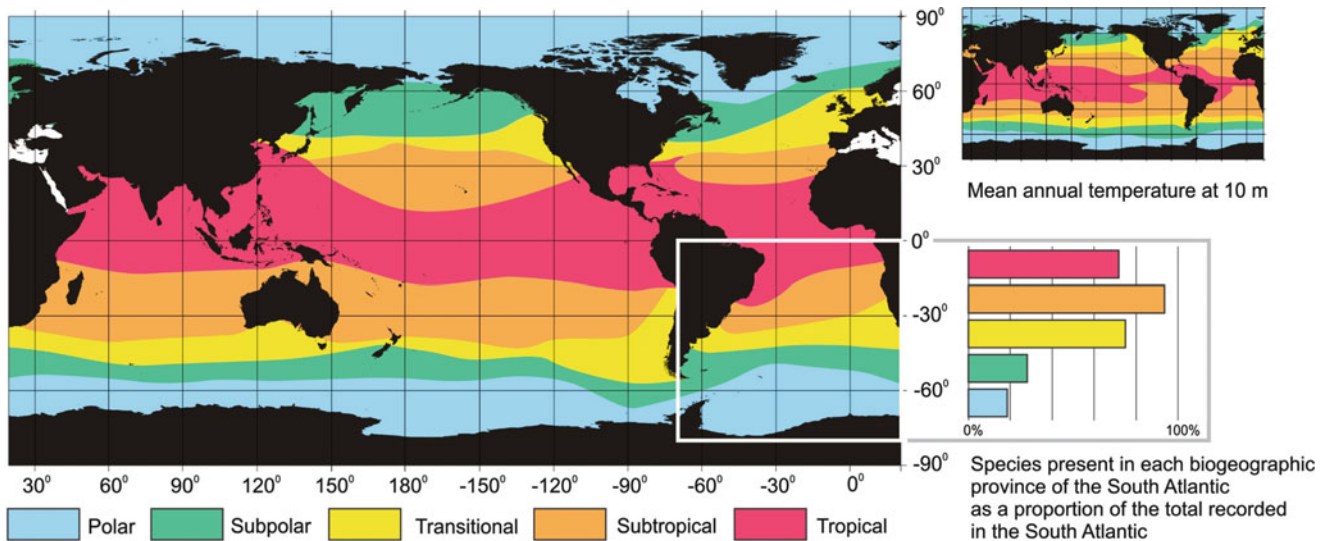
Most species are fairly omnivorous, feeding on a large spectrum of organisms including diatoms, dinoflagellates, coccolithophorids, radiolarians, ciliates, pteropods, various invertebrate larvae, copepods, etc. Cannibalism has been observed in non-spinose species, but not in spinose forms. Food items can be several times larger than the foraminifer itself. Spinose species tend to prefer animal prey, whereas non-spinose ones feed chiefly on phytoplankton. The prey is surrounded by the protist's rhizopodia which eventually engulf the organism and transfer ruptured pieces of its body to digestive vacuoles in the extra- or intrashell cytoplasm by protoplasmic streaming (Hemleben et al., 1989).

In addition to heterotrophic feeding, many planktonic foraminifers possess algal symbionts (dinoflagellates and chrysophytes) in their cytoplasm (Figure 2). Symbiotic algae are common in most (but not all) spinose species (where their presence often seems obligatory) and almost always absent in the non-spinose ones. These algae are normally located in the outer cell layer (where lighting is best), but have also been observed to perform diel migrations within the cell, withdrawing to the inner cytoplasm at night and dispersing around the periphery during the day (Bé et al., 1977). A single foraminifer may host as many as 10,000 symbiotic algae (Spero and Parker, 1985), which are either digested or released into the environment when the host reproduces (thus, offspring acquire their symbionts from the medium rather than from their parents). For the foraminifer, the advantages of this symbiotic relationship are the energy supply (either as free extracellular organic matter or when symbionts are digested by the host), enhancement of calcification, and intracellular elimination of host waste metabolites (Goldstein, 2003).

Taxonomy

During recent years, the taxonomy of most protists has undergone profound changes in association with the widespread use of molecular and biochemical data (e.g., rRNA gene sequences). A subject of particular interest has been
Foraminifers (Planktonic), Figure 2 Zooxanthellae (symbiotic algae) dispersed along the spines and rhizopodia of a specimen of *Globigerinoides ruber* (from Bé et al. (1977)).

the elucidation of phylogenetic relationships between higher-rank taxa, for which reason familiar and suprafamiliar assignments have changed repeatedly. According to Lee et al. (2000), planktonic foraminifers are distributed in two superfamilies and nine families included in the order Globigerinida of the class Foraminifera, phylum Granuloreticulosa. A few years later, Adl et al. (2005) placed the Foraminifera in the "supergroup" Rhizaria but refrained from further subdividing them because existing morphology-based schemes are not fully consistent with molecular phylogenetic data.

At the genus and species level, the classification of Foraminifera has traditionally been based on features of the test, such as spines, coiling, size and arrangement of chambers, ornamentation, etc. (see Hottinger, 2006, for a complete glossary of terms used in foraminiferal research). As opposed to other protozooplanktonic groups, like the radiolarians, the low diversity of planktonic Foraminifera and their comparatively large size have contributed toward developing a reasonably stable classification system. Most researchers recognize between 45 and 50 living morphospecies (Hemleben et al., 1989), although some stretch this number to 64 (Saito et al., 1981). Molecular data, which are presently available for a number of species, never suggest the need to lump existing morphospecies, but often indicate that traditional taxonomy has included several genetically different organisms under a single name (cryptic species). De Vargas et al. (2004) noticed that the eight morphological


Foraminifers (Planktonic), Figure 3 Major foraminiferal biogeographic provinces (slightly modified from Bé (1977)); notice resemblance with pattern of mean annual temperature at 10 m (based on data from Locarnini et al. (2006)); temperature intervals are <2 °C, 2–8 °C, 8–16 °C, 16–26 °C, and >26 °C. *Bar graph* at the *bottom right* shows numbers of foram species recorded in each biogeographic province in the South Atlantic (*highlighted* on main map), as a proportion of the overall total (39) for this area (based on data from Kemle-von Mücke and Hemleben (1999)).

species that have been genetically analyzed (DNA sequence coding for the small subunit and internal transcribed spacer of the nuclear ribosomal RNA genes) until that year contain between three and six distinct genetic entities ("sister species") each. Interestingly, upon closer examination, most of the new, genetically identified species within traditional morphological species turn out to show minor but recognizable morphological differences (De Vargas et al., 2004; Aurahs et al., 2009). It seems plausible that niche partitioning (driven by regional differences in food availability, salinity, temperature), rather than allopatric speciation through vicariance, is responsible for this diversification (Darling and Wade, 2008; Aurahs et al., 2009; Seears et al., 2012).

Geographic patterns of abundance and species composition

Data on the distribution patterns of living planktonic Foraminifera come from three sources: plankton tows, sediment traps, and surface sediment samples. Each has advantages and drawbacks. Plankton samples retrieve whole assemblages (unless the mesh size used is too large) unbiased by postmortem processes (see below), but the sample size is normally limited and the sample is but a snapshot representative of a very restricted time offset. Sediment traps are particularly suitable for investigating temporal cycles and sedimentation processes, but their yields are subject to several distorting mechanisms, such as lateral advection, selective dissolution, and fragmentation due to grazing. Surface sediment samples are by far the most widely available and used for biogeographic purposes, but as proxies of the distribution of the living

assemblages, they are also the most biased. The sedimentary remains of planktonic foraminifers can differ strongly from the corresponding planktonic assemblages due to a number of mechanisms, including selective dissolution of the less resistant shells (both on the way to the seafloor and after settling), reworking by bottom fauna, winnowing by bottom currents, lateral advection by subsurface and deep currents, submersion and extended survival of colder water forms under warmer water areas ("equatorward shadows"), fragmentation due to grazing, vertical integration of shallow- and deep-living species, different reproduction modes, and integration of seasonally dissimilar abundance patterns (Vincent and Berger, 1981; Boltovskoy, 1994; Schiebel and Hemleben, 2005). Many of these modifications tend to enhance the proportions of cold water species, resulting in assemblages indicative of colder waters than those overlying the corresponding sediments.

Despite these shortcomings, the worldwide biogeographic pattern originally proposed by Bé (1977), based chiefly on sedimentary samples, is the most widely accepted today and probably realistic in general terms (Figure 3).

As with most other zooplanktonic organisms, the two major attributes of foraminiferal distribution patterns respond to different constraints: species compositions depend mainly on temperature, whereas abundance depends on primary production. Within normal open-ocean values, other variables have little influence on foraminiferal biogeography. For example, planktonic Foraminifera are scarce or absent altogether in low- or high-salinity waters (i.e., below 30 and above 45 PSU: Boltovskoy and Wright, 1976; Hemleben et al., 1989),
Foraminifers (Planktonic), Figure 4 Vertical distribution of planktonic Foraminifera at three stations in the Sea of Japan in fall (from Kuroyanagi and Kawahata (2004)).

but within these values, the influence of salinity is rather limited (Hemleben et al., 1989; Bijma et al., 1990).

The worldwide biogeography of planktonic foraminifers is characterized by a system of latitudinally oriented belt-like provinces, punctuated by conspicuous north-south drifts where ocean currents distort the east-west orientation of isotherms (e.g., the Gulf Stream in the North Atlantic or the Humboldt Current in the South Pacific; Figure 3). The limits of these provinces are strikingly similar to near-surface isotherms (Figure 3), which reinforces the notion of the overwhelming importance of temperature for determining specific makeups. Each province is characterized by a particular combination of co-occurring species, but individual species ranges seldom coincide with province boundaries, so that specific ranges overlap extensively and species restricted to any one province are very few (normally below 10 % of those present anywhere in the province). Diversity drops conspicuously from the equator to the poles, but the highest numbers of species are often found in the subtropics (Figure 3). With a few exceptions, known morphospecies inhabit all three major oceans. Most species dwell in the surface waters, either during their entire life (all species of *Globigerinoides*, *Globigerina*) or as juveniles, while the adults migrate below 100 m (*Globigerinella adamsi*, *Sphaeroidinella dehiscens*, *Neogloboquadrina pachyderma*, etc.), but a number of forms are usually found at 50–100 m (*Globigerina bulloides*, *Hastigerina pelagica*, *Orbulina universa*, *Globigerinella siphonifera*, *Globigerina calida*, *Pulleniatina obliquiloculata*, *Neogloboquadrina dutertrei*, *Candeina nitida*, *Globigerina glutinata*, and others). Deep-water species (below 1,000 m) are *Hastigerinella digitata* and *Globorotalia truncatulinoides*.

Foraminiferal abundances normally range around 0.001 to >1 individual per L of water, with oligotrophic central oceanic gyres hosting the lowest densities and high-productivity upwelling regions the highest. Peak densities, however, have been recorded in sea-ice communities (ca. 500 individuals per L; Arnold and Parker, 2003). Although vertical abundance profiles depend on the vertical migrations (chiefly ontogenetic) which most species perform, normally they are characterized by peak abundances in the euphotic layer, around 10–50 m, and steeply decreasing values below this depth (Figure 4).

The annual flux of calcitic tests at 100 m water depth is around 1.3–3.2 Gt, which represents 23–56 % of the global, open marine $CaCO_3$ flux. Although much of the calcium carbonate dissolves before reaching the seafloor, the number of tests that do settle on the bottom is so high that the resulting carbonate oozes cover almost 50 % of the seafloor (Lisitzyn, 1974; Kennett, 1982; see "Deep-sea Sediments"), with remains of planktonic foraminifers largely dominating these deposits, especially in the open ocean. The distribution of this so-called *Globigerina* ooze, however, is uneven. Because the dissolution of calcite increases with depth (see "Carbonate Dissolution"), down to about 3,500 m (depending on ocean basin and area), preservation of foraminiferal tests is excellent or good; between this depth (known as the lysocline) and ca. 4,500 m, dissolution is considerably faster and preservation deteriorates rapidly. Below 4,500, which is known as the calcite compensation depth (see "Calcite Compensation Depth (CCD)"), the rate of supply of calcium carbonate is balanced by the rate of dissolution, so there is no net accumulation (Seibold and Berger, 1996).

Stratigraphic and paleoecologic applications

The geologic record of planktonic foraminifers dates back to the late Triassic or Jurassic (BouDagher-Fadel, 2012), becoming particularly abundant since the mid-Cretaceous. They have been used extensively for defining zonal stratigraphies from the upper Valanginian to the recent (Bolli et al., 1985), proving of great value for oil exploration purposes (see "Biochronology, Biostratigraphy").

Recent assemblages from the water column have been used in biogeographic surveys and as tracers of currents and water masses (e.g., Boltovskoy and Wright, 1976). Paleoceanographic studies with Foraminifera are based on several approaches (see "Paleoceanography" and "Paleoceanographic Proxies"). Past changes in the proportions of species as compared with present-day specific makeups (usually aided by more or less complex mathematical manipulations of the data, like the transfer function techniques proposed by Imbrie and Kipp (1971)) allow reconstructing past ecological and oceanographic settings (temperature, fronts, primary productivity; e.g., CLIMAP (1976)). Downcore changes in the relationship between right-coiling versus left-coiling specimens of some species (e.g., *Neogloboquadrina pachyderma*, whose proportions of right-coiling individuals increase with increasing temperature) have been used to reconstruct the water temperature at which these foraminifers lived. Right- versus left-coiling ratios, however, may also depend on other conditions (e.g., Thiede, 1971; Bolli et al., 1985). Stable isotopes of oxygen and carbon in foraminiferal tests are also used to determine shifts in the temperature, salinity, oxygen content, and fertility of the ocean over the past hundreds to millions of years (see Rohling and Cooke, 2003, for a review) (see "Carbon Isotopes" and "Oxygen Isotopes").

Conclusions

Planktonic foraminifers are among the most important marine microfossils. Their widespread occurrence and high abundances, their excellent stratigraphic record, and the comparatively good knowledge of their biology and ecology make them excellent tools for stratigraphic, paleoecologic, and biogeographic work. Their limited diversity and relatively stable taxonomy have been major advantages for their use as proxies of present and past oceanographic settings as well as for tackling distributional and evolutionary problems. However, recent changes in our understanding of the taxonomy of planktonic foraminifers brought about by molecular studies pose new challenges for the use of these protists in applied surveys.

GABBRO

Jürgen Koepke
Institute of Mineralogy, Leibniz University Hannover,
Hannover, Germany

Definition

Gabbro is a medium- to coarse-grained, mafic intrusive igneous rock, mostly grayish to greenish in color, and is the most abundant rock in the oceanic crust. Oceanic gabbros are mainly composed of three minerals: olivine, plagioclase, and clinopyroxene, sometimes associated with orthopyroxene, amphibole, and Fe-Ti oxides. They are formed in magma chambers (qv. "Mid-ocean Ridge Magmatism and Volcanism") under the mid-ocean ridges, where primitive MORB melts (mid-oceanic ridge basalt; qv. "mid-ocean ridge magmatism") differentiate by fractional crystallization. The accumulated minerals in dense crystal mushes and subsequent slow cooling lead to the formation of gabbros in the lower oceanic crust.

Introduction

Gabbro is the most common rock of the oceanic crust and forms its lower part (for review see Coogan, 2014). The name "gabbro" was suggested from the German geologist Leopold von Buch after a town in the Italian Tuscany region. Gabbros from the oceanic crust are named "oceanic gabbros" in order to distinguish them from gabbros from continents. Oceanic gabbros mostly consist of three minerals: forsterite-rich olivine, calcium-rich plagioclase feldspar (usually labradorite or bytownite), and clinopyroxene, which has the composition of augite. Orthopyroxene, amphibole, and Fe-Ti oxides might also occur, but only in small amounts, and usually crystallized late forming interstitial crystals.

Oceanic gabbros are regarded as the frozen crystal mushes accumulated during fractional crystallization of primitive MORB melts in the magma chambers under the mid-ocean ridges, forming – after subsequent cooling – the layer 3 of the oceanic crust (qv. "Layering of Oceanic Crust"). In contrast, the corresponding differentiated melts rise upward to erupt as sheeted dikes (layer 2b) or as basaltic sheet flows or pillow basalts (layer 2a).

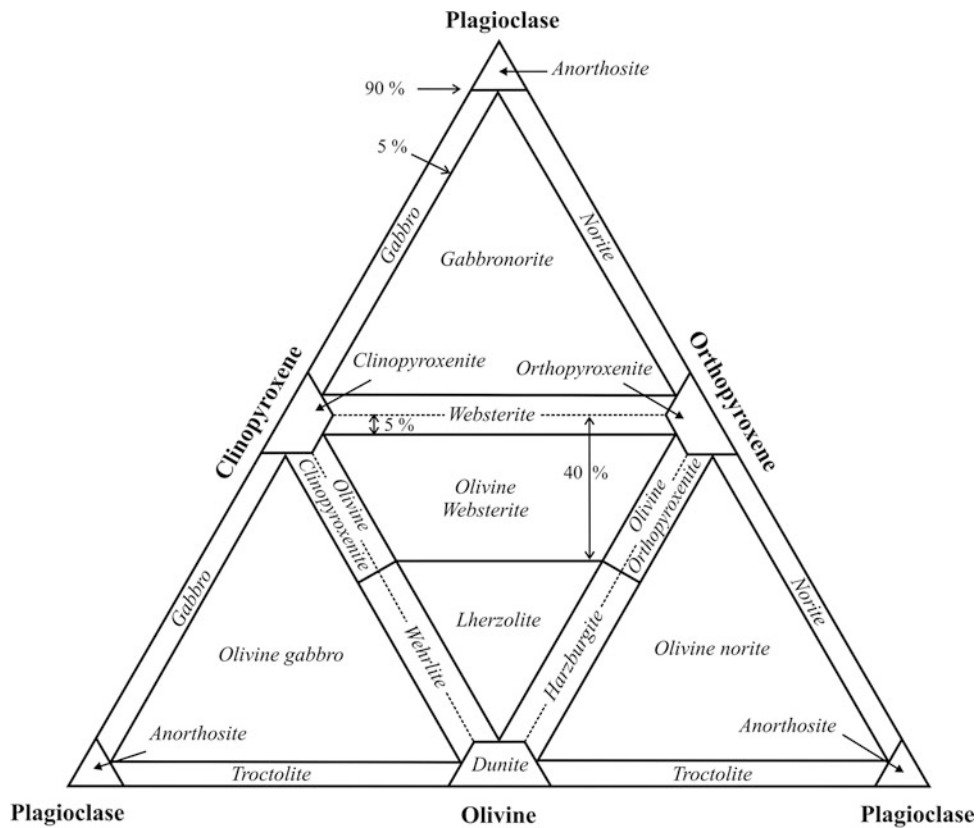
Owing to the scarcity of natural exposures of the deep gabbroic basement, especially from fast-spreading oceanic crust, complementary studies on ophiolites (qv. "Ophiolites") have helped establish models for the structure of the oceanic crust.

Classification of oceanic gabbros

Gabbroic rocks can be classified using the modal abundances of the constituent minerals olivine, plagioclase, clinopyroxene, and orthopyroxene, based on the International Union of Geological Sciences (IUGS) system shown in Figure 1 (Le Maitre, 1989). Figure 1 is composed of four individual triangular plots, the three outer ones define gabbroic rocks (or mafic plutonic rocks), while the inner triangle defines ultrabasic (or ultramafic) rocks. The presence of more than 5 vol% plagioclase in Figure 1 divides ultrabasic from gabbroic rocks. In addition to the major rock names given in Figure 1, the plutonic part of the oceanic crust may contain:

Diorite: in the IUGS classification, diorite is distinguished from gabbro by the anorthite content (An) of plagioclase. Diorites have plagioclase containing <50 mol% An, while gabbros have plagioclase containing >50 mol% An. The vast majority of oceanic gabbroic rocks are gabbros.

Oxide gabbros: gabbros with Fe-Ti oxides >2 vol%

Dolerite: is applied to fine- or medium-grained gabbroic rocks with dominant ophitic or subophitic textures


Gabbro, Figure 1 Modal classification scheme for mafic to ultramafic plutonic igneous rocks (after Le Maitre,1989).

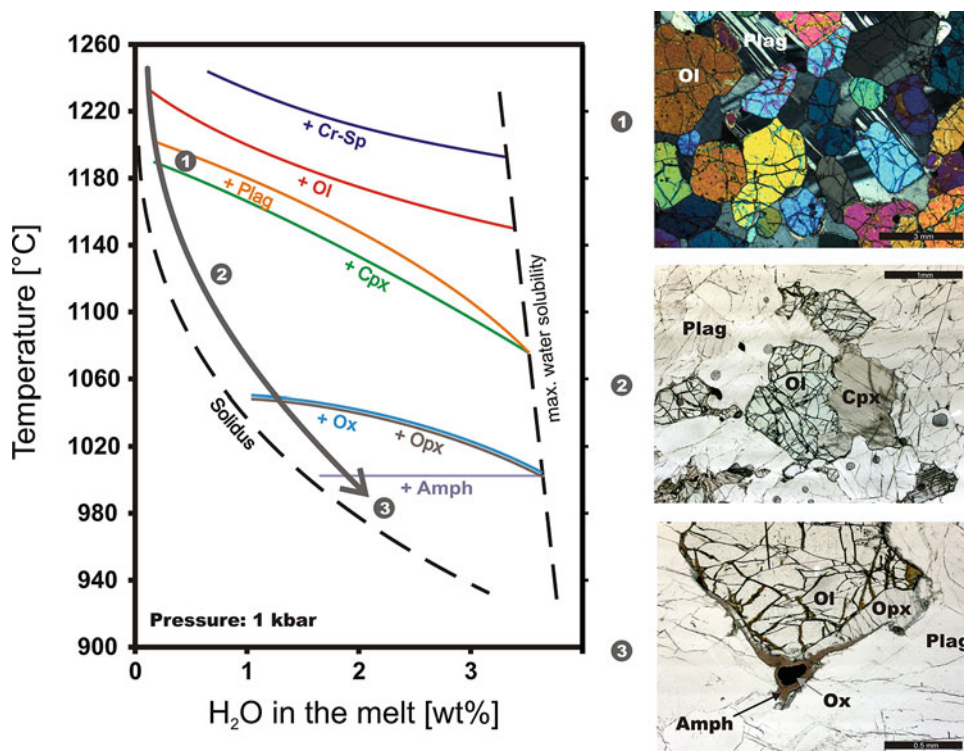
(larger clinopyroxene crystals enclose smaller plagioclase crystals).

Oceanic plagiogranite: the term "oceanic plagiogranite" is an often used field term for light-colored, felsic plutonic rocks within the oceanic crust (e.g., Coleman and Donato, 1979; Koepke et al., 2007), but its exact definition is often questioned. Its use is in accord with IUGS classification, defining the term "oceanic plagiogranite" as a "series of plutonic rocks of the oceanic crust consisting of plagioclase, ranging in composition from oligoclase to anorthite, quartz, and minor amounts of hornblende and pyroxene" (Le Maitre, 1989).

General characteristics of oceanic gabbros

Oceanic gabbros are cumulate (qv. "cumulate") rocks formed by accumulation of fractionated minerals during MORB differentiation in shallow magma chambers. Owing to the relatively slow cooling in the lower crust, these are mostly medium-grained (grain sizes, 1–5 mm) to coarse-grained (5–30 mm) rocks. Typical cooling rates for deeper gabbros from fast-spreading ridges (>500 m below the sheeted dike complex) are 100–10,000 °C per million years (between 1,000 °C and 600 °C, derived from Ca-in-olivine geospeedometry; for details see Coogan,

2014). Crystal settling in magma chambers results in monotonous equigranular, granular textures, mostly with subhedral major minerals such as prismatic olivine and clinopyroxene and tabular plagioclase in concordance with the formation as cumulate (see microphotographs in Figure 2).

Ophiolites show that deep gabbros from fast-spreading ridges exhibit a characteristic layering, which was recently confirmed by direct drilling into the lower crust of the fast-spreading East Pacific Rise (EPR) at Hess Deep (Gillis et al., 2014). A special gabbro type, so-called vari-textured gabbro, occurs at fast-spreading ridges at high level directly below the sheeted dike complex and is quite different in structure and appearance compared to the deeper cumulate gabbro. Vari-textured gabbros are highly heterogeneous, often showing domains with contrasting grain size and varying mode, frequently with poikilitic crystal growth and even pegmatitic growth (e.g., Coogan et al., 2002; Koepke et al., 2011). In contrast to the lower gabbros, which are regarded as cumulates, these gabbros are assumed to correspond more to frozen melts. Gabbros from slow-spreading ridges are in general isotropic and do not show any pronounced layering. A characteristic feature of gabbros from slow-spreading ridges is the abundant crystallization of a late, evolved melt producing


Gabbro, Figure 2 Phase diagram with temperature vs. water content in the melt for a primitive MORB and microphotographs of oceanic gabbros reflecting different stages of differentiation as indicated in the phase diagram. The phase diagram is for 1 kbar (corresponding to a crustal depths of ~3km), modified after Feig et al., (2006). The oxygen fugacity varies as a function of water content from QFM (corresponding to quartz-magnetite-fayalite oxygen buffer) for low water activities to QFM + 4 for high water activities. The phase boundaries correspond to the appearance (+) of the mineral phases. For details see Feig et al., (2006). The gray arrow corresponds to the evolution trend for MORB crystallization in typical shallow magma chambers, with numbers indicating specific stages of magma crystallization/evolution. The microphotographs show corresponding oceanic gabbros which crystallized at these stages. *1*: Early extensive crystallization of olivine and plagioclase leading to (spinel-bearing) troctolites. *2*: Main (cotectic) crystallization of olivine, plagioclase, and clinopyroxene leading to olivine gabbro. *3*: Late crystallization of orthopyroxene, amphibole and Fe-Ti oxide leading to interstitial growth between earlier phases formed during the main crystallization. Abbreviations: *Ol* olivine, *Cr-Sp* chromium-rich spinel, *Cpx* clinopyroxene, *Opx* orthopyroxene, *Plag* plagioclase, *Ox* Fe-Ti oxide, *Amph* amphibole. Samples: *1* troctolite from the Mid-Atlantic Ridge (MAR, 305-U1309D-248R-2, 7–9 cm; image from Expedition Scientific Party, 2005). *2* olivine gabbro from Southwest Indian Ridge (SWIR, 176-735B-166-R-2, 61–71 cm). *3* olivine gabbro from SWIR (176-735B-121-R-3, 65–75 cm). Microphotograph 1 under crossed, 2 and 3 under plane-polarized polars.

interstitial mineral assemblages composed of amphibole oxides, orthopyroxene ± apatite ± zircon.

Many oceanic gabbros show signs of deformation with specific characteristics for gabbros from fast- and from slow-spreading systems. Gabbros from fast-spreading ridges (including the gabbros from the Oman ophiolite) were deformed primarily in a partly molten regime as shown by the abundance of magmatic foliation. Subsequently, no or only minor sub-solidus crystal plastic deformation took place. In contrast, in gabbros from slow-spreading ridges, magmatic foliation is rare, but crystal plastic deformation in a melt-absent regime is common, indicated by the presence of high-temperature shear zones. These contrasting modes of deformation reflect significant differences in formation/emplacement of gabbros of the lower crust between fast- and slow-spreading ridges (see next chapter).

Gabbro accretion within the oceanic crust

In contrast to the upper oceanic crust, which consists generally of effusive MORBs, the structure, composition, mineralogy, and in situ physical properties of the lower gabbroic crust are poorly constrained. The mode of gabbro accretion (qv. "Crustal Accretion (incl. Gabbro Glacier Model)") is significantly different between fast- and slow-spreading ridges (qv. "Spreading Rates and Ridge Morphology").

At fast-spreading ridges, seismic tomography revealed that much of the lower oceanic crust represents a crystal mush and that a melt lens tens of meters thick exists near the top of the lower crust (e.g., Detrick et al., 1987). Conceptual models for the formation of the deep, fast-spread crust include the "gabbro-glacier" model (e.g., Phipps Morgan and Chen, 1993), where the lower crust is formed in the melt lens, and the "sheeted sill" model
Gabbro, Figure 3 Sketches of gabbro accretion models. (**a**). Intermediate model for fast-spreading oceanic crust, where parts of the lower crust are formed in the shallow melt lens, while other parts in lower crustal sills (modified after Natland and Dick, 2009). Gabbro sills in red are formed by actual magmatic activity; sills in darker color represent the record of earlier intrusions. (**b**). Gabbro accretion and emplacement via long-lived, low-angle detachment faults for slow-spreading crust after an example for an oceanic core complex at 23°N at MAR (after Dick et al., 2008). Gabbro bodies in red are formed by actual magmatic activity; bodies in darker color represent the record of earlier intrusions (drawings by Janna Lehmann).

(e.g., Bedard, 1991; Kelemen et al., 1997), where the lower gabbros are generated by the intrusion of sills of gabbroic mushes. Intermediate models, where part of the lower crust forms in the shallow melt lens and the rest in lower crustal sills, are also discussed (e.g., Boudier et al., 1996; Natland and Dick, 2009). A sketch of such an intermediate model is presented in Figure 3a. The gabbro layer at fast-spreading ridges is usually covered by a 1–2 km thick sequence of basaltic rocks. Thus, there are only three locations where gabbros at fast-spread oceanic crust were studied directly, all formed at the EPR. Two of them are complex tectonic windows where gabbros are exposed as a consequence of ridge/ridge interactions: Hess Deep and Pito Deep. The third location is the Site 1256 located in ~15 Ma-year-old crust formed at the EPR under superfast spreading conditions (for more details on these locations see Coogan, 2014).

While at fast-spreading ridges, axial magma chambers were seismically imaged at many locations, for slow-spreading ridges, this is the case only for one locality (at MAR, 9°N; Singh et al., 2006). The reason therefore is that at slow-spreading ridges extension often takes place in a regime where the magma flux is low. As a consequence considerable amounts of gabbros of the deeper part of the oceanic crust can be emplaced on the seafloor via long-lived, low-angle detachment faults (Figure 3b) (e.g., Cannat, 1993; Ildefonse et al., 2007). The tectonic extension produces Oceanic Core Complexes (OCC) which include smooth gabbro domes perpendicular to the mid-ocean ridge (e.g., Ildefonse et al., 2007). Thus, OCC provide access to the gabbro layer and underlying mantle rocks at slow-spreading oceanic ridges. Owing to the lack of magmatic activity at such localities, individual gabbro bodies may intrude directly into the shallow mantle at a range of depths (Figure 3b) – a model sometimes referred to as a "plum pudding." Many gabbros from oceanic core complexes show characteristic

deformations both in the plastic and in the brittle regime, which is a direct expression of tectonic shearing in a temperature regime varying from magmatic down to the sub-greenschist facies. Owing to the relatively easy access to oceanic gabbros in OCC, there are more detailed investigations of gabbros from slow-spreading ridges than from fast-spreading ridges. A detailed compilation on key locations is provided by Coogan (2014 and references therein).

Formation of oceanic gabbros

Experimental studies of MORB crystallization at low pressures reveal the characteristic crystallization sequence confirmed by the petrography of basalts and gabbros which is illustrated in the phase diagram of Figure 2. Since primitive MORBs are practically dry, containing only a very small content of water, the path of crystallization (gray arrow) starts at the left side of Figure 2. Chromium spinel is the first phase crystallizing at very high temperatures ($>1,250\ °C$) but disappears at lower temperatures. The first silicate phase to crystallize is olivine followed by plagioclase. The cotectic crystallization and subsequent accumulation of olivine and plagioclase lead to the formation of troctolitic cumulates. Correspondingly, Cr-spinel-bearing troctolites are the most primitive gabbroic rocks. At lower temperatures, clinopyroxene is saturated leading to the co-crystallization of olivine–plagioclase–clinopyroxene, which correspond to the main stage of crystallization, taking place over a temperature interval $>100\ °C$, explaining that the vast majority of oceanic gabbros correspond to olivine gabbro. At the pressure of 1 kbar, plagioclase is always crystallizing before clinopyroxene. This characteristic feature changes with pressure, and higher-pressure plagioclase crystallization is suppressed, stabilizing the co-crystallization of olivine–clinopyroxene (Gaetani et al., 1993; Feig

et al., 2006). About 200 °C below the liquidus of the system, orthopyroxene and Fe-Ti oxides crystallize (the latter strongly controlled by the prevailing oxygen fugacity), followed by amphibole, indicating that the water content in the residual melt has been raised to significant amounts, due to the crystallization of only water-free minerals in the main stage crystallization. At this stage, most of the melts are already crystallized and these minerals form interstitial parageneses.

Geochemistry of oceanic gabbros

Students' textbooks often state that gabbros are equivalent in composition to basalts and that the difference between the two rock families is their grain size, which is a direct function of the cooling rate (high cooling rates produce basalts; low cooling rates gabbros). However, oceanic gabbros are cumulates (=accumulated crystals; qv "cumulate"), and thus their bulk composition is strongly dependent of the presence and the modal amount of accumulated crystals. For example, if oceanic gabbros are strongly enriched in oxides ("oxide gabbro"; see above), the silica content of the bulk rock can be <40 wt% SiO_2, due to the high concentration of the heavy element oxide FeO. If crystallization of plagioclase dominates, anorthosites (Figure 1) may be formed with very high Al_2O_3 contents (>20 wt%), and abundant crystallization of olivine produces olivine-rich troctolites with MgO contents >25 wt%. In contrast, MORBs are frozen melts with more homogeneous major element composition, which varies only within a few wt% for the major element oxides as SiO_2, Al_2O_3, and MgO. Another consequence of the cumulate nature of oceanic gabbros is that the concentrations of incompatible trace elements are generally lower than those of MORBs. For example, the average content of K_2O and P_2O_5 in typical gabbros from the drilled core from Hole 735B at SWIR is 0.04 and 0.01 wt%, respectively (data set of Dick et al., 2000), while the corresponding value for typical primitive MORB is 0.07 and 0.09 (e.g., average from the data base PETD, Lehnert et al., 2000), respectively. This depleted nature of typical oceanic gabbros is a consequence of the accumulation of the cotectic assemblage olivine + plagioclase + clinopyroxene (±orthopyroxene) resulting in rocks which often represent nearly pure cumulates with very low proportions of residual melt (~1.4 % as average value for the gabbros from the SWIR drill core, Natland and Dick, 2001). Hence, the bulk content of incompatible elements of oceanic gabbros is more or less a direct function of the amount of interstitial late crystallization where incompatible elements are enriched in phases like amphibole and apatite, and which is in general decoupled from the main stage of crystallization.

Summary

Gabbros are the most common rocks in the oceanic crust and form its lower part (layer 3). They represent slowly cooled crystal mushes composed mainly of olivine, plagioclase, and clinopyroxene, corresponding to the accumulated phases during differentiation of primitive MORB in shallow magma chambers under the ridges. Their mode of accretion is strongly controlled by the spreading rate, with the formation of layered gabbros at fast-spreading ridges and more isotropic gabbros at slow-spreading ridges. The latter often show signs of plastic deformation and vast crystallization of evolved interstitial parageneses.

GENERAL BATHYMETRIC CHART OF THE OCEANS (GEBCO)

Hans Werner Schenke
Alfred-Wegener-Institute, Helmholtz-Centre for Polar and Marine Research, Bremerhaven, Germany

Definition

GEBCO, the General Bathymetric Chart of the Oceans, is a global seafloor mapping program under the auspices of the International Hydrographic Organization (IHO) and the Intergovernmental Oceanographic Commission (IOC) of UNESCO.

History

GEBCO was established in 1903 in Wiesbaden, Germany, in the course of the committee meeting on ocean nomenclature and charting, chaired by Prince Albert I of Monaco (Carpine-Lancre et al., 2003).

Five editions of GEBCO were published until 1983. The 5th edition was digitized and used for the development of the GEBCO Digital Atlas (GDA). With the latest version, published at the event of the GEBCO Centenary 2003 (GDA-CE), GEBCO entered the era of digital bathymetry. The GDA-CE includes also undersea feature names and is continuously updated with new single and multibeam soundings.

Structure

GEBCO is directed by a Guiding Committee which organizes the work of the subcommittees and acts for GEBCO toward the parent organizations. It supervises the development, maintenance, and updating of all GEBCO products and fosters the cooperation with related marine scientific associations.

GEBCO runs three subcommittees (SC):

1. Technical SC on Ocean Mapping (TSCOM): The main task is the development of modern gridding techniques and the continuous updating of the global bathymetric grid.
   Products: global grid, *GEBCO CookBook* (IHO Publication B-11).
2. SC on Undersea Feature Names (SCUFN): The function of SCUFN is to evaluate name proposals considering the IHO Publication B-6 "Standardization of Undersea Feature Names" and to maintain and update the IHO Publication B-8 GEBCO Web Gazetteer (http://www.ngdc.noaa.gov/gazetteer/).
3. SC on Regional Undersea Mapping (SCRUM): SCRUM was established in 2009 and tasked to initiate and support regional ocean mapping projects and coordinate the International Bathymetric Chart (IBC) programs, like the IBC of the Arctic Ocean (http://www.ibcao.org) and the Southern Ocean (http://www.ibcso.org). A GEBCO world map was compiled and published on http://www.gebco.net/data_and_products/gebco_world_map/.

The following international agencies and universities contribute to GEBCO:

1. The National Geophysical Data Center (NGDC) of the US National Oceanic and Atmospheric Administration (NOAA) operates and maintains the IHO Data Center for Digital Bathymetry (http://www.ngdc.noaa.gov/mgg/bathymetry/iho.html).
2. The British Oceanographic Data Centre (BODC) played a key role in GEBCO's transition from analog

to digital products. BODC maintains the GDA-CE and continuously updates the global bathymetric grid (https://www.bodc.ac.uk/data/online_delivery/gebco/gebco_08_grid/).

3. The **IHO** has embedded GEBCO in the Inter-Regional Coordination Program. IHO operates and maintains the GEBCO Gazetteer of Undersea Feature Names and publishes on behalf of GEBCO bathymetric publications (Ward, 2010) (http://www.iho.int/srv1/).

4. The **University of New Hampshire (UNH)** conducts since 2004 in cooperation with GEBCO the "Nippon Foundation/GEBCO Postgraduate Certificate in Ocean Bathymetry Training Program" in order to train academics and hydrographers in ocean mapping (http://ccom.unh.edu/gebco-students-scholars).

GENERAL OCEAN CIRCULATION - ITS SIGNALS IN THE SEDIMENTS

Hermann Kudrass
MARUM-Center for Marine Environmental Sciences, University of Bremen, Bremen, Germany

Definition

The worldwide pattern of ocean circulation is governed by a balance of surface and deep and bottom currents.

Ocean circulation

Ocean circulation is driven by the higher solar radiation at low latitudes compared to the radiation at high latitudes and the resulting differences in evaporation. The transport routes and the velocity of currents are determined by the Earth's rotation, the atmospheric circulation, and the configuration of the ocean basins. The meridional heat and salt transfer by warm tropical and subtropical water is mostly confined to the western side of the ocean basins and cold-water flow towards the equator along the eastern side. A considerable part of the poleward warm-water flow at the surface is balanced by cold bottom water flowing towards the equator. At a global scale, this flow pattern is simplified by the salt conveyor belt or the thermohaline circulation (Figure 1). On geological time scales, this circulation pattern considerably varied, mainly driven by changes of solar insolation and plate tectonic movements. The reconstruction of these

changes, the main subject of paleoceanography, entirely relies on the record of ocean currents preserved in marine sediments.

Surface currents and bottom currents produce different sedimentary records. Surface currents are mainly recorded in the underlying sediments by contrasting regional distributions of specific proxy parameters. In contrast, the signals of the subsurface currents, which flow in direct contact with the seafloor, can be more directly deduced from the sediment properties and composition.

Surface currents

A great variety of proxy parameters in the sedimentary archives is used to decode the extent and intensity of surface currents. First of all, the remains of surface-dwelling organisms of coccolithophorids, diatoms, radiolaria, planktonic foraminifera, pteropods, and dinoflagellates are good indicators for characterizing temperature, salinity, and fertility of the surface water. Geochemical composition of calcareous and siliceous tests (e.g., Mg/Ca, P, Ba, Cd) and their isotopic compositions (C, O, Si, Nd), as well as organic carbon and biomarkers (e.g., alkenones) and their isotopic compositions (C, N, H), are successfully used to identify origin and transport paths of the surface waters. In case that the surface currents are in contact with the seafloor, benthic communities also contain a record of changes, like corals for the ENSO signals (Cobb et al., 2003) or benthic foraminifera for the Indonesian Throughflow (Holbourn et al., 2011). In special cases, the spread of debris from drifting icebergs can define ocean-wide transport paths. A successful strategy to decipher changes in global oceanic circulation is the drilling of sediment core transects, e.g., by the International Ocean Drilling Program (IODP). The transects usually compromise drill holes along the postulated transport path. In special cases, the opening or closing of gateways by plate tectonic movements was investigated (e.g., Tasmanian Gateway for the Circum-Antarctic Current (Exon et al., 2004), mid-American uplift for the initiation of the Gulf Current (Pisias et al., 1995; Haug and Tiedemann, 1998), or the latitudinal shifts and intensity changes of the Equatorial Current in the Pacific Ocean (Lyle and Wilson, 2006)).

Bottom currents

As for the surface currents, the properties of bottom waters are documented by benthic biological communities of mollusks, ostracods, deep-water corals, and epi- and endobenthic foraminifera, as well as the isotopic and elemental composition of their shells, skeletons, and tests. Thus, changes in bottom currents can be reconstructed from fossilized remains of these organisms. In addition, bottom currents generate a much more direct sedimentary record than the surface currents, as they directly impact the sediment. First of all, the fine-scale structure and the composition of the sediments are shaped by the flow, which generates typically silty laminated sediments in extended
General ocean circulation - its signals in the sediments, Figure 1 Global thermohaline circulation and surface salinity (from Rahmstorf, 2002). *Yellow ovals* deep-water formation, *blue lines* deep currents, *purple lines* bottom currents, *red lines* surface currents, *green shading* salinity >36 ‰, *blue shading* salinity <34 ‰.

sediment waves and drift mounds. These drifts are aligned along the contour-following bottom currents and are called contourites. The variation of current velocities is recorded by bedding and grain-size distribution, the latter one mostly relying on the sortable silt. On a larger scale, the internal architecture and the horizontal distribution of these contourite beds can be studied by high-resolution seismics. The internal structure of the accumulation patterns of sediment waves and drift mounds indicates the direction of sediment transport (Stow et al., 2002). Especially the contourites generated by the Mediterranean Outflow (Roque et al., 2012), the Antarctic Circumpolar Current (Michels et al., 2001), and the western boundary currents of the North Atlantic Deep Water (Müller-Michaelis et al., 2013) contain a long-term record of bottom-water characteristics and variations of the flow intensity.

Summary

A high variety of physical and geochemical parameters of the circulating water masses are recorded by biological, geochemical, and petrophysical proxies, which are preserved in the bottom sediments and can be used to monitor changes of the general ocean circulation pattern.

GEOCHRONOLOGY: URANIUM-SERIES DATING OF OCEAN FORMATIONS

Vladislav Kuznetsov
Institute of Earth Sciences, Saint Petersburg State
University, St. Petersburg, Russia

Definition

Uranium-series methods allow estimating quantitatively an age of various types of ocean and terrestrial formations and are based on phenomenon of radioactive decay/accumulation of isotopes from two naturally occurring U-series, with parent isotopes being ^{238}U and ^{235}U.

Introduction

Deep-sea sediments are deposited under a thick water layer and protected from external influences such as climate change, wind erosion, and other destruction processes. Therefore, deep-sea sediments represent unique well-preserved record of climatic and geological events that occurred during the Quaternary period. Hence, they can be used for reconstruction of these events in time applying the U-series dating methods. Theory says that in natural objects in which the activities of all of the nuclides are equal, all isotopes from the same decay chain are in radioactive secular equilibrium (Figure 1). In most environmental materials, however, a break in the decay chain and a state of radioactive disequilibrium are observed, and it is the main prerequisite for the use of U-series dating methods.

The chemical behavior of U-series nuclides, their contents, and mechanisms of accumulation in the ocean environment were widely researched in the second half of the twentieth century. As a result, the basic principles and methods of radioisotope geochronology of ocean sediments are established and well summarized (Kuznetsov, 1976; Smart, 1991; Ivanovich and Harmon, 1992; Cochran, 1992; Wagner, 1998; Cochran and Masque, 2003; Edwards et al., 2003; Henderson and Anderson, 2003; Kuznetsov, 2008; Kuznetsov and Maksimov, 2012).

For dating different ocean formations, two types of the U-series disequilibrium methods are available which are based on radioactive (1) decay or (2) accumulation of daughter isotope (Ku, 1976; Ivanovich and Harmon, 1992).

At the present time, the most widespread and well-founded methods are ^{230}Th$_{excess}$, ^{231}Pa$_{excess}$, ^{230}Th/^{234}U, and ^{231}Pa/^{235}U dating methods of different ocean formations. This entry further discusses the use of such short-living U-series nuclides as ^{234}Th (half-life = 24.1 day), ^{224}Ra (3.64 day), etc., allowing assess rates of processes in the modern ocean, as well as ^{210}Pb (22 years), allowing estimates of accumulation rates of the marine shelf and lacustrine sediments.

^{230}Th$_{excess}$ and ^{231}Pa$_{excess}$ dating methods

In oxidizing aqueous conditions typical for most seawater, U forms the soluble uranyl carbonate species, and the most part of this element content is held in the ocean waters. ^{230}Th and ^{231}Pa are produced by decay of ^{238}U (and ^{234}U) and ^{235}U, respectively. Both elements form the positively charged or neutral hydroxide species which are strongly absorbed onto suspended particles and rapidly removed from the water to the ocean floor (Sackett, 1960; Scott et al., 1972; Kuznetsov, 1976; Anderson et al., 1983a; Anderson et al., 1983b; Taguchi et al., 1989; Cochran, 1992). Thus, significant concentrations/activities of ^{230}Th, as well as ^{231}Pa, are accumulated on the surface of the ocean floor, much more than in seawater (Moore and Sackett, 1964; Kuznetsov, 1976). ^{230}Th (and ^{231}Pa) in the sediments consists of both the ^{230}Th (^{231}Pa) derived from ^{234}U (^{235}U) decay in the seawater and small portion of ^{230}Th (^{231}Pa) contained in mineral detrital component. Only the unsupported ^{230}Th or ^{231}Pa, the so-called ^{230}Th$_{excess}$ (or ^{230}Th$_{xs}$) and ^{231}Pa$_{excess}$ (or ^{231}Pa$_{xs}$), derived directly from seawater ^{234}U (^{235}U) decay can be used to calculate the sediment age. Therefore, both isotope activities measured in the sediment samples must be corrected for this small portion of detrital ^{230}Th (and ^{231}Pa) to estimate ^{230}Th$_{xs}$ (^{231}Pa$_{xs}$). The correction technique is described (see Henderson and Anderson, 2003 for details).

There are a number of ocean objects suitable for ^{230}Th$_{xs}$ (or ^{231}Pa$_{xs}$) dating: (1) deep-sea sediments of different origin (foraminiferal or metalliferous sediments, for instance) and (2) ferromanganese formations (Fe-Mn nodules and crusts). The theoretical distribution of ^{230}Th$_{xs}$ or ^{231}Pa$_{xs}$ radioisotopes in sediments and Fe-Mn formations reflects exponential decay due to their half-life time.

Formerly, the alpha-emitting nuclides, such as ^{230}Th and ^{231}Pa, were measured by alpha spectrometry following analytical procedures needed to extract the isotopes from a sample. Effective age ranges, depending on the isotope's half-life ($T_{1/2}$ = 75.2 kyr for ^{230}Th and $T_{1/2}$ = 34.3 kyr for ^{231}Pa) and activity level in a sample, are ca. 3–350 kyr for the ^{230}Th$_{xs}$ method and ca. 5–150 kyr

for the $^{231}Pa_{xs}$ method. Modern mass spectrometric analysis allowed extending the age ranges for both methods. It is now possible to determine $^{230}Th_{xs}$ ages from several decades to ca. 500 kyr and $^{231}Pa_{xs}$ ages up to 250 kyr (Chen et al., 1986; Edwards et al., 1986; Edwards et al., 1987; Edwards et al., 1997). Mass spectrometric methods for measuring Th, Pa, and U isotopes have greatly reduced sample size requirements and improved analytical precision.

Theoretical prerequisites for the application of both the methods are:

1. ^{230}Th and ^{231}Pa as well as parent uranium may not migrate in the sedimentary stratum. A lot of data support the point of view that Th and Pa are always immobile in aqueous conditions (Kuznetsov, 1976; Huh and Ku, 1984; Cochran, 1992; Henderson and Anderson, 2003). Possible migration of U as a mobile element may not significantly affect the vertical distribution of the daughter nuclides due to its low concentration in sediments compared with ^{230}Th and ^{231}Pa (Kuznetsov, 1976).

2. The concentration of U producing ^{230}Th and ^{231}Pa in ocean water must remain constant during aging, i.e., for the last 300–350 kyr. Seawater U concentration does not change during at least for the last ca. 400 kyr according to Kuznetsov (1976), Chen et al. (1986), Rosenthal et al. (1995), and Henderson and Anderson (2003).

3. The ^{230}Th and ^{231}Pa sedimentation rate must be constant through time. However, fluctuations in sedimentation rate are often observed due to biogenic and/or terrigenous supply changes. These variations can be corrected by applying normalization of $^{230}Th_{ex}$ ($^{231}Pa_{ex}$) specific activities to carbonate-free material of sediments (Kuznetsov, 1976, 2008; Ivanovich and Harmon, 1992).

4. There are no any disturbances in sediment stratigraphy.

If these assumptions are fulfilled, the vertical distribution of both nuclides in sediments becomes close to their theoretical exponential decrease from the surface layers to the lower layers.

After deposition, the $^{230}Th_{xs}$ and $^{231}Pa_{xs}$ decay and tend to come to equilibrium with the parent uranium. The age

of individual sediment layer (i) can be calculated from $^{230}Th_{xs}$ and $^{231}Pa_{xs}$ values as

$$^{230}Th_{xs}(0) = {^{230}Th_{xs}(i)} \cdot e^{-\lambda(230)t} \text{ and}$$

$$^{231}Pa_{xs}(0) = {^{230}Pa_{xs}(i)} \cdot e^{-\lambda(231)t}, \qquad (1)$$

where:

- $^{230}Th_{xs}(0)$, $^{231}Pa_{xs}(0)$ = specific activities of the nuclides in the outer surface layer
- $^{230}Th_{xs}(i)$, $^{231}Pa_{xs}(i)$ = specific activities of the nuclides in the underlying layer i
- $\lambda = \ln2/T_{1/2}$, where $T_{1/2}$ is the nuclide half-life

These two methods are widely used in the determination of deep-sea sedimentation rates during the Holocene and Late and Middle Neopleistocene as well as age accumulation rates of Fe-Mn nodules and crusts (Ku and Broecker, 1967; Ku and Broecker, 1969; Kuznetsov, 2008). For example, the recent determinations of Fe-Mn nodule and crust time formation showed their ancient ages of several Myr and accumulation rates being in the wide range from millimeters to centimeters per million years (Finney et al., 1984; Huh and Ku, 1984; Claude-Ivanaj et al., 2001; Kuznetsov, 2008). Eisenhauer et al. (1992) used $^{230}Th_{xs}$ method to determine the growth rates of Mn crusts from the Pacific Ocean. The study showed that the Mn crusts grew faster during the warm climatic periods compared to the cold periods. Both the $^{230}Th_{xs}$ and $^{231}Pa_{xs}$ are applied to determine the age boundaries of marine isotope stages (MIS) reflecting global climate changes in the past. These data have played an important role in building the timescale of changes in the isotopic composition of oxygen in the foraminiferal shells from the ocean sedimentary columns (Broecker and Van Donk, 1970). For instance, the boundary between MIS 6 and MIS 5 detected in the foraminiferal shells by $\delta^{18}O$ analysis shows astronomical date about 127 Kyr and agrees well with the age range of 127–128 Kyr obtained by the U-series dating methods (Edwards et al., 1986; Edwards et al., 1987; Zhu et al., 1993). Currently, both the methods are widely used in the study of the sedimentation processes and paleoclimate changes in the Arctic (Not and Hillaire-Marcel, 2010).

^{230}Th/^{234}U and ^{231}Pa/^{235}U dating methods

Both the ^{230}Th/U and ^{231}Pa/U methods play an important role in dating marine carbonates (corals, mollusk shells) as well as the ^{230}Th/U method which is most widely applied in dating seafloor massive sulfide (SMS) deposits in the ocean hydrothermal zones. ^{230}Th/U dating involves calculating ages from radioactive decay and accumulation relationships among ^{238}U, ^{234}U, and ^{230}Th, whereas ^{231}Pa/U dating involves calculating ages from the ingrowth of ^{231}Pa from its grandparent ^{235}U. The age range for these methods is the same as for ^{230}Th$_{xs}$ and ^{231}Pa$_{xs}$ (see above).

The ^{230}Th (and ^{231}Pa) content in seawater is negligible, while the average concentration of U is about ~3 µg/l (Chen et al., 1986). The biogenic precipitation of calcium carbonate from seawater (e.g., when coralline skeleton is formed) is accompanied by the incorporation of uranium, which occurs in the soluble uranyl carbonate complexes in seawater, while the ^{230}Th (and ^{231}Pa) is strongly absorbed onto suspended matter. As a result, the carbonate radiometric system contains a deficiency of ^{230}Th (and ^{231}Pa) in comparison with parent ^{234}U (^{235}U). The first applications of both the ^{230}Th/U and ^{231}Pa/U methods in dating marine carbonates were demonstrated in the second half of the last century by Barnes et al. (1956), Rosholt and Antal (1962), Veeh (1966), Sakanoue et al. (1967), Ku (1968), Broecker et al. (1968), Kaufman et al. (1971), and others.

The SMS deposits (or sulfide ores, elsewhere in the publications) were formed from hydrothermal fluids originated from the seawater circulated in the basalts of the oceanic crust. The reduced hydrothermal fluids contain two orders of magnitude less uranium than the seawater (Michard et al., 1983). The hydrothermal fluids mix with seawater which results locally in reducing conditions. By this, easily soluble uranyl carbonate complexes dissolved in seawater become transformed into absorbable uranyl or poorly soluble U^{IV} ions. The latter coprecipitates with transitional sulfides discharged with the fluid. As a result, uranium (without its daughter nuclide ^{230}Th) is accumulated in the SMS deposits on the seafloor. Common uranium concentrations in the SMS deposits range up to 10 ppm (parts per million) or more (Lalou et al., 1996; Kuznetsov et al., 2002; Kuznetsov et al., 2006; Kuznetsov et al., 2007). First ^{230}Th/U ages of sulfide ores from the East Pacific Rise (EPR) and Mid-Atlantic Ridge (MAR) were obtained at the end of the last century by Lalou and Brichet (1982, 1987) and Lalou et al. (1988, 1993, 1995, 1996, 1998).

There are two main prerequisites for ^{230}Th/U (and ^{231}Pa/U) dating of both marine carbonates and sulfide ores (Ivanovich and Harmon, 1992; Lalou et al., 1996; Geyh, 2001; Kuznetsov, 2008; Kuznetsov et al., 2011): (1) sulfides/carbonates contain uranium without thorium immediately after deposition, and (2) during their aging, sulfides/carbonates were under conditions of chemically closed system with regard to uranium and thorium.

A thorough check whether the ^{230}Th/U (and ^{231}Pa/U) method is applicable is necessary in order to obtain reliable ^{230}Th/U (and ^{231}Pa/U) ages of both marine carbonates and sulfide ores. Different approaches to testing the theoretical positions of these methods are described by Edwards et al. (2003) for dating carbonates and by Lalou et al. (1996) and Kuznetsov et al. (2011) for dating SMS deposits.

The ^{230}Th/U age of a sample is derived from Eq. 2 (Ivanovich and Harmon, 1992):

$$\frac{^{230}\text{Th}}{^{234}\text{U}} = \frac{^{238}\text{U}}{^{234}\text{U}}\left(1 - e^{-\lambda_0 t}\right)$$
$$+ \left[\left(1 - \frac{\lambda_0}{\lambda_0 - \lambda_4}\right)\left(1 - \frac{^{238}\text{U}}{^{234}\text{U}}\right)\left(1 - e^{(\lambda_4 - \lambda_0)t}\right)\right],$$
$$(2)$$

where:

λ_0, λ_4 – decay constants for the ^{230}Th and ^{234}U; ^{230}Th/^{234}U and ^{238}U/^{234}U – AR; ^{234}U, ^{238}U, ^{230}Th – specific activities; and t – age of a sample

Both the ^{230}Th/U and ^{231}Pa/U methods play an important role in the study of sea-level changes in the past. Paired ^{230}Th/U and ^{14}C dating of coral sequences from a number of sites (such as the Barbados, Tahiti, Papua New Guinea) has allowed reconstructing the deglacial sea-level history (Bard et al., 1990; Edwards et al., 1993; Stein et al., 1993; Bard et al., 1996; Hanebuth et al., 2000; Cutler et al., 2003). For example, it was established that during the Last Glacial Maximum between 20 and 22 kyr ago, the minimum sea level was about 120 m lower than at the present time (Bard et al., 1990; Hanebuth et al., 2000). Sea-level reconstructions over the timescale of a full glacial-interglacial cycle during past ca. 140 kyr, as well as earlier interglacial periods, were also determined using a large number of ^{230}Th/U and ^{231}Pa/U datings of corals, carbonate bank sediments, and speleothems (e.g., see recent publications by Arslanov et al., 2002; Cutler et al., 2003; Frank et al., 2006; Andersen et al., 2008; Waelbroeck et al., 2008; Kuznetsov, 2008).

The discovery of massive sulfide deposits within the East Pacific Rise and Mid-Atlantic Ridge in the 1970s to 1980s has gathered great scientific and economic interest due to high concentration of Cu, Zn, Pb, Fe, Mn, Au, Ag, and a number of rare chemical elements as well as huge size of dozens of million tons each. Applying the ^{230}Th/U dating of sulfide ore deposits, the chronology of ore-forming processes having the episodic or pulse-type origin can be evaluated (Lalou et al., 1995; Lalou et al., 1998; You and Bickle, 1998; Kuznetsov et al., 2006; Kuznetsov et al., 2007; Kuznetsov, 2008; Kuznetsov et al., 2011; Kuznetsov and Maksimov, 2012). The recent dating results of SMS samples from the "Semenov" hydrothermal district (located at 13°31′ N, 44°59′ W in a depth between 2,360 and 2,580 m b.s.l.) at the MAR allowed evaluating the total ore formation period of

ca. 124 kyr (Kuznetsov et al., 2011). It was shown that the hydrothermal activity and related ore formation had a pulse pattern marked by the certain number of episodes with duration of up to several 1,000 years.

Summary

Two types of the U-series disequilibrium methods are available for dating different ocean formations and are based on radioactive (1) decay or (2) accumulation of daughter isotope. At the present time, the most widespread and well-founded methods are (1) $^{230}Th_{excess}$, $^{231}Pa_{excess}$, and (2) $^{230}Th/^{234}U$ and $^{231}Pa/^{235}U$ dating methods of different ocean formations.

A number of ocean objects are suitable for $^{230}Th_{xs}$ and $^{231}Pa_{xs}$ dating: deep-sea sediments of different origin such as carbonate (foraminiferal), silicate (radiolarian), or metalliferous sediments and ferromanganese nodules and crusts. Both the $^{230}Th/U$ and $^{231}Pa/U$ methods play an important role in dating corals and mollusk shells as well as the $^{230}Th/U$ method which is most widely applied in dating seafloor massive sulfide deposits in the ocean hydrothermal zones.

Modern mass spectrometric analysis allows to determine $^{230}Th_{xs}$ and $^{230}Th/U$ ages between several decades to ca. 500 kyr and $^{231}Pa_{xs}$ and $^{231}Pa/U$ ages up to ca. 250 kyr. Mass spectrometric measurement of Th, Pa, and U isotopes requires only tens or hundreds of milligrams of sample and provides high analytical precision.

Both the $^{230}Th_{xs}$ and $^{231}Pa_{xs}$ dating methods are widely used in the determination of sedimentation rates of deep-sea formations; they play an important role in building the timescale of global climate changes in the past as well. Both the $^{230}Th/U$ and $^{231}Pa/U$ methods are widely used in the study of sea-level changes in the past.

GEOHAZARDS: COASTAL DISASTERS

Gösta Hoffmann and Klaus Reicherter
Department of Geosciences and Geography, RWTH
Aachen University, Aachen, Germany

Definition

We define the term "hazard" as a potential source of harm, where "harm" is defined as the "injury or damage to the health of people, or damage to property or the environment" following the definition as given by ISO/IEC (2014). The term "risk" is defined as a "combination of the probability of occurrence of harm and the severity of that harm" (ISO/IEC, 2014). Furthermore, the term "risk" may be expressed as a function of hazard, exposure, and vulnerability. A geohazard is a geological state that may lead to widespread damage presenting severe threats to humans, property, and the natural and built environment. A coastal geohazard is a natural physical phenomenon usually associated with seacoasts but to a limited extent also along lakeshores, where the initiating process of the disaster may originate at great distances from the point of impact.

Introduction

There are numerous geohazards which affect coastal regions, including beach erosion, landslide/cliff collapse, wave attack, flooding, and tsunamis. They are always related to the landward movement of water. These processes can be either slow or fast and may be temporary or permanent in nature. Some hazards have meteorological causes (climatic hazards, e.g., storms, Nicholls, 2004), whereas others may be driven by Earth's endogenous forces such as seismic events (earthquakes and tsunamis, e.g., Atwater, 1987) and volcanic eruptions (e.g., Firth et al., 1996). Furthermore, coastal hazards can be gravity induced (landslide/cliff collapse, e.g., Dawson et al., 2009; Del Río and Gracia, 2009). Relative sea-level changes may pose a hazard to many low-lying countries as do subsurface changes induced by humans (e.g., due to groundwater extraction and associated settlement). As the coastal zone is a preferred area of human settlement, there is always some exposure to coastal hazards. Coastal cities host many different kinds of economically relevant infrastructure (e.g., harbors) and are often used for recreational purposes. Two percent of the world's surface is defined as low elevation coastal zone (LECZ). McGranahan et al. (2007) defined the LECZ as a contiguous area along the coast lower than 10 m above sea-level that is inhabited by 10 % of the world's population. Small and Nicholls (2003) estimate that around 1.2 billion people are living within 100 km of the coast throughout the globe. In addition to urbanization, population growth within the coastal zone is expected to be more rapid than in other areas in the near future. For example, Adger et al. (2005) calculate that more than 50 % of the world's population is likely to live in coastal areas by 2030. The areas affected by coastal hazards directly depend on the topography; low-lying countries such as the Netherlands or Bangladesh are particularly prone to the hazards caused by rising sea levels.

Cliff collapse and other types of mass movements are hazards when they occur close to settlements along cliff edges (Dewez et al., 2013). Furthermore, beaches at the base of a cliffed coastline might be used for recreational activities (Günther and Thiel, 2009). Mass movements occur if stability thresholds are crossed. Critical parameters are related to meteorological conditions and to tide- and wave-controlled shoreface processes. Cliff collapse is a form of episodic coastal retreat, and important parameters controlling the processes are mainly the lithology (including water content) and structure. Frost action, in particular the number of freeze-thaw cycles, plays an important role in the weathering of semiconsolidated rocks; the chalk cliffs of northern Europe is a good example of this (Duperret et al., 2002; Kuhn and Prüfer, 2014). Bioerosion becomes an important agent, especially in the retreat of limestone-dominated coasts within the tropics (Vita-Finzi and Cornelius, 1973; Taboroši and Kázmér, 2013).

Despite the immediate destruction by shock waves, earthquake-related coastal hazards are mainly attributed to coseismic (crustal) uplift or subsidence as witnessed, e.g., during the 1964 Alaska earthquake (Plafker, 1969).

A further criterion to distinguish coastal hazards is the duration of time, which ranges from seconds for tsunami landfall to thousands of years for relative sea-level changes. Another important issue is to separate coastal hazards into local, regional, and global hazards. All geohazards may cause significant loss of life and may have severe economic impacts. In the following, extreme wave events caused by storm surges and tsunamis are discussed.

Extreme wave events

Extreme wave events can develop into a coastal hazard, and they primarily result from two fundamentally different phenomena: storm surges and tsunamis. Whereas the intensity of such events is high, the frequency is usually low. The major difference between these two natural phenomena lies in the energy source responsible for the piling up of water. An earthquake-generated tsunami is the result of endogenous forces with the energy derived from the Earth's interior. A storm surge, however, is fueled by exogenous forces; the energy that drives this process,

which is ultimately derived from the sun, is transmitted via the climate system onto the coast. In contrast to normal ocean waves, tsunami waves are characterized by a longer wavelength (200–300 km) with periods from minutes to hours. The speed of a tsunami wave within the deep sea reaches up to 800 km/h with a very low amplitude of less than 1 m. The amplitude increases in shallow water (shoaling) as the wave gets compressed. A tsunami wave moves the entire water column, which causes refraction effects. Bryant (2005) notes 124 tsunami events as a result of 15,000 earthquakes for the period 1861–1948. In general, storm surges occur much more frequently than tsunami waves.

Storm surges

Storm surges are long-wavelength, low-amplitude sea surface displacements resulting in superelevated water levels that are over and above the regular astronomically forced highest water levels (high tides). Storm surges are a climatically driven phenomenon, accompanied with reduced atmospheric pressure. They are therefore surface gravity waves. The low pressure results in the reduction of the vertical force on the sea surface and hence leads to a rise of the water level. This phenomenon is also known as the "inverted barometer effect" (Wunsch and Stammer, 1997). A linear relationship exists between atmospheric pressure and sea-level. A sea-level drop of 1 cm is observed with an increase of 1 mbar of atmospheric pressure (Ross, 1854). Storm surges are short-term changes in water level. This is due to the presence of wind which moves the low-pressure system. The variations in sea-level can be about ±15 cm.

The coastal hazards associated with storm surge impacts are coastal flooding, erosion, and salinization. The flooding of a normally dry coastal zone occurs where there are large low-lying areas; hence, flooding is especially severe in estuaries and other coastal areas characterized by geologically young and unconsolidated sedimentary strata. The situation is enhanced in cases of local land subsidence which may be induced by humans, e.g., due to excessive groundwater extraction (Galloway and Burbey, 2011). Artificial drainage of swampy coastal areas, as practiced for centuries in the Netherlands, leads to peat compaction and oxidization. As a consequence, the surface is lowered and the flooding potential amplified.

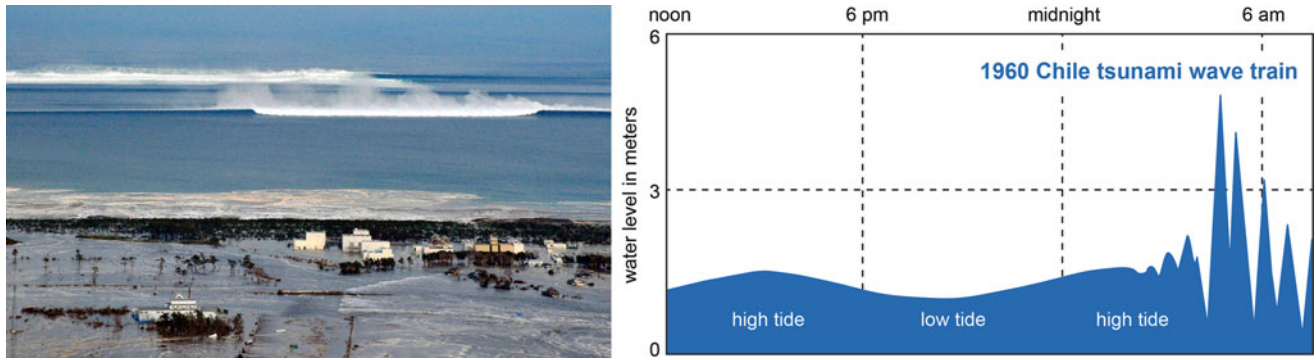
Wave impacts can result in significant erosion along the shore, a process which is sometimes amplified by additional erosional agents such as floating debris (e.g., trees) and sea ice. In addition to the effects along the coastline, the water level in rivers may rise. This is because severe weather conditions are often accompanied by extraordinary precipitation events, which can cause a noncoastal flooding hazard. Coastal flooding in river mouths (especially in backwater areas) may also occur without additional water from precipitation. This is because the base level changes during times of storm-induced higher sea level. Coastal storms have an "event" character as they result in comparatively sudden coastal changes and are the main reason for coastal retreat. This retreat is not a gradual and/or linear process but the sum of sporadic events and the intermittent movement of sediments. At least 70 % of sandy beaches around the world are recessional (Bird, 1985; Schlacher et al., 2007).

Coastal storms are generated by low-pressure weather systems such as tropical cyclones (synonyms: hurricanes, typhoons) as well as extratropical storms (low-pressure systems including blizzards). Extratropical cyclones form over both land and sea, in contrast to tropical cyclones that only form over the sea. Cyclones rotate anticlockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere due to the Coriolis effect. A sea surface temperature above 26 °C is one of the most important requirements for a tropical cyclone to form. Energy in the form of latent heat is transferred from the ocean into the climate system by the condensation of water vapor. Frontal activity associated with the interaction of warm and cold air masses is the main driving force in the formation of extratropical cyclones.

The severity of a storm surge is influenced by the wind conditions, the drag on the sea surface due to the wind fetch, the timing of the tides, the wind speed, and also the duration of the event. Of equal importance is the orientation of the coast relative to the storm path, as wind directed at a right angle causes the highest rise in water level. Furthermore, the storm surge extent depends on the speed of movement of the pressure system, the topography, the shape of the coastline, and the bathymetry.

The passing of an atmospheric pressure system and the associated storm surge activity may last from hours to days. Extratropical cyclones are usually larger and longer lasting than tropical cyclones, which are always nonfrontal storms (Gray, 1979). However, tropical cyclones are more severe as they contain more potential energy. The severity of the storm surge hazard increases if the situation persists over several tidal cycles, because the risk of flooding increases significantly if high tide and storm surge coincide. Furthermore, the maximum height of the water level is controlled by instantaneous water level changes caused by waves.

Tsunami

Tsunamis are the result of a large mass of water being displaced by different processes. Earthquake-induced tsunamis have small wave heights offshore and very long wavelengths which can reach several hundred kilometers (line source tsunamis). This is in contrast to tsunamis caused by mass movements (subaerial or underwater origin), volcanic eruptions and explosions, glacier calvings, or meteorite impacts, which have very high waves and very short wavelengths close to the origin (point source tsunamis). More than 85 % of tsunamis have tectonic causes such as fault movements; 5 % are caused by volcanic activity, 5 % by landslides, and 5 % by a combination


Geohazards: Coastal Disasters, Figure 1 Tsunami wave train approaching the Japanese coastline after the 2011 Tohoku earthquake; note that tsunami has already made landfall (*left*; photo by Douglas Sprott is licensed under CC BY-NC 2.0). Gauge data showing the wave train from the 1960 Chilean earthquake tsunami along the Japanese coast (Onagawa) with tide data superimposed (*right*; modified from Atwater et al., 1999).

of all other causes – impact tsunamis are very rare (Rhodes et al., 2006). Eighty percent of all tsunamis occur in the Pacific Ocean, but other oceans and seas (like the Mediterranean Sea) have also been affected by tsunamis. Tsunami evidence has also been documented on the shorelines of large and deep lakes, such as Lake Geneva in Switzerland (Kremer et al., 2012). The speed of a tsunami wave is calculated by the square root of the product of acceleration by gravity (9.8 m/s^2) and the water depth; in deep water, the wavelength of the tsunami must also be taken into account. Extreme waves can also be induced by storms and become tsunamis when approaching the coastline due to shoaling. These are then referred to as meteotsunamis (Monserrat et al., 2006). Shoaling can result in the superposition of waves and a dramatic reduction in wave velocity. The plural form is "tsunamis" or "tsunami."

A tsunami train is a series of waves, which are destructive when they make landfall. The first wave in the tsunami wave train is often not the largest one and therefore leaves almost no deposits (or only in favorable setting) as the deposits are usually reworked by following waves. The time interval between waves hitting the coastline varies (Figure 1) but can be around 10 min or more. Generally, three to four major wave landfalls can be documented in the sedimentary record. The ecology and the geomorphology of coastlines are severely affected and modified during earthquake-induced tsunami landfall.

Reconstructing paleostorm and tsunami events

Coastal zone management and improved decision-making in coastal planning and development depend on mitigation and adaptation strategies. These should be applied to reduce the risks associated with geohazards because the hazards themselves cannot be prevented (they are unavoidable by nature). The design of flood protection measures relies on inundation statistics on frequency and duration of water levels above a specified elevation threshold (exceedance probability statistics on extreme water levels). The risks can only be statistically assessed

if recurrence intervals (probability that harm will occur) are known and if the severity, as well as magnitude, of potential events can be quantified (severity of harm). Knowledge of past extreme wave events is therefore essential for risk assessment, which also forms the base of multihazard early warning systems. In the ideal case, statistical analyses rely on observed events and are based on instrumental measurements. However, the period covered by instrumental data may not be statistically significant, as extreme wave events typically have a low frequency (Wolman and Miller, 1960). Consequently, other archives need to be made accessible and summarized in the form of catalogs and databases in order to extend the record into the past. Historical data are useful, especially if the flooding level can be correlated to a reference level such as high water marks (Brázdil et al., 2006). Basic sources of documented data on floods might be found in written description (e.g., Satake et al., 1996; Lau et al., 2010; Atwater et al., 2014). Uncertainties concerning the timing of the event are usually low when using these descriptions; however, limitations arise because the maximum flooding level may only be reconstructed if the landmarks that are described still exist and are identifiable. Hence, precision of dating and magnitude commonly get more vague and uncertain with increasing event age in the preinstrumental period. The historical period is also often too short (Switzer et al., 2014). Therefore, for most areas, the archaeological and geological records prove to be the only archives reaching back sufficiently long enough into the past to cover the worst-case scenario which will have very long return periods. Event deposits can only be expected from the second half of the Holocene as older deposits would likely have been eroded and reworked with fast sea-level rise (Hoffmann and Lampe, 2007).

Paleostorm deposits

The sedimentary evidence left behind by a storm surge is referred to as "tempestite." Nott (2004) introduced the term "paleotempestology" as the study of prehistoric storms. The identification of paleostorm deposits along
Geohazards: Coastal Disasters, Figure 2 Tsunami parameters (*top*).

coastlines is based on geomorphological and sedimentological work. There is the potential for both sedimentary and erosional evidence. Paleostorm deposits may form individual layers which differ from the coastal facies. Such sandy event deposits are found as stratified, often shelly strata in back barrier lagoons and swamps where fine-grained sediments usually accumulate (e.g., Switzer and Jones, 2008). The deposits are commonly tens of centimeters thick and usually laminated due to individual wave pulses. Paleosoils are useful indicators in coastal profiles when overlain by a suspicious deposit. This indicates a hiatus that covers at least the time of soil formation and underlines the event character of the deposit. Geomorphological evidence of paleostorms can be seen in coastal ridges and splays. Landward thinning sheets, which appear as fan-shaped tongues in the coastal geomorphology, form as a consequence of the overtopping of dune morphology and the breaching of barriers and berms along sandy coasts. Besides these fine-grained sandy deposits, coarse-grained coastal deposits such as boulders have been described as built by tropical cyclones (e.g., Scheffers and Scheffers, 2006). Cox et al. (2012) convincingly demonstrate extratropical storm activation of boulder deposits along the west coast of Ireland. Another deposit associated with storm surges is wrack lines. These are composed of floatable material. Although the preservation potential might be low, Hoffmann and Reicherter (2014) recently documented how these deposits may be used to precisely date the flooding event. In general, reworking of older material along the shore is common during storm surge impact, and this may hamper dating of the event deposits.

Paleotsunami

Tsunami action is mirrored in geological records and archives as phases of erosion, reworking, and redeposition leaving unconformities and unusual sedimentary layers. Tsunamites or tsunami deposits are proof that past or prehistoric tsunami events have occurred along coastlines or lakeshores. Several parameters obtained from recent or historical tsunamis are used in paleotsunami research, the most important of which are the inundation distance and run-up height (Figure 2). The maximum run-up and inundation are delineated by the location of the wrack line or wrack line deposits (Figure 3a). These are then used as basic parameters for coastal evacuation and emergency planning. Local effects of coastal morphology such as bays, fjords, and rias can amplify wave heights and inundations. Refraction of tsunami waves (bending) may occur and mainly depends on the morphology and shape of the seabed in front of the coast. Wave reflection also occurs, which describes the wave bouncing back after striking the shoreline.

Sedimentary evidence for paleotsunamis is found along the shorelines of marine and lacustrine environments. There are clear sedimentological characteristics to identify such sediments as high-energy deposits. However, the distinction between storm- and tsunami-related deposits is almost impossible (e.g., Goff et al., 2004; Switzer et al., 2005; Kortekaas and Dawson, 2007; Morton et al., 2007; Bahlburg and Spiske, 2012; Shanmugam, 2012 and references therein) as the sediments have numerous similarities and a substantial lack of unequivocal diagnostic criteria.

The shorelines of the Earth vary from place to place and can be simplified into two characteristic environments: flat sandy coasts or marshes and cliffed rocky coasts (Figure 3a, b). The formation of a coast with sediments at the seashore depends on several parameters including the position of the sea-level, the tidal influence, and the presence of river inlets (e.g., sculpted into bays, cuspate forelands with mudflats, marshes, sandy beaches, or dunes). The geomorphology of a coast plays a major role in preserving tsunamigenic deposits.

Many shorelines have developed relatively recently due to Holocene sea-level rise. Other shorelines have been affected by tectonic movements (uplift or subsidence). Due to the glacial sea-level low stands, some tsunamis older than 5,000 years may not be preserved along the seashores as they are now drowned or have been reworked. However, interglacial/interstadial tsunamigenic deposits (during a high stand, e.g., MIS 5) have the potential to be preserved.

Paleotsunami research focuses on suitable archives along affected coastlines. To have a suitable archive, the deposits must firstly have had the potential to be preserved, which means subsidence and sedimentation
Geohazards: Coastal Disasters, Figure 3 (**a**) Tsunami landfall and deposits along sandy shores and various types of backwash deposits (*middle*). (**b**) Tsunami landfall at rocky coasts (*bottom*).

should prevail and not uplift and erosion; secondly, the deposits should be distinguishable from storm layers (tempestites); and thirdly, the deposits should yield datable material. The distinction of storm and tsunami deposits proves to be particularly difficult. Hence, many researchers (e.g., Lario et al., 2010) refer to extreme wave events (EWE). Lagoons or marshy flatlands have been widely used as archives for investigating tsunami deposits (Figure 3a). In these settings, tsunami landfall has a huge effect on the local sedimentary environment and ecology. Freshwater, brackish, or hypersaline lagoons will be affected by short durations of marine ingressions containing characteristic marine flora and fauna. Furthermore, coarse-grained deposits (sand sheets and washover fans) will be deposited in fine-grained lagoonal clays or evaporites. After landfall, the lagoonal environment may then reestablish itself including sedimentation, and hence sand sheets can be preserved (Figure 3a).

Along steep rocky shores, the locations of huge blocks and the arrangement of smaller blocks are used to delineate tsunami landfall. Tsunami boulders or "boulder trains" are chains of imbricated blocks interpreted as remnants of tsunami action (Figure 3b). These "boulder trains" have been found all around the world (Scheffers, 2008). However, Williams and Hall (2004) and Cox et al. (2012) describe the same type of deposits and clearly attribute storm waves as depositional agent.

Offshore records of paleotsunamis are rare, and related deposits are ambiguous; therefore, they cannot be reliably associated with tsunami action. Backwash deposits into the sea/lake after tsunami landfall by the backflow of the

water mass are also hard to identify. For relatively recent tsunamis, backwash deposits can be identified mainly by the presence of anthropogenic pollution as evidenced by some chemical proxies; however, older tsunamigenic deposits are complex and hard to recognize as they may not yield these characteristic constituents.

Tsunami sedimentology has advanced considerably in the past 25 years since Brian Atwater in 1987 associated sand layers on the Pacific Coast of Washington State with the occurrence of major tsunami-producing subduction earthquakes (Atwater, 1987). The 2004 Indian Ocean and 2011 Tohoku-oki tsunamis and their deposits significantly changed our understanding of sedimentary features, sediment architecture, and the processes of tsunamigenic deposition, preservation, and postdepositional changes. Prior to 2004, catastrophic events in the historical record were too infrequent to be satisfactorily studied, and the identification of tsunami remains was ambiguous. Paleotsunami sedimentology is complex, but more and more researchers have integrated sedimentological, geochemical, and paleontological analyses from post-tsunami field surveys and laboratory analyses. This multidisciplinary approach allows a datum to be assigned to the event layers using a combination of several dating methods. To some extent, a clear assignment of an event layer to tsunami action will always remain equivocal, but large storms have different wavelengths, have a major peak of wave action, and have no train of several major waves. Consequently, tsunami deposits should be different to those caused by storms. Some authors also refer to the recurrence periods of, e.g., tropical storms, which is

an order of magnitude higher than that of major (paleo)tsunamis (e.g., Nanayama et al., 2003). The tsunami database has been expanded during the last decades and, in combination with an improved understanding of tsunami depositional mechanisms (Shiki et al., 2008), has helped to identify paleotsunami deposits in many parts of the world.

Recognizing and identifying paleotsunami deposits and assigning the magnitude and extent of (pre)historic tsunamis are important parts of paleoseismological studies. An outstanding example of this is from Japan, where tsunami deposits of a historical event in AD 869 were identified on the Sendai plain by Minoura et al. (2001). The 2011 Tohoku-oki tsunami deposits now cover the AD 869 deposits in the same area. The presence of the older deposits was used to determine/verify the occurrence of a previous large earthquake and tsunami event and proved that this area is susceptible to large-scale tsunami inundation. The world then realized that this part of Japan had experienced magnitude 9 earthquakes with associated tsunamis in the past. Sedimentary, geochemical (inorganic, organic, isotopic), and paleontological proxies are usually used for the identification of tsunamites.

Field surveys aim to map the three-dimensional distribution of a sand sheet and to find evidence for a regional continuity of the layer. Washover fans, typically taper and fine landward, have a common height above mean sea-level and contain marine fossils. These observations can easily be achieved by shallow drillings and GPS control of the drilling locations for large strips along a coast. Ground-penetrating radar surveys as a shallow, nondestructive geophysical tool have been proven to produce reliable images of the facies architecture of fine-grained tsunami sediments (Koster et al., 2014).

When dating event deposits, the same challenges are faced as for paleostorm deposits. This is because reworking is a common process during deposition. Any dates obtained from the event deposits thus give a maximum age, and the youngest date would ideally give an indication of the timing.

Conclusions

Coastal hazards have the potential to cause havoc, especially where the coastline is densely populated. As the hazards involved are the consequence of natural processes, they cannot be avoided. Hence, adaptation strategies have to be implemented. A proper risk assessment should be based on knowledge of recurrence intervals as well as the definition of the worst-case scenario. As the recurrence interval might be rather long and historical information may not be available, this information can only be derived from deposits left behind by the impact of high-energy events. However, at the moment, there is no clear sedimentological fingerprint to discriminate storm and tsunami deposits; for more information, the reader is referred to the benchmark papers of Kortekaas and Dawson (2007), Morton et al. (2007), Switzer and Jones (2008), and Chagué-Goff et al. (2011). Mapping

of high-energy deposits along the world's coastal zones requires an interdisciplinary (geoarchaeology) multiproxy and holistic approach. Transdisciplinary studies between geoscientists and historians are necessary as catalogs of past extreme wave events should include instrumental, historical, and geological data. Based on the results of these investigations, coastal engineers should design defense structures accordingly.

GEOLOGIC TIME SCALE

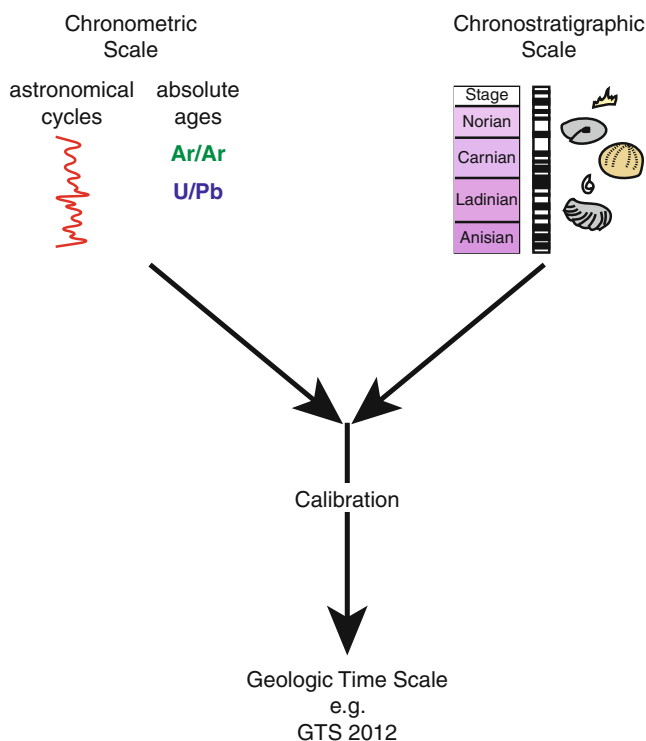
Felix M. Gradstein
Museum of Natural History, University of Oslo, Oslo,
Norway

Introduction

The geologic time scale (GTS) is the principal tool for deciphering and understanding the long and complex history of our planet, Earth. As Arthur Holmes, the father of the geologic time scale, once wrote (Holmes, 1965, p. 148): "To place all the scattered pages of earth history in their proper chronological order is by no means an easy task." Ordering these scattered and torn pages and understanding the physical, chemical, and biological processes that acted on them since Earth appeared and solidified require a detailed and accurate time scale.

This calibration to linear time of the succession of events recorded in the rocks on Earth has three components (Figure 1):

1. The international stratigraphic divisions and their correlation in the global rock record
2. The means of measuring linear time or elapsed durations from the rock record
3. The methods of joining the two scales, the stratigraphic one and the linear one

For clarity and precision in international communication, the rock record of Earth's history is subdivided into a "chronostratigraphic" scale of standardized global stratigraphic units, such as "Devonian," "Miocene," "*Zigzagiceras zigzag* ammonite zone," or "polarity Chron C25r." Unlike the continuous ticking clock of the "chronometric" scale (measured in years before the year AD 2000), the chronostratigraphic scale is based on relative time units in which global reference points at boundary stratotypes define the limits of the main formalized units, such as "Permian." The chronostratigraphic scale is an agreed-upon convention, whereas its calibration to linear time is a matter for discovery or estimation.


Geologic Time Scale, Figure 1 The construction of a geologic time scale is the merger of a chronometric scale, measured in years, and a chronostratigraphic scale, consisting of formalized definitions of geologic stages, biostratigraphic zonation units, magnetic polarity zones, and other subdivisions of the rock record.

By contrast, Precambrian stratigraphy is formally classified chronometrically, i.e., the base of each Precambrian eon, era, and period is assigned an arbitrary numerical age (Van Kranendonk, 2012). The reason for this is the difficulty to actually define globally correlative Precambrian rock units and date them. An exception is the final period of the Precambrian and the Ediacaran that now has a chronostratigraphic definition, with a GSSP (see below) for its base (Narbonne et al., 2012).

Under the auspices of the International Commission on Stratigraphy (ICS), over 65 % of the international stratigraphic divisions of the Phanerozoic and their correlative events are now (January 2013) standardized, using the GSSP (Global Boundary Stratotype Section and Point) concept. This concept identifies "globally" correlative levels in continuous (marine) sedimentary sections where stage boundaries are defined and (literally) pinned down, under state protection. Correlations from and to the rockbound pin level facilitate extra-regional and/or global stage boundary recognition. On the Internet site https://engineering.purdue.edu/Stratigraphy/, the GSSP record is summarized and kept track of.

Conventions and standards

Ages are given in years before "Present" (BP). To avoid a constantly changing datum, "Present" was fixed as AD 1950 (as in ^{14}C determinations), the date of the beginning of modern isotope dating research in laboratories around the world. For most geologists, this offset of official "Present" from "today" is not important. However, for archeologists and researchers into events during the Holocene (the past 11,500 years), the offset between the "BP" convention from radiogenic isotope laboratories and actual total elapsed calendar years becomes significant. The offset between the current year and "Present" has led many Holocene specialists to use a "2000 BP," which is relative to the year AD 2000.

For clarity, the linear age in years is abbreviated as *a* (for annum), and ages are measured in *ka*, *Ma*, or *Ga* for thousands, millions, or billions of years before present. Elapsed time or duration is often abbreviated as *yr* (for year) and longer durations in *kyr* or *myr*. Therefore, the Cenozoic began at 66 Ma and spans 66 myr (to the present day, defined as the year AD 2000).

The uncertainties in computed ages or durations are expressed as standard deviation with 2-sigma (95 %) confidence. The uncertainty is indicated by "±" and will have implied units of thousands or millions of years as appropriate to the magnitude of the age.

Historical overview of geologic time scales

Stitching together the many data points on the loom of time requires an elaborate combination of earth science and mathematical/statistical methods. Hence, the time and effort involved in constructing a new geologic time scale and assembling all relevant information is considerable. Because of this and because continuous updating in small measure with new information is not advantageous to the stability of any common standard, new geologic time scales come out sparsely.

Since 1981, six successive Phanerozoic GTSs have been published, each new one achieving higher resolution, better error analysis, and more users worldwide (Harland et al., 1982, 1990; Gradstein and Ogg, 1996; Gradstein et al., 2004 = GTS2004; Ogg et al., 2008; Gradstein et al., 2012 = GTS2012).

Geologic time scale (GTS2012)

The current standard geologic time scale is GTS2012 (Gradstein et al., 2012), constructed between 2004 and 2012 with a team of over 65 earth science and other specialists. Many of its coauthors are officers of ICS. Philosophy, methodology, chronostratigraphy, and geochronology are laid out in 32 chapters. Three data appendices detail stages of color coding, all radiometric dates, and Cretaceous through Cenozoic calcareous microfossils biochronology.

Construction of GTS2012 may be summarized in four steps:

Step 1. Construct an updated global chronostratigraphic scale for the Earth's rock record.

Step 2. Identify key linear-age calibration levels for the chronostratigraphic scale using radiogenic isotope age dates, and/or apply astronomical tuning to cyclic sediment, or scale and interpolate (near) linear segments of stable isotope sequences.

Step 3. Interpolate the combined chronostratigraphic and chronometric scale, for example, with a smoothing cubic spline, where direct information in specific stratigraphic intervals is wanting.

Step 4. Calculate or estimate error bars on the combined chronostratigraphic and chronometric information to obtain a geologic time scale with estimates of uncertainty on boundary ages and on unit durations.

The first step, integrating multiple types of stratigraphic information in order to construct the chronostratigraphic scale, is the most time-consuming; it summarizes and synthesizes centuries of detailed geological research while reconciling it with the most up-to-date information. The second step, identifying which radiogenic isotope and cycle-stratigraphic studies would be used as the primary constraints for assigning linear ages, is the one that is evolving most rapidly since the last decade. Historically, time scale building went from an exercise with very few and relatively inaccurate radiogenic isotope dates, as used by Holmes (1960), to one with many dates with greatly varying analytical precision (like GTS89).

The new philosophy for Step 2 that was started in GTS2004 and expanded in GTS2012 is to select stratigraphically meaningful radiogenic isotope dates with high analytical precision. More than 260 radiogenic isotope dates were thus selected for their reliability and stratigraphic importance to calibrate the geologic record in linear time. All 260+ GTS2012 age dates are detailed in Appendix 2 of GTS2012 by Schmitz (2012).

In addition to selecting radiogenic isotope ages based upon their stratigraphic control and analytical precision, GTS2012 also applied the following criteria or corrections:

1. Stratigraphically constrained radiogenic isotope ages with the U-Pb method on zircons were accepted from the isotope dilution mass spectrometry (IDMS) method, but not from the high-resolution ion microprobe (SHRIMP).
2. ^{40}Ar-^{39}Ar radiogenic isotope ages were recomputed to be in accord with the revised ages for laboratory monitor standards: 527.0 ± 2.6 Ma for MMhb-1 (Montana hornblende), 28.51 ± 0.06 Ma for TCR (Taylor Creek sanidine), and 28.201 ± 0.046 Ma for FCT (Fish Canyon sanidine). Systematic ("external") errors and uncertainties in decay constants are partially incorporated (Kuiper et al., 2008; Schmitz, 2012). As in GTS2004, no glauconite-based dates are used.

The bases of Paleozoic, Mesozoic, and Cenozoic are bracketed by analytically precise ages at their GSSP or
Geologic Time Scale, Figure 2 Methods used to construct Geologic Time Scale GTS2012 integrate different techniques depending on the quality of data available within different intervals.

primary correlation markers, respectively, 541 ± 0.63 Ma, 252.16 ± 0.5 Ma, and 65.95 ± 0.05 Ma, and there also are direct age dates on base Carboniferous, base Permian, base Jurassic, base Cenomanian, and base Eocene, but most other period or stage boundaries prior to the Neogene lack direct age control. No radiometric age dates were available to GTS2012 for Barremian, Bathonian, Norian, Kungurian through Wordian, Givetian, Pragian, Pridoli, Gorstian, Aeronian, Floian, and large parts of Cambrian. The Callovian through Hauterivian and Upper Triassic are particularly low in stratigraphically meaningful radiometric dates. Therefore, the third step, linear interpolation, still plays a key role for most of GTS2012, as it did in GTS2004. This detailed and high-resolution interpolation process incorporates several techniques, depending upon the available information (Figure 2):

1. A composite standard of graptolite zones spanning the uppermost Cambrian, Ordovician, and Silurian interval was derived from hundreds of sections in oceanic and slope environment basins using the Constrained Optimization (CONOP) method (Cooper and Sadler, 2012). With average zone thickness from many sections taken as directly proportional to zone duration, the detailed composite sequence was scaled using high-precision zircon and sanidine age dates.
2. High-precision ID-TIMS U-Pb zircon ages of a great many interstratified tuffs and tonsteins were used to

calibrate the detailed litho-, cyclo-, and biostratigraphic framework of Carboniferous basins of Eastern Europe. Age resolution of <0.05 % or *ca* 100 kyr was obtained for these Carboniferous volcanics. This precision allows the resolution of time in the Milankovitch frequency band and confirms the long-standing hypothesis that individual high-frequency Pennsylvanian cyclothems and bundles of cyclothems into fourth-order sequences are the eustatic response to orbital eccentricity (*ca* 100 and 400 kyr) forcing. Combining the new datings with orbital tuning of fourth-order sequences in the basins scales Carboniferous stages to a new level of precision (Davydov et al., 2012).

3. Only three Cretaceous stages have ratified GSSPs, but reasonable stable consensus definitions exist for the other nine ones (Ogg and Hinnov, 2012). The age model for the Berriasian through Barremian ammonite zones is mainly derived from correlations to the M-Sequence of marine magnetic anomalies plus intervals with cycle stratigraphy and/or linearization of strontium isotope trends. The Aptian-Albian ammonite zones are scaled according to their correlation to microfossil and nannofossil data, which, in turn, are scaled by cycle stratigraphy. Base Cenomanian has a direct age date, using the Japanese sediment record. A spline fit of numerous radioisotopic dates from

Geologic Time Scale, Figure 3 The new Geologic Time Scale 2012.

volcanic ash horizons interbedded with US Western Interior ammonites with adjustments for cycle stratigraphy of some intervals provides a high-resolution numerical scale for the Cenomanian through early Maastrichtian. The late Maastrichtian correlations rely on microfossil data calibrated to a spline and cycle fit of C-Sequence marine magnetic anomalies.

4. Astronomical tuning of cyclic sediments was used for Neogene, Oligocene, Paleocene, and most of Eocene and portions of the Cretaceous, Jurassic, and Triassic. The Oligocene through Neogene astronomical scale is directly tied to the Present (Hilgen et al., 2012; Vanden Berghe et al., 2012); the older astronomical scale provides linear duration constraints on polarity chrons, biostratigraphic zones, and entire stages.

5. Proportional scaling was undertaken relative to component biozones or subzones. This procedure was necessary in portions of the Triassic and Jurassic. Devonian stages were scaled from approximate equal duration of a set of high-resolution subzones of ammonoids and conodonts and tentative estimates of sedimentary cycles' duration, fitted to an array of dates.

The actual statistical procedures and error analysis employed for the above proportionally scaled zones and stages in major parts of GTS2012 were programmed and executed by O. Hammer (in Agterberg et al., 2012). The uncertainties on older stage boundaries systematically increase owing to potential systematic errors in the different radiogenic isotope methods, rather than to the analytical precision of the laboratory measurements. In this connection we mention that biostratigraphic error is fossil event and fossil zone dependent, rather than age dependent.

Ages and durations of Neogene stages derived from orbital tuning are considered to be accurate to within a precession cycle (~20 kyr) assuming that all cycles are correctly identified and that the theoretical astronomical tuning for progressively older deposits is precise. Paleogene dating combines tuning, radiometrics, and C-sequence splining; hence, stage age uncertainty is larger and varies between 0.2 and 0.5 Ma.

The Geologic Time Scale GTS2012 is displayed in Figure 3 (from Gradstein et al., 2012).

Stratigraphic charts and tables

The plethora of names for time and time-rock units in local regions lends itself to the production of wall charts and stratigraphic lexicons that visualize the links between regional schemes and the standard scale. The international standard is developed in collaboration with officers of the International Commission on Stratigraphy (ICS). The Commission for the Geological Map of the World (CGMW) in Paris and ICS closely collaborate on the map and color coding of chronostratigraphic units on the standard chart. The updated charts in PDF format are freely available from websites https://engineering. purdue.edu/stratigraphy/ and www.nhm2.uio.no/stratlex and also are distributed by the CGMW.

A sophisticated, albeit easy time scale, graphics program for GTS2012 is called *TSCreator @*. This popular software, with its large time scale dataset, is freely available from https://engineering.purdue.edu/Stratigraphy/tscreator/. Now there are more than 25,000 Cambrian through Holocene biostratigraphic, sea-level, magnetic, and geochemical events in the public software database, all calibrated to GTS2012. Cross-correlations are in place for trilobites, conodonts, graptolites, ammonoids, fusulinids, chitinozoans, megaspores, nannofossils, foraminifers, dinoflagellates, radiolarians, diatoms, strontium isotope, C-org and oxygen curves, eustatic sea-level curves, etc. Scalable vector graphics output of any time scale interval is an easy option. A majority of linear scale drawings, with its calibrated event and zonal data in the GTS2012 book, were initiated in TSCreator, before being drafted in a final format.

Summary

The geologic time scale (GTS) provides the framework for the physical, chemical, and biological processes in time on Earth. The most up-to-date GTS is available since October 2012. Geoscientists can easily create and print time scale charts, utilizing the freely available software package "Time Scale Creator @."

GLACIAL-MARINE SEDIMENTATION

Alexander P. Lisitzin and Vladimir P. Shevchenko
P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences (IO RAS), Moscow, Russia

Definition

Glacial-marine sedimentation is the process of sediment deposition in the sea after release from ice shelves, tidewater ice fronts, icebergs, or sea ice.

Introduction

Glacial type of sedimentation dominates in polar and subpolar parts of the World Ocean and continues the regions of glacial sedimentation both on the land (in region land ice sheets, mountain glaciation, and other types of inland ice) and in seas and oceans (Lisitzin, 1972, 2002, 2010). Water catchments are changed here by ice catchments and annually are replenished by new portions of snow. In this kingdom of snow, ice and cold minimal values of winter temperatures reach $-71\,°C$ in the Northern Hemisphere and $-89\,°C$ in the Southern Hemisphere. It influences on the development of life in the ocean and on the land and residual soils at the stage of preparation of sedimentary matter on the land. It determines at a large extent both quantity, composition, and properties of marine bottom sediments and suspended particulate matter in water column.

Glacial-marine dynamics and associated sedimentary processes are closely tied to glacial regime and reflect dominant climate conditions (Trusel et al., 2010). Glacial-marine processes such as sediment flux and yield, terminus fluctuations, calving rates, freshwater flux, and mass balance are useful for comparison among differing glacial and climatic regimes. Understanding the relationship of complex modern processes to those found in glacial-marine sediment record can enhance interpretation of past glacial-marine processes and changes in biological productivity (Powell, 1984; Trusel et al., 2010).

According to the composition and genesis of ice and sedimentary material, glacial type of sedimentation could be divided into two subtypes:

1. Sedimentation from glacier ice, including iceberg sedimentation (defined by land glaciers reaching the sea)
2. Sea-ice sedimentation (defined by sea ice)

Sedimentation from glacier ice

Icebergs are released where glaciers, ice sheets, and ice shelves terminate in the ocean (Warren, 1992). Often icebergs released in fjords (Mugford and Dowdeswell, 2010). The dominant sedimentary process in most fjords is sedimentation from the brackish plumes rich in suspended particulate matter that emerges from either glacier-fed river mouths or tidewater cliff. Modern glacial-marine environments are widely spread in the Antarctic, Alaska, Greenland, Baffin Island, British Columbia, Svalbard, Norway, Novaya Zemlya, and Severnaya Zemlya (Drewry and Cooper, 1981; Elverhøi et al., 1983; Molnia, 1983; Cowan and Powell, 1991; Syvitski et al., 1996; Gilbert et al., 2003; Kehrl et al., 2011; Politova et al., 2012; Szczucinski and Zajaczkowski, 2012; Chewings et al., 2014; Miller et al., 2015).

The vertical sediment fluxes in these areas are relatively high. For example, maximum sediment flux from temperate glaciers in southeastern Alaska was measured in McBride Inlet; in average it was 53 kg m^{-2} day^{-1} (Cowan and Powell, 1991). In Kongsfjorden, Svalbard, near Kronebreen, glacier sediment flux reached
Glacial-marine Sedimentation, Figure 1 Kronebreen and Kongsvegen terminate at the head of Kongsfjorden, western Svalbard (Kehrl et al., 2011). Two point sources deliver sediment to the complex's terminus: an ice-marginal stream (*dashed white circle*) and a subglacial stream (*solid white circle*). The *gray circle* indicates a subglacial stream that emerged between Landsat images taken on 30 June and 7 July 2002. All three sediment sources form plumes that extend into the fjord. *Green* and *red lines* indicate 2005 and 2009 echo-sounding transects, respectively.

18.6 kg m^{-2} day^{-1} (Trusel et al., 2010). Studies in Billefjorden, a subpolar fjord in Svalbard, demonstrate that vertical downward particulate matter fluxes can reach up to several kg m^{-2} d^{-1} in subpolar non-glacier contact and glacier contact setting during the short summer season (Szczucinski and Zajaczkowski, 2012).

Studies in Kongsfjorden, western Svalbard, demonstrated that glacial-marine sedimentation processes continue to shape the fjord floor (Kehrl et al., 2011). Two point sources supply sediment to the fjord floor adjacent to the glacier complex: (1) a subglacial stream that exits Kronebreen just north of the centerline and (2) an ice-marginal stream that flows alongside the southern margin of Kongsvegen (Figure 1). Sedimentation rates are greatest near the ice cliff (>100 mm a^{-1}) and decrease to 50–100 mm a^{-1} ∼10 km away from the terminus (Elverhøi et al., 1983). About 90 % of the total sediment input is deposited within 400 m of the ice front, thereby decreasing water depth at the grounding line (Elverhøi et al., 1983; Svendsen et al., 2002).

Icebergs transport sediments far from glaciers, in some cases up to thousands of kilometers, releasing them gradually as they melt (Dowdeswell and Murray, 1990; Syvitski et al., 1996). There are no rivers and multiyear pack ice in the Antarctic. The distance of one-year ice field

transport, having a small reserve of cold, is small. Polar regions of the Southern Ocean are the main area of iceberg sedimentation now. In the Northern Hemisphere, Greenland and Canadian archipelago are the main areas of iceberg sedimentation. Load-carrying ability of icebergs in contrast to sea-ice fields reaches tens and hundreds of tons. Their large sizes (up to hundreds of km, generally less) ensure large reserve of cold; in some years icebergs cross the Southern Ocean and reach the southern ends of continents.

The area of distribution of icebergs reaches 62 * 10^6 km^2 in the Southern Hemisphere and only 3.3 * 10^6 km in the Northern Hemisphere (Lisitzin, 2002). More often (according to satellite data) they are found not only a continent together with one-year ice but far out of limits of sea-ice distribution, up to 26–30°S; i.e., they dominate in the Southern Hemisphere, crossing temperate zone and reaching arid zone.

A belt of icebergs girdles the Antarctica. Its width ranges from 400 to 1,200 km, averaging 500–700 km (Lisitzin, 2002). The zones of their distribution and concentrations of coarse material in bottom sediments have been established during expeditions. Near the coasts concentration of ice-rafted material exceeds 100 kg/m^3 of sediments and gradually decreases to values less than

1 kg m^{-3}. Most Antarctica icebergs discharge their load near the place of their origin; here submarine moraines are formed.

Fine material of icebergs is formed in bottom layers of glaciers as a result of the detachment of rock fragments from the glacier bed and their breaking up and abrasion (up to glacier milk).

Sea-ice sedimentation

The average time of life of sea ice in the Northern Hemisphere is 1.3 years (here the center of existence of multiyear ice is situated). There is no multiyear ice in the Southern Hemisphere. Sea ice is developed at the area of $26 \pm 3 *10^6 \text{ km}^2$; $13.1 *10^6 \text{ km}^2$ of them are in the Arctic Ocean (Lisitzin, 2002). The average thickness of sea ice is about 1.5 m, though in the area of multiyear ice, it reaches 4–6 m. The thickness of ice in water determines its carrying capacity – it is sufficient to carry coarse material including boulder with weight of tens to hundreds of kg (for icebergs the weight of boulders can be many tons).

In the main area of modern multiyear ice distribution in the Arctic, the average area of ice cover changes during a year from $11.4 * 10^6 \text{ km}^2$ in March to $7 * 10^6 \text{ km}^2$ in September. In the last years the area of ice cover considerably decreased as a result of climate warming.

Sea ice could be divided into one-year ice (which melts in summer and loses sedimentary matter included in it) and multiyear (packs) that could exist in a few years (up to 10–15 years in the Beaufort Gyre).

Correspondingly, one-year ice is the agent of nearby and middle-range transport of sedimentary matter, while multiyear ice is the agent of long-range transport (for 100–1,000 km). Major routes of their drift and horizontal fluxes according to satellite data and drifting station observations are demonstrated in Figure 2. One-year ice fields and pack ice fields discharge sedimentary matter differently. For one-year ice fields the spring melting along the outer periphery takes place at large area and sedimentary matter deposits as a result of the so-called carpet-like discharge. The discharge runs differently for pack ice. The melting occurs along the contact with warm waters (temperature from 0 °C to 1–2 °C above zero) in the Fram Strait (meeting with the North Atlantic Current) and in confluence of the Kuroshio and Oyashio currents (northwestern Pacific Ocean) (Lisitzin, 1968, 1996).

The distribution of ice-rafted material is analyzed in comparison with data on ice exposition (time of ice covering at this bottom part). After that the granulometric composition of ice-rafted material is studied by sieve method, roundness index is determined in comparison with standard samples, and fouling by organisms and concretions (for ancient samples) is estimated.

The most important part of the study of ice-rafted stones is petrographic analysis with selection of typical samples of standard collection and with looking through thin sections under a microscope. It allows to judge about complexes of rocks and to sort out provinces of ice-rafted

material distribution in bottom sediments (the same as sorting out results of mineralogical analysis of aleuritic fraction).

In some cases, for example, in the Kara Sea, an unusual wide distribution of basalt stones is registered (Lisitsin et al., 2004; Lisitsyn et al., 2004). Their source is situated in the catchment area at the Putorana Plateau. Comparative petrochemical analyses and determination of age confirmed marker value of this type of rocks. The preparation of maps of distribution of different types of rocks (generally few tens) in the upper layer of bottom sediments in the Sea of Okhotsk, Bering Sea, and northern Pacific Ocean made possible to establish areas of each rock type distribution and places of their supply from the continent (according to growth of concentrations). It became possible to determine the sources of these rocks as a result of comparison of collected rocks with rocks in the catchment area and to reveal ways of migration of ice fields marked by rock material (according to their contents in bottom sediments) (Lisitsin, 1968, 1972, 1996, 2001, 2002, 2010; Lisitsin et al., 2004; Lisitsyn et al., 2004).

Coarse waste material is an impressive indication of ice rafting, but it is not sole. The study of finer fractions (sand-aleuritic and politic) and biogenic material gives important data. Analysis of sedimentary matter obtained by melting of sea ice gives important materials also. These studies made possible to reveal one unexpected source of glacial sediments – aeolian (Darby et al., 1974; Lisitzin, 2002; Shevchenko et al., 2002; Shevchenko, 2010; Chewings et al., 2014; Miller et al., 2015). The main feature of aeolian supply here is that aeolian material is deposited mostly during polar winter at low temperatures. In summer aeolian material is washed out rapidly from the atmosphere by rains. In winter most part of catchment area is covered by snow and frozen. The sedimentary aeolian matter in winter is supplied mainly as a result of long-range (often more than 1,000 km) transport of matter in the atmosphere at levels higher than clouds.

Lastly, it is important to say about the new mechanism of fine sediment supply by sea-ice fields, which originated in polynyas along the boundary between fast ice and drift ice. Polynyas formation is related to strong winds separating the drift ice from the fast ice; the winds are particularly strong along the periphery of the east Siberian anticyclone (Kara, East Siberian, and Laptev seas) and accompanied by very low temperatures (-30 to -40 °C). The extent of some polynyas from time to time reaches 1–3,000 km. This giant freezing plant combines open water of polynyas with strong wind and very low temperature. This leads to overcooling of both the surface layer and a significant part of the water column. Frazil ice and sometimes bottom ice are formed around centers of crystallization represented by suspended particles. The tiny freshwater ice crystals become even less dense compared to the host marine water (the process of cold distillation) and appear as hanging to the suspended particles; like floats, they
Glacial-marine Sedimentation, Figure 2 Major routes of ice drift and ice-rafted sedimentary material transport (Lisitzin, 2002, 2010). Horizontal fluxes of sedimentary matter, entrainment areas, transportation dynamics, and major areas of discharge, cryodepocenters (fronts of contact with warm waters): *1*, discharge zones, basins, and cryodepocenters of ice-rafted sedimentation; *2*, areas adjacent to Greenland where ice is supplemented by icebergs; *3*, major (*a*) and minor (*b*) areas of iceberg supply; *4*, areas of fast ice development (entraining shallow water sediments). *Arrows*, major routes of ice drift; *dashed arrows*, iceberg drift; *dashed line*, major Arctic ice divide separating Eurasian and North American sedimentary matter transport. Numbers in rectangles, ice volume (km^3): first number, at the end of winter; second number, ice carried in the central part of the Arctic Ocean. Numbers in cryodepocenters: volume of annual ice melt (km^3/year); semibold, ice-rafted and iceberg-rafted material supply (10^6 tons/year).

quickly rise to the surface and aggregate to form shuga. This phenomenon, called as ice pump (Lisitzin, 2010), is widely spread, but studied insufficiently due to operation in the polar night. Ice pump transfers fine suspended particulate matter from water to sea ice of the shelf. It is this type of processes that facilitates the sedimentary matter transportation from the major suppliers of newly formed ice (the Laptev, Kara, East Siberian, Chukchi, Beaufort seas) into the Central Arctic and after that to cryodepocenters (Nürnberg et al., 1994; Reimnitz et al., 1994; Lindemann et al., 1999; Eicken et al., 2005; Dethleff and Kuhlmann, 2010; Darby et al., 2011, 2015). Sediments can be entrained in sea ice during anchor ice formation (Reimnitz et al., 1987; Darby et al., 2011). Polar researches studying ice flows leaving the Arctic Ocean through the Fram Strait have noticed that the ice in general becomes darker and contains more dark spots of sedimentary matter ("dirty ice") (Figure 3).

[7]The activity in the ice recently was used to estimate that the annual transport and release of sediments to the ablation area of the Fram Strait is about 500 g m^{-2} (Cámara-Mor et al., 2011), a value comparable to previously measured fluxes in sediment traps deployed in this area and larger than in the areas mostly covered by ice (Table 1).

Conclusions

Thus, the zone of modern glacial sedimentation, connected with sea ice and icebergs, integrally occupies about 20 % of the World Ocean surface, i.e., this type of sedimentary process is very important in the ocean both now and in the past (Lisitzin, 1968, 1996, 2002, 2010; Powell, 1984; Dowdeswell and Scourse,1990; Stein, 2008; Levitan and Lavrushin, 2009). During of glacial periods it became the major not only on continents but in World Ocean. Thus, the studies of the last few decades convincingly proved the existence of particular material-genetic type of bottom sediments, which occupied during the interglacials about 20 % of the surface of Cenozoic oceans and during glaciations (now we know about 6 of them) about 30 %, i.e., the global material-genetic type of marine and continental sedimentation, discovered and studied in the last century, is very important.

Glacial rebound; Isostasy

Definition

Isostasy refers to the response of the Earth to surface loading. Glacio-hydro-isostasy refers to the specific case of surface ice and water loads during glacial cycles. The most important observation of this process is the change in sea levels around the world.

Introduction

Isostatic adjustment of the Earth refers to the response of the Earth to changes in surface loading. The classic examples are the Airy or Pratt models (Watts, 2001) in which the surface load (of, for example, sediments) is supported locally either by a deflection of the crust (Airy) or by a change in crustal density (Pratt) beneath the load such that, at some deeper and constant depth in the mantle, pressures are constant. In these models, the crust (or lithosphere) does not support shear stresses. In models of regional isostatic adjustment (e.g., the Vening Meinesz model), the load is supported by the elastic strength of the crust or lithosphere and by the buoyancy forces acting at the base of the layer (Heiskanen and Vening-Meinesz, 1958). In these regional elastic models, small-amplitude, short-wavelength bulges form in the crustal deformation around the load, and in the geological literature, reference is sometimes made to a lithospheric forebulge. In both cases, the mantle is represented as a zero-viscosity fluid and the isostatic state is indicative of the Earth's deformational response only when the loading histories are longer than the relaxation time of the mantle. This relaxation time is characteristically of the order of 10^4 years, and the models are not appropriate for analyzing the response of the Earth-ocean system to changing glacial loads where both the mantle flow and gravity field changes are dominant factors in determining the shape of the solid Earth and ocean surface.

The Earth's response to changing ice and water loads

The glacio-hydro-isostatic adjustment refers to the Earth's response to the changing ice and water surface loads during glacial cycles, particularly to the last phase of deglaciation, that have characteristic load-cycle time scales of 10^3–10^5 years, of similar magnitude as the mantle relaxation times. Hence response models must consider the flow induced in the mantle by the surface loading cycle, and in consequence, the response continues for some thousands of years after the ice loads have stabilized.

When ice sheets grow, the crust and lithosphere beneath the ice subsides as mantle materials flow away from the stressed regions. At the same time, water is taken out of the oceans to feed the growing ice sheets, unloading the underlying mantle and resulting in ocean floor uplift relative to the center of mass of the Earth. The reverse occurs during the decay phase of the ice cycle. The glacio-hydro-isostasy is therefore a global phenomenon, and models of which will have to consider both the ice and water loads through time.

Several observational measures of the Earth's response exist: (i) the deformation of the land surface and this is measured by geodetic methods, most notably by GPS, (ii) changes in the planet's gravity field as both internal and surface mass redistribution occurs and this is measured with gravity meters as well as inferred from perturbations in Earth-satellite orbits, (iii) changes in the Earth's rotation measured by astronomical and satellite methods, and (iv) changes in sea-level as measured by tide gauges and as preserved in the geological record. The

instrumental records extend back for decades to at most about 100 years and measure only the response long after the end of the last major deglaciation phase. They are, therefore, likely to also include the Earth's response to any recent changes in the residual ice sheets.

The geological evidence for sea-level change is particularly important since it extends back in time, primarily to the time of the Last Glacial Maximum (LGM) but with scattered evidence for earlier periods. The observation is of the change in sea-level relative to the land surface and is, therefore, a relative measurement and includes both the crustal deformation associated with the changes in surface loads and the changes in the shape of gravitational equipotential surfaces. A raised shoreline could mean either that there has been land uplift, that there has been a reduction in ocean volume, or that there has been a redistribution of water within the ocean basin. The glacio-hydro-isostatic effect is a combination of all three. Observations of sea-level therefore contain information on the Earth's rheology as well as on the ice history, and on any other processes, principally of tectonic and geodynamic origin.

Models for predicting the Earth's response to glacial cycles and the concomitant water loading have been well developed over recent decades with a focus on linear viscoelastic models for the mantle rheology and in particular on a Maxwell rheology with realistic radial elastic and density stratification (Peltier, 1974; Cathles, 1975). The rheological parameters are usually expressed as depth-dependent effective viscosities and as an effective elastic thickness of the lithosphere that provide a formulation that appear to work remarkably well in explaining much of the observational evidence even though the relations between these parameters and laboratory evidence for mantle behavior under stress remains unclear. A critical element in these models is the treatment of the water loading on a deforming Earth such as to be gravitationally consistent and conserve ice-water mass in which the water load itself is a function of the deformation of the Earth and of the redistribution of the water (Farrell and Clark, 1976; Mitrovica and Milne, 2003).

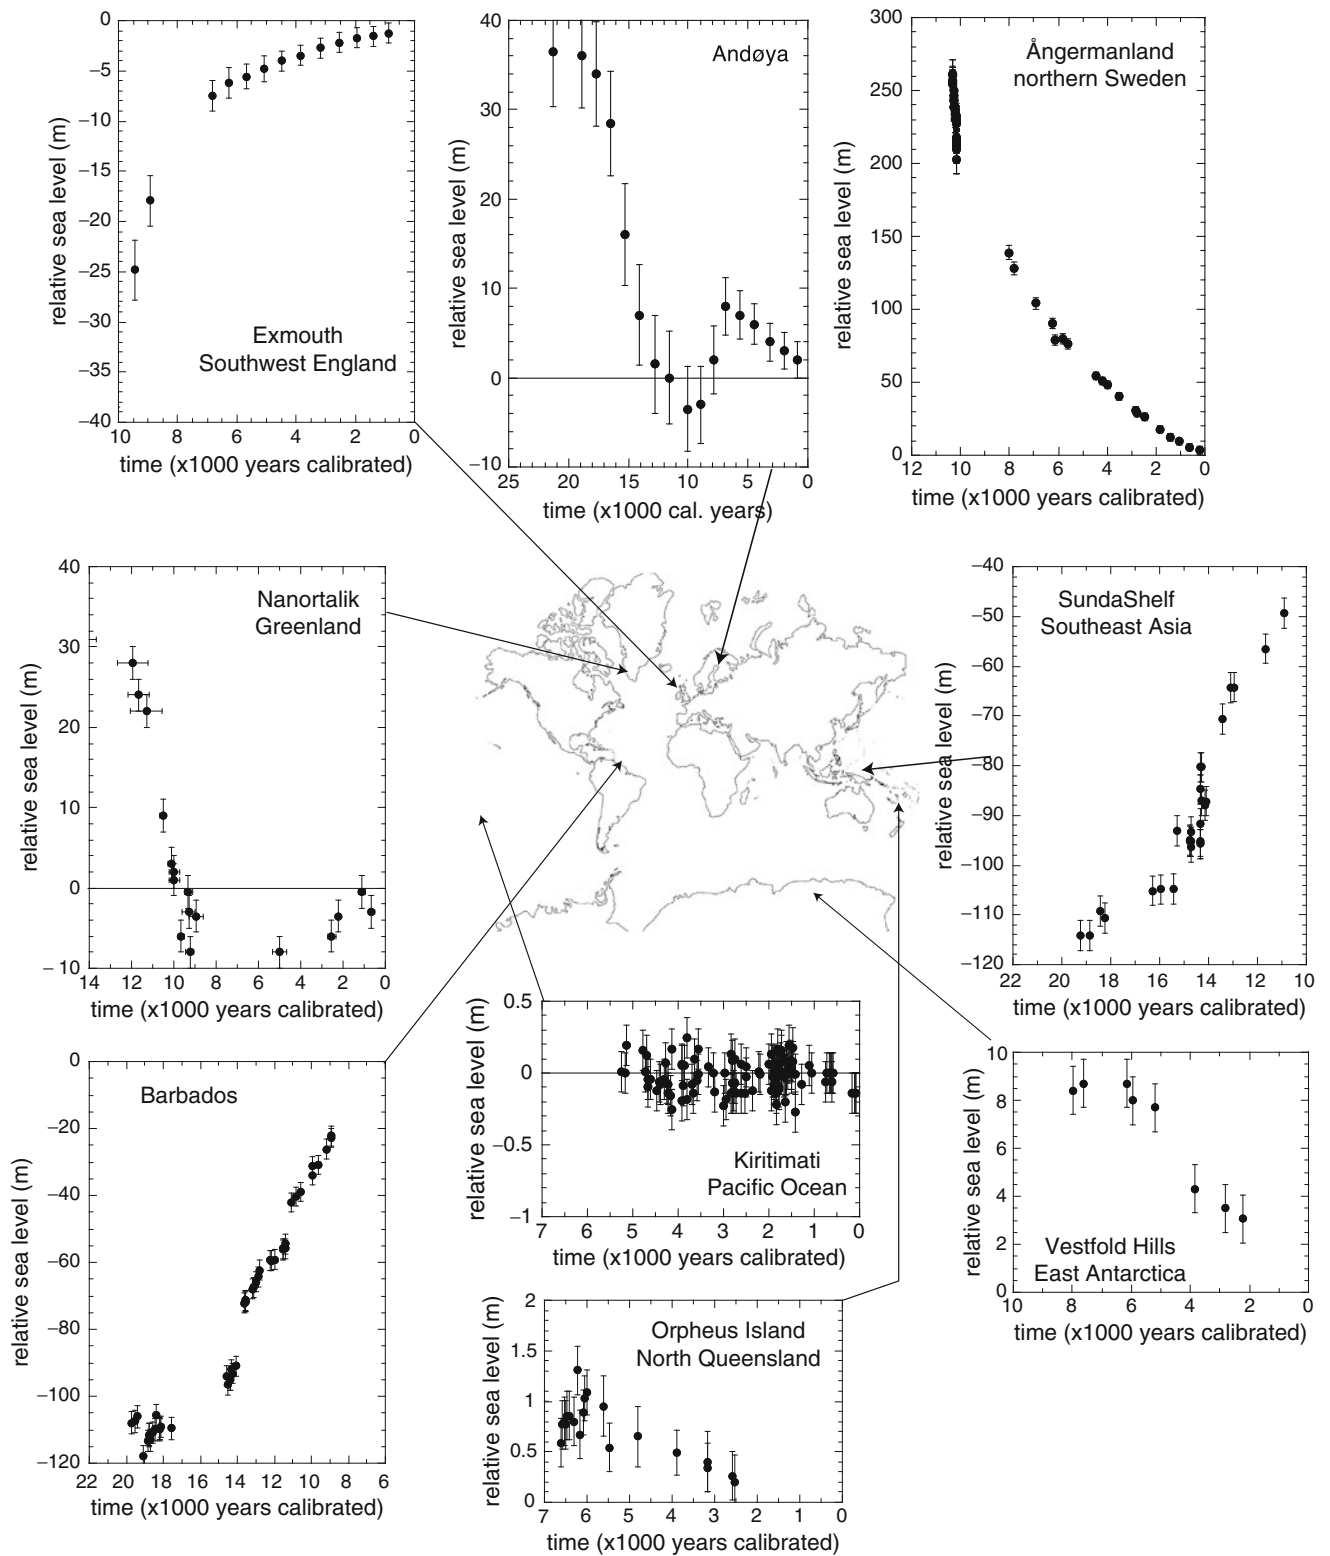
The pattern of global sea-level change

The pattern of sea-level induced by the growth and decay of ice sheets is conveniently divided into three zones: areas within or near the margins of the former ice sheets (near-field), areas far from these ice sheets (far-field), and an intermediate-field. During deglaciation, the dominant contribution to sea-level change in the near-field is the crustal rebound as mantle materials flow back beneath once ice-loaded continents. This is the glacio-isostatic component. For the largest ice sheets, perhaps up to 4,000 m thick and 1,000 km or more radius, the total rebound since the LGM approaches the local isostatic limit of 800–1,000 m but only the rebound that occurred after the region became ice-free is preserved in the record. Rates of crustal uplift of up to 1 cm/year still occur in areas

such as the Hudson Bay (Canada) or the Gulf of Bothnia (Fennoscandia). The other not insignificant contributions are from changes in the gravitational attraction in the Earth-ocean-ice system, the change in the ocean volume and the deformation of the Earth caused by the changing water load. The net result is that where there once were large ice sheets, sea-level has been falling and continues to fall long after the last of the ice has vanished. Toward the edge of the ice sheet, the crustal rebound component is reduced, and the other contributions begin to dominate the signal such that the relative sea-level signal may oscillate in time between rising and falling.

In far-field regions, it is the change in the ocean volume and the deformation of the Earth caused by the water loads that are the dominant contributors. With increasing water, the ocean floor subsides, approaching the local isostatic limit in mid-oceans of about 25 % of the change in the ocean depth. Along continental margins, because of the elastic properties of the lithosphere and the viscous flow in the mantle, the subsidence will be about half this. This is the hydro-isostatic component. Since the LGM, $\sim 50 \times 10^6 \, \text{km}^3$ of ice has been added into the oceans raising globally averaged sea-level by ~ 135 m but by less along the continental far-field margins because of the isostatic effects. At the end of glaciation, the ocean volume remains constant but the isostatic effects continue and sea levels fall, producing small-amplitude (up to ~ 3 m) highstands peaking at around 6,000 years ago that will be strongly dependent on nearby coastline geometry.

In the intermediate-field, the deformational, gravitational, and ocean volume contributions are often of similar magnitudes but opposing signs, such that the sea-level signal can be spatially complex. But the dominant feature of this response is the combination of the subsidence of a broad zone of crustal uplift that developed around the ice sheet during the loading phase and the change in the gravitational attraction between ice and ocean. Together, these factors result in sea levels outside of the ice margins rising throughout the post-glacial phase at rates that are a function of the ice sheet dimensions and of the distance from the ice margin. This pattern will extend out to several thousand kilometers beyond the center of the largest ice sheets.

Viewed globally, the glacio-hydro-isostatic response can therefore be expected to present a complex spatial and temporal variability, and this is indeed observed (Figure 1). For Hudson Bay and the Gulf of Bothnia, near the centers of the North American and Fennoscandian ice sheets respectively, sea-level has been falling over past millennia, and observations of the timing and rates of this fall provide constraints on both the mantle response function and local ice thickness. In the northwestern Norway example of Andøya in Figure 1, sea levels since the respective areas became ice-free have fallen and risen in time due to competing contributions from the crustal rebound and ocean volume increase, and observations from these locations provide insight into the local details of the ice sheet. The Andøya record, for example,


Glacio(hydro)-isostatic Adjustment, Figure 1 (Continued)

indicates that thick ice must have extended out to the edge of the continental shelf before the formation of the oldest sea-level signals at ~20,000 years ago. The record from the Vestfold Hills, East Antarctica, is of shorter duration than that of Andøya, but the fall in level during the past 6,000 years is similar and indicative of this area having been extensively glaciated. Further outside the ice margins as in southern England, sea-level has continued to rise up to the present as a result of the subsidence of the crust beyond the ice margins, and the spatial variability of this rise provides information on the mantle response function. At the far-field continental margin site of Orpheus Island, Australia, sea-level has been falling for the past 6,000 or so years, reflecting the Earth's response to the water loading, and the spatial variability of this highstand provides a measure of the Earth's response as well as any changes in ocean volume during this period. Far-field observations from the time of the LGM, such as the Bonaparte Gulf (Australia) or Sunda Shelf (Southeast Asia), provide a first approximation estimate of the total change in ice volume that has occurred since the LGM, and records from the late glacial period, such as from Barbados, constrain in a first approximation the timing and rate of melting of the global ice sheets. Second approximation solutions require that these observations be corrected for the isostatic (and, where relevant, the tectonic) contributions to the local sea-level change.

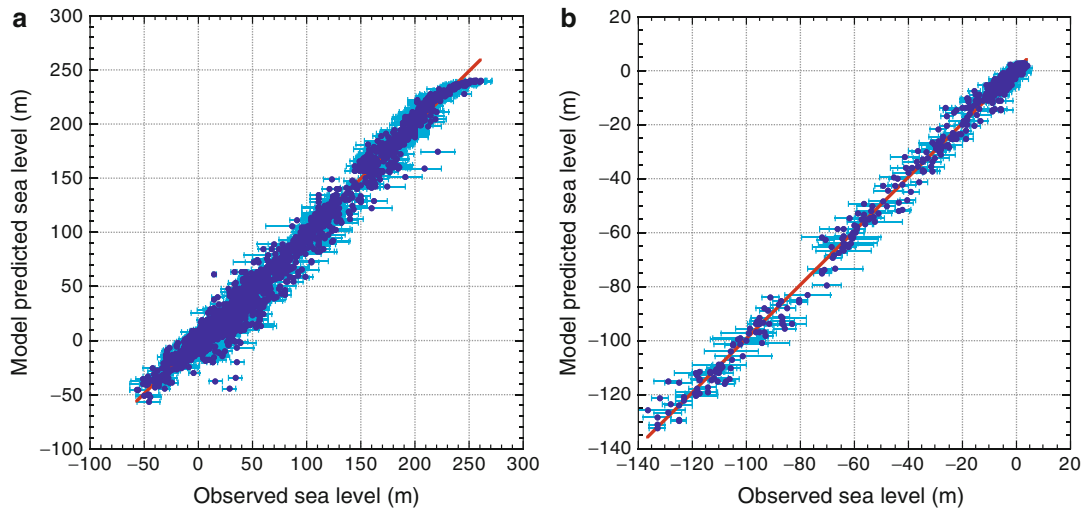
Inversion of sea-level data for geophysical and glaciological parameters

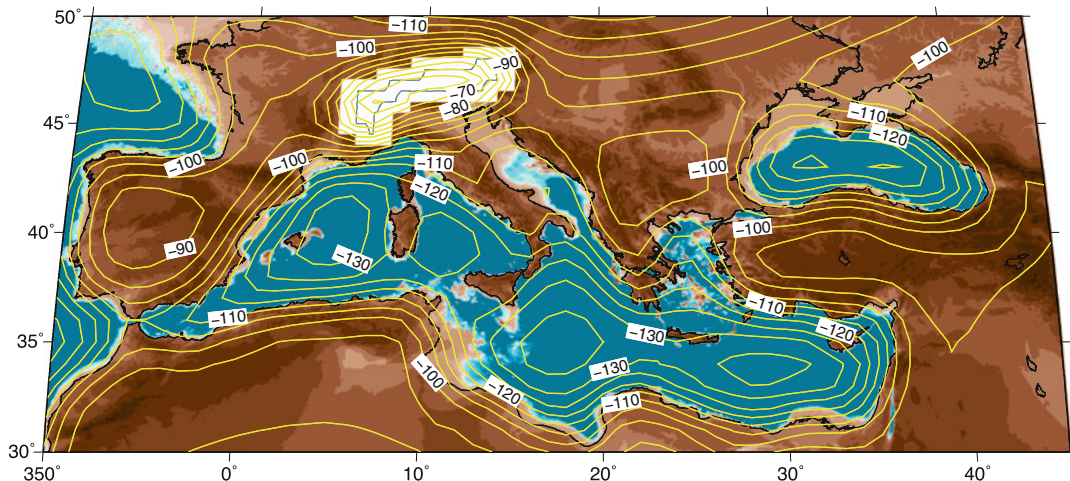
From this brief global survey, it should be evident that geophysical inversion of global data sets should be able to provide constraints on both the Earth's rheology and on ice sheet histories. There are often a number of caveats to such models concerning the distribution of the sea-level data, the parameterization of the rheology function, assumptions about the role of tectonics, or the nature of independent constraints on the location of former ice margins and on ice thickness through time.

The resolution for the radial dependence of mantle viscosity is limited in these inversions (Paulson et al., 2007) in part because of the limiting nature of the distribution of field data and in part because of uncertainties in the knowledge of the ice sheets, but solutions do point to an increase in mantle viscosity from the average upper mantle value to the average lower mantle value by a factor of 50–100 or more, consistent with independent – geodynamically reasoned – estimates (e.g., Mitrovica and Forte, 2004; Čížková et al., 2012).

Limitations in the knowledge of the past ice sheets are particularly severe in their impact on the inferred rheologies. The usual assumption is that the ice margin history is known, and the ice thickness through time is treated as a partially known function. Of the major past ice sheets, the Fennoscandian ice models is best constrained from rebound analyses because of an extensive and reliable database of both sea-level change within its former maximum margin and of the ice margin history. The North American ice sheet is less well constrained, and the Antarctic ice sheet remains largely unconstrained. Recent ice models obtained from sea-level data inversions include Peltier (2004) for a global model, Lambeck et al. (2010) for northern Europe, Fleming and Lambeck (2004) for Greenland, and Whitehouse et al. (2012) for Antarctica.

Generally, the models provide a good description of the observational evidence (Figure 2) and a basis for predictive models for the evolution of coastlines and water depths from the LGM to the present, provided that the model parameters are from consistent Earth-ice solutions because of the trade-offs that can occur between them through incomplete a priori information of the ice sheets. Figure 3 provides one such example for the Mediterranean where the contours provide lines of constant sea-level change from the LGM to the present. Of note is that these contours follow closely the coastline, indicative of the importance of the water loading within the Mediterranean basin. The influence of the local Alpine ice sheet is restricted to the northern Adriatic and Gulf of Genoa. Less visibly evident is the longer wavelength influence of the North American and Eurasian ice sheets consisting of a north–south gradient across the region. Results such as these are model-parameter dependent and can be, and have been, tested against local independent sea-level data, but they provide useful starting points for discussing

Glacio(hydro)-isostatic Adjustment, Figure 1 Representative sea-level curves from different localities around the world from the time of the Last Glacial Maximum to the present. Note the different time and sea-level change scales. The Ångerman result, from central Sweden, is representative of a location near the center of a former ice sheet, with crustal rebound exceeding the increase in ocean volume throughout the melting and post-glacial phase. The Andøya result, from the northwest coast of Norway, and the Nanortalik result, from southern Greenland, are representative of sites near the edge of an ice sheet. Initially, the rebound dominates, followed by a period when the increase in ocean volume dominates and a later phase when the rebound is again dominant. In the case of the Greenland signal, a major contributor to the sea-level change is from the North American deglaciation. The East Antarctic site of Vestfold Hills is similar to that of Andøya indicating that substantial changes in ice volume occurred here before the area became ice-free. The southwest England result is representative of locations outside of the ice sheet where the crustal rebound after the onset of melting is one of subsidence. The signal is initially dominated by the increase in ocean volume and later by the crustal response. The Sunda Shelf and Barbados locations are far-field sites, and the sea-level signal is dominated by the change in ocean volume, modulated by glacio-hydro-isostatic contributions. The North Queensland site is representative of far-field continental margins where a small-amplitude highstand forms in Late Holocene time due to the water-loading component. At the mid-ocean island site of Kiritimati, the change in sea-level is virtually constant for 5,000 years due to a cancellation out of the various isostatic contributions to sea-level change.


Glacio(hydro)-isostatic Adjustment, Figure 2 Two examples of comparison of sea-level observations from the past 20, 000 years with predictions based on glacio-hydro-isostatic models. The red lines are linear regressions, in both cases with gradients that depart from unity by less than 1 % and with correlation coefficients greater than 99 %. (**a**) For a near-field solution of Fennoscandia, with nearly 3,300 data points. The anomalous points below the linear regression line identify sites where the ice model is either deficient in ice or where the retreat occurred earlier than assumed in the ice model. These sites are all from the Norway coast and indicate that thick ice covered the continental shelf during the LGM. (**b**) For a global far-field solution consisting of some 990 data points. Systematic departures from the regression line, such as occurring at observed depths between -70 and -80 m and corresponding to ages around 14,000 years ago, point to a need to modify the global ice volume function. By combining far- and near-field analyses of sea-level data, it becomes possible to improve the ice models for the individual ice sheets as well as for the total changes in ice volume from the time of maximum glaciation to the present.


Glacio(hydro)-isostatic Adjustment, Figure 3 Reconstruction of the difference in sea-level between the Last Glacial Maximum and today for the Mediterranean basin, based on the glacio-hydro-isostatic model whose ice sheet and Earth-rheology parameters have been constrained by sea-level data from both far- and near-field sites. The contours (at 5 m intervals) are of equal change in sea-level between the LGM and present. Such models can be compared against archaeological and geological sea-level indicators from across the region to test the models themselves or to infer tectonic contributions to sea-level change.

geological and archaeological data from coastal areas or as a reference surface for evaluating tectonic rates of vertical motion. At the LGM and early late glacial period, much of the northern Adriatic is predicted to be subaerial, as are other shelf areas, most notably the Gulf of Gabes. Land bridges are predicted between mainland Italy and Malta and the crossing between Corsica-Sardinia, and continental Europe is reduced to little more than 10 km.

Glacial rebound before the last glacial maximum

While most discussions on glacio-hydro-isostatic adjustment have focused on the last phase of deglaciation, it is

important to note that this process is important also on longer time scales when it comes to interpreting interglacial sea levels in terms of differences in ice volumes relative today (Lambeck et al. 2012; Raymo et al. 2011. First, the response to the glacial history immediately before the interglacial will determine the nature of the interglacial sea-level function in the same way as the LGM determined the character of Holocene sea levels. Second, the observation of the past interglacial sea levels are with respect to present sea-level which is still evolving in response to the last glacial loading-unloading phase. This latter part can be predicted with some confidence from analyses of the recent interval, but the accuracy of the first part will be very much limited by the knowledge of ice extent during the earlier glacial maxima. Hence, estimates of the differences in ice volumes between present and earlier interglacials remain uncertain.

Summary

Glacio-hydro isostasy is an important physical process describing the Earth-ocean response to changes in ice sheets during glacial cycles. It is a global phenomenon and operates long after the surface loads have stabilized. It manifests itself in a wide range of geophysical and geological observations of which the most important is sea-level change. Observations of the isostatic response provide an important input for understanding the evolution of past ice sheets and ocean volumes.

GRAVITY FIELD

Udo Barckhausen and Ingo Heyde
Federal Institute for Geosciences and Natural Resources,
Hannover, Germany

Definition

The gravity field in marine geosciences is the gravitational force that the Earth's mass exerts on objects on or near its surface.

Introduction

The basic principle for the Earth's gravity field in classical mechanics is Newton's law of universal gravitation. It states that every massive body exerts an attractive force on all other massive objects. The force is proportional to the product of the bodies' masses and inversely proportional to the square of the distance between them. For extended bodies like the Earth, their mass can be assumed to be concentrated as a point mass in their center (strictly this is only true for spheres with a symmetrical mass distribution). In geophysics, Newton's law is used in the form

$$\underline{K} = G \frac{mM}{r^2} \underline{r^0}$$

where $G = 6.672 * 10^{-11} \mathrm{Nm^2 kg^{-2}}$ is the gravitational constant, m the mass of a body on or near Earth's surface, M Earth's mass, r the distance between m and the Earth's center, and $\underline{r^0}$ the unit vector giving the direction from m to the Earth's center.

Since the Earth is rotating, centrifugal acceleration has to be taken into account when calculating resulting gravity:

$$z = \Omega^2 R \cos \varphi$$

z points vertically away from Earth's rotational axis with Ω being the angular velocity, φ the geographic latitude, and R Earth's radius.

The resulting acceleration of gravity is

$$g = (982{,}037 - 3{,}389\cos^2\varphi)\,\text{mGal}\quad \text{with}\,\text{mGal} = 10^{-5}\text{m/s}^2$$

for the simplifying assumption that Earth has the shape of a sphere. As a result of the latitude dependence, g is smaller at the equator than at the poles.

Another effect of the centrifugal forces is that Earth's body is not a perfect sphere, but has a bulge at the equator and in first approximation has the shape of a spheroid. The commonly used model for the reference spheroid is the WGS84 (Stacey, 1992) which uses the following values:

Equatorial radius 6,378,136 m
Polar radius 6,356,751 m
Flattening 1/298.257

The International Union for Geodesy and Geophysics (IUGG) has set the following formula for the gravity on the spheroid (Stacey, 1992):

$$\gamma_0 = 978{,}032.7\big(1 + 0.0053024\,\sin^2\varphi$$
$$-0.0000058\,\sin^2 2\varphi\big)\text{mGal}$$

where φ is the geographical latitude.

An even better approximation of the Earth is the so-called geoid which reflects the deviations from the rotationally symmetric shape of the reference spheroid. The deviations are on the order of a few tens of meters and only in the area south of India reach a value of more than 100 m. The geoid can be described with spherical functions, which has recently been done to degree and order 2,159 (Pavlis et al., 2012). Over the oceans, the surface of the geoid is equivalent to the mean sea surface.

Measurements

The classical way of measuring gravity on the sea surface is by using straight line gravity meters which are installed on board of ships to measure the vertical component of the gravity field. A marine gravity meter typically consists of a gyrostabilized platform and a gravity sensor. Different types of sensors are in use, most of which have a mass that is suspended on a metal spring to measure local differences in gravity. Thus, they measure relative differences which have to be tied to a point of known absolute gravity in a harbor. Similar instruments are being used on aircrafts as well.

As an example, the Sea-Air-Gravimeter System KSS32M (BGGS GmbH, Meersburg, Germany) consists of a gravity sensor, a gyrostabilized platform containing the power supply and all electronics for gravimeter and gyro, and a standard laptop for controlling and data acquisition. The gravity sensor GSS30 is based on a non-astatized axially symmetric spring-mass system (Figure 1). The mass consists of a vertical tube which is held by spring-suspended wires such that a friction-free
Gravity Field, Figure 1 Gravity sensor GSS30 principle, BGGS GmbH, Meersburg.

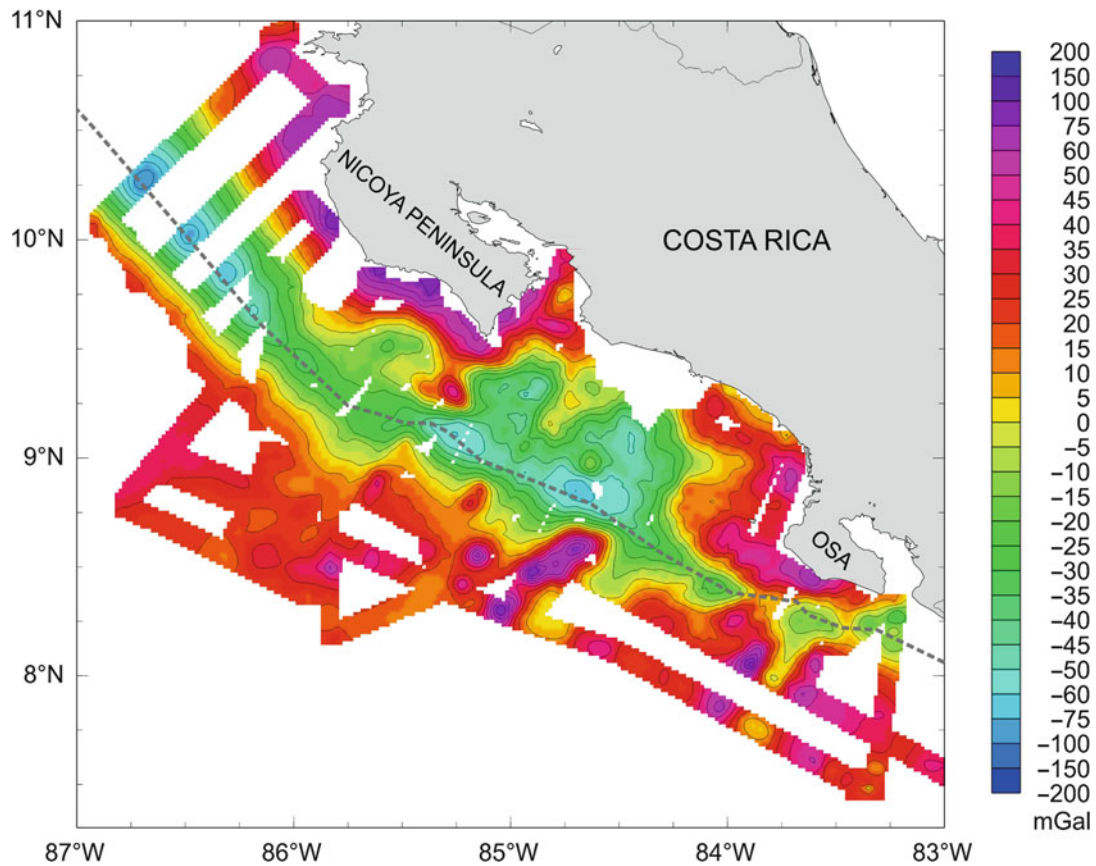
movement is limited to the vertical direction. The measuring spring inside the tube generates an equilibrium with respect to gravity. Displacements are sensed by a capacitive pickoff and after processing voltage changes serve to adjust the mass to the zero position (Torge, 1989).

Due to the installation of the sea-air-gravity meter on a platform moving relative to the Earth, a centrifugal acceleration (the Earth being assumed at rest) and a Coriolis acceleration (rotating Earth) occur. The vertical components of these inertial accelerations affect the measured gravity value (Eötvös effect, von Eötvös, 1919). At normal ship speeds, the Eötvös correction, E_c, can be approximated by

$$E_c = 7.503\,v\,\sin\alpha\,\cos\varphi + 0.004154\,v^2\,\text{mGal}$$

where v is the platform velocity in knots, α is the course, and φ is the latitude.

Correcting the measured gravity for the Eötvös effect and the normal gravity of the reference spheroid, free-air gravity anomalies are obtained. They reflect the gravitational attraction due to submarine topography and geological structure.

A dramatically improved view of the marine gravity field came with Earth-orbiting satellites which carried radar altimeters able to measure the height of the sea surface with great accuracy (Tapley et al., 1982). Since the gradient of the sea surface at short wavelengths depicts the gravitational effect of the density boundary between the water and the rocks of sea bottom, it was possible to calculate a predicted topography of the seafloor which revealed the large-scale tectonic fabric of the ocean floor


Gravity Field, Figure 2 Gravity map of an area offshore the Pacific coast of Costa Rica. The map was compiled from data acquired with a sea-air-gravity meter on a ship. The *dashed line* indicates the position of the deep-sea trench where the Pacific plate subducts beneath Central America. Seaward of the trench, local high gravity values are related to seamounts on the Pacific plate. Landward of the trench, the complex geology of the subduction zone is reflected by the large number of local gravity highs and lows.

(Smith and Sandwell, 1997). Today the spatial resolution of the satellite altimetry-derived gravity maps of the world's oceans as well as the constructed bathymetry is better than 20 km. Ship-based measurements reach significantly higher resolutions; however, they are only available along ship tracks and small areas which have been surveyed systematically but cover only a fraction of the oceans. Since to date all satellite missions measuring the gravity field have been flown at an orbital inclination, gaps still exist in high polar regions where little or no gravity data are available.

Marine gravity and tectonics

For marine geosciences, the gravity field provides a wealth of information related to tectonics regionally and globally (Figure 2). The large structures of the mid-ocean ridges became visible in the gravity maps for the first time thus confirming the concept of plate tectonics (Haxby et al., 1983; Smith, 1998). Thousands of seamounts could be detected by their local gravity anomalies and reveal plate boundaries, magmatic processes associated to hot spots, plate motions, and others (Craig and

Sandwell, 1988). Where both gravity and independently measured bathymetry data exist, gravity anomalies not directly related to the seafloor topography indicate density contrasts within the Earth's crust. These can be modeled in order to get insight into geologic structures at plate boundaries and other places where the geology is more complex. Areas which are out of isostatic equilibrium due to uplift or depression also become visible in the gravity field. Typically a combination of gravity, magnetic, seismic, and bathymetric data is used for integrated studies in marine geosciences. In the case of the gravity field, satellite-derived data with full spatial coverage of the longer wavelengths and high-resolution shipboard data supplement each other.

GROUNDING LINE

Antoon Kuijpers and Tove Nielsen
Geological Survey of Denmark and Greenland (GEUS),
Copenhagen, Denmark

Definition

The grounding line, or more properly the grounding zone, of glaciers and ice sheets is where their marine margins cease to be in contact with the seafloor (Dowdeswell and Fugelli, 2012).

A variety of features indicative of ice sheet and glacier dynamics marks the grounding zone. These grounding zone features indicate episodic rather than catastrophic ice sheet retreat (Dowdeswell and Fugelli, 2012), but can still yield important information on ice sheet and glacier response to changes in climate and ocean temperature. Observations of the Antarctic ice sheet show grounding line retreat and ice shelf collapse at the Antarctic Peninsula associated with warming in the Amundsen Sea (Payne et al., 2004). Enhanced submarine melting at the grounding line has also been proposed as trigger mechanism for recent acceleration of large, marine-based glaciers in Greenland (Rignot et al., 2010). Modeling results confirm how ocean warming and enhanced subglacial drainage lead to increases in melting near the grounding line (Jenkins, 2011). Ice sheet and glacier retreat leave grounding zone depositional systems on the seabed which include ice-contact deltas and moraines and fans associated with subglacial and basal meltwater discharge (Powell, 1990). At quasi-stable grounding lines, the fans may grow to sea-level and form ice-contact deltas (Seramur et al., 1997). Formation of the grounding line features helps stabilization of the ice sheet in protecting it from retreat driven by sea-level rise (Alley et al., 2007).

GUYOT, ATOLL

Eberhard Gischler
Institute of Geosciences, Johann Wolfgang Goethe
University, Frankfurt am Main, Germany

Definition

Atolls are circular- to irregular-shaped, isolated oceanic reef structures at or near sea-level that enclose a lagoon
Guyot, Atoll, Figure 1 (a) Bikini Atoll and Wodejabato Guyot (*top* at 1.3 km water depth) in the western Pacific (Modified from Ladd et al., 1950). (b) Geomorphology and zonation at Bikini Atoll (modified from Wells, 1954). 1,000 ft = 300 m; 1 fathom = 1.85 m.

usually tens of meters deep. The term atoll derives from the Divehi (Maldivian) word atolu. Atoll reefs occur in all oceans; they are most common in the Indo-Pacific realm.

Guyots, a term coined by Hess (1946), are flat-topped seamounts located in several hundred to several thousand meters water depth. They are most common in the northwestern Pacific Ocean. Guyots usually are former volcanoes that are in many cases capped by drowned atoll reefs and pelagic sediments.

Occurrence, geomorphology, and sediments
Atolls

Atolls are circular to irregular, narrow, shallow-water reef structures that enclose a deeper lagoon (Figure 1). Therefore, their shape has been likened to that of a bucket

(Purdy and Gischler, 2005; and references therein). There are some 400 atolls worldwide (Stoddart, 1965). The majority occurs in the open Pacific and Indian oceans where they typically have a volcanic basement. There are also some atolls that rest on continental crust, for instance, on the topographic and structural highs of fault blocks at passive margins, e.g., in offshore Belize, in the southern Great Barrier Reef, and in the Red Sea. Tiladummati-Miladummadulu in the Maldives (Indian Ocean) covers 3,800 km^2 and is the largest atoll on Earth. Kwajalein (Marshall Islands) covers 2,200 km^2 and is the largest Pacific atoll. Great Bahama Bank (ca. 78,000 km^2) and Great Chagos Bank (12,650 km^2) are very large isolated carbonate platforms in the Atlantic and Indian Oceans, respectively, which are not considered atolls. They lack continuous surface-breaking reefs at their margins and a deeper interior lagoon in the case of the Bahamas.

The shallow and partly emergent margin of atolls includes reef crest, reef flat (pavement), sand apron, and marginal islands (Figure 1b). It is relatively narrow (up to several hundred meters) as compared to the much larger lagoon area. The margin is characterized by coral reefs, which exhibit geomorphological and ecological zonations (Ladd et al., 1950; Wiens, 1962, 234–243). On the ocean side of the reef crest, which is often composed of an algal ridge in the Pacific, there is a fore-reef slope that in many cases dips about 30°. The shallow fore-reef slope is usually characterized by the spur and groove system, a comb-shaped structure of ridges perpendicular to the reef crest that may have either constructional or erosional origins (Gischler, 2010). The fore-reef slope transitions to a break in slope and a steep wall several hundreds of meters high (James and Ginsburg, 1979). On the lagoon side of the reef crest, a cemented pavement, occasionally with islands, and a sand apron occur. It is not uncommon that a distinct sandy slope transitions to the lagoon proper. Sand aprons are significant in that they contribute to the lateral infilling of atoll lagoons by lagoonward progradation (Purdy and Gischler, 2005). Atoll margins are usually not continuous but feature several passes that connect the open ocean with the interior lagoon. In many Pacific atolls, the passes are located on the leeward sides (Wiens, 1962).

Atoll lagoons get up to 100 m deep; the average depth amounts to some 36 m based on an analysis of the geomorphology of 295 atolls (Purdy and Winterer, 2001). The same authors showed that atoll lagoon depths covary significantly with precipitation rates, thereby supporting the contention that inherited karst relief from solution during glacial sea-level lowstands is crucial in atoll development. As compared to the atoll margin that exhibits accretion rates of several meters per kyr, background sedimentation within Quaternary atoll lagoons averages decimeters per kyr (Purdy and Winterer, 2001; Purdy and Gischler, 2005). Atoll lagoons usually accommodate numerous coral patch reefs. In the Maldives, lagoonal reefs as well as some marginal reefs may form characteristic ringlike structures called faroes. Their formation is largely attributed to the changing wind and current regime of the Indian monsoon (Purdy and Bertram, 1993).

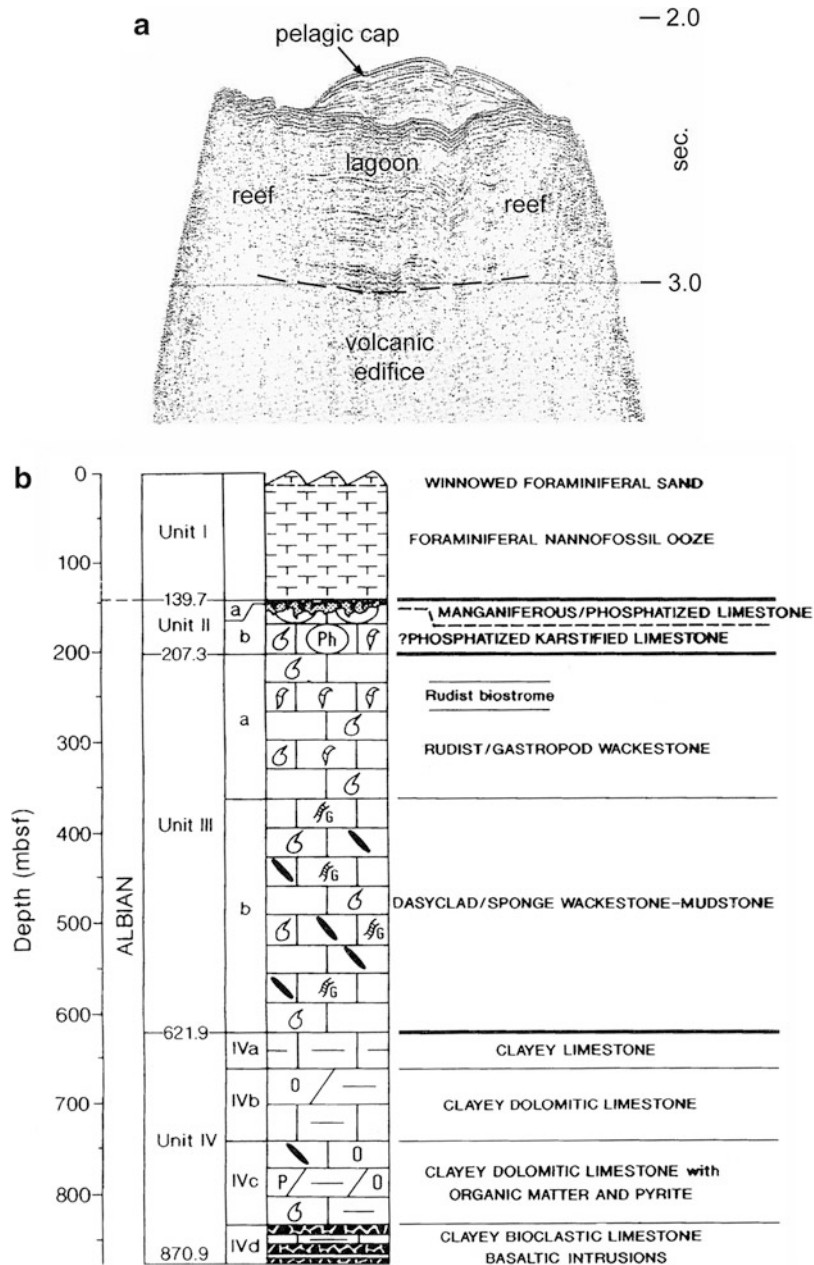
Sand and rubble islands termed cays are common on both marginal and lagoonal atoll reefs. Beachrock is a very common characteristic of sandy beaches on reef islets (Gischler, 2007). Elongated cays on Pacific reef margins are called motu, and the channels between them hoa. Motus are in many cases relatively stable due to underpinning by mid- to late Holocene (ca. 4–2 kyrs BP) reef flat deposits that formed during higher-than-present sea-level (Dickinson, 2009). Human colonization in the Pacific only started after high tide levels had fallen below the upper level of these older Holocene deposits, some 2,000 years ago (Dickinson, 2009).

Modern atoll sediments are usually coralgal grainstones on marginal and lagoonal reefs. Atoll lagoon sediments often include mollusk-rich and foraminifer-rich wackestones and packstones as well as nonskeletal facies (Gischler and Lomando, 1999; Gischler, 2006; and references therein). Atoll lagoon deposits have also been successfully used as archives of event sedimentation (Klostermann et al. 2014).

Guyots

Guyots are seamounts with more or less flat tops that in many cases lie in about 1–2 km water depth (Figure 1). The tops typically are 3.0–4.5 km above the surrounding seafloor and may exhibit reliefs of tens of meters. The large majority can be found in the northwestern Pacific at 8–27°N and 146–165°E (Hess, 1946; Hamilton, 1956; Menard, 1984; Wessel, 1997; Flood, 1999). There are some 50,000 seamounts, many of them guyots, in the Pacific Ocean, about 50 % of them not charted and <1 % sampled for dating (Wessel, 1997). Some guyots are also known from other oceans (e.g., Pratt, 1963, 1967). Their shape is circular to oval. Guyot size varies and diameters may reach >200 km (Davies et al., 1972). Slopes of guyots are concave and reach 20° inclination toward the top. Guyots have been repeatedly investigated by dredging, seismics, and drilling. ODP cruises 143 and 144 were especially devoted to the Pacific guyots (Winterer et al., 1995; Haggerty and Premoli-Silva, 1995).

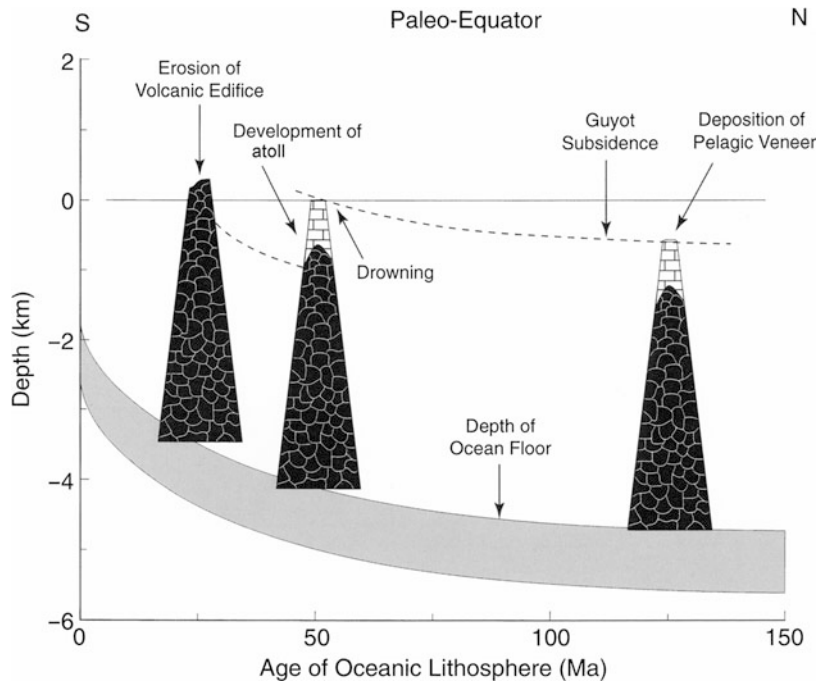
Ideal successions of guyot tops include the volcanic (basaltic) edifice, a shallow-water atoll reef section with elevated rims, and a package of pelagic ooze, usually capped by a manganese-iron or phosphorite crusts (Schlanger et al., 1987; Grötsch and Flügel, 1992; Jenkyns and Wilson, 1999; Flood, 1999, 2001) (Figure 2). However, there are also a number of guyots that are purely volcanic, lack a reefal succession, or feature mixed volcanic and limestone breccias (Jenkyns and Wilson, 1999).

The shallow-water reef deposits often are Cretaceous to the Eocene in age. They may get as thick as 1.6 km as on Resolution Guyot and contain clear indicators of a reefal origin such as corals, rudist mollusks, calcareous sponges (stromatoporoids), calcareous algae, larger foraminifera, and nonskeletal grains including ooids (Grötsch and Flügel, 1992; Jenkyns and Wilson, 1999; Flood, 1999, 2001). The majority of shallow-water reefs on guyots drowned in the Cretaceous (Matthews et al., 1974; Wilson et al., 1998; Jenkyns and Wilson, 1999). The age range of pelagic oozes comprises the Cretaceous to the Quaternary. The oozes get as thick as 150 m as on top of Allison Guyot. They are characterized in many cases by stratigraphic gaps and the so-called ghost faunas, i.e., mixtures of reworked foraminifera that comprise many biostratigraphical zones. The formation of ferromanganese crusts is likely the result of microbial activity. Additional processes include phosphatization and aragonite dissolution (Grötsch and Flügel, 1992). Collectively, these features are characteristic of very low sedimentation rates and/or nondeposition (omission), erosion, condensation of sediment, and dissolution (Hamilton, 1956; Lonsdale et al.,


Guyot, Atoll, Figure 2 (**a**) Seismic cross section and (**b**) sedimentary succession on top of Allison Guyot (modified from Winterer and Metzler, 1984; Jenkyns and Wilson, 1999).

1972; Grötsch and Flügel, 1992; Gischler, 1996). Lonsdale et al. (1972) recorded current speeds of up to 15 cm/s on the top of Horizon Guyot and observed substantial erosion due to winnowing of sediment. On the top of guyots, flow acceleration and eddies, internal waves, and upwelling, called Taylor columns (Boehlert and Genin, 1987), apparently increase nutrient concentrations, enhance primary productivity, and sustain filter-feeding organisms such as soft corals, crinoids, or sponges.

Genetic connection between atolls and guyots

In his universally known subsidence theory, Darwin (1842) genetically connected fringing, barrier, and atoll reefs. During the subsidence of volcanic islands, fringing reefs develop into barrier reefs and eventually to atolls due to vertical reef accretion. For example, the distribution of reef types in the Society Islands (south Pacific) may be used in support of Darwin's theory. Away from the hot spot toward the west, volcanic islands are progressively older (Guillou et al., 2005) and reef types change from


Guyot, Atoll, Figure 3 Idealized development of a Pacific guyot (modified from Jenkyns and Wilson, 1999).

fringing to barrier to atoll reefs (Gischler, 2011). During continued subsidence during cooling and transport of oceanic lithosphere away from the area of active volcanism, atoll reefs eventually drown and guyots develop (Figure 3). Impressive manifestations of this development are reef and seamount chains (Grigg, 1982; Konishi, 1989; Grigg, 1997). The several thousand km-long Hawaiian reef chain and the Emperor seamounts are imposing examples of northwestward and northward movement of reefs and seamounts away from a hot spot location (Greene et al., 1978; Grigg, 1982, 1997; Flood, 1999, 2001). Further examples include the Line and Marshall Island chains (Schlanger and Premoli-Silva, 1986). Wave planation of the volcanic island plays a central role in the glacial-control theory of reef development (Daly, 1915). Island erosion has subsequently been used when explaining guyot development (Hess, 1946; Hamilton, 1956). However, results of ODP legs 143 and 144 support the contention that the more or less flat summit of guyots is constructional and a consequence of carbonate accretion (Flood, 1999, 2001).

The significance of subsidence of a volcanic island for the development of isolated reefs in the open ocean was proven for the first time by drilling on Enewetak Atoll, Marshall Islands (Ladd et al., 1953), which recovered 1.25–1.4 km of reefal limestone overlying Eocene basalt. Darwin's theory may indeed be applied to the long-term development of oceanic reef structures; however, it fails when being applied to short-term and especially to Quaternary reef development because glacio-eustatic sea-level fluctuations are not considered. For example, Saller and

Koepnick (1990) showed that reef facies in Enewetak had not simply aggraded and/or slightly retrograded as predicted by Darwin's theory, but significantly prograded; furthermore, major unconformities were identified in the drill cores. Similar observations were made in Mururoa (Camoin et al., 2001). The former observation is a consequence of falling sea-level trends; the latter results from repeated subaerial exposure during sea-level lowstands.

Sea-level fluctuations have been proven to be a major environmental factor of reef growth and, hence, of atoll formation (e.g., Camoin et al., 2001; Montaggioni, 2005). Reef and carbonate platform architecture, i.e., aggradation, progradation, or retrogradation and backstepping of reef sequences as well as drowning, has been largely attributed to the course of sea-level in combination with sediment supply, i.e., the productivity of the carbonate factory (e.g., Schlager, 1993). There are atolls which have a very complex geological history of separation and coalescence of platforms during aggrading, prograding, retrograding, and drowning episodes, largely controlled by sea-level change and subsidence, e.g., the Maldives archipelago that is composed of 22 major atolls since the Neogene (Purdy and Bertram, 1993; Belopolsky and Droxler, 2003).

Meteoric dissolution (karst) during sea-level lowstands may even produce atoll and barrier reef geomorphologies, as shown during experiments with limestone blocks and acid and in the examples of uplifted carbonate islands with erosional atoll and barrier reef shapes, e.g., Kita Daito Jima (Japan), Makatea (French Polynesia), or Mangaia

(Cook Islands) (Purdy, 1974; Purdy and Winterer, 2001, 2006). Purdy and Winterer (2001, 2006) also found a significant correlation between atoll and barrier reef lagoon depths and precipitation rates. They showed statistically that barrier reef lagoon depths are not lower as compared to atoll lagoon depths as would be expected when applying Darwin's model of continued subsidence. Purdy and Winterer (2006) also argued that fringing reefs located within barrier reefs also do not fit the idea of a progressive development of fringing and barrier reefs. Based on results obtained during ocean drilling project legs 143 and 144 (Winterer et al., 1995; Haggerty and Premoli-Silva, 1995), Winterer and Metzler (1984) and Winterer (1998) concluded that many guyots with Cretaceous reef caps located in the western Pacific experienced a subaerial karst phase before drowning, which enhanced their atoll geomorphology.

The mechanisms of reef drowning, however, still remain somewhat enigmatic and controversial. Grigg (1982, 1997) suggested that movement of the lithospheric plate has been transporting reefs of the Hawaiian chain out of the warm tropical-subtropical realm toward higher latitudes where reef growth rates are progressively slower, thereby causing reef demise and drowning. Hallock and Schlager (1986) and Rougerie and Fagerstrom (1994) argued that drowning of many mid-Cretaceous reefs, including those in the Pacific, coincided with oceanic anoxic events (OAEs), i.e., during the upwelling of nutrient-rich, oxygen-depleted water masses. Wilson et al. (1998) and Jenkyns and Wilson (1999) were able to prove that numerous Cretaceous reefs, now forming the tops of western Pacific guyots, were exterminated when the reefs were situated in equatorial latitudes. Possibly, very high temperatures caused reef decline, as observed today, e.g., during strong El Niño years. Reef-building scleractinian corals may lose their photosymbionts, bleach, and eventually die off (Hoegh-Guldberg, 1999). Likewise, equatorial upwelling of nutrient-rich waters might have been detrimental to coral and rudist reef growth. Based on the observation that the growth potential of corals and coral reefs usually exceeds the rate of rise of sea-level, Schlager (1981) concluded that only very rapid pulses of sea-level rise and/or environmental deterioration may cause reef drowning. While some late Quaternary reefs in the Indo-Pacific region have indeed been accreting at rates of up to 20 m/kyr (Montaggioni, 2005), the majority of Holocene Atlantic reefs accumulated with average rates of 3–5.5 m/kyr (Gischler, 2008; Hubbard, 2009). These rates are well below rapid rates of glacio-eustatic sea-level rise, e.g., during the last post-glacial and that predicted by the ICDP for the twenty-first century. Thus, rapid sea-level rise alone is a potential cause of reef drowning. Interestingly, guyots, i.e., drowned atolls, exist adjacent to living atolls, e.g., in the Marshall Islands. An instructive example is Wodejabato (Sylvania) Guyot (Figure 1), which is positioned next to Bikini Atoll (Ladd et al., 1950; Hamilton, 1956; Schlanger et al., 1987). Wodejabato is a former atoll

reef that drowned in the latest Cretaceous and the top of which is now 1,335 m below sea-level (Camoin et al., 1998). In this case, environmental deterioration such as nutrient excess cannot be used as an explanation for drowning. It is highly unlikely that nutrient excess would cause the demise of some reefs in the middle of the Pacific Ocean while adjacent ones would not be harmed. A more plausible explanation could be differences in the elevation of the reef foundation. Elevation controls the timing and, hence, the rate of initial eustatic sea-level rise over a platform. The latter is crucial as full carbonate accretion may be delayed initially due to the time necessary for biotic colonization (Kim et al., 2012). Likewise, the relief of the inundated reef pedestal during sea-level rise, providing a variety of habitats of reef builders, might be of significance (Camoin et al., 1998).

Summary

Many atolls and guyots in the Pacific are genetically connected by the processes of subsidence of volcanic islands, reef accretion, and reef drowning. Still, subsidence alone may not satisfactorily explain reef development and drowning. Sea-level is another crucial factor of reef development. Sea-level rise results in reef aggradation and retrogradation and/or backstepping. Sea-level stalling and fall may cause progradation and karstification during subaerial exposure. Possible causes of drowning include rapid pulses of sea-level rise, reef elevation and relief, and environmental stress such as low sea-surface temperatures as well as high sea-surface temperatures and upwelling of nutrient-rich and oxygen-depleted waters.

HIGH-PRESSURE, LOW-TEMPERATURE METAMORPHISM

Hayato Ueda
Department of Geology, Niigata University, Niigata, Japan

Synonyms

High-pressure/temperature (high-P/T) metamorphism; High-pressure metamorphism

Definition

Metamorphism: Changes of mineral textures and phases in rocks at depths without significant change of bulk-rock chemical composition except for vapor components.

High-pressure/low-temperature metamorphism: Metamorphism that undergoes at high pressure with low-temperature conditions than usual, typically with thermal gradients as low as 10 °C/km.

High-pressure/temperature metamorphism: Metamorphism under conditions of high pressure versus temperature ratios, i.e., of low thermal gradients.

Introduction

In Earth's interior, temperature generally increases as the depth increases as a result of heat conduction. Because rocks as well as melts and fluids sometimes migrate fast enough for evident heat advection, geothermal fields are modified by regional or local geodynamics. In *subduction* and collision zones, lower temperatures than normal geotherms are maintained with thermal gradients as low as 10 °C/km, because the slabs cooled on the surface are constantly supplied to the depths. High-pressure/low-temperature (HPLT) metamorphism is believed almost exclusively to occur at such cool conditions inside the convergent plate margins. Although only a few cases of

seafloor exposures of HPLT metamorphic rocks are so far known, HPLT metamorphism might be ongoing inside every subduction zone corresponding to deep-sea trenches. HPLT rocks occasionally record physical and chemical conditions, dynamics and element transport, and their historical changes inside deep subduction or collision zones as mineral phases and textures. HPLT metamorphic rocks commonly contain significant amounts of hydrous and/or carbonate minerals. When these rocks are further subducted down to deeper portions with increasing temperature and pressure, they release volatile fluids such as water and carbon dioxide as well as other elements as solutes via dehydration or decarbonation. The released volatiles affect chemistry, rheology, and melting conditions of the upper mantle. Therefore, HPLT metamorphic rocks act as containers which deliver volatiles from the surface to the mantle.

Geodynamic settings and source rocks

Source rocks (protoliths) of HPLT metamorphic rocks differ between two contrasting convergent settings of collision and subduction zones (Maruyama et al., 1996). In collision zones, materials being subducted are leading edges of *passive continental margins* consisting of granitic basements, clastic and calcareous sediments of *continental shelves and slopes*, and rift-related basaltic rocks. Aluminous and/or iron-rich metapelites originated from mud and soil affected by subaerial weathering are also occasionally accompanied. Materials input into subduction zones consist of *oceanic crust* and overlying pelagic sediments, as well as trench-fill deep-sea *turbidites* and mudstone, and *seamounts*. This subduction zone rock assemblage is comparable to rocks of accretionary complexes. Basaltic rocks have chemical compositions correlative to *mid-ocean ridge* and oceanic island basalts. Metachert characteristically occur, and some of them are occasionally manganese. HPLT metamorphic rocks are
High-pressure, Low-temperature Metamorphism, Figure 1 Metamorphic facies in a pressure versus temperature coordinate (compiled from petrogenetic grids by Oh and Liou, 1988; Evans, 1990; Frey et al., 1991) with references of geothermal gradients (*gray* bands) and geotherms of subducted cold (*NE Japan*) and warm (*SW Japan*) oceanic crusts (sand hatches: after Peacock and Wang, 1999). Abbreviations: *AM* amphibolite facies, *BS* blueschist facies, *EA* epidote amphibolite facies, *EC* eclogite facies, *GR* granulite facies, *GS* greenschist facies, *HGR* high-pressure granulite facies, *LA* lawsonite-albite facies, *PA* prehnite-actinolite facies, *PP* prehnite-pumpellyite facies, and *Zeo* zeolite facies.

commonly associated with *serpentinites* especially abundant on seafloor exposures in intraoceanic subduction zones and on-land regional metamorphic belts accompanied by *ophiolites*.

Mineralogy and metamorphic facies

A chemically equilibrated rock consists of the most stable assemblage and compositions of minerals for a given pressure, temperature, and chemical compositions of bulk-rock and interstitial fluids. When these conditions change, chemical reactions occur consuming some mineral components or phases and producing others in order to maintain the stability. As pressure increases, sodic plagioclase diminishes and finally disappears, generating sodic pyroxene (jadeite or omphacite) and sodic amphibole (e.g., glaucophane), both diagnostic of HPLT metamorphism. Lawsonite and aragonite are formed exclusively in HPLT conditions. In mafic rocks, Fe-Mg garnet tends to develop at high pressure as well as high temperature.

As a result of changes above, blueschist (glaucophane schist) at lower temperatures and eclogite (garnet-omphacite rock) at higher temperatures represent HPLT

metamorphic rocks of basaltic compositions. Typical mineral assemblages of both the rocks define the blueschist and eclogite facies, respectively (Figure 1).

The blueschist facies mafic rocks characteristically contain sodic amphiboles such as glaucophane, occasionally with lawsonite, sodic (jadeitic) pyroxene, aragonite, epidote, pumpellyite, chlorite, phengite, and titanite. Plagioclase (albite) occurs at relatively lower pressures but disappears as pressure increases. Pelitic rocks are typically phengite-chlorite schist. Winkler (1967) set the lawsonite-albite facies, in which lawsonite coexists with neither sodic pyroxenes nor sodic amphiboles. It suggests lower pressure conditions than the typical blueschist facies and can be regarded as sub-facies of the latter. The typical blueschist facies is subdivided into lawsonite-blueschist and epidote-blueschist sub-facies (Evans, 1990) where sodic pyroxenes and sodic amphiboles coexist with lawsonite in the former and epidote in the latter.

The eclogite facies is characterized by the occurrence of Fe-Mg garnet and omphacite in the absence of plagioclase. Epidote or lawsonite, hornblende or barroisite, phengite, paragonite or kyanite, talc, and rutile are
High-pressure, Low-temperature Metamorphism, Figure 2 A sketch of HPLT metamorphism in a conceptual subduction zone system. *Red dashed lines* show schematic isothermal contours.

occasionally accompanied. Lawsonite occurs at lower temperatures than epidote; and kyanite + omphacite occurs at higher pressures than paragonite. Amphiboles disappear as pressure increases. Equivalent pelitic rocks are typically garnet-phengite schist occasionally with talc + chloritoid and talc + kyanite associations (Mottana et al., 1990). Stability of the eclogite facies extends to the wet solidus temperatures, so that merely "high-pressure (HP) metamorphism" is often applied to such rocks. At higher pressure than ~2.7 GPa (ca. 100 km deep), coesite occurs instead of quartz, and such rocks are referred to as ultrahigh-pressure (UHP) rocks.

Metamorphic facies suggesting warmer conditions than typical HPLT metamorphism are also not uncommon in subduction and collision zones. These are the pumpellyite-actinolite facies, high-pressure parts of the greenschist and amphibolite facies (epidote amphibolites and epidote-garnet amphibolites). Sodic-calcic amphiboles such as winchite and barroisite are common in these rocks.

Prograde and retrograde metamorphism

Many of HPLT metamorphic rocks originated from volcanic and sedimentary rocks once on the surface and then were subducted to depths and finally returned back to the surface again. Such transports result in a general metamorphic history with increase and subsequent decrease of pressure and temperature. Recrystallization at the highest temperature and/or pressure which a rock experienced is assigned to the peak metamorphism, and transitional processes toward and after the peak are prograde and retrograde metamorphism, respectively.

Starting materials of HPLT metamorphic rocks are rich in hydrous minerals (clays in mudstone and alteration minerals in basalt, etc.). Increasing temperature and pressure induce dehydration reactions. Prograde dehydration reactions usually well proceed with scarce obstructing factors. It is thus sometimes difficult to find traces of prograde stage, except for mineral inclusions and relic cores capsuled by progressively grown minerals.

Conversely, retrograde metamorphism is governed by hydration reactions, and its extent is controlled by supply of water fluids from outside the rocks. In cases of limited water supply, rocks are incompletely recrystallized preserving mineralogy of the peak condition. However, in subduction zones, rocks may migrate upward above the subducting slab, which constantly releases water fluids upward (Figure 2). Probably by this reason, retrograde recrystallization is sometimes quite extensive in HPLT rocks. It is not uncommon that the peak-stage mineralogy had been almost completely erased by retrograde mineralization.

Pressure-temperature paths and dynamics

Pressure and temperature of each metamorphic stage can be better estimated when geobarometers and geothermometers are applicable. These estimates are based on chemical equilibria including solid solution minerals, and pressure and temperature dependence of each equilibrium constant is calibrated by experimental results or thermodynamic data for minerals. Major geothermometry for HP rocks (e.g., Carswell and Harley, 1990; Ravna and Paquin, 2003) uses Fe-Mg exchange reactions between garnet and other ferromagnesian minerals (e.g., Ellis and Green, 1979) and net transfer reactions (e.g., Ravna and Terry, 2004), in which reactant components are consumed for products.

Net transfer reactions result in appearance and disappearance of minerals, as well as their compositional changes. The pressure and temperature conditions for these limits and mineral chemistry for a specific bulk-rock composition can be simulated using thermodynamic dataset of minerals (e.g., Holland and Powell, 1998). Such petrogenetic grids, called as P-T pseudosections, have also become useful approaches to investigate metamorphic conditions and paths. Thermo-Calc (Powell and Holland, 1998) and PerpleX (Connolly and Petrini, 2002) are examples of the software for these calculations.

A transition from the peak to the retrograde conditions, with prograde ones if available, draws a pressure-temperature (P-T) path, which we expect to reflect thermal structures and modes of material flow in subduction zones. When an HPLT rock returned back to shallower levels, nearly adiabatic, isothermal decompression represented by a clockwise P-T path is predicted for the case of fast ascending, whereas significant cooling with decompression with a hairpin path for sluggish ascending (Ernst, 1988). Such contrasting exhumation rates has been supported by geochronology (Rubatto and Hermann, 2001; Anczkiewicz et al., 2004; Baldwin et al., 2010). On the other hand, numerical simulations commonly predict characteristic inverted thermal structure in subduction zones with deeply subducted but still cool slab overlain by the hot wedge mantle (e.g., Peacock and Wang, 1999; Figure 2). When an oceanic crustal rock is detached from the subducted slab, it is expected to ascend via a higher-temperature conduit than descending one on the slab, resulting in clockwise P-T paths (Gerya et al., 2002). Counterclockwise P-T paths with isobaric cooling known in the Franciscan Complex in California (Wakabayashi, 1990) are difficult to explain by ordinary thermal structures in subduction zones. They are attributed to transient cooling of the subduction zone just after its inception.

Exhumation tectonics

Exhumation, the processes in which HPLT metamorphic rocks ascend from depths to the surface, is one of the controversial subjects on subduction zones dynamics. There are many ideas for the driving forces to lift up the HPLT rocks. Buoyancy of the subducting edifices (continents, oceanic plateaus, mid-oceanic ridges, etc.: Maruyama et al., 1996), of subducted crustal materials (Chemanda, 1995), or of serpentinized wedge mantle (Guillot et al., 2001) is one of the likely candidates. Isostatic rebound of the subducted buoyant slab is expected when the dense precursor parts of the slab is broken off at depths (Davis and von Blanckenburg, 1995). Traction force of the subducting slab could induce a counter flow above the subduction interfaces (Cloos, 1982). Underplating accretion at depths could jack up the HPLT rocks (Platt, 1986).

Because HPLT rocks are exposed not at trenches but inside the hanging-wall crusts, unroofing mechanisms to remove the overlying crustal materials are also necessary

for HPLT rocks to reach to the surface. Erosion plays an important role for unroofing on land (Chemanda et al., 1995), whereas its effect might be minimal in cases of marine subduction settings. One of the proposed ideas is gravity collapse of an *accretionary wedge* when it is too steepened by underplating accretion (Platt, 1986). Upper plate rifting (Hill et al., 1993), and transtension by oblique subduction (Ave Lallemant and Guth, 1990) also, could remove the overburden for the HPLT rocks. When HPLT rocks uprise along with serpentinite diapir, it would penetrate the hanging-wall crust by its buoyancy.

Recently developed numerical simulation techniques provide useful deductions for subduction zone dynamics. For example, Gerya and Stöckhert (2006) modeled at least two kinds of induced flow in a subduction zone depending on contrasting rheology of crustal and mantle rocks. One is a set of drag and counter flows in serpentinized parts of the wedge mantle (serpentinite channel: Guillot et al., 2001) along the subduction interface, and the counter flow carries up higher-grade HP and UHP rocks from greater depths to the base of the hanging-wall crust. The others are shallower intra-crustal flows, which lift up lower-grade HPLT rocks with fragments of higher-grade rocks. This generally agrees with natural occurrences that low-grade HPLT accretionary rocks tend to occur as coherent masses (Kimura et al., 1996) whereas higher-grade blocks of eclogites and amphibolites are occasionally hosted in serpentinite mélanges (Coleman and Lanphere, 1971) in ancient subduction complexes.

Occurrences in the sea

Except for submerged extensions of landmass terrains, sea-bottom occurrences of HPLT metamorphic rocks have been so far recognized only in the Philippine Sea Plate.

The first finding (Maekawa et al., 1992, 1993; Maekawa, 1995) was from ODP Leg125 drill core (Hole 778A), which penetrated the Conical Seamount, a forearc serpentinite *seamount* ~50 km arc-ward from the Mariana Trench. HPLT metamorphic minerals, such as lawsonite, pumpellyite, sodic pyroxene, aragonite, and blue amphibole (winchite), were found in pebble-sized metabasite clasts hosted in serpentinite. Mineral chemistry and occurrences suggest the fragments underwent low-grade blueschist facies, in which lawsonite does not coexist with sodic amphibole and sodic pyroxene, with the metamorphic conditions of 150–200 °C 0.5–0.6 GPa (Maekawa et al., 1993, 1995). These results first confirmed that HPLT rocks are really formed in modern subduction zone. The serpentinite seamount itself is build up of highly fractured and sheared serpentinites, and groundwater vents and serpentine mudflows were also observed (Fryer et al., 1990). Based on these occurrences, the HPLT metabasites are considered to have carried up from the subduction interface of ~20 km depths by diapir or mud volcanism. Fragments of HPLT rocks with serpentinites are also found in other serpentinite seamounts and inner trench slopes in the Izu-Bonin-Mariana

forearc (Tararin, 1995; Fryer et al., 2000; Maekawa et al., 2004).

Relics of HP metamorphism were found in amphibolites collected from the Ohmachi (Omachi) Seamount near the volcanic front of the Izu-Bonin arc (Ueda et al., 2004). These rocks are extensively recrystallized during the retrograde stage, resulting in garnet amphibolite and epidote-albite amphibolite mineralogy. Eclogite and blueschist facies minerals such as omphacite, kyanite, and glaucophane occur as micro-inclusions in zoisite, epidote, hornblende, and garnet. The highest grade sample underwent the peak metamorphism at 600–700 °C and 2–2.5 GPa (ca. 60–80 km deep), followed by a retrograde overprint at 550–600 °C and < ~1 GPa (shallower than approx. 30 km deep). Although the age of these HP rocks has not been published, pre-Eocene exhumation was suggested by Ueda et al. (2004) based on the age of cover volcano-sedimentary sequence. These HP metamorphic rocks are hosted in part of a serpentinite body consisting of antigorite schist and massive antigorite serpentinite. These serpentinites comprise a coherent body without pulverization, and schistose parts exhibit lateral extension in ductile manners (Hirauchi et al., 2010; Ueda et al., 2011). These modes of occurrence differ from the forearc serpentinite seamounts, and Ueda et al. (2011) considered that the serpentinite body preserves the structure of deep serpentinite channel in an *intraoceanic subduction zone*.

Summary

Petrology, structural geology, and numerical modeling of HPLT rocks commonly depict dynamic flows beneath forearcs with great vertical and lateral displacements of regional rock masses, which might be commonly ongoing in subduction zones. Such deductions have, however, not been well linked with seafloor geology of forearc areas. For example, stacks of thrust sheets (nappe piles) and hanging-wall low-angle normal faults (detachment) are ones of the typical structures of HPLT terranes exposed on land. However, such structures have not yet been detected in forearcs on the seafloors. Serpentinite diapirs and mud volcanoes that penetrate the Mariana forearc crusts are in turn not so suitable with dominantly flat-lying structures of HPLT terranes. Filling these gaps and comprehension of subduction zone dynamics will greatly owe to further investigations by marine geoscience.

HOT SPOTS AND MANTLE PLUMES

William M. White
Department of Earth and Atmospheric Sciences, Cornell University, Ithaca, NY, USA

Definition

Hot Spot. Persistent volcanism over many millions or tens of millions of years at fixed location on the Earth's surface in an absolute reference frame. This leads to a chain of volcanic islands and seamounts that get progressively older in the direction of *lithospheric plate motion*. The Hawaiian Islands provide the classic example.

Mantle Plume. Mantle plumes are relatively narrow columns of hot, buoyant rock rising from the deep mantle, probably the core–mantle boundary in many cases, and partially melting in the uppermost mantle. The magma produced in this way is responsible for hot spot volcanism and oceanic volcanic islands and *seamounts*.

Introduction

Wilson (1963) pointed out the existence of chains of volcanic islands in the Pacific whose alignment was nearly parallel and whose age increased with distance from the East Pacific Rise. He proposed that the volcanoes formed as convection currents in the shallow mantle dragged oceanic floor over a fixed melting region in the deeper mantle. He also pointed out that ridges in the Atlantic seemed to form Vs centered on the Mid-Atlantic Ridge and argued that these stationary "hot spots" (he did not use the term) provided compelling evidence of the combination of continental drift and seafloor spreading that, by the end of the decade, would come to be known as plate tectonics.

Among the great successes of plate tectonics is its explanation of most magmatism on Earth. The largest fraction occurs at mid-ocean ridges, where every year some 20 km^3 of magma solidifies into new oceanic crust as a direct consequence of the mantle convection that drives *plate motion*. As mantle rises beneath *mid-ocean ridges*, it partially melts (e.g., Klein and Langmuir, 1987).

The resulting magma then rises to fill the gap between the spreading plates. The second most voluminous type of magmatism is *island arc volcanism*, which occurs at *subduction zones*, where oceanic crust returns into the mantle. The primary cause of melting there is water released by dehydration of the subducting oceanic crust, which lowers the melting point of the overlying mantle wedge (e.g., Grove et al., 2006). However, plate tectonics sensu stricto fails to provide an explanation for *intraplate volcanism*, such as hot spot volcanoes, even though hot spots inspired the early evolution of plate tectonic theory. This group includes some of the most active volcanoes on the planet, such as Kilauea in Hawaii and Piton de la Fournaise on Reunion.

Wilson did not attempt to explain why stationary melting regions in the mantle should occur. It was Morgan (1971) who proposed the now widely accepted explanation: Wilson's "hot spots" were the surface manifestation of convection plumes of solid rock rising from the lower mantle (Figure 1). Morgan described these mantle plumes as similar to convection cells in the atmosphere that give rise to thunderstorms. Like air, hot mantle is buoyant and consequently can rise in a more or less vertical column. The analogy can be taken one step further as well. The rising air in a thunder cell eventually undergoes a phase change with water vapor partially condensing. Similarly, rising solid mantle eventually undergoes a phase change and partially melts. While gravity causes the raindrops to fall, it causes the buoyant melt to rise.

Early laboratory and numerical experiments revealed that plumes could readily arise at a hot thermal boundary layer (Whitehead and Luther, 1975). As seismic studies revealed that no thermal boundary layer exists at the 670 km seismic discontinuity or elsewhere in the mid-mantle (e.g., Jordan et al., 1993), a thermal boundary layer at the base of the mantle, across which temperature may increase as much as 1,000 °C, seemed to be the only possible source of mantle plumes. Hence, the idea that plumes are generated at the core–mantle boundary became an integral part of the mantle plume theory. The idea that plumes are generated at the core–mantle boundary found further support from the calculations of Davies (1988) and Sleep (1990) showing the total heat flux of mantle plumes matched the expected heat flux from the core (as it is only about 10 % of the heat flux associated with spreading centers). More recent numerical simulations of mantle convection, which take advantage of higher computational power and contain more realistic physics, suggest this need not be the case. Farnetani and Samuel (2005) showed that thermochemical plumes (plumes that differ in density from surrounding mantle because of both temperature and chemistry) may come in "a great variety of plume shapes and sizes" and may neck to the point where they are no longer visible seismically. This is particularly true as they pass through the 670 km discontinuity. Davies and Bunge (2006) found that cold mantle downwellings plunging into regions of hot mantle can initiate upwelling plumes on the fringes
Hot Spots and Mantle Plumes, Figure 1 Cartoon illustrating the Hawaiian mantle plume. Plumes are thought to arise from the hot thermal boundary layer (D″) at the core–mantle boundary in most cases and can incorporate heterogeneities present in that layer. They may be deflected by mantle convection currents and encounter resistance at the upper–lower mantle boundary due to a phase change. Melting is concentrated in the uppermost 100 or 200 km of the plume "stem" and shield volcanoes develop it. As it flattens against the lithosphere, the plume is drawn out in the direction of the plate motion. Smaller extents of melting extend downstream and may be responsible for post-shield and rejuvenescent magmatism.

of the hot regions. The deformed hot regions and upwellings look much like the splash of a water droplet, so Davies and Bunge called them "splash plumes."

At first controversial, Morgan's plume theory is now widely, but not universally (e.g., Anderson, 2000), accepted as the explanation for most intraplate volcanism. It does not, however, explain all intraplate volcanism, which can have a variety of causes. These include tensional rifting and lithospheric extension (e.g., Van Wijk and Blackman, 2005), plate flexure (Hirano et al., 2006), shear-driven upwelling (e.g., Conrad et al., 2010), and small-scale convection features immediately beneath the lithosphere (Ballmer et al., 2007; King, 2007). Indeed,

there are hundreds of thousands of small volcanic sea-mounts, most unrelated to mantle plumes. This entry will focus on only hot spots related to mantle plumes. Campbell (2007) and White (2010) provide additional reviews.

Plumes and large igneous provinces

Early laboratory and numerical simulations of plumes (e.g., Whitehead and Luther, 1975; Campbell and Griffiths, 1990; Griffiths and Campbell, 1990; Olsen, 1990) suggested that plumes necessarily start with a large voluminous head. As Morgan (1972) noted, a number of oceanic island and sea-mount chains extrapolate to large igneous provinces, or LIPs, which include flood basalts or "traps" on continents and oceanic plateaus in the oceans and result from massive eruptions of basalt over a relatively short period of time. For example, the Reunion plume, currently beneath volcani-cally active Reunion Island, can be connected through Mauritius, the Mascarene Plateau, and the Chagos-Laccadive Ridge to the Deccan Traps flood basalt province of India, produced 65 Ma ago by the eruption of more than 500,000 km^3 of basalt in roughly a million-year period. These observations led to the hypothesis that LIPs are the products of plume heads and oceanic islands are the product of plume tails (Richards et al., 1989). This idea became an essential component of the plume theory. However, rela-tively few oceanic island chains can be confidently associ-ated with LIPs. Subsequent numerical simulations indicate that the surface expression of thermochemical plumes, as opposed to purely thermal plumes, "may be a headless, age-progressive volcanic chain" (Farnetani and Samuel, 2005). *Oceanic plateaus*, a variety of LIP, are the subject of a separate entry and will not be further discussed here.

How many plumes?

Table 1 lists 29 oceanic island chains/hot spots possibly produced by mantle plumes, but just how may mantle plumes are presently active is unclear and debated. Morgan suggested there were about 20 mantle plumes. Sleep (1990) estimated buoyancy fluxes for 37 plumes. Courtillot et al. (2003) considered 49 "hot spots" and con-cluded that only 7–10 were products of deep mantle plumes based on five criteria: (1) a long-lived track, (2) a LIP at initiation, (3) a topographic anomaly indicative of a buoyancy flux in excess of 10^3 kg/s, (4) high $^3He/^4He$ and $^{20}Ne/^{22}Ne$ ratios, and (5) negative shear-wave anom-alies indicative of hot mantle. Only those hot spots meet-ing at least three or more of these criteria were considered to be of "primary plumes" of likely deep man-tle origin. They suggested that many of the remaining hot spots were "secondary," perhaps triggered by large low shear-wave velocity provinces (LSSVPs) located at the base of the mantle and extend up to 1,000 km above it beneath Africa and the central equatorial Pacific.

As noted earlier, it is possible that plumes might begin without large buoyant heads and some may be short lived or young. In addition, Courtillot's noble gas isotope crite-rion assumes mantle plumes always consist of relatively undegassed material, whereas other chemical evidence discussed below suggests recycled oceanic crust may be the dominant component in many cases. Thus, of the Courtillot's 5 criteria, the last, seismic evidence of hot mantle, is perhaps the most important. Subsequent seismic studies by Montelli et al. (2004, 2006) found slow seismic wave velocity anomalies under 30 of 33 hot spots that extended at least to depths greater than the upper–lower mantle boundary at 660 km. Of these, the velocity anom-alies extend to depths of greater than 1,450 km in 23 of the hot spots examined. In addition, Montelli et al. (2006) identified three "plumes" in the lowermost mantle that did not extend into the upper mantle (and are not associated with surface hot spots).

Ebinger and Sleep (1998) suggested that ponding and flow of the "Ethiopian" or Afar plume beneath the African lithosphere could account not only for the Mid-Tertiary Ethiopian flood basalt province and modern Afar volca-nism but also hot spots in central North Africa such as Tibesti, the Cameroon line volcanism, and the oceanic island volcanism on the Comoros. Furthermore, some of the plumes imaged by Montelli et al. appear to merge at depth, such as the Ascension and St. Helena plumes. Thus, a single plume in some cases might be responsible for more than one hot spot.

Hot spots aren't entirely stationary

Both Wilson (1963) and Morgan (1971) noted the appar-ently fixed nature of hot spots, and this became integral to mantle plume theory and was often used to reconstruct plate motions. Subsequent work showed that hot spots do move relative to one another (e.g., Molnar and Stock, 1987), although the velocities are much lower than those of lithospheric plates. In addition, the relative motion between Pacific hot spots and between Indo-Atlantic hot spots is much smaller than the relative motion between a Pacific hot spot and an Atlantic or Indian hot spot (e.g., Courtillot et al., 2003). It was perhaps always overly sim-plistic to expect hot spots to remain stationary; after all, convection plumes in the atmosphere are not stationary: thunderstorms move and can be bent by atmospheric shear. We might expect similar behavior in the mantle. Indeed, based on a mantle convection model, Steinberger et al. (2004) were able to explain nearly all the apparent relative motion between hot spots. The surprising thing is how little, not how much, hot spots move relative to one another. The most likely reason is that three-fourths of a plume's journey to the surface takes place through the lower mantle, whose viscosity is probably one to two orders of magnitude greater than that of the upper mantle and consequently flow is sluggish.

Petrology and geochemistry of oceanic island basalts and mantle plumes

Morgan (1971) pointed out that his model was compatible with the compositional difference between oceanic island basalts (OIB) and mid-ocean ridge basalts (MORB)

Hot Spots and Mantle Plumes, Table 1 Mantle plumes and oceanic island chains

[c]Depth of the s- or p-wave seismic velocity anomaly from Montelli et al. (2006)

established by earlier studies, such as those of Gast (1969) and Hedge (1966). There are several reasons for this difference. First, Morgan predicted that plumes should bring "relatively primordial material" to the shallow mantle, and hence basalts produced by melting of plumes should be chemically distinct from the upper mantle. Second, Morgan predicted that plumes should bring "heat" as well, this too should influence the composition of melts; all other things being equal, one would expect the extent of melting in plumes to be greater than beneath mid-ocean ridges. However, all other things are not always equal, as will be explained below. Finally, if plumes are buoyant, the rate of melting and extents of melting should be different than beneath mid-ocean ridges. Each of these will be considered in the following sections.

Plumes consist of a diverse mix of primitive and recycled materials

Melting of the mantle preferentially removes elements that, because of their ionic size or charge, are not easily accommodated in mantle minerals. These so-called
Hot Spots and Mantle Plumes, Figure 2 Rare earth patterns in selected oceanic island and mid-ocean ridge (*MORB*) basalts. Oceanic island basalts are relatively enriched in incompatible elements such as the light rare earth elements, while mid-ocean ridge basalts are relatively depleted in such elements (modified from White (2013)).

incompatible elements, including K, Rb, Sr, Ba, Nb, Ta, Hf, Zr, U, Th, Pb, and the light rare earths, are relatively depleted in MORB but are enriched in OIB (e.g., Figure 2). Schilling (1973) demonstrated a progressive change in the La/Sm ratio of basalts erupted along the Reykjanes Ridge as Iceland was approached and argued this reflected chemical variation in the mantle source of these basalts (see "Hotspot-Ridge Interaction"). Changes in elemental ratios such as La/Sm in basalts can, however, result from differences in magma generation and evolution, such as the extent of partial melting and fractional crystallization, as O'Hara (1973) argued at the time. In contrast, radiogenic isotope ratios are insensitive to these processes. Consequently, the study by Hart et al. (1973), which showed that $^{87}Sr/^{86}Sr$ also increased along the Reykjanes Ridge toward Iceland, clearly demonstrated a difference between the mantle beneath Iceland and the Mid-Atlantic Ridge to the south. Subsequent studies documented similar variations along mid-ocean ridges in the vicinity of other hot spots, including the Azores (White et al., 1976), the Galapagos (Schilling et al., 1976, 1982), Afar (Schilling et al., 1992), Tristan da Cunha (Hanan et al., 1986), etc.

Schilling (1973) followed Morgan and referred to the Iceland mantle plume as "primordial," in the sense that it

consisted of mantle from which little or no melt had been previously extracted. A natural evolution of this idea was a two-layered mantle, in which the upper mantle source of MORB had been incompatible element-depleted (see "Depleted Mantle") by melt extraction to form the crust and the lower mantle consisted of primitive, unprocessed material (e.g., DePaolo and Wasserburg, 1976; O'Nions et al., 1979; Jacobsen, 1988). Relatively high $^3He/^4He$ ratios in Icelandic and other OIB seemed consistent with this idea (Kurz et al., 1982). Subsequent work has shown that plumes cannot consist entirely of primitive or primordial mantle (see below). First, Pb isotope ratios of OIB cannot be explained through mixing of primordial material and incompatible element-depleted upper mantle. Second, Nd isotope ratios in OIB extend well below any plausible value for primitive mantle, which likely lies between ϵ_{Nd} of 0 (DePaolo and Wasserburg, 1976) and +7 (Caro and Bourdon, 2010). Furthermore, as Figure 3 illustrates, Sr and Nd isotope ratios in OIB exhibit dispersion well beyond what can be explained by simple two-component mixing of depleted and primitive mantle (White and Hofmann, 1982). Finally, mantle seismic tomography reveals whole mantle convection that is inconsistent with the idea of a simple two-layered mantle initially envisioned by geochemists (Grand et al., 1997).

It became subsequently clear that mantle plumes come in a variety of geochemical "flavors" implying the deep mantle consists of material that has evolved through a variety of processes (White, 1985). Perhaps the most significant of these is subduction of oceanic crust and sediment into the deep mantle (Hofmann and White, 1982). The signature of ancient crustal material is particularly apparent in the so-called EM II OIB (Figure 3), notably Samoa and the Society Islands, which have non-mantle *oxygen isotope ratios* (Eiler et al., 2005), extreme radiogenic isotopic compositions (Jackson et al., 2007), and crustal-like trace element ratios (White and Duncan, 1996). More recently, Cabral et al. (2013) have found mass-independent-fractionated sulfur isotope ratios in sulfide inclusions in a lava from Mangaia of the Cook Islands, which belong to the HIMU group (Figure 3). Mass-independent fractionation of sulfur isotopes occurred only in the atmosphere prior to the great oxidation event 2.3 billion years ago. Thus the source of at least some HIMU lavas also includes anciently recycled surface material. Willbold and Stracke (2010) have argued based on trace element and isotope systematics that the EM I group (Figure 3), which includes islands such as Kerguelen and Tristan da Cunha, carry the chemical signature of lower continental crust, which returns to the mantle either through lower crustal foundering/delamination or *subduction erosion*. Finally, Blichert-Toft et al. (1999) documented a strong, curved correlation between Hf and Pb isotope ratios in Hawaiian basalts that almost certainly reflects mixing between mantle and an ancient crustal component, most likely sedimentary. Thus, crustal material subducted into the deep mantle may be pervasive in mantle plumes.

Hot Spots and Mantle Plumes, Figure 3 Sr and Nd isotope ratios in selected oceanic island and mid-ocean ridge basalts. ε_{Nd} is the deviation in parts in 10,000 of the $^{143}Nd/^{144}Nd$ ratio from the chondritic value (=0.512638). Island chains form a variety of distinct trends on this diagram, indicating their sources have evolved in a variety of ways (White, 1985). HIMU, EM I, EM II, and PREMA are the end-member names of Zindler and Hart (1986). *Gray areas with lines* indicate the likely composition of primitive mantle or bulk silicate Earth.

In contrast, there is no evidence in any OIB of a component produced by melting in the deep mantle, although there is seismic evidence that localized melting might occur in small regions near the core–mantle boundary. Experiments show that partitioning of elements between deep mantle minerals (those in which silicon is octahedrally coordinated by oxygen) and liquids is quite different from solid–liquid partitioning in the upper mantle (e.g., Corgne et al., 2005). So far, element abundances in all OIB are consistent with their distinct signatures having formed in the upper mantle or crust and not in the lower mantle.

Noble gas isotope ratios, however, indicate that a near-primitive component is present in many mantle plumes. As noted above, high $^3He/^4He$ ratios in many OIB indicate they are derived from mantle that has been substantially less degassed than the *depleted* upper *mantle*. Decay of U and Th constantly produces ^4He in the mantle so that the $^3He/^4He$ ratio decreases through time. When mantle melts, He is efficiently degassed from the mantle into the atmosphere and lost to space. Consequently, processed mantle as well as recycled crustal material should have low $^3He/^4He$ (Porcelli and Elliott, 2008). Some OIB do, but high ratios predominate. Hanan and Graham (1996) noted the association of high $^3He/^4He$ ratios with intermediate Pb isotope ratios and argued that a primitive component, which they termed "C," is present in all or most

plumes. Thus, while recycled material dominates the geochemical signature of plumes just as strawberries, vanilla, and chocolate dominate the flavor of ice cream, this may not be the main ingredient.

Recent studies of other noble gas isotope ratios, particularly of xenon, support the notion that at least some plumes contain a very primitive component indeed. Xenon isotopic composition varies because of decay of two extinct radionuclides: ^{129}I, which decays to ^{129}Xe with a 15.7 Ma half-life, and ^{244}Pu, which has a 82 Ma half-life and whose principal fission products include the heavy Xe isotopes (Xe isotopic composition also varies due mass-dependent fractionation and fission of ^{238}U). $^{129}Xe/^{130}Xe$ ratios in OIB are higher than in the atmosphere and are higher still in MORB. These differences, as well as those in heavy fissogenic Xe isotopes must have been established within the first 100 Ma of Earth's history, require that the plume source to less degassed than the MORB source and that subsequent mixing between them over the next 4.3 billion years must have been limited (Mukhopadhyay, 2012). The primitive signal appears to be largely confined to noble gases; concentrations and isotope ratios of other elements indicate plumes consisting primarily of processed material.

Mantle plumes can also be heterogeneous, exhibiting systematic geographic variation in composition. The

best-documented examples are Hawaii and the Galapagos. Tatsumoto (1978) and Stille et al. (1986) showed that the Hawaiian hot spot consists of two volcanic chains: Loa and Kea, whose Pb isotopic compositions are distinct and have remained so for about 5 Ma. Subsequent studies (e.g., Abouchami et al., 2005; Bryce et al., 2005; Weis et al., 2011) fully support that early work and show the difference extends to other isotope ratios as well. Parallel chains having distinct radiogenic isotopic characteristics have also been identified in the Marquesas, the Society Islands, Samoa, and the Tristan da Cunha–Gough hot spot (Desonie et al., 1993; Huang et al., 2011; Chauvel et al., 2012; Payne et al., 2013; Rohde et al., 2013). In the Galapagos, four distinct plume components, northern, central, southern, and a depleted eastern one, can be distinguished in the mixing trends (White et al., 1993; Harpp and White, 2001). Hoernle et al. (2000) showed that these same domains occur in the same relative positions in a geochemical profile across the Cocos Ridge (the Galapagos hot spot track on the Cocos Plate) indicating that the spatial zonation of the Galapagos hot spot has continued for at least 14 Ma. As they point out, this implies "that plume material can ascend from the lower mantle, possibly from the core-mantle boundary, with little stirring occurring during ascent, and that zonation in hotspot lavas may in some cases reflect spatial heterogeneity within the lower mantle source." These zonations may in turn reflect chemical zonation and structure in the lowermost mantle (Weis et al., 2011; Farnetani et al., 2012; Harpp et al., 2014).

In summary, plumes carry a variety of material from the deep mantle to the surface, including anciently subducted oceanic and continental crust and very primitive noble gas signal preserved from the earliest days of Earth's history.

Lithological composition of plumes

The lithology of plumes, which is their mineralogical makeup, is more difficult to assess because it cannot be directly observed, only inferred. Without question, the mantle consists predominately of *peridotite*. However, populations of mantle xenoliths always contained a small but significant fraction of rocks, such as eclogite and pyroxenite, similar in composition to basalt. Allègre and Turcotte (1986) pointed out that continuous production and subduction of oceanic crust over billions of years was likely to produce a "marble-cake" mantle with ubiquitous stringers of mafic material embedded in an ultramafic matrix. Indeed, recent numerical simulations suggest 97 % of the mantle has been processed through the oceanic crust cycle (Huang and Davies, 2007). If, as isotopic and trace element studies suggest, plumes are particularly rich in recycled crustal materials, one might expect them to be lithologically distinct from asthenospheric mantle and particularly rich in mafic materials such as eclogite and pyroxenite. Since this material melts at lower temperature than peridotite, might the mantle plume melts be derived predominantly from pods and stringers of mafic material

rather than the more refractory peridotite in which they are embedded?

This question remains unresolved and debated. Stracke et al. (1999) argued against the existence of garnet-pyroxenite or eclogite in the Hawaiian source on the basis of combined Hf-Nd-Th isotope and trace element systematics. On the other hand, Reiners (2002) argued that "temporal-compositional trends in the form of decreasing incompatible elements and MgO, with increasing SiO_2, as the eruption proceed"... "reflect sequential eruption of melt from increasing depths in mantle melting regions that are compositionally zoned because of different solidi and melt productivities of distinct peridotite and pyroxenite lithologic domains."

A particularly interesting, provocative, and consequently controversial idea was proposed by Sobolev et al. (2005), who argue on the basis of SiO_2, Ni, and Mn concentrations that part of the Hawaiian source is olivine-free. They suggested that eclogite, which originates as recycled oceanic crust, composes up to 30 % of the Hawaiian plume. As a consequence of its much lower solidus, the eclogite melts at greater depth than peridotite. This melt then reacts with surrounding peridotite to form pyroxenite, which subsequently melts at shallower depth. Sobolev et al. (2007) argue that recycled oceanic crust in the form of eclogite stringers, and consequently this two-stage melting process, is pervasive in the mantle; according to them even MORB are composed of 10–30 % pyroxenite-derived melts. A number of other studies have also concluded that pyroxenites play an important role in the genesis of Hawaiian magmas. Putirka et al. (2011), however, argue that high Ni contents and high FeO/MnO ratios in Hawaiian basalts compared to MORB reflect higher temperatures (by 300°) and pressures (4–5 GPa vs. 1–3 GPa) of melting under Hawaii than beneath mid-ocean ridges and that both Hawaiian basalts and MORB are generated by melting of peridotite rather than pyroxenite or eclogite. They suggest that subducted material is thoroughly mixed back into the peridotite matrix and does not survive "high temperatures and potentially long residence times" in the deep mantle as a distinct lithological component.

Evidence that plumes are hot and buoyant

If plumes are hotter than the depleted upper mantle, this should produce petrologic and chemical distinctions. To begin with, one would expect them to melt more. Because melting in both plumes and at mid-ocean ridges results from adiabatic decompression of rising mantle, the extent of melting depends both on temperature, which determines the depth at which melting begins, and lithospheric thickness, which determines the height to which mantle can rise, and consequently the total amount of melting for mantle of a given temperature and composition. At mid-ocean ridges, the lithosphere is thin to nonexistent and melting continues to shallow depth (<30 km). Older lithosphere, for example, beneath Hawaii, may approach

90 km. Thus, the extent of melting alone is not a good indicator of mantle temperature.

A useful comparison is between melting in ridge-centered plumes and mid-ocean ridges distant from them. Dick et al. (1984) found that abyssal peridotites in the vicinity of hot spots had mineral abundances and compositions suggesting they had melted to greater degree than had peridotites away from hot spots. They noted that the peridotite mineralogy was correlated regionally with basalt chemistry and concluded that hot spots were indeed hotter and hence likely products of mantle plumes. Michael and Bonatti (1985) reached similar conclusions from a study of peridotite compositions. Klein and Langmuir (1987) concluded from a comprehensive study of MORB chemistry that mantle temperatures beneath the mid-ocean ridges varied by as much as 250 °C. The highest temperatures, and highest extents of melting, invariably occurred near hot spots such as Iceland. This, of course, makes some sense because Iceland crust is far thicker (~30 km) than normal oceanic crust (~6–7 km), requiring much greater amounts of melt for its creation.

Putirka et al. (2007) used a refined version of the Roeder and Emslie (1970) olivine geothermometer to calculate melt temperatures of magmas from mid-ocean ridges and oceanic islands and from them derived mantle potential temperatures. They calculated mantle potential temperatures of $1,454 \pm 81$ °C for mantle beneath mid-ocean ridges, 1,722 °C for mantle beneath the Hawaiian and Samoan chains, and 1,616 °C for mantle beneath Iceland. These translate to excess temperatures of 268 °C and 162 °C, respectively, in overall good agreement with earlier studies. Consistent with this, Putirka et al. (2011) calculated that the Hawaiian magmas are generated by up to 20 % melting, compared to 8 % for MORB.

Potential temperatures calculated by Herzberg et al. (2007) for ambient mantle beneath mid-ocean ridges were lower: in the range of 1,280–1,400 °C, but they nevertheless concluded that plumes are typically 200–300 °C hotter. Herzberg and Asimow (2008) estimated mantle excess potential temperatures for a variety of other plumes and found that they scattered between those for Hawaii (~200 °C) and for Iceland (~100 °C). These estimates are also in good agreement with studies that use entirely different approaches, such as the width of the geochemical anomaly along ridges (Schilling, 1991) and excess topography and geoid height (Watson and Mckenzie, 1991). Finally, Courtier et al. (2007) found a correlation between petrologically determined temperatures in OIB and MORB and the seismically determined thickness of the underlying mantle transition zone. Beneath hot spots, the transition zone is thinner, precisely the expected result if hot spots result from hot mantle rising through the transition zone. There is, however, not a complete consensus on this point as Green et al. (2001) and Falloon et al. (2007), also using the olivine geothermometer, found no difference in potential temperatures between the sub-ridge and the sub-Hawaiian mantle. Possible explanations for this discrepancy are discussed by Putirka et al. (2007).

The melt production rate is related to the upwelling rate. The extent of radioactive disequilibrium between ^{230}Th and its parent, ^{238}U, should depend on these rates (e.g., Spiegelman and Elliot, 1993). Consequently, the degree to which the ^{230}Th/^{238}U activity ratio (activity ratios will hereafter be designated by parentheses) exceeds 1 should be a measure of the rate of mantle upwelling. Indeed, Chabaux and Allegre (1994) demonstrated that $(^{230}$Th/^{238}U) ratios in OIB are inversely correlated with buoyancy flux as estimated by Sleep (1990). Bourdon et al. (2006) demonstrated that the relationship observed by Chabaux and Allègre is precisely that of the expected based on simple assumptions about melt porosity and partition coefficients and the relationship between melt production and upwelling rate. They further showed that $(^{230}$Th/^{238}U) and $(^{231}$Pa/^{235}U) ratios vary with distance from the assumed center of plumes in a manner that is consistent with buoyancy fluxes and excess temperatures in the range of 100–300 °C.

Rejuvenescent volcanism

One aspect of oceanic island volcanism that remains somewhat puzzling is the so-called "post-erosional" or "rejuvenescent" volcanism: eruptions that occur after a long hiatus, sometimes several million years. The Honolulu volcanic series of Oahu, which includes the iconic Diamond Head cone, is the classic example. This phenomenon was first recognized in Hawaii (e.g., Sterns, 1946; MacDonald, 1968) and has since been recognized in at least Samoa, the Society Islands, the Marquesas, Madeira, the Canaries, the Louisville Seamounts, Mauritius, and, most recently, Jasper Seamount (Konter et al., 2009). Usually these cases mimic the Hawaiian pattern in which the post-erosional phase involves eruption of alkaline to highly alkaline, low-silica lavas enriched in incompatible elements (all of which indicate low extents of melting) but with a more depleted isotopic signature than lavas of the main shield-building phase (e.g., Chen and Frey, 1983). The eruption rates in the post-erosional phase are, however, far lower than in the shield-building phase. Garcia et al. (2010) estimated the rejuvenescent Koolau Series on Kaua'i comprising about 0.1 % of the volcano volume, while Moore et al. (2011) estimate the rejuvenescent phase on Mauritius comprising about 0.05 % of the volume, even though these lavas cover most of the island's surface. Rejuvenescent volcanism has not been identified in on- or near-ridge hot spots such as the Galapagos and Azores.

In Samoa, the rejuvenescent volcanism is so extensive on the westernmost island of Savai'i that it was initially thought that age progressed from east to west, opposite of the prediction of the hot spot model (Hawkins and Natland, 1975). Natland (1980) argued that Samoan volcanism resulted from lithospheric flexure as the Pacific plate passes north of the Tonga–Kermadec subduction

zone rather than a mantle plume. However, Koppers et al. (2008) obtained $^{40}Ar-^{39}Ar$ ages of 5 Ma on basalts dredged from the flanks of Savai'i, which agree well with the predicted age assuming a lithospheric motion of 7.1 cm/year and a current location of the hot spot beneath the young, volcanically active seamount Vailulu'u. The volume of Samoan rejuvenescent volcanism does seem unusually large; Konter and Jackson (2012) estimate that it is responsible for up to 2 % of the volume of Savai'i. It is also unusual in that the post-erosional volcanics do not have a depleted radiogenic isotope signature (Wright and White, 1987; Konter and Jackson, 2012).

The two main questions are why does volcanism flair up again after the volcano has moved off the plume and what is melting to produce post-erosional magmas? Several ideas have been put forth as to the cause. The numerical model of plume dynamics of Ribe and Christensen (1999) predicts small secondary melting zone downstream from the hot spot as a consequence of upwelling and decompression of the mantle plume as it interacts with the overlying lithosphere. Jackson and Wright (1970), ten Brink and Brocher (1987), and Bianco et al. (2005) have proposed it results from lithospheric flexure caused by the growth of the next volcano in the chain. Liu and Chase (1991) proposed that rejuvenescent magmas are derived from the base of the lithosphere which is conductively heated by the plume sufficiently to melt to a small degree.

Because rejuvenescent lavas are isotopically distinct from the shield phase lavas, they must have a different source. Chen and Frey (1983) suggested the source was oceanic lithosphere, but in detail the isotope and trace element systematics are inconsistent with this hypothesis (Yang et al., 2003; White, 2010). White and Duncan (1996) and Fekiacova et al. (2007) suggested it was deep mantle viscously entrained by the plume, and geodynamic models do indeed show a region of melting deep in the plume extending well downstream of the principal melting regime (e.g., Hofmann and Farnetani, 2013; Figure 1). Bianco et al. (2005) and Paul et al. (2005) proposed that the Hawaiian and Reunion mantle plumes, respectively, are lithologically heterogeneous with a relatively incompatible-element-enriched mafic component embedded within a depleted peridotite. According to these models, the pyroxenite melts more or less completely in the plume stem as it rises beneath the growing shield volcano. Subsequently, due either to lithospheric flexure or buoyant lateral spreading of the plume, small degree melts of the depleted peridotite are generated and erupt as the post-erosional lavas. Moore et al. (2011) proposed a variant of the Chen and Frey hypothesis in which pyroxenite veins form in the lowermost lithosphere as early shield-building stage melts react with it when it is still cold. Eventually, conductive heating by the plume causes these veins to melt to a small degree (Gurriet, 1987), producing the rejuvenescent magmas. Except for Samoa, where lithospheric flexure appears to be the cause, no consensus has formed around any of these hypotheses.

Summary

Hot spots are the surface manifestation of mantle plumes. This hypothesis, proposed by Morgan (1971) to explain Wilson's "hot spots," was initially controversial, but over the last 40 years, a wealth of geophysical, geochemical, and petrological data now place it on firm ground. Oceanic island chains are located on bathymetric "swells," which allow estimates of the buoyancy fluxes of the plumes (Davies, 1988; Sleep, 1990). The total heat flux carried by plumes is about 10 % of the total mantle heat flux, indicating that plumes are a secondary feature of mantle convection, with plate tectonics being the dominant one. Estimated buoyancy fluxes correlate with upwelling ratios estimated from $(^{230}Th/^{238}U)$ ratios in the lavas (Bourdon et al., 2006). Regions of slow seismic velocity, indicative of high temperatures and extending into the deep mantle and the base of the mantle in many cases, have been found under most of the oceanic hot spots (Montelli et al., 2006). Consistent with this, petrological studies demonstrate that the potential temperatures of the mantle from which OIB are generated are some 100–300 °C hotter than ambient asthenosphere (e.g., Putirka et al., 2007). Isotope and trace element geochemistry reveal that plumes contain a variety of materials originating on or near the Earth's surface that have been recycled into the deep mantle through subduction, subduction erosion, or lower crustal foundering. Many plumes also appear to sample very primitive material, which may have remained essentially unprocessed since the Earth's earliest days.

Synonyms

Plume-ridge interaction

Definition

The exchange of material (magma, mantle rock) between an intraplate mantle melting anomaly (hotspot, thought to be caused in places by the presence of a mantle plume) and the global spreading ridge system. Evidence for the interaction is found in the depth of the spreading axis, its morphology, the chemistry of the lavas (both on the spreading axis and possibly at the hotspot), and sometimes by the presence of linear volcanic ridges between spreading axis and hotspot. These linear volcanic ridges generally do not show clear age-progressive volcanism, in contrast to the volcanoes of the hotspot itself.

Description

As a result of the relative fixity of hotspots with respect to the moving plates, their distance from active spreading centers changes over geological time. Depending on the plate tectonic situation, hotspots can both migrate toward and away from ridges over time, respectively, weakening and strengthening the hotspot-ridge interaction. At some limiting minimum separation (which may be several hundred km and is dependent on whether the two are approaching or separating from each other), the two begin to interact. Evidence for hotspot-ridge interaction comes from both present-day systems and from fossil traces preserved on the seafloor.

In some cases, such as Iceland, the hotspot lies directly beneath the spreading center (the Mid-Atlantic Ridge), and there is evidence that the spreading axis regularly relocates via ridge jumps to maintain this situation despite plate motion ("ridge capture"). In others (e.g., Galapagos hotspot and Galapagos Spreading Center) there is evidence that the spreading axis is currently moving away from the hotspot (e.g., Ito and Lin, 1995). It has been proposed (Mittelstaedt et al., 2011) that ridge jumps occur more regularly at slow spreading rates which may explain, for example, the tendency for Atlantic hotspots (e.g., Azores, St. Helena, Tristan, Bouvet, as well as Iceland) to cluster near the axis. When the hotspot lies directly on the spreading axis, mantle upwelling can extend to relatively shallow depths, producing a large volume of magma. This is at least one factor (in addition to plume temperature and composition) for Iceland's large land surface compared to other volcanic ocean islands and has been suggested as a mechanism by which large oceanic igneous provinces (such as the Ontong Java-Hikurangi-Manihiki cluster) could have attained their exceptional

size (e.g., Taylor, 2006). Ridge-centered hotspots produce volcanic trails on both plates on either side of the ridge, as is seen, for example, in the Greenland-Faroe Ridge, which the Iceland hotspot has produced since opening of the North Atlantic, and the dual Carnegie-Cocos Ridges produced by the Galapagos hotspot (e.g., Harpp et al., 2005).

Off-axis hotspots produce variable effects on the bathymetry of the adjacent axis, related to both the hotspot-ridge separation distance (the effect falls off with increasing separation) and the intensity of hotspot volcanism (more productive hotspots have larger effects on the ridge). The Galapagos hotspot, for example, produces a large bathymetric anomaly (e.g., Christie et al., 2005) on the Galapagos Spreading Center (hotspot-ridge separation 150 km). In the past, this hotspot lay directly on the spreading axis, which led to the construction of a volcanic ridge (the Cocos Ridge) on the Cocos Plate. The Easter hotspot, in contrast, has only very limited effect on the bathymetry of the East Pacific Rise bathymetry (separation 350 km), and no trace is visible on the opposite plate (see, e.g., Haase et al., 1996).

The hotspot supplies material to the spreading axis. Whether this is in the form of direct magma transport or the flow of mantle material is still unclear (c.f., Braun and Sohn, 2003; Kokfelt et al., 2005; Stroncik et al., 2008; Villagomez et al., 2014). The geochemical influence of the hotspot on the ridge often leads to the axis erupting magmas with compositions more enriched in mantle-incompatible elements than surrounding segments of the ridge, although evidence for the eruption of extremely depleted magmas at both hotspots and their adjacent axes has also been found (Portnyagin et al., 2009; Stroncik and Devey, 2011). Several hotspot-influenced ridges have been found to erupt magmas more fractionated than basalt – in some cases, these magmas have compositions very similar to early continental crust (Haase et al., 2005). Hotspot-ridge interaction also clearly influences the composition of the hotspot magmas – the extent to which this influence results from (a) the effects of lithospheric thickness on depth and degree of melting, (b) the flow of material from the ridge to the hotspot, or (c) the consequence of the removal of hotspot material toward the ridge is hotly debated (Haase et al., 1996; Keller et al., 2000; Stroncik and Devey, 2011)

When the hotspot is close to the ridge, the seafloor separating them is also the site of intense volcanism (e.g., Christie et al., 2005; Fretzdorff et al., 1996; Maia et al., 2000). Sometimes this is manifested as linear volcanic ridges running between hotspot and ridge (e.g., Kopp et al., 2003; Maia et al., 2000) which show no systematic age-distance relationship, in contrast to the hotspot volcanoes themselves (O'Connor et al., 2001).

Summary

Hotspot-ridge interaction affects large areas of the seafloor, resulting in bathymetric, structural, and geochemical anomalies on both ridge and hotspot.

HURRICANES AND TYPHOONS

Don Resio[1] and Shannon Kay[2]
[1]Taylor Engineering Research Institute, University of North Florida, Jacksonville, FL, USA
[2]Coastal Projects, Manson Construction Co., Jacksonville, FL, USA

Definition

Hurricanes and typhoons are atmospheric circulation systems of tropical origin characterized by low pressure at the center and near surface winds spiraling inward around this center, typically storm size ranges from 10 to 80 km for the radius to maximum wind speeds with cloud cover extending from about 150 to 1,500 km. In meteorological terms, hurricanes and typhoons are low pressure, warm-core cyclones, originating in warm waters with closed surface winds rotating about an eye. Table 1 shows that several different names are used in different areas around the world to refer to these storms. The origins of the local names for these storms, hurricanes and typhoons, come from the languages of people who lived in areas most affected by tropical cyclones.

- "Hurricane" was derived from the ancient Mayan God of Storms, "Hurakan," known for causing the great flood which destroyed humanity, based on ancient Carib God, "Hurican," the god of evil (Mythica, 2013).
- "Typhoon" originates from the Chinese word "dàfēng (tai fung)" meaning big wind.
- "Willy Willy" is a local term that originated along west coast of Australia.

For simplicity, the generic meteorological term, tropical cyclone, will be used this entry.

Introduction

As shown in Figure 1, tropical cyclones represent a serious, persistent threat to coastal communities around the world. Given the existence of ongoing, possibly accelerating, global sea-level rise along with the increasing importance of ports and harbors in global trade, it is very likely

Hurricanes and Typhoons, Table 1 Common terms used to reference tropical cyclones around the World

Region	Term Definition
North America	Tropical depression: maximum 1-min wind speed < 39 mph (62 km/h)
	Tropical storm: maximum 1-min wind speed >39mph (62 km/h)
	Hurricane: maximum 1-min winds speed > 74 mph (120 km/h)
Southern Hemisphere and Fiji	Tropical low: maximum sustained wind speed < 90 km/h
	Tropical cyclone: maximum sustained wind speed > 90 km/h
	Severe tropical cyclone: > 165 km/h
Western Pacific	Tropical depression: maximum sustained wind speed < 61 km/h
	Tropical storm: maximum sustained wind speed > 61 km/h
	Severe tropical storm: maximum sustained wind speed > 89 km/h
	Typhoon: maximum sustained wind speed > 118 km/h
	Super typhoon: maximum sustained wind speed > 252 km/h
India	Tropical depression: maximum sustained wind speed < 62 km/h
	Tropical storm: maximum sustained wind speed > 63 km/h
	Tropical cyclone: maximum sustained wind > 118 km/h
	Intense tropical cyclone: maximum sustained wind speed > 166 km/h

that the cost of coastal disasters in terms of both economic impacts and loss of life will continue to rise, making the study of these storms a critical priority within scientific, engineering, and planning communities.

Formation of a tropical cyclone

Tropical cyclones derive their energy from rising air above warm ocean waters, coupled with the earth's rotation. Key factors contributing to cyclone formation include (Gray, 1968, 1979; Emanuel, 1991):

1. Ocean water must contain abundant heat to compensate for heat loss via evaporation at the air-sea interface (typically above 26 °C, to a depth of about 50 m).
2. The atmosphere must cool sufficiently with height to retain potential instability in the rising air, otherwise the density of the rising air will approach that of the surrounding air and its vertical motion will dissipate.
3. Relatively high atmospheric water content in the mid-tropospheric level is needed since condensation of water vapor fuels continued development of thunderstorms at this level and condensation rates depend on relative humidity.
4. A horizontal displacement of the circulation center at least 500 km from the equator is needed to enable Coriolis acceleration (the effect of the earth's rotation on motions in an inertial frame of reference) to force horizontal air paths toward a closed circulation via a quasi-gradient balance before the winds and pressure differential within the storm become sufficiently large to shift toward a cyclostrophic balance.
Hurricanes and Typhoons, Figure 1 Highest ranking estimated mortality due to tropical cyclone generated storm surges (Dube, 2007).
Hurricanes and Typhoons, Figure 2 Schematic diagram of airflow through a tropical cyclone (NASA, 2013).

5. A disturbance must exist over a sufficiently broad ocean surface to allow Coriolis acceleration to produce horizontal trajectories that move toward a closed circulation.
6. Since vertical wind shear can disrupt the organized energy flow that drives a hurricane (heat taken from the ocean surface by evaporation carried vertically where it is released by condensation), such shear can inhibit the formation and/or strengthening of tropical cyclones.

Anatomy of a tropical cyclone

Tropical cyclogenesis is initiated by large areas of convection developing in warm ocean regions around the world. Organized synoptic-scale motions (spatial scales in the range of 10–100 s of km and temporal scales in the range of hours to days) are typically required to initiate cyclogenesis. Features such as easterly waves, stationary fronts, or broad areas of atmospheric divergence represent types of disturbances which can create such organized convection. Rising air within a large area of convection begins to create generally decreased pressures, which, in turn, draws near-surface air from surrounding areas into the low-pressure region. The speed of air moving over the ocean surface directly influences the transfer rate of moisture; thus the vertical motions create a feedback which increases the amount of heat transferred into the overriding air passing into the region of low pressure, i.e., the faster the air moves the more moisture it accumulates. The air trajectories spiral inward toward the center of the low pressure system due to Coriolis acceleration and contribute additionally to the convection in this region. The heat in the rising air is released when it condenses in the vicinity of the top of the frictional boundary layer within

the atmosphere (about 1–2 km above the water surface), further adding to the convective instability and contributing to a continued pressure reduction. In developing storms a stable layer in the atmosphere, located about 15 km above sea-level, creates a region of high pressure above the storm center and causes the air at this level to spiral outwards with an opposite rotation from the lower trajectories, as shown in Figure 2.

Emanuel (1986, 1991) provides an excellent treatise on the formation of tropical cyclones in terms of a Carnot engine that converts the heat from evaporation at the ocean surface into mechanical energy. This energy cycle can continue to grow in strength as long as the rate of gain of heat (from the ocean into the atmosphere) from the evaporation at the surface and condensation in the cloud layer exceeds the sum of energy losses in the system, loss of kinetic energy due to drag at the air-sea interface, loss of heat energy due to upwelling of cooler water from subsurface regions, etc. As an interesting consequence of this theoretical work, parametric models for the maximum potential intensity (MPI) of a hurricane have been formulated (Emanuel, 1988; Holland, 1997; Tonkin et al., 2000). These models indicate that the MPI increases as a function of sea surface temperate (SST); and since SST is known to be increasing around the world (Trenberth et al., 2007), recent work (Knutson et al., 2010) has suggested that the frequency of intense tropical cyclones can be expected to rise in the future.

- **Effects of storm translation on wind fields**: As might be expected from the conceptual framework presented, there is no mechanism which will produce strong asymmetry in a stationary storm; hence such storms tend to have approximately symmetric wind fields around their centers, often termed the eye of these storm. However,

storms are imbedded within steering currents produced by large-scale motions (spatial scales greater than about 5,000 km and temporal scales greater than five days) within the atmosphere. These steering currents roughly coincide with many of the average seasonal circulation features around the globe, producing east to west motions at latitudes between 30° latitude north and south and curving toward west to east motions at latitudes poleward of 35° latitude north and south. Tropical cyclones move with the general speed of these large-scale currents in which they are imbedded. The winds in the tropical cyclone and large-scale wind system are superposed vectorially. Relative to the earth's surface, this creates higher wind speeds on the side of the storm moving in the same direction as the large-scale motion and lower wind speeds on the side moving against the large-scale motion. At the same time, the vector addition changes the wind directions slightly (typically less than 10°). The overall effect is to create an asymmetric wind field with generally stronger(weaker) winds on the right (left) side of a tropical cyclone in the northern hemisphere and stronger (weaker) winds on the left side of a tropical cyclone in the southern hemisphere.

Features within a tropical cyclones

- **The eye and eye wall**: As shown in Figure 2, there is an often cloudless region of relatively calm winds, termed the "eye" of the storm, around which the rest of the storm rotates. In the eye, the atmospheric pressure typically reaches its minimum values accompanied by the warmest temperatures. The warming in this region is caused by slowly sinking air from the high pressure region above. In well-developed storms, the eye is surrounded by an eyewall, as illustrated in Figure 2. The eyewall is where the strongest winds and highest rainfall rates are usually located. The existence of the eye and eyewall is related to the dynamics of flow within tropical cyclones. As air nears the center of the storm, the centrifugal acceleration would become very large if wind speeds around the eye remained constant. The pressure gradient required to maintain a cyclostrophic balance cannot be maintained inside the eyewall area and the slowly sinking air inside the eyewall slowly merges with the air in the eyewall, where it rises to complete the cycle.
- **Rain bands**: Although many well-developed tropical cyclones are relatively symmetric, lower intensity or storms during the early formative stage of developments can be much less symmetric and contain more irregular organized motions. This creates regions of higher and lower winds throughout the storm, leading to somewhat unique patterns of clouds and winds in tropical cyclones. One prevalent feature related to these organized variations is termed a rain band. Rain bands are heavily convective regions containing high rainfall rates and typically higher wind speed than adjacent portions of the storm. These bands form long, narrow cloud

systems which are oriented in the direction of the wind. Along the lower level of these bands, convergence is a maximum, leading to some low-level subsidence in adjacent areas. In many cases the spiral bands converge into the storm center merging into the eyewall.

Extratropical transition

When tropical cyclones encounter pronounced horizontal temperature gradients in the atmosphere, as typical of many ocean areas poleward of 35° north or south, they begin to undergo extratopical transition (Jones et al., 2003). This introduces a new source of energy into the energy balance, termed a baroclinic energy source, which is the same mechanism that supplies energy to extratropical storms. Most hurricanes along the US East Coast are undergoing extratropical transition by the time they get into the New York Bight; consequently, it should not be a surprise that Hurricane Sandy was deriving a substantial part of its energy from baroclinic sources (Shen et al., 2013) when in made landfall. This also means that the MPI is not a viable concept for quantifying the maximum storm intensity at this latitude.

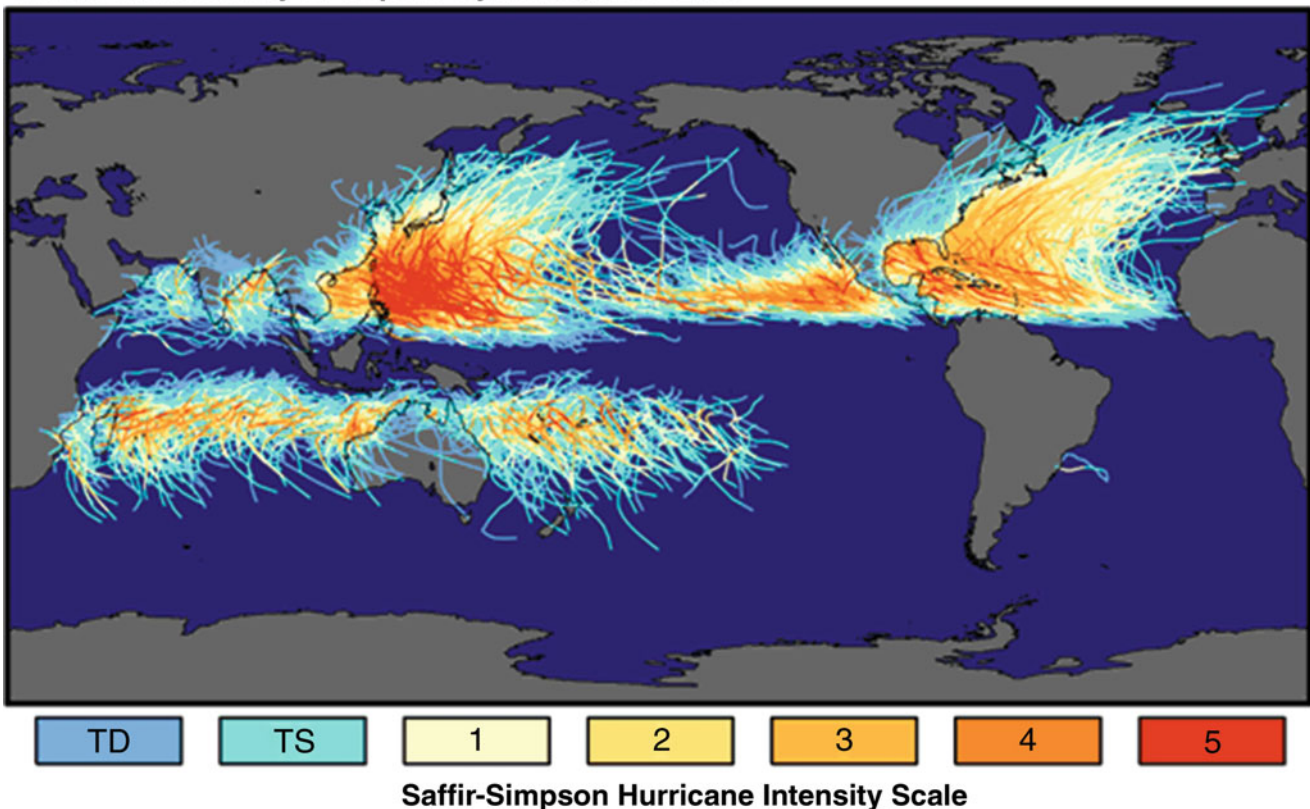
Impacts of tropical cyclones

Tropical cyclones represent a major threat to property, livelihood and safety around the world. Critical threats are underestimated in many areas due to their relative rarity; and even in areas frequently exposed to tropical cyclones, an extreme cyclone can produce inundation, inland flooding, mudslides and wave run-up which significantly exceed the experience of local inhabitants. For this reason, such storms often produce catastrophic, unanticipated impacts, even when appropriate warnings are issued. The principal contributors to damages from tropical cyclones are storm surge, damaging waves, strong winds and inland flooding.

- **Storm surge**: The rise of water level generated by the storm winds and waves is termed the storm surge and is responsible for the majority of deaths in most areas. The superposition of storm surge on local tides is sometimes termed the storm tide. Inundation due to the storm tide, or total water level, is driven by three main processes: (1) lower atmospheric pressures at the water surface, termed the "inverted barometer effect" (roughly 1 m of sea-level rise for a 100 mb lowering of the atmospheric pressure at the surface), (2) direct momentum transfer from wind to water, and (3) fluxes into the water column from breaking waves approaching the coast. Additional, factors affecting surge include: storm size, forward velocity, angle of coastal incidence, wave stress (Irish et al., 2009), coastal bathymetry (Resio and Westerink, 2008) and interactions with rivers (Kerr et al., 2013; Resio et al., 2013). In areas with broad continental shelves, direct wind forcing is usually the dominant surge generation mechanism, while on steep coasts, typical of many island areas around the world, waves and wave run-up are often the dominant flooding

Tracks and Intensity of Tropical Cyclones, 1851-2006

| TD | TS | 1 | 2 | 3 | 4 | 5 |

Saffir-Simpson Hurricane Intensity Scale


Hurricanes and Typhoons, Figure 3 Worldwide distribution of combined tropical cyclone frequency and intensity. The lack of tropical cyclones near the equator can be clearly seen in this analysis by NASA available online at www.goes-r.gov/users/comet/tropical/textbook_2nd_Edition/. The Saffir-Simpson scale referenced here was developed initially as a 1–5 scale as an indicator of wind damage to structures on land and should not be used as a scale for surge, wave or inland flooding hazards (Kay, 2010).

mechanism. There is typically a pronounced asymmetry in surge heights along the coast, related to the wind speed asymmetry previously noted and the direction of the wind, with higher surges to the right of landfall (relative to direction of storm heading) in the northern hemisphere and to the left in the southern hemisphere.

- **Rough seas**: Large waves pose a major threat to off-shore structures, such as oil platforms and transshipment facilities, as well as to commercial shipping and recreational boating. Besides the loss of life and property when a vessel is damaged or sinks, delays in the transport of goods and the impact of increased ship time related to rough seas can dramatically influence shipping costs. In addition to the effects of waves offshore, large waves along coasts, particularly when superposed upon the elevated water levels, are also responsible for substantial loss of life and property in coastal communities.
- **Strong winds**: Strong winds associated with tropical cyclones also pose a major threat to coastal communities. Roofs can be lifted, trees uprooted, and power lines torn down by the magnitude of force from the wind. In some areas of the world with minimal building codes,

damage from winds alone can produce massive devastation.

- **Inland flooding**: Coastal areas of many islands around the world are bounded by steep topography. When the moisture laden air in tropical cyclones is forced up these slopes, orographic lifting can produce extreme rainfall rates, which often produce extreme flooding in coastal rivers and streams. The effects of such high precipitation rates can be compounded by mudslides on water-soaked slopes; and in many areas where the mountain rivers lead into coastal ports and harbors, the coupling of elevated coastal water levels and the very high river discharges can combine to inundate entire coastal towns.

A global perspective

Tropical cyclones play a vital role in the global atmospheric circulation and provide vital rain to many areas of the world. However, when these storms exceed local threshold values related to wind speed, precipitation or surge generation, their impacts are extremely devastating. Recent events, such as Hurricane Katrina and the hybrid

cyclone Sandy in the United States, show that even highly industrialized countries continue to be very vulnerable to these storms. The relative rarity of intense tropical cyclones makes it very difficult to develop, execute, and maintain effective mitigation plans. Even areas experiencing frequent many tropical cyclones can be devastated by an unusually intense storm, as was the case recently with Typhoon Haiyan in the Philippines in November 2013 which set a new world record as the most intense landfalling tropical cyclone. Figure 3 (www.goes-r.gov/users/comet/tropical/textbook_2nd_Edition/) gives an overview of areas around the world that are most likely to experience tropical cyclones; however, as shown by the hybrid cyclone Sandy, even if an area is only infrequently affected, these storms still pose a very real and increasing threat.

Summary

Tropical cyclones represent one of nature's most destructive forces and the effects of climate variability and continued coastal development are likely to exacerbate these impacts. Disasters and disaster recovery will depend heavily on improved predictions over short time intervals for evacuation decision-making and over many years for community planning and development of resilient coastal areas for natural and urban landscapes (Brantley et al., 2014; Sealza and Sealza, 2014).

These storms are fundamentally a heat engine taking energy from the sea via the latent heat of evaporation and depositing the energy at mid-tropospheric levels via condensation. This engine converts the heat energy directly into mechanical energy (winds, waves and currents). Potential positive feedbacks, related to the dependence of evaporation rates on wind speed and storm intensity and mid-tropospheric heating rates, exist in this system. Therefore, tropical cyclones will continued to strengthen in ocean areas with high water temperatures, minimal vertical shear, and moist air aloft until the mechanical and heat energy losses equal the heat sources.

HYDROTHERMAL PLUMES

Edward T. Baker
Joint Institute for the Study of Atmosphere and Ocean –
NOAA/PMEL, University of Washington, Seattle,
WA, USA

Definition

Hydrothermal plumes. Near-bottom oceanic layers, with distinct chemical and physical signatures, formed by the mixing of ambient ocean water and discharging hydrothermal vent fluids.

Introduction

Hydrothermal circulation is a primary agent for the exchange of heat and chemicals between the Earth's crust and ocean (see "Hydrothermalism"). Hydrothermal discharge occurs on the seafloor where crustal fluids have access to magmatic heat sources, such as along mid-ocean ridges on divergent plate boundaries, volcanic arcs at convergent plate boundaries, and intraplate hot spots (see "Mid-ocean Ridge Magmatism and Volcanism," "Hot Spots and Mantle Plumes"). These hydrothermal vents occupy only a tiny fraction of the seafloor, but the hydrothermal plumes formed by the mixing of vent fluids and seawater can be traced even across ocean basins. Mapping and sampling hydrothermal plumes locates vent fields, describes the dispersal of chemicals from vent fields, estimates hydrothermal fluxes of heat and chemicals, traces ocean circulation, and provides information on the transfer of heat and chemicals to the ocean during eruptions that construct the Earth's crust.

Hydrothermal plume characteristics

Hydrothermal plumes form above the sites of venting as hot hydrothermal fluids rise, entraining ambient seawater with a consequent continuous increase in plume volume, until nonbuoyancy is achieved and the plume disperses laterally. Models of plume formation are based on observations of atmospheric plumes and the principles of turbulent entrainment described by Morton et al. (1956). Plume rise height, which depends on the buoyancy flux of the discharge (a function of temperature and volume flux) and the ambient vertical density gradient, typically ranges from 10s to 100s of meters. Entrainment ultimately dilutes high-temperature ($\sim$150–400 °C) vent fluids by roughly a factor of 10^4 or more. At the level of lateral spreading, hydrothermal plumes have different hydrographic characteristics depending on the local salinity profile (Speer and Rona, 1989). In the deep Pacific, where salinity increases with depth, the plume is warm and salty compared to ambient seawater. In the deep Atlantic, where salinity decreases with depth, the plume is relatively cool and fresh. Using these models and local hydrographic profiles, it is possible to calculate the true hydrothermal temperature anomaly within the laterally spreading plume. Several detailed papers on plume formation can be found in Humphris et al. (1995).

Hydrothermal fluids are enriched, relative to typical oceanic deep waters, by up to a factor of $\sim$10^7 in several key chemical tracers found in vent fluids (see "Hydrothermal Vent Fluids (Seafloor)") (e.g., ^{3}He, Mn, Fe, CH$_4$, H$_2$, H$_2$S, suspended particles, and other trace species). These tracers allow hydrothermal plumes to be detected at significant distances away from hydrothermal vent sites (Figure 1). Hydrothermal species can be classified as conservative or nonconservative. Conservative species include heat and ^{3}He, and their concentration in plumes changes only by dilution. Nonconservative species, such as suspended hydrothermal precipitates, Mn, Fe, CH$_4$, H$_2$, and H$_2$S, are also lost by chemical and biological degradation or by deposition. Their residence time in the plume varies widely, from several years for dissolved Mn and Fe and Mn oxyhydroxides to months or days for suspended particles and CH$_4$ and to days or hours for H$_2$ and H$_2$S. These differences in residence time make it possible to roughly estimate the age of a plume and thus its distance from the source.

Hydrothermal plumes can be categorized on the basis of their discharge and temporal characteristics. Discrete vent sources are individual orifices that discharge high-temperature fluids ($\sim$150–400 °C). These include the familiar "black smokers" emitting opaque smokestack-like plumes with high concentrations of precipitated hydrothermal metal sulfides and oxyhydroxides (see "Black and White Smokers"). Diffuse vent sources leak low-temperature (a few 10s of °C) fluids over a broadly distributed area. Plumes from diffuse vent sources have few suspended particles and have insufficient rise height to form a distinct above-bottom layer. Plumes from stable vents that discharge for years are termed chronic plumes. Plumes formed in association with a magma eruption or intrusion are termed event (or mega-) plumes. Event plume discharge lasts only minutes to days yet forms large, eddy-like plume features extending up to a kilometer above the seafloor (Baker et al., 2011).

Hydrothermal plume applications
Exploration

The earliest hydrothermal plume sampling occurred during a near-bottom sensor tow that detected a temperature spike (Weiss et al., 1977) and ^{3}He anomalies (Lupton et al., 1977) on the Galapagos Rift. This observation led directly to the discovery of seafloor vents at the same location, the first ever found on a mid-ocean ridge (Corliss et al., 1979; see "Mid-ocean Ridge Magmatism and Volcanism"). This success demonstrated the power of using hydrothermal plumes as a tool for finding the vents themselves. Researchers quickly recognized that "tow-yoing" a sensor package through near-bottom water to construct a two-dimensional transect of plumes is an efficient and high-resolution search and sampling strategy (Figure 1; Baker et al., 1985).
Hydrothermal Plumes, Figure 1 (*Top*) A hydrothermal plume formed on the East Pacific Rise ridge axis rises ~300 m above the seafloor before local currents advect it westward into the ocean interior (see Figure 2). A CTD tow-yo (*gray sawtooth line*) maps the plume at its origin, supplemented by two off-axis vertical casts (*gray vertical lines*) through the distal plume. The plume spreads along density contours (*dashed lines*). Color scale is applicable to hydrothermal anomalies of both temperature (ΔT °C) and suspended particle concentration (estimated by Nephelometric Turbidity Units (ΔNTU)). Plume data from Baker and Urabe (1996). (*Bottom*) An idealized drawing of how plume chemistry changes over time and distance. Each curve shows the change in the relative concentration of a tracer ((X_p/X_v)) to hydrothermal heat (Q_p) in the plume (p) relative to the same ratio in undiluted vent (v) fluids (X_v/Q_v). All tracers are dissolved species except FeS and Fe oxyhydroxides, which precipitate from dissolved species as vent fluids are diluted. About half the hydrothermal Fe is deposited close to the vent as sulfides, while the other half more slowly precipitates and settles as fine-grained Fe oxyhydroxides. Manganese precipitates and settles similarly to Fe. Only [3]He is conservative throughout the dispersal.

These hydrothermal plume mapping strategies pursued over the last 30 years have allowed researchers to build maps of vent distributions on scales from local to global. As of 2011, a quarter of all oceanic spreading centers have been systematically explored for hydrothermal plumes, more than 11,000 km in detail and another 6,500 km with sparser sampling by vertical profiles alone (http://www.pmel.noaa.gov/eoi/PlumeStudies/global-vents/index.html). This effort has been instrumental in accumulating a global inventory of almost 600 active vent fields (http://www.interridge.org/IRvents). This distribution demonstrates that the spatial density of vent fields on mid-ocean ridges increases roughly linearly with increasing spreading rate. Because the rate of magma supply also increases with spreading rate, the presence of a magmatic heat source, not tectonically controlled crustal permeability, is thus shown to be the first-order control on the global distribution of vents (Baker and German, 2004).

More recently, the advent of Autonomous Underwater Vehicles (AUVs) has improved synchronous sampling of hydrothermal plumes even further. Hydrothermal plumes mapped by sensor tow-yos can typically locate seafloor vent sites to within a few kilometers to a few hundred meters. That precision can then be improved by a detailed AUV search, using observations of near-bottom maxima in physical and chemical anomalies to pinpoint a vent site (German et al., 2008).

Ocean chemistry

Because buoyant hydrothermal plumes entrain a volume of seawater ~10^4 times greater than the discharging vent fluids, a volume equivalent to the entire ocean cycles through hydrothermal plumes every 4–8 kyr (Elderfield and Schultz, 1996), similar to the ~1 kyr mixing time of the global deep ocean. Thus vent fluids, with concentrations of Fe and Mn often enriched ~10^6:1 relative to normal seawater, influence ocean chemistry to a surprising degree (German and Von Damm, 2003). In buoyant plumes, metals such as Cu, Zn, and Pb coprecipitate with Fe as sulfide phases and settle rapidly to the seafloor. In the near-vent nonbuoyant plume, P, K, V, As, Cr, U, and others are rapidly scavenged by fine-grained Fe oxyhydroxides and, under oxic conditions, maintain constant Fe/metal ratios. The Fe/metal ratios reflect the concentration of the dissolved species in local seawater. The Fe/P ratios in near-ridge sediments, for example, might prove useful in paleoceanographic studies of ancient ocean P concentrations (Feely et al., 1998). Elements such as the rare earths show a different behavior, progressively
Hydrothermal Plumes, Figure 2 Plumes of $\delta(^3He)\%$ along $15°S$ in the Pacific Ocean ($\delta(^3He\%)$ are the percentage deviation of the $^3He/^4He$ ratio in water from the ratio in air). A plume originating from hydrothermal venting along the axis of the East Pacific Rise ($113°W$ at this latitude) advects westward almost to Australia (see Figure 1). A second major plume, centered near $180°$ at a depth of ~1,700 m, apparently has a local origin near the northern end of the Tonga Arc (reprinted with permission from Lupton et al. (2003)).

increasing their concentration on Fe and Mn oxyhydroxides as scavenging continues during plume dispersal. For many of the above elements, hydrothermal removal rates exceed or roughly equal their oceanic input by rivers (Rudnicki and Elderfield, 1993).

Hydrothermal flux measurements

Estimates of hydrothermal heat and chemical fluxes from entire vent fields are important for geophysical, chemical, and ecological studies. Such measurements are difficult, and only about 30 have been reported (Ramondenc et al., 2006). Almost all have used some form of plume observations, either of the rising buoyant plume or of the dispersing nonbuoyant plume. At an individual vent, the heat flux has been calculated by measuring the temperature, salinity, and velocity of the rising plume at multiple depths above the seafloor (e.g., Bemis et al., 1993) and by direct measurements of flow at the vent orifice (e.g., Ramondenc et al., 2006). The heat flux from high-temperature vent structures typically ranges between ~1 and ~50 MW. Heat flux estimates from an entire vent field are commonly made by measuring the net current flow through a two-dimensional transect of the hydrothermal heat anomaly down current from a vent field (e.g., Thomson et al., 1992). A geochemical approach, determining the plume inventory of a short-lived isotope, such as ^{222}Rn, emitted at the plume source, has also been employed (e.g., Rosenberg et al., 1988). Published estimates of vent field heat fluxes vary widely, ranging from ~0.1 to 4 GW.

Global ocean tracers

Understanding patterns of mixing and transport in the deep ocean requires knowledge of the circulation patterns on the scale of decades to centuries. Measurements at this scale are impractical, but hydrothermal venting provides a tracer that can image flow at scales from regional to ocean basin (Lupton et al., 2003). Helium is stable, completely conservative, and injected into the deep ocean only by hydrothermal venting along mid-ocean ridges, volcanic arcs, and a few intraplate volcanoes. Hydrothermal plumes are highly enriched in the isotope ^3He, which can be very precisely measured. Ocean-basin scale sampling, such as by the Geochemical Ocean Section Study (GEOSECS) and World Ocean Circulation Experiment (WOCE) programs, has produced images of ^3He-enriched plumes, typically centered between 2,000 and 3,000 m, that span the meridional and zonal extents of the Pacific, Indian, and Atlantic Oceans (http://cchdo.ucsd.edu/). For example, the abundance of fast-spreading ridges in the Pacific creates intense ^3He plumes that illustrate a varied zonal flow pattern. Westward deep flow is centered along $40°N$ and in two subequatorial jets at $10°N$ and $10°S$ (Figure 2). Compensating eastward flows occur at $20°N$ and $30°S$.

The hydrothermal plume distribution can also be used to judge the performance of global circulation and mixing models. On the global scale, most models can adequately reproduce the differences in ^3He concentration between the major ocean basins. Relative to the observed ^3He distribution, however, existing models tend to underestimate the ventilation of the deep ocean and are too coarse to reproduce the strong and meridionally narrow currents implied by the ^3He data in the Pacific.

Event plumes

The creation of ocean crust by lava eruptions is a fundamental Earth process, involving immediate and
Hydrothermal Plumes, Figure 3 A schematic comparison of event and chronic hydrothermal plumes; contours are $\delta(^3He)\%$ (compare to Figure 2). Chronic plumes closely overlie seafloor vent sites (*red arrow*), typically near the spreading axis of a mid-ocean ridge. Because the vents can be active for years, the plume is quasi-steady state and spreads under the influence of local currents. Event plumes form from brief and massive releases of fluids during a seafloor eruption, forming three-dimensionally symmetrical vortices rising much higher than chronic plumes. Using the hydrothermal heat anomaly (*Q*) as a reference, Mn/Q (*nM/J*) and $^3He/Q$ (*fM/J*) are high in chronic plumes, while H_2/Q (*nM/J*) is high in event plumes.

immense transfers of heat and chemicals from crust to ocean (see "Explosive Volcanism in the Deep Sea"). This transfer creates unique hydrothermal plumes called "event plumes" (or "megaplumes"). First observed in 1986, event plumes are massive ellipsoidal eddies with distinctive and consistent chemical signatures (reviewed in Baker et al., 2011). Confirmed diameters range from ~1 to 20 km (and perhaps up to 70 km) and thicknesses from ~0.05 to 1.2 km (Figure 3). These characteristics indicate they form from a linear source, such as a dike eruption, rather than a vent-like point source (Lavelle, 1995). Concentrations (in terms of the species/heat ratio) of diagnostic magmatic tracers such as ^3He and dissolved Mn are nearly uniform among all event plumes, implying the same formation process for each.

Confirmed eruption events at five separate locations have each created from one to at least eight individual event plumes. At three other locations where event plumes were found, no information on recent eruptions is available. Possible formation processes include the release of preformed hydrothermal fluids during crustal rupturing, the rapid cooling of an intruded dike, and the rapid cooling of an erupting lava flow. Observations favoring the preformed fluids hypothesis include the similarity between ^3He/heat ratios in event plumes and mature vent fluids and the discovery of thermophilic, presumably crustal dwelling, microbes in one event plume. No convincing mechanism for the storage and instant release of such crustal fluids has yet been proposed. A primary role for dikes or lava is supported by extremely high concentrations of H_2 in event plumes, proof of extensive interaction between molten lava and event plumes during their formation. However, theoretical models of lava cooling and studies of cooled lava on the seafloor indicate that any transfer of heat from molten lava to seawater during an eruption occurs far too slowly to generate the enormous buoyancy flux required to form an event plume (see "Submarine Lava Types"). Thus, the physical and chemical processes that create event plumes remain elusive, and we have only a poor understanding of a fundamental Earth

process: the interactions that occur between the solid and liquid Earth as new magma builds the ocean basins.

Conclusions

Hydrothermal plumes disperse heat, chemicals, and organisms from the solid Earth throughout the deep ocean. Their broad extent and varied chemistry facilitate the search for seafloor vent sites and the quantification of vent discharge. Although the search for plumes has been intensive over the last 30 years, over three quarters of spreading center length, and a similar proportion of volcanic arc length, remain unexplored.

Definition

Hydrothermal vent fluid (seafloor): a hot (up to >400 °C) aqueous solution discharging at the seafloor that typically originates from the reaction of seawater with oceanic crust under high-temperature high-pressure conditions, leading to enrichments in dissolved components such as metals and gases. Hydrothermal vent fluids may also originate from discharges of magma-derived waters from beneath submarine volcanoes, which typically mix with seawater or other vent fluids prior to venting.

Introduction

Hydrothermal fluids on the seafloor typically form by circulation of seawater in fractured oceanic crust at volcanically active sites in the ocean (Figure 1) (Von Damm, 1995; German and Seyfried, 2014). These places include mid-ocean ridges, back-arc spreading centers, and hot-spot or arc-related submarine volcanoes. Circulating seawater is heated by a heat source such as a magma chamber or associated hot rock and, during heating and chemical reaction with the surrounding rock, undergoes a suite of chemical modifications. These include acidification, leaching of major and trace components (including trace metals such as copper, zinc, and gold) from the rock, precipitation of specific mineral phases, and redox reactions including the formation of reduced gases such as methane, hydrogen sulfide, and hydrogen. In the reaction zone in the subsurface, the fluids can reach temperatures of several hundred degrees Celsius, which makes them very buoyant. Furthermore, if fluid temperatures reach the boiling point under the respective pressure conditions during their circulation and ascent back to the seafloor, the fluids can boil and phase-separate into a vapor phase and a residual brine phase. This process is a major cause of salinity variations in vent fluids. After ascent the hot, low pH, and reduced fluids discharge at the seafloor through larger channels or finer cracks, reacting with the cold seawater and forming hot (up to >400 °C) focused black-smoker fluids and, in most cases, sulfide edifices or "chimneys." Mixing with seawater and the associated cooling and chemical changes induce the precipitation of sulfide minerals either forming sulfide structures or "black smoke" particles. When the fluid is cooled or diluted deeper in the subsurface prior to discharging at the seafloor, diffuse and translucent fluid emissions at lower
Hydrothermal Vent Fluids (Seafloor), Figure 1 Simplified sketch showing the evolution of hydrothermal fluids in a geologically active site; cold seawater entrains the fractured crust, heats up and reacts with the rock in the reaction zone, and then flows up again as hot hydrothermal fluid to the seafloor. If it is not significantly cooled and remains largely undiluted, it forms hot black smokers or white smokers (with whitish minerals forming at slightly lower temperatures) during mixing with cold ambient seawater. If mixing and cooling already takes place in the subsurface, part of the mineral load will precipitate here, and the fluids will be emitted as mostly transparent, cooler diffuse fluids. *Green ovals* show sites where hydrothermal habitats can be found.

temperatures seep through cracks in the seafloor. The metals discharged and minerals formed by the vent fluids are important for the formation of potentially valuable ore deposits at the seafloor and contribute to the chemical composition of the ocean. The reduced gases in the fluids also nurture rich specially adapted hydrothermal ecosystems that are based on chemosynthetic primary production (i.e., by gaining energy and chemical components directly from the fluids) rather than photosynthesis (see Figure 1).

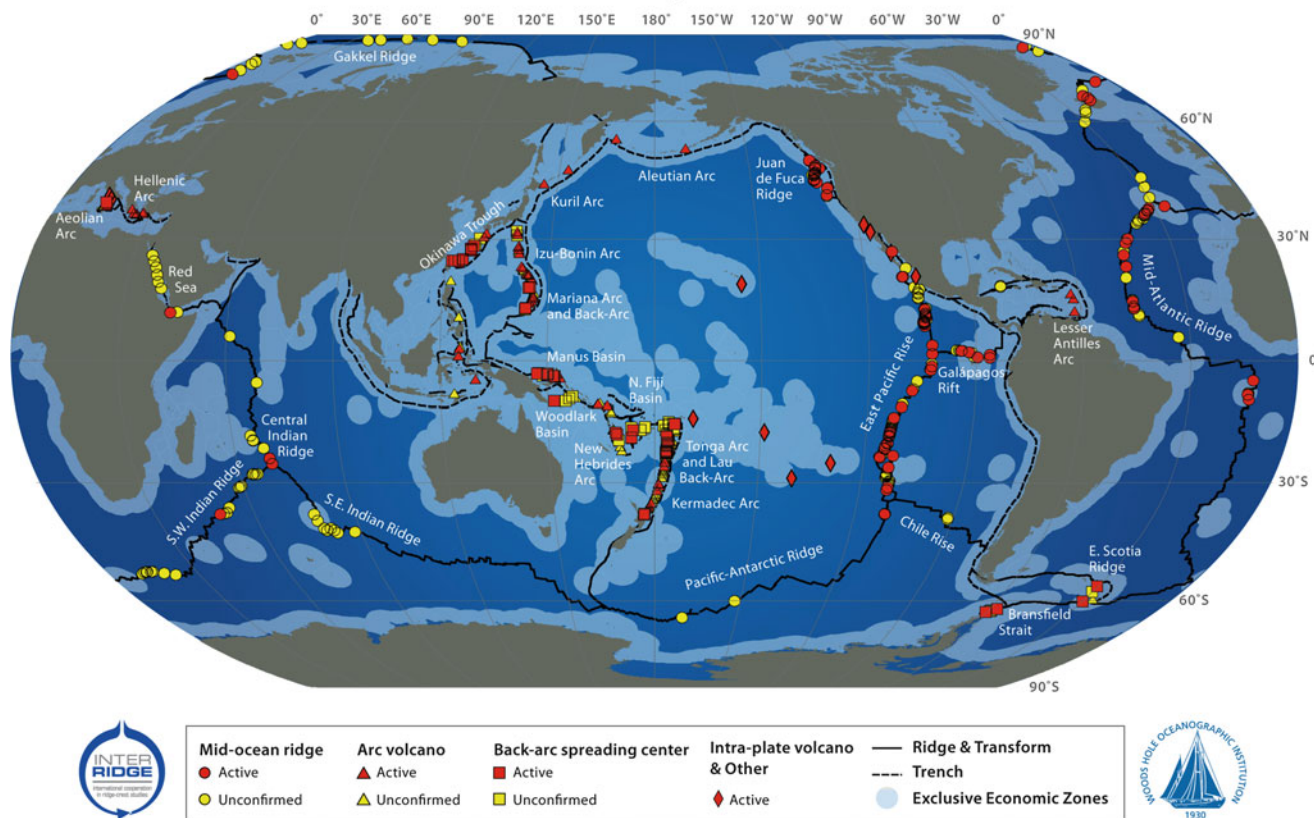
Occurrence of hydrothermal vent fluids

The majority of hydrothermal circulation producing vent fluids occurs along the mid-ocean ridges, which span about 60,000 km through the global oceans (see, e.g., http://vents-data.interridge.org/ventfields and Figure 2). The first low-temperature (up to 17 °C) hydrothermal vents had been discovered at the Galapagos Spreading Center in 1977 (Corliss et al., 1979; Edmond et al., 1979), while the first black smokers with temperatures around 380 °C had been found at 21°N on the East Pacific Rise (EPR) in 1979 (Spiess et al., 1980). While hydrothermal fluid emanations seem to be more abundant on fast-spreading ridges such as the EPR, dozens of active hydrothermal vent sites have also been discovered on slow-spreading ridges such as the Mid-Atlantic Ridge (MAR) or Central Indian Ridge (see compilation by Edmonds (2010)). Even a few off-axis systems with fluids of a very distinct composition, such as the Lost City field on the MAR (Kelley et al., 2001), have been discovered. While hydrothermal activity and fluid composition seem to be highly variable on fast-spreading ridges on timescales of

months to years, due to frequent volcanic activities (e.g., Baker et al., 1998), vent fluid composition has been shown to be rather stable over many years in systems on the MAR (e.g., Edmonds, 2010; Schmidt et al., 2011). Hydrothermal fluid venting is also found associated with hot-spot-related intraplate volcanism, such as at some Pacific islands like Hawaii, as well as at arc volcanoes and back-arc spreading centers such as the Manus Basin and North Fiji Basin in the Western Pacific.

Composition of hydrothermal vent fluids

Hydrothermal fluids from different locations or even within discrete vent fields can span a wide range of chemical composition, with individual parameters often varying over several orders of magnitude (see, e.g., German and Seyfried, 2014). The fluids are usually acidic, with pH values down to ~2, major ions (such as Na, Ca, Cl, etc.) either increased or decreased relative to seawater, and the majority of elements including Si and most trace metals significantly enriched relative to seawater. The reducing nature of the hydrothermal fluids is reflected by the absence of oxygen and the presence of reduced gases such as hydrogen, methane, and hydrogen sulfide. Parameters determining the chemical composition of hydrothermal vent fluids include pressure (both the pressure of the sub-seafloor reaction zone and the emanation site at the seafloor), temperature during fluid evolution and emanation, the mineralogical and chemical composition of the host rock, and the reaction time. In back-arc hydrothermal systems, magmatic fluids (i.e., waters exsolved from water-rich magmas) also can affect hydrothermal

Global Distribution of Hydrothermal Vent Fields


Hydrothermal Vent Fluids (Seafloor), Figure 2 Global distribution of seafloor hydrothermal systems and related mineral deposits, with about 300 sites of high-temperature hydrothermal venting (Beaulieu, 2010).

fluids if they are added at depth within the reaction zone (Gamo et al., 2006; Reeves et al., 2011). These magmatic fluids may also discharge directly toward the seafloor forming unique acidic hydrothermal vents. Apart from in situ studies and direct sampling and analysis, laboratory experimental studies and thermodynamic calculations (e.g., Bischoff and Rosenbauer, 1985) have also helped to understand factors controlling the composition of hydrothermal fluids.

High temperatures, as well as acidity, are necessary to leach large amounts of metals such as Fe and Cu from the rock and keep them in solution. Fluids emanating with very high temperatures and very rich in metals (up to millimolar amounts of Fe and Mn and micromolar amounts of Cu and other metals) can be found in deep ($\geq$3,000 m water depth) hydrothermal systems, where the pressure-dependent boiling point allows the fluids to reach temperatures of $\geq$400 °C (e.g., Koschinsky et al., 2008). Fluids reaching the boiling point phase-separate into a vapor phase rich in gases and a residual brine phase being rich in major ions and trace metals. Emanation of low-chlorinity vapor and high-chlorinity brine phases

can be observed both spatially and temporally segregated, with the denser brine phase often emanating subsequent to the vapor phase (Butterfield et al., 1997; von Damm et al., 1997).

The difference in composition for fluids from different types of hydrothermal systems is also related to the different host rocks that react with the entraining seawater. At fast-spreading centers, the fluids are characterized by reaction with basalt, resulting in high concentrations of S, Si, and many metals. At slow-spreading ridges such as the MAR, fluids often carry a pronounced ultramafic signature from reactions with mantle rocks, such as very high hydrogen and methane concentrations due to serpentinization reactions (e.g., Kelley et al., 2001; Charlou et al., 2002; Kelley et al., 2005; Schmidt et al., 2011). The few available fluid data from back-arc basins and island arcs indicate typically very low pH values and a strong enrichment of trace metals including As, Au, Hg, Pb, Sn, and Sb originating potentially from magmatic sources as well as leaching of the rocks (e.g., andesites) (e.g., Hannington et al., 2005; Yang and Scott, 2006; De Ronde et al., 2011; Reeves et al., 2011).

Role of hydrothermal vent fluids for the formation of ore deposits

When the hot metal-rich hydrothermal fluids mix with ambient seawater, either in the sub-seafloor or when they emanate at the seafloor, they precipitate large amounts of its metal and sulfur load as minerals, forming massive sulfide deposits, mineral chimneys, and black smoke in the rising plume (e.g., Hannington et al., 2005). The steep temperature and geochemical gradients in the mixing zones lead to a sequence of precipitation of sulfide minerals and others, such as anhydrite, carbonates, silicates, and finally, in more oxidized zones, oxyhydroxides of Fe and Mn. These deposits are an important sink of metals mobilized from the oceanic crust by the hydrothermal fluids and thus limit the amount of material that is transported into the oceanic water column. They are very rich in many valuable metals such as Au, Ag, Cu, and Zn (e.g., de Ronde et al., 2011), depending on the composition of the ore-forming fluid. Hence, they may represent important metal resources for our future needs in modern technologies, although estimated overall quantities of deposits are small in scale relative to terrestrial metal resources (Hannington et al., 2011; Hein et al., 2013).

Role of hydrothermal vent fluids for supporting deep-sea vent communities and the origin of life

Hydrothermal vent fluids do not only feed hydrothermal ore deposits with precious metals but also nurture rich hydrothermal ecosystems with their chemical energy and material released in the fluids mixing with seawater (e.g., van Dover, 2000). The members of these ecosystems are both adapted to extreme conditions in the fluids, such as low pH, high temperatures, and high metal contents, and are able to sustain bioproductivity without any light but based on the material and energy available in the vent fluids (e.g., Tunnicliffe, 1992). During chemosynthesis, microorganisms gain energy from redox reactions in the mixing zone to build up biomass and feed a rich community of grazers, symbiotic mussels, shrimps, tube worms, and other organisms. While the type and composition of the fluid has an impact on the evolution of the ecosystem, at the same time the organisms change the fluid composition in the mixing zone. They mediate redox reactions, take up chemical components, and excrete others that may influence the (bio)chemical reactivity and fluxes of these metals. Hydrothermal fluids are also discussed to be potential sites where life on Earth may have evolved. While in early Earth history the surface of the Earth was a rather hostile place, the seafloor was a more protected place with hydrothermal fluids providing energy and chemical components suitable to sustain microbial life (Martin et al., 2008). However, also in the search for extraterrestrial life, the potential existence of hydrothermal fluids plays a major role. Astrobiological research focuses on geothermally active bodies in our solar system in which water exists or may have existed, such as Mars and Venus, or the icy satellites of the giant planets in the outer solar system, such as Titan and Europa (e.g., Vance et al., 2007). Hence, knowledge on the functions of hydrothermal fluids for life on Earth is an important prerequisite for the search for life elsewhere in our solar system.

Role of hydrothermal vent fluids for heat and energy transfer from the oceanic crust into the ocean

Hydrothermal fluids are a crucial medium for the exchange of heat and matter between the oceanic crust and the ocean (Kadko et al., 1995; Baker, 2007). The globally widespread occurrence of hydrothermal fluid emanations on the seafloor, which has been operating for most of Earth's history, makes hydrothermal input one of the main, but poorly quantified, sources of components such as trace metals into the global oceans. The magnitude of hydrothermal input seems to be on the order of riverine input for some elements, such as Mn (Edmond et al., 1979; Elderfield and Schulz, 1996). Among the many problems that exist for a more precise assessment of hydrothermal element fluxes to the ocean are the unknown total number and size of hydrothermal vent fields and their chemical variability, the role of poorly quantified or undiscovered off-axis flow, and an incomplete understanding of the transformation processes of fluid components during mixing of fluid and ambient seawater and within the rising and dispersing hydrothermal plume. Formation of mineral deposits, oxidation of Fe and Mn in the plume, and scavenging of trace metals on Mn and Fe oxides in the hydrothermal plumes (German et al., 1997) significantly reduce the hydrothermal metal fluxes of many elements, for example. However, modeling and chemical speciation studies have shown that for Fe, the hydrothermal metal flux must be significantly higher than previously assumed, probably contributing to the biogeochemical cycling of Fe in the oceans (Tagliabue et al., 2010). While the exact mechanisms of metal transport and transformation from the vent sites into the ocean are still unclear, several studies hint at a strong role of colloidal sulfides or hydroxides and organic metal complexes (Sander and Koschinsky, 2011).

Summary and conclusions

Hydrothermal fluid emanations at the seafloor are a widespread phenomenon in volcanic, magmatic, or tectonically active areas in the world oceans, such as mid-ocean ridges and submarine volcanoes. Their wide range in emanation temperatures (up to >400 °C), chemical composition (up to millimolar concentrations in reduced gases and metals), and temporal variability reflect the specific nature (such as water depth and host rock) of the site location. Hydrothermal fluids are important on a global scale for the formation of metal ore deposits on the seafloor, for nurturing chemosynthetic ecosystems specifically adapted to extreme conditions, and for metal fluxes into the water column and the chemical budget of the ocean. However, the exact nature and quantity of the related processes is

still not fully understood. It can be expected that each expedition discovering new hydrothermal vent systems will broaden our view on the diversity of hydrothermal vent fluids and help understand their relevance for the exchange of heat and material between the oceanic crust and the ocean.

Definition

Hydrothermalism refers to the convective circulation of seawater through oceanic lithosphere with possible contributions of volatiles and metals from underlying magma chambers.

Introduction

The circulation of seawater through oceanic lithosphere is the principal mechanism for the transfer of heat and chemicals between the ocean and underlying crust and has a direct effect on the composition and heat budget of oceanic lithosphere and the composition of seawater (e.g., German and Seyfried, 2014). Along submarine tectonic plate boundaries (see "Mid-ocean Ridge Magmatism and Volcanism," "Magmatism at Convergent Plate Boundaries," "Intraoceanic Subduction Zone," "Hydrothermal Plumes") and hot-spot chains, the heat associated with crystallization in shallow magma reservoirs and cooling of hot rock drives the circulation of seawater through the permeable crust. As the fluid circulates, it is heated, reacts chemically with the surrounding rock, and ultimately discharges back at the seafloor (see "Hydrothermal Vent Fluids (Seafloor)"). To date, over 500 hydrothermal discharge sites have been discovered along submarine tectonic boundaries, at an average spacing of about one major discharge site per 100 km of ridge axis (http://www.interridge.org/IRvents). Cooling of the crust by hydrothermal circulation accounts for about 30 % of the heat lost from newly formed (<1 million year old) oceanic lithosphere (Wolery and Sleep, 1976; German and Seyfried, 2014).

The circulation of seawater and the fluid-rock interactions (both chemical and thermal) that occur are a direct result of magmatic heat input into the system and cooling of the newly accreted lithosphere. Our understanding of these processes derives mainly from observations of alteration minerals within oceanic crust exposed on large-scale oceanic faults and from Ocean Drilling Program drill cores (Alt and Teagle, 2003; Teagle et al., 2003). Additional information has been gained from slices of oceanic crust that have been thrust onto land by plate tectonic processes (i.e., ophiolites; (Gillis, 2002). As seawater flows downward into the crust and reacts with the surrounding rock, progressive chemical alteration of both the rock and fluid takes place. As a consequence of this process, some dissolved components within the original seawater are transferred to the rock, whereas chemical constituents within the host rock may be leached by the fluid (Figure 1). Evidence from seismic studies indicates that the depths within the crust to which fluids circulate can vary from less than 1 km to greater than 4 km, depending on factors such as the depth of the axial magma chamber and the depth of the brittle-ductile transition zone. Temperatures of the circulating seawater-derived fluids can reach more than 500 °C in the reaction zone at the base of the circulating cell. Here, the intensity of fluid-rock interactions reaches a maximum, and the high temperatures cause the fluid, which is now rich in dissolved metals and reduced sulfur leached from the surrounding rock, to become positively buoyant. Seawater is converted to variable salinity fluids in the course of supercritical phase separation, and these fluids rapidly ascend back to the surface along focused, deep-seated permeable pathways such as fault planes (Figure 1). Where hot, mineral-laden fluid reaches the seafloor, it mixes with cold ambient seawater, causing a sudden change in temperature, redox conditions, and the precipitation of sulfide minerals from the hydrothermal fluid. The precipitated minerals both accumulate at the vent site, forming massive sulfide spires and mounds, and are vented into the overlying water column as "smoke," which has led to such vents being referred to as "black or white smokers" or "chimneys." Several (tens to hundreds) individual vents often occur in a cluster, or vent field, that can be spread over hundreds of m above a hydrothermal upflow zone. As the chimneys grow, they often collapse, and a new chimney begins to grow on the talus of the collapsed chimney. Over time, the sulfide material from neighboring vents coalesces to form massive sulfide mounds (Figure 1). Most of the dissolved material, however, is ejected into the water column, forming a *hydrothermal plume* that can rise to several hundred meters above the seafloor (Figure 1). The thermal and chemical anomalies associated with these plumes can be traced over several kilometers from the vent site, and the
Hydrothermalism, Figure 1 Generalized schematic of a hydrothermal system at a fast-spreading mid-ocean ridge showing fluid temperature gradients and fluid-rock chemical exchange.

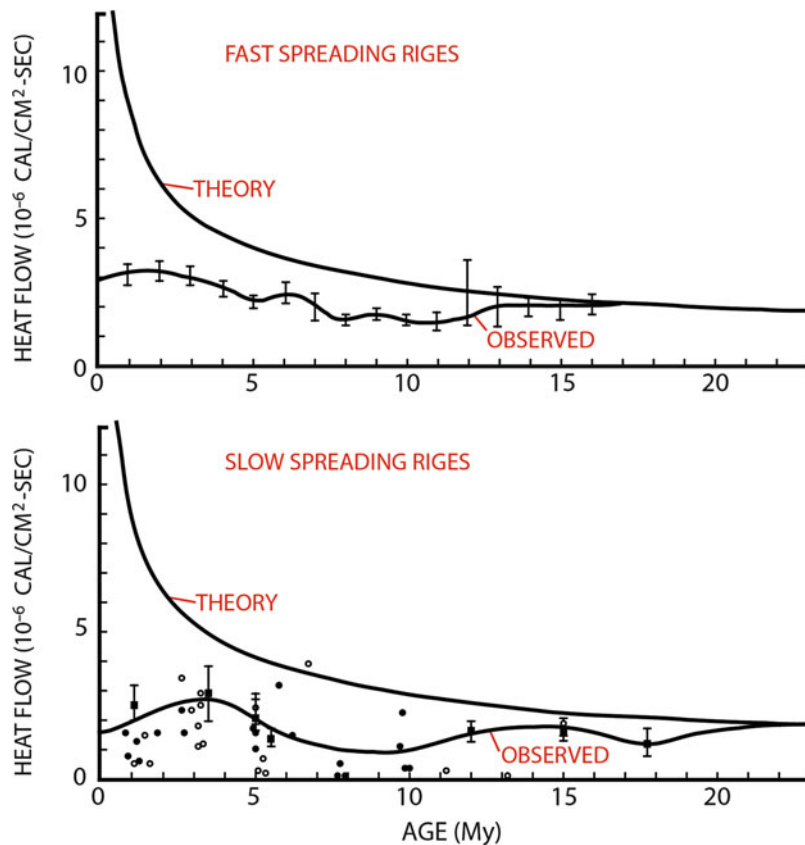
detection of hydrothermal plumes, historically, has been the primary method for the discovery of hydrothermal venting on the seafloor.

The massive sulfide deposits that form on the seafloor are composed primarily of sulfide minerals, as well as sulfates (anhydrite and barite) and amorphous silica. The deposits can contain economically significant concentrations of Cu, Zn, Pb, Au, and Ag, and massive sulfide deposits that have been discovered in ancient oceanic crust now obducted on land (referred to as *volcanogenic massive sulfide* deposits) have been mined for their precious and base metal content and continue to be an important source for these metals. With the increasing global demand for metal resources and the decreasing rate of discovery of large ore deposits on land to satisfy this demand, modern hydrothermal sulfide deposits on the seafloor are increasingly being considered as a viable future source for metals (see "Marine Mineral Resources"). Although, at the time of writing, no modern seafloor massive sulfide deposits have been exploited, several companies and national governments are actively exploring the seafloor

for massive sulfide deposits that are sufficiently large and exhibit sufficiently high metal concentrations to be exploited.

The following sections provide an overview of the physical and chemical characteristics of typical submarine hydrothermal systems. Many aspects of hydrothermal systems (e.g., *black and white smokers*, *hydrothermal fluids*, *hydrothermal plumes*, *volcanogenic massive sulfides*, *chemosynthetic life*) are covered in more detail in their own separate entries, and the reader is directed to those entries for further details.

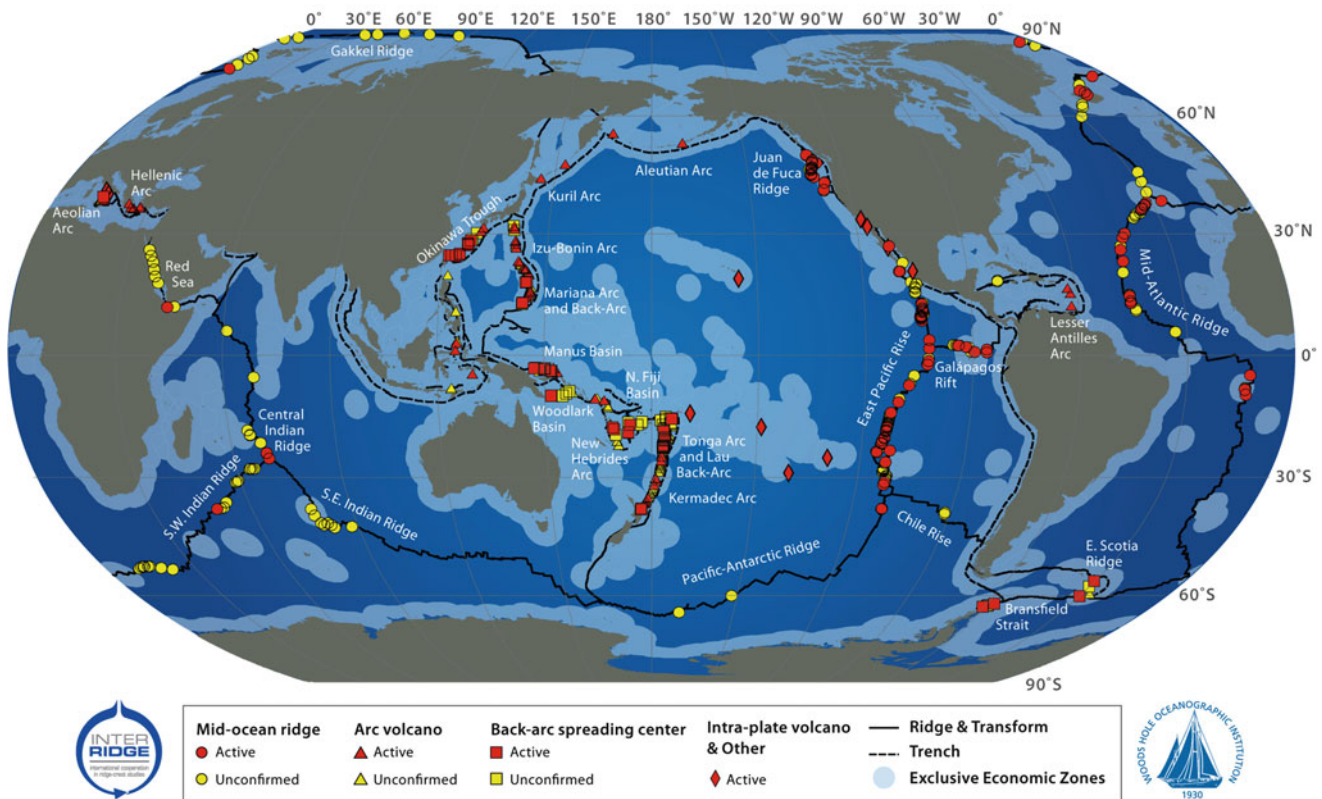
Discovery

The discovery of active hydrothermal venting on the seafloor, and especially their link to chemosynthetic life, was among the most significant scientific advances of the twentieth century. The link between seafloor volcanism and hydrothermalism in the oceans was first articulated as an outgrowth of plate tectonic theory in the 1960s, about 20 years before the discovery of black


Hydrothermalism, Figure 2 Theoretical versus observed heat flow profiles as a function of crustal age for fast- and slow-spreading ridges (modified from Wolery and Sleep, 1976).

smokers, although the notion of massive sulfide deposits forming at submarine volcanoes existed among economic geologists long before then. By the late 1970s, many of the details of ore formation in the submarine environment had already been established from the study of fossil hydrothermal sulfide deposits on land. A significant metal enrichment had also been identified in sediments flanking the East Pacific Rise mid-ocean ridge, which was attributed to, as yet undiscovered, hydrothermal activity along the nearby ridge (Boström, 1966). Thus, the discovery of seafloor hydrothermal vents and the associated massive sulfide deposits came about not only because of technological advances that allowed deep diving to the mid-ocean ridges but also because of existing ideas about the likelihood that some form of hydrothermal activity should exist on the seafloor. However, those who participated on the discovery cruises did not foresee the spectacular "black smoker" chimneys that formed at the vents or the unusual biological communities that were found thriving in such extreme environments.

The first clue to the magnitude of seafloor hydrothermal activity along the ridges came from heat flow measurements in young oceanic crust adjacent to the East Pacific Rise. The observed heat flow was found to be much lower than that predicted for conductive cooling of the new crust forming along the ridge, and a number of researchers postulated that hydrothermal convection of seawater through the ridges must account for this discrepancy (Figure 2) (Lister, 1972; Wolery and Sleep, 1976). Shortly thereafter, evidence for the injection of mantle helium into the oceans was discovered above the Galapagos Rift, and the first warm-water vents and vent animals were found at the Galapagos hot springs in 1977 (Lupton et al., 1977; Weiss et al., 1977; Corliss et al., 1979). Two years later, black smoker vents and chemosynthetic tube worms were discovered at 21°N on the East Pacific Rise, providing the first direct evidence of vigorous hydrothermal circulation and the formation of sulfide deposits on the seafloor (Francheteau et al., 1979; Spiess et al., 1980; Hekinian et al., 1983). This discovery began more than two decades of intensive exploration of the oceans for additional evidence of seafloor hydrothermal activity. Within the next 5 years, more than 50 sites of hydrothermal venting and related mineral deposits were found on the mid-ocean ridges; by the early 1990s there were 150. At the time of writing, more than 500 sites of seafloor hydrothermal activity and related mineral deposits have been found (Figure 3; Beaulieu et al., 2013).

Global Distribution of Hydrothermal Vent Fields


Hydrothermalism, Figure 3 Global distribution of confirmed and inferred seafloor hydrothermal systems (from InterRidge at http://www.interridge.org/irvents/. About 300 are sites of active high-temperature hydrothermal venting; 165 are confirmed sites of volcanogenic massive sulfide accumulation.

Besides mid-ocean ridges, vent sites are now known at a variety of submarine tectonic settings, including island arcs, and back-arc basins in both oceanic and continental crust and associated with more isolated hot-spot-related seafloor volcanic chains. Large differences are seen in the compositions of the hydrothermal fluids and in the compositions of the deposits, reflecting variations in both the depth of venting (hence, pressure) but more significantly, variations in the host rock lithologies and makeup of the basement in the different settings.

Hydrothermal circulation

With the exception of well-defined discharge sites, the parameters that describe the geometry of hydrothermal systems (e.g., depth, fluid volumes, and recharge sites) are poorly defined. Insights can come from direct observations of the seafloor, seismic tomography, or analysis of bathymetric data. However, these observations are limited to only the surface expressions of hydrothermal systems. For example, although seafloor discharge sites are often observed to occur on or in close proximity to exposed faults, the relationship between hydrothermal upflow,

discharge, and the permeable fault planes remains unclear (Tivey and Johnson, 2002). Much of our understanding of the subsurface geometry of hydrothermal systems has come from studies of ancient hydrothermal systems preserved in ophiolites (Hannington et al., 1995). For example, Richards et al. (1989) showed that hydrothermal upflow zones occur as discrete pipes beneath vent sites. Further evidence for a narrow, focused upflow zone has come from studies of thermally induced crustal demagnification (or "burn holes") beneath hydrothermal discharge sites (Tivey and Johnson, 2002) and numerical fluid flow simulations (Coumou et al., 2008).

Hydrothermal recharge zones are especially enigmatic, since recharge is effectively invisible on the seafloor, especially compared to the dynamic activity at high-temperature discharge sites. Numerical models and heat flow measurements indicate that hydrothermal recharge can occur at scales ranging from tens of meters to several kilometers from the discharge area (Figure 1) (Coumou et al., 2008; Johnson et al., 2010; Hasenclever et al., 2014). Recharge that occurs near the discharge site can include a component of recirculated, hot, hydrothermal fluid that did not vent at the surface, which results in a

significant increase in the temperature of the circulating fluids in proximity to the discharge site. Recent numerical modeling indicates that about two thirds of the recharge occurs on-axis by warm (up to 300 °C) recharge close to the discharge sites, while one third occurs as colder and broader recharge up to several kilometers away from the axis (Hasenclever et al., 2014).

The following is a brief description of the evolution of hydrothermal fluid as it circulates through the oceanic lithosphere and the fluid-rock interactions that occur. The reader is directed to the entry on *hydrothermal vent fluids* for a more detailed description of the physical and chemical properties and evolution of hydrothermal fluids.

Hydrothermal recharge

Seawater undergoes important chemical changes when heated. These changes were first established experimentally by Bischoff and Seyfried (1978) and Bischoff and Rosenbauer (1988) and are in agreement with the first measurements of hydrothermal fluids (Edmond et al., 1979). At ~130 °C, anhydrite, which has retrograde solubility, will begin to precipitate from dissolved Ca^{2+} and SO_4^{2-} in the seawater, removing almost all of the Ca^{2+} and about one third of the sulfate. Beginning at about 25 °C, magnesium begins to precipitate from seawater in a brucite-like molecule $[Mg(OH)_2]$ as part of the smectite structure. When seawater is heated slowly in the recharge zone, Ca^{2+} is released at the same rate that Mg^{2+} is taken up (Elderfield et al., 1999) and the pH remains near neutral. At temperatures in excess of 150–250 °C, calcium is then lost from the fluid, when Ca silicates (prehnite, clinozoisite, tremolite) become stable. If seawater is heated rapidly (i.e., in chimney walls), protons may be released in exchange for Mg when magnesium hydroxide sulfate hydrate (MHSH) may precipitate and the pH drops. Considerable acidity is also generated when protons are released into solution in exchange for Ca^{2+}. The released Ca^{2+} also combines with the remaining sulfate to form more anhydrite. Leftover sulfate is thermochemically reduced to hydrogen sulfide by reaction with ferrous iron in the host rock. As a result, SO_4^{2-} concentrations decrease to nearly zero by the time fluids reach their maximum temperature.

Sequential water-rock reactions along the hydrothermal fluid flow path are responsible for the exchange of different elements between the fluid and substrate at progressively higher temperatures. At temperatures of about 40–60 °C, basaltic glass in the substrate is altered to clay minerals, zeolites, and Fe oxyhydroxides. Alkali elements such as K, Rb, and Cs are precipitated out of seawater and fixed in the rock at temperatures up to about 100 °C. Initially, this exchange is balanced by the leaching of Fe and Si from volcanic glass. At 150 °C, the alkali elements that were originally fixed in the rocks at low temperatures are leached, and Ca, Mg, and Na are added to the rock to maintain charge balance. Magnesium is fixed first as Mg-rich smectite (<200 °C) and then as chlorite (>200 °C). The H^+ released during Ca fixation is partly consumed by the hydrolysis of the igneous minerals, but contributes to the overall acidity of the fluids and promotes metal leaching from the rock. At about 250 °C, Na^+ is fixed as albite, partly replacing the remaining plagioclase. In the highest-temperature parts of the hydrothermal system (>350 °C), all Mg is lost from the hydrothermal fluid, and Ca fixation causes the formation of secondary plagioclase and epidote and the release of even more H^+, which is then buffered in a system that has become rock-dominated (e.g., Seyfried, 1987). At the same time, reaction of water with Fe-bearing minerals in the rock (e.g., olivine, pyroxene, Fe sulfides) liberates metals and H_2 and results in major reduction of the fluids. Thus, for a system hosted in basaltic/gabbroic oceanic crust, the highest-temperature fluids are in equilibrium with an assemblage of plagioclase-epidote-quartz-magnetite-anhydrite-pyrite, referred to as the PEQMAP buffer (Pester et al., 2012). The major sources of Fe, Mn, Zn, and Cu in hydrothermal fluids are immiscible sulfides and ferromagnesian minerals in basalt. Feldspar is a major source of Pb and Ba especially in more felsic volcanic rocks associated with hydrothermal systems related to volcanic arcs and in back-arc regions.

High-temperature reaction zones in different geological environments

The sum of the reactions occurring along the path of hydrothermal circulation at basaltic mid-ocean ridge segments results in a fluid that is slightly acidic, reduced, silica- and alkali-rich, and Mg-poor relative to seawater. Metals and reduced sulfur reach maximum concentrations in the high-temperature "reaction zone," at temperatures in excess of ~400 °C and pressures of 400–500 bars (~2 km depth). Here, fluids in equilibrium with the PEQMAP buffer assemblage have a narrow range of aH_2S and aH_2, and elements such as Si and Fe become so enriched that they are major constituents of the hydrothermal fluids. Under these conditions, SiO_2 concentrations quickly rise to near quartz saturation. Because quartz solubility is pressure dependent, silica concentrations measured in the highest-temperature fluids at the seafloor may provide an indication of the depth of the reaction zone, which commonly reaches the top of the crystallizing subvolcanic intrusions.

In subduction-related environments, the more felsic composition of the melts results in higher concentrations of alkali elements and other trace elements such as Ba and Pb (Hannington et al., 2005). Higher volatile contents of the fluids (e.g., CO_2 and SO_2) are also common, relative to mid-ocean ridge fluids, and likely reflect direct contributions from volcanic degassing.

Where ultramafic rocks are exposed to hydrothermal circulation of seawater, a number of different reactions lead to fluid compositions that are dramatically different from those of ordinary mid-ocean ridges, including both low-pH, metal-rich fluids and high-pH, metal-depleted

fluids over a wide range of temperatures (Allen and Seyfried, 2004; Seyfried et al., 2011). Very high concentrations of H_2 (up to 16 mmol/kg) are mainly produced by oxidation of ferrous iron in olivine during serpentinization. Large methane plumes are also common in the water column above the exposed peridotite. The abundant CH_4 is produced during serpentinization through a series of redox reactions that convert carbon dioxide to CH_4 (i.e., $CO_2 + 4H_2 = CH_4 + 2H_2O$).

$$18(Mg_{1.67}Fe_{0.33})SiO_4 + 23H_2O \rightarrow 9Mg_3Si_2O_5(OH)_4$$

Olivine solid solution   Serpentin

$$+ 3Mg(OH)_2 + 2Fe_3O_4 + 2H_2$$

     Brucite   Magnetite

The compositions of the hydrothermal fluids also appear to be sensitive to small differences in the mineralogy of the ultramafic rocks (e.g., different proportions of olivine and pyroxene). For example, the low pH of the vent fluids at Rainbow is interpreted to result mainly from Ca-Mg exchange with pyroxene and the precipitation of tremolite and talc in the gabbroic rocks (Allen and Seyfried, 2004). Unusually high Fe concentrations in the end-member fluids are believed to result from leaching of magnetite by the low-pH fluids.

Hydrothermal discharge

Hydrothermal venting is the most recognizable feature of hydrothermal systems. High-temperature, focused venting produces *black and white smokers* and *volcanogenic massive sulfide* deposits that are often associated with diverse *chemosynthetic ecosystems*.

The hot hydrothermal fluid that formed at depth has a low density relative to cold seawater and thus rises buoyantly to the seafloor in a matter of minutes (at meters per second) along focused zones of high permeability (e.g., deep normal faults). Whereas convecting seawater has a residence time in the crust of several years from the point of recharge to the reaction zone, the transit from the base of the hydrothermal system to the seafloor is rapid (Kadko and Moore, 1988; Kadko and Butterfield, 1998). Observations of the rock record indicate that the rate of ascent is so fast that the fluid does not reequilibrate with the surrounding rock during ascent, although there may be some reaction (e.g., silicification of the wall rock and precipitation of metals). Minor amounts of sulfide are precipitated, but the major subseafloor deposition of sulfide occurs only in well-developed "stockwork zones" or feeder systems immediately beneath the seafloor vents where entrainment of seawater (which reduces the fluid temperature) and possibly boiling contribute to the precipitation of sulfide minerals (see below). Significant mixing and precipitation of sulfides below the seafloor result in the venting of clear fluids and a distinct lack of black or white "smoke."

Measured concentrations of most elements in fluids that are discharged at the seafloor are somewhat lower than in the reaction zone because of mineral precipitation and dilution caused by mixing with seawater. However, the concentrations in the unmixed fluids can be calculated by assuming that Mg and SO_4 were quantitatively removed from hydrothermal seawater at depth and any Mg or SO_4 in the sample fluids must therefore be a result of mixing with seawater at or below the seafloor. This is the basis for the "end-member" fluid model (Edmond et al., 1979; Von Damm et al., 1985). In this model, the concentrations of major elements in samples collected at different temperatures or degrees of mixing can be extrapolated back to their original values along mixing lines between seawater and an undiluted, zero-Mg or zero-SO_4 fluid. Under some conditions, the uptake of Mg by altered rocks can be reversed, and SO_4 may be added to the fluids from other sources, so the zero-Mg, zero-SO_4 end-member model cannot be universally applied.

Venting of hydrothermal fluids results in the precipitation and accumulation of sulfide-rich chimneys and mounds at the vent site. Chimneys that form at ~350 °C "black smoker" vents on mid-ocean ridges are composed of an assemblage of Cu, Fe, and Zn sulfide minerals including pyrite (±marcasite), pyrrhotite, chalcopyrite, Fe-rich sphalerite, and minor isocubanite and bornite, together with anhydrite. Lower-temperature vents (so-called white smokers) are dominated by pyrite, marcasite, sphalerite, and minor galena and sulphosalts, together with abundant amorphous silica, barite, and minor anhydrite; pyrrhotite and chalcopyrite are rare or absent. Mineral assemblages from extinct chimneys can be readily ascribed to a high- or low-temperature origin by analogy with the mineralogy of active vents. Mineralogical zoning in the chimneys reflects strong gradients in fluid temperatures (e.g., Tivey, 2007). High-temperature fluid conduits in black smokers commonly are lined by chalcopyrite together with pyrrhotite, isocubanite, and locally bornite; the outer portions of chimneys are commonly made up of the minerals deposited at lower temperature, such as sphalerite, pyrite, and marcasite. However, detailed examination reveals complex intergrowths, replacements, and recrystallization of the minerals resulting from a dynamic and locally chaotic environment of sulfide precipitation within the chimneys.

Subseafloor stockwork mineralization

The feeder zones of most hydrothermal vent sites contain vertically extensive networks of sulfide veins and disseminated sulfides, referred to as the "stockwork zone," and intensely altered rocks (i.e., the "alteration pipe"). Stockwork mineralization can contain as much as 30–40 % of the total metal transported by hydrothermal fluids. The main alteration minerals are quartz, chlorite, illite, and kaolinite. These are produced by reaction of the hydrothermal fluids with the host rocks and by entrainment of local seawater into the upflow zone. Pyrite, which occurs as a replacement of Fe-bearing igneous phases, is commonly associated with the intense clay alteration in the central portion of the stockwork. Intense silicification

adjacent to sulfide veins typically destroys any primary igneous textures in the volcanic rocks and converts them to a dominantly quartz-chlorite assemblage. Alteration temperatures in the cores of the stockwork were likely close to the exit temperatures of black smoker vents at the surface, as indicated by fluid inclusion homogenization temperatures in quartz and anhydrite in the veins (Petersen et al., 2000). In most cases, the alteration also causes the rocks surrounding the discharge zone to become insulated, sealing the system against the ingress of seawater and allowing higher-temperature fluids to occupy the alteration pipe (Lowell et al., 1993). However, chloritized pillow rims are also common beyond the main stockwork zone, indicating fluid flow between pillows even where sulfide veins are not present. Much of this chlorite alteration is likely caused by entrainment of seawater into the hydrothermal upflow rather than precipitation from the high-temperature fluids (Janecky and Shanks, 1988). Abundant anhydrite is also found within some feeder zones, precipitated from the progressive heating of seawater that is drawn into the mound beneath black smoker vents. Lenses of massive sulfide are also found within permeable zones in the volcanic rocks below the seafloor, such as interflow breccias, hyaloclastite, or sediments.

The role of phase separation

In the high-temperature reaction zone, some fluids have temperatures and pressures higher than the critical point of seawater (i.e., 407 °C and 298 bars, Figure 4) and a small amount of high-salinity brine condenses from the bulk fluid (Bischoff and Rosenbauer, 1988). Dissolved gases such as CO_2, H_2, and H_2S partition strongly into the less dense phase, whereas chloride partitions into the denser condensate. The majority of monovalent cations, such as Na^+ are not fractionated relative to chloride, but divalent cations like Ca^{2+} and the metals become highly concentrated in the brine phase (Butterfield et al., 2003). The large differences in chloride concentration control the metal concentrations in the fluids, as most cations are carried in solution at high temperatures as aqueous chloride complexes (e.g., $FeCl_2$) (Helgeson et al., 1981). Evidence of high-temperature phase separation has been found in numerous studies of fluid inclusions from rocks in the reaction zone (i.e., fluids with salinities both greater and less than seawater) (Delaney et al., 1987; Vanko et al., 1992; Kelley and Fruh-Green, 2001). However, active venting of supercritical fluids has been documented only recently along the southern Mid-Atlantic Ridge (e.g., Koschinsky et al., 2008).

At lower pressures and temperatures, fluids rising to the seafloor may intersect the two-phase curve for seawater at temperatures below the critical point and will begin to boil. At the depth ranges typical for the majority of mid-ocean ridges (>2,500 m), most fluids at the point of discharge are well below the two-phase curve for seawater. However, at water depths of less than about 1,500 m,
Hydrothermalism, Figure 4 Two-phase curve for seawater (after Bischoff and Rosenbauer, 1987) and temperature/depth information of known active vent fields in various geological settings (data from Beaulieu et al. (2013) with additions for systems discovered after 2012). The critical point of seawater (CP, red diamond) is at 407 °C and 298 bars. A 350 °C ascending hydrothermal fluid will undergo subcritical phase separation and cooling at venting depths of < ~1,500 mbsl.

for example, at locations where hot-spot and mid-ocean ridges interact (Iceland, Azores, Ascension, Axial Seamount), the near-vertical adiabats of typical black smoker fluids at 350 °C will intersect the two-phase boundary more than 100 m below the seafloor (Figure 4). These fluids will cool dramatically as they rise along the boiling curve. At these low pressures, the density difference between the vapor and liquid is much greater than in the reaction zone, resulting in the rapid separation of the vapor phase.

As a result, there are important physical limitations to the depth at which high-temperature massive sulfide deposits can form if the pressure at the seafloor is insufficient to prevent boiling (Ohmoto, 1996). In particular, it is unlikely that a Cu-rich massive sulfide deposit could develop at water depths of less than 500 m (i.e., a boiling temperature of <265 °C), unless the composition of the hydrothermal fluids is very different from that of typical black smokers. Metals such as Cu, which are most effectively transported at high temperatures, will be deposited in a subseafloor boiling zone; metals that are soluble at

lower temperatures (e.g., Au, Ag, As, Sb, Hg, Tl, Pb, and Zn) will be transported to the seafloor above the boiling zone and deposited in the seafloor precipitates (Hannington et al., 1999). The extent of boiling is therefore a major control on the bulk composition of the hydrothermal deposits forming at the seafloor and could lead to abundant subseafloor vein mineralization over a large vertical depth range coincident with the boiling zone.

Global distribution

Mid-ocean ridges

On mid-ocean ridges spreading at between 50 and 150 mm/year, the occurrence and distribution of hydrothermalism is roughly proportional to the spreading rate (Baker and German, 2004). The frequency of hydrothermal vents along the magmatically robust fast-spreading ridges is high, relative to the more magma-starved slow-spreading ridges (Beaulieu et al., 2013). However, associated hydrothermal sulfide deposits on the fast-spreading ridges tend to be small, and the fewer deposits on slow-spreading ridges are commonly larger, reflecting longer-lived hydrothermal deposition. The incidence of large hydrothermal plumes is unexpectedly high at ultraslow-spreading ridges. Although most high-temperature hydrothermal systems occur in the axial zones of the ridges, a number of important hydrothermal systems also have developed at ridge-axis volcanoes and at the intersections of ridges with major transform faults or hot spots (mantle plumes). Widespread but typically low-temperature hydrothermal activity also has been found on off-axis volcanoes. Curiously, although intra-plate hotspot volcanoes account for a large proportion of seafloor volcanism (about 12 % of the Earth's magmatic budget (Schmidt and Schmincke, 2000), almost no high-temperature hydrothermal activity has been reported that is associated with these volcanoes, except in proximity to ridges. This apparent contradiction may be due to the great depth of the heat source and the narrow magma conduits beneath hotspot volcanoes (Hannington et al., 2005). The lack of documented hydrothermalism in other parts of the oceans (e.g., the polar regions and the Southern Ocean, Figure 3) mainly reflects the difficulties of marine research at these latitudes. Discoveries of hydrothermal plumes and massive sulfide deposits in the high Arctic (e.g., Gakkel Ridge) and in Antarctica (e.g., Bransfield Strait, East Scotia Ridge) confirm that seafloor hydrothermal activity in remote parts of the oceans is little different from that observed elsewhere. Along slow- and ultraslow-spreading ridges (<20 mm/year full spreading rate), at high latitudes and elsewhere, hydrothermal activity appears to be demonstrably more abundant than predicted based on the relation between magma budget and hydrothermal activity established for ridges spreading at faster rates.

A variety of geophysical measurements indicate that about 3 to 6×10^{13} kg/year of seawater must be circulated through the axial zones of the world's mid-ocean ridges and heated to a temperature of at least 350 °C to remove the heat from newly formed crust (Schultz and Elderfield, 1997; Alt, 2003; Mottl, 2003). Other estimates, based on geochemical mass balances, have ranged as high as 1.5×10^{14} kg/year (Baker et al., 1996) and as low as 7×10^{12} kg/year (Nielsen et al., 2006). These calculations assume that the component of lower-temperature diffuse flow (responsible for up to 90 % of the total heat discharge) represents end-member fluid in which the elements have been conservatively diluted with seawater. The combined flux of low- and high-temperature fluids is $>10^{14}$ kg/year, enough to cycle the entire mass of the world's oceans (1.37×10^{21} kg) through the axis of the mid-ocean ridges every 5–10 Ma (Elderfield and Schultz, 1996). If the flux of heat from the flanks of the ridges is included in this calculation (crust older than 1 Ma but <65 Ma), the cycling time for the worlds' oceans through the ridges is less than 1 Ma.

Based on an assumption that fast-ridge EPR-style venting was globally representative, Mottl (2003) and Sinha and Evans (2004) estimated that the heat transport associated with high-temperature convection at ridge axes is $1.8 + 0.3 \times 10^{12}$ W. As noted above, only about 10 % of this heat is discharged at black smoker temperatures because of mixing and conductive cooling of fluids on their way to the seafloor (Ginster et al., 1994). Conversely, German et al. (2010) argue that closer to 50 % of the total on-axis heat flow on slow-spreading ridges may be in large black smoker systems. Assuming a heat flux of 2–5 MW for a single black smoker vent (Converse et al., 1984; Bemis et al., 1993; Ginster et al., 1994), between 50,000 and 100,000 black smokers would be required to account for the high-temperature flux (10 % of $1.8 + 0.3 \times 10^{12}$ W) or a density of at least one black smoker for every 1 km of ridge axis. Because their distribution is far from uniform, it is more likely that this heat is removed by fewer larger-scale hydrothermal systems. For example, some large vent fields contain as many as 100 black smoker vents with a heat output equivalent to 200–500 MW (Becker and von Herzen, 1996; Kelley et al., 2002). Only 1,000 high-temperature vent fields of this magnitude would be required to account for the high-temperature flux, equivalent to one large hydrothermal system every 100 km along the ridges. Fewer than 100 vent fields of this size are presently known, but only about 20 % of the mid-ocean ridge system has been explored in detail so far. The annual flux of metals and sulfur from these vents is estimated to be on the order of 10^6 tonnes per year, assuming a discharge rate of 200–500 kg/s and total combined metal and sulfur concentrations of about 250 mg/kg. This may be only a small fraction of the metal and sulfur originally mobilized by high-temperature fluids at depth, if a large proportion is retained in the crust as a result of cooling, mixing, and water-rock interaction in the subseafloor (Alt, 2003).

Independent estimates based on the actual distribution of known vent sites suggest that the spacing of sulfide occurrences is quite regular. Hannington and Monecke (2009) examined the spacing of large vent fields on

32 ridge segments and calculated an average spacing between sulfide deposits of 98 km. The spacing is greater on the slow-spreading ridges (167 km) than on the fast-spreading ridges (46 km), but the individual sulfide occurrences, and therefore the cumulative heat output, on the slow-spreading ridges are larger on average (Bach and Frueh-Green, 2010; Hannington et al., 2011). The spacing of known mineral deposits is similar to the global incidence of venting detected remotely as hydrothermal plumes (Baker and German, 2004; Baker, 2007).

Ultramafic environments

At some slow-spreading ridges, tectonic processes locally expose gabbroic and ultramafic rocks. Near large faults, vertical tectonics and especially low-angle detachment faulting expose large sections of the underlying oceanic lithosphere, referred to as oceanic core complexes. At several locations on the Mid-Atlantic Ridge, hydrothermal systems have been located on top of oceanic core complexes (e.g., Rainbow, Logatchev, Ashadze, Nibelungen, Semyenov, Irinovskoe, Von Damm fields). Although it has been suggested that some hydrothermal circulation at these sites is driven by the heat of serpentinization of the exposed ultramafic rocks, high-temperature black smoker activity in these settings is considered to reflect a deep magmatic heat source (Kelley et al., 2002; Mevel, 2003; Melchert et al., 2008). Gabbro has been shown to intrude the lithospheric mantle prior to uplift and exposure (Cannat, 1996), which may drive high-temperature hydrothermal circulation in the ultramafic rocks, and the hydrothermal fluids are interpreted as products of high-temperature reactions with both gabbroic subvolcanic intrusions and peridotite.

The Lost City vent field, located at the intersection of the Mid-Atlantic Ridge and the Atlantis Fracture Zone, is an example of a rare hydrothermal system that may be driven primarily by the heat of serpentinization. Here, peridotite exposed at the seafloor is reacting directly with cold seawater, releasing significant quantities of a Mg-poor, CH_4- and H_2-rich fluid but no metals (Kelley et al., 2001). The fluids are buffered by equilibrium with diopside, brucite, and serpentine produced by the hydration of peridotite, which results in pH values of ~10–11. As the warm, up to 91 °C, high-pH (thus OH-rich) fluids mix with Mg-rich seawater, brucite is formed directly on the seafloor and in subseafloor fractures (Kelley et al., 2005). The formation of serpentine and other Mg-silicates also buffers Si to very low concentrations, and only traces of silica are deposited at the seafloor. The high pH of the vent fluids causes the conversion of HCO_3^- in the seawater to carbonate ions and triggers carbonate precipitation. Towering carbonate (aragonite) chimneys, 10–30 m in height (up to 60 m), and travertine-like deposits form (Kelley et al., 2001; Palandri and Reed, 2004). Polymetallic sulfides are absent because of a lack of metals and H_2S in the vent fluids, and the low temperatures prevent anhydrite saturation. The

serpentinization of olivine is exothermic and generates enough heat to raise the subseafloor temperatures to as much as 150 °C. However, theoretical calculations based on major cation concentrations in the fluids and heat balance suggest that exothermic reactions cannot be the only source of heat (Allen and Seyfried, 2004).

Suprasubduction zones

Hydrothermal systems in subduction-related environments are broadly similar to those at the mid-ocean ridges, and features typical of mid-ocean ridge hydrothermal systems (e.g., black smokers, hydrothermal plumes) are also observed in arc and back-arc settings. In contrast to the mid-ocean ridges, however, convergent margins are characterized by a range of different crustal thicknesses, heat flow regimes, and magma compositions. The compositions of the volcanic rocks vary from mid-ocean ridge basalt (MORB) to more felsic lavas (andesite, dacite, and rhyolite) with geochemical affinities to island arcs. This variability leads to major differences in the composition of the hydrothermal fluids and the mineralogy and bulk composition of the sulfide deposits. For instance, many of the arc-related systems are directly affected by influx of magmatic SO_2, which disproportionates to native sulfur and sulfuric acid. These seafloor solfataras are characterized by large accumulations of sulfur and fields of white smokers venting fluids with pH <1.5. About one third of the known high-temperature seafloor hydrothermal systems occur at submarine volcanic arcs or in back-arc basins. Although there are no estimates of the total hydrothermal flux, distributions along axis, as determined from overlying hydrothermal plume incidence, appears directly proportional to the lengths of the arc and back-arc segments, just as seen along mid-ocean ridges (Beaulieu et al., 2013) hence, accounting for about 20 % of the mid-ocean ridge flux. The spacing of hydrothermal systems along the volcanic fronts of island arcs remain poorly known, as these volcanoes are still being discovered and explored. On the Mariana and Kermadec arcs, which are the most completely surveyed, hydrothermal plumes have been found above one third of the submarine volcanoes, which occur at intervals of ~70 km along the lengths of the arcs (de Ronde et al., 2003). However, the incidence and intensity of hydrothermal activity associated with these volcanoes are highly variable and not yet well characterized. Some plumes detected within or above the summit calderas of arc volcanoes are related to high-temperature hydrothermal venting and black smoker activity, but many of the plume signals appear to be due to passive degassing or diffuse venting rather than high-temperature hydrothermal vents (Embley et al., 2006).

The major controls on vent fluid compositions in arc and back-arc settings are the same as those at mid-ocean ridges, although there is abundant evidence that magmas directly supply a number of components, including CO_2 and metals, to the hydrothermal fluids and boiling affects many of the hydrothermal systems at the volcanic fronts

of the arcs. Nearly all of the volcanoes at the fronts of the arcs have summit calderas at water depths of less than 1,600 m. This has a major impact on the temperatures of the hydrothermal fluids due to boiling, and there is abundant visual evidence of phase separation at many of the vents (Stoffers et al., 1999) (see section on phase separation for further details). Higher-temperature hydrothermal vents are found mainly in the back-arc rifts or on volcanoes with large and deep calderas, which are below the boiling depth of the hydrothermal fluids. The Lau Basin was among the first of the Western Pacific arc- and back-arc systems to be recognized as a young ocean basin formed by the splitting of an island arc (Karig, 1970). And, one of the first known occurrences of seafloor hydrothermal mineralization anywhere in the oceans was recovered by accident from the northern part of the Lau Basin in 1975, long before the discovery of black smoker deposits on the East Pacific Rise (Bertine and Keene, 1975). Black smoker activity has since been found on all of the spreading segments of the Lau Basin and in all of the other back-arc spreading centers of the Western Pacific region.

Massive sulfide deposits in volcanic arc/back-arc environments also may contain abundant native gold, Ag-rich galena (PbS), Pb-As-Sb sulphosalts (including tennantite and tetrahedrite), stibnite (Sb_2S_3), orpiment (As_2S_3), realgar (AsS), and locally cinnabar (HgS). These differences reflect the composition of the underlying volcanic rocks, which commonly included more fractionated suites of lava (andesite, dacite, rhyolite) and possibly direct contributions of metals from magmatic volatiles.

Sedimentary environments

About 5 % of the world's active spreading centers are covered by sediment from nearby continental margins (Hannington et al., 2005). These include sediment-covered ridges such as Middle Valley and Escanaba Trough on the Juan de Fuca and Gorda Ridges and rift grabens that have become major depocenters for sediment (e.g., Guaymas Basin in the Gulf of California). Subseafloor intrusions (e.g., sill-sediment complexes) are common and are indicated by high heat flow in the sedimented valleys, where high-temperature hydrothermal venting is locally focused around the margins of buried sills (Einsele, 1985; Zierenberg et al., 1993). The highest-temperature fluids originate in the volcanic basement where the upper few hundred meters of fractured basalt is several orders of magnitude more permeable than the overlying sediments and can accommodate large-scale fluid flow.

Although the hydrothermal fluids originate in the basement, extensive interaction and buffering by sediments occur en route to the seafloor. The fluids are generally depleted in metals and enriched in the alkalies, boron, ammonia, and organic-derived hydrocarbons compared to seawater-basalt systems. They have a higher pH and are more reduced than fluids that reacted only with basalt. Sill intrusions into the sediments produce organic matter derived hydrocarbons, mainly methane, as well as CO_2

and H_2. Lower venting temperatures compared to sediment-free mid-ocean ridges result from subseafloor mixing and interaction with the sediments; together with the higher pH, this accounts for the low metal concentrations at the seafloor (German and Von Damm, 2004). The high pH and alkalinity of the vent fluids, combined with high SiO_2 concentrations, results in the precipitation of abundant Mg-silicates (e.g., talc and stevensite) and carbonate during mixing with seawater, and chimneys composed only of anhydrite, barite, amorphous silica, smectite, or carbonate are common. Calcite, dolomite, and manganiferous carbonates are also important constituents of the hydrothermal precipitates. Products of the thermal degradation of organic matter, including liquid petroleum and solid bitumens, are commonly preserved in the hydrothermal precipitates (Peter et al., 1991), and higher hydrocarbons (e.g., C1 through C6) are also present in the vent fluids (Simoneit, 1988). The high concentrations of ammonia in the vent fluids, which are several orders of magnitude higher than in typical mid-ocean ridge black smokers (e.g., 10–15 mmol/kg at Guaymas Basin compared to <0.01 mmol/kg NH_4 at 21°N EPR), originate from the breakdown of N-bearing organic compounds in the sediments, and this produces a strong pH buffer via the reaction $NH_3 + H^+ = NH_4^+$.

The massive sulfide deposits that form at sediment-covered mid-ocean ridges (e.g., Escanaba Trough, Southern Gorda Ridge, and Guaymas Basin, Gulf of California) are locally more complex than the black smoker chimneys at sediment-starved mid-ocean ridges. Hydrothermal fluids that interact with continent-derived turbiditic sediments leach Pb, Ba, and other elements from feldspar and other detrital components in the sediments, and the sulfide deposits include such minerals as arsenopyrite (FeAsS), tetrahedrite ($Cu_{12}Sb_4S_{13}$), loellingite ($FeAs_2$), stannite (Cu_2FeSnS_4), jordanite ($Pb_{14}As_7S_{24}$), native bismuth, and other Pb-As-Sb sulphosalts (Koski et al., 1988; Zierenberg et al., 1993). Due to the strongly reduced nature of hydrothermal fluids that have reacted with organic material in the sediment, pyrrhotite is also a common constituent of these deposits.

Many of the characteristics of hydrothermal systems within sedimented ridge environments are also observed in sedimented back-arc basins, such as in the Okinawa Trough (Ishibashi et al., 2015). The basin sediments are dominated by terrigenous material, commonly with a high organic matter content. This can lead to concentrations of hydrocarbons, including gas hydrates, in the sediment-filled basins (Glasby and Notsu, 2003). Abundant carbonate minerals, similar to those found on sediment-covered mid-ocean ridges, also occur in sedimented back-arc environments (Nakashima et al., 1995).

Plumes

A characteristic feature of high-temperature hydrothermal vents is hydrothermal plumes that form above the active vent-sources. The plumes, consisting of a mixture of

hydrothermal fluid diluted by seawater, rise several hundred meters above the seafloor until they attain neutral buoyancy, at which point the plume spreads laterally along the direction of the local currents (see "Hydrothermal Plumes"). Plumes can readily be detected for several kilometers away from their source, from measurements of physical and chemical parameters in the water column (e.g., positive temperature, ^{3}He, CH_4 and turbidity anomalies, and negative Eh anomalies). The detection of plumes in the water column has been the primary method for detecting active hydrothermal venting on the seafloor. While it was long believed that most transition metals from hydrothermal vents are deposited near the vent sites, hydrothermal plumes have recently been recognized as a potentially important source of dissolved iron throughout the oceans (Tagliabue et al., 2010).

The minerals that precipitate out of hydrothermal fluids at a vent site and are entrained into the buoyant ascending plume (i.e., the "smoke") are commonly dispersed over a wide area by near-bottom and mid-depth currents and do not contribute to the growth of sulfide deposits, except in rare cases. At typical black smoker vents, at least 90 % of the metals and sulfur discharged at the seafloor is lost to the hydrothermal plume. Sulfide particles larger than about 50 μm in size settle out of the plume within a kilometer of the vent, but finer particles, typically less than 20 μm in size, are dispersed (Baker et al., 1985; Mottl and McConachy, 1990; Feely et al., 1994). The finer particles account for most of the particle load of the plumes, but a large proportion of these may oxidize and dissolve before settling, releasing metals back into seawater (Feely et al., 1987; Metz and Trefry, 1993). However, up to 10 % of total Fe within a plume may be in the form of nanoparticles (<200 nM size fraction) that are resilient to both oxidation and particle settling and can therefore be dispersed significant distances off-axis (Yucel et al., 2011).

The metalliferous sediments in the Atlantis II Deep of the Red Sea are an exceptional example of metal deposition from hydrothermal fluids vented into the water column. In the Atlantis II Deep, metal-rich fluids are injected into the base of a highly stratified brine pool by hydrothermal vents located within the deep (Zierenberg and Shanks, 1983; Scholten et al., 2000). These metal-bearing brines have salinities, which are many times greater than vent fluids on the mid-ocean ridges, most likely as a consequence of seawater circulation through Miocene evaporites on the flanks of the rift. The brines sink, rather than rise as buoyant hydrothermal plumes, settling into several deep anoxic basins and depositing the metals as thick horizons of oxides and sulfides on the basin floor.

Summary

The circulation of seawater through oceanic lithosphere and the associated fluid-rock thermal and chemical exchange that occurs in the subsurface has a major effect on the composition of both seawater and oceanic lithosphere. The wide range of different mineralogical and geochemical characteristics of hydrothermal systems is a result of a combination of source rock composition, pressure- and temperature-dependent solubility controls, and possible direct contributions of metals and gases from subvolcanic magmas. These characteristics provide clues to the geology and chemical processes that are occurring in the underlying crust. The heating and subsequent venting of circulated seawater is the major mechanism for cooling hot, newly formed oceanic crust. The resulting chemical exchange includes the leaching and transport of base and precious metals from the underlying rock to the seafloor. The mixing of hot, metal-rich hydrothermal fluids with cold seawater at sites of focused black or white smoker discharge on the seafloor result in the formation of volcanogenic massive sulfide deposits that often host chemosynthetic-based ecosystems. The massive sulfide deposits that formed in ancient oceans and are now exposed on land are an important source for Cu, Zn, Pb, Au, and Ag and are mined for their metal contents. In the future, hydrothermal sulfide deposits on the modern seafloor may similarly be exploited for their rich metal content.

Definition

Ice-rafted debris (IRD) is a terrigenous material transported within a matrix of ice and deposited in marine or lake sediments when the ice matrix melts (US National Climatic Data Center).

History of observations

Coarse-grained clasts interpreted as ice-rafted debris were first recognized in seabed samples collected during a 1928 expedition of the US Coast Guard vessel "Marion" in the northern Labrador Sea and Baffin Bay (Ricketts and Trask, 1932). A decade later, Bramlette and Bradley (1940) described glacially transported striated clasts and erratics from North Atlantic seabed sediments. The more common use of IRD as a proxy of glacial variability commenced with the systematic sampling of deep-sea sediments in the early 1970s, notably by the international Deep Sea Drilling Programme (DSDP) and the "Vema" cruises operated from Lamont-Doherty Earth Observatory in the USA. Initially, IRD analyses were mainly applied to understand the long-term Cenozoic evolution of ice sheets (Berggren, 1972). This was highlighted by the study of Shackleton et al. (1984), who traced the development of major northern hemisphere glaciations back to about 2.5 Ma ago. A different approach demonstrated by, among others, Ruddiman (1977) was the application of ice-rafted sand-sized material measured in multiple core records to investigate late Quaternary ice dispersal patterns in the North Atlantic. In 1988, a milestone article by Hartmut Heinrich, reporting on the origin and consequences of late Quaternary cyclic ice rafting, set the stage for a new understanding of rapid ice sheet–ocean interactions during the last glacial in the North Atlantic region (Heinrich, 1988). Subsequent work by Andrews and Tedesco (1992) and Broecker et al. (1992) identified these ice rafting cycles (so-called Heinrich, H-events) as distinct layers rich in detrital carbonate derived from Paleozoic limestone formations in the Hudson Bay region, thus pointing to the Laurentide Ice Sheet (LIS) as the main iceberg source. Heinrich (1988) documented that these cyclic layers were marked by their high lithic-to-foraminifera ratio and increased relative abundance of the polar planktic foraminifera *N. pachyderma* sinistral with low $\delta^{18}O$ values indicative of low-salinity polar water. Bond et al. (1997) noted the carbonate-rich layers to have a sharp basal contact suggesting short-lived, catastrophic discharges of icebergs from the LIS. These IRD horizons are widely distributed in late Quaternary North Atlantic sediments between 40° and 55° N, occurring with intervals of about 7,000 years that partly correspond to shorter (<1,000 year), but intense cooling periods in Greenland ice core records (Bond and Lotti, 1995). The geochemical composition of the Heinrich layers shows a Hudson Strait source for H1, H2, H4, and H5, but chemical and mineralogical analyses suggest another source for H3 (Gwiazda et al., 1996). Since the mid-1990s, numerous paleoceanographic studies have utilized IRD to document regional and temporal ice sheet variability and the effect of meltwater on ocean thermohaline circulation (e.g., Vidal et al., 1997; Knutz et al., 2002). In the past decade, focus on the topic has further increased due to the ongoing debate on climate warming, Antarctic and Greenland Ice Sheet stability, and implications for sea-level rise and ocean circulation.

Ice rafting processes and IRD analysis

Icebergs form the primary transport agent for IRD (Figure 1), but sediments can also be carried by sea ice drift. Even when using detailed IRD analytical techniques, it appears difficult to distinguish between these two transport mechanisms (Tantillo et al., 2012). The sediment load of individual icebergs depends on the basal (cold-based versus warm-based) thermal regime of the glacier from which the iceberg has calved (Drewry, 1986). Aeolian deposition and rock fall from exposed, ice-free cliffs are other mechanisms supplying IRD load to glaciers. Sea ice-derived IRD originates from seabed grounding and beach contact processes as well as wind-blown depositions (Gilbert, 1990). Ice melting and rafting processes and subsequent deposition of IRD is largely a function of ambient ocean water temperatures. Although there is no standard technique for IRD analyses, the proxy is commonly measured as the number of detrital grains in the >150 µm size fraction per gram bulk sediment (dry weight). Another approach is simply to define IRD as weight percentage of material with grain sizes larger than coarse silt (>63 µm). These thresholds are arbitrary, since all grain sizes, from clay to boulder size, may potentially be ice rafted. In proximal glacimarine environments, the finer grain sizes generally make up the largest amount of glacially derived sediments. X-ray analysis of intact sediment cores is often used for counts of larger-sized (e.g., gravel) IRD components.

Sources and distribution of IRD

IRD is not only present close to formerly glaciated continental margins, but has been found widespread in the subpolar North Atlantic, and occasionally even further south, i.e., in the eastern North Atlantic off the Strait of Gibraltar. Studies of North Atlantic glacial IRD provenance have provided important information on the relative contributions of the Laurentide, Greenland, and NW European ice sheets. During H-events 1 and 2, ice discharge from Hudson Strait contributed with large amounts of detrital carbonate, at approx. 14,500 and 20,000 ^{14}C year BP, respectively. (Andrews and Tedesco, 1992; Broecker et al., 1992). Furthermore, H-event layers contain igneous fragments of hornblende and feldspar displaying a dominant Paleoproterozoic (1,600–1,800 Ma) provenance age (Hemming et al., 1998), which is consistent with a Laurentide Ice Sheet (LIS) origin. On the other hand, IRD showing younger isotopic ages and containing chalk coccoliths are inferred to have been derived from NW European glacial outlets (Scourse et al., 2000). These isotopic and mineralogical fingerprints of European/Scandinavian derived icebergs appear to have formed precursors to the main LIS response, thus adding to the complexity of H-events. A possible IRD contribution to H-events by icebergs from the Greenland Ice Sheet has been a matter of discussion. Despite the scarcity of high-resolution records from the Greenland margin and lack of consistent chronological framework, some studies show that Greenland Ice Sheet iceberg calving events occurred more frequently than H-events (Stein et al., 1996; Andrews, 2000). An independent behavior of the Greenland Ice Sheet during the last deglaciation has been shown by Knutz et al. (2011) and is illustrated by the vast amount of continental ice still present in Greenland today. Timing of iceberg surging stages on the NW European margin reflects also here different ice sheet behaviors before and during Heinrich events (Scourse et al., 2000; Knutz et al., 2002). The arrival of European and Icelandic
Ice-rafted Debris (IRD), Figure 1 Example of drifting ice transporting a significant load of land-derived sediments which is being deposited on the seabed as "IRD" as a result of the ice melting process (photo courtesy J.T. Andrews, INSTAAR, Boulder, Colorado).

detritus preceding the deposition of detrital carbonate-rich debris from the LIS (Bond et al., 1999; Grousset et al., 2001) further support the conclusions by Dowdeswell et al. (1999) that the dynamics of Quaternary ice sheets surrounding the Nordic Seas and North Atlantic were asynchronous. This implies that each glaciated margin may have behaved differently in response to external ocean–climate forcing.

Iceberg surging mechanisms

Since the early 1990s, several possible mechanisms responsible for forcing large-scale IRD events have been proposed (e.g., Alley and Clark, 1999). The binge–purge hypothesis of MacAyeal (1993) invoked internal ice sheet dynamics as a driver for H-events. However, this mechanism is not supported by the detailed structure of H-events and cannot explain North Atlantic records showing millennial and centennial scale IRD fluctuations that appear to be closely coupled to the ocean–atmosphere climate system (e.g., Bond and Lotti, 1995). Apart from internal ice sheet dynamics, ocean circulation changes, sea-level fluctuations, variations in solar parameters, as well as ice-load-induced earthquakes have been proposed being responsible for iceberg surging. In addition, Hulbe et al. (2004) postulate catastrophic ice shelf breakup induced by climate-controlled meltwater infilling of surface crevasses as recently witnessed along the Antarctic Peninsula. Observations of recent iceberg discharge processes and ice rafting in an east Greenland fjord reported by Reeh et al. (1999) demonstrated that the transport and deposition of iceberg-derived IRD increased in periods of enhanced (subsurface) advection of "warm" Atlantic water. These findings were used in a study by Moros et al. (2002) and Kuijpers et al. (2005) who concluded that large-scale IRD events in the North Atlantic most likely were triggered by enhanced northward ocean heat transport which caused bottom melting of floating outlet glaciers and ice shelves, leading to ice sheet destabilization and iceberg surging. More recently, a sudden acceleration, thinning, and retreat of the Jakobshavn Isbræ, west Greenland, were observed, which have been attributed to the warming of the subsurface ocean currents off west Greenland (Holland et al., 2008). Studies of sedimentary records of the past ca. 100 years from this area and from another active glacier calving site on the southeast Greenland coast (Lloyd et al., 2011; Andresen et al., 2012) have meanwhile confirmed a correlation between enhanced ocean subsurface warming and associated glacier bottom melting and increase in glacier acceleration and iceberg IRD production. It is without doubt that also the other factors referred to above as, for instance, surface (air) temperature warming and ice sheet dynamics, influence iceberg calving activity. However, increasing evidence has demonstrated the important role of ocean (sub)surface warming when trying to explain iceberg surging over larger areas, such as during the Heinrich events (e.g., Alvares-Solas et al., 2010), or more locally, as recently observed in South Greenland fjords. Within this context, one should keep in mind that ocean heat transport pathways are influencing the temperature regime of various parts of the North Atlantic not everywhere in the same way, which may be one of the reasons for reported asynchronous behavior of glacial ice sheets. The occurrence of iceberg-derived IRD in sedimentary records thus not only provides a tool to reconstruct former ice sheet dynamics, glacier calving activity, and iceberg drift but also yields information on ocean current patterns. In addition, having a different origin and a distribution pattern more depending on atmospheric circulation, sea ice-derived IRD can provide additional information for assessing prevailing wind directions and albedo conditions.

Summary

IRD has been found to be widely distributed in the entire subpolar North Atlantic. Glacial sedimentary records from this region display discrete IRD layers at time intervals of about 7,000 years named "Heinrich" layers that witness large-scale iceberg surging of the North American Laurentide Ice Sheet. This conclusion was made based on the lithology of the IRD involved, showing, among others, a large contribution of detrital dolomitic carbonate derived from the sedimentary rocks around Hudson Bay and Strait. Mineral studies have provided also evidence for IRD originating from European and Greenland glaciers. Asynchronous deposition of IRD from these various sources suggests a different stability regime of ice sheets west and east of the North Atlantic. Although several mechanisms may have played a role, increasing evidence arises which demonstrates that (sub)surface ocean warming and associated bottom melting of floating glaciers and ice shelves have been an important mechanism triggering large-scale iceberg calving ("Heinrich") events, both under glacial climate and under present-day warming conditions.

INTEGRATED COASTAL ZONE MANAGEMENT

Gerald Schernewski
Leibniz Institute for Baltic Sea Research Warnemünde,
Rostock, Germany

Synonyms

Coastal area planning or sustainable coastal zone development; Integrated coastal area management (ICAM); Integrated coastal resources management; Several terms are used for concepts and approaches that share similar objectives with ICZM

Definition

A large number of ICZM definitions are available (e.g., Sorensen, 1997; Cicin-Sain and Knecht, 1998; Salomons et al., 1999). A comprehensive international definition is provided by the European Commission (1999): "ICZM is a dynamic, continuous and iterative process designed to promote sustainable management of coastal zones. ICZM seeks, over the long-term, to balance the benefits from economic development and human uses of the Coastal Zone, the benefits from protecting, preserving, and restoring Coastal Zones, the benefits from minimizing loss of human life and property, and the benefits from public access to and enjoyment of the Coastal Zone, all within the limits set by natural dynamics and carrying capacity." The term "integrated" refers to the integration of objectives; multiple instruments needed to meet these objectives; relevant policy areas, sectors, and levels of administration; the terrestrial and marine components; time and space; as well as different disciplines. Although referring to "management," ICZM covers an iterative cyclic process of information collection, planning, decision making, management, and monitoring of implementation. The term "planning" is meant in a broad sense as strategic policy development. Participation of all interested and affected parties (stakeholders) is a core element in ICZM.

A general definition of the "coastal zone" does not exist. It has to cover a band of land and sea that can be defined based on, e.g., functional relationships, geographic properties, or administrative boundaries. Depending on national definitions, the seaward boundary can be several 100 m or far offshore up to the outer limit of the exclusive economic zone (EEZ). The same is true for the landward boundaries. In general, a trade-off exists between a comprehensive large-scale definition of the coastal zone and a narrow, small-scale approach with high practical, administrative, and political acceptance.

Background and history

Coastal regions are among the most populated and productive areas, with outstanding economic and ecologic value. Increasing competition for maritime and coastal space and increasing pressures on resources lead to a deterioration of natural, socioeconomic, and cultural resources. The impacts of climate change are expected to further increase the exposure of the coast. In the past, coastal planning activities or development decisions took place in a sectorial way, hardly being linked to each other. This fragmented approach to planning and management leads to inefficient use of resources, conflicting claims on space, and missed opportunities for more sustainable coastal development.

The United States Coastal Zone Management Program (CZMP), established under the Coastal Zone Management Act (CZMA) of 1972, can be regarded as one of the first policy frameworks for coordinated coastal zone planning and management (Knecht and Archer, 1993). During the last 40 years, ICZM as a concept evolved from nonintegrated sectorial toward integrated approaches (Sorensen, 1997; Cicin-Sain and Knecht, 1998; Salomons et al., 1999). Initially the emphasis of ICZM was on the environment, later economic aspects as well as social and ethical components were included (Turner, 2000). ICZM received worldwide recognition after the United Nations Conference on Environment and Development (UNCED) in 1992 in Rio de Janeiro, Brazil. The resulting Agenda 21, Chapter 17.1, called for "new approaches to marine and coastal area management and development, at the national, sub-regional, regional and global levels, approaches that are integrated in content and are precautionary and anticipatory in ambit."

State and challenges

Many ICZM policies, projects, initiatives, and activities have developed during the last decades at local, regional, and national level (e.g., Sorensen, 1997; Shipman and Stojanovic, 2007). The exchange of experiences and learning from best practice examples plays an important role in ICZM (Olsen et al., 1998). Against this background the European Commission maintains the OURCOAST online database with about 350 case studies on major

themes like adaptation to coastal risks and climate change, planning and land management instruments, institutional coordination mechanisms, as well as information and communication (OurCoast, 2011).

Despite all efforts, ICZM still suffers from weaknesses, e.g., insufficient political and legal status or the lack of a consistent and applicable process for practitioners and policy makers (e.g., Shipman and Stojanovic, 2007). Shipman (2012) outlined future demand: ICZM has to be politically robust and legitimate, coherent in its outcomes and benefits, and with a clear guidance of how to achieve them. Recently, ICZM agreements have been developed and adopted for international, large-scale regional sea frameworks. For example, the "Protocol on Integrated Coastal Zone Management in the Mediterranean," the first supranational (21 countries located in Europe, Africa, and Asia), legally binding ICZM agreement entered into force in 2011. The ratification includes the European Union and is legally binding for all member states. Formally, it addresses recent ICZM demands, provides a vision of sustainable development, defines the coastal zone, and has legitimacy, a hierarchy of strategies and plans, as well as a coherence of governance and actions. It is outcome focused, provides process guidelines for each stage, and is interactive and expandable. The future will show if it can serve as model for regional seas around the world (Rochette and Billé, 2012; Shipman, 2012).

Some major future challenges are the integration of ICZM with maritime spatial planning (Smith et al., 2011), maritime policy and marine environment protection (Cicin-Sain and Belfiore, 2005), the integration of land and marine spatial planning, and the further development and application of tools, like systems approach frameworks (SAF) for coastal zones (Hopkins et al., 2011).

Measuring success

Several indicator sets have been suggested to measure the state of and the progress toward sustainability in coastal zones on a local (Henocque, 2003; Hoffman, 2009), European (Burbridge, 1997; Pickaver et al., 2004), and worldwide level (Olsen, 2003; Belfiore et al., 2006). Indicators provide a simplified view on complex phenomena, quantify information, and make it comparable. Many application exercises (e.g., Pickaver, 2009) and critical evaluations (Wallis, 2006; Bell and Morse, 2008) took place. Indicator sets are regarded as important tools, e.g., in European coastal and maritime policy (Meiner, 2010), and are used to monitor the EU Sustainable Development Strategy. On a local level, ICZM indicator sets are still poorly accepted. Recent approaches provide indicator sets, a scoring system, and participative self-assessment approaches to comprehensive policy tools for local coastal authorities (SUSTAIN partnership, 2012). It not only allows the evaluation of the sustainability

performance but can be used as a local planning and management tools.

Conclusions

Existing conflicts in the coastal zone as well as future challenges, like climate change, call for an ICZM. ICZM principles and concepts are not new but still need to evolve and to prove its applicability and practical relevance.

INTERNATIONAL BATHYMETRIC CHART OF THE ARCTIC OCEAN (IBCAO)

Martin Jakobsson
Department of Geological Sciences, Stockholm University, Stockholm, Sweden

Definition

The International Bathymetric Chart of the Arctic Ocean (IBCAO). Mapping project focused on assembling and compiling all available depth information from the Arctic Ocean to portray the shape of its seafloor.

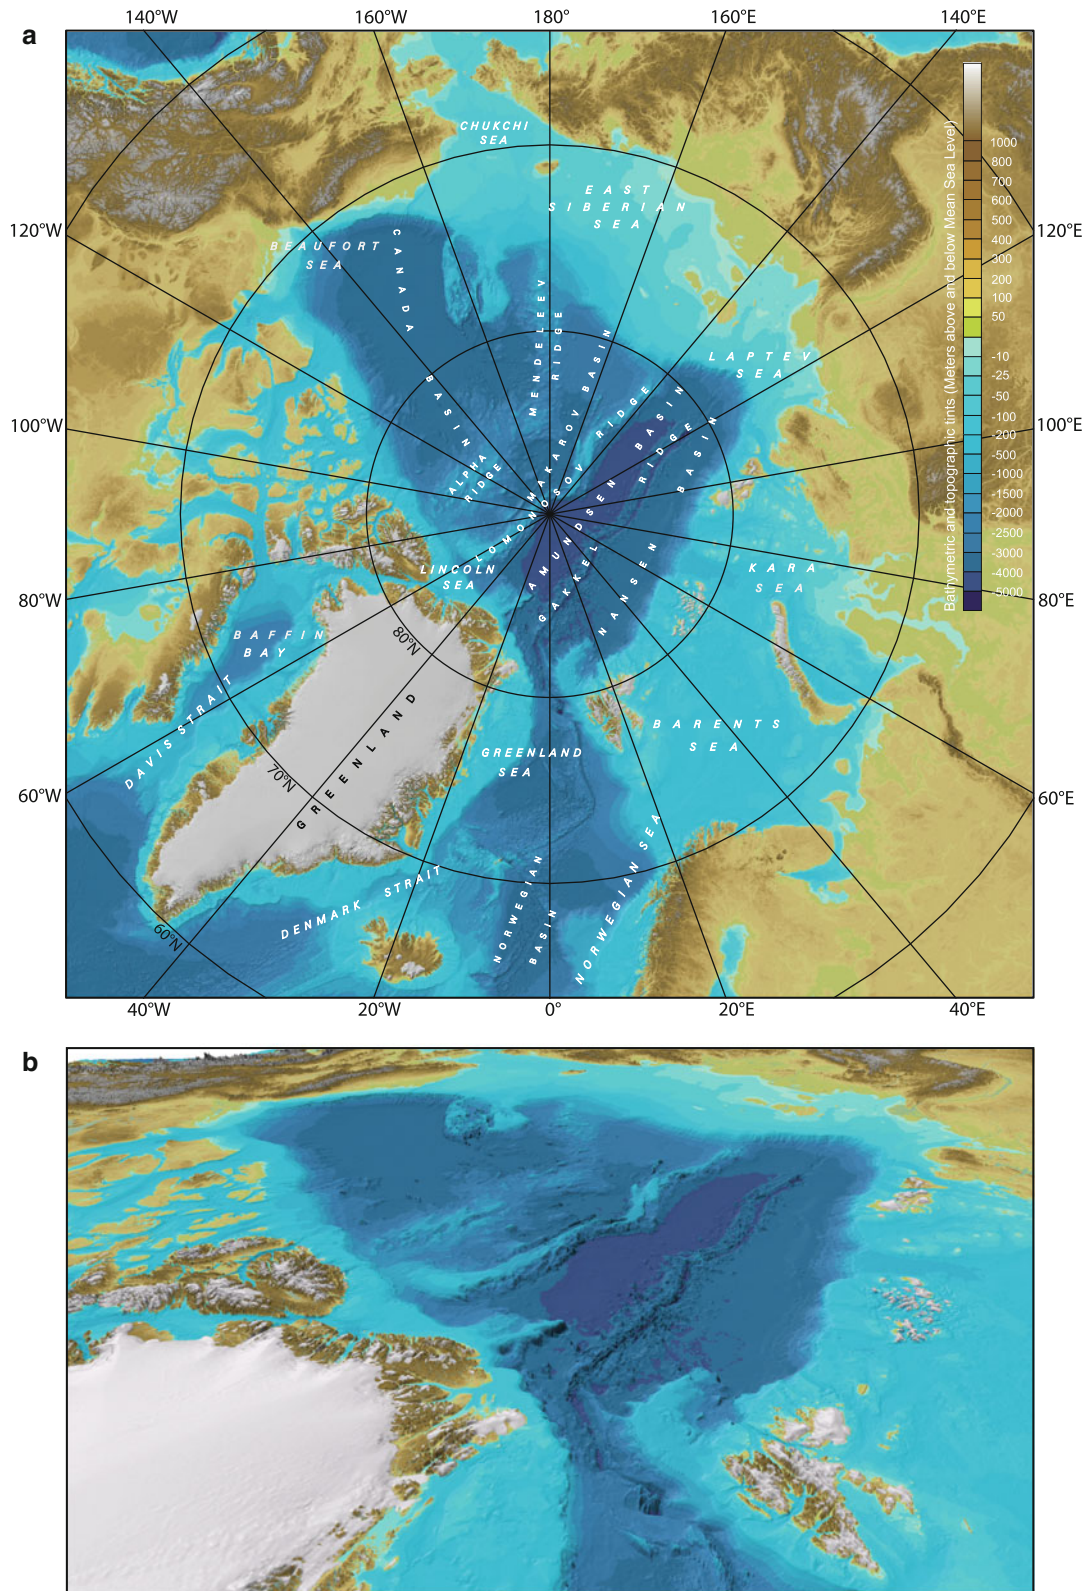
Introduction

IBCAO was initiated as a bathymetric mapping project in St. Petersburg, Russia, in 1997 (Macnab and Grikurov, 1997). The goal was to develop a digital database containing all available bathymetric data north of 64°N and from this compile a bathymetric map and digital bathymetric model (DBM) representing the shape of the Arctic seafloor. DBM is a digital terrain model (DTM) representing the bathymetry of the seafloor. The most common format of a DBM is a regular grid with defined cell spacing. Each grid cell is represented by a bathymetric value, i.e., a depth. IBCAO builds on the volunteer efforts of investigators and data contributions from countries that carry out mapping in the Arctic Ocean. An established editorial board comprises its main organizational structure. The activity has been endorsed by the Intergovernmental Oceanographic Commission (IOC), the International Arctic Science Committee (IASC), the International Hydrographic Organization (IHO), and the General Bathymetric Chart of the Oceans (GEBCO). IBCAO products are available for download from http://www.ibcao.org/.

IBCAO digital bathymetric models

The first IBCAO compilation was released to the public in 2000 (Jakobsson et al., 2000). This "beta version" consisted of a DBM with grid cell spacing of 2.5 × 2.5 km on a polar stereographic projection. After feedback from the Arctic research community resulting in corrections of artifacts and incorporation of additional data, Version 1 was completed and released in 2001 (Jakobsson and IBCAO Editorial Board Members, 2001).

In 2008, a finer grid spacing of 2 × 2 km was implemented in Version 2.0 when several large multibeam surveys became available (Jakobsson et al., 2008). The subsequent Version 3.0, completed in 2012, represents the largest improvement so far taking advantage of new data sets collected by Arctic nations to substantiate an extension of the continental shelf under the United Nations Convention on the Law of the Sea (UNCLOS) Article 76, opportunistic data collected from fishing vessels, and data acquired from submarines and from research ships of various nations (Jakobsson et al., 2012). Version 3.0 has grid spacing of 500 × 500 m, and the area covered by multibeam surveys has increased from ~6 % in Version 2.0 to ~11 % in Version 3.0. A shaded relief map and a 3D portrayal based on Version 3.0 are shown in Figure 1.

Compilation of the IBCAO DBM is based on gridding the bathymetric database with the algorithm continuous curvature splines in tension (Smith and Wessel, 1990) available in the Generic Mapping Tools (GMT) (Wessel and Smith, 1991). Soundings always have the priority in the gridding procedure before isobaths digitized from published maps. Compilation of Version 3.0 involved an additional final gridding step where data with a spatial


International Bathymetric Chart of the Arctic Ocean (IBCAO), Figure 1 Shaded relief map (**a**) and 3D portrayal (**b**) of IBCAO Version 3.0.

density of 500 m between points or higher were added using the remove-restore method (e.g., Smith and Sandwell, 1997; Hell and Jakobsson, 2011).

IBCAO printed map

In 2004, a printed map at a scale of 1:6,000,000 was published based on the IBCAO Version 1.0 DBM. Based on a shaded relief generated from the DBM and overlaid depth contours, this map portrayed the shape of the Arctic Ocean seafloor north of 64°N. A polar stereographic map projection was used with the true scale set at 75°N and the WGS 84 horizontal datum. The map limit, scale, and projection were taken from the GEBCO Arctic Ocean Sheet 5.17 published in 1979 (Johnson et al., 1979).

Oceanic subduction zone

Definition

Intraoceanic subduction zone. A subduction zone developed beneath the leading edge of an oceanic lithosphere.

Introduction

Intraoceanic subduction zones were developed beneath leading edges of *oceanic crusts*. Although the accompanied *volcanic arcs* (intraoceanic island arcs) have thickened crusts compared with normal oceanic crusts, they are still immature and thinner than continental crusts. It is thus distinguished from continental arcs (Active Continental Margins). An intraoceanic subduction zone is associated with an oceanic basin, i.e., *back-arc basin*, behind the volcanic arc. Continental island arcs such as Northeast Japan and Kurile arcs are also accompanied by back-arc basins (marginal basins) at least partly of oceanic crusts. These arcs developed upon old continental crusts split from continents behind and can also be distinguished from intraoceanic arcs consisting essentially of arc magmatic rocks developed in intraoceanic settings.

Modern intraoceanic subduction zones cluster in the western Pacific and also occur in the western Atlantic (Figure 1). They contrast with eastern Pacific margins bounded almost entirely by continental subduction zones. Among them, the Izu-Bonin-Mariana, Lesser Antilles (Barbados), and South Sandwich subduction zones developed along margins of independent small oceanic plates mechanically decoupled with continents. The Tonga-Kermadec and Aleutian subduction zones are situated along margins of well-developed oceanic basin connected with continents. In Southeast Asia to Melanesia regions, shorter subduction zones are complicatedly arranged. Some arcs are bounded by subduction zones of opposite polarities or being switched from one to another (e.g., Philippine and Solomon arcs). There are also many indistinct trenches with poorly developed volcanic arcs and abandoned trenches in these areas.

Intraoceanic subduction zones are the major sites for descending of the Earth's surface materials (oceanic crust, sediments, and fluids), seismic and volcanic activities, *hydrothermalism*, and growth of sialic continental crusts. They could be modern analogues for origins of *ophiolites* on land and can also give hints to consider tectonics and environments in the early Earth's history when continental crusts had not yet been well-developed.

Intraoceanic Subduction Zone, Figure 2 A cross-sectional picture for the features of intraoceanic subduction zone. Schematic crust and mantle structures refer to seismic profiles across the Izu-Bonin-Mariana arc back-arc system (Suyehiro et al., 1996; Takahashi et al., 2008, 2009), except for speculative illustration of forearc parts close to the trench concerning geological evidences. UC upper crust, MC middle crust, LC lower crust, and UM upper mantle.

General architecture

Features of topography and crustal structures resulting from intraoceanic *subduction* are illustrated in Figure 2. The plate boundary on the surface is marked by a trench, and a volcanic arc with thickened crust is arranged parallel to the trench. Typical back-arc basins are formed by *seafloor spreading*, which initiates from intra-arc rift splitting the volcanic arc. A half of the split and inactivated arc, referred to as a remnant arc (Karig, 1972), is left behind the back-arc basin far from the trench comprising a non-seismic ridge. The counterpart of the remnant arc may comprise the basement of new volcanic arc after back-arc spreading (daughter arc) or is occasionally found as the outer arc, a currently non-volcanic structural high to the trench side of the active volcanic arc. In a well-developed intraoceanic subduction system, there are thus multiple arrays of arcs.

Intraoceanic trench

Because remote from continental margins, trenches of typical intraoceanic subduction zones are starved with terrigenous clastic sediments except for the trench off Barbados and Aleutian as shown later. Trench floors are marked by rough topography with horst and graben resulting from slab bending and with subducting *seamounts* (Figure 2) and are accompanied by thin pelagic sediment covers and local landslide debris. The subducting plate in the Western Pacific are dominantly old, cool, and thus dense. Scarce sediment fill over dense subducting plate created the Earth's deepest trenches there. Limited sediment

supply and fast convergence result in poor development or absence of *accretionary wedges* and, instead, facilitate *subduction erosion* removing hanging-wall materials around trenches. On the contrary, abundant clastic turbidites from adjacent continents bury trenches of the Lesser Antilles (Barbados) and eastern Aleutian subduction zones, where sediments are being scraped off to comprise *accretionary wedges*.

Forearc

Forearc regions between the trench and the volcanic front consist of inner trench slope, forearc basin, and outer arc. Surface slope dips greatly change between the steeper inner trench slope and the flat forearc basin, and the boundary between them is called as a trench-slope break.

Inner trench slopes to outer margins of forearc basins of intraoceanic non-accretionary margins are dominated by normal faults with stepping fault scarps and/or horsts and grabens (Hussong and Uyeda, 1981). In Izu-Bonin-Mariana and Tonga-Kermadec forearcs, the basement rocks there show ophiolitic assemblage of serpentinized *peridotites*, *gabbro*, and early arc volcanic rocks including *boninites* (Ishii, 1985; Bloomer and Fisher, 1987; Bloomer et al., 1995). Minor occurrences of mid-ocean ridge basalts (MORB: see "Mid-ocean Ridge Magmatism and Volcanism") and alkali basalts of *seamount* origins, chert, and limestone were presumably accreted from the subducted Pacific plate (Johnson et al., 1991).

In outer margins of the Mariana forearc basin, serpentinite seamounts of conical shapes are aligned parallel to the trench, in addition to serpentinite horsts of tectonic features (Fryer, 1992). Similar serpentinite seamounts also occur in the inner trench slope of the Bonin forearc (Fryer, 1992). The Mariana forearc serpentinite seamounts are *mud volcanoes* of highly fractured and clayey serpentinites, occasionally with serpentine mud flows and cold-water vents with carbonate chimneys (Fryer et al., 1990). These serpentinites originated from residual peridotites after extensive extraction presumably of arc magmas and boninites (Ishii et al., 1992) and are thought to represent forearc mantle rocks.

Forearc basins are filled by thick sediments comprising of flat and smooth surfaces. Tectonic deformation is less extensive compared with trench-side areas, suggesting more rigid basements. The Moho surfaces beneath forearcs become indistinct as seismic velocity of the mantle is reduced toward the trench (Suyehiro et al., 1996). If successfully imaged, forearc crust is thinner than volcanic arc crust and partly as thin as normal oceanic crust (Kodaira et al., 2010).

Subduction interface

There has been no drill hole which penetrated intraoceanic subduction boundaries of non-accretionary type. However, it is probable that the wedge mantle extends to or very close to the trenches (Bloomer and Fisher, 1987; Kamimura et al., 2002) in the cases of the Tonga-Kermadec and Izu-Bonin-Mariana subduction zones, taking into account thin forearc crusts and common occurrences of peridotite and serpentinites on inner trench slopes. Reduction of seismic velocity in the wedge mantle toward the trench suggests *serpentinization* of peridotites (Hyndman and Peacock, 2003). These lines of evidence imply that serpentinites are in contact with the subducting oceanic crust since shallow depths of these intraoceanic subduction zones and that crust-crust interface is limited. This may result in narrow zones of seismic coupling, in contrasts to continental subduction zones, where contacts of thick continental crusts and the subducted slabs comprise extensive *seismogenic zones* (Hyndman et al., 1997).

Serpentinized subduction interface is also supported by the occurrences of serpentinite seamounts in the Mariana forearc. Basaltic clasts recording *high-pressure/low-temperature metamorphism* enclosed in the serpentinite suggest the origin of the mud volcanoes from the subduction interface (Maekawa et al., 1993). Mixed occurrences of sheared serpentinite matrix and clasts and blocks of ophiolitic and metamorphic rocks are correlative to serpentinite melange.

Because water fluids might be supplied from the underlying slab, a wedge mantle is expected to be serpentinized from its base, where mechanical strength is significantly reduced. This predicts a structure that the weak serpentinite zone is sandwiched between more rigid layers: the slab and the unhydrated mantle wedge (Figure 2). Strain resulted from plate convergence concentrate to this serpentinite zone, where material flows are channelized. The concept *serpentinite channel* (Guillot et al., 2001) is applied to the zone and is regarded as a conduit for upwelling of deeply subducted rocks.

Extension and weak seismic coupling

Uyeda and Kanamori (1979) classified subduction zones into Mariana and Chilean types in terms of stress regime in the hanging-wall plate. The Mariana type is characterized by extensional stress evidenced by active back-arc rifting or spreading. It is associated with steep dip subduction and tends to occur with west-dipping subduction polarity. Large inter-plate *earthquakes* are scarce, suggesting weak coupling between the two converging plates. The Chilean type in contrast is characterized by compression without active back-arc spreading, gently dipping slabs dominantly of eastward subduction, and common large inter-plate earthquakes with strong coupling. As evident from its nomenclature, typical intraoceanic subduction zones such as Izu-Bonin-Mariana and Tonga belong to the Mariana type. Extension and weak inter-plate coupling is attributed to relative retreat of the trench off the hanging-wall plate. Uyeda and Kanamori (1979) argued several ideas to explain the trench retreat: by sinking of the slab (trench rollback); migration of the hanging-wall plate away from the trench fixed to the deep mantle, and eastward migration of trenches reflecting the global asthenosphere flow.

Crustal growth

Magma supply from the mantle in subduction zones (see "Island Arc Volcanism, Volcanic Arcs" and "Magmatism at Convergent Plate Boundaries") progressively thickens arc crusts. Continental arcs develop overprinting the preexisting continental crust of long histories and complex structures, whereas intraoceanic arcs are more juvenile (less than several tens m.y. old) with simpler starting materials of hanging-wall oceanic *lithosphere*. They can thus provide more elementary models for magma genesis and crustal growth, whose processes are referred to as subduction factory.

Intraoceanic arc crusts are 10–30 km thick with significant variation even in a single arc (e.g., Kodaira et al., 2007). They are intermediate between those of oceanic and continental crusts in terms of thickness and composition. The Izu-Bonin-Mariana arc characteristically has the middle crust layer of 6–6.5 km/s (Suyehiro et al., 1996) not found in oceanic crusts. It is assigned to felsic plutonic rocks such as tonalite (low-K variety of granitoids), compared with crustal section exposed in the Izu collision zone (Tanzawa Mountains) scraped off the Izu arc (Kawate and Arima, 1998).

Magma input from the mantle is dominantly basaltic, whereas the bulk continental crusts are estimated as andesitic (Turcotte, 1989). The transformation mechanism from basaltic ingredients to more felsic products is a major subject on subduction factory. Removal of mafic components from the differentiated crusts via delamination is one of the convincing candidates (Turcotte, 1989; Kay and Kay, 1993). Tatsumi et al. (2008) tested several hypotheses for crustal differentiation with volumetric simulation comparing to the Izu-Bonin-Mariana arc. They showed that remelting (anatexis) of basaltic crust producing a tonalitic middle crust and a high-density basal layer of mafic restites and *cumulates* is the most compatible model with the present crustal structure, and the low-Vp mantle (crust-mantle transition zone) observed in seismic refraction profiles (e.g., Kodaira et al., 2007; Takahashi et al., 2008) is assigned to the basal layer. Comparable restites occur as mafic garnet granulite at the base of the Kohistan arc crustal section (Garrido et al., 2006), a fossil intraoceanic arc exposed on land. If such basal layer is delaminated from the overlying crust, average composition of the rest crust could be more felsic.

Earliest stage of subduction

It is generally accepted that the an intraoceanic subduction begins at a *fracture zone* or a *transform fault* among preexisting oceanic crust, since Uyeda and Ben-Avraham (1972) considered for the genesis of the Philippine Sea plate by an idea that an oceanic transform boundary in the Pacific switched to be convergent when Pacific plate motion changed in the Eocene. Stern (2004) synthesized possible processes of subduction initiation into two major types. One is induced by compression as exampled by the Solomon subduction system, where the collided Ontong

Java Plateau jammed the previous trench to the north of the arc and new subduction initiated facing the south. Another is spontaneous slab sinking resulting from a high-density contrast between the adjacent oceanic lithosphere and characterized by extension and eruption of *boninites* in the forearc as exampled in the Izu-Bonin-Mariana subduction zone.

Boninites are high-magnesian varieties of basaltic andesite characteristically occurring in not all but some intraoceanic subduction zones and ophiolites. It suggests anomalously high temperature at shallow parts of the mantle above the slab (Crawford et al., 1989; Pearce et al., 1992). Stern and Bloomer (1992) assumed the spontaneous sinking model of the colder oceanic lithosphere at a transform boundary, initially without convergence. They argued that the asthenosphere might inject to fill the vacancy above the sinking slab, promoting a preferable condition for the boninitic genesis. This model is supported by a numerical simulation by Hall et al. (2003), in which however initial push to help bend the thick lithosphere was necessary. Recently, Reagan et al. (2010) and Ishizuka et al. (2011) found occurrences of MORB-like basalts (FAB: forearc basalts) underlying boninites in the Mariana and Bonin forearcs, respectively. They attributed them to the first injection of asthenosphere prior to the boninite stage with major supply of water from the slab. They also explained a common ophiolite succession, where boninite magmatism followed just after formation of MORB-like oceanic crusts, by analogy of the Mariana and Bonin forearc succession.

Summary

Although most of the system is immersed in deep water, an intraoceanic subduction zone may be one of the most dynamic regions on the Earth's surface. Lateral convergence and divergence, sinking and uprising, and accretion and removal concurrently occur in a single system of adjoining areas. Intraoceanic subduction zone could also give hints to consider how Earth's simplest layering of the mantle, oceanic crusts, marine water, and atmosphere interacted and evolved to more diverse and complicated structure and chemistry as seen in the present. Comprehensive understanding of such dynamics and evolution is still in progress, and further investigations are necessary heavily depending on oceanic surveys, as well as prediction and testing by numerical modeling recently significantly developed (Gerya, 2011).

INTRAPLATE MAGMATISM

Millard F. Coffin and Joanne M. Whittaker
Institute for Marine and Antarctic Studies, University of
Tasmania, Hobart, TAS, Australia

Definition

Intraplate magmatism constitutes igneous activity distal
from the boundaries of the tectonic plates and is thus con-
sidered to be unrelated to the processes of seafloor spread-
ing, subduction, and transform faulting.

Introduction

Intraplate magmatism is pervasive within both oceanic
and continental crust. Expansive spatially and across geo-
logic time, it is complex because of both its causative mag-
matic processes as well as its interplay with Earth's mantle
geodynamics and plate tectonic processes. The scale of
intraplate magmatism ranges from large igneous prov-
inces (LIPs) encompassing millions of cubic kilometers
of igneous rock to small individual volcanoes. Similarly,
compositions of intraplate igneous rock span the spectrum
of extrusive compositions between highly mafic and
highly silicic. However, intraplate volcanic rocks are dom-
inantly basaltic and have compositions distinctly different
from those found at "normal" mid-ocean ridges and in
arc-trench systems. Herein we focus on intraplate
magmatism in the oceans that cover 71 % of Earth's sur-
face. We examine intraplate magmatism both present and
past in the oceans, which has occurred predominantly

within oceanic crust. The geological record of oceanic
crust flooring much of the world's oceans extends back
to ~200 million years ago, or slightly less than 5 %, of
Earth history.

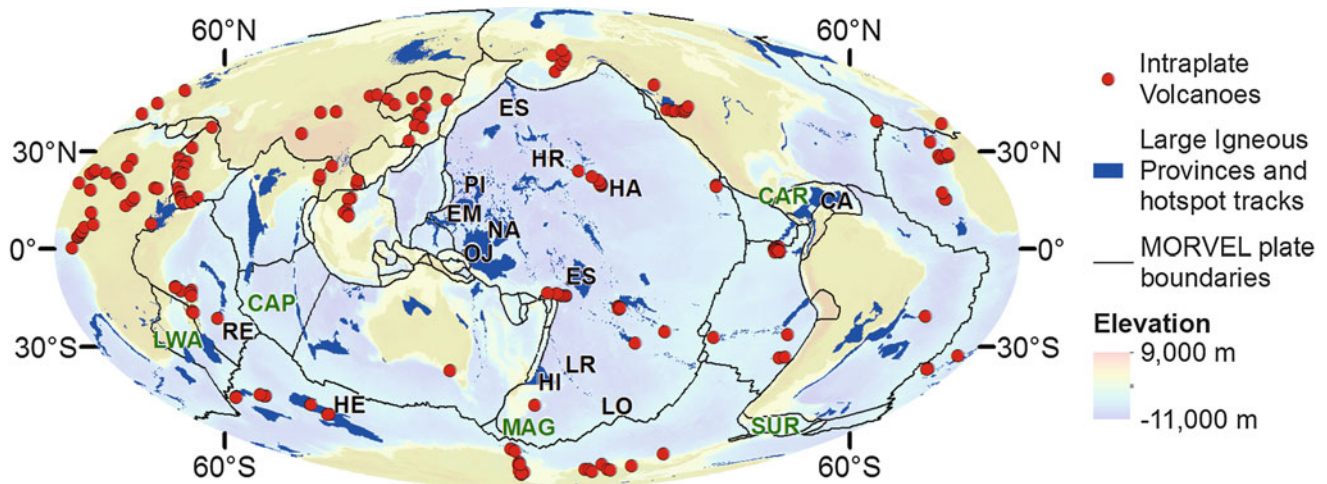
Tectonic setting

Tectonic setting determines whether or not magmatism is
considered intraplate. Although it may appear relatively
straightforward to distinguish between intraplate
magmatism and plate boundary magmatism, this is cer-
tainly not the case. Diffuse zones of plate deformation,
forebulges (flexural bends on subducting plates), and
zones of intraplate extension and convergence complicate
the present-day picture, together with magmatism
exploiting ancient plate boundaries and other zones of
weakness. Moving back through geologic time, identifica-
tion of plate boundaries and the times when they were
active becomes increasingly more challenging, as does
our knowledge of the geochronology of candidate intra-
plate igneous rocks, so we focus on the present, aug-
mented by our knowledge of the past 200 million years
in the oceans.

   Currently, 25 tectonic plates collectively occupy 97 %
of Earth's surface (DeMets et al., 2010). Boundaries of
the majority of these are relatively distinct; however, dif-
fuse boundaries characterize portions of the Capricorn,
Caribbean, Lwandle, Macquarie, and Sur plates
(Figure 1). Forebulges, in this case flexural lithospheric
bulges seaward of subduction zone trenches, are common
features throughout the global ocean and are considered to
be intraplate rather than part of a plate boundary. Intraplate
stress can result in zones of extension and convergence,
examples of which are found in the global ocean; these
may or may not develop into plate boundaries.

Morphology and characteristics of oceanic intraplate magmatism

The scale of intraplate volcanic features in the oceans
ranges over many orders of magnitude, from small volca-
noes on the seafloor that rise <100 m above surrounding
seafloor to massive oceanic plateaus with areas exceeding
10^6 km^2 and volumes of igneous rock greater than
10^7 km^3. Within this continuum are volcanoes rising hun-
dreds to thousands of meters above the ambient seafloor,
linked chains of volcanoes, and submarine ridges, all of
which can have subaerial expressions. Below, we examine
these various features, including key examples, in more
detail.

   Individual undersea volcanoes, known as seamounts,
sea knolls, and/or guyots (hereafter all referred to as "sea-
mounts"), are among the most ubiquitous landforms on
Earth (Wessel et al., 2010) and are found across the entire
range of ages of oceanic crust, i.e., from zero age to
approaching 200 million years. Excluding subduction-
related island arc volcanoes but including volcanoes
formed near seafloor spreading centers, Wessel
et al. (2010) predict the population of seamounts in the


Intraplate Magmatism, Figure 1 Global distribution of intraplate magmatism. Holocene intraplate volcanoes in the oceans and on the continents are depicted in *red* (modified from Siebert et al., 2010). Current "MORVEL" (Mid-Ocean Ridge VELocity) plate boundaries are indicated in *black* (DeMets et al., 2010). Large igneous provinces, mostly younger than 250 million years, but some of which were emplaced at plate boundaries, are shown in *blue* (Coffin and Eldholm, 1994). Intraplate magmatism abbreviations: *CA* Caribbean, *EM* East Mariana, *ES* Emperor Seamount Chain, *HA* Hawaii (island), *HR* Hawaiian Ridge, *HE* Heard Island, *HI* Hikurangi, *LO* Louisville, *LR* Louisville Ridge, *MA* Manihiki, *NA* Nauru, *OJ* Ontong Java, *PI* Pigafetta, *RE* Réunion Island. Plate abbreviations: *CAP* Capricorn, *CAR* Caribbean, *LWA* Lwandle, *MAC* Macquarie, *SUR* Sur.

global ocean >1,000 m in height (above surrounding sea-floor) to be ~125,000, but it could range from 45,000 to 350,000. For seamounts >100 m in height, they predict a population of 25,000,000, but it could range from 8,000,000 to 80,000,000. However, only a minuscule fraction of these features have been sampled and dated (e.g., the online Seamount Catalog (http://earthref.org/SC/) includes approximately 1,800 seamounts).

The most comprehensive database of volcanoes active during the past ~10,000 years (Holocene) includes 1,559 volcanoes, of which 215 are classified as intraplate (Siebert et al., 2010; http://www.volcano.si.edu/). However, 25 of these are situated on or near plate boundaries (DeMets et al., 2010). Of the remaining 190 considered intraplate, 47 are in the ocean (Figure 1). This number is similar to estimates of active hot spots in the ocean (e.g., Courtillot et al., 2003). While it is likely that most, if not all, active volcanoes that form islands in the ocean are included in the Holocene database, volcanic islands constitute only a small fraction of volcanic features in the ocean. Among the most active intraplate volcanoes on Earth currently are the islands of Hawaii in the Pacific Ocean, Réunion in the Indian Ocean, and Heard in the Southern Ocean (Figure 1).

Hawaii, on which Mauna Kea rises >9,000 m above surrounding Pacific Ocean seafloor forming Earth's tallest volcano and mountain (Figure 1), is the largest volcano in what is arguably the best-studied intraplate volcanic chain – the Hawaiian-Emperor hot spot track – on the planet. Analyses of extensive subaerial and submarine surficial lavas on Hawaii, and of buried lavas obtained by the

Hawaii Scientific Drilling Project, indicate a shield-building phase of dominantly tholeiitic magmas and high eruption rates followed by a major decrease in eruption rates coinciding with a shift to alkaline magmas (e.g., Clague and Dalrymple, 1987; Stolper et al., 2009). Tholeiitic shield volcanism followed by alkaline post-shield volcanism is a general characteristic of many intraplate volcanoes. Hawaiian volcanoes form two parallel geographic chains with distinct isotopic compositions (Loa and Kea trends) believed to reflect distinct mantle sources for the two chains.

Piton de la Fournaise on Réunion ascends >7,000 m above adjacent Indian Ocean seafloor (Figure 1). Although it shares many characteristics with Hawaii, it displays both early and waning stages of alkaline volcanism bracketing a steady-state stage of tholeiitic activity (e.g., Albarède et al., 1997). The relatively simple elemental and isotopic geochemistry of Piton de la Fournaise lavas suggests a rather homogeneous mantle source.

Heard surmounts the Kerguelen Plateau in the Southern Ocean (Figure 1), and the Big Ben massif reaches a maximum elevation of 2,745 m above sea-level at Mawson Peak. Because the island is 80 % glaciated, knowledge of Heard Island lava petrology and geochemistry is quite limited compared to Hawaii and Réunion. However, the elemental and isotopic geochemistry of Heard rocks studied to date displays among the largest range of compositions of any oceanic island lavas (e.g., Barling et al., 1994). This heterogeneity is attributed to continent-derived material in the mantle source, shallow-level contamination of magmas ascending through continental

crust of the Kerguelen Plateau, or both (Barling et al., 1994).

A small subset of seamounts are sea knolls confined to the forebulge of oceanic plates seaward of trenches; these have been termed petit spots (e.g., Hirano et al., 2001). These features rise 100–200 m above surrounding seafloor, with a volume typically <1 km^3. Lavas from petit spots are alkaline, and their elemental and isotopic compositions suggest that the magmas originate in the asthenosphere (Hirano et al., 2006).

Little differentiates age-progressive chains of volcanoes from submarine ridges, e.g., the Hawaiian-Emperor seamount chain consists of the younger Hawaiian Ridge and the older Emperor seamount chain (Figure 1). Similarly, an age-progressive chain of seamounts in the South Pacific is known as the Louisville Ridge (Figure 1). While both the Hawaiian-Emperor seamount chain and Louisville Ridge are intraplate, the tectonic settings of emplacement of other prominent age-progressive submarine ridges (e.g., Walvis/Rio Grande and Greenland-Iceland-Faroes in the Atlantic Ocean, Ninetyeast and Chagos-Laccadive/Mascarene in the Indian Ocean) appear to be on, or proximal to, plate boundaries. The crustal nature – oceanic or continental – of still other submarine ridges (e.g., Alpha-Mendeleev in the Arctic Ocean) remains controversial.

The archetypal Hawaiian-Emperor chain of volcanoes extends for more than 5,800 km from the active intraplate submarine volcano of Loihi southeast of the island of Hawaii to Meiji Seamount on the outer slope of the Kuril-Kamchatka Trench in the northwest (Figure 1). The chain includes more than 80 islands, atolls, reefs, banks, and seamounts. Overall, lavas from the Hawaiian-Emperor chain show significant heterogeneity, including tholeiitic and alkalic basalts and their differentiates, and silica-undersaturated lavas (e.g., Regelous et al., 2003).

In contrast to the Hawaiian-Emperor chain, lavas of the entirely submarine Louisville seamount chain ("Louisville Ridge," Figure 1) are relatively homogeneous. Only alkaline rocks have been dredged and drilled from Louisville seamounts, and it may be that Louisville shield volcanoes are produced by massive alkaline volcanism, as opposed to the tholeiitic shield volcanism characterizing Hawaiian-Emperor chain volcanoes (e.g., Koppers et al., 2013).

On the massive end of the scale of intraplate magmatism lie some oceanic plateaus, one category of large igneous province (LIP, e.g., Coffin and Eldholm, 1994). Oceanic plateaus constitute a subset of submarine plateaus; the latter may be continental (e.g., Campbell), oceanic (e.g., Ontong Java), or hybrid (e.g., Kerguelen) in crustal nature. The sole oceanic plateau forming today is Iceland astride the Mid-Atlantic Ridge, so it does not meet the intraplate criterion. Some ancient oceanic plateaus, e.g., Shatsky in the northwest Pacific Ocean and the conjugate Ceara/Sierra Leone provinces in the central Atlantic Ocean, also formed at or near plate boundaries (e.g., Seton et al., 2012).

The volcanic rocks of many oceanic and hybrid plateaus formed during the Cretaceous Normal Superchron (~121 to ~83 million years ago), which makes identification of tectonic setting challenging due to the absence of marine magnetic anomalies in adjacent ocean basins. These Cretaceous oceanic – Caribbean, Conrad, Crozet, East Mariana, Hess, Hikurangi, Manihiki, Nauru, Ontong Java, Pigafetta – and hybrid – Broken, Kerguelen, Madagascar, Naturaliste, Wallaby – plateaus may have formed proximal or distal to plate boundaries.

Among the best studied of these plateaus, i.e., those with multiple samples of igneous basement rocks, are greater Ontong Java (Ontong Java, East Mariana, Nauru, Pigafetta), the conjugate Manihiki/Hikurangi, and the Caribbean (Figure 1). Lying in the western equatorial Pacific Ocean, the greater Ontong Java Plateau, including the Plateau proper as well as the neighboring East Mariana, Nauru, and Pigafetta basin flood basalts, encompasses $\sim 4.27 \times 10^6$ km^2, or ~0.8 %, of the Earth's surface (Ingle and Coffin, 2004) (Figure 1). Emplaced ~120 million years ago (e.g., Neal et al., 1997; Fitton et al., 2004), the Ontong Java Plateau appears to have formed within ~130- to ~160-million-year-old oceanic lithosphere (e.g., Ishikawa et al., 2005), thus qualifying as intraplate magmatism. The elemental and isotopic geochemistry of greater Ontong Java Plateau tholeiitic lavas is remarkably homogeneous, suggesting a homogeneous mantle source (e.g., Fitton et al., 2004).

The conjugate Manihiki and Hikurangi plateaus in the southwest Pacific Ocean (Figure 1) also formed ~120 million years ago (e.g., Hoernle et al., 2010; Timm et al., 2011), and it has been proposed that they formed adjacent to the Ontong Java Plateau (Taylor, 2006). Plate tectonic reconstructions suggest a plate boundary proximal to Manihiki and Hikurangi when they formed (e.g., Seton et al., 2012), casting some doubt as to whether they represent intraplate magmatism. Nevertheless, tholeiitic lavas of igneous basement of both plateaus show strong elemental and isotopic geochemical similarities to Ontong Java basalts, suggesting a common mantle source (Hoernle et al., 2010).

The Caribbean flood basalt province (Figure 1), consisting of basalts, picrites, and komatiites, formed over a relatively long time span from 139 to 69 million years ago, with a major portion emplaced ~90 million years ago and a secondary peak of volcanism at ~75 million years ago (e.g., Kerr et al., 1997; Sinton et al., 1998; Hoernle et al., 2004). Elemental and isotopic geochemistry shows that the two major pulses are largely compositionally distinct, indicating at least two mantle sources (Hoernle et al., 2004).

Causes of intraplate magmatism

The concept of intraplate magmatism developed at the same time as the plate tectonic paradigm. Such magmatism requires an explanation other than the plate tectonic processes of seafloor spreading and subduction.
Intraplate Magmatism, Figure 2 Cartoon depicting source regions of intraplate magmatism: (i) core-mantle boundary/D″/LLSVP, (ii) lower mantle-upper mantle boundary/670-km discontinuity, and (iii) upper mantle. LLSVP, large low shear velocity provinces (after Coffin and Eldholm 1994 and Courtillot et al. 2003).

Age-progressive volcanism along the Hawaiian island chain (McDougall, 1964) provided the first insights into potential causes of intraplate magmatism. The age of volcanism systematically increases to the northwest from the island of Hawaii, a "hot spot" generating significant magmatism that is distal from any current plate boundary (Wilson, 1963, 1965). Another explanation for intraplate magmatism is mantle ascending and partially melting via fissures and faults where the lithosphere is extending (e.g., Turcotte and Oxburgh, 1973; Anderson, 1995). The trend of the Hawaiian-Emperor seamount chain, however, is oblique to preexisting fracture zones, which show no evidence for extension.

Observations of multiple age-progressive volcanic island chains led to the interpretation that hot spots are surface expressions of deep mantle plumes (Morgan, 1971, 1972), to which large igneous provinces have also been attributed, both on the continents (e.g., Richards et al., 1989) and in the oceans (e.g., Coffin and Eldholm, 1994). Subsequently, other interpretations of hot spot islands arose, e.g., channeled asthenospheric flow from a hot spot to a seafloor spreading center (Morgan, 1978; Sleep, 2002). Estimates of the depth of the source of hot spots vary considerably, from the core-mantle boundary to the upper mantle (Figure 2; e.g., Anderson, 1998; Clouard and Bonneville, 2001; Courtillot et al., 2003), with Morgan's (1971, 1972) original deep mantle interpretation being the deep end-member. Buoyancy fluxes of hot spots also vary considerably – by a factor of 20 – with Hawaii being the largest (Sleep, 1990).

Hot spots can be categorized into three different types, depending on which mantle boundary layer is the source, according to a set of five criteria (Courtillot et al., 2003). The five criteria are (1) long-lived tracks, (2) flood basalts at their initiation, (3) large buoyancy flux, (4) high He or Ne ratio, and (5) underlying low shear velocities. In a constellation of 49 active hot spots globally, seven meeting at least three of these criteria were proposed to originate deep in the mantle (core-mantle boundary): Hawaii, Easter, and Louisville in the Pacific hemisphere and Iceland, Afar, Réunion, and Tristan in the Indo-Atlantic hemisphere. Five of these "primary" hot spots are intraplate, with Iceland and Afar being the exceptions. Another ~20 "secondary" hot spots, including Caroline, McDonald, Pitcairn, Samoa, and Tahiti, may originate at the boundary between the upper and lower mantle, the 670-km discontinuity. The remaining ~20 may originate entirely within the upper mantle, possibly passive responses to lithospheric extension (e.g., Natland and Winterer, 2005; Foulger, 2007). In alignment with the different types of hot spots, finite-frequency tomography of the Earth's mantle reveals plumes traceable to different depths in the mantle (Montelli et al., 2004, 2006), although discrepancies exist between these and the Courtillot et al. (2003) results.

Conceptually, mantle plumes are columns of hot, solid material that ascend buoyantly from the core-mantle boundary or the 670-km discontinuity toward the Earth's surface (Figure 2; e.g., Campbell and Griffiths, 1990; Griffiths and Campbell, 1990, 1991; Farnetani and Richards, 1994; Campbell, 2005). New plumes consist of a large head followed by a small tail. When the head of a plume reaches the base of the lithosphere, it flattens and spreads laterally to a diameter exceeding 1,000 km. The temperature excess of a plume head is highest at the center of the head and decreases toward the margin. Both plume heads and plume tails should produce high-temperature picrites, which erupt early and be most abundant near the center of the plume head and less abundant toward the margin. Flood volcanism resulting from decompressional melting should be preceded by domal uplift of hundreds of meters at the center of the dome. The lithosphere acts as a lid on the ascending plume and the extent of decompressional melting, with the thickness of the lithosphere being a key factor in controlling the amount of melt produced.

The concept of predominantly thermal mantle plumes has evolved to thermochemical plumes that incorporate both thermal and chemical heterogeneities in the mantle (e.g., Davaille et al., 2002, 2003, 2005; Farnetani and Samuel, 2005; Lin and van Keken, 2006a, b). Models of thermochemical plumes suggest that upwelling characteristics depend on the buoyancy ratio, which is the ratio of the stabilizing chemical density anomaly to the destabilizing thermal anomaly. Low ratios suggest the absence of a plume tail, and high ratios suggest long-lived hot spot tracks.

In contrast to solely deep Earth processes accounting for intraplate magmatism, an exogenous cause, namely, impacts of large bolides, has also been postulated to instigate such magmatism (e.g., Rogers, 1982; Glikson, 1999; Abbott and Isley, 2002; Jones et al., 2002, 2005; Muller, 2002; Ingle and Coffin, 2004). Large impacts in the ocean basins can excavate some or all of the lithosphere and potentially the uppermost portions of the asthenosphere, thereby inducing voluminous decompressional melting of mantle material. Oblique impacts may impart high shear to the core-mantle boundary, triggering one or more mantle avalanches and mantle plumes.

Thus, whether caused by endogenous or exogenous processes, and whether originating at the core-mantle boundary, the 670-km discontinuity, or within the upper mantle, intraplate magmatism results from decompressional melting of mantle material as it ascends toward the Earth's crust through the asthenosphere and lithosphere.

Nature and source of intraplate magmatism type examples

The three highly active intraplate hot spots described earlier – Hawaii, Réunion, and Heard islands (Figure 1) – are classified by Courtillot et al. (2003) either as originating (Hawaii, Réunion) or possibly originating, with more data (Heard), at the core-mantle boundary (Figure 2). By implication, this implies that the entire Hawaiian-Emperor chain (Figure 1) was created by a hot spot with its origin at the core-mantle boundary. Louisville Ridge (Figure 1) is classified similarly.

In stark contrast, petit spots appear to be sourced entirely within the upper mantle (Figure 2). They form where the outer rise of a subducting plate flexes and develops normal faults, providing pathways for mantle to ascend and melt via decompression (e.g., Hirano et al., 2008). Melt volumes are orders of magnitude less than hot spots such as Hawaii, Réunion, and Heard.

The upper mantle is also likely to be the source for the vast majority of the tens of millions of intraplate seamounts rising >100 m above surrounding seafloor that aren't petit spots (Figure 2). Fissures and faults allow anomalously warm and/or wet mantle to ascend and melt via decompression, producing these features (e.g., Natland and Winterer, 2005). Faults may also influence where seamounts form that possibly originate from deeper in the mantle (e.g., McNutt et al., 1989).

The sheer volumes of igneous rock comprising the Ontong Java, Manihiki, Hikurangi, and Caribbean flood basalt provinces (Figure 1) would suggest an origin in the lower mantle (Figure 2; e.g., Coffin and Eldholm, 1994; Eldholm and Coffin, 2000). Evidence is equivocal for the Louisville hot spot being the source of Ontong Java, Manihiki, and Hikurangi flood basalts (e.g., Mahoney et al., 1993; Neal et al., 1997; Richards et al., 1989; Riisager et al., 2003; Antretter et al., 2004; Chandler et al., 2012). The Caribbean flood basalts have been linked to the Galapagos hot spot (e.g., Duncan and Hargraves, 1984; Kerr et al., 1997; Sinton et al., 1998), which has been classified as possibly originating, with more data, at the core-mantle boundary (Figure 2; Courtillot et al., 2003).

Models for the formation of the Ontong Java Plateau include various plume incarnations (e.g., Bercovici and Mahoney, 1994; Farnetani and Richards, 1994; Larson, 1997; Neal et al., 1997; Ito and Clift, 1998; Tejada et al., 2004; Hoernle et al., 2010), bolide impact (e.g., Rogers, 1982; Jones et al., 2002, 2005; Ingle and Coffin, 2004), and upwelling eclogite (Korenaga, 2005). None of the models to date satisfy all of the observations (e.g., Kerr and Mahoney, 2007). Plume models have also been invoked for the Manihiki and Hikurangi plateaus (e.g., Larson, 1997; Ito and Clift, 1998; Hoernle et al., 2010). In contrast to Ontong Java, plume models seem to satisfy most observations from these two plateaus. The dismembered nature of the Caribbean flood basalt province means that it doesn't lend itself readily to modeling; however, to date only the plume model has been invoked for its formation (e.g., Duncan and Richards, 1991; Kerr et al., 1997).

Summary

Intraplate magmatism in the ocean occurs over many orders of magnitude in scale, and the predominant volcanic rock type is basalt. Type examples of robust active intraplate magmatism – the islands of Hawaii, Réunion, and Heard, all probably sourced from the core-mantle boundary – show a general pattern of alkaline pre-shield, tholeiitic shield, and alkaline post-shield volcanism. Classic seamount chains such as the Hawaiian-Emperor and Louisville, also probably sourced from the core-mantle boundary, display differing degrees of elemental and isotopic compositional variations, with the Hawaiian-Emperor chain quite heterogeneous and Louisville rather homogeneous. The massive oceanic plateaus (Ontong Java, Manihiki, Hikurangi) and ocean basin flood basalts (Caribbean, East Mariana, Nauru, Pigafetta), all likely sourced from the core-mantle boundary, although perhaps instigated by exogenous mechanisms, range from homogeneous (e.g., Ontong Java) to heterogeneous (e.g., Caribbean) in their elemental and isotopic compositions. Finally, the tens of millions of seamounts, including petit spots, that rise >100 m above surrounding seafloor probably originate

overwhelmingly in the upper mantle and mostly exploit fissures and faults in the oceanic lithosphere.

ISLAND ARC VOLCANISM, VOLCANIC ARCS

Jim Gill
Earth & Planetary Sciences, University of California,
Santa Cruz, CA, USA

Synonyms

Arc magmatism; Magmatism at convergent plate boundaries; Subduction zone magmatism

Definition

Island arcs are the marine subset of currently active or formerly active volcanoes located near the boundary between two converging tectonic plates (see Figure 2 in Stern, Magmatism at Convergent Plate Boundaries). Convergence results in the denser plate being thrust (subducted) beneath the rigid overlying plate creating an arcuate-shaped plate boundary on a spherical Earth that is usually marked by an oceanic trench. The volcanoes are located 150–350 km away from the trench on the overlying plate and define an arc in plan view (Frank, 1968). When the crust of the overlying plate is less than ~25 km thick, most of the volcanoes lie below sea-level. Only the largest volcanoes form islands, which, therefore, constitute an island arc. A similar distribution of subduction-related volcanoes also characterizes active continental margins where the crust of the overlying plate is thicker and subaerial so that the volcanoes are not islands (e.g., in western North, Central, and South America; Kamchatka, Russia), but the general processes are similar. "Volcanic arc" refers to the volcanoes produced by subduction in both settings.

Characteristics of island arcs

Almost 80 % of the active subaerial volcanoes on Earth lie within 500 km of a convergent plate boundary and, therefore, are "island arc volcanoes." Their lavas range from basalt to rhyolite. The rock type "andesite," named for the Andes mountains in South America, occurs at about 80 % of these volcanoes. Therefore, volcanism in island arcs is more andesitic than in other tectonic environments on Earth, which are mostly basaltic. Because average continental crust is broadly andesitic in composition, continental crust is either created or recycled or both by island arc magmatism. And because modern plate tectonics is unique to Earth within our solar system, so also are arc volcanism and continental crust of andesitic composition.

Most active island arc volcanoes lie 50–100 km apart and 125 ± 30 km above the underlying earthquakes that occur near the top of the subducting plate (the Wadati-Benioff-Zone). Most individual arcs (see Figure 2 in Stern, Magmatism at Convergent Plate Boundaries, for their names and distribution) differ from one another by the pairing of the converging plates, although some continuous plate boundaries are conventionally divided into two or more arcs by a morphological contrast in the upper plate (e.g., Kermadec vs. Tonga, Mariana vs. Bonin and Izu, Sunda vs. Banda). Within any one arc, the volcanoes are remarkably linear over distances of several hundred kilometers subparallel to, but displaced from, the plate boundary. This line often is called the volcanic or magmatic front, which is the locus of volcanoes closest to the convergent plate boundary.

All of the magma types in island arcs are characterized by distinctive ratios of trace elements and isotopes as the result of recycling material from the underthrust plate. More-fluid-mobile elements (e.g., Sr and Pb) are enriched in arc magmas relative to less-fluid-mobile elements (e.g., REE), and the isotopic compositions of Sr and Pb are more radiogenic, especially relative to the isotopic composition of Nd, a REE.

Arc crust

The seismically best-imaged island arc crust and upper mantle are at the Izu-Bonin-Mariana and Aleutian arcs

(Takahashi et al., 2007; Kodaira, 2007; Calvert, 2011). In Izu, the crust varies sinusoidally from <25 to ~35 km thick along the length of the arc with a wavelength of 80–100 km. Crust is thicker where the Quaternary arc front volcanoes have erupted mostly basaltic magma and thinner where the magmas are mostly rhyolitic in composition. The velocity structure is similar in both cases, with a $Vp = 6.0–6.5$ km/s middle crust at 5–10 km depth that is characteristic of continents and consistent with an andesitic composition and a lower crust that is consistent with plagioclase-bearing mafic cumulates ($Vp = 6.8–7.2$ km/s) overlying plagioclase-free mafic rocks (olivine, pyroxene, amphibole: $Vp = 7.2–7.6$ km/s). This highest-velocity layer is sometimes assigned to the lowermost crust (Kodaira, 2007) and sometimes to the uppermost mantle (Takahashi et al., 2007; Tatsumi et al., 2008). The Aleutian arc differs in that its $Vp = 6.0–6.5$ layer is at a shallower depth (<5 km) and velocities generally are higher at all depths, indicating a more mafic composition. The overall velocity structure of arcs is consistent with a two-stage process of arc crustal production and internal differentiation whereby juvenile magma from the underlying mantle is basaltic and the crustal structure reflects in situ magmatic differentiation and anatexis (e.g., Tatsumi et al., 2008). The crust in all modern island arcs has higher velocity at depths >10 km than old continental interiors.

Across-arc variations

All island arcs include volcanoes farther from the plate boundary than the volcanic front in what is called the "rear arc." Rear arc volcanoes are usually smaller and more likely to be submarine seamounts rather than subaerial islands. Consequently, they are less well known. There can be hundreds of them that extend up to 100 km behind the volcanic front. The volcanic front and rear arc volcanoes together constitute the island arc or volcanic arc. The thickness and velocity structure of the crust are roughly the same for ~100 km across unrifted volcanic arcs (Kodaira, 2007). Therefore, although the volcanoes are smaller in modern rear arcs, the majority of arc crust may be created in the rear arc because it is wider than the volcanic front.

Volcanic rocks in the rear arc usually differ in chemical composition from those at the front. They have higher concentrations of K and most incompatible trace elements (those favoring melt over crystals) but less enriched Sr, Nd, Pb, and Hf isotope ratios. They are more likely to have amphibole phenocrysts in mafic rocks. The differences usually are attributed to smaller degrees of mantle melting beneath the rear arc in response to less fluxing by liquids from the subducting plate that are themselves less water rich than beneath the volcanic front (e.g., Hochstaedter et al., 2001).

Backarc magmas gradually lose their subduction-related character altogether by several hundred kilometers behind the volcanic front and become like those at

mid-ocean ridges (MORB) where there is active seafloor spreading in the backarc (e.g., Central Lau, North Fiji, and Manus Basins) or like those at ocean islands (OIB) in broad extensional zones without spreading. The distinction between rear arc and backarc, and consequently the width of volcanic arcs, is somewhat subjective depending on what evidence of "subduction-related character" is used. The following concentration ratios are indicative of subduction-related magmatism: U/Nb > 0.03, Ba/La > 20, Pb/Ce > 0.08, H_2O/Ce > 250, and La/Nb >1. However, enrichment in these elements derived from the subducting plate can postdate active subduction by as much as a few million years.

Along-arc variations

As noted above, the volcanic fronts of island arcs are characterized by along-arc spacing of both volcanoes and the thickness of the middle crust at 50–100 km intervals. In addition, there are similarly spaced chains of volcanoes across the width of many volcanic arcs (e.g., across the Kermadec, Tonga, Mariana, Izu, Kurile, and Sangihe arcs; e.g., Hochstaedter et al., 2001). In NE Honshu, Japan, the along-arc spacing of these volcanic chains correlates with the spacing of low-gravity anomalies at the surface and low seismic velocities (especially Vs/Vp) in the upper mantle (Tamura et al., 2002). This along-strike three-dimensional structure of island arcs suggests spatial periodicity of magma production and mantle upwelling. This spacing has been attributed directly to the rheology of melt from the subducting plate (Marsh, 1974; Behn et al., 2011) or indirectly to the rheology of flux-melted mantle in the overlying wedge (Honda and Yoshida, 2005).

Relationship of island arcs to subduction parameters

Island arcs differ most among themselves in the age and velocity of the subducting plate and, therefore, slab surface temperatures and in the nature and thickness of subducting sediment. The location of volcanic fronts is thought to be controlled by the thermal structure of the subducting plate or the overlying mantle or both. A generic arc cross section is shown in Figure 2 of Stern (Magmatism at Convergent Plate Boundaries). P-T paths of the slab surface for different subducting plates, and for different layers within the subducting crust of any one arc, are shown in Figs. 1 and 2 (Syracuse et al., 2010; van Keken et al., 2011). The location of the volcanic front sometimes corresponds to the depth of maximum dehydration or the onset of melting, in one or more layers of subducted crust. Alternatively, the volcanic front may overlie where the anhydrous solidus of the convecting mantle comes closest to the plate boundary (England and Katz, 2010). The across-arc width of island arcs may be related to the loci of slab melting. Subducting sediment is expected to melt beneath all volcanic fronts, and subducting basalt beneath most volcanic fronts, if they are water saturated (Figure 1). Because the P-T path of
Island Arc Volcanism, Volcanic Arcs, Figure 1 Thermal models for slab surface temperatures beneath 30 different island arcs from Syracuse et al. (2010). Each *colored line* is a thermal model for a different arc. Although the calculated slab surface temperature varies by 200 °C beneath different arcs, in all cases it crosses the water-saturated solidi of sediment (*solid white line*) and basalt (*dashed white line*) slightly trenchward of the volcanic front that typically is ~125 ± 20 km above the slab. The labeled contours, and the shades of gray, show the maximum calculated amount of water in wt% bound in minerals in the slab.

Island Arc Volcanism, Volcanic Arcs, Figure 2 Slab temperatures beneath the Izu island arc where the slab below the volcanic front is at 3.2 GPa (125 km) and the slab below the rearmost arc volcanism is at about 6 GPa. Figure is from Version 4 of the Arc Basalt Simulator (Kimura et al., 2010). Each color is a different portion of subducting oceanic crust: SED (sediment), UBAS and LBAS (upper and lower basalt; oceanic crust layer 2), and UGAB and LGAB (upper and lower gabbro; oceanic crust layer 3). The overlying and underlying mantles are MwP and SlbP, respectively. The wet (*open circle*) and dehydration (*closed circle*) solidi apply to both sediment and basalt. The slight difference in wet solidi from Figure 1 below 3 GPa reflects the range of experimental results chosen in the papers cited. The thermal model for Izu is from Figure 1 (Syracuse et al., 2010). Note that both the sediment and uppermost basalt are predicted to start melting slightly trenchward of the volcanic front and to remain partially molten beneath the full width of the arc.

the slab surface is predicted to be steeper than the water-saturated solidi, the width of arcs corresponds roughly to where the slab surface temperature exceeds the solidi (Figure 1). Moreover, slab surface temperatures calculated from geodynamic and geochemical models agree ±100 °C for volcanic front magmas (Cooper et al., 2012). For this to be other than coincidence, water-saturated melting near the slab surface may be ubiquitous, minerals like monazite and phlogopite must be residual during sediment melting for the geochemical models to work, and arc magmas must rise quasi-vertically from the slab.

Arc magmas differ from one another in composition for many reasons, but chief among them are differences in locally subducting sediment. Figure 3 shows that the Th/La ratio of the slab-derived component in arc magmas correlates well with that ratio in locally subducting sediment on a global basis (Plank, 2005). That is, what goes in largely controls what comes out in many cases. Because isotope ratios are unaffected by melting processes, they would be an even better test of this conclusion, but no similar global synthesis is available.

Temporal evolution

It has been thought that individual arc volcanoes and entire arcs become more enriched in incompatible elements and less enriched in iron through time (Gill, 1981, Chap. 7). That is, arc magmas seemed to become higher K, more calcalkaline, and less tholeiitic with time. However, there are many exceptions to this generalization at all time scales. Moreover, recent studies of the oldest volcanic rocks in the Mariana, Bonin, Izu, and Tongan arcs (Reagan et al., 2010, Ishizuka et al., 2011, Todd et al., 2012), and of supra-subduction zone ophiolites, suggest a more complex evolution during the initiation of an island arc. The magmatic sequence starts with tholeiitic basalt generated by decompression melting with little or no contribution from the subducted plate, followed by boninite (high-Mg, low-Ti andesite) generated by flux melting of the shallow mantle and then by low-K arc tholeiite with more of a recycled component than during the initial phase. In some locations, two or more of these rock types erupt simultaneously in the same place. Higher-K and less-Fe-enriched magmas appear occasionally later in arc history, especially in the rear arc, and sometimes in response to special tectonic events like arc rifting or
Island Arc Volcanism, Volcanic Arcs, Figure 3 Th/La of the slab-derived component in arc magmas compared to the Th/La ratio of sediment subducting beneath the same arcs. See Plank (2005) for details about both axes and the error bars.

seamount collision. These calcalkaline magmas are more common where crust is thicker or the subducting plate is younger.

Ore deposits

Island arcs host many economically important ore deposits. For example, venting of high-temperature hydrothermal fluids into ocean water by submarine arc volcanoes causes Fe-Pb-Cu-Zn-Ag sulfides to precipitate and accumulate as volcanogenic massive sulfide deposits (Hannington 2014). Hydrothermal systems that are thermally and chemically driven by plutons associated with continental andesitic to rhyolitic volcanic centers in unusually compressional settings in produce the Cu and Mo porphyry deposits that are the principal sources for these and many other societally important metals (e.g., Richards and Mumin, 2013). Much of the world's Au precipitated in shallower portions of arc magmatic systems where hydrothermal fluids boil (e.g., Cook et al., 2011).

Summary

Terrestrial island arcs or volcanic arcs are regions up to 100 km wide of subaerial and submarine volcanoes whose trenchward limit is ~120 km above the subducting plate. Their magmas are more andesitic than elsewhere on Earth or other planets and contribute to continent formation. Their volcanoes are often explosive, and their magmatism creates important metal ore deposits. There are 3-D variations in the spacing of volcanoes and the composition of magmas both of which are related to the thermal structure of the subducting plate and overlying convecting mantle.

LAGOONS

Andrzej Osadczuk
Institute of Marine and Coastal Sciences, University of Szczecin, Szczecin, Poland

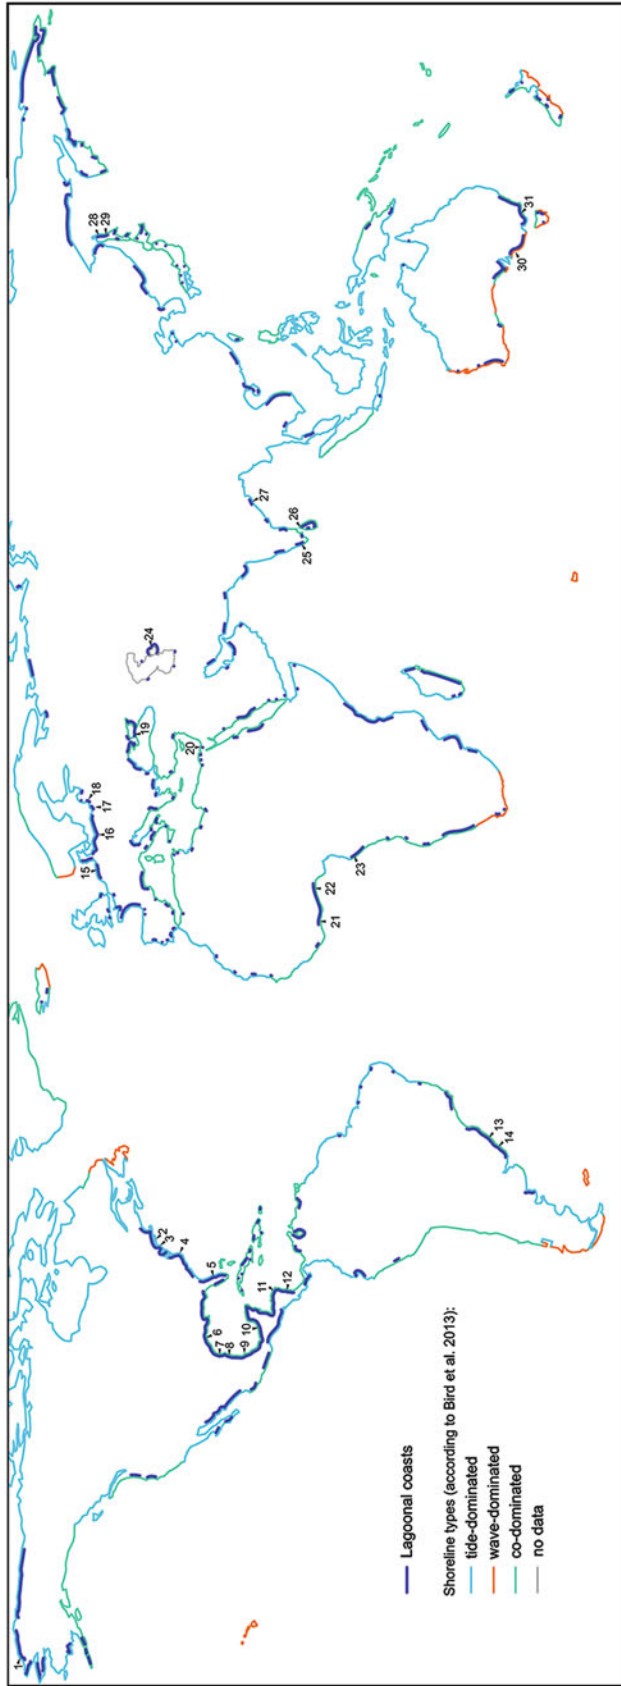
Definition

The term *lagoon* is derived from the Latin *lacun* and the later Italian *laguna*, which originally referred to the shallow water body around Venice (Skeat, 1893). Although there are many definitions of lagoon, they differ only in details. A lagoon is defined as a *body of brackish, marine or hypersaline water impounded by a sandy barrier and having an inlet connecting with the open ocean* (Phleger, 1981) or *water areas separated from the sea by narrow and low-laying land strips and usually differing from the sea in salinity* (Kaplin, 1982) or a *shallow coastal water body separated from the ocean by a barrier, connected at least intermittently to the ocean by one or more restricted inlets, and usually oriented shore-parallel* (Kjerfve, 1994). A full overview of the definitions of the term "lagoon" in relation to various coastal environments has been given by Tagliapietra et al. (2009).

Key features and variety of lagoons

Coastal lagoons represent about 11 % of the world's coastlines and are widespread all along the world's ocean coasts (Nichols and Boon, 1994). However, lagoons develop on aggrading or formerly aggraded coastal plains which are gently sloping seaward. They are most common in microtidal environments, although many examples of lagoons can be found in mesotidal and even macrotidal environments (Hayes, 1979; Nichols and Boon, 1994). Many lagoons are well developed on coasts of mid-latitudes, especially along the Atlantic coast of the North and South America (Figure 1). Also, many lagoons

occur on southern coast of Europe, on southern shores of the North Sea, and in some enclosed seas, such as Black Sea, Caspian Sea, and southern Baltic. Lagoons can also be found in low (tropical) and high (polar) latitude zones. In the first case, lagoons in particular are common along both coasts of Middle America (Gulf of Mexico, Caribbean Sea). On the other hand, along the shores of Alaska and the Chukchi Peninsula, we can find many examples of arctic lagoons (e.g., Kasegaluk Lagoon, Elson Lagoon, Kunergvin Lagoon). The size of coastal lagoons varies greatly, from about a hectare to more than 10,000 km^2 (Bird, 2008). Some lagoons extend over 200 km, e.g., Lagoa dos Patos (Brazil) and Laguna Madre (Gulf of Mexico).

With respect to hydrodynamics and water exchange with the adjacent open sea, coastal lagoons are often classified as *closed*, *partly closed*, *open*, and *estuarine* (Nichols and Allen, 1981) (Figure 2) or *choked*, *restricted*, and *leaky* (Kjerfve, 1986). A *closed lagoon* is produced by intermediate to high waves, and strong longshore drift. Such lagoon has no entrance channel, but that does not mean that there is no water exchange with the sea. Water flow, although very limited, can take place through the permeable sediments of the barrier. Washovers or winds across the barrier are the leading processes of sediment influx. Organic production or chemical precipitation is often a chief sediment-producing process in such conditions. In a *partly closed lagoon*, high wave energy acting on the nearshore bed or headlands and strong longshore currents build an extensive barrier island with prominent flood delta and poorly developed ebb delta. Over long periods, tidal currents and wave power may reach a dynamic balance. Ocean-lagoon exchange is poor, and entrapment of both sandy and muddy sediments is good. An *open lagoon* is a result of wave action in combination with moderate tidal action and river inflow. High waves and longshore drift build short barrier islands, while tidal


Lagoons, Figure 1 Worldwide distribution of modern coastal lagoons (*medium blue*). Shoreline classification according to relative wave and tidal ranges after Bird et al. (2013), modified (tide dominated, *sky blue*; wave dominated, *orange*; co-dominated, *green*; no data, *gray*). Numbers indicate the location of the largest lagoons (longer than 40 km). *1*, Kasegaluk Lagoon; *2*, Great South Bay; *3*, Barnegat Bay; *4*, Pamlico Sound; *5*, Indian River; *6*, Galveston Bay; *7*, Laguna Madre (USA); *8*, Laguna Madre (Mexico); *9*, Laguna de Tamiahua; *10*, Laguna de Terminos; *11*, Laguna de Caratasca; *12*, Laguna de Perlas; *13*, Lagoa dos Patos; *14*, Lagoa Mirim; *15*, Wadden Sea; *16*, Szczecin Lagoon; *17*, Vistula Lagoon; *18*, Curonian Lagoon; *19*, Sivash Lagoon System; *20*, Lake Bardawil; *21*, Ébrié Lagoon; *22*, Lagos Lagoon and Lekki Lagoon; *23*, Lagune Nkomi; *24*, Garabogazköl Aylagy (Kara-Bogaz-Gol); *25*, Vembanad Lake; *26*, Jaffna Lagoon (Sri Lanka); *27*, Chilika Lake; *28*, Zaliv Piltun; *29*, Zaliv Nyyskiy; *30*, Coorong Lagoon; *31*, Gippsland Lakes.
Lagoons, Figure 2 Types of costal lagoons according to Nichols and Allen (1981).

currents maintain several moderate-size entrance channels with well-developed flood and ebb deltas. In such lagoon, muddy sediments tend to accumulate on flats along inner parts, whereas sandy sediments accumulate in the immediate vicinity of entrance channels. An *estuarine lagoon* is characterized by strong tidal action augmented by large river inflow. Wave energy and longshore drift are of little importance in this case. Tidal currents maintain several broad inlets that provide an intensive exchange of water (Nichols and Allen, 1981).

Choked lagoons (according to Kjerfve, 1986) are usually connected to the sea by a single narrow and shallow entrance and occur along coasts affected by high wave energy or significant littoral drift (e.g., Lagoa dos Patos in Brazil, Coorong in Australia). A *restricted* lagoon consists of a large and wide water body, usually parallel to the shore, which has two or more entrance channels or inlets (e.g., Laguna de Terminos in Mexico, Lake Pontchartrain in the USA). *Leaky* lagoons are elongated shore-parallel water bodies with many tidal passes along coasts where tidal currents are sufficient to overcome the tendency to closure by wave action and littoral drift (e.g., the Mississippi Sound, intertidal areas of Wadden Sea) (Kjerfve, 1986; Kjerfve and Magill, 1989; Kjerfve, 1994). Duck and da Silva (2012) have attributed certain dominant hydromorphological conditions and geomorphological features to these three types of lagoons.

Some of geoscientists distinguish between "estuarine lagoons" into which rivers flow and "marine lagoons" without a major freshwater input (Barnes, 1980). "Marine lagoons" are often called "coastal lakes," especially when the connection with the sea is reduced or temporarily obliterated (Tagliapietra et al., 2009). However, the use of the term "estuarine lagoon" should be very prudent, because the word "estuary" is derived from the Latin words "aestus" and "aestuarium," which means "tide" and "tidal place" (tidal inlet). Thus, in the absence of tides, the term "estuarine lagoon" is unsuitable (Osadczuk et al., 2007).

Depending on local conditions, lagoons exhibit salinities which range from almost completely fresh (e.g.,

Szczecin Lagoon, Poland/Germany; Curonian Lagoon, Lithuania/Russia) or brackish (e.g., Chilika Lake, India; Lagoa dos Patos, Brazil) to hypersaline (e.g., Laguna Madre, USA; Coorong, Australia).

Formation and evolution of lagoons

Contemporary lagoons owe their origin largely to eustatic sea-level rise near the end of the Pleistocene 15,000 year ago. The consequence of a rapid but variable rate of sea-level rise was inundation of river valleys and low-lying coastal depressions (Nichols and Biggs, 1985). Most modern lagoons have developed during the sea-level rising of the last 6–8 thousand year ago (Phleger, 1981). Lagoons develop on aggrading or formerly aggraded coastal plains which are gently sloping seaward. Very often they are associated with modern or ancient river valley. From the geological point of view, lagoons are ephemeral. They form, evolve, and infill within a short timespan and may be considered as effects of events or processes on generally prograding coasts (Phleger, 1981; Bird, 1994; Cooper, 1997).

The emergence of a barrier is a primary requirement for the creation and functioning of a lagoon (Figure 3). The barriers may take a variety of forms, including headland spits (single and double sided), emergent offshore bars, coral reefs, and barrier inland chains. Differences in the genesis and structure of the barriers are a consequence of differences in controlling mechanisms, such as regional topography; the stage in the shore development; the source, type, and rate of sediment supply; the pace and direction of change in sea-level, tidal range; and meteorological and climatic conditions (Fisher, 1982).

There are several models of the development of barrier relating to sea-level changes. Most of them are related to marine transgression. As sea-level rises, a barrier may undergo of three responses: erosional (the Bruun role), translational (rollover model), or stationary (overstepping model) (Carter, 1988; Cooper, 1997). The barrier's response to the sea-level rise has a direct impact
Lagoons, Figure 3 Block diagram depicting major features of lagoon environment (according to Cooper, 2007).

on the evolution of a lagoon. If a transgressive lagoonal barrier stabilizes against a break in slope or topographic high and accretes upward rather than landward, the volume of the lagoon may increase if the sea-level rise exceeds the fluvial sediment supply. If the barrier continues to move landward as the sea-level rises, the actual lagoon volume may remain constant (Cooper, 1997). However, evolutionary models for coarse-grained barriers and associated lagoons in temperate latitudes show that they differ from sandy barriers (Carter et al., 1989).

An important element of each lagoon system is connection to the open sea. Typically, there are one or more entrances or tidal inlets. Most inlets form by the following mechanisms: (1) storm-generated scour channels, (2) spit growth across the entrances to flooded valleys during the mid-Holocene, (3) intersection of major tidal channels by landward-migrating transgressive barrier islands, and (4) tidal prism-controlled, evenly spaced inlets that evolve in regions lacking major former river valleys (Hayes and FitzGerald, 2013).

Based on the morphology of the barrier-inlet elements, Davis and Hayes (1984) distinguished three types of barrier coasts based on the morphology of the barrier-inlet elements: (1) "wave dominated" (the barrier is narrow with abundant washover features and a generally low elevation; inlets are typically widely spaced, small, and unstable); (2) "mixed-energy" (barriers are typically short and drumstick shaped, with one end prograding in the form of beach/dune ridges and the other transgressing landward; inlets are large and stable); (3) "tide dominated" (barriers are absent, and sand bodies tend to be oriented with an onshore-offshore orientation as the result of strong tidal currents).

Gibeaut and Davis (1991), taking into account previous findings relating to the synergies between wave and tidal energy, have identified four categories of barrier inlets: (1) tide dominated, (2) mixed-energy straight, (3) mixed-

energy offset, (4) wave dominated. This relationship also affects the shape of the ebb delta. Generally, the "tide-dominated" ebb delta extends well beyond the barriers and is dominated by channel-margin linear bars. The "mixed-energy" ebb delta has a distinct terminal lobe but also with well-defined channel-margin linear bars. The barrier shorelines may be aligned or offset. The "wave-dominated" ebb delta is very small and is dominated by the terminal lobe if the inlet is not completely closed (Davis, 2013). Although the comparative influence of waves and tides is the fundamental relationship in barrier-inlet morphodynamics, in the opinion of Davis (2013), variables such as tidal prism, sediment abundance, and sea-level change are equally important.

In general, coastal lagoons are naturally net sediment sinks. However, sometimes some portion of sediments may escape a lagoon by flushing into the sea, by wind erosion of coastal flats, or by oxidation of organic matter. Sediments can be supplied to lagoons from various sources. In many lagoons, the sediment components are derived locally from shore or barrier erosion or from sources inside lagoon, which are organic production and chemical precipitation. In other lagoons, sedimentary material can come also from distant sources. Very often, a catchment area is a source of significant amounts of fluvial sediments. Some amounts of sediment may reach the lagoon from the sea during tide action (Nichols and Allen, 1981). It should be noted that the supply of sediment is strongly influenced by climate. Comparison of lagoon features and processes in different climatic zones was given by Nichols and Allen (1981).

Lagoons act as sinks of particles through sedimentation, acting as important buffers of the land-sea interface. A large number of processes are responsible for this phenomenon. During transport and recycling, fine particles are modified by aggregation, disintegration, and reforming. Microorganisms and benthic fauna play an

important role in these processes. Of particular importance are also wind waves that induce sediment resuspension. Although sediments are extensively reworked, especially by storms, lagoons primarily function as net sediment sinks in which the accumulation rates adjust to submergence (Nichols and Allen, 1981; Boyd et al., 1992; Nichols and Boon, 1994; Brito et al., 2012). On the other hand, submerged aquatic vegetation and salt marsh vegetation as well microphytobenthos may exert a strong influence on the morphology of the lagoons bottom by bio-stabilization of sediment (Widdows and Brinsley, 2002). Generally speaking, lagoonal sediments are a mixture of components, derived either from external sources (river, sea, shore, barrier) or from internal sources (organic production, chemical precipitation, erosion of older deposits) (Nichols and Boon, 1994).

From an ecological perspective, coastal lagoons are highly productive ecosystems, 10–15 times higher than continental shelves (Valiela, 1995), excluding, of course, some hypersaline lagoons. Thus, many of them can also provide a wide range of natural services, very important for the development of society. Anthony et al. (2009) perceive a wide range of social values of lagoons, in such categories as pragmatic, scholarly, aesthetic, and tactic, especially highlighting commercial, recreational, and tourism uses of lagoons. A comprehensive and reliable overview of some European semi-enclosed coastal systems, including lagoons, mainly from the ecological and socioeconomic perspective, has been given by Newton et al. (2014).

Coastal lagoons act as buffers of the land-sea interface, providing valuable ecosystem services such as nutrient recycling, decomposition of organic matter, and removal of pollutants. Lagoons are regions of restricted exchange, subject to anthropogenic pressures that result in problems such as eutrophication. Lagoons are extremely vulnerable to climate changes. Climate change, especially sea-level rise and global warming, is likely to affect shallow coastal lagoons and to increase their vulnerability to eutrophication (Brito et al., 2012).

In arid regions, lagoonal sediments are formed primarily as a result of chemical precipitation and biological extraction of calcium carbonate. Hot and dry climate creates favorable conditions for the deposition of evaporites. Thus, carbonates, chlorides, and sulfates can accumulate in the lagoonal environment. Such processes are observed, for example, on the southern coast of the Persian Gulf, where lagoonal waters have a salinity of up to 67 ‰. In the local lagoons, e.g., the Khor al Bazam, many variations of carbonate sediments occur, such as pelleted lime muds, oolites, and pellet aggregates, as result of high organic production (Alsharhan and Kendall, 2003). Their distribution and the characteristics of individual grain types are controlled largely by their hydrodynamic setting, with interactions between wave and current action, sediment mobility, burial rate, and cementation. Coastal shallows are covered by cyanobacterial mats and mangrove swamps, and the supratidal salt flats (sabkhas) are covered by gypsum-salt deposits (Kendall and Alsharhan, 2011).

There are some conceptual models of lagoon evolution. One of the earliest concepts of lagoon evolution, known as "Lucke model," assumes that coastal lagoons evolve from a marine embayment to a relatively deep, partially enclosed, back-barrier lagoon (Lucke, 1934). In developing this concept, Oertel et al. (1992) point out that at wave-dominated coasts, the floors of barrier lagoons are initially smooth after lagoon formation, and basin infilling is dependent on changes in capacity relative to sea-level rise and sediment input from siltation, runoff, inlets, and cross-island transport. At tide-dominated coasts, the lagoon floors are irregular and reflect the antecedent topography of pre-transgressed landscape. The interfluve areas of the topography produced very shallow areas in the lagoon that form tidal flats or are colonized by marshes. In "Lucke model," the open-water embayment represents the first stage in the evolutionary sequence, while a model proposed by Oertel et al. (1992) assumes that the open-water embayment may become end-member of the evolutionary cycle. However, it should be considered that "Lucke model" was developed for stationary sea-level conditions. A model of transgressive evolution of lagoons was presented by Nichols (1989), based upon the interplay between sedimentation rate and relative sea-level rise. The model assumes three different types of lagoons: a "deficit lagoon," a "surplus lagoon," and an "equilibrium lagoon." In a "deficit lagoon," sea-level rise exceeds sediment supply and lagoon becomes deeper. In a "surplus" lagoon, sediment supply exceeds sea-level rise and lagoon becomes increasingly filled with sediments. In "equilibrium lagoon," the rate of sedimentation is in equilibrium with the rate of submergence from sea-level rise, thus lagoon morphology remains unchanged.

In general, the evolution of many coastal lagoons is a result of the combined effects of marine and fluvial processes leading to trapping and infilling of semi-enclosed coastal systems, including coastal lagoons, and the reshaping of seaward boundaries (Kjerfve and Magill, 1989). However, there is wide variation in the evolution of coastal lagoons. Their development can progress in a variety of ways and with different results. Thus, lagoons can be found at various stages of development in an evolutionary sequence.

Overall, lagoon development is the result of the balance between those processes which act to reduce the size of a lagoon and those which act to increase it. It is mainly related to the balance between the supply of sediment and the rate of sea-level rise. The response of a barrier to sea-level rise has a direct bearing on lagoonal evolution. If a transgressive lagoonal barrier stabilizes against a break in slope or topographic high and accretes upward rather than landward, then the volume of the lagoon may increase if sea-level rise exceeds fluvial sediment supply. If the barrier continues to move landward as sea-level rises, then the actual lagoon volume may remain constant.

In certain cases, the barrier progrades seaward, and this may reduce contact with the sea (Cooper, 1997). However, it should be noted that the rate and direction of the lagoon evolution depend on many factors. According to Cooper (1997), these factors may be divided into macroscale and local or microscale variations. Macroscale controls include sea-level changes, climate, and tectonic stability. Local controls include fluvial sediment supply, longshore drift, salinity, surrounding geology, costal morphology, lagoon orientation, wave energy, and tidal range. Carter et al. (1989) proposed a hierarchy of controls on the effect of sea-level changes on coarse-grained barrier-lagoon evolution. Such hierarchical arrangement of dependencies shows the complexity and interrelationships between various factors.

Very often, lagoon evolves from an estuary or marine embayment to a partially enclosed barrier-lagoon system and then, with progressive infilling, to a marsh or deltaic-filled lagoon, ending the cycle with a depositional plain or with an eventual destruction by marine erosion (Nichols, 1989). For example, the area of the Odra River mouth, southern Baltic coast, is subjected to such an evolution since the late Pleistocene (Borówka et al., 2005; Osadczuk et al., 2007).

Based on detailed studies of sedimentation processes in one of the world's largest lagoons (Laguna Madre, Texas), Morton et al. (2000) have found that the historical average annual accumulation rate in the lagoon (1 mm/year) is substantially less than the historical rate of relative sea-level rise (4 mm/year). Lagoon submergence coupled with erosion of the western shore indicates that Laguna Madre is being submerged slowly and migrating westward rather than filling, as some have suggested.

According to Adlam (2014), the existence of numerous examples of lagoons that remain unfilled suggests that a discontinuity in their geologic evolution occurs before maturity is reached. He has presented a new hypothesis that geologic evolution of lagoons takes place in two phases which are defined by changes in physical processes. The early phase aligns with the traditional view but ends when a depth threshold is reached. In the late phase, sedimentation is inhibited by the local energy regime and can only proceed if the lagoon surface area is reduced. Validation of the existence of these two distinct process-based phases of geologic evolution will improve the reliability of predictive models for lagoon shoreline changes and rates of basin fill as well as reduce the risk of misinterpreting past conditions from the geological record.

Conclusions

The formation and evolution of coastal lagoons is controlled by many factors, including global, regional, and local determinants at different levels of importance. Very important is the hierarchy of the circumstances and processes that control the evolution of this environment. A comprehensive model of lagoons' evolution should take into account as many factors as possible. The model should include, in particular, such variables as geolecical conditions; neotectonic movements; lagoon morphology and its orientation; connection with the sea; sea-level changes, tidal amplitude, and waves energy; climate and local meteorological conditions; character of sediments supply; sedimentation rate; salinity; primary production; and anthropogenic influences. Although there were several attempts to create a comprehensive and universal model of the lagoons' evolution, unfortunately, it was not created, so far, one that would take into account all variables.

Laminated sediments are characterized by the presence of planar, bed-parallel layers that originate from changes in particle composition or grain size, with thickness of the order 1 cm or less. The physical processes involved in the transport and deposition of sedimentary particles may produce parallel laminae in sands or silts, but the term "laminated sediment" is more commonly associated with the formation of laminae by successive depositional or "flux" events in hemipelagic or pelagic settings. Such laminae may be of biogenic origin, formed by the remains of marine phytoplankton such as diatoms or coccolithophores, or in marine systems nearer land, may comprise terrigenous clay and silt particles.

Since the pioneering bottom camera observations of the deep sea in the early 1980s, it has been understood that pelagic sediments are formed by rapid settling from seasonal productivity events that occur in the surface ocean. Rapid sedimentation to the sea floor, within days to weeks, is mediated by aggregates of phytoplankton, often enhanced by sticky, transparent extrapolymer particles and by zooplankton fecal pellets. Normally this seasonal input is rapidly reprocessed on the sea floor by the feeding activity of benthic surface dwellers and burrowers that effectively homogenize the sediment to depths of several centimeters. When the activity of benthic organisms is suppressed or eliminated, laminated sediments that record the seasonal flux cycle are preserved. The benthos is most commonly suppressed by low levels of bottom water oxygenation. This oxygen depletion generally occurs in basins with sills where the bottom waters are not in direct contact with the open ocean and so are not renewed.

Silled basins in which laminated sediments are preserved range in size from coastal fjords such as the Saanich Inlet in British Columbia to the California borderland basins including the Santa Barbara Basin. On even larger scales preservation of laminated sediments also occurs in marginal seas with shallow sills such as the Baltic Sea or the Black Sea. Bottom water oxygenation may also be sufficiently reduced to preserve laminae beneath highly productive upwelling regimes over open shelves, such as the Gulf of California or the Peru Shelf, where the intense flux of organic matter uses all available water column dissolved oxygen. In many of these marginal settings, there is an alternation of biogenic algal remains, often formed by the spring bloom or "fall dump" with laminae of terrigenous sediment commonly supplied by river run-off from seasonal rains. It is common to observe an annual couplet of laminae (biogenic and terrigenous), but up to 22 individual laminae per year have been identified in the Saanich Inlet which has rates of deposition exceeding 1 cm per year.

A further mechanism for the preservation of laminae is the physical suppression of benthic activity by the rapid deposition of tough mats of diatoms in "laminated diatom mat deposits." These are generated by the rapid flux of diatoms beneath oceanic frontal systems and occur extensively in ancient sediments of the equatorial Pacific and around the Southern Ocean.

Annually laminated marine sediments are also referred to as "marine varves" and may be used to develop marine varve chronologies to form a method of establishing the absolute and relative timing of climatic events. Time series of interannual variability are also derived from lamina sequences and are used to investigate past variation in the frequencies of climatic phenomena such as El Niño.

LAYERING OF OCEANIC CRUST

Juan Pablo Canales
Woods Hole Oceanographic Institution, Woods Hole, MA, USA

Magma generated by decompression melting of the upwelling mantle beneath mid-ocean ridges (MORs) rises buoyantly and accumulates in crustal magma chambers (e.g., Forsyth, 1992). The long-held view is that oceanic crust is built from in situ crystallization of melts in these reservoirs, as well as from melts extracted from the magma chamber(s) in the form of dikes that eventually break the seafloor during submarine eruptions (e.g., Sinton and Detrick, 1992). These processes result in oceanic crust that is magmatically layered, with a lower section typically 4–5 km thick composed of mafic plutons (gabbros), a 1–2 km thick layer of sheeted basaltic dikes above it, and a carapace of a few to several hundred meters thick of extrusive basalts (pillow lavas and sheet flows), known as the Penrose model of oceanic crust (Penrose Conference participants, 1972). Although these units all have common parental magmas, they exhibit distinct elastic properties because of differences in mineralogical textures produced by crystallization processes and different porosity structure (i.e., the shallower extrusive section is highly porous, with porosity decreasing with depth throughout the crust). As a result, the speed of seismic waves propagating through the crust increases with depth while at the same time the rate at which seismic velocities increase with depth (velocity gradient) diminishes with depth. These seismic layers have been historically known as seismic Layer 2 (upper and mid-crust, subdivided in 2A and 2B based on changes in velocity gradient) and Layer 3 (lower crust) (e.g., White et al., 1992). To a large degree they correspond to the lithological layering of the oceanic crust, although deviations from this direct correlation are known to exist (Christeson et al., 2007; Detrick et al., 1994; Wilson et al., 2006).

The lithological and seismic layering described above has successfully explained many observations made at ophiolites (sections of oceanic crust exposed on land) as well as observations at crust formed at MORs with

fast-spreading rates (>80 mm/year full rate), where magmatism is the dominant mode of lithospheric accretion. However, it is becoming increasingly accepted that the Penrose model fails to explain many features observed at MORs where plates spread apart at slower rates. Along slow- and ultra-slow-spreading MORs, the lithosphere is generally thicker and colder than at fast-spreading MORS, tectonic activity is a dominant process accommodating plate separation, and magmatism is highly variable both in time and space (e.g., Dick et al., 2010; Michael et al., 2003; Schroeder et al., 2007). In these settings, the interplay between magmatic and tectonic extension and their space-time variability result in oceanic lithosphere in which the crust is no longer stratified but disrupted, forming a heterogeneous mixture of magmatic and mantle rocks (Cannat, 1993).

LITHOSPHERE: STRUCTURE AND COMPOSITION

Martin Meschede
Institute of Geography and Geology, Ernst-Moritz-Arndt University, Greifswald, Germany

Definition

The lithosphere (from the Greek words *lithos* [λίθος] meaning rocky and *sphaira* [σΦαῖρα]meaning sphere) is defined as the outermost rigid shell of the Earth (Skinner et al., 2003). It comprises the crust and the upper portion of the mantle which is stiff and rigid and behaves elastically over millions of years. The mantle part of the lithosphere is named the "lithospheric mantle." Beneath the lithospheric mantle follows the asthenosphere (from the Greek words *asthenḗs* [ἀσθενής] meaning weak and *sphaira* [σΦαῖρα] meaning sphere). Both the lithospheric mantle and the upper part of the asthenosphere are mainly composed of peridotitic rocks.

Introduction

The crust overlying the lithospheric mantle is either of oceanic type which is mainly composed of gabbroic and basaltic rocks resulting in a mean density of 3.0 g/cm^3, or of continental type with a gabbroic/granulitic layer at its base and a variety of rock types in the upper part formed by magmatic differentiation, metamorphism, and/or sedimentation over long periods of the Earth's history (Figure 1). The mean density of the continental crust is 2.8–2.9 g/cm^3 in the deeper portion and 2.6–2.7 g/cm^3 in the upper portion. The boundary between the Earth's crust and the lithospheric mantle is known as the Mohorovičić discontinuity (short form: Moho; Figure 1), named after the Croatian geophysicist Andrija S. Mohorovičić (1857–1936).

Oceanic lithosphere is continuously formed at mid-oceanic ridges and returned into the mantle at subduction zones. Oceanic lithosphere is, therefore, much younger than continental lithosphere. The oldest oceanic lithosphere is about 185 myrs old (Müller et al. 2008), whereas continental lithosphere comprises remnants of all periods of the Earth's history. The oldest parts of
Lithosphere: Structure and Composition, Figure 1 Variations in thickness of continental and oceanic lithosphere. Numbers refer to mean density (g/cm^3). Moho, Mohorovičić discontinuity.

continental lithosphere are represented by cratons which are composed of billions of years old mostly metamorphic and/or magmatic rocks. The lithosphere of cratons is thicker and less dense than typical lithosphere and acts as a stabilizer for these regions.

Structure

The oceanic lithosphere is composed of the lithospheric mantle and the oceanic crust with mainly gabbroic and basaltic rocks formed at the oceanic spreading centers. The thickness of the oceanic lithosphere increases with increasing distance to the spreading center because new lithospheric material is continuously added at the base of the lithosphere by conductive cooling (Figure 2). At about 1200 °C, the partially molten asthenospheric material gets completely solid and is converted into lithospheric mantle. The density of the solid material increases a little from 3.25 g/cm^3 for the asthenosphere to about 3.30 g/cm^3 since thermal contraction makes it denser than the asthenospheric material. As a consequence the mean density of the oceanic lithosphere as an entirety (lithospheric mantle plus oceanic crust) increases with the thickness of the lithospheric mantle. At a certain point depending on the spreading velocity and the distance from the spreading center, the stable layering changes into instability with a slightly denser lithosphere on top of the lighter asthenosphere (Figure 2). This configuration applies for lithosphere older than 80–90 myrs in relation to the onset of spreading at a mid-oceanic ridge. With an instable layering, a new subduction zone may be initiated spontaneously by gravitational downwelling of old oceanic lithosphere.

The continental lithosphere is composed of the lithospheric mantle and the continental crust with a large variety of rocks formed during the entire Earth's history. Continental crust is unsubductable because of its little density. Although the lower part is made up of gabbroic/basaltic and granulitic rocks, the mean density of the entire continental crust is about 2.7 g/cm^3 and thus significantly lower than oceanic crust (Figure 1). Rocks of the upper

portion of the continental crust were formed mostly by processes that changed the primary composition of the parent material. Basaltic magmas differentiate into lighter melts, forming felsic (word combines letters from feldspar and silica), plutonic, and volcanic rocks (e.g., granite, granodiorite, and, resp., rhyolite, dacite, etc.) that are enriched in silica and light elements (O, Al, Na, K). Erosion, transportation, and sedimentation result in the formation of sedimentary rocks, and, caused by continuous sedimentation and orogenic processes, the rocks may be metamorphosed by elevated pressure and temperatures. During the Earth's history, the amount of continental crust has been increasing, and the growth appears to have occurred in spurts of increased activity corresponding to the preservation of juvenile continental crust due to the formation of supercontinents (Condie, 2000). It is assumed that basaltic eruptions of superplumes and the subsequent magmatic and erosional processing of the basaltic protolith are the most important contribution of crustal growth (Albarède, 1998).

The thickness of the lithosphere depends on the plate tectonic setting. Normally, an evolved continental lithosphere has a thickness of about 90–120 km; oceanic lithosphere is slightly thinner with 70–90 km (Figure 1). This is mainly the result of the different thicknesses of oceanic vs. continental crust. Oceanic crust has a thickness of 5 to mostly 8 km, whereas an evolved continental crust has an average thickness of 30–35 km. Abnormal thin lithosphere exists in continental rifts, where the continental lithosphere may be less than 50 km thick, and at mid-oceanic spreading centers, where new oceanic lithosphere is formed. In these narrow zones, the lithosphere is confined to a thin layer (2–5 km) of oceanic crust only. The oceanic lithosphere is getting thicker with increasing distance from the spreading ridge (see above). Continental lithosphere may be substantially thickened during orogenetic processes. The collision of two continental plates results in the development of large mountain ranges such as the Himalayas or the Alps where overthrusting of large portions of the continental crust occurs. This may result in
Lithosphere: Structure and Composition, Figure 2 Increasing thickness and mean density of the oceanic lithosphere as a function of temperature (T), pressure (p), and age (distance to the mid-oceanic spreading center). The stable layering becomes instable with the increasing age of the lithosphere. Numbers refer to mean density of total oceanic lithosphere and upper mantle, respectively.

the thickening of the continental lithosphere to more than 200 km and a doubling of the crustal part of the lithosphere which may sum up to more than 75 km in maximum (Figure 1). This yields an isostatically instable situation which over long periods of time will be compensated by surface erosion and isostatic rebound until the average thickness of continental crust of 30–35 km is restored.

Composition

The lithosphere is the most rigid layer of the Earth. It behaves far less ductile than the asthenosphere, which is partially molten (from 1 % to 5 %, higher percentage underneath mid-oceanic spreading ridges) and thus able to provide the mobility necessary for the tectonic movement of the lithospheric plates. However, the exact composition of the mantle is not known with certainty. For the upper mantle, it is inferred from rock material found as xenoliths in volcanic lavas originating from deep magma sources of up to 300 km depth and from ophiolites which are considered to represent lithospheric mantle and oceanic crust material. The mean composition of the upper

mantle rocks is geochemically determined as 45 % SiO_2, 38 % MgO, 8 % FeO, 4.5 % Al_2O_3, 3.5 % CaO, and 1 % other additional compounds (Schubert et al., 2001). In terms of mineralogic composition, it consists mostly of olivine (~58 %), a magnesium-silicate undersaturated in silica (($Mg,Fe)_2[SiO_4]$), of two different pyroxenes, the orthopyroxene enstatite ($Mg_2[Si_2O_6]$; ~14 %) and the clinopyroxene diopside ($CaMg[Si_2O_6]$; ~16 %), and garnet (~12 %). Because of increasing pressure in deeper parts of the mantle, the olivine is transformed into the denser crystallographic spinel structure in the transition zone below the asthenosphere at about 400–410 km depth (Figure 2), where the seismic velocity strongly increases.

Typical mantle rock types formed by the minerals mentioned above belong to the group of peridotites. The asthenosphere consists on average of a garnet-bearing lherzolite as a specific type of peridotite (type locality at Lac de Lherz, French Pyrenees). It is mostly composed of olivine, orthopyroxene, clinopyroxene, and garnet. The lherzolitic composition is modified when the asthenospheric material ascends into a wedge below a mid-oceanic spreading center. The rise of peridotite causes
Lithosphere: Structure and Composition, Figure 3 Strength profiles of oceanic vs. continental lithosphere (modified after Kearey et al. 2009). *qtz-fsp* quartzo-feldspathic rocks, *ol* olivine-dominated peridotite.

an increase in partial melting because of pressure reduction. This melt has a basaltic composition and forms the new oceanic crust at spreading centers. The original lherzolitic peridotite of the asthenosphere changes into a harzburgite composition (type locality at Bad Harzburg, Germany) which is mainly composed of olivine and orthopyroxene and dunite (mostly olivine). The clinopyroxene predominantly migrates into the basaltic melt at the spreading centers. Eclogites with omphacite (a pyroxene) and garnet as main compounds develop at subduction zones when gabbroic/basaltic rocks reach high-temperature/low-pressure metamorphic conditions with the descending slab of oceanic lithosphere (Figure 2). All observed mantle material, which is today exposed, for instance, in ophiolitic assemblages, is not primary but has had a liquid fraction removed by partial melting. The removed material is of basaltic composition. To reconstruct the original composition, Ringwood (1962) assumed that the upper part of the lithospheric mantle consists mainly of dunite and peridotite. More primitive material follows further downward. Chemically, these rocks correspond to a mixture of one part of basalt to four parts of dunite. He named this hypothetical primitive material "pyrolite" which is taken as an equivalent for primitive fertile mantle.

Strength

Depending on loading conditions and time scale, the lithosphere exhibits elastic, brittle, or ductile properties

(Kirby, 1983; Turcotte and Schubert, 2002). At relatively low temperatures near the surface, rocks tend to break under stress. This is called brittle deformation. At greater depth, as temperature and pressure increase, it is more likely that rocks will accommodate stress by changing shape or deforming (compression, stretching, bending), rather than breaking. This is called ductile deformation which means the ability of a solid material to deform under stress without breaking. The strength of the lithosphere (i.e., the total force per unit width necessary to deform a lithospheric section at a given strain rate) is a function of temperature, composition, and crustal thickness. Confining pressure increases the rock strength but, on the other hand, increasing temperature weakens the rocks. At low temperatures frictional processes dominate and brittle deformation occurs. With increasing depth, the temperature overcomes the strengthening effect of confining pressure, leading to a ductile behavior (Figure 3).

The large-scale strength characteristics of oceanic and continental lithosphere differ. The oceanic lithosphere increases in strength down to the brittle-ductile transition in the lithospheric mantle at a depth of about 30–40 km. Beneath the brittle-ductile transition zone, the ductility increases and the strength decreases. The continental lithosphere has a bimodal strength profile. The first maximum in strength occurs at the brittle-ductile transition in the continental crust at a depth of about 20–30 km, where most of the earthquakes nucleate. A second maximum is observed below the Moho in the lithospheric mantle at a

depth of about 40–50 km where the rock composition changes from quartzo-feldspathic rocks to olivine-dominated peridotite (Figure 3).

Lithospheric rocks are considered elastic, but not viscous, and exhibit at least a minimum of strength. At some depth the temperature reaches a critical point when rocks start behaving like a viscous fluid. That depth is treated as the boundary between lithosphere and asthenosphere. The asthenosphere is viscous because partial melting occurs in the order of 1–5 %, which allows for the movement of lithospheric plates relative to each other. This process is known as plate tectonics.

LITHOSTRATIGRAPHY

Rüdiger Henrich
Department of Geosciences, University of Bremen, Bremen, Germany

Lithostratigraphy comprises the categorization of sediment/rock strata based on lithology (e.g., color, texture, grain size, and composition), physical properties (seismic character, nature of well log response, magnetic susceptibility), and structural sedimentary inventory.

A broad spectrum of methods is applied to describe and correlate marine lithostratigraphic units. This includes visual core description, smear slide analysis, digital imaging, diffuse color reflectance spectrophotometry, magnetic susceptibility, physical properties (gamma ray attenuation, moisture, density, sonic), grain size analysis, and geochemical analysis (e.g., $CaCO_3$, TOC, element composition measured with an XRF sediment scanner).

Fundamental unit of lithostratigraphy is the formation comprising beds as subunits that may reveal similar lithologies or were deposited in a certain environment. The higher hierarchy of classification terms includes groups and supergroups. Sediments deposited under similar conditions revealing distinct lithological, structural, and paleontological characteristics are summarized as facies. Walther's law, the most important principle concerning lateral variation and vertical stacking of facies, implies that facies that occur in conformable vertical succession of strata also occur in laterally adjacent environments. Also, it is essential to realize that the extension of facies bodies is always limited. They laterally and vertically pinch out and/or transit into another facies. Hence, the spatial arrangement of facies is in the form of more or less elongated lens-shaped bodies that are vertically stacked on top of each other. In the marine realm, pelagic facies often develops far extending flat lens-shaped units, whereas continental margin and shelf settings comprise less-extensive and complex-shaped facies bodies often interfingering in complex manner. These aspects bear essential implications when applying lithostratigraphic correlations. The use of bed and facies boundaries as chronostratigraphic time lines is limited and thus should always be calibrated with chrono- and biostratigraphic methods. In open ocean settings, different surface water masses are characterized by typical pelagic communities with distinct feed webs and production patterns (see Hüneke and Henrich (2011) for review). In addition, changes in surface water mass configurations and their properties, in particular their pelagic production rate, often correspond with climate shifts and thus represent time lines that can be traced over far distances. Hence, certain pelagic parameter records, for example, carbonate records, have been successfully applied as stratigraphic tools. However, due to variable lateral advection of terrigenous material (see Henrich and Hüneke 2011), the applicability of carbonate records as stratigraphic tools is rather limited in continental margin and shelf settings. On the other hand, distinct short-term sedimentation events like volcanic eruptions (e.g., volcanic ash layers) or glaciomarine diamictons and IRD layers (i.e., Heinrich events) deposited during the rapid decay of the marine-based parts of huge ice sheets (see review by Henrich and Hüneke (2011)) provide excellent time lines for lithostratigraphic correlations.

M

MAGMATISM AT CONVERGENT PLATE BOUNDARIES

Robert J. Stern
Department of Geosciences, University of Texas at Dallas, Richardson, TX, USA

Synonyms

Arc magmatism; Island arc; Magmatism; Subduction zone magmatism

Definition

Convergent margin magmatism – also called arc magmatism – occurs at straight or curved alignments (arcs) of discrete volcano-plutonic complexes that form above a subduction zone, where oceanic plate material (lithosphere plus sediments) is recycled into Earth's mantle (Figure 1). Convergent plate margins are one of the two types of plate boundaries where abundant igneous activity is caused by plate tectonics (the other is associated with divergent plate boundaries or mid-ocean ridges (MOR); hot-spot or within-plate igneous activity may be related to mantle plumes). Convergent margins and associated igneous activity occur in three regions: (A) around most of the Pacific Ocean (circum-Pacific Ring of Fire), (B) along much of the southern margin of Eurasia; and (C) in two short arcs in the western Atlantic Ocean (Figure 2).

Principal Components: Convergent margins are subdivided into forearc, volcanic front, and backarc (Figure 1) with increasing distance from the plate boundary, marked by the trench. Forearcs are stable regions underlain by cool mantle, in contrast to the volcanic front, which is underlain by hot mantle. Forearc crust is generated when the subduction zone first formed and is often emplaced on land as ophiolite (Stern et al., 2012).

Accretionary Wedges are found only for active continental margins with high sedimentation rates. Island arc magmatic activity is concentrated at the volcanic front (sometimes called the magmatic front, because not all magmas erupt), defined as the locus of the first volcanoes inboard from the trench. Some island arcs are under tension. Extension can be so strong that true seafloor spreading occurs, forming a backarc basin (Taylor, 1995). Backarc basins are entirely submarine, lying ~2–5 km below the sea surface. Actively spreading backarc basins are associated with the Aeolian, S. Sandwich, Tonga-Kermadec, New Hebrides, Andaman-Nicobar, and Mariana arcs, and are also found in the western Mediterranean Sea (Figure 2). Many marginal seas originated as backarc basins. Active backarc basin spreading ridges erupt basalts that are similar in composition to those erupted at mid-ocean ridges except for containing much higher concentrations of magmatic water and fluid-mobile trace elements. In contrast to subduction zones and associated island arcs, which remain active for several tens or even hundreds of millions of years, backarc basins stay active for only 10–20 million years, perhaps because continued widening due to seafloor spreading eventually separates the region of mantle upwelling from subduction-related water inputs needed for melt generation (Stern and Dickinson, 2010). Interarc rifts also can be found where island arcs experience extension, but not to the point of seafloor spreading. Interarc rifts are associated with the Ryukyu, Izu, and Aegean arcs.

Subduction zone and mantle wedge processes

Generally built above a dipping zone of earthquakes, convergent margin magmatism demonstrates that a subduction zone operates deep beneath a region. Subduction zones mark the subsurface expression of convergent plate boundaries, one of the three main types of plate tectonic boundaries, the others being divergent and transform plate
Magmatism at Convergent Plate Boundaries, Figure 1 Simplified cross-section of a convergent plate margin and underlying subduction zone, emphasizing flow of asthenospheric mantle in Mantle Wedge (*thin black arrows*) driven by motion of subducted oceanic plate (Subducted Slab) accompanied by transfer of fluids and melts emanating from subducted oceanic crust and sediments to mantle wedge (*thin blue arrows*). *Yellow and red regions* indicate seismically slow regions based on seismic tomography beneath NE Japan (Nakajima et al., 2005); these are interpreted as partially melted mantle. boundaries. There are 55,000 km of convergent plate boundaries on Earth (Figure 2; Lallemand, 1999). Subduction zones were first recognized by dipping arrays of earthquakes, called Wadati-Benioff zones (WBZs) after the two Japanese and American seismologists who recognized this geometry (see earthquake foci, Figure 1). Subduction zone earthquakes are unique in that they can occur much deeper (down to 670 km) than in any other tectonic environment, where seismicity is shallower than 30 km. Because earthquakes occur where rocks are cold enough to break, the greater depth indicates that subduction zones are unusually cold regions of Earth's mantle, due to downwelling of cold surface rocks. The somewhat puzzling recognition that convergent margin magmatism is associated with cold regions of mantle downwelling is explained by what happens where cold, wet, subducted seafloor mixes with hot circulating mantle (asthenosphere) above a subduction zone.

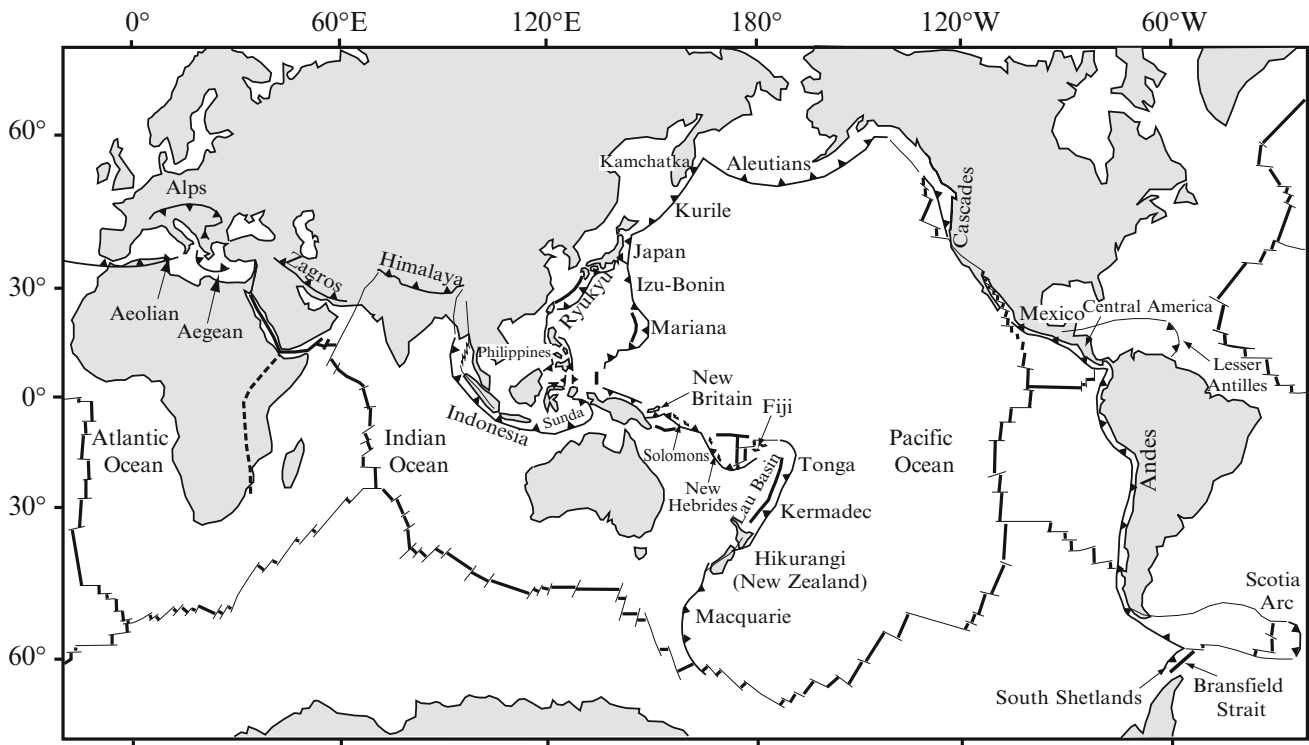
Oceanic plate material (slab) is ~100 km thick. It is overwhelmingly composed of relatively cool upper mantle lithosphere, ~6 km of variably altered oceanic crust, and a few hundred meters of sediment. These three components of the subducted slab play different roles in subduction zone processes. The density of the mantle component makes the slab sink, the altered oceanic crust provides most of the water to stimulate the overlying mantle to melt, and the thin sediments (<0.5 % of subducted slab mass) control the geochemically distinctive composition of convergent margin magmas. Because it has been seafloor for tens or even hundreds of millions of years, the upper parts of slabs (sediment, oceanic crust, and uppermost mantle) are cold and wet as the plate arrives at an oceanic trench and starts to sink into a subduction zone. This material is progressively squeezed and baked as it descends (1 in Figure 1), first liberating water and then at greater depth, partial melts of the subducted sediments. Subducted oceanic crust generally does not melt except where very young, hot seafloor or an active mid-ocean ridge is subducted or along subducted plate edges (Drummond and Defant, 1990). Hydrous fluids and melts rise into the overlying wedge of mantle, hydrating and altering (metasomatizing) its base (2.1 in Figure 1).


Magmatism at Convergent Plate Boundaries, Figure 2 Global map of major convergent and divergent plate boundaries, also showing the location of oceanic convergent margins (map modified from Stern (2002). Reproduced by permission of American Geophysical Union).

The wet base of the mantle wedge is viscously coupled with the sinking slab and is also carried down with, releasing more fluids as these descend together (2.2 in Figure 1).

Somehow – the general process is clear but the details are still being worked out – hydrous fluids, sediment melts, and (rarely) oceanic crust melts ascend through several tens of kilometers of downward-flowing mantle to reach mantle that is hot enough to melt when fluxed by hydrous fluids or sediment melts (3 in Figure 1). This is because the addition of such liquids reduces the melting temperature of mantle peridotite by several hundred °C (Grove et al., 2012). Partial melting of the mantle generally occurs where the subduction zone lies 100–130 km deep. Mantle melting forms primitive magma, called "basalt." Like basalt melts from other tectonic environments, those of convergent margins have low contents of Si and high contents of Mg. Because of the way they are generated, primitive convergent margin magmas contain much higher concentrations of water than primitive basalts from other tectonic environments, typically 3–4 wt% H_2O, compared to <0.5 wt% H_2O in mid-ocean ridge basalts (Stern, 2002). Arc magmas also are enriched in trace elements that are transported in fluids (especially alkali metals and alkaline earths K, Rb, Ba, and Sr; also U and Pb), sweated out of subducted sediments and altered oceanic crust.

Crustal processes

Although deep subduction zone processes are everywhere similar, eruptive products, eruptive style, and mineralization vary widely, largely depending on the crust on the overriding plate. If this is thick continental crust, then an active continental margin with towering volcanic mountains like the Andes results; if this is thin oceanic crust, then chains of mostly submerged volcanoes known as island arcs develop. These volcanic islands may rise from bases 2–3 km below sealevel and can be wholly submarine seamounts or partially subaerial if the summits of stratovolcanoes are tall enough to emerge from the sea. Whether they rise above sealevel or not, arc volcanoes are typically spaced 20–30 km apart (mean = 27 km; de Ronde et al., 2003). The total length of island arcs is ~22,000 km (de Ronde et al., 2003], about one third of the total length of mid-ocean ridges (Baker et al., 2008). About one third of this is made up of intraoceanic arcs (i.e., built on oceanic crust: Izu-Bonin-Mariana, Tonga-Kermadec, Aleutians, and South Sandwich arcs; Figure 2); the remainder are built on thinned or rifted continental crust, such as Indonesia or Japan Intra-oceanic arcs are particularly difficult to study because these are mostly under water but they are of special interest because constructing formation of juvenile arc crust is thought to be the first step in forming continental crust (Stern 2010).
Magmatism at Convergent Plate Boundaries, Figure 3 Idealized convergent margin volcano-plutonic complex, from Stern (2002). Trench is to the right. Only an idealized section through an intraoceanic arc is shown; similar processes are expected beneath Andean-type arcs. Note that the asthenosphere is shown extending up to the base of the crust; delamination or negative diapirism is shown, with blocks of the lower crust sinking into and being abraded by convecting mantle. Regions where degassing of CO_2 and H_2O is expected are also shown (Reproduced by permission of American Geophysical Union).

Primitive basaltic melt is typically ~1,300 °C as it rises out of the mantle wedge but such hot, primitive melt rarely erupts without interacting with and being changed by the crust that it has to pass through. Some rising primitive melts heat the crust and cause it to melt, yielding secondary "anatectic" magmas, which form at much lower temperatures of ~800 °C. Other primitive basaltic melts pool in crustal magma chambers, fractionating as the cooling magma forms crystals that settle out, changing the composition of the residual melt. Both secondary melting and fractional crystallization yield melts that are significantly enriched in silica. These are felsic magmas, akin to granite, and known by their volcanic names: dacite and rhyolite. Felsic igneous rocks are important components of island arcs and are even more important parts of plutonic arc crust. Felsic magmagenesis is complemented by formation of denser lower crust gabbro and pyroxenitic upper mantle cumulates (Figure 3).

The abundance of felsic magmas in convergent margins partly results from the fact that these volcanoes remain over the same crustal tract for unusually long times. In contrast to volcanoes at divergent plate boundaries and hot spots on fast-moving plates, which have short and simple lives, convergent margin volcanoes and the magma plumbing system beneath them are more complex because they grow where magma flows up to the surface for millions of years. Such long volcano lifetimes result because the volcanic front occurs where the subducted plate is ~110 km deep. The volcanic front migrates if the dip of the subducted slab varies much, moving farther away from the trench if slab dip decreases, closer to the trench if slab dip increases. However, subduction zones are massive, slow-moving features that extend deep into the Earth. Unless something happens to disrupt well-established downwelling – such as subduction of buoyant continental crust or break-off of part of the slab – the subduction zone geometry and the location of the volcanic front, with its underlying magmatic plumbing system, will remain approximately in the same position for many millions of years.

Because the location of the volcanic front may not change much, arc volcanoes tend to develop "hot zones" at the base of the crust overlain by variably warm, weak crust surrounding conduits (Annen et al. 2006). This

reflects cumulative heating by innumerable pulses of ~1,300 °C magma moving from the upper mantle through the crust towards the surface. The crust is further heated when basaltic magma stalls in it without erupting. Crustal melts and products of fractional crystallization are both felsic combine to generate andesitic and felsic melts. The more felsic the magma, the more polymerized it is, because Si and O link up to form long chains of silicon and oxygen that resist flow. The Si-rich, viscous nature of magmas are half of the reason that convergent margin eruptions are the most violent of among the three great tectonic settings.

The volatile-rich nature (especially H_2O, CO_2, and S) of convergent margin magmas is the other half of the reason that convergent margin magmas can erupt so explosively – and why most ore deposits are associated with ancient arcs. Of the three great magmatotectonic settings, convergent margin magmas contain by far the greatest concentration of magmatic gases and volatiles (Roggensack et al., 1997; Plank et al., 2013). Convergent margin high-Si melts inherit the water- and sulfur-rich nature of the mantle melt, which ultimately result from the fluids released by the subducted slab. The volatiles are dissolved in the magma when it forms in the upper mantle but are released as magma approaches the surface and pressure is greatly reduced. The exsolved volatiles turn into gas bubbles with a tremendous increase in volume. The gas bubbles can escape quietly through low-viscosity mafic magma but must break out violently if they are in viscous felsic magma.

A significant proportion of convergent margin melts crystallize several kilometers deep within the crust, where they form large bodies of crystalline rocks known as plutons (Figure 3). Plutons are similar in scale to the overlying volcano, typically several to a few tens of kilometers in diameter. Although lavas and other products of volcanoes characterize an active island arc, once a subduction zone stops operating (perhaps due to plate collision), the associated magmatic arc shuts down; erosion remove the volcanic rocks and exposes the plutonic roots of the arc. Because island arcs are elongate magmatic systems, an ancient arc can be identified by similarly elongate aggregations of plutons called batholiths. Batholiths, like island arcs, are typically about 100 km wide and thousands of kilometers long. Examples of batholiths include the Sierra Nevada of California, which is spectacularly exposed at Yosemite National Park, USA.

Volcanism

Eruptions from island arc volcanoes can be especially violent and dangerous. This is partly due to high volatile contents (especially water) in both primitive (basaltic) convergent margin magmas and more evolved felsic magmas, and this powers the violence of eruptions from volcanoes at convergent margins. Because the solubility of volatiles in magma decreases as pressure falls during magma ascent, volatiles are progressively released as magma rises towards the surface prior to eruption. This involves a tremendous increase in volume when pressure is low enough for magmatic volatiles to flash into gas. Depending on the viscosity of the magma, the rate of volatile diffusion from the melt into the gas phase varies, which – depending on magma ascent rate – can lead to volatile supersaturation in magmas and dramatic explosive bubble nucleation and greater magma acceleration. Because magmatic volatiles readily exsolve out of low viscosity mafic magmas and the bubbles can rise faster than the melt phase (i.e., are decoupled), basaltic eruptions tend to be less dangerous (but note that there are examples of more violent "Plinian" basaltic eruptions, such as 1886 Mt. Tarawera, New Zealand eruption). In contrast, in high viscosity felsic melt bubbles often remain coupled, driving high magma buoyancy and acceleration, making subaerial felsic eruptions the most violent on Earth.

Today, eruption violence is measured using the Volcanic Explosivity Index (VEI; Newhall and Self, 1982) a logarithmic scale (base 10) for erupted volume. The largest Cenozoic eruptions have VEI = 8: Yellowstone 630 ka; Toba 74 ka; Taupo 26.5 ka. These entail violent and catastrophic eruptions where >1,000 km^3 of magma is erupted over short durations of likely weeks to months.

Submarine arc volcanism is not yet well understood compared to subaerial volcanism but stunning discoveries (Embley et al., 2007) encourage further exploration. In some ways submarine volcanism is very different than subaerial counterparts. In contrast to eruptions into the atmosphere, eruption into water strongly modifies eruption and pyroclast transport processes due to the contrasting properties of water compared to air. Increasing hydrostatic pressure associated with increasing eruption depth influences volatile exsolution and particularly expansion in the shallow conduit during magma ascent. Magma fragmentation and pyroclast transport processes are also strongly modified in the submarine setting due to the greater heat capacity, density and viscosity of water compared with air.

Submarine arc volcanism is not yet well understood, however it is very likely that this mode of eruption shows as much variability in style as subaerial volcanism. Submarine basaltic eruptions range from quiet effusion (including pillow basalts), and low to moderate intensity explosive eruptions. Felsic eruptions are also common along submarine volcanic arcs, from effusive dome growth and spalling of the pumiceous carapace to low – moderate explosive cone-forming eruptions and likely catastrophic caldera-forming eruptions (Fiske et al., 2001; Smith et al., 2003). Subaqueous eruptions are poorly understood for several reasons, most notably the lack of witnessed eruptions, but it is clear from theory and seafloor exploration with submergence vehicles that increasing hydrostatic pressure has a profound effect on limiting explosivity (e.g., Allen and McPhie 2009). In the last decade remote sensing methods together with some good luck has led to the observations of both basaltic and felsic submarine eruptions (e.g., West Mata volcano in

Island Arc Mineralization
Magmatism at Convergent Plate Boundaries, Figure 4 Schematic illustration of the major geological characteristics of mineral deposit types that typically occur in oceanic arc environment and back-arc spreading center, modified after Figure 14 of Lydon (2007).

the NE Lau Basin (Resing et al., 2011; https://www.youtube.com/watch?v=xRaEcGHHsVY), NW Rota in the Mariana Arc (Chadwick et al., 2008; https://www.youtube.com/watch?v=Cz4niudHwMs); Havre volcano in the Kermadec arc, NZ (Carey et al., 2014; Figure 2). Such events have dramatically increased our knowledge of submarine eruption and pyroclast transport processes, and challenged existing paradigms in volcanology.

Sulfur

Consonant with their volatile-rich nature, convergent margin magmas generally contain more S than those from other tectonic settings (Sharma et al., 2004). This is manifested in several ways. One is that lakes of molten sulfur are sometimes found on convergent margin volcanoes, both above and below sealevel. Sulfur pools at the bottoms of crater lakes exist on subaerial volcanoes in Central America, Indonesia, Andes, and Japan (Kim et al., 2011). Molten sulfur forms as a result of the disproportionation of magmatic sulfur dioxide (SO_2), released from degassing magma, according to the reaction $SO_2 + H_2O = H_2SO_4 + S$. Pools of molten sulfur in equilibrium with acid water is the result. Examples of active disproportionation associated with a submarine eruption has been investigated at NW Rota-1 in the Mariana arc, where yellowish clouds of newly-formed sulfur billowed out of the eruption pit http://www.youtube.com/watch?

v=RY3a7rIFlEs. Pools of molten sulfur are also found in craters of some submarine volcanoes, for example the summits of Nikko and Daikoku in the Mariana Arc (Embley et al., 2007) and in Volcano O in the Lau Basin (Kim et al., 2011; Figure 2).

The combined effects of magmatic sulfur and explosive arc volcanism can affect climate. During Plinian eruptions, magmatic SO_2 is converted to small (0.1-1 mm diameter) droplets of sulfuric acid and, if injected into the stratosphere, can remain suspended for many months, encircling the globe. These droplets reflect incoming sunlight, cooling the Earth below and modifying climate. As an example of this, the 1991 eruption of Pinatubo in the Philippines resulted in Northern Hemisphere were lower than normal by up to 3 °C in the winters of 1991–1992 and 1992–1993 (Robock, 2000).

Mineral deposits

Sulfide mineral deposits are another important manifestation of magmatic sulfur in convergent margin magmas. Important mineral deposits are associated with modern and ancient island arcs, including interarc rifts and backarc basins (Figure 4). Arc mineral deposits are dominated by Cu-Pb-Zn-Au sulfides (Hannington et al., 2005). The style of mineralization is related to arc crust composition and thickness (Kessler, 1997). Some deposits form via submarine hydrothermal and magmatic degassing systems on the

seafloor (de Ronde et al., 2003) and others are associated with subvolcanic intrusions above sealevel (Lydon, 2007). In both cases, mineralizing fluids transport metals to the site of deposition.

There are two sources of mineralizing fluids in submarine arc volcanoes: (1) metals derived through leaching of pre-existing rock by ambient surface water; and (2) metals derived from a degassing magma body. In the first case, seawater or groundwater is heated and acidified by reaction with degassing sulfur. Fluids associated with convergent margin magmas are very acidic and corrosive because these magmas release tremendous amounts of sulfur; this combines with H_2O to produce H_2SO_4, sulfuric acid. These hot, acid waters are produced when heated by a magma body, resulting in development of a hydrothermal convection cell. This draws in cold water to be heated and acidified above the magma body, which then rises to the surface along faults and fractures, which become upflow channels. Hydrothermal circulation and mineralization are enhanced in calderas, where major faults favor fluid circulation above a shallow magma body. The circulation of hot, acidic solutions through the surrounding rock leaches and breaks down primary igneous minerals into clays – hydrothermal ore deposits are invariably associated with a lot of extremely altered rocks – and such alteration liberates a lot of metals, which are carried away by the acidic fluids. In the second case, metals are released by magmatic degassing of metal-enriched volatiles. Most ore-bearing fluids reflect the combined effects of both hydrothermal leaching and magmatic degassing, and the relative contributions are likely to vary in time and space (Yang and Scott, 1996).

However the metal-bearing acid solutions are generated, the metals these transport will ultimately be deposited where and when the fluid interacts with a different chemical environment, especially where the rising acid fluid mixes with higher pH fluids, such as seawater. This can form massive sulfide deposits associated with backarc basin hydrothermal vents, which are very much like black smokers associated with mid-ocean ridges. Another style of mineralization occurs if the fluid rises into a region where P is low enough that the fluid boils away, leaving the metals behind. This is what happens in shallow subvolcanic intrusions such as porphyry deposits (Sillitoe, 1997). Phase separation (boiling) is also common in arc and even backarc basin hydrothermal systems. Some ore deposits that form in other tectonic environments reflect the generation of immiscible sulfide liquid, which separates from the silicate melt and sinks to the bottom to form mineral deposits, such as the giant Bushveld deposit of S. Africa. This mode of mineralization is not common in island arcs because the magma is too rich in H_2O and O_2 to form much reduced sulfur (sulfide) in the magma body.

The composition of the host magma can also exert important controls on mineralization. For example, sulfide deposits that are commonly associated with felsic igneous activity (both intrusive and extrusive) are typically Pb, In, Bi, and Sb (+/− Au, Ag)-rich, compared to those associated with predominantly mafic igneous rocks, which tend to be more Cu, Zn and Co (+/− Au, Ag)-rich (Timm et al., 2012). Similarly, styles of mineralization vary according to whether igneous activity is submarine (volcanogenic or Kuroko-type massive sulfides) or at shallow depth beneath a large volcano (porphyry and epithermal deposits).

The hydrothermal system associated with Brothers Volcano in the Kermadec arc, NZ (Figure 2) is a good example of submarine arc hydrothermal mineralization. Hydrothermal vents are found at three sites in the caldera at 1,300–1,800 m water depth associated with dacite and rhyodacite domes above a mafic substrate. Hot (max. 305 °C), acidic (pH > 1.9) fluids vent through sulfide chimneys up to 7 m tall (de Ronde et al., 2005). Hydrothermal vents are concentrated along caldera faults. Two main types of chimneys predominate: Cu-rich (up to 28.5 wt% Cu) and more common Zn-rich (up to 48.5 wt% Zn; de Ronde and 18 others 2011). Brothers hydrothermal fields only ~3 km apart provide useful examples of the range of hydrothermal processes and sources seen in submarine arc volcanoes. The Cone hydrothermal site is today more strongly affected by degassed magmatic components than is the NW Caldera site. These two Brothers vent fields represent near end-members of a continuum that spans magma-dominated and seawater-dominated hydrothermal system.

Porphyry Cu-Au deposits are another important style of arc mineralization. This mineralization is found in shallow plutonic rocks affected by rapid uplift, cooling, and depressurization of upper crustal magma chambers, releasing metal-bearing magmatic fluids. Porphyry Cu-Au and epithermal deposits seem to be more common in atypical arc settings and in association with unusual, especially highly potassic, igneous rocks (Sillitoe, 1997).

Summary

Igneous activity at convergent plate boundaries is one of the most important manifestations of plate tectonics. Convergent-margin basalts demonstrate that crust and sediments are being recycled back down into earth's mantle in the underlying subduction zone, and that some of this deeply-recycled material has escaped up into and mixed with overlying mantle and caused it to melt. Basaltic magmas rise from the mantle above the subduction zone towards the surface. Among all Earth magmas, those produced at convergent margins contain the highest concentrations of magmatic volatiles, especially water. Long, curved alignments of volcanoes in the ocean define island arcs, and similar alignments on continental margins mark where the flux of magma out of the mantle above a subduction zone is especially great. Some mantle-derived magmas don't rise to the surface but stall in the crust. The interaction of mantle-derived magma with pre-existing crust sometimes leads to fractional crystallization and secondary melting, forming magmas that are

much richer in silica than mantle melting yields. Because of the combination of high silica and water contents, arc volcanic eruptions are the most violent on Earth. Fortunately silica-rich arc magmas often stall in the crust, where they cool and form granitic plutons. Subterranean alignments of plutons in the crust beneath volcanic arcs define batholiths, which may be exposed after subduction stops and the volcanic cover is removed by erosion. Convergent margin igneous activity over Earth history is responsible for forming most continental crust and economic ore deposits.

MAGNETOSTRATIGRAPHY OF JURASSIC ROCKS

María Paula Iglesia Llanos
IGEBA, National Scientific and Research Council,
University of Buenos Aires, Buenos Aires, Argentina

Rocks can retain a magnetic imprint acquired in the geomagnetic field that existed during their formation. The main goal of magnetic polarity stratigraphy is to document and calibrate the global geomagnetic polarity sequence in stratified rocks and to apply this geomagnetic polarity scale for high-resolution correlation of marine magnetic anomalies and of polarity zones in other sections.

Magnetic polarity scales younger than 160 Ma are derived from seafloor magnetic anomalies. For older times, such scales must be derived from polarity successions obtained in the continents yielding a precise age control such as that provided by ammonites, i.e., 1 myr.

In this study, emphasis is paid to the Jurassic period. Five ammonite-bearing sections located to the north and center of the Neuquén basin, west-central Argentina, have been sampled for paleomagnetic purposes. These sections are made up of ammonite-bearing sedimentary and, subordinately, volcanic rocks of Lower Jurassic age.

The paleomagnetic study showed that there are two magnetic components, one soft that coincides with the dipolar field of the region and another one harder that is dissimilar from any younger magnetization. According to the field tests for paleomagnetic stability and petrographical studies, the latter component has been acquired during or shortly after the deposition (cooling) of sedimentary (volcanic) rocks. Thus, the hard component is interpreted as the original Jurassic.

With polarities isolated in all five sections, the first Lower Jurassic magnetostratigraphic scale of the Southern Hemisphere scale has been constructed. To anchor the polarities to the international geomagnetic scale, we used the ammonite zonation and correlation from Riccardi (2008), and the international geomagnetic polarity scale from Ogg (2004) has been considered. Thus, the resultant magnetostratigraphic scale is made up of 11 dominant reverse (JR_1 to JR_{11}) and 12 dominantly normal (JN_1 to JN_{12}) polarities, included in 19 ammonite zones. They comprise the Andean P. rectocostatum which is correlated with the Tethyan P. planorbis zone to the Andean Phymatoceras that is correlated with the Tethyan G. thouarsense.

With respect to the isolated polarities, a good correlation was achieved with the international scale that helped to constrain some issues that were still at loose ends. In the first place, in the Hettangian-Sinemurian interval, polarities comprised within the international Liasicus and Semicostatum biozones should be displaced down until the dominant normal polarity coincides with the regional JN_3. In the second place, during the Pliensbachian and Toarcian, the frequency of reversals increases, and yet, correlations between the scales are more solid. Results allowed assigning precise ages to those levels devoid of diagnostic fossils. This is the case of the Sinemurian-Pliensbachian boundary as well as the Toarcian in the north and the Pliensbachian-Toarcian in the center of the basin.

MANGANESE NODULES

James R. Hein
U.S. Geological Survey, Santa Cruz, CA, USA

Synonyms

Fe-Mn nodules; Ferromanganese nodules; Iron-manganese nodules; Polymetallic nodules

Definition

Manganese and iron oxide mineral deposits formed on or just below the sediment-covered surface of the deep-ocean seabed by accretion (precipitation) of oxide layers around a nucleus, thereby forming nodules of various shapes and sizes and which contain minor but significant amounts of nickel, copper, cobalt, lithium, molybdenum, zirconium, and rare earth elements.

Introduction

The existence of manganese (Mn) nodules (Figure 1) has been known since the late 1800s when they were collected during the Challenger expedition of 1873–1876. However, it was not until after WWII that nodules were further studied in detail for their ability to adsorb metals from seawater. Many of the early studies did not distinguish Mn nodules from Mn crusts. Economic interest in Mn nodules began in the late 1950s and early 1960s when John Mero finished his Ph.D. thesis on this subject, which was published in the journal Economic Geology (Mero, 1962) and later as a book (Mero, 1965). By the mid-1970s, large consortia had formed to search for and mine Mn nodules that occur between the Clarion and Clipperton fracture zones (CCZ) in the NE Pacific (Figure 2). This is still the area considered of greatest economic potential in the global ocean because of high nickel (Ni), copper (Cu), and Mn contents and the dense distribution of nodules in the area. While the mining of nodules was fully expected to begin in the late 1970s or early 1980s, this never occurred due to a downturn in the price of metals on the global market. Since then, many research cruises have been undertaken to study the CCZ nodules, and now 15 contracts for exploration sites have been given or are pending by the International Seabed Authority (ISA). Many books and science journal articles have been published summarizing the early work (e.g., Baturin, 1988; Halbach et al., 1988), and research has continued to the present day (e.g., ISA, 1999; ISA, 2010). Although the initial attraction for nodules was their high Ni, Cu, and Mn contents, subsequent work has shown that nodules host large quantities of other critical metals needed for high-tech, green-tech, and energy applications (Hein et al., 2013; Hein and Koschinsky, 2014).

Occurrence and distribution

Mn nodules are concretions that occur on or near the surface of the sediment that covers abyssal plains throughout the global ocean, where sedimentation rates are low, less than 10 centimeters (cm) per thousand years (Figure 2). Low sedimentation rates occur if the abyssal plain is distant from a continental margin or the margin is adjacent to a deep-sea trench, has a wide continental shelf, or is arid. In the open ocean, low sedimentation rates occur away from regions of strong upwelling and high biological productivity, such as the equatorial zone of high productivity. Nodules are generally about golf ball sized, most commonly 1–12 cm, but can vary in diameter from millimeter (mm)-size (micronodules) to as large as 20 cm. The maximum size of nodules increases with increasing diagenetic input of metals (see next section). Nodules of greatest economic interest occur in areas of moderate primary productivity in surface waters (ISA, 2010). The location of nodule growth relative to the calcite compensation depth (CCD), controlled by productivity in surface waters, is important because above the CCD, biogenic calcite increases sedimentation rates and dilutes the organic matter required for diagenetic reactions in the sediment that release Ni and Cu (Verlaan et al., 2004; Cronan, 2006). The most Ni- and Cu-rich nodules form near, but generally below the CCD.

Most Mn nodules form at water depths of about 3,500–6,500 meters (m), although abyssal plains can have hills and ridges several hundred meters high and seamounts up to 2 kilometers (km) high rising above the plains. Nodules can occur on all of those structures if they are covered by sediment. Mn nodules have been collected from many of the large seamounts on which Fe-Mn crusts form, but most of those nodules differ significantly from abyssal plain nodules since the seamount nodules form by hydrogenetic accumulation only (see below) and commonly have a large rock fragment as the nucleus. The seamount nodules are mostly Mn- and iron (Fe)-oxide-coated rock pebbles and cobbles, while abyssal plain nodules usually have a minute nucleus relative to the thickness of the accreted Mn- and Fe-oxide layers.

The greatest concentrations of metal-rich nodules occur in the following regions: in the NE Pacific CCZ (Figure 2) that extends from the Mexico EEZ to as far west as the longitude of Hawaii, in the SE Pacific Peru Basin, in the central South Pacific Penrhyn Basin, and in the Central Indian Ocean Basin. In the CCZ, the Mn nodules lie on abyssal sediments covering an area of about nine million square kilometers with up to 75 kilograms (kg) of nodules per square m of seabed, but more commonly average less than 15 kg per square m wet weight. Their high abundance in this region can be attributed to slow rates of sedimentation, the abundant availability of material for the Mn and Fe to nucleate around, and moderate productivity in
Manganese Nodules, Figure 1 Manganese nodule photographs: (**a**) cross-section of a manganese nodule from the CCZ showing concentric layering (laminations), fractures, and a nucleus composed of an old nodule fragment, 4,353 m water depth; (**b**) diagenetic-hydrogenetic manganese nodules from the CCZ, NE Pacific Ocean; each nodule is 3 cm in diameter; (**c**) seafloor photograph of nodules within the CCZ nodule field and the trigger weight; field of view is about 3 × 4 m.

surface waters. Most Mn-nodule fields are found in areas beyond national jurisdictions, with the exception of the Penrhyn Basin field, which lies predominantly within the exclusive economic zone (EEZ) of the Cook Islands (Figure 2). Fewer large abyssal plains occur in the Atlantic and Indian Oceans compared to the Pacific, which are dominated topographically by the mid-ocean ridge systems. The large Argentine Basin in the SW Atlantic may possess nodule fields, but little exploration has occurred there.

Formation

Mn nodules grow by precipitation of Mn and Fe oxides around a nucleus that is commonly composed of a fragment of an older nodule. Unlike Mn crusts, the Mn and Fe minerals in nodules precipitate from two sources, cold seawater (hydrogenetic) and sediment pore waters (diagenetic), which is seawater modified by chemical reactions within the sediment. Nodules can be solely hydrogenetic (e.g., Penrhyn Basin and Atlantic Ocean; Figure 2) or solely diagenetic (such as Peru Basin; Figure 2), but most nodules acquire metals from both

sources. Hydrogenetic nodules grow remarkably slowly, at a rate of about 1 to 5 mm per million years, like Mn crusts, whereas diagenetic nodules grow at rates up to 250 mm per million years. Because most nodules form by both hydrogenetic and diagenetic precipitation, they grow at intermediate rates of several tens of mm per million years. Average nodule growth rates are four orders of magnitude slower than the sedimentation rates, yet the nodules remain at the sediment surface. There have been a number of proposals (e.g., Halbach et al., 1988) as to how this happens, although the actual cause is still a mystery.

Sediment pore fluids are the predominant source of Ni, Cu, and Mn, and seawater is the dominant source of cobalt (Co). Metals in the pore fluid are derived from early diagenetic oxidation-reduction (redox) reactions in upper sediment layers and are incorporated into the Mn-oxide minerals forming at the seabed.

Composition

Mn nodules are composed predominantly of the minerals δ-MnO_2 (hydrogenetic vernadite), 10 Å manganate (diagenetic todorokite, buserite, asbolan), and less
Manganese Nodules, Figure 2 Map of global distribution of Exclusive Economic Zones (EEZ, *gray shading*), areas beyond national jurisdictions (*dark black-blue* to *pale gray-blue*), and global permissive areas for development of abyssal plain manganese nodules; the Clarion-Clipperton Zone (CCZ) is the zone of greatest economic interest and is enclosed by a *yellow line*; all other areas are marked with a *white line*; a permissive area does not mean that economic nodule deposits will be found in that area; small patches of scattered nodules will occur in other areas; the equator and 180th parallel are marked by *gray lines*; *CIOB* Central Indian Ocean Basin.

commonly diagenetic birnessite; lesser amounts of X-ray amorphous Fe oxyhydroxides also occur. Minor amounts of detrital aluminosilicate minerals and quartz and authigenic minerals (formed in the sediment from alteration of other materials: volcanic glass, minerals, microfossils) are also present. The sheet and tunnel structures of the diagenetic Mn-oxide minerals, which allow for the acquisition from sediment pore fluids of large amounts of Ni, Cu, and other metals that strengthen the mineral structure, are important physical properties of Mn nodules.

Mn nodules typically have three to six times more Mn than Fe (Table 1), in contrast to Fe-Mn crusts, another type of deep-ocean mineral deposit (see entry on "Cobalt-rich Manganese Crusts"). Mn concentrations can be greater than 30 % in diagenetic nodules, such as Peru Basin nodules. Nickel and Cu have been the metals of greatest economic interest and have mean concentrations in four nodule fields that vary from 0.38 % to 1.32 % and 0.23 % to 1.07 %,

respectively (Table 1; 1,000 ppm = 0.1 %). These percentages will vary somewhat in mine-site-size areas (about 20,000 square km) within these major nodule fields. Nodules are also more enriched in Ni, Cu, and Li than Fe-Mn crusts, while crusts are more enriched in the other rare metals and the rare earth elements (REEs). The market for Li is growing because of its use in rechargeable batteries. Li in CCZ nodules averages 131 ppm and is especially high in diagenetic nodules, averaging 311 ppm in Peru Basin nodules (Hein and Koschinsky, 2014), the latter of which is comparable to grades in some terrestrial Li ores. REEs in nodules are also of economic interest but are generally two to six times lower than in Mn crusts, with maximum total REEs plus yttrium (Y) in CCZ nodules of about 0.08 %; however, the average for Cook Island nodules is 0.17 %. The main carrier for REEs and Y, in general, is the hydrogenetic component. Platinum (Pt) is very low in nodules compared to crusts and not of economic interest. Mean concentrations of other metals of interest as potential

by-products of Ni-Cu-Mn mining include Co (0.05–0.41 %), Mo (262–600 ppm), and zirconium (Zr; 307–752 ppm).

Resource consideration

The tonnages of nodules and therefore of the amount of contained metals are moderately well known for the CCZ and the Central Indian Ocean Basin nodules. A conservative estimate for the CCZ nodules is about 21,100 million dry tonnes. That tonnage of nodules would provide nearly 6,000 million tonnes of Mn, more than the entire land-based reserve base (LBRB) of Mn (Hein et al., 2013; Hein and Koschinsky, 2014). In addition, the tonnage of Ni is twice that of the entire LBRB, and Co is three times greater than the LBRB; the LBRB includes resources that are currently economic (reserves), marginally economic, and subeconomic. The amount of Cu in the CCZ nodules is about a fifth that of the LBRB. In addition, nodules in the CCZ have 1.4 times more tellurium (Te) and 4 times more Y than the entire LBRB. Metals in CCZ nodules as a percent of the LBRB are Mo 63 %, Li 19 %, and total REEs plus Y as oxides 11 %. Peru Basin nodules have the highest Li contents, and nodules there have roughly 2.7 million tonnes of contained Li; this tonnage of Li is the same as in the CCZ nodules, but with less than 42 % of the total dry tonnage of the CCZ nodules.

The high potential ore grades mentioned above in addition to other drivers have sparked an incredible amount of interest in mining Mn nodules. Some of these drivers include (1) the global population increasing beyond seven billion people and a growing middle class in developing countries with increased demands for goods containing many rare metals, (2) decreasing ore grades in existing land-based mines, and (3) the need to remove enormous amounts of barren-rock overburden to access ore bodies, necessitating development of ultra-deep open-pit mines and mega-underground operations.

The CCZ is the area of greatest economic interest and where 14 exploration contracts of 75,000 square km each and one of 58,620 square km have been signed or are pending with the ISA; there is also one nodule contract of 75,000 square km in the Central Indian Ocean Basin, signed with India. The total area of seabed under contract for nodule exploration amounts to 1,183,620 square km. States and state agencies with contracts in the CCZ include China, France, Germany, Japan, Korea, Russia, and Inter-Ocean Metals which is composed of a group of States: Bulgaria, Cuba, The Czech Republic, Poland, The Russia Federation, and The Slovak Republic. The rest of the CCZ contracts are with companies, four of which have partnered with a developing country: Nauru, Tonga, Kiribati, and Cook Islands.

The mining process does not present a major technological challenge because the nodules can be removed fairly easily from the surface of the sediment-covered seabed on which they rest. Trial excavation as early as 1978 was successful in transporting Mn nodules to a ship. New technology for the mining equipment is under development and is being scaled-up to work in larger areas for long-term operations. Riser pipe or other lifting technologies required to transport the ore from the seabed to the ship developed in the 1970s are also being improved with modern technology. The actual area of seabed that is mined will probably not exceed about 25 % of the 75,000 square km contract sites because of topographic obstacles and the lower abundance distribution of nodules. Before large-scale mining of nodules can be carried out, questions related to the environmental impact of mining activities must be addressed. Mining of Mn nodules would considerably disturb parts of the seabed and suspend sediment that will be carried by currents for as yet to be determined distances. The development of mining technology that significantly reduces the sediment plume would be an important advancement.

Summary

Mn nodules are found on the surface of sediment on all abyssal plains throughout the global ocean where sedimentation rates are low, less than 10 cm per thousand years. Nodules generally grow at rates of a few tens of mm per million years, yet they remain at the sediment surface even though sedimentation rates are four orders of magnitude higher, which is still a mystery. Nodules are composed predominantly of Mn minerals that precipitate from seawater and from sediment pore fluids and acquire abundant metals and other elements from those two sources by adsorption. Metals essential to many emerging technologies are enriched in nodules (Ni, Cu, Co, Mo, Li, Zr, REEs) to the extent that they are considered a potential resource for mining in the near future. Fifteen contracts for exploration for nodules have been taken out or are pending with the ISA that cover more than one million square km of seabed.

MANGROVE COASTS

Norman C. Duke
James Cook University, TropWATER – Centre for Tropical Water and Aquatic Ecosystem Research, Townsville, QLD, Australia

Synonyms

Coastal swampland; Coastal swamps; Coastal wetland; Mangrove forested coast; Mangrove shoreline; Tidal wetland coast

Definition

Mangrove Forests: Vegetated tidal habitat comprised of saltwater-tolerant trees and shrubs. Mangroves are part of a unique combination of plant types called tidal forests or mangrove forests to distinguish them from individual trees and shrubs, also called mangroves.

Mangrove Plants: Mangroves are trees, shrubs, palms, or ground ferns, generally exceeding one-half meter in height, that normally grow above mean sea-level and below highest tidal levels in soft sediments along the intertidal zone of less exposed marine coastal environments and estuarine margins.

Mangrove Coasts, Figure 1 Luxuriant mangrove vegetation cloaking the shoreline of semiarid regions exemplifies the significance and importance of mangrove coast habitats; as for Badu Island in Torres Strait, Australia.

Tidal Salt Marsh: Shrubbery often associated with mangroves. Tidal salt marsh consists of shrubbery, sedges, and grasses, generally less than one-half meter in height, that normally grow above mean sea-level and below highest tidal levels in soft sediments along the intertidal zone of less exposed marine coastal environments and estuarine margins.

Tidal Salt Pan: Often associated with mangroves and tidal salt marsh, tidal salt pans consist of carpeted surface layers of microphyte vegetation covering flat-pan areas above mean sea-level and below highest tidal levels along the intertidal zone of less exposed marine coastal environments and estuarine margins.

Tidal Wetlands: Tidal wetland habitats are the combination of the three intertidal vegetation assemblages as mangroves, tidal salt marsh, and tidal salt pan. These characteristically occur between mean sea-level and the highest tidal levels. Mangroves dominate in wet tropical conditions. In arid and cooler latitudes, the proportion of mangroves is notably diminished to nonexistent, replaced by the corresponding dominance of tidal salt marsh shrubbery and flat expanses of tidal salt pan.

Introduction

Mangrove coasts are shorelines fringed by mangrove and salt marsh vegetation. They form a significant part of coastal tidal wetlands as distinctive habitats of tropic and temperate shorelines. Tidal wetlands have vegetation of varying complexities from forested mangrove woodlands, thick mangrove and salt marsh shrubbery, and low dense samphire plains to microalgal covered salt pans

(Tomlinson, 1994). In the tropics, mangroves are often the dominant shoreline ecosystem comprised chiefly of flowering trees and shrubs uniquely adapted to coastal and estuarine tidal conditions (Duke, 2011). They form distinctly vegetated and often densely structured habitat of verdant closed canopies cloaking coastal margins and tidal waterways of equatorial, tropical, and subtropical regions of the world. Normally, but not exclusively, these vegetation assemblages grow in soft sediments above mean sea-level in the intertidal zone of sheltered coastal environments and estuarine margins (Figure 1).

The plants of mangrove coasts are well known for their morphological and physiological adaptations coping with salt, saturated anoxic soils, and regular tidal inundation; notably with specialized attributes like: exposed air-breathing roots above ground; extra, above-ground stem support structures; salt-excreting leaves; low water potentials and high intracellular salt concentrations to maintain favorable water relations in saline environments; and viviparous water-dispersed propagules. With such attributes, these habitats have essential roles in coastal productivity and connectivity, often supporting high biodiversity and biomass not possible in upland vegetation, especially in more arid regions.

Mangrove coasts are key sources of primary production with highly dependent trophic linkages between plants and animals, as nursery and breeding sites of benthic and arboreal life, as well as physical shelter and protection from severe storms, river flows, and large tsunami waves. Within tropical latitudes, mangrove coasts nestle mostly between two other iconic ecosystems of coral reefs and tropical rainforests. All three are intimately

interconnected, providing mutual protection and sustenance. Each of these ecosystems also creates biota-structured environments, where the organisms themselves provide and build the physical structure among which associated life is nurtured and sheltered. Without this living structure, these habitats and the many organisms dependent on them simply would not exist. This essentially identifies how such a large group of plants and animals are so vulnerable.

For example, bordering mangrove coasts, colonial coral reefs often flourish in the shallow warm seas created and protected from land runoff by mangrove vegetation (Duke and Wolanski, 2001). Mangroves absorb unwanted nutrients and sediments of turbid waters to stabilize eroding and depositional shorelines. In modern human times, this buffering role also includes the capture of harmful chemicals in runoff waters from agricultural lands. The specialized plant assemblages of mangrove coasts provide a broad range of essential, and often undervalued, ecosystem services along with their more acknowledged roles as habitats of high productivity and as fishery nursery sites (Robertson and Duke, 1990). In such ways, the consequences of disturbing mangrove coast habitats are expected to have far-reaching implications and impacts on neighboring ecosystems and dependent biota.

Uniquely vulnerable mangroves require special management

Ancestral mangroves are believed to have reinvaded marine environments in multiple episodes from diverse earlier lineages of land-based, flowering plants over the previous 50–100 million years, culminating in today's mangrove flora. The evolution of mangrove plants appears constrained by key functional attributes essential to their survival in characteristically saline, inundated settings where isotonic extremes, desiccation, and hydrologic exposure combine as uniquely harsh restrictions on organisms living in the tidal zone and within estuaries (Duke et al., 1998). Such is the mangrove coast. This land-sea interface is also a highly dynamic environment, where even subtle changes in climate, sea-level, sediment, and nutrient inputs have dramatic consequences for the survival, distribution, and health of organisms living there. Specifically, the predominant direct human disturbances affecting mangrove coasts include: eutrophication, pollution, dredging, landfill, overfishing, and sedimentation. The combination of these pressures, coupled with changes in global climate and sea-level rise, has resulted in once healthy mangrove areas becoming endangered communities with local extinction evident in some places (Duke et al., 2007). Lessons from various rehabilitation projects demonstrate that restoration is costly and unlikely to succeed. This places even greater urgency on managers to develop and apply effective protective measures beforehand, to avoid irreplaceable losses and further degradation of remaining, remnant mangrove coast ecosystems.

Over the past two centuries, human progress and development have increased dramatically. And, human society has prospered and flourished accordingly. These great human achievements have come at a huge environmental cost though, with massive alterations to natural landscapes to accommodate demands of expanding industry, trade, and population. Mangrove coasts are particularly vulnerable because of their naturally highly dynamic geophysical circumstances, coupled with a preference by human communities for development along coastlines and waterways. This explains why there have been significant losses of tidal wetland habitats in most coastal areas. But, the longer-term consequences and implications have only been partially considered. It is reasonable to ask, does it really matter? Are remaining ecosystems sustainable? And, how do we quantify and monitor changes so we might manage both the changes and the consequences better? The answers can only come from knowing more about the factors that affect functioning of habitats along mangrove coasts.

Factors influencing mangrove coasts: a strategy

There is an urgent need for local resource managers and environmental enthusiasts to learn more about the range of factors influencing mangroves and tidal wetlands in their area. Help is also needed for optimization of sustainable management outcomes, with best-practice assessment methods to direct how mangrove coasts might best be managed in view of current sociopolitical, economic, and environmental pressures.

To achieve such outcomes, six key strategies are recommended:

1. Identification and quantification of the type and biota of tidal wetlands
2. Surveys of past changes in extent and character of wetland areas
3. Assessment of ecosystem health and how these ecosystems are changing
4. Identification of the chief drivers of change and assessment of longer-term implications
5. Determination of what will be lost in terms of ecosystem goods and services
6. Decisions on management options based on assessments of extent, change, health, pressures, and values

The far greatest problem facing tidal wetlands is the ever-growing global population with its predictable, continually expanding demand for natural resources and space, including mangrove coasts. One key consequence also is that our global climate is changing dramatically, and the loss of vital natural habitats and biological resources is a direct result (Duke et al., 2007). Where we acknowledge the value of these natural ecosystems for the numerous direct and indirect services they provide, then we must act urgently to become their diligent guardians. It is imperative that communities are aware of the changes taking place, and what is being lost, so they can

support more informed management to respond in more effective ways. This awareness starts with a better knowledge and appreciation of the types of changes observed on mangrove coasts and what can be inferred from key indicators of change.

Mangrove coasts as indicators of change

Tidal wetlands of the mangrove coast are ancient ecosystems having evolved over 100 million years. During this time, the earth, sea-level, and climate have changed dramatically. Mangrove coasts of today are comprised of plants that are the survivors of all previous changes through the millennia. These ecosystems consequently have well-developed strategies for survival with a defined capacity for dealing with change. As tidal wetland ecosystems respond to change, they rely on inherent adaptive capacity (Duke et al., 1998). Where changes can be identified, described, measured, and monitored, they form the basis for a more enlightened monitoring and assessment strategy. For example, if a tidal wetland habitat had shifted upland, this might demonstrate and quantify the effects of sea-level rise. Two deductions to be made from such observations are that mangroves responded to sea-level rise and that we might evaluate the rate of net change. The value in this approach in combination with direct instrument measures, like sea/tide level elevation stations, is that mangrove coast plants integrate daily and seasonal term fluctuations. These changes, when viewed from above, are significantly enhanced along characteristically low-profile slopes in numerous locations. Furthermore, the exaggerated shifts can be readily determined retrospectively based on interpretation of vegetative condition and specific location from historical aerial imagery.

There are also questions about what causes such changes. This would be better understood if we were able to expand our general knowledge and monitoring of the full complement of forces or drivers that influence mangrove coasts. Such drivers act at local and global levels, with some delivered directly, others indirectly, and, of course, some are natural. In all situations, tidal wetlands are responding to changing influences in characteristic ways that are useful as indicators of change. With systematic identification of the different types of change in tidal wetlands, we are able to identify the responsible drivers and quantify their importance and anticipated consequences.

Key pressures on mangrove coasts

Pressures on mangrove coasts with their tidal wetlands (Figure 2) can be conveniently grouped under three broad headings (Duke et al., 2003):

- Direct human pressures, as mostly intended and obvious
- Indirect human pressures, as mostly unintended and less obvious
- Natural; being not obviously human influenced, if at all

These classifications are useful when making decisions about sustainable management of coastal and estuarine ecosystems, and they form the basis for classification of all types of observed change. As it happens, the more direct human influences are those that are more easily mitigated, resulting in relatively rapid, improved environmental outcomes. By contrast, it has been inherently difficult to differentiate between human and natural influences on global temperatures. So, it is appropriate at this time to group these more indirect human influences along with the natural pressures. This accepts that some drivers might be somewhat subjective with overlaps and ambiguity.

Indicators of change in mangrove coasts

Changes are usually measured in terms of ecosystem responses to external pressures. Estuarine, coastal, and marine ecosystems are influenced by a number of key factors acting as primary stressors and drivers. The responses of affected habitats are often unique and distinctive making them useful indicators of the key drivers.

The six overall drivers of change for mangrove coasts may be grouped under the following headings:

- Severe Human Disturbance
- Hydrology and Sediments
- Pollutants
- Pests and Pathogens
- Climate Change
- Severe Natural Disturbance

While these drivers often act in combination, their effects on tidal wetland ecosystems however predominantly result in recognizable and distinct responses. These outcomes are often observed in patches of habitat dominated by dramatic and noticeable change. In such instances, the key characteristics and features present can be used as an indicator, or proxy, of each dominant prevailing driver. Based on such information, it is possible to develop more effective management intervention actions taking account of the full array of circumstances. For instance, where pressures are largely natural or globally affected, then a local management response might best be one of adaptation and accommodation. By contrast, if a stressor were predominantly locally derived, then this could be managed and controlled locally to mitigate such effects. The difference between these two management response options is extreme. It emphasizes why prior knowledge of influencing factors and change can greatly facilitate effective and sustainable outcomes.

In general, the many specific types of change can be grouped under each of these headings (Figure 2). Twenty-one types of change are listed. These represent most of all possible changes likely. The following sections describe briefly the drivers of change and the influencing factors affecting mangrove coasts; along with some illustrative examples. Comparative quantification of these pressures essentially can be derived from measures of area

Mangrove Coasts, Figure 2 A listing of the 21 key types of change in tidal wetlands grouped under three pressure categories (human direct, indirect, and mostly natural), for six groupings of drivers of change, along with listings of respective factors that influence coastal and estuarine habitats (Duke et al., 2003).

of each indicator observed across the landscape, as specific estuarine systems or coastal enclaves.

Severe human disturbance
Predominant drivers

The drivers of severe human disturbance are grouped as direct human influences. They mostly include removal and replacement of tidal wetlands with coastal development as shoreline lands for ports and cities (Figure 3). However, with increasing populations in such areas, there are additional more cryptic influences of excessive access, encroachment, and inappropriate use. In rural areas, significant direct damage is caused by livestock grazing by foliage removal and breakage, plus trampling and sediment disturbance. In arid areas, particularly during
Mangrove Coasts, Figure 3 Severe human disturbance with reclamation between 1972 and 2003 of extensive mangrove areas at the mouth of the Brisbane River, Queensland, Australia, for port and coastal industry expansion.

drought periods, fires also severely damage mangroves, further destroying the shallow root systems as well as foliage. These latter drivers often result in the largely unquantified loss of tidal wetlands and their function associated with significant habitat damage, degradation, and disruption. Furthermore, these activities exacerbate negative perceptions of tidal wetlands where many damaged areas become breeding grounds for mosquitoes and other biting insects, as well as becoming a prime source of noxious smells from degrading sulfurous soils.

Factor indicators

Tidal wetlands are removed with landfill and replaced with artificial rock walls, particularly as a direct result of reclamation in areas of expanding human development of coastal and estuarine margins. Remnant intact areas are subject to notable damage and degradation as a direct result of excessive amounts of access and abuse indicated by tracks, paths, wheel ruts, mangrove cutting, inappropriate digging, fires, plus livestock grazing and trampling. Quantification of these effects can be made by measuring the surface area of: altered land use for port, industry, and urban development along coastal and estuarine margins and river mouths; recruitment and expansion of new mangrove area assisted by site hydrological preparation, planting, and sometimes installation of protective devices; and inappropriate human access, curiosity, and recreation activities. Comparatively high turbidity levels are likely to be found in associated estuarine waters since such areas

will have lost buffering capacity and fine sediment retention. Turbidity can be measured using automated instruments or by hand.

Change type and corresponding factors

For severe human disturbance (Figure 2), measurable areas of disturbance for respective types of change include: reclamation loss with removal (Duke, 1997; Duke et al., 2003), constructed wetlands with replacement (Spurgeon, 1998; Primavera, 2000; Lewis-III, 2005), and direct damage as excessive access and other damage (Rubin et al., 1999; Duke et al., 2003; Walters, 2005; Jupiter et al., 2007).

Hydrology and sediments

Predominant drivers

Drivers related to hydrology and sediments are often grouped as indirect human influences. While the influences of hydrology and sediment displacement are present naturally in coastal and estuarine waters, they have been greatly increased as a consequence of accidental or unintended human impacts. The disturbance of coastal environments in the name of human progress has led to significant alterations in water flow accompanied by notable increases in coastal sediment loads. These drivers are disturbances that alter flows and mobilize sediments in waterways, including: catchment erosion through removal of vegetation especially riparian vegetation, increased runoff flow rates with urban hardening, straightened and

hardened runoff drainage channels, vessel wake and turbulence, and dredging of vessel channels and coastal development projects that generate dust. Alterations to flows will also influence plant distributions sensitive to, and dependent on, upstream salinity gradients.

The impacts of fine sediment deposition are further observed downstream within estuaries of disturbed catchments, indicated by: increased and prolonged turbidity in estuarine coastal waters with enlarged plumes during periods of greater runoff; blocking and choking estuarine waterways with sediments reducing overall channel depths; depositional gains as measured by increased formation of mudbanks downstream, often colonized by mangroves; and the unusually rapid formation of mangrove islands and verges at the mouths of estuaries and surrounding coastal foreshores.

Factor indicators

Changes due to hydrology and sediments are influenced by a number of factors. Constructions, like roads and sea walls, and natural features, like beach berms, all alter water flow and tidal exchange. Tree death is caused mostly by excessive inundation of breathing roots, erosion of sediments, or deposition of sediments. Mangrove occupation of downstream mud banks is the result of clearing catchment vegetation, causing soil erosion coupled with alterations to estuarine margins because of changes in channel hydrology. Raised deposition ridges burying mangroves are caused by the influence of waves and hydrological conditions altered by storms and dredging. Construction of weirs, barrages, and dams reduces freshwater runoff so saline conditions and salt-tolerant mangrove species penetrate further upstream. Comparatively high turbidity levels in estuarine waters are measured using automated instruments and by hand.

Change type and corresponding factors

For hydrology and sediments (Figure 2), measurable areas of disturbance for respective types of change include: restricted flow with impoundment (Olsen, 1983; Gordon, 1988; Jupiter et al., 2007), estuarine shift from barriers to flow from upstream (Duke et al., 2003) and root burial from deposition above mean sea-level (Ellison, 1999, 2009; Duke et al., 2003) depositional gain from deposition below mean sea-level (Duke and Wolanski, 2001; Wolanski and Duke, 2002; Duke et al., 2003).

Pollutants
Predominant drivers

Pollutants in tidal wetlands are mostly the indirect consequence of human activities elsewhere. Pollutants are either excess amounts of naturally occurring substances or foreign and manufactured compounds. Such substances are grouped as two distinct types, namely, those natural ones including those that stimulate plant growth like nutrients and others which inhibit plant growth like toxicants. Two chief nutrients, nitrogen and phosphorus, are essential nutrients for plant and animal growth, but they are derived from two quite different sources. While nitrogen is obtained naturally from the atmosphere by bacteria and microalgae and phosphorus is derived naturally from eroded inorganic sediments, this effectively limits their availability respectively. However, with human development, this has changed dramatically, and there are now two new chief sources, namely, point source sewage outflows from urban and industrial treatment sites and diffuse source runoff from agricultural lands and urban-industrial development. The effects downstream are readily noticeable with unnaturally elevated levels of nutrients. The effects on tidal wetlands are largely unquantified but include abundant growth of epiphytic algae and excess wrack smothering sensitive above-ground breathing roots. Also washed downstream are chemical agents like agricultural herbicides in catchment runoff. Other toxic chemicals, notably petroleum hydrocarbons, are added to estuaries in chronic oil spill incidents in port areas. The fact that these chemicals are not often, if ever, found in natural environments indicates that the biota often have no prior adaptation, or capacity, to respond successfully to some toxic elements. Another natural pollutant are dust clouds although these will have a negative effect on canopy health where photosensitive foliage is covered by fine sediments leading to reduced photosynthetic capacity and loss of foliage density, with possible dieback.

Oil spills are mostly accidental and unintended, but while the application can be direct, it is often delayed by a matter of days. This is significant since delay is usually substantial where petroleum hydrocarbons degrade rapidly in the open with most toxic fractions lost first. Spilled oil on reaching mangrove coasts noticeably smothers plant surfaces resulting in tree death in extreme circumstances. Herbicides, by contrast, are essentially water soluble and invisible to see. Their presence is cryptic but their effect is more obvious, with the notable death of sensitive species. The source of agricultural chemicals is agricultural lands upstream in the catchment.

Factor indicators

Changes due to pollutants, nutrients, and toxicants are influenced by a number of factors. Nutrient-laden fertilizers used on crop lands in surrounding catchment areas plus sewage outflows and septic seepage increase smothering, algal growth on mangrove roots. In Eastern Australia, a currently unknown agent, in combination with high nutrient loads, has led to the rapid decomposition of below-ground roots, resulting in sediment collapse, subsidence and centre sinking. This leads to shallow anoxic pools within mangroves and salt marsh vegetation. In other instances, species specific death of Avicennia trees was correlated with toxic herbicides in runoff from catchment in coastal areas (Duke et al. 2005a). Spillage of toxic chemicals used in local transport causes tree death from toxicity and smothering of breathing surfaces. Dust buildup on foliage notably affects plant health and survival.

Change type and corresponding factors

For pollutants (Figure 2) measurable areas of disturbance for respective types of change include: algal excess with high nutrient levels (Dennison and Abal, 1999), center sinking likely related to a toxicant and/or nutrient (Duke et al., 2010), species specific with toxic pesticides in runoff (Duke et al., 2005a), and spill damage from toxic and suffocating petroleum spills (Duke and Watkinson, 2002; Duke and Burns, 2003; Duke et al., 1997; Duke et al., 1999; Duke et al., 2000) along with dirty foliage from excessive dust (Duke et al., 2003).

Pests and pathogens
Predominant drivers

Pests and pathogens are mostly indirect drivers resulting from the accidental or unintended consequences of human activities elsewhere. Pests are organisms detrimental to other more benign biota. They are often exotic and invasive, but this is not always the case. Local biota may also be pest species. The source of exotic pests includes: constructed wetlands, aquaculture, aquaria, vessel fouling, ballast water, and dredge spoil. Pest species can replace native species, cause alteration to habitat, or result in toxic blooms. Pathogens are bacteria, virus, or fungi which cause disease in biota, including humans. Some pathogens occur naturally in marine and estuarine waters. However, high concentrations of microorganisms are carried downstream in runoff from upstream sources of human and agricultural waste following storm events. In addition to catchment runoff and stormwater flows, further potential sources include: aquaculture cultures, exotic species, imported stock feed, and sewage discharges.

Factor indicators

Changes due to pests and pathogens are influenced by a number of factors. Herbivore life cycles may also be influenced by high nutrient content in foliage and additional habitat stressors. Further indicators of pests and pathogens include: presence and abundance of pest species and pathogens, evidence of harm to native species, loss of native species, and habitat disruption. Indicators of pathogens include: presence of pathogens in water, plant and animal lesions, responses of sensitive species, disrupted reproductive success, evidence of diseases, and mass mortality events.

Change type and corresponding factors

For pests and pathogens (Figure 2), measurable areas of disturbance for respective types of change include: diseased as a result of a pathogen (Fomba and Singh, 1990; Wesre et al., 1991; Duke, 1997), introduced species involving invasive biota (Allen, 1998; Allen et al., 2000), and herbivore attack with an active herbivore (Johnstone, 1981; Robertson and Duke, 1987; Rau and Murphy, 1990; Feller and McKee, 1999; Duke, 2002; Clarke and Kerrigan, 2002).

Climate change
Predominant drivers

Climate change combines both human and natural influences delivered as discrete drivers affecting different types of change. Mangrove coasts have always existed in a state of change. Their efficient and effective responses to altered conditions are the hallmark of their very existence. The tidal zone where they thrive is constantly changing, and it has always been a habitat at considerable risk. Over geological time, for example, inhabitants of the tidal zone have successfully followed sea-level changes ranging over tens to hundreds of meters. Therefore, mangrove coast habitats present today must be appreciated as the survivors of millions of years of adaptation and change. The component organisms have well-developed and specialized attributes to facilitate their survival in response to natural influences like temperature, rainfall, and sea-level. The question is: can they cope now with the accelerated influences of human-induced climate change?

Factor indicators

Changes due to climate change are influenced by a number of factors. Increased air and water temperatures will allow predominantly cold-restricted mangroves to recruit and survive in previously inhospitable higher-latitude locations. Rainfall variability notably affects soil moisture and salinity conditions to influence species at physiological extremes causing species at key ecotones to die or recruit. And, finally with sea-level change, as an added consequence of global warming, the entire tidal zone must shift upward with mangrove encroachment into upland habitat and corresponding losses at the waterfront. This type of change will curiously be similar to the responses of mangrove coasts to more localized changes in tidal amplitude, as observed in Southern Moreton Bay in Eastern Australia (Figure 4).

Change type and corresponding factors

For climate change (Figure 2) , measurable areas of disturbance for respective types of change include: latitudinal shift with temperature change (Gilman et al., 2008; Wilson and Saintilan, 2012, Williams et al., 2013), ecotone shift with rainfall variability (Fosberg, 1961, Duke et al., 2003; Meynecke et al., 2006; Gilman et al., 2008), and zonal shift with sea-level change (Duke et al., 2002; Gilman et al., 2008).

Severe natural disturbance
Predominant drivers

The drivers of severe natural disturbance complement and expand on the influences noted above concerning climate change. As noted, mangrove coasts have always existed in a state of change. And, they will continue to do so. Some changes will also add to these influences, based on arguably natural factors, like wrack buildup as a result of higher sea waves. The continued influence of severe storms, is excepted to have worsened with changing

Mangrove Coasts, Figure 4 Severe natural disturbance with localized raised sea-level in Southern Moreton Bay, Queensland, Australia, in 2003. Note tidal salt marsh seedlings among dead and decaying *Casuarina* trees that marked an extensive supra-tidal zone 25 years earlier.

climatic conditions. For instance, more frequent lightning strikes will result in more forest gaps leading to increased forest replacement, recruitment, recovery, and turnover (Duke 2001). And, all extreme events exemplified by large seas, storm surges, and especially tsunami waves have added influences on waterfront stands, ever vulnerable to erosion and severely limited opportunities for recruitment and replacement.

Factor indicators

Changes due to severe natural disturbances are influenced by a number of factors. Following severe storm activity and blooms emanating from deteriorating water quality, bloom and storm debris will accumulate and build up to smother mangrove and salt marsh plants. Affected plants may or may not die. By contrast, severe storms, cyclonic winds, twisters, gusts, hailstorms, strong wave activity, and high flows will usually have notable and severe impacts on mangrove coast plants. This is expected to be exacerbated by climate change with increased severity of storms and other pressures. Forest light gaps will be created more frequently and they may well increase in size. Such impacts will be enhanced by large waves and strong currents from severe storms, large run off events, chronic boat wash, tectonic events and tsunami waves.

Change type and corresponding factors

For severe natural disturbance (Figure 2) easurable areas of disturbance for respective types of change include: wrack accumulation with storm seas (Boston, 1983; Ellison, 2009), storm damage with strong winds and hail (Houston, 1999; Greening et al., 2006; Proffitt et al.,

2006), light gaps with lightning (Sousa, 1984; Duke, 2001; Amir and Duke, 2009), and waterfront erosion with large waves and tsunami (Danielsen et al., 2005; Dahdouh-Guebas et al., 2005; Gedan et al., 2011).

Conclusions

Mangroves and tidal wetlands of the mangrove coast are essential to the sustainability of highly productive natural coastal environments. However, these ecosystems and their dependent biota are under serious threat this century from the escalation of large-scale land clearing and conversion of coastal wetlands (including mangrove coasts) associated with the development of coastal lands for agricultural, aquaculture, port, urban, and industrial use. In populated areas, key coastal rivers have become little more than drains transporting eroded mud and effluent to settle in downstream estuarine reaches, as well as on shallow embayments and inshore coral reefs. The mangrove coasts that remain are becoming depauperate, nonfunctional vestiges of their former state. Where healthy, mangrove-lined estuaries had traditionally offered respite and critical dampening of land runoff, in recent years these bastions of coastal buffering – the unique "coastal kidney," mangrove coasts – are succumbing to the increasing and unrelenting pressure of expanding human population into coastal and estuarine tidal wetland habitat of tropical and subtropical shorelines worldwide.

To help allay the worsening situation, a program called MangroveWatch (Duke and Mackenzie 2009; 2010; www.mangrovewatch.org.au) specifically fosters and facilitates partnerships between community volunteers

and scientists for raising awareness and for rigorous monitoring and assessment of habitat biodiversity and health. The ready adoption of this program so far raises the possibility of enormous potential benefits; where local community members take responsibility for monitoring the health and well-being of their sections of the mangrove coast.

Synonyms

Marginal basin; Back-arc basin; Back-arc sea

Definition

In geology, a marginal sea is the sea bordering continents, semi-isolated from open ocean by *island arc* or land ridge, and underlain by *oceanic crust* (Karig, 1971). Thus a marginal sea is a deep-sea basin with water depth in general over ~3,000 m, while its slopes and shelves are called as its *continental margins*.

As a geographic and oceanographic term, a "marginal sea" represents a partially enclosed sea adjacent to or widely open to open ocean at the surface, but bounded by submarine ridges on the seafloor (Wikipedia). The presence of oceanic crust is not required.

As a geopolitical term, a marginal sea is equivalent to a territorial water, which is important in determining what maritime resources that a state can exploit (Wikipedia).

Geographic distribution

The marginal seas in geological context are distributed mainly in western Pacific Ocean, forming a giant sea chain of ~12,000 km long from the north to the south. A small number of marginal seas are seen in Caribbean, Andaman, and off Antarctica. See Figure 1 for the names and locations of the marginal seas. The Gulf of California is regarded as having oceanic crust in its southern portion and thus may be considered as a marginal sea in geological context (Curry et al., 1982).

The marginal seas in geography and oceanography context include not only the marginal seas in geological context but also their continental margins, as well as other semi-enclosed seas such as the Arabian Sea, Baltic Sea, Bay of Bengal, Bering Sea, Beaufort Sea, Black Sea, Gulf of Mexico, the Mediterranean Sea, Red Sea, Ross Sea, Weddell Sea, all four of the Siberian seas (Barents, Kara, Laptev, and East Siberian) [Water Encyclopedia], Yellow Sea, East China Sea, and Bohai Sea.

Features and formation models of marginal seas in geological context

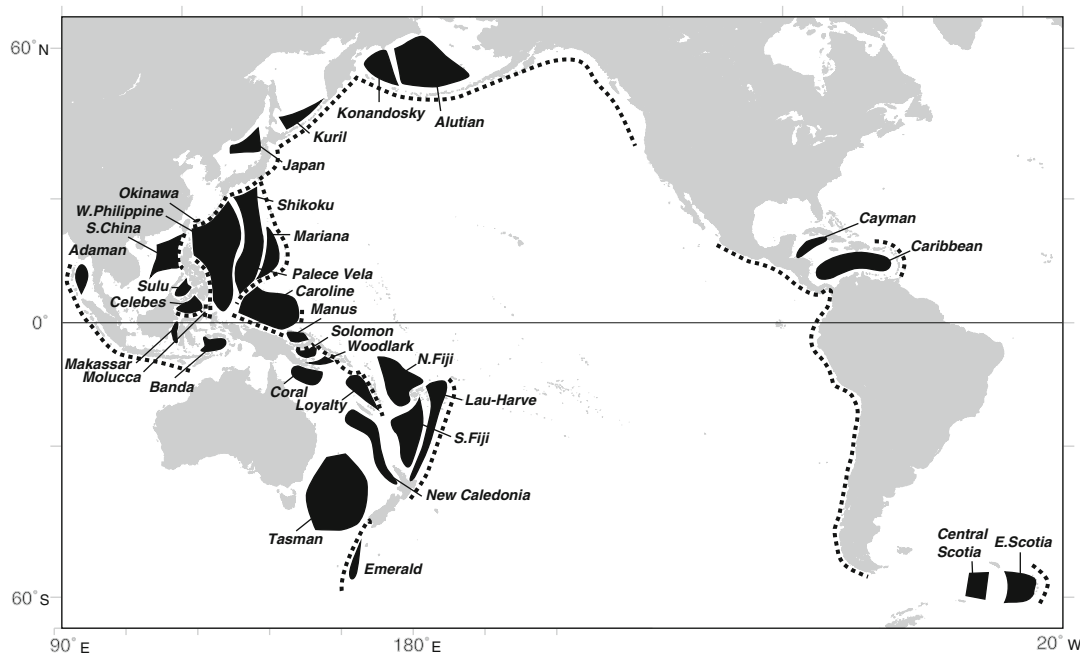
History of the concept

Although the term "marginal sea" appeared much earlier in context of geography and oceanography, the clear definition of marginal sea or marginal basin in the geological context was given several years after establishment of *plate tectonics* (Karig, 1971). Early researches on marginal seas concentrated to their nature and origin (Matsuda and Uyeda, 1971; Packham and Falvey, 1971; Sleep and Toksöz, 1971). Then there were a long period of extensive geological and geophysical investigations including *ocean drilling*, which revealed basic features and led to various formation models of marginal seas (cf. the summary in Tamaki and Honza (1991)). Recent studies of marginal seas have extended to climate and environmental impacts of the marginal seas in the present and in the geological history (Wang, 1999).

Features

Marginal seas in geological context are of similar water depths as normal oceans, but different from open oceans in several aspects (Tamaki and Honza, 1991; Wang, 1999): (1) Almost all marginal seas are located on the east side of a continent and separated from an open ocean by a *trench-arc system*. (2) Marginal seas have a short life span from their opening by the breakup of *lithosphere* to the stop of *seafloor spreading*, usually less than 25 Ma. After the cessation of spreading, many marginal seas are closed by *subduction* of themselves. (3) Marginal seas may change their spreading directions due to the movements of surrounding tectonic terrains. (4) Compared with open oceans of the same age, marginal seas usually have 600–800 m deeper water depths. (5) The marginal seas in geographic context are the sites for active *land-sea interactions* and have one to two orders of magnitude higher deep-water sedimentation rates, larger *mass flux and energy flux*, and higher *biodiversity* compared with open oceans.

Formation models

The formation of a marginal sea is indicated by the generation of oceanic crust as the consequence of lithosphere breakup and *seafloor spreading*. The models of formation mechanism of marginal seas can be grouped into three categories: *back-arc spreading* models, the slab-pull model, and the pull-apart model. Because most marginal seas are formed behind island arcs, several formation models focus on the mechanism of back-arc spreading (Figure 2), which may be grouped further into active models (Models 1 and 2) in which *asthenosphere* flow provides the driving force for the opening of marginal sea, and passive models where the driving force is slab movement, either the retreat of the overriding back-arc continental slab (Model 3) or the retreat of the subducting oceanic slab (Models 4 and 5).


Marginal Seas, Figure 1 Distribution of marginal seas around the Pacific Ocean. *Solid areas* show marginal seas, and *blocked lines* show trenches. Abbreviations: *E* east, *N* north, *S* south, *W* west (from Tamaki and Honza (1991)).

Back-arc spreading models predict the axis of marginal sea opening should be parallel to the subduction trench and island arc; but this is not always seen. For the marginal seas do not have trench-parallel axes, non-back-arc spreading models are proposed. The slab-pull model (Model 6) suggests the marginal sea opened by the pulling force of a frontal subducting oceanic slab. This driving force is caused by the *negative buoyancy*, which occurs when the heavier oceanic slab subducts into the lighter *asthenosphere*. Other non-back-arc spreading models are related to tectonic forces. For example, the pull-apart model (Model 7) suggests that the marginal sea was formed by the *pull-apart* force associated with large *strike-slip fault*(s).

Features of marginal seas in geographic and oceanographic context
Water circulation
Water circulation patterns in marginal seas depend largely on bathymetry, freshwater input (e.g., river runoff and precipitation), evaporation, and connectivity to the open ocean circulations.

As marginal seas are highly isolated from the open ocean, the water circulation is dependent largely on the balance between freshwater input and evaporation. If freshwater input exceeds evaporation, as is the case in the Black and Baltic Seas, the excess freshwater will tend to flow seaward near the sea surface, diluting the marginal sea. If evaporation exceeds freshwater input, as in the Mediterranean Sea, the marginal seawater becomes saltier

and then sinks and flows near the bottom toward the less salty open ocean. These general water circulation patterns are often modified by local bathymetry, which in some instances serve to restrict water flow (Water Encyclopedia).

In the marginal seas with relatively good connection with open oceans, the water circulation is significantly influenced by the connectivity to the open ocean circulations, which is in turn influenced by the *sea-level changes*. For example, in the system of western Pacific marginal seas, the water circulation is strongly influenced by the inflow of the western boundary currents (Kuroshio and Oyashio) of the western Pacific Ocean (Figure 3). During glacial periods, the sea-level is low and the boundary currents are flowing only outside the marginal seas, while in interglacial periods, the western boundary currents are partially running through the marginal seas. This change in water circulation might influence the climate system of the Earth. For example, the reduction of Kuroshio warm water in glacial times decreased heat and humidity supply to East Asia (Wang, 1999).
