Singh and co-workers (18) pointed out the role of hydrogen bonding between phenolic hydrogen and chemisorbed oxygen present as oxygen surface groups. They also calculated the diameter of the phenol molecule as 0.62 nm. It is interesting that the computer simulation studies of liquid phenol (19) led to the diameter of 0.6 nm.

Loughlin and co-workers reported differences in the kinetics of phenol adsorption on carbons in the presence or absence of oxygen and proposed a model (20). They found that phenol diffusion is pore and surface diffusion and the reaction between phenol and oxygen is observed to be first order. They explained the results obtained as follows: both the molecules of oxygen and phenol diffuse to the surface of carbon and are adsorbed. Reaction occurs on the carbon surface and is catalyzed by it. If the order is assumed to be first, the dissociation of the oxygen molecules occurs before their reaction with phenol. On the contrary, if the order is second, the adsorbed oxygen molecules react directly with phenol.

Abuzaid and Nakhla (21) continued the study on this subject showing that temperature increases the rates of adsorption as well as phenol polymerization. They found values of diffusion energy around 15 kJ/mole, of the same magnitude as determined by others (22,23). The detailed study of phenol adsorption in oxic and anoxic conditions together with the results published by other authors led Terzyk and co-workers to the free-radical mechanism of phenol polymerization on carbons (22–24). The authors mentioned also concluded that the incorporation of surface oxygen groups, called “lactones” in Boehm’s method, leads to a decrease in the amount of chemically bound phenol.

Barton and co-workers (25) studied the effect of chemical heterogeneity on phenol adsorption. They showed that the fit of adsorption data described by the Dubinin–Radushkevich (DR) equation is good, and the characteristic adsorption energy values varied from 19–22 kJ/mole. Stoeckli et al. (26,27) showed that the Dubinin–Astakhov (DA) adsorption isotherm equation is applicable for describing phenol adsorption data on a series of microporous carbons and that the parameter n of this equation can be successfully approximated as 4. Following this idea, Terzyk developed a relationship between the characteristic energy of phenol adsorption ($n = 4$) and the average micropore diameter of carbon slit-like micropores (22,23).

The results of Barton et al. (25) supported the previous study by Singh (28) showing that phenol and aniline are more strongly adsorbed (from water) by basic than by acidic carbon. Their explanation is as follows: the process of phenol adsorption via hydrogen bonding with acidic surface sites should be accompanied by an energetically unfavored process of water–phenol bond breaking. Therefore, adsorption takes place mainly by the formation of electron donor–acceptor complexes between basic sites (principally π electron-rich regions on the basal planes of the carbon and the aromatic ring of the adsorbate). It appears, however, that further adsorption takes place by pore filling. The presence of water adsorbed by oxygen groups decreases the adsorption of phenol. The rise in phenol adsorption after oxidation as well as alkylation of coal was found by Jaoui et al. (29).

An interesting study of phenol and benzene adsorption on zeolites was recently done by Klemm and co-workers (30). They showed that the most important interactions in phenol adsorption are coulombic with Na^+ cations. An interesting study of the adsorption of phenols, stressing the role of solute–solvent interactions, was done by Dargaville and co-workers (31). Laszlo and co-workers (32) pointed out that phenol molecules and also water are present on the surface; therefore, the competition between them should be taken into account in calculating the cross-sectional area of adsorbed phenol; moreover, some pores can be inaccessible to adsorbed phenol–solvent aggregates.

Interesting results have been recently published by Nevskaia and co-workers (33). They showed that for nonoxidized carbon, the mechanism of adsorption is based mainly on the interaction between π electrons in phenol and π electrons of carbon; after oxidation, donor–acceptor complexes arise between basic surface oxygen groups and phenol aromatic rings. The study of the kinetics of phenol adsorption performed by the same group (34) showed that for nonmodified carbon, diffusion within the porous structure controls the adsorption rate; for oxidized carbon, the controlling step is the adsorbate–surface interaction, and a shorter time is required to reach the adsorption equilibrium in comparison with the original carbon.

Mahajan et al. (35) pointed out that both water and phenol can form hydrogen bonds with surface groups. Salvador and Merchan (36), studying the thermal desorption of phenolic compounds adsorbed on carbons, concluded that the values of adsorption energies are in the range of the energy of hydrogen bonds. Moreover, they concluded that this energy does not increase with ring substitution but rather with an increase in the electrophilic nature of the substituents.

A very important paper confirming this point of view was also published recently by Franz and co-workers (37). The authors emphasized the importance of the hydrogen bonding created by the molecules of solute and surface groups and suggested a mixed mechanism between the π–π dispersion interactions and bonding of water molecules to surface groups (mainly “carboxylic”). They also postulated that this effect is different for different solute molecules and it is absent in phenol adsorption from water solutions (i.e., water adsorption on active surface groups predominates). The final conclusion was that Mattson's mechanism is not a driving force for adsorption of aromatics on carbons.

Terzyk (38), studying the adsorption of a series of organic compounds on carbons, concluded that the effect of carbon surface chemistry on the adsorption of organics decreases with a rise in temperature. Thus it seems obvious that, differences in the mechanisms of adsorption (more accurately the domination of one of them), observed by different authors are caused by the temperature dependence of the energy of intermolecular interactions. The dispersion forces are temperature independent, whereas the electrostatic interactions between dipoles of adsorbed molecules (and solvent) and surface polar groups generally decrease with a rise in temperature. This implies that the measurements of the temperature dependence of adsorption can be a very useful tool for elaborating the mechanisms of this process. The study published recently by Garcia - Araya and co-workers (39) pointed out the importance of papers showing the temperature dependence of adsorption from solutions on carbons. Costa et al. (40) attributed the rise in phenol adsorption with temperature to an activated adsorption effect, Chiou and Manes (41) concluded that this results from packing effects, and Mattson and co-workers (6) that it is chemisorption. In the opinion of the authors of this study, chemisorption is usually small, so the temperature dependence of adsorption is mainly due to the decrease in the amount of electrostatically interacting molecules with surface groups located at the entrances to small micropores where the so-called "primary micropore filling" process occurs.

A more general mechanism of adsorption was proposed by Radovic and co-workers (2). They pointed out the importance of the pH of the solution and the surface chemistry of carbon, as well as the relative importance of electrostatic and dispersive adsorbate/adsorbent interactions. They also concluded that even though different surface functional groups are responsible for the amphoteric character of carbon, their specific identification is less important than the determination of the isoelectric point and the point of zero charge. The authors concluded that adsorption of aromatic anions occurs primarily on the basal plane of carbon and the electron-withdrawing effects of surface groups suppress the interaction of basal planes with the adsorbate's aromatic rings. Adsorption of aliphatic anions also occurs predominantly on the basal plane, and the same electron-withdrawing effects enhance the interaction with carboxyl anions. Although electrostatic interactions are important, the $\pi-\pi$ dispersion interactions appear to be dominant in the adsorption of aromatic solutes. They also pointed out that if dispersion forces dominate the functionalization (of the carbon adsorbent or the aromatic adsorbate), which decreases the π electron density, this leads to suppressed or weaker adsorption.

In his review, Moreno-Castilla (3) also pointed out the importance of the irreversible adsorption of phenols on carbons. This process was studied extensively in the pioneering paper of Grant and King (42) and by Tamon et al. (43,44) and others (22,24). The occurrence of this effect complicates the observation of regularities during the adsorption process.

It can be seen that despite an enormous number of papers, there are still unsolved problems:

The role of porosity; some authors implied that the adsorption of phenol is mainly controlled by the porous structure, and others thought that it is not. There is no correlation between phenol uptake and total surface area of carbons, and the details of the role of surface functional groups in phenol adsorption are still unknown; although different general mechanisms of phenol adsorption have been proposed, we still lack the general adsorption mechanism taking into account the "micropore filling" process and also answering the question, exactly what types of surface functional groups influence the value of phenol adsorption beneath the previously mentioned limit of micropore filling. The irreversibility of phenol adsorption on carbons is fairly well established, however, the detailed mechanism of this process as well as the well documented answer to the question, what types of surface functional groups (and why) are responsible for this process are still unknown. The influence of surface functional groups on the kinetics of phenol adsorption has not yet been determined, that is it is not known what types of surface functionalities determine the kinetics of adsorption of that compound.

Recently, Terzyk (22) presented the results of phenol adsorption–desorption (and kinetic) measurements at three temperatures and at two pH levels on a series of microporous activated carbons. Comparing the results of phenol adsorption with those determined for paracetamol, acetanilide, and aniline, it was shown that at a low equilibrium concentration, phenol adsorption decreases with the basic and carboxylic group content of the carbon surface. A linear correlation was observed between the average adsorbability of phenol and the total concentration of surface bases and carboxyls [the same author showed that the results for two Polish adsorbents follow the same line (23)]. The plot of the results tabulated in the paper by Biniak and co-workers (14) shows a similar tendency Therefore, carboxyls, that is, the most acidic and some of the basic groups, play the most important role in phenol adsorption at low concentrations. For adsorption at the acidic pH level, the value of adsorbability was correlated with the enthalpy of carbon immersion in water (therefore, with the total content of surface acidic groups and the pH of the zero point charge). Consequently, at an acidic pH, where all the carbons studied are below the pH of the point of zero charge, the more polar the surface of carbon, the lower the adsorbability of phenol. Therefore, it can be presumed that at infinite dilution and neutral pH, the positive surface charge resulting from adsorption of protons by the strongest surface bases leads to an increase in water adsorption and blocks some more active sites. The same effect is caused by undissociated surface acidic groups, and both of them decrease phenol adsorbability, compared to that observed for nonmodified carbon. The same author showed that in the range of micropore filling the pore blocking effect by phenol molecules dominates, and this effect weakens with a rise in temperature. Thus, the mechanism of phenol adsorption process is mixed, and

$\pi-\pi$ interactions between the phenol aromatic ring and pore walls are "screened" by the blocking of pore entrances by water and phenol molecules (interactions *via* hydrogen bonds) (38).

CARBONATE GEOCHEMISTRY

Kenneth F. Steele
University of Arkansas
Fayetteville, Arkansas

Calcite ($CaCO_3$) is one of the most common minerals at or near the surface of the earth and thus is one of the main contributors to carbonate geochemistry. Less common carbonate minerals include dolomite [$MgCa\,(CO_3)_2$]; aragonite, a calcite polymorph (mineral of the same composition as calcite but having a different atomic structure); azurite and malachite (copper hydroxycarbonate minerals); siderite ($FeCO_3$); and rhodochrosite ($MnCO_3$) which can be important spatially and economically.

Although calcite does occur in igneous and metamorphic rocks, the mineral is present dominantly in the sedimentary environment which is the focus of this article. Calcite may be precipitated to form a relatively pure monomineralic rock (limestone), be present as a cement binding sediments into indurated rock, occurs simply as a trace mineral in rocks, and composes many shells and fossils. Weathering of calcite is relatively easy and depends largely on the amount of carbonic acid present. Other carbonate minerals, except dolomite, generally are dissolved and precipitated in a manner geochemically similar to calcite.

CALCITE SOLUBILITY PRODUCTS

The solubility of $CaCO_3$ depends on which polymorph is considered and the reference for the equilibrium constant.

For example, at 25 °C, the ion concentration products (K_{sp}) for calcite and aragonite (the most common polymorphs of $CaCO_3$) are $10^{-8.48}$ and $10^{-8.34}$, respectively (1). Krauskopf and Bird (2) provide calcite and aragonite K_{sp} values of $10^{-8.35}$ and $10^{-8.22}$, respectively. The K_{sp} values for calcite solubility from Krauskopf and Bird (2) are 35% greater than those from APHA (1). A similar relationship exists for aragonite; Krauskopf and Bird (2) present K_{sp} values for aragonite that are 31% higher. Variation in solubility experiments can yield significant differences in the K_{sp}.

Temperature

Counter to the typical increase of mineral solubility with increasing temperature observed for most minerals, many carbonate minerals are more soluble in cold water. For example, the K_{sp} for calcite at 0 °C and at 50 °C are $10^{-8.02}$ and $10^{-8.63}$, respectively (3). These values represent about a fourfold difference in calcite solubility caused by temperature alone. A thorough discussion of the thermodynamic reactions of carbonate minerals solubilities is beyond the scope of this article. A simplified explanation why carbonate minerals are more soluble in cold water is that the dissolution reaction for carbonate minerals is exothermic, which results in higher temperatures favoring the solid phase over dissolved ions. A more detailed discussion for this unusual behavior can be found in Langmuir (4).

In addition to an increase in solubility products with decreasing temperature, carbon dioxide is more soluble at lower temperatures, further favoring carbonate mineral dissolution in cooler environments. More carbonic acid is present in cold water at a given partial pressure of carbon dioxide (p_{CO_2}), and carbonic acid concentration is the controlling factor for the solubility of carbonate minerals under natural conditions. Carbon dioxide is obtained from the air or from decomposition of organic matter that releases carbon dioxide which reacts with water to form carbonic acid. These factors combine to form the calcite compensation depth (about 4500 m) below which calcite dissolves (2).

When geothermal waters reach the surface of the earth and precipitate tufa, a calcium carbonate rock, some reaction must overcome the temperature decrease, or these waters would dissolve calcite rather than deposit tufa as the water cools. The required reaction is the loss of CO_2 due to lower p_{CO_2} pressure at the earth's surface and subsequent decrease in the amount of carbonic acid, which controls the amount of dissolved calcite (see Calcite Solubility below).

Pressure

The increased partial pressure of CO_2 near the surface of the earth increases the amount of CO_2 that dissolves in water, therefore, increasing the solubility of carbonate minerals such as calcite. Pressure alone does not affect the solubility of calcite as much as the effect of temperature. Nonetheless, where pressure is large, for example, deep within the ocean, its effect alone can increase calcite solubility about twofold (2).

Ionic Strength

Other ions in solution shield Ca^{2+} and CO_3^{2-} ions from interacting and precipitating. Faure (5) describes this situation as "… the activity of the ions in electrolyte solutions is less than their concentration. It is plausible to expect that the interference by the other ions increases with their concentrations and charges." Activity can be defined as the concentration of an ion at zero ionic strength. The effect of the concentration and charge of ions is represented by the ionic strength (I) of the solution:

$$I = 0.5\ \Sigma\ m_i z_i^2 \tag{1}$$

where m_i is the molar concentration of an ion (i) and z is the charge of the ion.

Ionic strength can be use to calculate the activity coefficient γ which relates molar concentration to activity; γ is 1 or less.

$$m_i(\gamma) = a \tag{2}$$

where a is the activity of the ion.

γ can be calculated from the Debye–Hückel equation (Eq. 3) or other similar equations that use I and some constants that relate to the dielectric constant of water and temperature (A and B) and effective size (a) of ions. Values of the constants can be obtained from Faure (5).

$$-\log\gamma = \frac{Az^2I^{1/2}}{I + aBI^{1/2}} \tag{3}$$

SATURATION INDEX

Waters tend to precipitate $CaCO_3$ when oversaturated with $CaCO_3$, and tend to dissolve $CaCO_3$ if undersaturated with $CaCO_3$. The Saturation Index (SI) is the most widely used method to determine the amount of calcite that will be precipitated or dissolved. Many water chemistry computer programs calculate RS (relative saturation) which is related to SI as

$$\mathrm{SI} = \log \mathrm{RS} \tag{4}$$

where RS = ratio of $CaCO_3$ activity product (K_a) to $CaCO_3$ solubility product (K_{sp}).

SI values of 1 indicate saturation, negative values indicate undersaturation, and positive values indicate oversaturation.

MEASURED ALKALINITY

Alkalinity is the measure of the acid-consuming ability (power) of a solution expressed as mg/L $CaCO_3$. In nature, the main ions that neutralize H^+ ions are HCO_3^- and CO_3^{2-} (6). Although OH^-, PO_4^{3-} and other negative ions can neutralize H^+ ions, generally the concentrations of these ions is so small in the natural environment that HCO_3^- and CO_3^{2-} are the only significant acid-neutralizing ions. In some situations, especially in anthropogenically influenced situations, OH^- can be important (e.g., the impact of cement on water chemistry); thus, OH^- is included in the following calculations. Alkalinity is usually determined by titrating a 50 or 100 mL water sample with 0.02 N H_2SO_4 to a pH of 8.3 for CO_3^{2-} and/or OH^-. This 8.3 pH end point is often referred to as the phenolphthalein (or *P*) end point because this indicator changes colors at pH 8.3. Titration continues past 8.3 to a pH of about 4.5 as any HCO_3^- (originally present or formed from partial neutralization of CO_3^{2-}) is neutralized. The pH of 4.5 can vary from 4.3–4.9 depending on the presence and amounts $CaCO_3$ and certain anions (1). This final end point is referred to as total alkalinity. These pH titration end points are based on inflection points on the titration curve of pH versus milliliters of acid added to the water sample titration curve for neutralization of the bases. The amount of acid necessary to reach the phenolphthalein end point is equivalent to the amount of base ($CaCO_3$) neutralized and is referred to as *P* alkalinity. The amount of $CaCO_3$ to neutralize "completely" or "totally" the H^+ ions added is referred to as *T* alkalinity. Thus, *T* must be larger than or equal to *P*. There are five alkalinity conditions possible: (1) only HCO_3^-, (2) only CO_3^{2-}, (3) only OH^-, (4) HCO_3^- plus CO_3^{2-}, and (5) CO_3^{2-} plus OH^-. Bicarbonate and OH^- ions cannot coexist under typical natural conditions because these ions react to form CO_3^{2-} ions and H_2O. These five situations are discussed briefly below.

Bicarbonate Alkalinity. If the initial pH of a sample is less than 8.3, there is only bicarbonate alkalinity and no *P* alkalinity. Or one can state that there is only *T* alkalinity (the amount of acid necessary to lower the pH below 4.5).

Carbonate Alkalinity. There are two abrupt changes in pH during alkalinity titration, one at 8.3 and the other at 4.5. If only CO_3^{2-} ions are present, the amount of acid necessary to lower the pH below 8.3 is one-half the total acid (i.e., *T*) necessary to lower the pH below 4.5. The first abrupt pH change at 8.3 represents the conversion of carbonate to HCO_3^- (i.e., half of the carbonate has been neutralized), and the second abrupt pH change at 4.5 represents neutralization of the HCO_3^- created from carbonate. If only CO_3^{2-} ions are present, $T = 2P$.

Hydroxide Alkalinity. If the initial pH is greater than 8.3 and the addition of acid rapidly lowers the pH below 4.5, there is only hydroxide alkalinity and thus $T = P$.

Bicarbonate Plus Carbonate Alkalinity. Because P represents the conversion of CO_3^{2-} to HCO_3^-, the same amount of acid (*P*) is required to neutralize the HCO_3^- ions formed from the CO_3^{2-} ions; 2*P* represents complete neutralization of CO_3^{2-} ions present. In addition, HCO_3^- originally present is included in *T*, which means that $T > 2P$. Because CO_3^{2-} ions are present, there will be two abrupt changes in pH (at 8.3 and 4.5).

Carbonate Plus Hydroxide Alkalinity. When both CO_3^{2-} and OH^- ions are present, the amount of acid required to lower the pH below 8.3 is that necessary to convert CO_3^{2-} to HCO_3^- plus that necessary to neutralize OH^- ions (i.e., the OH^- milliequivalent/L (meq/L) concentration is equal to T minus CO_3^{2-} meq/L). In addition, T-P is equal to 1/2 the CO_3^{2-} (the amount of CO_3^{2-} converted to HCO_3^{2-} concentration) or CO_3^{2-} meq/L equals 2(T-P). These two relationships can be combined to yield OH^- meq/L equals to 2P-T. These conditions constrain the *P* and *T* titration relationship to $T < 2P$.

Table 1. Alkalinity Determined by Titration

Result of Titration	Bicarbonate Alkalinity	Carbonate Alkalinity	Hydroxide Alkalinity
$P = 0$	T	0	0
$2P = T$	0	T	0
$P = T$	0	0	T
$P > 0.5T$ or $T > 2P$	$T - 2P$	$2P$	0
$P < 0.5T$ or $T < 2P$	0	$2(T - P)$	$2P - T$

Table 1 summarizes the equations necessary to determine the portion of alkalinity due to HCO_3^-, CO_3^{2-} ions, and OH^-. At pH 9, the OH^- concentration is only 1.0 mg/L as $CaCO_3$ and can generally be neglected in alkalinity determinations for water whose pH is less than 9.0.

CALCULATION OF BICARBONATE, CARBONATE, AND HYDROXIDE ALKALINITY

Bicarbonate, carbonate, and hydroxide alkalinity can be calculated from total alkalinity (TA) if the pH is known. These concentrations are often calculated, especially for carbonate and hydroxide ion concentrations that are generally low and difficult to measure. The ion concentrations must be given in molar (M) concentrations, which are indicated by brackets in this article. For most natural situations, Eq. 5, which takes into account charge differences, is adequate for determining the various sources of alkalinity:

$$2\text{TA} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{OH}^-] \tag{5}$$

TA is commonly expressed as mg/L $CaCO_3$ and must be converted to moles/L (M) to make the following calculations. The conversion of mg/L to M $CaCO_3$ is accomplished by using Eq. 6

$$(\text{TA moles/L CaCO}_3) = \frac{\text{mg/L CaCO}_3}{100{,}000\ \text{mg/mole}} \tag{6}$$

Rearranging the second disassociation constant for carbonic acid (Eq. 7) in terms of $[CO_3^{2-}]$ yields Eq. 8:

$$K_2 = \frac{[\text{H}^+][\text{CO}_3^{2-}]}{[\text{HCO}_3^-]} = 10^{-10.3} \tag{7}$$

$$[\text{CO}_3^{2-}] = \frac{K_2[\text{HCO}_3^-]}{[\text{H}^+]} \tag{8}$$

Substitution of Eq. 8 for $[CO_3^{2-}]$ in Eq. 5 and expressing $[OH^-]$ in terms of $\frac{K_w}{[H^+]}$, based on Eq. 9, yields Eq. 10.

$$[\text{OH}^-] = \frac{K_\text{w}}{[\text{H}^+]} = \frac{10^{-14}}{[\text{H}^+]} \tag{9}$$

$$2\text{TA} = [\text{HCO}_3^-] + 2\left[\frac{K_2[\text{HCO}_3^-]}{[\text{H}^+]}\right] + \frac{K_\text{w}}{[\text{H}^+]} \tag{10}$$

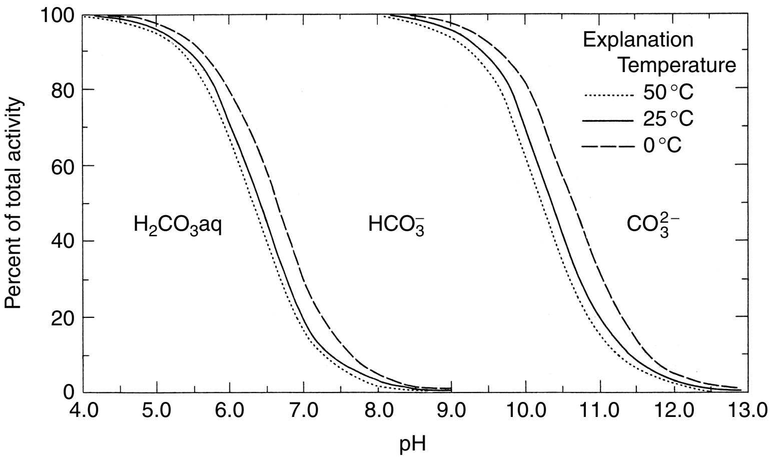

Figure 1. Plot of percent of total activity of carbonate species versus pH at 0, 25 and 50 °C. From Hem (7).

Rearranging Equation 10 to solve for HCO_3^- (Eq. 12) is carried out by the following step (Eq. 11) and expressing K_w as exponent of 10 and negative pH as exponent of 10.

$$2\text{TA} - \frac{K_w}{[H^+]} = [HCO_3^-]\left(1 + \frac{2K_2}{[H^+]}\right) \qquad (11)$$

$$[HCO_3^-] = \frac{2\text{TA} - 10^{K_w + \text{pH}}}{1 + 2K_2 10^{\text{pH}}} \qquad (12)$$

Once $[HCO_3^-]$ has been calculated (or determined by titration), this concentration can be substituted in Equation 8 and $[CO_3^{2-}]$ can be calculated. To determine the hydroxide alkalinity, only the pH must be known (Eq. 9).

To convert these molar alkalinity concentrations (Eqs. 8, 9, and 12) to mg/L, the molar concentrations must be multiplied by the molecular weight of $CaCO_3$ (100,000 mg/mole) and for $[HCO_3^-]$ and $[OH^-]$, a factor of 1/2 is required because 1 mole of $CaCO_3$ is equivalent to 2 moles of HCO_3^- and 2 moles of OH^-, whereas 1 mole of CO_3^{2-} is equivalent to 1 mole of $CaCO_3$.

These are the equations necessary for calculating bicarbonate, carbonate, and hydroxide alkalinities as $CaCO_3$ mg/L:

Bicarbonate alkalinity ($CaCO_3$ mg/L)

$$= 50{,}000\ \left(\frac{2\text{TA} - 10^{K_w + \text{pH}}}{1 + 2K_2 10^{\text{pH}}}\right) \qquad (13)$$

Carbonate alkalinity ($CaCO_3$ mg/L)

$$= 100{,}000\ (K_2[HCO_3^-](10^{\text{pH}}) \qquad (14)$$

Hydroxide alkalinity ($CaCO_3$ mg/L)

$$= 50{,}000\ (10^{K_w + \text{pH}}) \qquad (15)$$

CARBONATE SPECIES

Concentrations of the carbonate species $[H_2CO_3]$, $[HCO_3^-]$ and $[CO_3^{2-}]$ can be calculated if the total dissolved inorganic carbonate (DIC) concentration and pH are known. [DIC] is often expressed as HCO_3^- because it is the dominant ion at typical pH values (Fig. 1). Figure 1 shows the concentrations of the carbonate species for an aqueous solution with respect to the pH and temperature of the solution. Note that activities (concentrations) are higher at lower temperatures. The pertinent equilibrium reactions are the two disassociation constants for H_2CO_3 (Eqs. 8 and 16).

$$K_1 = \frac{[H^+][HCO_3^-]}{[H_2CO_3]} = 10^{-6.4} \qquad (16)$$

$$[\text{DIC}] = [H_2CO_3] + [HCO_3^-] + [CO_3^{2-}] \qquad (17)$$

By rearranging K_1 (Eq. 16) to express $[H_2CO_3]$ in terms of $[HCO_3^-]$, by rearranging K_2 (Eq. 7) to express $[CO_3^{2-}]$ in terms of $[HCO_3^-]$, and then substituting these values in Equation 17, the following equation is obtained:

$$\begin{aligned}[\text{DIC}] = {} & [[H^+]\ [HCO_3^-](K_1^{-1})] \\ & + [HCO_3^-] + [[H^+]^{-1}\ [HCO_3^-](K_2)] \qquad (18)\end{aligned}$$

Factoring out $[HCO_3^-]$, rearranging Eq. 16 to solve for $[HCO_3^-]$, and expressing $[H^+]$ as pH (negative exponent of 10) yields the following:

$$[HCO_3^-] = \left[\frac{[\text{DIC}]}{(10^{-\text{pH}-K_1}) + (10^{\text{pH}+K_2}) + 1}\right] \qquad (19)$$

Because K_1, K_2, and K_w are temperature dependent, the concentrations of the carbonate species must be determined by using the appropriate values for a specific temperature.

CALCITE SOLUBILITY

If only calcite were present in an aqueous solution with no carbon dioxide, one could determine the solubility of calcite by obtaining the square root of the solubility product for calcite (Eq. 20). Reported K_{sp} values for calcite vary with the reference and range from $K_{sp} = 10^{-8.3}$ to $K_{sp}\ 10^{-8.5}$ at 25 °C (1,2). The value of $10^{-8.3}$ will be used throughout this article.

$$[CaCO_3] = [Ca^{2+}][CO_3^{2-}] = K_{sp} = 10^{-8.3} \qquad (20)$$

Hydrolysis

Although one can calculate the solubility of Ca^{2+} as $10^{-4.15}$ M or 6.8×10^{-5} from Equation 20, the CO_3^{2-} ion will undergo hydrolysis (Eq. 21):

$$CaCO_3 + H_2O = Ca^{2+} + HCO_3^- + OH^- \quad (21)$$

$$K = [Ca^{2+}][HCO_3^-][OH^-] = 10^{-12} \quad (22)$$

Inspection of Eq. 21 indicates that all three product ions are equal. The cube root of 10^{-12}, yields a concentration of 10^{-4} M for all three ions; thus, the pH of the solution is 10. At this high pH, there is appreciable disassociation of HCO_3^- to CO_3^{2-} and H^+ (which is quickly neutralized). Then these CO_3^{2-} ions undergo hydrolysis producing equal amounts of HCO_3^- and OH^- (Eq. 23).

$$CO_3^{2-} + H_2O = HCO_3^- + OH^- \quad (23)$$

Furthermore, water with a pH of 10 has a $[CO_3^{2-}]/[HCO_3^-]$ ratio of 1/2 (from Eq. 7). The total carbonate in this situation is the sum of HCO_3^- and CO_3^{2-} (H_2CO_3 is negligible at this high pH—see Fig. 1), and total carbonate is equal to Ca^{2+} (Eq. 24).

$$\Sigma[CO_3^{2-}] = [HCO_3^-] + [CO_3^{2-}] = [Ca^{2+}] \quad (24)$$

Because $\dfrac{[CO_3^{2-}]}{[HCO_3^-]} = 0.5$, Eq. 7 can be modified to

$$[Ca^{2+}] = [HCO_3^-] + 0.5\ [HCO_3^-] = 1.5\ [HCO_3^-] \quad (25)$$

Instead of Ca^{2+} having the same concentration as HCO_3^- and OH^-, Ca^{2+} will be equal to 1.5 $[HCO_3^-]$ and 1.5 $[OH^-]$ because $[HCO_3^-] = [OH^-]$ (Eq. 23).

Equation 22 is then modified to

$$K = [Ca^{2+}]\ 1.5\ [HCO_3^-]\ 1.5\ [OH^-] \qquad K = 2.25 \times 10^{-12} \quad (26)$$

Because $[Ca^{2+}] = 1.5[HCO_3^-] = 1.5[OH^-]$, the Ca^{2+} concentration can be estimated by the cube root of 2.25×10^{-12} (Eq. 26) or 1.3×10^{-4} (Eq. 26). M (equivalent to 5.2 mg/L). This value is about twice that obtained in Equation 20 and represents the lowest equilibrium concentration of Ca^{2+} for pure water *not* in contact with CO_2. Using this method results in a pH change from 10.00 to 9.94. Recalculation using this method based on the new pH of 9.94 yields a 2% change in $[Ca^{2+}]$ and a new pH of 9.93. Another iteration of these calculations yields a $[Ca^{2+}]$ difference of 1% and the pH remains 9.93.

Carbonic Acid

The main factor controlling carbonate solubility in nature is the amount (partial pressure) of CO_2 that forms H_2CO_3 (Eq. 27). The partial pressure of CO_2 in the atmosphere is 0.0003 or 0.03% of the atmospheric pressure at the surface of the earth (i.e., 1 bar or atmosphere). Partial pressure is equal to moles per liter (5); thus, there is $10^{-5.0}$ M H_2CO_3 in water in contact with the atmosphere (Eqs. 26 and 27).

$$CO_2 + H_2O = H_2CO_3 \quad (27)$$

$$K = \frac{[H_2CO_3]}{[CO_2](H_2O]} = \frac{[H_2CO_3]}{(0.0003)(1)} = 10^{-1.5} \quad (28)$$

$$[H_2CO_3] = 3 \times 10^{-4}(10^{-1.5}) = 10^{-5.0}M \quad (29)$$

In most natural environments, the appropriate equation for calcite solubility is Equation 30 where CO_2 is present:

$$CaCO_3 + H_2CO_3 = Ca^{2+} + 2HCO_3^- \quad (30)$$

Equation 29 (2) takes into account the presence of CO_2 at the earth's surface which forms carbonic acid (Eq. 27) that readily dissolves $CaCO_3$:

$$K = \frac{[Ca^{2+}][HCO_3^-]^2}{[H_2CO_3]} = 10^{-4.4} \quad (31)$$

$[HCO_3^-] = 2[Ca^{2+}]$ from inspection of Eq. 30; therefore,

$$K = 10^{-4.4} = \frac{[Ca^{2+}][2Ca^{2+}]^2}{[H_2CO_3]} = \frac{4[Ca^{2+}]^3}{10^{-5.0}} \quad (32)$$

The Ca^{2+} concentration calculated from Equation 32 is 4.7×10^{-4} M (equivalent to 18.8 mg/L). This is the solubility of calcite at surface conditions, 25 °C and 1 atmosphere pressure, which provides a "minimum" concentration of atmospheric carbonic acid. More CO_2 can be dissolved in cold water, and the CO_2 partial pressure in soil can be rather high, leading to increased calcite solubility. Decaying vegetation in soil can have a CO_2 partial pressure in excess of 0.1 atmospheres (2) which can significantly raise H_2CO_3 concentrations of infiltrating meteoric water. The solubility of calcite in water in contact with 0.1 atmosphere of CO_2 can be calculated as in Eqs. 28 and 32, producing a calcite solubility of 3.2×10^{-3} M (equivalent to 128 mg/L Ca^{2+}). This value is not an absolute maximum but does give an approximate upper limit for Ca^{2+} concentrations from limestone near the surface of the earth. Other acids, for example, sulfuric from the oxidation of sulfide minerals such as pyrite (FeS_2), can also have a significant effect on calcite solubility locally.

CAVE FORMATION

Carbonic acid-rich water forms limestone caves, which is the most common type of cave. When the water table is high, carbonic acid-rich water dissolves the limestone (calcite). Later when the water table drops, a "void" filled with air is formed and a large void is called a cave. Smaller amounts of water rich in Ca^{2+} and HCO_3^- may continue to flow through the void. When these waters enter the void, CO_2 partial pressure decreases and CO_2 is released. This degassing of CO_2 drives the reactions in Equations 27 and 30 to the left, leading to the precipitation of calcite and formation of stalagmites, stalactites, and other cave features. Although evaporation may play a small role in the deposition of calcite, the loss of CO_2 is the most important factor.

HARDNESS

Water hardness is a measure of how difficult it is for soap to lather; most of the divalent ions in water must be precipitated by soap before soap can produce suds. The most abundant divalent ions in nature are Ca^{2+} and Mg^{2+}, although Fe^{2+} and other divalent ions can be important in some waters. The major source of Ca^{2+} and Mg^{2+} is carbonate minerals; therefore, hardness is expressed as mg/L $CaCO_3$. The range in hardness values with descriptive terms is shown in Table 2.

In the past, hardness was determined by a titration analysis of divalent ions (7). Today, hardness is calculated by converting Ca^{2+} and Mg^{2+} molar concentrations to mg/L $CaCO_3$ by multiplying the mg/L concentrations of the two ions by the inverse of the equivalent weights of the ions and summing the two concentrations (Eq. 31):

$$\text{Hardness as mg/L } CaCO_3 = 2.497\ (Ca^{2+}\ \text{mg/L}) + 4.118\ (Mg^{2+}\ \text{mg/L}) \qquad (33)$$

Some scientists consider hardness more of a water quality (use) factor that relates to scaling in hot water heaters and in industrial setting, rather than an important geochemical factor. However, comparison of hardness and alkalinity (both expressed as mg/L $CaCO_3$) can yield helpful water chemistry information. If hardness exceeds alkalinity, the excess is termed "noncarbonate" hardness, meaning that there are noncarbonate mineral sources of Ca^{2+} and Mg^{2+} ions. The remainder of the hardness is considered "carbonate" hardness derived from carbonate minerals. In this discussion, it is assumed that there is "no" hydroxide alkalinity. If alkalinity exceeds hardness, there must be carbonate mineral sources that do not contain Ca^{2+} and/or Mg^{2+}, for example, $NaHCO_3$, or cation exchange has occurred with clay minerals (e.g., Ca^{2+} replacing Na^+).

Table 2. Hardness Ranges. Units are in mg/L of Calcium Carbonate[a]

0–60	Soft
51–120	Moderately hard
121–180	Hard
>180	Very hard

[a] Reference 7.

DOLOMITE

Dolomite has a very small K_{sp}; values range from 10^{-17} to 10^{-19} (2). The K_{sp} is too small to produce large thicknesses of dolomite and furthermore there is no true dolomite being precipitated today. Some "protodolomite" is precipitated in restricted environments, such as evaporite lagoons. Dolomite should not exist, and yet there are thick sequences of dolostone throughout the world and throughout the geologic record—hence, the "dolomite problem."

Dolostone characteristically preserves fossils poorly, is coarse grained, and commonly has cavities/pore spaces, which all indicate replacement of limestone as the origin of the rock. In addition, it is known that saline water, high pH, a low Ca^{2+}/Mg^{2+} ratio, and elevated temperatures all favor dolostone formation. Based on these factors, various marine and deep water reflux models have been proposed, as well as mixing models for fresh water and sea water, but no "perfect" model has been developed for the formation of dolomite. The dolomite atomic structure is highly ordered which may affect the amount of time necessary to develop the structure. Dissolution of dolomite also is complicated because dolomite undergoes incongruent dissolution as Mg^{2+} dissolves before Ca^{2+} (2). At any rate, the formation and dissolution of dolomite is complex and not well understood in comparison with other carbonate minerals.

CARBONATE IN NATURAL WATERS

Robert Y. Ning
King Lee Technologies
San Diego, California

INTRODUCTION

Carbonate is the divalent anion resulting from complete neutralization of carbonic acid. In natural waters, it is in dynamic equilibrium with carbon dioxide gas, carbonic acid, bicarbonate anion, and solid forms of insoluble carbonate minerals—mainly calcium carbonate:

$$CO_2(g) + H_2O \Longleftrightarrow H_2CO_3 \Longleftrightarrow HCO_3{}^- \Longleftrightarrow CO_3{}^{2-} \Longleftrightarrow \text{Carbonate(s)}$$

Various aspects of the CO_2–carbonate systems in natural waters have been extensively reviewed (1–6). Practical interests lie in the areas of geochemistry, biochemistry, water treatment and usage, and environment.

GEOCHEMISTRY

Carbonate Dissolution

Typically, limestone [$CaCO_3$] and dolomite [$CaMg(CO_3)_2$] rocks are dissolved by infiltrating rainwater which has taken up biogenic CO_2 in the soil zone. As this solution percolates downward, continuously dissolving solid carbonates, the hydrogeochemical system will change from "open" with respect to a CO_2 gas phase in the unsaturated zone to "closed" with respect to that phase in the saturated zone. Thus, the solution passes through various stages of a system, which are intermediate between the limiting cases, in general. In modern times, the dissolution of carbonate rocks is enhanced by the action of acids of sulfur and nitrogen oxides from atmospheric pollution.

Carbonate Deposition

Carbonate rocks, mainly aragonite and calcite, constitute about 11% of the total sediments of the earth's crust. Bicarbonate salts are relatively soluble in water, but calcium carbonate is not. Freshwater does not sustain extreme supersaturation of calcium carbonate. In most cases, the phase precipitated is calcite—the polymorph of calcium carbonate that has the lowest solubility product. Carbonate solubility in seawater is governed essentially by the same parameters, but kinetically the precipitation of calcium carbonate is complicated by high concentrations of Mg^{2+} and the actions of marine organisms.

pH Buffer

The pH of natural waters on land is controlled mainly by the bicarbonate–carbonate system. Most of the CO_2 absorbed into the ocean is in the form of HCO_3^- (93%) and CO_3^{2-} (6%). The pH of the upper regions of the sea is controlled by the carbonate as well as the borate systems. In the lower regions of the sea, pH appears to be controlled by the precipitation and solution of various minerals. The bicarbonate alkalinity of natural waters has the following typical ranges: rainwater 0 to 2.5 ppm (mg/L), river and groundwater 6 to 600 ppm, and seawater 140 to 159 ppm.

Geochemical Carbon Cycle

The atmospheric CO_2 concentration of about 0.04% on a timescale of million of years is controlled mainly by a combination of degassing from the earth's interior balanced by the uptake of carbon dioxide via the weathering of calcium and magnesium silicate minerals (7,8). Carbon dioxide in water as carbonic acid is converted to dissolved calcium and magnesium bicarbonate on land during weathering. This carbon form is stored in lakes and aquifers or carried to the sea by rivers and precipitated there as calcium and magnesium carbonate minerals. The overall reactions shown here were first formulated by Urey (8) in 1952.

$$CO_2 + CaSiO_3 \Longleftrightarrow CaCO_3 + SiO_2$$

$$CO_2 + MgSiO_3 \Longleftrightarrow MgCO_3 + SiO_2$$

The reactions from left to right represent carbon dioxide absorption via weathering. The reactions from right to left represent degassing due to the thermal decarbonation of carbonates after burial at sufficient depth in the earth's crust. Added to the Urey reactions should also be the organic carbon subcycle. It exerts an important additional control on the atmospheric carbon dioxide level. This involves the removal of carbon dioxide from the atmosphere through photosynthesis by organisms, the burial of organic matter in sediments, and the weathering of organic matter (or its thermal decomposition) which returns carbon dioxide. The overall reaction is represented as

$$6\ CO_2 + 6\ H_2O \Longleftrightarrow (CH_2O)_6 + 6\ O_2$$

Together, these reactions regulate carbon dioxide on a geologic timescale.

BIOCHEMICAL ASPECTS

Biological Pump

Life has developed on the earth in the water phase and in general requires buffering of the pH at around 7.0. Here carbonate–bicarbonate plays a major role. The process of photosynthetic fixation of CO_2 in the photic zone of the upper ocean in the presence of sunlight and nutrients is balanced by the export of organic carbon (soft tissues, secretions) and carbonate (bones, shells) out of the mixed layer into the deep ocean by gravity. Chemically, the "biological pump" is composed of the organic carbon pump and carbonate pump (2):

$$\begin{aligned} CO_2 + H_2O + \text{energy} &\Longleftrightarrow (CH_2O)_X \\ &\quad (\text{organic carbon}) + O_2 \\ Ca^{2+} + 2\ HCO_3^- &\Longleftrightarrow CaCO_3 \\ &\quad (\text{bones, shells}) + H_2O + CO_2 \end{aligned}$$

The organic carbon pump sequesters CO_2 from the mixed surface layer and dumps it as particulate organic carbon into the deeper ocean, sometimes seen as white flakes of "marine snow." The carbonate pump, on the other hand, acts in the direction opposite to the organic carbon pump by producing CO_2.

Oceanic Chalk

Much of the calcium carbonate is in the form of hard parts in calcareous organisms (e.g., foraminifera, cocolithophores). Other marine carbonates (aragonite, magnesian, calcite) are metastable phases whose origin is in the reluctance of the Mg^{2+} to be dehydrated and converted to dolomite, [$MgCa(CO_3)_2$] and magnesite,

[$MgCO_3$]. Carbonate sediments in sunlit waters of tropical seas originate as organically secreted solids. They occur either as skeletal debris, as organically secreted carbonate mud, or in various combinations of the two. More than 70% of the total $CaCO_3$ contained in large reef systems is in the form of fine, unconsolidated sand deposited in thick beds across large areas adjacent to a living reef frame (4). In addition to skeletal particles, nonskeletal carbonate particles are important, for example, ooids, pellets, pelloids, intraclasts, and grapestones that produce thick carbonate deposits in the rock record. Enormous petroleum reservoirs discovered in carbonate rocks (Devonian of Canada, Pennsylvanian and Permian strata of New Mexico and Texas, Mesozoic and Cenozoic deposits in Middle East) point to the intimate association of organic carbon with carbonate deposits.

Biological Carbonates

Calcite and aragonite, two polymorphs of $CaCO_3$ represent the bulk of the carbonates formed in biological systems. The solubility products of these two forms are 4.7×10^{-9} (calcite) and 6.9×10^{-9} (aragonite), which shows that aragonite is less stable than calcite. Surface seawater to a depth of 3,000 m is commonly supersaturated with respect to aragonite and calcite (6). This disequilibrium state is attributed to a series of inhibitors, most notably magnesium and dissolved organic matter, that interfere with the nucleation of a $CaCO_3$ seed crystal. By the same token, it appears to offer an optimal condition for the biocontrolled crystallization of $CaCO_3$ to sustain an abundance of marine life.

WATER TREATMENT AND UTILIZATION

Carbonate Scaling

Relevant to water treatment is the fact that natural waters contain high concentrations of soluble bicarbonate salts in dynamic equilibrium with carbonic acid (dissolved carbon dioxide) and insoluble carbonate salts. To estimate the amount of the three forms in water, it is important to know that carbonic acid (H_2CO_3) is a divalent acid whose $pK_1 = 6.35$ and $pK_2 = 10.33$. At $pH = 6.35$, the un-ionized acid and the bicarbonate ($HCO_3{}^-$) ion exist in equal concentrations. pH is a logarithmic scale, so at $pH = 7.35$ (one unit higher), the solution would contain 90% bicarbonate and 10% carbonic acid, and at $pH = 8.35$, the solution would contain 99% bicarbonate and 1% carbonic acid. The pH of 8.2–8.4 (phenolphthalein end point in alkalinity titrations) is also significant in that above this pH, carbonate ($CO_3{}^{2-}$) ions begin to appear. At $pH = 9.3$, about 10% of the bicarbonate ions would have converted to carbonate ion, and at $pH = 10.33$, carbonate and bicarbonate ion concentrations would be equal. Calcium carbonate is quite insoluble (14 mg/L water at 25°C), so natural waters are usually found in the pH range of 6–8; bicarbonate ions range between 6 to 600 mg/L, and calcium ranges from 2 to 200 mg/L. Seawater representing 98% of blended natural waters on the surface of the earth typically contains 410 mg/L of Ca^{2+} ions and 143 mg/L of $HCO_3{}^-$ ions. Magnesium carbonate is about 100 times more soluble than calcium carbonate, so the magnesium ion concentration in seawater is much higher (about 1310 mg/L). Carbonate scaling potentials in surface waters are focused mainly on calcium carbonate crystallization because it is the first carbonate scale to form under treatment or use (9,10).

Calcium Carbonate Scaling Indexes

The Langelier saturation index (LSI) and the form modified for high salinity water called the Stiff and Davis stability index (S&DSI) are widely used to predict calcium carbonate scaling potentials in cooling systems and boiler waters (9,10). These indexes are widely applied for predicting the same in reverse osmosis systems (11). The formulas for calculating the indexes (9–11) are given here:

$$\mathrm{LSI} = \mathrm{pH} - \mathrm{pH_s}$$

where $\mathrm{pH_s}$ is the pH at which the water is saturated in calcium carbonate and is calculated by the following:

$$\mathrm{pH_s} = (9.3 + A + B) - (C + D)$$

where

$$A = (\mathrm{Log_{10}[TDS]} - 1)/10$$
$$B = -13.12 \times \mathrm{Log_{10}}(^\circ\mathrm{C} + 273) + 34.55$$
$$C = \mathrm{Log_{10}}[\mathrm{Ca^{2+} as\ CaCO_3}] - 0.4$$
$$D = \mathrm{Log_{10}}[\mathrm{alkalinity\ as\ CaCO_3}]$$

In this model, we see that calcium carbonate saturation is affected by salinity (total dissolved solids, TDS) and temperature along with calcium and bicarbonate ion concentrations. The Langelier index loses its accuracy in predicting the solubility of calcium carbonate in water when salt concentrations exceed 4,000 mg/L (11). Stiff and Davis modified Langelier's formula for highly saline waters by using empirically derived values. The Stiff and Davis stability index (S&DSI) is calculated as follows:

$$\mathrm{S\&DSI} = \mathrm{pH} - p_{\mathrm{Ca}} - p_{\mathrm{ALK}} - K$$

where

p_{Ca} is the negative log of the calcium concentration expressed as molarity;
p_{ALK} is the negative log of the total alkalinity concentration expressed as molarity;
K is a constant whose value depends on the water temperature and ionic strength.

At an index of less than 0, water will have a very limited scaling potential. At increasingly positive index values, the scaling potential increases. By projecting the pH, TDS, calcium, and alkalinity concentrations, calcium carbonate scaling indices can be calculated.

Carbonate Scale Control with Acid versus Antiscalant

Carbonate scale control in the purification or use of water and wastewater typically involve using either acid to reduce pH and carbonate concentration or antiscalant to inhibit the growth of calcium carbonate crystals, or a combination of the two. Sodium hexametaphosphate

(SHMP) is a generic antiscalant widely used due to its low cost. It acts, as do the newer organic antiscalants, by inhibiting the growth of calcium carbonate seed crystals (11,12). The limitations of SHMP are that it is stable only as an anhydrous solid. It is difficult to dissolve in the plant, and once dissolved in water, it slowly hydrolyzes to phosphate ions which precipitate calcium, magnesium, aluminum, iron, and other ions as insoluble phosphate salts; in addition, it is a stimulant for microbial growth. As an antiscalant for simultaneous control of other types of scales, it is much less effective than the newer types of organic antiscalants. Great advances have been made in the development and use of organic antiscalants. In a line of six distinctly differentiated organic antiscalants, all classified under ANSI-NSF Standard 60 for drinking water production by reverse osmosis (13), the maximum calcium carbonate scaling control possible ranges from LSI = 2.8 to 3.2 and S&DSI = 3.9 to 4.5. Under these high limits for calcium carbonate control, the differentiated antiscalants are selected more on the basis of simultaneous control of calcium, strontium, and barium sulfates, calcium fluoride, silica, iron, aluminum, and heavy metal scales. In each case when used, acidification of feedwater is not necessary.

ENVIRONMENTAL IMPACT

Concern for the environmental impact of the natural CO_2 balance in the biosphere is raised by the modern trend of deforestation, industrialization, burning of fossil fuels, and population explosion. Understanding the natural processes is the starting point for monitoring environmental changes and modulating human activities.

Natural Balance

The earth's atmosphere contains approximately $2,000 \times 10^9$ tons of CO_2, the oceans $130,000 \times 10^9$ tons, and the rocks of the earth together with fossil fuels approximately $40,000 \times 10^9$ tons. The concentration of CO_2 in the atmosphere is maintained at a relatively constant value of about 0.03% by weight by an annual exchange between the oceans and the air of approximately 100×10^9 tons of CO_2 gas. Fluctuations of CO_2 in the atmosphere occur due to photosynthesis in daylight hours, which fixes approximately 60×10^9 tons of CO_2 per year, and to biological respiration and decay, which release about the same amount.

Ocean Storage of CO_2

It is known that CO_2 will form solid hydrates with water at temperatures below 10°C and pressures higher than 4.4 MPa (450 m depth); at 0°C, the hydrate is stable at pressures higher than 1.2 MPa (125 m depth). The cold deep waters of the world's oceans are unsaturated with respect to CO_2 and have an enormous and under used capacity to dissolve CO_2. The high dissolved inorganic carbon level of the oceans (38,000 Gt C) would be little changed, even if they were to gain all the carbon in the known fossil fuel reserves (4,000 Gt C). The idea of injecting human-produced CO_2 directly into the deep ocean has attracted much interest (2).

CHLORINE-36 AND VERY OLD GROUNDWATERS

Gholam A. Kazemi
Shahrood University of Technology
Shahrood, Iran

INTRODUCTION

Chlorine has nine isotopes whose mass numbers range from 32 to 40, but only three of these occur naturally. The remaining six have half-lives shorter than 1 hour, (1), and this is why they do not occur in nature. The three abundant isotopes of chlorine include two stable isotopes, chlorine-35 and chlorine-37, with 75.53% and 24.47% abundances, respectively, (2) and one radioactive isotope, chlorine-36, with a half-life of 301,000 ± 2000 years (some references ± 4000 years). The natural mixture of these three isotopes makes up environmental chlorine.

PRODUCTION OF CHLORINE-36

Chlorine-36 is produced by the following processes:

1. cosmic ray splitting of ^{40}Ar in the atmosphere:

   $$^{40}\mathrm{Ar} + \mathrm{x} \longrightarrow {}^{36}\mathrm{Cl} + \mathrm{x}' + \alpha$$

   The amount of ^{36}Cl produced by this process depends mainly on the geographic latitude and is greater in middle latitudes. For example, the fallout rate of ^{36}Cl at Stripa in Sweden at 57 °C latitude is 14±3 atoms $\mathrm{m}^{-2}\ \mathrm{s}^{-1}$ (3), the mean atmospheric flux of ^{36}Cl over the United States is 19.6 ± 4.5 atoms $\mathrm{m}^{-2}\ \mathrm{s}^{-1}$, and the mean global ^{36}Cl flux is 30.5 ± 7 atoms $\mathrm{m}^{-2}\ \mathrm{s}^{-1}$ (4).
2. neutron activation of stable ^{35}Cl in the subsurface:

   $$^{35}\mathrm{Cl} + {}_0{}^1\mathrm{n} \rightarrow {}^{36}\mathrm{Cl}$$

   The rate of production of ^{36}Cl by this process varies depending on the type of rocks, minerals, and solutions, and the availability of neutron sources (neutrons are produced by bombardment of rocks with alpha particles as well as through spontaneous fission of ^{238}U). For instance, the ^{36}Cl production rate at the top of Murray Group Limestone was calculated by Davie et al. (1) (using the following equation) as 0.09 atoms/cm^3/year.

   $$\mathrm{P}_{36} = {}^{36}\mathrm{Cl}/{}^{40}\mathrm{Ca} \times \rho/\mathrm{MW} \times N_\mathrm{A} \times \log_\mathrm{e}{}^2/t_{1/2}$$

   where P_{36} is production rate of ^{36}Cl, ^{36}Cl/^{40}Ca is the equilibrium ratio of ^{36}Cl to ^{40}Ca, ρ is the density of the limestone, MW is the molecular weight of limestone, N_A is Avogadro's number, and $t_{1/2}$ is the half-life of ^{36}Cl.
3. Weapon testing of fusion devices starting in late 1952 and extending through mid-1958 has led to the production of up to 70,000 atoms $\mathrm{m}^{-2}\ \mathrm{s}^{-1}$ (5). Chlorine-36 produced by this phenomenon is used as a marker to age-date young groundwaters that are less than 50 years old (6,7).

It has been recently suggested that the operation of two nuclear reactors in the United States has led to the production of ^{36}Cl (8).

MEASUREMENT OF ^{36}CL CONTENT OF WATER SAMPLES AND REPORTING THE RESULTS

To analyze water samples for ^{36}Cl content, the following steps are undertaken (4,8): A specified volume of a water sample, depending on its chlorine concentration, is selected (the selected volume should contain a minimum of 2 mg chlorine). In some studies, sample volumes of up to 4 liters have been collected. The sample is then prepared for target loading. This means preparing about 20–350 mg pure AgCl and pressing it into copper sample holders. The samples are prepared for target loading by adding $\mathrm{AgNO_3}$ solution to the samples to precipitate AgCl. The precipitate (AgCl) is then purified by dissolving it with $\mathrm{NH_4OH}$. Next, $\mathrm{Ba(NO_3)_2}$ is added to precipitate unwanted sulfur as $\mathrm{BaSO_4}$. $\mathrm{HNO_3}$ is added next to neutralize the solution and in the last stage, the AgCl is reprecipitated with $\mathrm{AgNO_3}$ for target loading. If the $\mathrm{Cl^-}$ concentration of the sample is very low, a carrier must be added to it. The carrier may be AgBr of very low sulfur and chlorine content. The prepared water samples are then analyzed for ^{36}Cl content using an accelerator mass spectrometer (AMS). Usually, standard and blank samples are tested to identify the reproducibility and accuracy of the measurements. Davie et al. (1) reported that ^{36}Cl measurements by AMS have a long reproducibility of about 6% and a sensitivity for ^{36}Cl/Cl of a few parts in 10^{15}.

The measured chlorine-36 is reported in two ways:

1. as a ratio of $^{36}\mathrm{Cl/Cl} \times 10^{15}$ (the number of ^{36}Cl atoms to total number of chlorine atoms). The multiplication factor (10^{15}) is used because the actual concentration of ^{36}Cl is very small.
2. as atoms of chlorine-36 per liter of water using the following equation (8):

$$^{36}\mathrm{Cl}\ (\text{in atoms per liter}) = 1.699 \times 10^4 \times B \times R$$

where B is the concentration of chlorine in mg/l and R is the (^{36}Cl/total Cl) × 10^{15} ratio. Therefore, to determine the concentration of ^{36}Cl, the concentration of $\mathrm{Cl^-}$ in water samples must be measured by conventional methods such as titration or ion chromatography.

Example

The $^{36}\mathrm{Cl/Cl} \times 10^{15}$ of a water sample is 550 and its chlorine concentration is 200 mg/l. What is the ^{36}Cl concentration in this sample?

$$^{36}\mathrm{Cl}\ (\text{in atoms per liter}) = 1.699 \times 10^4 \times B \times R$$

$^{36}\mathrm{Cl}$ (in atoms per liter) $= 1.699 \times 10^4 \times 200$ mg/l $\times 550 = 186.89 \times 10^7$ atoms/liter (see Table 1 for more examples).

APPLICATIONS OF CHLORINE-36 AND PRINCIPLES OF THE ^{36}CL DATING METHOD

Chlorine-36, in this article, is treated as a tool to age-date very old groundwaters. However, it has many other applications such as the geochronological study of young volcanic rocks (9), estimation of groundwater recharge (10,11), calculation of dispersivity (12) and a mixing study of two waterbodies (13).

The principle of this method is simple. It is based on the radioactive decay of ^{36}Cl in the subsurface groundwater system. Above the earth's surface, chlorine-36 produced (atmospheric ^{36}Cl) with an initial value, C_0, enters groundwater by rainwater infiltration. After time t, it decays and reaches a new concentration, C, according to the following equation:

$$C = C_0 e^{-\lambda t}$$

Table 1. ^{36}Cl and Cl^{-} Measurements of Murray Mallee Samples[a]

Well	^{36}Cl/Cl × 10^{-15b}	Cl^{-} mg/l	^{36}Cl^{-} Atoms/l × 10^{6b}
1	19 + 4	264	85 + 18
2	22 + 4	551	205 + 37
3	35 + 6	361	215 + 37
4	32 + 4	576	315 + 39
5	28 + 6	1067	510 + 110
6	3p17	314	195 + 37
7	31 + 7	475	250 + 56
8	31 + 7	468	245 + 55
9	43 + 7	804	585 + 95
10	22 + 8	747	280 + 100
11	32 + 15	752	410 + 190
12	42 + 7	2023	1450 + 240
13	21 + 6	3191	1140 + 330
14	39 + 7	2573	1710 + 310
15	33 + 6	1607	900 + 160
16	22 + 4	5327	1990 + 360
17	13 + 4	32,600	7200 + 2200
18	22 + 6	5566	2080 + 570

[b] The number after + is the error range.

From the initial concentration, C_0, and the present concentration, C, one can calculate the length of time that the ^{36}Cl has resided in the subsurface groundwater system. For example, if the concentration of ^{36}Cl in a groundwater sample is 2000 atoms/liter and its initial concentration (in the infiltrating rainwater) was 3000 atoms/liter, then the time "t" would be 176,136 years. This means that the water molecule, which contain the ^{36}Cl in question, entered the groundwater system 176,136 years ago.

However, many inaccuracies and problems surround C_0 and C values, the initial and the present concentration of ^{36}Cl, respectively. We do not accurately know the concentration of ^{36}Cl in the rainwater when it entered the subsurface system. Davis et al. (8) present six ways to find the C_0 value and argue that all contain weaknesses and inaccuracies. These approaches include:

1. calculation of theoretical cosmogenic production and fallout,
2. measuring ^{36}Cl in present-day atmospheric precipitation and using it as C_0,
3. assuming that shallow groundwater contains a record of C_0,
4. extracting ^{36}Cl from vertical depth profiles in desert soils,
5. recovering ^{36}Cl from cores of glacial age, and
6. calculating subsurface production of ^{36}Cl for water that has been isolated from the atmosphere for more than 1 million years.

The situation is no better with regard to C. The assumption in using the decay equation is that the ^{36}Cl atoms which enter subsurface groundwater system behave as an isolated packet when they migrate through the flow system (piston flow theory). As explained above, ^{36}Cl is produced in the atmosphere, and it is also produced in the subsurface. There are other subsurface sources of ^{36}Cl such as what is called "dead chlorine," chlorine present in fluid inclusions; ancient formation waters; saline water from compacting clays; and chlorine from salt beds and evaporites. In addition, subsurface mixing (mixing of low and high ^{36}Cl content waters), cross formational flow, diffusion between aquitard and aquifer, and dilution and evaporation processes all unite to complicate the job of finding which C should be used in the decay equation, the C that is measured in the laboratory or the C that is obtained when the contributions/effects of all the above factors have been eliminated.

Apart from ^{4}He which is considered an age indicator not a dating method (14), ^{36}Cl is the only method to age-date very old groundwaters quantitatively. However, in only a very few cases were groundwater ages satisfactorily determined. In many instances, the chlorine-36 dating study was not successful due to many factors such as the uncertainty in estimating C_0, the effect of dilution/evaporation processes on the value of C, and the much longer half life of ^{36}Cl compared with the age of the groundwater (1,15,16). Other counterproductive factors include relatively recent introduction of the method, less interest in very old groundwaters, a limited number of well-defined regional aquifers worldwide for which this method is appropriate, many analytical considerations and the unavailability of equipment in a large number of countries, difficulty in interpreting the results (initial value problem, local interferences, many sources of ^{36}Cl, etc,), and inherent inadequacies [for example, Park et al. (19) show that if the chlorinity of the water sample exceeds ~75–150 mg/kg, the ^{Cl}36 method cannot be used for groundwater dating]. These may be the reasons that an important text book such as that by Mazor (14) does not include a section on ^{36}Cl to describe it as an age-dating tool. A valuable recent paper by Park et al. (17) describes the principles and limitations of age-dating very old groundwater by ^{36}Cl.

CASE STUDIES

The work by Davis and Schaeffer (18) was the first attempt to apply ^{36}Cl isotopes to environmental problems. However, Davie et al. (1) argue that extensive application of ^{36}Cl in environmental studies started only after the introduction of the accelerator mass spectrometry (AMS) technique for detecting ^{36}Cl by Elmore and his colleagues in 1979 (19). Because earlier methods of analysis such as decay counting required 13 g of chlorine, a difficult task, and it had much less sensitivity than AMS.

Examples of aquifers subjected to chlorine-36 dating include the Great Artesian Basin (GAB) of Australia (20,21); the fractured metamorphic rock aquifer in the Clare Valley, South Australia (22); the Milk River aquifer of the western Canada sedimentary basin (23,24); the Aquia aquifer in the Maryland Coastal Plain (25); the palaeochannel groundwater of Kalgoorlie in Western Australia (15); and the groundwater brines of the Dead Sea area (16). Of these aquifers, GAB is perhaps the most studied as far as chlorine-36 is concerned. A list of directly related publications dealing with chlorine-36 in various aquifers around the globe is included at the end of this article for further consultation. It is interesting to note that all publications dealing with ^{36}Cl have been produced by groups of authors; there is no single author publication, which may be an indication of the complexity of the matter.

One of the early studies dealing with ^{36}Cl in groundwater is that by Davie et al. (1), in which the ^{36}Cl content of limestone groundwater in the Murray Basin of Australia was measured. The results of their analysis, as an example, are presented in Table 1. This publication was selected for detailed explanation because it has not been cited elsewhere and it is a valuable study. Table 1 shows that the ^{36}Cl/Cl ratios of the Murray Mallee samples are low, generally lower than those reported by Davis et al. (8) for groundwaters of the United States (It may be inappropriate to compare the two study areas because of the large difference in their sizes). This study showed that the ratio of ^{36}Cl/Cl in the aquifer increases along the flow path most probably because of significant localized recharge.

The age of the deep Jurassic confined aquifer in the GAB was estimated by Bentley et al. (20) at $(1200\pm500) \times 10^3$ years (much older than the hydraulic age). Notle et al. (23) measured the ^{36}Cl concentration of 12 samples from the Milk River aquifer, Alberta, Canada, and found that the ages of the groundwater ranged from 0.6–2 Ma at a distance of 80 km from the recharge area.

By analyzing 17 samples from water wells and seeps, Turner et al. (15) showed that the ^{36}Cl/Cl ratios and ^{36}Cl content of palaeochannel groundwater in Kalgoorlie, Western Australia, ranged from $32–129 \times 10^{-15}$ and 1460 to 79,000 atoms/l, respectively. Similarly, the ^{36}Cl/Cl ratios of 17 samples from the Continental Terminal aquifer in Niger calculated by Le Gal La Salle et al. (26) ranged from $3–27 \times 10^{-15}$.

Davis et al. (8) measured the concentration of ^{36}Cl in the groundwater of the United States to determine what they call the "preanthropogenic levels" (natural = pristine = background level) of ^{36}Cl in groundwater. This study which was subsequently completed by Moysey et al. (4) is the most comprehensive study worldwide of ^{36}Cl in groundwater so far; a total of 183 water samples from unpolluted wells and springs were analyzed. Davis et al. (8) showed that natural ratios of ^{36}Cl/Cl are lowest near the coast and increase to a maximum in the central Rocky Mountains of the United States (less than 50×10^{-15} in Florida to more than 1200×10^{-15} in the Rocky Mountains). They attribute this pattern to an inland decrease in the stable chlorine content of atmospheric precipitation; the increase in the ratio of ^{36}Cl/Cl inland is due to an inland decrease in stable chlorine, not an increase in ^{36}Cl.

CHLOROFLUOROCARBONS (CFCs)

Gholam A. Kazemi
Shahrood University of Technology
Shahrood, Iran

INTRODUCTION

The following paragraph, extracted mostly from a comprehensive paper by Badr et al. (4), is a brief yet valuable introduction to chlorofluorocarbons (CFCs). Thereafter, an overview of CFC applications in hydrologic studies, especially for age-dating young groundwater, is presented.

Before 1930, the refrigerants commonly used were ammonia (R-717, the most popular refrigerant in the industrial and heavy commercial sectors), carbon dioxide (R-747), ethyl chloride (R-160), isobutane (R-600a), methyl chloride (R-40), methylene chloride (R-30), and sulfur dioxide (R-764). Because of either, toxicity or fire hazard, the need for a safer refrigerant became clear. The new refrigerant had to be nonflammable, have a boiling point between −40 and 0 °C, be highly stable, and low in toxicity. In response to these requirements, the CFC family of refrigerants was developed. Dichloromonofluoromethane (R-21) was the first CFC developed that had attractive thermodynamic properties for use as a refrigerant, but due to its low toxicity, stability, and inertness, it had never been used commercially as a refrigerant. The first CFC suitable for commercial applications was dichlorodifluoromethane (R-12), whose discovery was announced in 1930 at the American Chemical Society meeting in Atlanta, Georgia. CFCs have been among the most useful chemical compounds ever developed. There is no known natural source of CFCs (5).

In addition to their uses as working fluids in refrigerators and air-conditioning systems, CFCs have also been employed, since 1950, as blowing agents for foams and plastics, aerosol propellants, solvents for cleaning precision and delicate electronic equipment, as well as for dry cleaning, in sterilizers for surgical instruments and catheters, and as working media in Rankine-cycle engines for waste-heat recovery systems. By 1974, approximately one million tonnes per year of CFCs were being produced worldwide. Within the European Countries (EC), the main uses for CFCs (according to 1988 consumption figures) are as aerosol propellants (38%), foam-blowing agents (35%), solvents (17%), and refrigerants in cooling systems (10%). In the USA, CFCs are used for the following purposes: foam-blowing (34%), refrigeration and air conditioning (35.5%), solvents (18%), sterilizers (5.4%), and other applications (7.0%). CFCs along with some other gases harm the earth's atmosphere by two phenomena: (1) depletion of the ozone layer and (2) the greenhouse effect (or global warming). A major cause of environmental concern for CFCs is their long atmospheric lifetime (55 years for CFC-11 and 140 years for CFC-12). Hydrochlorofluorocarbons (HCFCs) are now replacing CFCs and recent data suggests that the growth rate of CFCs concentration in the atmosphere has begun to decrease (6).

The concentration of CFCs in the atmosphere is measured regularly at a few stations worldwide. The atmospheric concentrations for CFC-11, CFC-12, and CFC-113, those species that are used to age-date young groundwaters (less than 50 years old), are illustrated in Fig. 1. Industrial use of CFC-12 started in the 1930s, CFC-11 in the 1950s, and CFC-113 in the 1970s (7). Atmospheric concentrations of these species show little spatial variation; only 10% variation is observed among average concentrations in Ireland, Oregon, Barbados,

CFCs in hydrological studies—Age dating young groundwaters

The use of CFCs in hydrology began when Thompson et al. (1) discussed the usefulness of a special type of fluorocarbon known as Freon 11, as a tracer in both groundwater and surface water hydrology. They found good agreement between CCl_3F data and hydrologic and tritium age data. Brown (2) also examined the use of fluorocarbons as groundwater tracers through soil column studies. There was no significant use of or development in CFC dating techniques during the 1980s, possibly due to the availability of other methods such as the tritium method and the low resolution of the available CFC analytical techniques. From 1992, the application of CFCs in groundwater studies, especially for age dating and determination of rainfall recharge became important (3). In groundwater textbooks, not many contain a section on the CFC age-dating technique. One text that deals briefly with the topic is by Domenico and Schwartz (9). A book chapter by Plummer et al. (10) is a valuable resource that covers most aspects of the CFC age-dating technique.

SAMPLING GROUNDWATER FOR CFCS

In sampling groundwater for CFC analysis, care must be exercised to prevent the sample from contacting air. The average CFC concentration in the air is about 300 times that in groundwater. Therefore, any small contamination from air will have a very large impact on the concentration of CFCs in the groundwater sample. A sophisticated sampling apparatus like that developed by CSIRO (Commonwealth Scientific and Industrial Research Organization), Australia, is necessary to meet this condition (Fig. 2). Prior to sampling, about three volumes of well water are purged. A 6-mm nylon tube and a stainless steel bailer are sent downhole to obtain the sample. Both nylon tube and bailer are initially flushed with ultrahigh purity (UHP) nitrogen to remove any air from the system. The sample containers are 62 cm^3 borosilicate glass ampules that are flushed, prior to filling, with UHP nitrogen for two minutes. After filling, the ampules are flame sealed using a propane–oxygen torch. The CFC content of the samples is measured using a purge-and-trap gas chromatograph with an electron capture detector (ECD). An illustrative and practical text that deals with sampling for CFCs is that by Kazemi (11).

In another method of sampling for CFCs, the ground water is pumped via a copper tube for a considerable length of time. While the water is flowing through the tube, a small length of the tube is cut and flame sealed quickly to avoid contamination from air. One other method of sampling involves pumping a large volume of groundwater into a big container and then sampling groundwater from the water inside the container.

HOW TO CALCULATE CFC AGE

Apparent CFC ages are obtained by converting measured CFC concentrations in groundwater to equivalent air concentrations using known solubility relationships (12) and the recharge temperature (13). Therefore, the first step is to measure the CFC concentration in groundwater (usually less than 400 pg/kg). The second step is to determine the air temperature at which the rainfall recharge occurs. This is usually average summer temperature (for regions of summer dominated rainfall), average winter temperature (for regions of winter dominated rainfall), and mean annual air temperature (for regions of all year round rainfall). The third step is to calculate the solubility of the CFCs at the temperature considered (summer, winter, or annual) by using the Warner and Weiss (12) relationship. The final step is to use all three above and the following formula to obtain the equivalent atmospheric concentration (EAC) of CFCs:

$$\mathrm{EAC} = \frac{\mathrm{CFCs_{gw}}}{S \times 121}\text{(adapted from Ref. 13)}$$

where EAC is the equivalent atmospheric concentration, $\mathrm{CFCs_{gw}}$ is the concentration of CFCs in the groundwater, S is solubility, and 121 is the molecular weight of CFCs in units of g/mol. The EAC is then compared to the graphs of CFC concentrations in the atmosphere (Fig.1), and the year when the recharge occurred is determined.

LIMITATIONS AND POSSIBLE SOURCES OF ERROR IN THE CFC DATING TECHNIQUE

Error in Estimating Recharge Temperature and Excess Air

Temperature plays a major role in the solubility of CFCs in rainwater. If the air temperature at the time of recharge is overestimated, then the solubility of CFCs that are calculated will be greater than real values. This leads to overestimation of groundwater ages. Note that the error in estimating the recharge temperature is minimal for waters recharged before 1985 (3).

Excess air is the air bubbles trapped during recharge. The CFC content of these air bubbles is slowly dissolved in the groundwater, leading to a rise in the CFC concentration in groundwater. This results in underestimating groundwater ages.

Thick Unsaturated Zone (More Than 5 Meters) and the Associated Error

It is assumed in the CFC technique that the concentration of CFCs immediately above the water table is the same as the CFC concentration in air. If there is a thick unsaturated zone and the soil water content is high, then CFCs may be dissolved preferentially into the soil water. Consequently, the CFC concentration above the water table differs from the CFC concentration in air. Furthermore, there will be a lag between the time that rainwater, containing CFCs, leaves the earth surface and the time that it enters the groundwater. This phenomena leads to overestimating the groundwater age.

Contamination During Sampling

There is always a possibility that groundwater could be contaminated during sampling. Apart from air contamination, CFCs may enter the sample through sampling equipment.

Microbial Degradation of CFCs in the Aquifer

Experiments by Oremland et al. (14) have shown that CFCs are degraded by microbial activity especially in the soil zone. However, the magnitude of degradation is low. If CFCs are decomposed to a large extent, then it is difficult to obtain the true age of the groundwater.

Sorption and Desorption of CFCs from the Aquifer Matrix, Diffusion, and dispersion

Russell and Thompson (15) showed that CFCs are adsorbed to and released from soil particles. This has two implications for the CFC dating technique:

1. Rainwater infiltrating through the soil zone adsorbs some CFCs from soil particles (in addition to the CFCs gained from the atmosphere), and hence it is enriched in CFCs.
2. Some of the CFC content of infiltrating rainwater may be adsorbed to soil particles, and hence it is depleted in CFCs.

In the saturated zone, CFCs are adsorbed to the aquifer matrix. Some time later, the adsorbed CFCs may be released to the groundwater system. Diffusion and dispersion of CFCs in groundwater leads to underestimation of CFC concentration in groundwater and hence overestimation of groundwater age.

Mixing of Water of Different Ages

The problem of mixing of groundwaters from different sources and different aquifers that surrounds most of the hydrological calculations affects the CFCs technique, too. Groundwater in fractured rock aquifers is the most problematic because of the large difference between the age of fracture water and the age of matrix water (15). This problem may present the biggest challenge to the CFC dating technique but could be alleviated, to some extent, by comparing CFC ages with hydraulic ages or ages obtained by other techniques.

Uncertainty in Estimating the Atmospheric Input Function

There is always some uncertainty in estimating the historical concentration of CFCs in the atmosphere at a particular site, especially if the site is far from CFC measurement stations. This could lead to underestimation or overestimation of groundwater ages. However, the nearly homogeneous concentration of CFCs in the atmosphere across long distances reduces the uncertainty.

EXAMPLES OF THE APPLICATION OF CFCS IN GROUNDWATER STUDIES

Reilly et al. used CFC and tritium dated ages as well as a numerical simulation technique to quantify the groundwater flow rate, recharge ages of shallow groundwater, and mixing properties of the groundwater system in Locust Grove, Maryland, U.S.A. They showed that the two methods together (the age-dating method and the simulation technique) enabled a coherent explanation of the flow paths and rates of movement; at the same time, they indicated weaknesses in understanding the system. They also showed that the numerical simulations in the absence of the environmental tracer information provided nonunique and therefore, uncertain estimates of the quantities of water and flow paths within the groundwater system.

Bohlke and Denver (18) used CFC age dating along with chemical and isotopic techniques to resolve the history and fate of nitrate contamination in two agricultural watersheds of the Atlantic Coastal Plain, Maryland, USA.

Cook and Solomon (19) showed that only the thick unsaturated zone would have a major influence on the result of CFC dating. Cook et al. (20) showed that the problem of excess air and degradation of CFCs are two factors that may negatively affect CFC dating results. They also concluded that

1. CFC-11 appears to be degraded both in the highly organic unsaturated zone and below the 3.5-m depth in the aquifer.
2. Degradation of CFC-11 resulted in apparent ages that greatly overestimate groundwater travel times at all depths.
3. There is no evidence for degradation of either CFC-12 or CFC-113, whereas CFC-113 shows evidence of retardation. It was, therefore, decided that the best age tracer that matches hydraulic ages is CFC-12.

Cook et al. (21) used CFCs age data in County Musgrave on Eyre Peninsula and the Clare Valley, both in South Australia, to determine the recharge rate to the shallow groundwater. The results showed that the recharge rate to the aquifer was about 20–50 mm per year.

Szabo et al. (22) dated the shallow groundwater in the southern New Jersey coastal plain using CFCs and ^{3}H/^{3}He. They found an excellent correlation between ages obtained from the two methods and also with those obtained by a groundwater flow model.

Cook and Solomon (8) compared the results of CFC, ^{3}H/^{3}He, and ^{85}Kr measurements to date young groundwater, to estimate the groundwater flow path, and to determine vertical and horizontal flow velocities. They noted that in most cases the results from the three methods are in good agreement. However, where there is a difference between the ages, the difference could be used to

1. obtain other information on flow processes;
2. determine the mixing of water of different ages; and
3. identify a fracture flow system because of the different rates at which these tracers diffuse between fractures and matrix.

The residence times of groundwater seepage to streams in the New Jersey coastal plain were determined by Modica et al. (23) using CFC data. They found a negative correlation between the age of groundwater and its nitrate concentration.

CFC groundwater ages proved to be a helpful tool for managing salinized catchments in Eastern Australia (24).

Having measured the CFC ages of groundwater from a number of aquifers in Eastern Australia, Kazemi (11) showed that the groundwater does not become older along the flow line. He also showed a negative correlation between the age of groundwater and the maximum fluctuation in the water table.

MacDonald et al. (25) used CFC concentration in the groundwater of the Permian Aquifer in Dumfries, Scotland, to identify trends in groundwater quality. They clearly demonstrated a positive correlation between the percentage of modern water and the concentration of nitrate in the aquifer; the higher the percentage of modern water in the aquifer, the higher its nitrate concentration.

WORLDWIDE CFC MEASUREMENT LABORATORIES AND COSTS

As of 1999, the following organizations were able to measure CFC concentration in groundwater (11):

1. The Center for Groundwater Studies (CGS), Adelaide, Australia
2. United States Geological Survey, Reston, Virginia
3. Institute fur Umveltphysik, University of Heidelberg, Germany
4. Geological Survey, Switzerland
5. Institute of Geological and Nuclear Studies, New Zealand
6. University of Waterloo, Canada.

The cost of analyzing groundwater for CFCs was about US $100 per sample as of 1999. The total cost of a single analysis is about double considering the expenses of (1) the labor, (2) the ultra high purity (UHP) C size nitrogen gas cylinder, (3) the oxygen and fuel (for sealing ampules), and (4) the shipment of samples to laboratories and hiring of sampling equipment (11).

COAGULATION AND FLOCCULATION

Kirsten Exall
National Water Research
Institute
Burlington, Ontario, Canada

INTRODUCTION

Removal of suspended or colloidal solids is an integral component of both drinking water and wastewater treatment. Natural waterbodies from which drinking water is obtained contain a variety of particulates, including clays, silt, organic detritus, and microorganisms. Municipal and industrial wastewaters contain high concentrations of solids, as well as nutrients, organics, and pathogens. Many contaminants of concern to human and environmental health are commonly associated with particles (e.g., certain heavy metals and polynuclear aromatic hydrocarbons, PAHs) or are of colloidal size themselves (e.g., pathogenic microorganisms such as *Cryptosporidia*) (2). Removal of suspended or colloidal particles is therefore necessary to reduce a variety of health hazards.

The addition of chemical coagulants to aid in removing solids and organic matter is a fundamental step in conventional drinking water treatment. In wastewater treatment, coagulants may be added to enhance primary settling (known as chemically enhanced primary treatment or advanced primary treatment) or to improve separation of sludge in the secondary clarifier. Additionally, flocculants may be applied during sludge thickening and dewatering; this application has recently been discussed by Bache (1). This article focuses on chemical coagulant addition and subsequent flocculation processes during drinking water and wastewater treatment; various factors that influence the effectiveness of these processes are discussed.

COAGULATION AND FLOCCULATION

Colloidal Stability

Colloidal particles, as broadly defined, exist in the size range of nanometers to micrometers. Such particles do not readily settle out of suspension in natural water or wastewater due to very low settling velocities and do not aggregate quickly due to electrostatic or steric stabilizing influences. Many colloidal materials in natural water and wastewater have negatively charged surfaces, which lead to the formation of an electrical double layer (the charged surface with adsorbed ions and a more diffuse, surrounding ion cloud). Repulsion between like-charged surfaces of neighboring colloids imparts electrostatic stability to the particles. The degree of stability depends on the magnitude of the surface charge, which can be indirectly measured by the zeta potential of the particle. Further discussion of the origins, impact, and modeling of the electrical double layer and electrostatic stabilization (as they relate to water treatment) can be found in Letterman et al. (2).

Steric stabilization may occur when polymer segments adsorb on a particle's surface, leaving loops and tails extending into solution. Interactions between adsorbed polymers on nearby colloids then lead to repulsion, as mixing or compression of the extended polymer segments increases local concentration of those segments (which may directly repel one another) and reduces the volume available to each segment (a reduction in entropy). Steric stability in natural waters can arise from the adsorption of materials such as humic substances on colloid surfaces (2).

MECHANISMS OF COAGULATION AND FLOCCULATION

Most colloids are not indefinitely stable and aggregate after some time. Coagulation in water treatment uses physicochemical processes to accelerate the kinetics of destabilization (coagulation) and aggregation (flocculation). Coagulation involves adding a chemical agent to destabilize colloids in the water and requires intensive mixing to disperse the coagulant rapidly. Flocculation, on the other hand, the formation of aggregates, or flocs, of the destabilized colloids, requires gentle mixing to allow interparticle collisions to form flocs without shearing the aggregates (2). Separation of the flocs and other particulate matter from the water may then occur by gravity settling (sedimentation), dissolved air flotation, or filtration (3).

Coagulation processes include double layer compression, charge neutralization, sweep coagulation, and complex formation; these processes are described below:

- *Double layer compression* occurs on addition of simple salts (e.g., Na^+) to a colloidal suspension; this mechanism of colloid destabilization is impractical for water and wastewater treatment because the salt concentrations required are high and particle aggregation is slow.
- *Charge neutralization* is a common mechanism of contaminant removal employed in water treatment, whereby cationic (positively charged) coagulant species adsorb to the negatively charged particle surface, neutralizing the surface charge and thereby reducing electrostatic stability. Addition of excess coagulant, or overdosing, can result in the reversal of surface charge and restabilization of the dispersion (2). In the case of polymeric coagulants, neutralization is described by the electrostatic charge patch model, where polymer species adsorb to portions of the colloid surface, resulting in the formation of charge-neutral or positively charged "patches," which cause electrostatic attraction and aggregation of colloidal species (4,5).
- In *sweep coagulation*, voluminous metal hydroxide flocs bring about removal of colloidal contaminants through enmeshment as they move through the suspension. The relationship between floc structure and operating problems during sweep coagulation has been reviewed by Bache et al. (6).
- Dissolved contaminants, such as organic species or phosphate, may also be removed by *formation of insoluble complexes* or by adsorption to flocs (2).

Flocs are aggregates of primary particles bound together by intermolecular forces. Flocculation, or floc growth, occurs through interparticle collisions. Both particle collision frequency and collision efficiency (sticking) influence the formation of flocs; floc strength and mixing intensity, or shear, influence the final floc size (7). Polymer flocculants (described below) can improve flocculation through adsorption and *interparticle bridging*. In this mechanism of flocculation, segments of a polyelectrolyte are bound to one colloid particle, but loops and dangling chains of the polymer extend into solution and can attach to nearby particles, leading to an increase in the size of the agglomerate (4,5). It may be difficult to distinguish between charge neutralization and bridging when using polymers for flocculation, because both processes can take place simultaneously (8).

COAGULANTS AND FLOCCULANTS

Coagulation has long been used as an aid to sedimentation in water and wastewater treatment. Common coagulants include both metal salts and charged polymers (also termed polyelectrolytes); flocculants are typically composed of high molecular mass polymers.

Inorganic Coagulants

When simple inorganic coagulants, such as aluminum sulfate (alum) or ferric chloride, are added to water, the salts dissociate, and the metal ions undergo hydrolysis to form a variety of hydroxoaluminum or hydroxoiron species. In these reactions, the acidity of the metal cation causes deprotonation of waters of hydration. The resultant species may be cationic, anionic, or neutral and can include an insoluble metal hydroxide; the distribution of species depends on the concentration of the metal ion, pH, and other materials in the water.

Successive reactions in a solution of an aluminum salt lead to the formation of the species Al^{3+}, $Al(OH)^{2+}$, $Al(OH)_2{}^+$, $Al(OH)_3$, and $Al(OH)_4{}^-$. Note that for the sake of simplicity, the waters of hydration (e.g., $Al(H_2O)_6{}^{3+}$) are conventionally not shown. The cationic species can destabilize colloids through surface charge neutralization. At higher concentrations or pH, both Al^{3+} and Fe^{3+} are converted to insoluble hydroxides, which form voluminous, amorphous flocs. These flocs are responsible for sweep coagulation and can enmesh colloidal material as they pass through the suspension. Depending on the conditions of hydrolysis, polynuclear aluminum species (those containing more than one aluminum ion) may also be formed. These include dimeric [e.g., $Al_2(OH)_2{}^{4+}$], trimeric [$Al_3(OH)_4{}^{5+}$], and tridecameric ($Al_{13}O_4(OH)_{24}{}^{7+}$) forms (9). Concerns exist over the potential health effects of aluminum in drinking water, so coagulation conditions should be chosen to minimize residual levels of the metal in the finished water (2). Similar reactions occur when using iron salts, and equivalent mononuclear and polynuclear iron species exist (2,9).

Prehydrolyzed Coagulants

Various prehydrolyzed coagulants have been prepared and investigated, including polyaluminum chloride (PACl) (e.g., 10,11), polyaluminum silicate sulfate (PASS) (12), polyaluminum sulfate (PAS, also known as polyaluminum hydroxysulfate, PAHS) (e.g., 13,14), and various iron-based and mixed Fe-Al coagulants (15,16). PACl is the most commonly used of these (9). Prehydrolyzed coagulants are formed by partial neutralization of a simple salt solution, such as aluminum chloride, by a base. The degree of prehydrolysis is expressed as a hydroxide-to-metal ion ratio and can be expressed as a percent basicity (10), where

$$\text{Basicity (\%)} = 100 * [OH^-]/(3 * [M_T]) \qquad (1)$$

Prehydrolysis favors the formation of soluble polynuclear species, such as the tridecamer (9,10). The rate of particle destabilization is faster with PACl than with alum, and the prehydrolyzed product, PACl, is less dependent on pH for efficient coagulation. The performance of prehydrolyzed aluminum coagulants is also less affected by low temperatures than that of alum [9, and references therein]. Though effective in organic matter removal, prehydrolyzed coagulants are not superior to alum in this regard (9) and may even display higher sensitivity to organic matter concentration (19). Other reported benefits of prehydrolyzed coagulants have included lower aluminum residuals, reduced sludge volume, less alkalinity consumption, and improved settling efficiency (9,18).

Organic Polymers

Synthetic polymers are commonly used as coagulants or flocculants in water and wastewater treatment (4,20,21). Typical polymers include polyacrylamide (PAM), polydiallyldimethyl ammonium chloride (PolyDADMAC), and epichlorohydrindimethylamine (Epi-DMA). Many polymers are derivatized (chemically altered) to contain charged functional groups, such as quaternary ammonium groups, to improve coagulating characteristics (4). The behavior of a polymer is governed by the nature of its charge, whether cationic (positively charged), anionic (negatively charged), zwitterionic (containing both positively and negatively charged groups), or nonionic. Although anionic and nonionic polymers are effective in removing colloidal contaminants under some conditions and may be used as flocculants in conjunction with inorganic coagulants, the polymers used as primary coagulants in water and wastewater treatment are most often cationic (2,4,20).

Synthetic polymers may be used as either coagulants or flocculants, depending on the molecular character and mode of action on suspended solids. Polymer coagulants typically have a low molecular mass and high charge density and commonly act on colloids to bring about coagulation through charge neutralization. In this case, removal is considered to proceed by the electrostatic charge patch model (discussed above). As with inorganic coagulants, charge reversal and restabilization is possible with polymer coagulants. Polymer flocculants, on the other hand, generally have very high molecular mass and low charge density and typically act through a bridging mechanism. Flocculants are also commonly known as coagulant aids because they are often used in conjunction with inorganic or polymeric coagulants (4,5).

The effectiveness of polymers (particularly the large molecular mass flocculants) can depend strongly on their conformation, which in turn depends on the preparation of polymer solution. Many flocculants are supplied in concentrated, highly entangled forms, often as dispersions or emulsions in mineral oils. The polymer must be dissolved in water and at least partially disentangled, or "activated," for optimal flocculation behavior. The intensity of mixing during dispersion can impact the dissolution process; a balance must be achieved between rapid dispersion of the polymer and rupture of polymer chains under high shear conditions (8). Other factors that may influence the effectiveness of a polymer solution include other ions in the water (8) and the age of a polymer solution (22).

Concerns over the use of synthetic polymers in water and wastewater treatment have been raised with regard to the toxicity of residual trace levels in the effluent and formation of toxic by-products on reaction of residues with disinfectants (e.g., 23,24). Polymers are expected to be largely partitioned into the solid phase, but the amount of residual polymer remaining in the liquid stream depends on the dosage. Careful dosage selection and control is therefore needed. Other concerns exist with respect to contaminant monomer concentrations (e.g., acrylamide in polyacrylamide formulations); many countries regulate the composition and allowed dosages of polymers used in drinking water treatment (2,25,26).

Natural Coagulants

Natural products, including chitosan (a derivative of chitin, found in the shells of crustaceans), starch derivatives, seed extracts of such plants as *Moringa oleifera*, tannin- and lignin-based materials, and alginate have also been studied for use in municipal water or wastewater treatment (4,27). These products have been examined primarily for use in developing countries, but often display many of the advantages of synthetic polymeric coagulants and flocculants, while providing the additional benefits of biodegradability and reduced toxicity (27).

Ballasted Flocculation

Under conditions that would lead to the formation of poorly settling flocs, such as low solids and high organics concentrations, ballasted flocculation may be used. In this technique, additional solids are added with (or shortly after) the coagulant to improve floc formation and settling. Polymers may also be dosed to improve adhesion of the forming flocs to the solids, and the solids may be recovered and recycled through the process (4,28). Various solids have been used as ballast, including bentonite, fly ash, powdered magnetite, and microsand (3,29).

ORGANIC MATTER REMOVAL

Organic species exist in many forms in natural waters and wastewaters and, even when not directly harmful to human health, can be carriers of contaminants such as pesticides and can interfere with treatment processes. Reaction of organic matter (OM) with disinfectants may also lead to the formation of harmful disinfection by-products, including trihalomethanes (2). In drinking water treatment, the term "enhanced coagulation" refers to the practice of optimizing coagulation conditions for removing natural organic matter (NOM), which is typically accomplished through increased coagulant dosage and adjustment of pH (30).

In general, the presence of organic matter increases the required dosage of a metal salt coagulant. Once the coagulant demand is met, turbidity and NOM removal occur simultaneously (31–33). A linear relationship often exists between OM concentration and the coagulant dose required for coagulation. The presence of such a "stoichiometric" relationship between the concentration of humic substances and alum dosage was first described by Hall and Packham (31) and has since been observed with various coagulants and organic species (e.g., 33,34).

The nature of the organic matter present affects its removal by coagulation. Many researchers (e.g., 32,33) have observed preferential removals of hydrophobic, dissolved organic carbon compounds over hydrophilic organic fractions and of higher molecular mass organic matter over lower molecular mass compounds.

Metal ion concentration and pH are important factors governing the mechanism of OM removal by coagulation. Two distinct regions of organic matter or color removal have been observed (32,34,35), one near pH 5.5 and one centered near pH 7. The two domains have been explained in terms of removal mechanisms. The lower pH and aluminum concentration region is thought to represent removal by charge neutralization/precipitation, where cationic aluminum species interact directly with OM to bring about removal (2,32). The higher pH/higher coagulant dosage domain is thought to indicate sweep coagulation, where organic species adsorb directly to the surface of formed $Al(OH)_3$ flocs (32,35). Removal of OM may not occur by a single, simple mechanism, however. It has been suggested that even the OM that is ultimately removed by adsorption to $Al(OH)_3$ surfaces may first be complexed by cationic coagulant species (17,33).

The presence of organic matter also increases the required dosage of polymer coagulants and flocculants, thereby greatly increasing the cost of treatment (4,36). As with metal salts, the more hydrophobic OM fractions are more easily removed by polymer, and increasing polymer charge density improves OM removal (37). Polymer molecular mass also influences organic matter removal, although the effect is inconsistent (e.g., 37,38).

FACTORS AFFECTING EFFICIENCY OF COAGULATION AND FLOCCULATION

Many variables may influence the progression of coagulation and flocculation processes, but the primary factors include pH, temperature, mixing conditions, and other ions.

pH Dependence

The speciation of aluminum and iron in aqueous solution are highly dependent on pH. Under acidic conditions, cationic coagulant species (e.g., $Al(OH)^{2+}$) are dominant; in highly basic solution, the anionic hydroxoaluminum or iron form ($Al(OH)_4{}^-$ or $Fe(OH)_4{}^-$, respectively) predominates. At intermediate pH, both the pH and metal ion concentration affect the speciation of aluminum or iron, in turn influencing the interactions between the coagulant species and colloidal solids or organic matter (2). The optimum pH for solids removal and organic matter removal may differ slightly and depends on the mechanism of coagulation (32,34,35).

To minimize residual aluminum or iron in treated water, it is preferable to conduct coagulation under conditions of minimum metal hydroxide solubility. Aluminum hydroxide exhibits a minimum in solubility at 25 °C at approximately pH 6.3; the minimum solubility of iron at the same temperature is at approximately pH 8 (2). In general, synthetic polymers are much less sensitive to pH than metal salt coagulants (4,20).

Temperature

It has long been known that cold temperatures increase the coagulant dose required and change the nature of the flocs produced during coagulation by simple salts (39). Many reasons for the temperature effects have been suggested, including changes in water viscosity (which could affect mixing efficiency), change in the rate and extent of hydrolysis, and changes in the size and strength of flocs formed at lower temperatures (40,41).

The effect of pH varies in cold waters; the optimum pH value for coagulation and flocculation changes with both coagulant concentration and temperature (39). Kang and Cleasby (40) noted that the value of pK_w is temperature-dependent, and adjusting the pH of the solution so that a constant pOH value was held in cold and warm waters was found partially effective in reducing the impact of low temperature on flocculation kinetics.

Prehydrolyzed coagulants are generally less susceptible to temperature changes than are simple aluminum or iron salts (11,18). Synthetic polymers are also not as sensitive to water temperature as metal salt coagulants, although storage of polymer solutions at elevated temperatures may increase the rate of degradation and lowers the effective polymer concentration (22).

Mixing Effects

Coagulation and flocculation processes require both a rapid mix phase to achieve complete and uniform distribution of the coagulant in the water to be treated and a slow mix phase, which promotes interparticle collisions so that flocs may form and grow. Both mixing phases influence the efficiency of contaminant removal.

Although the intensity of rapid mixing is not particularly important for sweep coagulation processes (where contaminant removal occurs by physical interaction between amorphous metal hydroxide flocs and colloids), charge neutralization with metal salt coagulants requires contact between the rapidly changing cationic aluminum or iron species and the colloids in the water before hydrolysis is complete and the metal hydroxide solid forms. For effective charge neutralization, the coagulant species must therefore be distributed throughout the water sample as quickly as possible. Optimization of the rapid mix parameters improves turbidity removal considerably for a given water sample and lowers the required coagulant dosage (42). To optimize the rapid mixing phase of treatment, the intensity of mixing (often expressed as the velocity gradient, G), duration of mixing, and container geometry should all be considered (44).

Increased agitation accelerates floc formation and aggregation through interparticle collisions; if mixing is too vigorous, however, turbulent shear forces cause the breakup of flocs. Interparticle collisions occur through transport by fluid shear, which is controlled by characteristics of the slow mixing phase of treatment, such as vessel geometry, flow patterns, and the turbulence and intensity of mixing (2). Floc breakup may occur through surface erosion of primary particles or fracture of the relatively fragile floc aggregate and is dependent on the intensity of the slow mix phase. The competing processes of aggregation and floc breakup result in a stable floc size for a given set of formation conditions (7).

As discussed above, mixing intensity is significant in the activation of polymer flocculants (8). It is also an important parameter in the application of polymer coagulants and flocculants. In general, higher intensity mixing (higher energy input) is required for the dispersion of polymers than for metal salts, but care must be taken not to shear the polymer (20,43).

Other ions

A number of aspects of water quality impact coagulation processes, including the alkalinity of the water. At very low alkalinity, small additions of an acidic metal coagulant (such as alum) can depress the pH of the water below that of efficient coagulation; at very high alkalinity, coagulant demand may be extremely high (32).

Some anions, such as fluoride, phosphate and certain organic acids, can strongly complex cationic metal species, inhibiting coagulation by reducing free cations in solution (2). The presence of divalent cations, such as Ca^{2+}, typically broadens the pH range for effective organic matter removal and lowers the coagulant dosage required. This is likely due to the complexation of such cations with anionic organic functional groups, lowering the stability of the organic species and thereby decreasing demand on the coagulant (32,45). Sulfate may enhance coagulation by suppressing charge reversal or by catalyzing the kinetics of precipitation through the formation of outer sphere complexes with aluminum ions (45). The presence of silicate or sulfate during prehydrolysis of aluminum salts may also influence aluminum speciation, thereby altering the coagulant composition and activity (12).

The selection and effectiveness of polymers may also be affected by the ionic strength of the system. The addition of simple salts (such as NaCl) causes a contraction in polymer conformation, reducing the effectiveness of polymer flocculants (5).

The conflicting effects of many variables make prediction of coagulant demand for a given water type difficult, so the required dosage of coagulant or flocculant is typically determined empirically by laboratory jar tests.

SUMMARY

Coagulants and flocculants are commonly used in the destabilization and aggregation of suspended solids during water and wastewater treatment. Both inorganic salts and organic polymers may be used as coagulants, and various synthetic and natural organic polymers are applied as flocculants. Organic matter removal is another common objective of coagulation during drinking water treatment, although it generally requires a higher coagulant dosage. Other factors that influence the effectiveness of coagulants and flocculants include pH, temperature, mixing conditions, and other ions in the water. To maximize the efficiency of contaminant removal while minimizing residuals, careful coagulant or flocculant dose selection and control are essential.

CONDUCTIVITY-ELECTRIC

David M. Gray
Mettler-Toledo Thornton Inc.
Bedford, Massachusetts

Electrical conductivity is the ability of a material to carry electrical current. In water, it is generally used as a measure of mineral or other ionic concentration. Conductivity is a measure of the purity of water or the concentration of ionized chemicals in water. However, conductivity is only a quantitative measurement: it responds to all ionic content and cannot distinguish particular conductive materials in the presence of others. Only ionizable materials will contribute to conductivity; materials such as sugars or oils are not conductive.

In a metal conductor, electrical current is the flow of electrons and is called *electronic* conductance. In water, electrical current is carried by ions because electrons do not pass through water by themselves. This is *electrolytic* conductance.

When a voltage is applied between two inert electrodes immersed in a solution, any ions between them will be attracted by the electrode that has an opposite charge. Ions will move between electrodes and produce a current depending on the electrical resistance of the solution. This is the basis of conductivity measurement—an application of Ohm's law. For high purity waters, it is common to express conductivity as its reciprocal, resistivity.

To prevent altering a sample by major ionic movement and electrochemical reaction at the electrodes, alternating current is always used for measurement. Using ac, the polarity changes frequently enough that ions do not move or react significantly. Measuring systems must control the voltage, frequency, and current density to minimize errors due to electrode polarization and capacitance. Modern instrumentation may change one or more of these variables automatically, depending on the conductivity range being measured.

UNITS OF MEASURE

Conductivity is the conductance of a standardized volume of water of 1 cm^2 cross-sectional area and electrodes spaced 1 cm apart, as shown in Fig. 1. The same results will be obtained with various geometries as long as the ratio of length/area is equal to 1 cm^{-1}, the cell constant. Units of measure are related as listed in Table 1. Most conductivity values are quite small, so unit multiplier prefixes of milli (m, 10^{-3}) and micro (μ, 10^{-6}) are commonly used.

The standardized geometry of the cell constant ensures that the conductivity measurement is a property of the sample and not of the sensor. The cell constant is determined with precision by calibration in standard solutions of known conductivity. Accepted standard potassium chloride solutions are established in an ASTM standard method. Standard reference materials are also available from NIST.

Cell constants other than 1 cm^{-1} may be used as long as the measuring instrument readout is normalized accordingly. A lower cell constant sensor is needed to enable the measuring instrument to measure accurately in low conductivity (high resistivity) samples. Higher cell constants are needed to measure in high conductivity samples. The exact requirements depend on the measuring instrument.

Most practical cells do not use the parallel plate electrode arrangement of Fig. 1. They have greater durability and allow more convenient installation in other arrangements. For example, typical pure water sensors for on-line measurement use concentric electrodes that maintain the spacing and geometry for 0.01 to 0.1/cm constant. A variety of two-electrode process conductivity sensors is illustrated in Fig. 2.

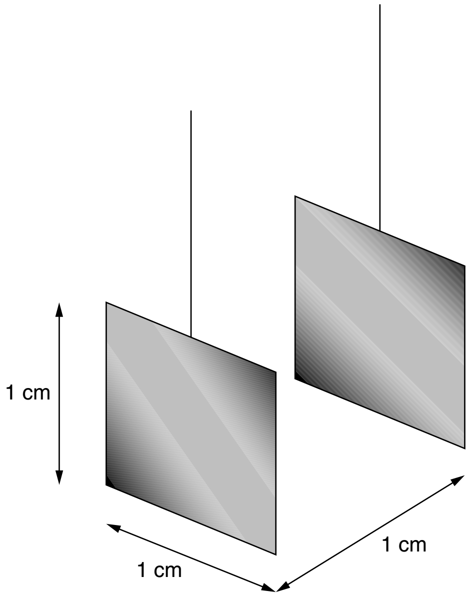

Figure 1. Cell constant = 1 cm electrode spacing divided by 1 cm^2 cross-sectional area of sample.

Table 1. Units Related to Conductivity Measurement

Measurement	Application	Units
Resistance	Electrical circuit	ohm (Ω)
Conductance	Electrical circuit	ohm^{-1} (Ω^{-1}) = siemens (S) = mho (now obsolete)
Resistivity	High purity water	ohm · cm (Ω· cm)
Conductivity	Most water samples	siemens/cm (S/cm) = mhos/cm (now obsolete), siemens/m (S/m)[a]

[a] Most users employ units of S/cm. However, SI conductivity units used in some parts of the world are S/m which can easily be confused. 1 S/cm = 100 S/m.

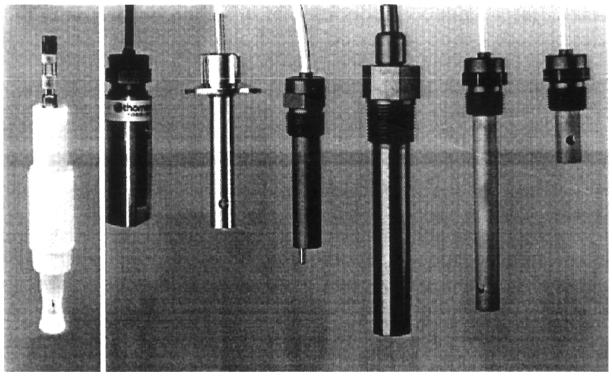

Figure 2. Conventional two-electrode conductivity sensors: 0.1 cm^{-1} in retractable housing, 0.1 cm^{-1} in flow chamber, sanitary 0.1 cm^{-1}, 10 cm^{-1} insertion, 50 cm^{-1} insertion, long 0.1 cm^{-1} insertion, short 0.1 cm^{-1} insertion.

The conductivity of very dilute solutions can be calculated from physical chemistry data based on Equation 1 which sums the conductivity contribution of all ions in the solution:

$$\Lambda = \rho \Sigma(\lambda_i c_i) \tag{1}$$

Λ = conductivity
ρ = density of water
λ_i = equivalent ionic conductance of ion ‘i’
c_i = concentration of ion ‘i’

TEMPERATURE EFFECTS

Conductivity is affected by temperature because water becomes less viscous and ions can move more easily at higher temperatures. Conventionally, conductivity measurements are referenced to 25 °C, though occasionally a 20 °C reference is used. The variation with temperature is apparent in Equation 1 because λ_i and, to a lesser degree, ρ are temperature dependent. The conductivity of most ions increases by about 2.2% of their value per °C which allows for simple temperature compensation. This is suitable for most midrange conductivity measurements. Very low and very high conductivity samples require special handling of temperature effects.

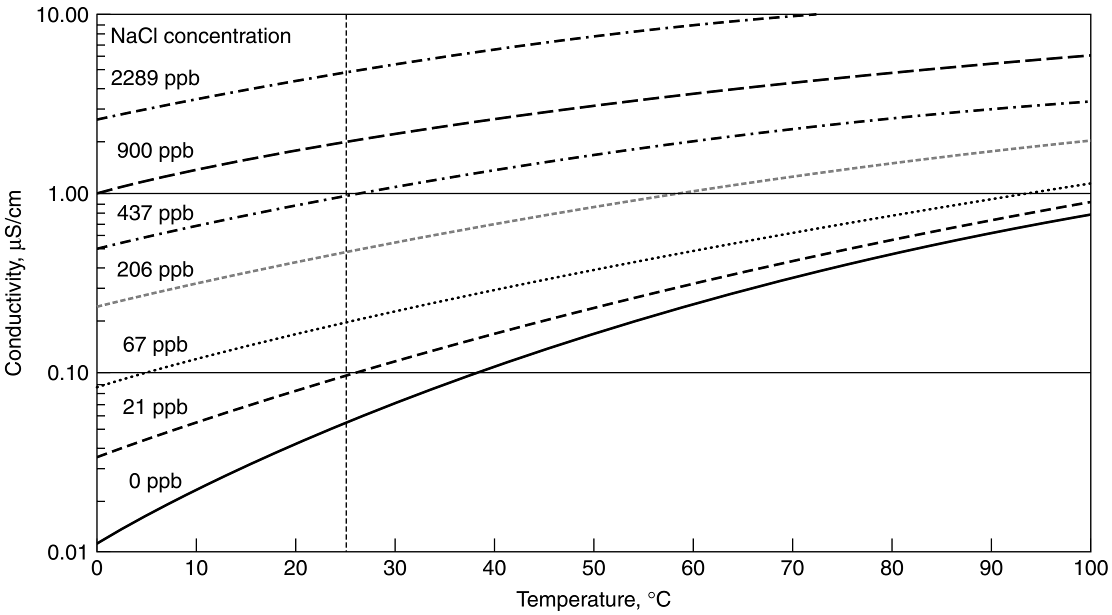

Figure 3. High purity water conductivity vs. temperature.

As water is purified below 5 µS/cm (>0.5 MΩ·cm), the small amount of hydrogen (H^+) and hydroxide (OH^-) ions from water itself become a significant part of total conductivity, that is, the concentrations, c_i, in Eq. 1, of H^+ and OH^- must be included. Water self-ionizes to a much greater degree at higher temperatures, producing a higher concentration of ions. Those ions are also more conductive. The temperature coefficient increases to 4–7%/°C, depending both on purity level and temperature; both effects are nonlinear. These effects are evident in Fig. 3. Specialized high purity temperature compensation must be employed for accurate measurements in this low conductivity range.

Highly concentrated solutions also exhibit deviant behavior. In modest concentration ranges, conductivity is roughly proportional to concentration. At higher concentrations, Eq. 1 does not apply, and ionic interference restricts the mobility of the ions. Conductivity levels off and in many cases decreases as concentration increases, as shown in Fig. 4. Measurement near the peaks of these curves is ambiguous and cannot be relied on for inference of concentration because there are two possible values.

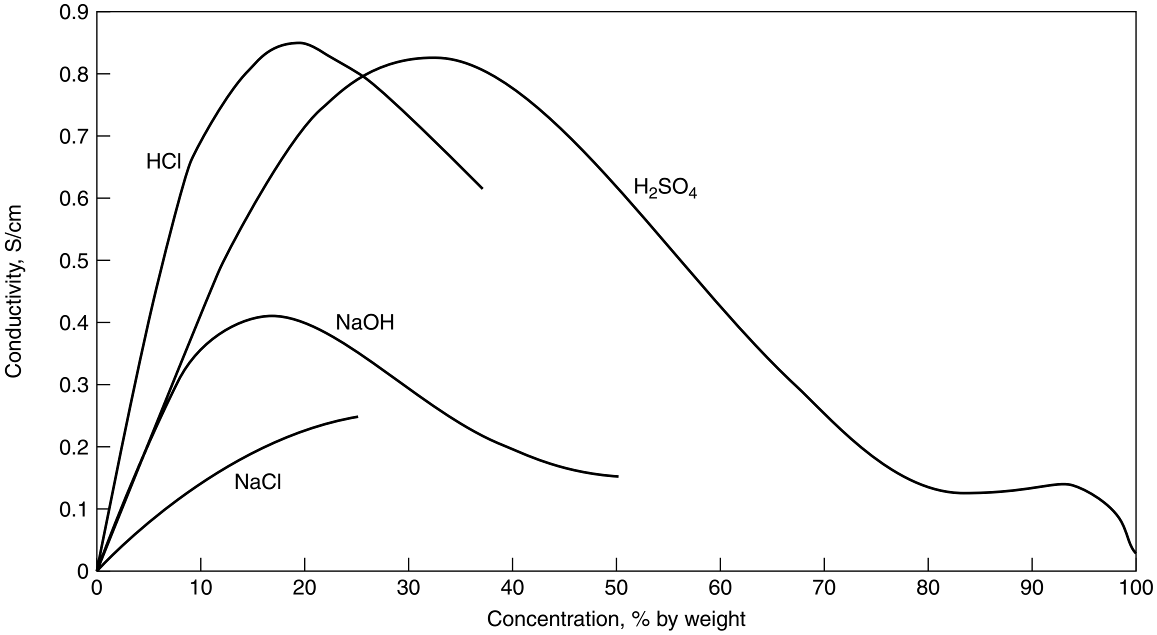

Figure 4. Conductivity vs. concentration at 25°C.

Highly conductive solutions also have a lower temperature influence, typically less than 2%/°C.

ALTERNATIVE MEASUREMENT TECHNOLOGIES

Figure 1 and its description refer to the conventional two-electrode sensor and measurement technique. Four-electrode conductivity measurement uses a sensor incorporating four electrodes. It is useful for highly conductive and/or dirty water samples which would foul the surfaces or plug the narrow passages of conventional high constant two-electrode sensors.

Four-electrode measurement applies ac through the sample via two outer drive electrodes, as shown in Fig. 5. These electrodes may become fouled, and the circuit will compensate to maintain the ac current level constant. Two inner measuring electrodes are used to sense the voltage drop through the portion of solution between them. The circuit makes a high impedance ac voltage measurement, drawing negligible current and making it much less affected by additional resistance due to fouling of the measuring electrode surfaces. Sensors for four-electrode conductivity measurement are shown in Fig. 6.

Inductive (also known as noncontact, electrodeless, or toroidal) conductivity measurement is made without any direct electrical contact with the sample. The sensor consists of two parallel coils sealed within a doughnut-shaped insulated probe, as shown in Figs. 7 and 8. The instrument energizes one coil with ac. A weak ac current is induced in the surrounding sample, depending on its conductivity. That current, in turn, induces a signal in the measured coil which provides the measurement signal. The sample acts like the core of a transformer. A temperature sensor is incorporated into the probe body to enable compensation in the instrument.

Because there are no electrodes in contact with the sample, extreme fouling conditions can be tolerated. Coatings can cause errors only if there is so much accumulation that they reduce the diameter of the hole.

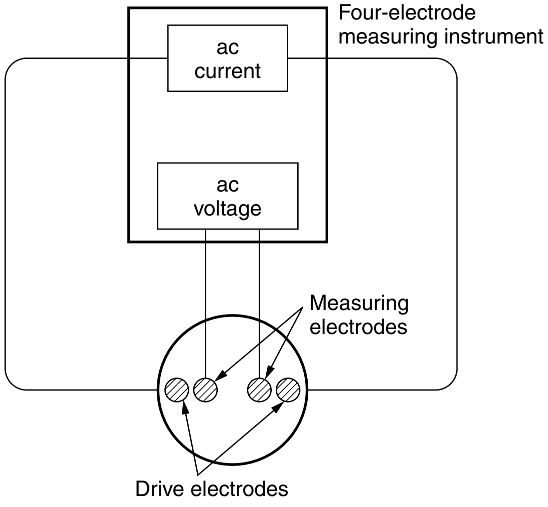

Figure 5. Four-electrode conductivity measurement.

Figure 6. Four-electrode conductivity sensors.

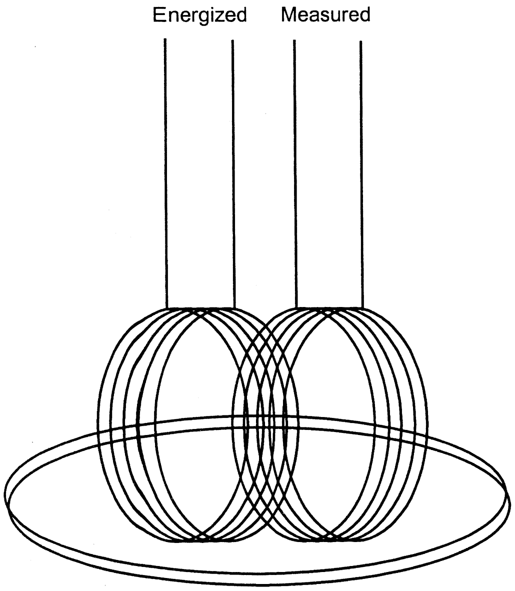

Figure 7. Inductive conductivity measurement.

Care is needed in installating an inductive sensor to allow for the specified spacing around it. Otherwise, the cross section of sample immediately around the probe (cell constant) will be affected, and recalibration may be required.

TOTAL DISSOLVED SOLIDS (TDS)

TDS is sometimes inferred from conductivity and is reported in units of parts per million. However, the relationship of conductivity and concentration is not standardized and to be meaningful, should be specified whenever TDS units are used. Typical conversions are based on sodium chloride (which may also be called salinity) at approximately 0.5 ppm TDS per μS/cm. Alternatively, a "natural water" mineral composition including bicarbonates would have a conversion of 0.6–0.7 ppm TDS per μS/cm. Conversions may also be slightly nonlinear with concentration.

Figure 8. Inductive conductivity measurement equipment.

CONSERVATION AND THE WATER CYCLE

Natural Resources
Conservation Service

Water is probably the natural resource we all know best. All of us have had firsthand experience with it in its many forms—rain, hail, snow, ice, steam, fog, dew.

Yet, in spite of our daily use of it, water is probably the natural resource we least understand. How does water get into the clouds, and what happens to it when it reaches the earth? Why is there sometimes too much and other times too little? And, most important, is there enough for all the plants, and all the animals, and all the people?

Water covers nearly three fourths of the earth; most is sea water. But sea water contains minerals and other substances, including those that make it salty, that are harmful to most land plants and animals. Still it is from the vast salty reservoirs, the seas and oceans, that most of our precipitation comes—no longer salty or mineral laden. Water moves from clouds to land and back to the ocean in a never ending cycle. This is the water cycle, or the hydrologic cycle.

Ocean water evaporates into the atmosphere, leaving impurities behind, and moves across the earth as water vapor. Water in lakes, ponds, rivers, and streams also evaporates and joins the moisture in the atmosphere. Soil, plants, people, and animals, and even factories, automobiles, tractors, and planes, contribute moisture. A small part of this moisture, or water vapor, is visible to us as fog, mist, or clouds. Water vapor condenses and falls to earth as rain, snow, sleet, or hail, depending on region, climate, season, and topography.

Every year about 80,000 cubic miles of water evaporates from oceans and about 15,000 cubic miles from land sources. Since the amounts of water evaporated and precipitated are almost the same, about 95,000 cubic miles of water are moving between earth and sky at all times.

Storms at sea return to the oceans much of the water evaporated from the oceans, so land areas get only about 24,000 cubic miles of water as precipitation. Precipitation on the land averages 26 inches a year, but it is not evenly distributed. Some places get less than 1 inch and others more than 400 inches.

The United States gets about 30 inches a year, or about 4300 billion gallons a day. Total streamflow from surface and underground sources is about 8.5 inches a year, or about 1200 billion gallons a day. This is the amount available for human use—homes, industry, irrigation, recreation.

The difference between precipitation and streamflow -21.5 inches a year, or 3100 billion gallons a day—is the amount returned to the atmosphere as vapor. It is roughly 70 percent of the total water supply. It includes the water used by plants.

People can exist on a gallon or so of water a day for drinking, cooking, and washing though we seldom do or have to. In medieval times people probably used no more than 3 to 5 gallons a day. In the 18th century, especially in Western nations, people were using about 95 gallons a day. At present in the United States, people use about 1500 gallons a day for their needs and comforts including recreation, cooling, food production, and industrial supply.

When water hits the ground some soaks into the soil, and the rest runs off over the surface. The water that soaks into the soil sustains plant and animal life in the soil. Some seeps to underground reservoirs. Almost all of this water eventually enters the cycle once more.

People can alter the water cycle but little, so their primary supply of water is firmly fixed. But we can manage and conserve water as it becomes available—when it falls on the land. If we fail to do so we lose the values that water has when used wisely.

Water management begins with soil management. Because our water supply comes to us as precipitation falling on the land, the fate of each drop of rain, each snowflake, each hailstone depends largely on where it falls—on the kind of soil and its cover.

A rainstorm or a heavy shower on bare soil loosens soil particles, and runoff—the water that does not soak into the soil—carries these particles away. This action, soil erosion by water, repeated many times ruins land for most uses. Erosion, furthermore, is the source of sediment that fills streams, pollutes water, kills aquatic life, and shortens the useful life of dams and reservoirs.

Falling rain erodes any raw earth surface. Bare, plowed farmland, cleared areas going into housing developments, and highway fills and banks are especially vulnerable.

In cities and suburbs, where much of the land is paved or covered—streets, buildings, shopping centers, airport runways—rainwater runs off as much as 10 times faster than on unpaved land. Since this water cannot soak into the soil, it flows rapidly down storm drains or through sewer systems, contributing to floods and often carrying debris and other pollutants to streams.

Grass, trees, bushes, shrubs, and even weeds help break the force of raindrops and hold the soil in place. Where cultivated crops are grown, plowing and planting on the contour, terraces, and grassed waterways to carry surplus water from the fields are some of the conservation measures that slow running water. Stubble mulching protects the soil when it has no growing cover. Small dams on upper tributaries in a watershed help control runoff and help solve problems of too much water one time and not enough another time.

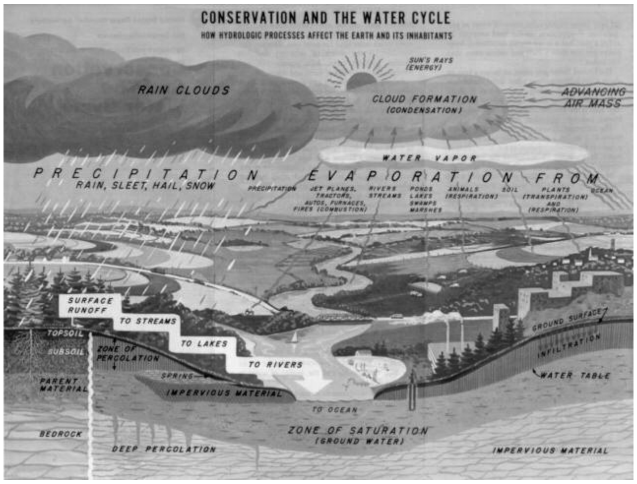
Throughout the world the need for water continues to increase. Population growth brings demands for more water. Per capita use of water, especially in industrialized countries, is increasing rapidly.

It is our management of the precipitation available to us that determines whether or not we have both the quantity and the quality of water to meet our needs.

It is our obligation to return water to streams, lakes, and oceans as clean as possible and with the least waste.

THE WATER CYCLE is an endless process of water circulation going on throughout the world.

To trace the movement of water through the cycle, begin at the far right of the diagram. There the sun's energy is transferring water from the sea and earth to the atmosphere in the form of water vapor. The soil and inland water bodies through *evaporation* and plants through *transpiration* add large amounts of water vapor to the atmosphere, but most of it comes from the oceans. Man, animals, and machines add small amounts by means of *respiration* and *combustion*.



Air masses (top of diagram) carry the water vapor across the earth, and the water vapor condenses into *precipitation*.

At the left, precipitation falls as rain, snow, sleet, hail. Some evaporates while falling and returns to the atmosphere. A small amount is intercepted and held by plants or by buildings, automobiles, and other structures and machines until it evaporates back into the atmosphere.

Most of the precipitation soaks into the soil; the part that doesn't run to the sea by way of streams and rivers. Ground water gets there more slowly.

Misuse and poor management of the soil will decrease the amount of water that soaks into the soil and increase the amount that runs off over the surface. Runoff on bare land leads to erosion. Grass, trees, and other plants hold the soil in place and slow the runoff, allowing more water to soak into the soil.

Some of the water that soaks into the soil is used by plants. Part of it percolates beyond the reach of plant roots to the water table, to underground reservoirs, and to springs and artesian wells.

Runoff on its way to the sea can be intercepted and stored for industrial or household use, and it can be diverted for irrigation.

Little water has been added or lost through the ages. The water cycle prevails in all places and at all times with neither beginning nor end.

DEFLUROIDATION

Eli Dahi
Environmental Development
Corporation
Søborg, Denmark

DEFINITION

Defluoridation refers to methods of water treatment that reduce the concentration of fluoride in the water, normally in order to make it safe for human consumption. Some water treatments that have the capacity of reducing the fluoride concentration along with most other anions, or anions and cations, in the water are not considered defluoridation methods. Thus, general demineralizing methods like distillation, reverse osmosis, electrodialysis, and resin deanionization, which are able to remove fluoride fully or partly from the water, are not considered defluoridation methods. On the other hand, methods that only remove fluoride without any addition or reduction of other parameters are not yet discovered, which is why the expression "fluoride removal" lacks precision. Defluoridation is used to characterize methods that reduce the fluoride ion specifically, without other ***major*** changes to the quality of the treated water.

OBJECTIVES AND EFFECTS

The objective of defluoridation is to prevent or to mitigate ***endemic fluorosis***. The term endemic fluorosis covers a wide variety of clinical manifestations of accumulative fluoride poisoning, mainly because of long-term consumption of relatively high concentration fluoride water. In mild cases, fluorosis is observed as a more or less repulsive mottling of teeth, ***dental fluorosis*** (Fig. 1). More severe cases are known as ***skeletal fluorosis*** (Fig. 2), including deformities like knock knees (genu varum), bowleg (genu valgum), antero-posterior bowing of tibia, humpback (kyphosis), exostosis, and others.

Also, ***nonskeletal fluorosis*** includes swollen joints, muscular tenderness, rheumatism-like pain especially in the joints, systematic rigidity, stiffness, and impaired movement, all symptoms that give a feeling of rapid aging. Also, gastric problems, burning sensation during urination, mental retardation, and paraplegia are reported as clinical manifestation of fluorosis.

SAFE CONCENTRATIONS

According to WHO, the “optimum” and the maximum water concentrations are **0.8 and 1.5 mgF/L**, respectively. These guidelines are adopted on the background of studies carried out mainly in low fluoride areas and in the decades before the widespread fluoridation of toothpaste. Presently, in a fluorotic area, most professionals consider **0.5 and 1.0 mg/L** as the desired and maximum allowable concentrations, respectively. In a defluoridation process, the aim is to treat down to 0.5 mg/L, whereas 1 or 1.5 mg/L can be tolerated as the saturation level. Experience, as well as mass balances, show that once the drinking and cooking water is within these limits, the users do not need to worry about the daily intake of fluoride from other sources like food and normal use of toothpaste, even when residing in a fluorotic area.

Figure 1. Dental fluorosis.

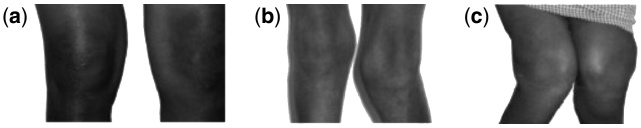


Figure 2. Skeletal fluorosis. (**a**) Stage I: swollen joints, pain, and rigidity. (**b**) Stage II: deformed but still moving. (**c**) crippled, only moving short and with difficulties and pain.

FLUORIDE OCCURRENCE

Fluoride occurs in all natural waters. Ocean waters contain about 1 mg/L, whereas most fresh surface and subsurface waters contain less than 0.5 mg/L. Groundwater is, in general, subject to more variation at higher range. In fluorotic areas, groundwater and/or surface waters may contain up to 20–30 mg/L. As an extreme case, the concentration of 90 mg/L has been recorded in one Rift Valley Lake, where the water is soft but alkaline and the evaporation is high. Fluoride-rich waters that are subject to defluoridation for human consumption are in the range 1.5–20 mg/L.

APPROPRIATE TECHNOLOGY

Defluoridation differs from most other water treatments in four main aspects:

First, because fluoride does not deteriorate the piped water quality technically or oganoleptically, it is normally only required for the small part of the water that is used for drinking and cooking.

Second, defluoridation of large quantities of water, out of which only a small part is used for human consumption, is environmentally unsound, which is because of accumulation of correspondingly large quantities of toxic sludge that would create a new problem, more severe to deal with.

Third, most large cities and towns do not need defluoridation, because they are historically built in sites privileged to have good water resources.

Fourth, defluoridation is easily avoided in industrialized countries, as they have no difficulties in prospecting and transporting low fluoride water.

APPROPRIATE CRITERIA

As a result of the above-mentioned four factors, defluoridation is often required in small scale and in rural areas in developing countries. As such, many defluoridation approaches have been launched, proclaiming success without unbiased field proof and thorough optimization. Further confusion comes with the fact that the process or the technical setup that may work in one context of socio-economic and environmental conditions may fail in another. Local availability and acceptability of the required materials, fluoride contamination level, and water quality are major factors to be considered when selecting the process and the design that minimizes the capital and running costs.

THREE OPERATIONAL LEVELS

Defluoridation technology has to be simple, affordable, reliable, and operational at least at three different levels:

1. Domestic level, e.g., in the kitchen where piped water may not be available, see Fig. 3.
2. Institutional level, e.g., in schools or a working place where piped water may be available and the defluoridator is protected, see Fig. 4.
3. Community level, e.g., in a village or a market where the defluoridator is supplied with water often

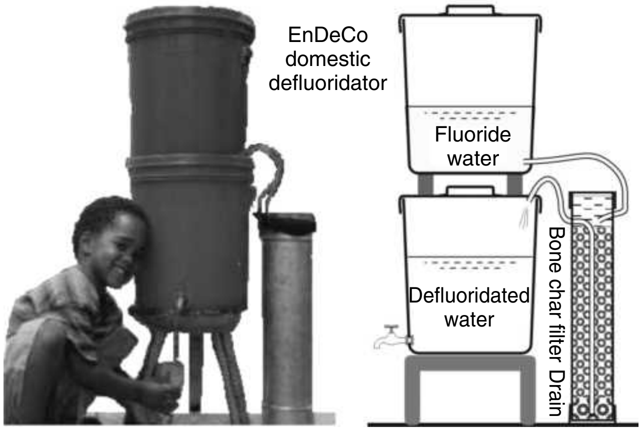

Figure 3. An example of field-tested and optimized domestic defluoridator. It can treat 3000 L of water containing 5 mgF/L, suitable for one family and one-half yearly recharge.

intermittently through a pipe or a hand or power pump, see Fig. 5.

TREATMENT PRINCIPLES

Defluoridation is carried out in one of three different processes:

1. A sorption process in a plug flow filter column with a medium that has a certain capacity of absorption, adsorption, or ion exchange of the fluoride. This process requires recharge or regeneration of the medium upon saturation. Numerous media are known to have defluoridation properties, see Table 1. However, because of capacity, availability, and subsequent water quality limitations, only bone char and activated alumina are worth mentioning. The plants shown in Figs. 1–3 are based on bone char sorption, which is the process of choice if acceptable

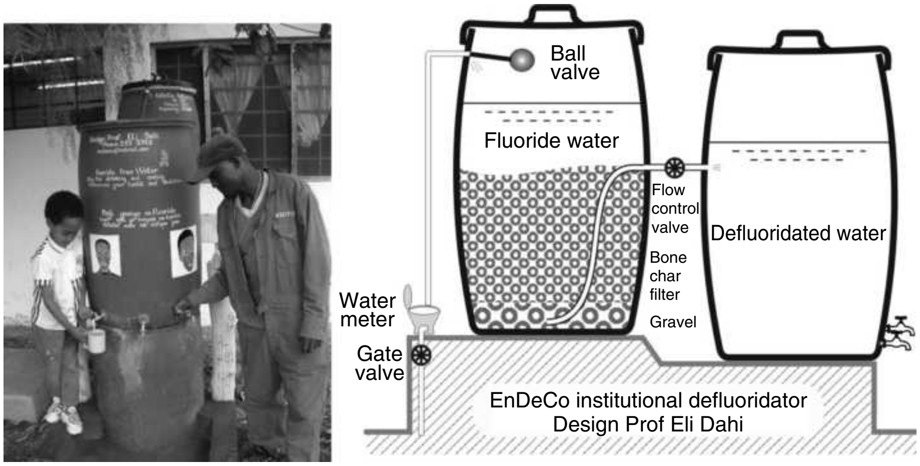

Figure 4. The EnDeCo Institutional Defluoridator. It can be made at any desired capacity, normally in the range 20–160 m^3 for a raw water fluoride of 5 mg/L.

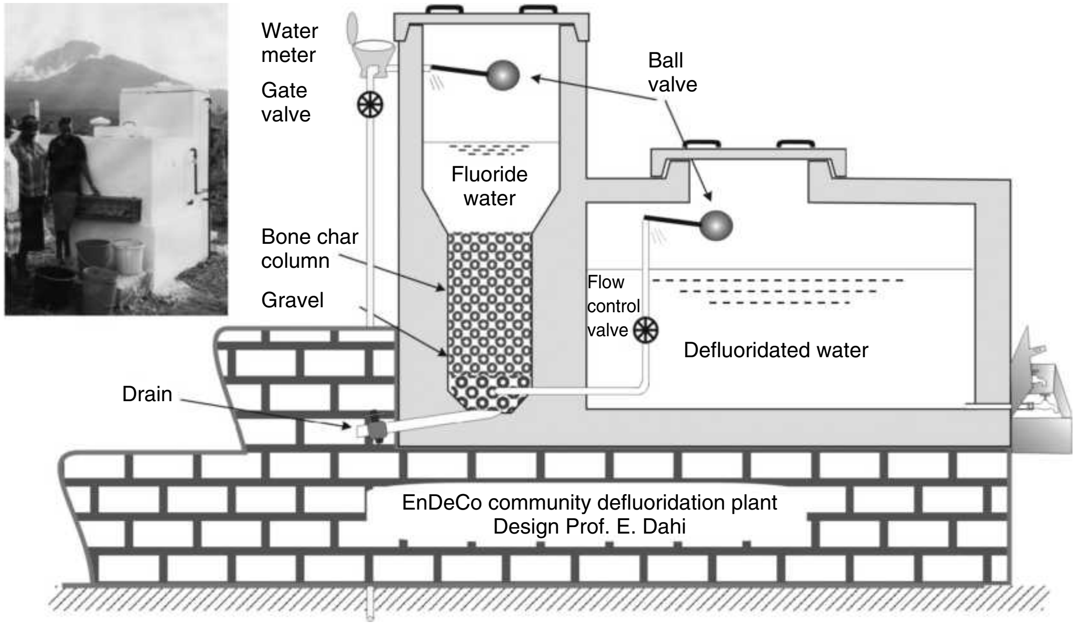

Figure 5. An example of a community defluoridator that has been operating continuously since 1994.

Table 1. Some Natural Media Capable to Sorb Fluoride

Magnesite	Apophyllite	Natrolite
Stilbite	Clinoptilolite	Gibbsite
Goethite	Kaolinite	Halloysite
Bentonite	Verimiculite	Zeolite(s)
Serpentine	Alkalkine soil	Aiken soil
Acidic clay	Kaolinitic clay	China clay
Fuller's earth	Diatomaceous earth	Ando soil

to the community. Alternatively, the same setups can be used in the activated alumina process, which is often preferred, e.g., in strictly vegetarian societies that consider the use of (cow) bone char as unethical.

2. A coprecipitation process in batch containers, where the precipitating chemicals are totally mixed with the raw water. This process requires filling of water and chemicals, mixing and settling, and subsequent withdrawal of the treated water and the produced sludge. In the so-called Nalgonda technique, a high dosage of alum and lime are used in a coagulation/sedimentation process, where the precipitation of aluminium hydroxide instantly binds a part of the water fluoride. A domestic approach for the Nalgonda process is given in Fig. 6.
3. Contact precipitation is a process where the water is mixed with the precipitating chemicals, calcium and phosphate ions, flowing into a catalytic filter column. So far, this process is only known to operate in a fluoride-saturated bone char, being the catalyst, dosed with calcium chloride and sodium dihydrogen phosphate. Contact precipitation is considered to be the process of choice in the future, when the local availability of bone/bone char reaches its limit.

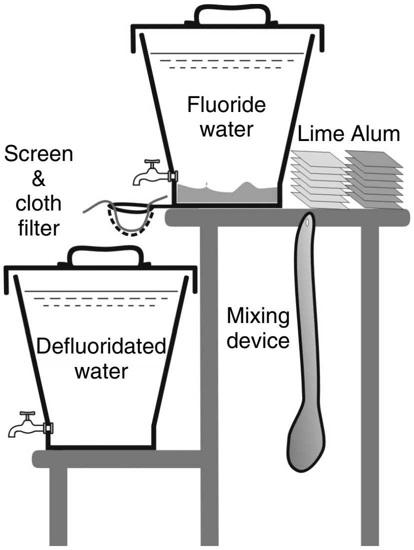

Figure 6. The Nalgonda process as optimized for use in the Rift Valley.

SORPTION DESIGN

The sorption process may be designed on the basis of daily water demand, capacity of the medium, the raw water contamination level, proposed length of operation period, and the bulk density of the medium. The required column treatment capacity and the amount of medium required in a filter column are calculated (Eqs. 1 and 2). From the bulk volume of the medium (Eq. 3), the dimensions of the column are derived (Eqs. 4 and 5):

$$\kappa = D \cdot P \tag{1}$$

$$M = \frac{D \cdot P \cdot (F_r - F_t)}{1000 \cdot C} \tag{2}$$

$$V_m = \frac{M}{\sigma} \tag{3}$$

$$d = \sqrt{\frac{4000 \cdot V_m}{\pi \cdot h}} \tag{4}$$

$$H = 1.2 \cdot h \tag{5}$$

where D is daily water demand, L/day.
C is capacity of the medium, g/kg.
F_r is raw water contamination level, mgF/L.
F_t is treated water concentration, (0.5) mgF/L.
P is proposed length of operation period, days
σ is bulk density of the medium, kg/L.
κ is required column capacity, L.
M is amount of medium required in a filter column, kg.
V_m is bulk volume of the medium, L.
d is inner diameter of the filter column, cm.
h is height of medium in the column, cm.
H is height of the column, cm.

Unfortunately, the capacity of the medium, and its purity, is subject to batch variation. Further, it depends on the fluoride concentration in the raw water. In practice, however, the capacities of 4, 1, and 0.03 g/kg are for good qualities of bone char, activated alumina, and activated clay, respectively.

NALGONDA PROCESS DESIGN

In the Nalgonda and similar processes, the container used has to have a volume well over the daily usage, which will allow for comfortable mixing in the container as well as include provision for the sludge water loss. A plastic bucket of 20 L is often sufficient for the daily use of a family. About 18 L can be treated at a time, out of which about 16 can be used.

The Nalgonda process design is complicated and must be confirmed empirically, which is mainly because of the coprecipitation that lacks stoichiometry, the great variation in media quality and solubility, and the efficiency being dependent on the raw water quality, in particular the fluoride concentration, pH, and the alkalinity. The best possible estimation is based on the Freundlich equation:

$$m = \frac{V_b \cdot (F_i - F_o)}{\alpha \cdot F_o^{1/\beta}} \tag{6}$$

where m is amount of alum required for a daily treatment of a batch, in g.
F_r is fluoride concentration in the raw water, in mg/L.
F_t is residual fluoride concentration in the treated water, in mg/L.
V_b is volume of water to be treated in batch, L.
α is sorption capacity constant, $L^{(1-1/\beta)}$ $mg^{2/\beta}g^{-1}$.
β is sorption intensity constant.

Any resulting pH between 6.2 and 7.6 is adequate. For $pH = 6.7$ and required residual fluoride between 1 and 1.5 mg/L, $\alpha = 6$ and $\beta = 1.33$. The amount of lime required may be 20–50% of the alum dosage.

Alum and lime are added simultaneously to the raw water bucket where it is dissolved/suspended by stirring. The operator should stir fast while counting to 60, i.e., about 1 minute, and then slowly while counting to 300, i.e., about 5 minutes. The mixture is left for settling for about one hour. The treated water is then tapped through the cloth into the treated water bucket from where it is stored for daily drinking and cooking. This separation of the water from the sludge is essential in order to avoid escape of the toxic aluminium to the treated water and in order to avoid the detachment of removed fluoride from the aluminium hydroxide flocs during storage.

TESTING OR METERING

The coprecipitation technique, although arbitrary in nature, is reliable in the sense that the same removal is obtained if the procedure followed exactly.

On the other hand, the process results in poor removal efficiency, and it demands burdensome daily preparation.

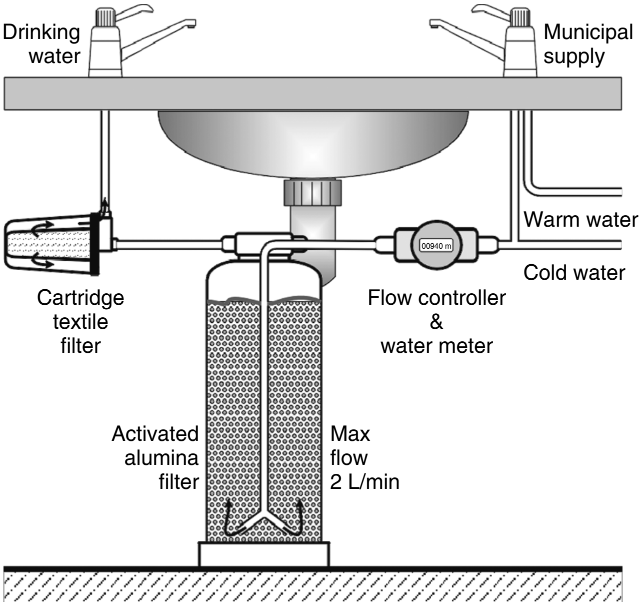

Figure 7. A safe and user-friendly setup of defluoridation based on sorption, in case of activated alumin. The system, containing 8 kg AA, is commercially available in Scandinavia and declared to be able to treat 2000 L of water containing 5 mg/L.

The sorption process is less burdensome. It is also able to provide high removal efficiencies, even at high fluoride levels in the raw water. However, the operator has to watch for the break through the column at saturation. As fluoride is oganoleptically neutral, this cannot be done without either regular testing of the treated water fluoride or checking the accumulated water flow.

Testing the fluoride concentration in the treated water was impossible without expensive laboratory equipment. Now, simple, reliable, and cheap test kits are available.

Figure 7 shows a user-friendly setup for household defluoridation. The secondary cartridge filter ensures that no toxic aluminium can escape with the treated water, and the water meter ensures that accumulated water flow can be compared with declared capacity.

DEUTERIUM

Gholam A. Kazemi
Shahrood University of Technology
Shahrood, Iran

INTRODUCTION

The nucleus, the chief ingredient of the atom, consists of two main types of particles: protons (positive charge) and neutrons (neutral). The number of neutrons is either equal or slightly greater than the number of protons. Some elements have only one type of atom, but most have several types. Isotopes of an element have the same number of protons in the atomic nucleus but a different number of neutrons; this results in the same atomic number but different atomic weight. The average atomic weights of the elements have been determined from two sets of data: the atomic weight of each isotope and the relative abundances of the isotopes (1). Isotopes with a higher number of neutrons are commonly referred to as heavy isotopes of that element.

HYDROGEN ISOTOPES

The hydrogen atom is believed to have been created during the “Big Bang” by proton–electron combinations (2). Together with an oxygen atom, it forms the water molecule and has three isotopes: ^1H (common hydrogen), ^2H (deuterium, D), and ^3H (tritium, T). Deuterium, discovered by Urey et al. (3) in 1932, is much heavier than ^1H. Common hydrogen has one proton, deuterium has one proton and one neutron, and tritium has one proton and two neutrons. Deuterium (also referred to as the heavy stable isotope of hydrogen) and common hydrogen are stable, but tritium is radioactive. In seawater, the relative abundances of hydrogen isotopes are H (99.984%), D (0.016%), and T (5×10^{-5}%) (1). In the hydrosphere, there is only one deuterium atom per 6700 H atoms (4). Note that the arena of this article is limited to deuterium as it is a part of the water molecule. Hence, deuterium that may exist in other materials such as methane will not be dealt with here.

ANALYZING WATER SAMPLES FOR DEUTERIUM AND REPORTING THE RESULTS

To analyze water samples for deuterium, first the sample is reduced to H_2. There are a variety of techniques to achieve this; most have been reviewed by Vaughn et al. (5). A common method is the use of zinc in quartz ampoules at 700 °C. The analysis is then carried out using a mass spectrometer such as a Finnigan MAT 250 triple collector mass spectrometer (6). The precision attainable in many laboratories in sample preparation and analysis of water samples for deuterium is 1‰ (7). The subsidized cost of analysis for deuterium as of 1999 is about A$35 per sample (approximately US$25) (8).

An automated system for high precision deuterium analysis on large numbers of water samples was introduced by Vaughn et al. (5) at the Institute of Arctic and Alpine Research at the University of Colorado. This system does not require sample preparation and is capable of extended unattended operation, an attractive option when analyzing thousands of samples during a weekend.

The results of deuterium analysis are expressed in delta (δ) units per mil (parts per thousand or ‰) differences relative to an arbitrary standard known as standard mean ocean water (SMOW):

$$\delta‰ = [(R - R_{\text{standard}})/R_{\text{standard}})] \times 1000$$

where R is the isotopic ratio ($^2H/^1H$) of the sample and R_{standard} is the isotopic ratio ($^2H/^1H$) of the standard (9). Negative δD values represent water that has less than SMOW δD (i.e., they are isotopically depleted), and positive values represent water that has more than SMOW δD (i.e., they are isotopically enriched). In this system, therefore, δD of SMOW is zero. However, a more recent unit to express these isotopes has been proposed (10). In this system, the hydrogen isotopic ratios are reported relative to VSMOW (Vienna standard mean ocean water) on a normalized scale, so that the (δ^2H) of SLAP (standard light Antarctic precipitation) relative to VSMOW is −428‰ (10). Therefore, the δ^2H of VSMOW is 0‰.

DEUTERIUM IN THE GLOBAL WATER CYCLE

At the first onset of the water cycle, the deuterium content of the ocean water is increased when water evaporates to form clouds (see Isotope Fractionation article for more information). Thus, water vapor in the atmosphere (in the form of clouds or in any other form) has less deuterium compared to ocean water. The evaporated water (clouds) is then condensed into precipitation to form rivers, surface waters, lakes, and groundwater, all of which is isotopically lighter than ocean water, unless subjected to considerable evaporation. The final destination of surface and ground water that has less deuterium than ocean water is the ocean that was originally enriched in deuterium due to evaporation. Therefore, the deuterium content of ocean water remains constant over time. [However, the early ocean was plausibly deuterium-depleted in comparison with the present-day ocean, see Lecuyer et al. (11)]. Therefore, it is evident that the deuterium content of water in any part of the hydrologic cycle is influenced by a variety of parameters; the most important is evaporation. The factors that influence the deuterium content of atmospheric precipitation are described here (7):

Altitude Effect. Generally the higher the altitude, the more depleted the precipitation (−0.15 to −0.50‰ per 100-m elevation);

Latitude Effect. The deuterium content decreases as latitude increases.

Continental Effect. The deuterium content decreases inland from the coast.

Seasonal Variation. The deuterium content of winter rainfall is less than that of summer rains.

Amount Effect. The greater the rainfall, the more depleted the deuterium.

Apparent Temperature Effect. This effect is similar to the effect of latitude because the higher the latitude, the lower the temperature. Therefore, it is not easy to find the cause of the deuterium difference, whether deuterium depletion is due to the decrease in temperature or due to the increase in latitude. Because of this complexity, Mazor (1) ignored the latitude effect and did not mention it as a factor that influences deuterium content.

Having considered the many factors above, it is now easy to realize that atmospheric precipitation in each part of the world is unique in its deuterium content. Harmon Craig (12) studied the deuterium and ^{18}O content of a large number of precipitation samples worldwide. He drew a line to express the relationship between these two isotopes in a global perspective which is now known as the Craig Line, the World Meteoric Water Line (WMWL), or sometimes, Global Meteoric Water Line (GMWL). The Craig line equation is $\delta D = 8\delta^{18}O + 10$. In this equation, 8 (coefficient) is the slope of the line, and 10 (the intercept) is called the deuterium excess ($d = \delta D - 8\delta^{18}O$). The lower the slope, the higher the effect of evaporation on the water samples studied. A typical evaporation line has a slope of five. The higher the deuterium excess, the higher the effect of evaporative enrichment on the water samples in question. Generally speaking, samples plotted to the right of the Craig line are isotopically enriched, and those plotted to the left are depleted. However, it should be stressed that each region has its own meteoric water line, a local meteoric water line (LMWL), that should be prepared by analyzing the deuterium and ^{18}O content of a number of local atmospheric precipitation samples. The equation of a number of LMWLs for various parts of the world is given by Mazor (1).

APPLICATIONS OF DEUTERIUM AS A TRACER—ISOTOPIC HYDROLOGY

In almost all water related studies, both deuterium and ^{18}O are measured simultaneously. The applications of stable isotopes of oxygen (δ^{18}O) and hydrogen (^{2}H) in water studies, especially for analysis of flow path and fractionation processes dates back to the early 1950s (9). Undoubtedly, measurement of deuterium in water, whether it is river, lake, ground, rain, or porewater is the fundamental of an important field of knowledge "isotopic hydrology," a technique or science whose many applications have been summarized by Payne (13). The textbook by Mazor (1) and the recent works by Clarke and Fritz (14) and Cook and Herczeg (15) deal extensively with the topic.

To interpret the deuterium data, the most common procedure is to plot δD and δ^{18}O on a diagram on which the Craig line and, if possible, LMWL are also illustrated. It is then possible to interpret the data, for example drawing an evaporation line, calculating the slope of the line, and determining the deuterium excess. As an example, the results of an isotopic hydrology study by Kazemi (8) on the Buckinbah Creek Watershed in Eastern Australia are presented in Table 1 and Fig. 1. As can be seen from Fig. 1, only two samples show the effect of evaporative enrichment. From Fig. 1, it can also be inferred that the deep groundwater, compared to shallow groundwater, has been subjected generally to less enrichment by evaporation. Note that the approximate positions of summer and winter precipitation samples are also shown in Fig. 1.

The deuterium content of water samples is measured to (1) find the cause of groundwater salinization (16,17); (2) estimate groundwater inflow into wetlands (18,19); (3) separate the streamflow hydrograph into baseflow and an event water component (20,21); (4) calculate surface evaporation via a stable isotope evaporation model (22); (5) study the mechanism, timing, and area of recharge to groundwater (23–26); (6) study the pattern of groundwater circulation and identify the hydrogeologic characteristics of karst groundwater flow (27); (7) identify the origin of groundwater, whether groundwater was recharged in modern time or in the Holocene (28); (8) study the infiltration processes in clayey soils (29); (9) determine groundwater discharge from forests (30); and (10) be used as a tracer in groundwater artificial recharge schemes (31,32).

Case Studies

A large number of case studies are regularly published through the International Atomic Energy Agency (IAEA) and International Association of Hydrological Sciences publications, IAHS (33) and IAEA (34). Examples of the deuterium content of groundwater from the Amman–Zarkan Basin in Jordan are −32 to −26‰ and from the Aladag karstic aquifer in Turkey −100.1 to −58.4‰ (33).

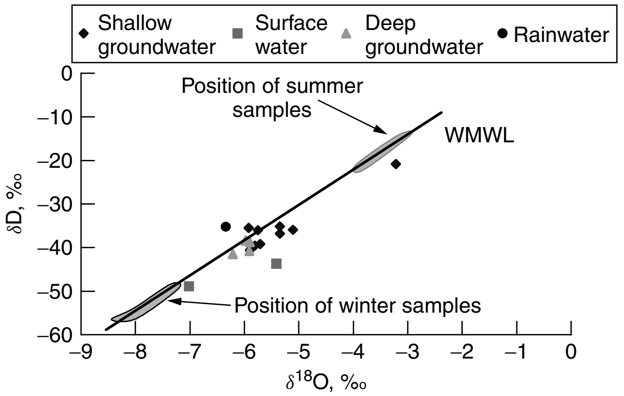

Figure 1. Deuterium versus oxygen-18 plot of water samples from the Buckinbah Creek Watershed, NSW, Australia (8). The Craig (World Meteoric Water Line) is also illustrated.

DISTILLED WATER

Aldo Conti
Frascati (RM), Italy

Water is never pure in nature. It normally contains some salts and minerals in solution and even bacteria and pollutants. Most of these substances, salts and minerals, in particular come from rocks and soils with which the water has been in contact. All these impurities make water useless for some purposes. It must be cleaned of pollutants and bacteria for human consumption, for instance. But for some other uses, even salts and minerals are dangerous. At home, in our vapor iron, water should be free of calcium carbonate that forms a layer on the heating resistor and eventually breaks it. The easiest method of purification is distillation, during which water is heated until it turns into vapor. The vapor is then collected on a cold surface, where it condenses. Because salts and other impurities do not vaporize, they normally remain in the boiling solution. Distilled water is never perfectly pure, because there are substances with nearly the same boiling point as that of water and some liquid droplets can be carried by the steam. Nevertheless, distilled water can be 99.9% pure and, if needed, can be distilled a second time. Distillation is very efficient in removing heavy metals, radionuclides, and solid particles, and it kills bacteria and viruses.

From a chemical point of view, even the purest distilled water is always a solution containing a very small amount of hydroxide (OH^-) and hydronium (H_3O^+) ions, which happens because water, like many other solvents, reacts with itself. At room temperature, one can expect one molecule in every ten million to dissociate and donate a hydrogen atom to another molecule.

Distilled water does not remain pure for long. If left exposed to air, it absorbs carbon dioxide very efficiently and reacts with it producing carbonic acid (H_2CO_3), which is why distilled water often becomes acidic. If one leaves distilled water exposed to air for 24 hours, a pH between 5.5 and 6.0 can be expected. To neutralize this acidity, it is sufficient to boil the water for 5 to 10 minutes, so that it releases the dissolved carbon dioxide, bringing the pH very close to 7.

The acidity induced by carbon dioxide is enough to make distilled water unhealthy for human consumption. Moreover, water contains electrolytes (sodium, potassium, chloride) and many other elements, such as magnesium, that are essential for our body. Most, if not all, of these substances can be found in food, too, but nevertheless, drinking large amounts of distilled water is not advisable.

ELECTRICITY AS A FLUID

David P. Stern
Mauricio Peredo
Goddard Space Flight Center,
NASA

The preceding sections did not follow the conventional order:

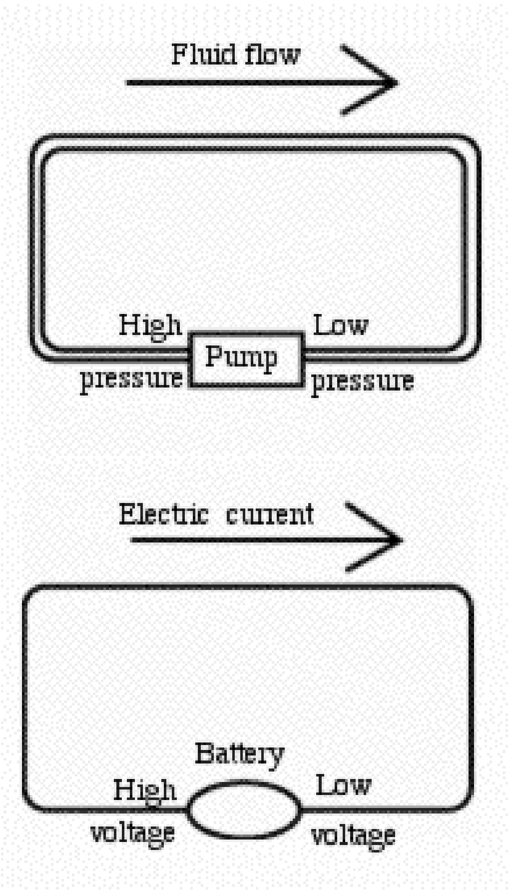
> First **electric currents** were brought up, in connection with Oersted's work.
>
> Then **electric charges,** in connection with electrons.

That may be OK, because most of us are **familiar** with currents and charges. **Currents** run electric lights, radios, TVs, clocks and appliances in the home, and **"static" electric charge** causes papers and clothes to cling together in dry weather. An electric current is essentially the continuous flow of electric charge. **This section** goes a little further, to the concepts of **voltage** and of the **electric field**.

OHM'S LAW

It is easier to understand electricity if we regard electric charge as a sort of **fluid,** like water, as scientists did for the first 200 years. Yes, it does consist of individual electrons, but those are so small that any large charge behaves like a continuous fluid. In the same way sand pours like a fluid, and water in a glass is usually regarded as a fluid, even though it consists of individual molecules.

Using a pump we can push water through a pipe around a closed circuit (top drawing). The rate at which it flows past any point in the pipe–measured in **gallons** (or liters) **per second**–depends on the **pressure** produced by the pump (measured in pounds per square inch, or kilograms per square centimeter). More accurately, it depends on the **pressure difference** between the entrance to the pipe (left) and the exit from the pipe (right).



The greater the pressure difference, the greater the flow. In addition, given a certain pressure difference, a **fatter** pipe will carry more water, and a **longer** one will resist the flow and carry less.

ALL THIS MIRRORS EXACTLY THE BEHAVIOR OF THE ELECTRIC FLUID

No pipes here, though: electricity in our homes and appliances usually flows in metal wires, most often of copper. Electrons in a metal can jump from atom to atom, and that way carry negative charge around the circuit.

Like a fluid, they are driven by a kind of electric pressure, known as **voltage,** because it is measured in units known as **volts,** named after the Italian scientist Alessandro Volta. An electric battery produces (by a chemical process) a **voltage difference V** between its two ends, and therefore acts like a pump (bottom drawing).

The **electric current I** flows from high voltage to low voltage and is measured in units known as **Amperes,** named for André-Marie Ampere whom we met in section #2. And as with water, we expect that if we increase the driving voltage V, the driven current I will also increase. In fact, the two are pretty much proportional: double the

---

voltage, and you get double the current. That relation is known as **Ohm's Law,** after Georg Ohm who first formulated it.

Ohm's law (with some extra details concerning the length and thickness of the wire) is usually among the first things taught in electricity classes, and many students therefore view it as one of the fundamental laws of electricity. **It isn't.** It holds quite well for metal wires, but as will be shown in section #7a, it fails badly in fluorescent tubes–while in space currents exist which flow without any voltage driving them (section #10a).

ELECTRIC FIELDS

One small caution here. By long tradition, the direction of the electric current is defined as the direction in which **positive** charges move. We may blame Ben Franklin for deciding–by pure guess–what kind of electricity is called "positive" and which "negative." A century later it was found that most electric currents were carried by negative electrons, which move in the opposite direction.

One may therefore argue that the flow direction which should be assigned to electric fluid is really the **opposite** of what we say it is. But it's much too late to change the old convention.

In our homes, electric currents and effects of electricity are usually channeled along insulated wires. **In 3-dimensional space,** on the other hand, electric phenomena tend to spread out. If the way electric current flows in the home resembles water flow in pipes, then in space the flow is often like ocean currents or air motion in the atmosphere, spread out in 2 and even 3 dimensions.

In a wire, voltage depends only on one dimension–on the distance along the wire. **In space,** every point can have its own voltage. Currents that flow may depend on such voltages, but don't look to Ohm's law for guidance, because the flow of current is primarily dictated by magnetic fields, which makes a difference.

The **3-dimensional voltage distribution** is often called the **electric field.**

Compare:

In a **magnetic field** the **direction of the field** is that of the force. If **isolated N magnetic poles** existed, they too could do so, by moving in the direction of the field, while S poles would move in the opposite direction. The poles at the ends of a compass needle move this way, and thus line up the needle in the direction of the field.

Similarly

An **electric field** is a region where electric forces can be felt by charged objects, and the **direction of the field** is the one in which **positive** charges would move. A positive ion moves in the direction of the field, a negative electron moves in the opposite direction.

If **both** magnetic and electric fields are present, the motion of ions and electrons gets complicated. **That** however is left for a later section.

ANALYSIS OF AQUEOUS SOLUTIONS USING ELECTROSPRAY IONIZATION MASS SPECTROMETRY (ESI MS)

William Henderson
University of Waikato
Hamilton, New Zealand

INTRODUCTION

Electrospray ionization mass spectrometry was developed primarily by Fenn and co-workers in the late 1980s for the analysis of macromolecules such as polyethers and proteins (1). Since then, the technique has undergone an exponential growth in applications, in many areas of chemical and biochemical sciences. A considerable number of textbooks (2,3) and major reviews (4) describing the experimental basis of the technique (5–8) and applications have appeared (8–10) and ESI MS has been widely used for the analysis of aqueous solutions.

THE ESI TECHNIQUE

The key features of the technique are:

1. The ability to analyze materials directly from solution. Almost any solvent, including water, can be used, depending on the solubility of the analyte under study.
2. Ionization is very gentle; this is of great importance for thermally labile analytes such as proteins or weakly bound metal complexes.
3. The technique provides information on mixtures of compounds, which may be in equilibrium in solution, and is applicable to paramagnetic materials (such as many transition metal and lanthanide ions and complexes thereof).
4. The technique is well suited for the analysis of both positive- and negative-ion species.
5. As with all mass spectrometry techniques, miniscule amounts of sample are required, and detection limits are usually very low.

In electrospray ionization, a solution of the compound is nebulized, at atmospheric pressure, from a metal capillary held at a high potential. Nebulization is assisted by an inert gas, typically nitrogen. This produces a spray of charged liquid droplets that, through processes of droplet fission, solvent evaporation, and ion evaporation, produce gas phase ions. The ions are then detected using one of a number of mass analyzers (such as quadrupole or ion trap). Fragmentation of the initially formed ions can be achieved by the technique of collision-induced dissociation (CID), whereby ions undergo collisions with gas and/or solvent molecules. The application of a *cone voltage*—a potential difference that accelerates the ions—is one such method that can effect fragmentation of the original ions.

For analyte species that are already charged, the electrospray process simply transfers existing solution ions into the gas phase. For analytes that are uncharged, ionization must occur for the material to be detected by the mass spectrometer; a number of processes may operate, depending on the actual system, but can include protonation, deprotonation, metallation (e.g., attachment of adventitious alkali metal cations present in aqueous solutions stored in glass), and oxidation.

APPLICATIONS OF ESI MS TO THE ANALYSIS OF AQUEOUS SOLUTIONS

Aqueous solutions are highly amenable to analysis by ESI MS. In many cases, an organic cosolvent is added, to reduce the surface tension of the resulting solvent mixture, which aids in spray formation (7). The surface activity of an analyte ion can affect its ESI response; a high surface activity will result in a high response in the ESI mass spectrum. As an example, an equimolar solution of Cs^+ and $C_{10}H_{21}NMe_3{}^+$ in 1:1 methanol–water gives a substantially more intense signal for the high surface activity ammonium cation (11).

ESI MS can be used for both qualitative and quantitative analysis. As an example, the negative-ion electrospray mass spectrum of an aqueous solution of $NaBrO_3$ (containing 5% methanol) is shown in Fig. 1. Under gentle ionization conditions (cone voltage 30 V), the BrO_3^- ion is exclusively observed at *m/z* (mass-to-charge) 127, but at a high cone voltage (120 V), fragmentation occurs, giving BrO_2^- (*m/z* 111), BrO^- (*m/z* 95), and Br^- (*m/z* 79). The distinctive two-line pattern for each ion arises due to the isotopic signature of bromine (^{79}Br 100%, ^{81}Br 97.3% relative abundances) and *m/z* values are given for the ^{79}Br isotopomer. Electrospray mass spectrometry has been used to quantify levels of oxyhalide anions in aqueous solutions; for example, bromate (12) and other oxyhalide anions (13) can be measured at sub-ppb levels.

For a metal salt M^+ X^- dissolved in water or an organic solvent–water mixture, the ions that are typically observed over a wide mass range are ion clusters of the type $[(MX)_n + M]^+$ in positive-ion mode and $[(MX)_n + X]^-$ in negative-ion mode; salts containing doubly charged ions behave in a similar manner (14).

The tendency for ions to retain a hydration (or more generally a solvation) sphere in the gas phase can easily be investigated using ESI MS. As an example, ESI MS of the sodium salts of the doubly charged sulfur oxyanions SO_4^{2-} (sulfate), $S_2O_6^{2-}$ (dithionate), and $S_2O_8{}^{2-}$ (peroxydisulfate) reveals differences in the gas phase stabilities of these ions. The unsolvated $SO_4{}^{2-}$ ion cannot be detected, and instead a series of hydrated ions $[SO_4 + nH_2O]^{2-}$ ions are observed with $n = 5–16$. Ions with $n < 3$ are unstable and undergo charge separation to give $HSO_4{}^-$ and OH^-. However, for $S_2O_6{}^{2-}$ and $S_2O_8{}^{2-}$, the unsolvated ions can be observed in the gas phase, because of the greater charge delocalization, and hence lower charge density of these ions, which results in higher gas phase stabilities (15).

Metal cations also have a strong tendency to retain a hydration sphere, with divalent cations being more

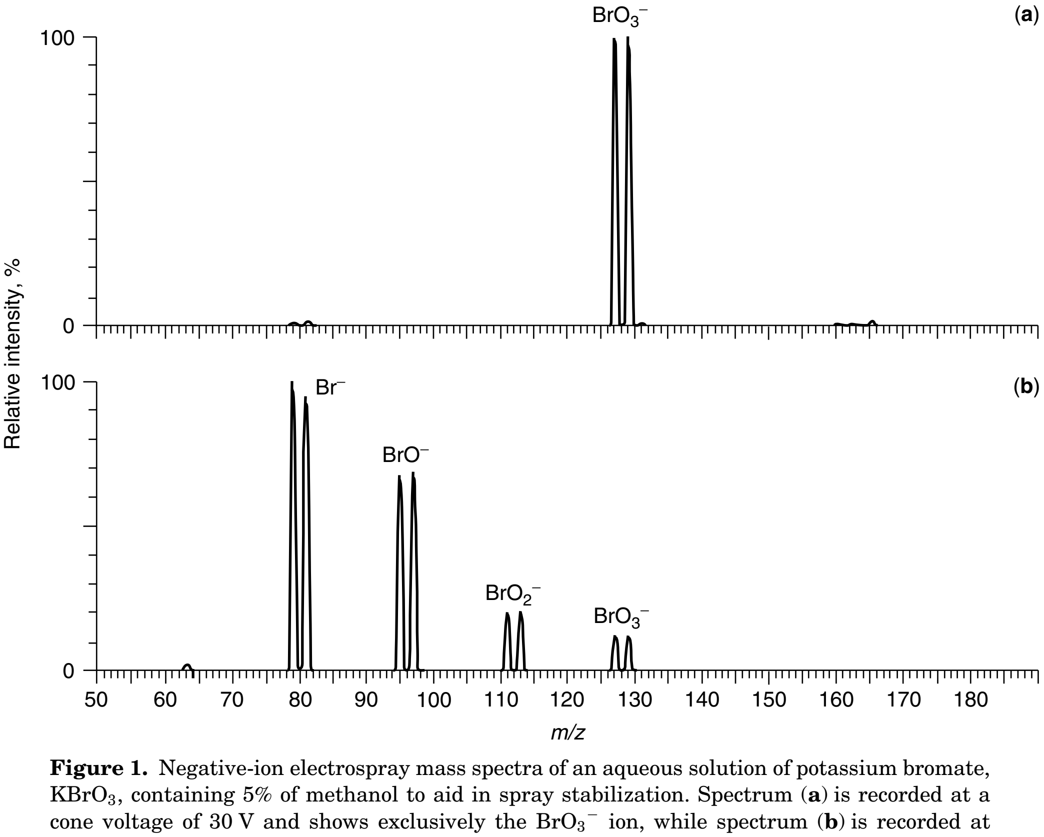


Figure 1. Negative-ion electrospray mass spectra of an aqueous solution of potassium bromate, $KBrO_3$, containing 5% of methanol to aid in spray stabilization. Spectrum (**a**) is recorded at a cone voltage of 30 V and shows exclusively the $BrO_3{}^-$ ion, while spectrum (**b**) is recorded at 120 V and additionally shows the series of fragment ions $BrO_2{}^-$, BrO^-, and Br^-.

strongly solvated than monocations, as expected. For example, $[M(H_2O)_n]^{2+}$ ions have been generated for a range of divalent metal ions, and ion–water binding energies were determined (16). For trivalent cations, and to a lesser extent for divalent cations, charge reduction will occur in the gas phase if the hydration sphere is unable to stabilize the charge on the metal cation. For example, for a solvated trivalent cation

$$[M(H_2O)_n]^{3+} \rightarrow [M(OH)(H_2O)_{n-2}]^{2+} + H_3O^+$$

In the case of copper(II) systems, reduction to copper(I) is often seen. For other metals, under forcing CID conditions, further charge reduction to low valent metal ion species can occur (17): for example, the lanthanide ions give $[Ln(OH)(H_2O)_n]^{2+}$, which give ions LnO^+, $LnOH^{2+}$, and ultimately Ln^+ (18). This experimental regime is often referred to as *bare metal* or *elemental* mode, and mass analysis of the resulting ions can be used to provide isotopic information on the elemental ion concerned.

In addition to the applications described above, the list below gives a selection of some applications of ESI MS in the analysis of aqueous (or mixed aqueous–organic) solutions:

Biochemical materials of many types (19), including proteins (20)
Polyoxometallate anions (21)
Aqueous polysilicate anions (22)
Polyhalide (23) and polyselenide (24) anions
Polyphosphates (25)
Sulfur oxyanions (15,26)
Chromium(III) and chromium(VI) species (27)
Oxyhalide anions EO_n^- ($E = Cl$, Br, I; $n = 0–4$) (12,13,28)

FENTON'S REACTION AND GROUNDWATER REMEDIATION

JAMES A. JACOBS
Environmental Bio-Systems, Inc.
Mill Valley, California

Hydrogen peroxide, an *in situ* chemical oxidizer in the form of Fenton's Reaction, can rapidly treat waste waters, sludges, and contaminated soils and groundwater. The effect of the Fenton's Reaction is organic contaminant destruction, toxicity reduction, and biodegradability improvement. In addition, removal of biological oxygen demand (BOD), chemical oxygen demand (COD), odor, and color occur. If Fenton's Reaction is allowed to be carried to completion, then all organic molecules will ultimately be broken into carbon dioxide and water. Fenton's Reaction is a nonselective oxidizer. Fenton's Reaction also called Fenton's Reagent or Fenton's Chemistry in the literature.

Soils contaminated with toxic and recalcitrant organic wastes such as petroleum hydrocarbons and chlorinated solvents can be effectively treated with Fenton's Reaction (1–3). *In situ* chemical oxidation (ISCO) uses contact chemistry of the oxidizing agent to react with petroleum hydrocarbons, volatile organic compounds, munitions, certain pesticides, and wood preservatives in the vadose zone or in the groundwater. The gasoline additive, methyl tertiary butyl ether (MtBE), has been shown to break down with Fenton's Reaction (4–6).

HISTORY

Hydrogen peroxide is one of the earliest chemical oxidants to be discovered and used in industry. It was discovered in the late 1700s and was commercialized in the early 1800s. Hydrogen peroxide works as a remedial treatment chemical in two ways: free radical production and direct chemical oxidation using hydrogen peroxide.

A British Professor H. J. H. Fenton (7,8) described the exothermic and somewhat violent reaction of hydrogen peroxide with iron salts (ferrous sulfate). A very thick and heavy brown foam forms early in the reaction with soil. Fenton's chemistry or Fenton's Reaction uses a transition metal catalyst or an acid to enhance the oxidation chemical reaction of hydrogen peroxide by producing the hydroxyl radical. The hydroxyl radical is a powerful oxidation agent, second behind fluorine.

During the 1930s, the reaction mechanisms were described, although even today, the details are not completely understood because of the large number of side reactions. Commercial reactors have been available for the water treatment industry over the past 20 years. Within the past decade, *in situ* groundwater treatment with Fenton's Reaction have been developed. Within the last several years, commercialization of these methods has become more commonplace.

REACTIONS

Fenton's Reaction produces the hydroxyl free radical, which cleaves and oxidizes organic compounds such as gasoline resulting in producing successively smaller organic compounds. The intermediate compounds of the Fenton's Reaction are generally mono-carboxylic and dicarboxylic acids. These products are nontoxic, naturally occurring, and can be oxidized further to carbon dioxide and water (9).

The breakdown products of the Fenton's Reaction as well as the hydrogen peroxide and iron do not produce additional organic compounds or inorganic solids such as permanganate and dichromate, because there are no carbon atoms in the treatment chemicals. Although many organic compounds can be oxidized with Fenton's Reaction, compounds resulting from the oxidation products of larger molecules, such as small chlorinated alkanes, n-paraffins, and short-chain carboxylic acids, appear to resist further destruction by the Fenton's Reaction. Laboratory bench tests are highly recommended to define feasibility and optimal chemistry on a site-by-site basis.

For *in situ* chemical oxidation, the metal catalyst is usually provided by iron oxides within the soil or fill material, or added separately as a solubilized iron salt, such as iron sulfate. In addition, pH adjustment using an acid such as sulfuric (H_2SO_4) is common because the chemical oxidation is more rapid and efficient under lower pH conditions (pH 2–4 is optimal). The supportive chemical processes that essentially result in the destruction of petroleum hydrocarbons, and other volatile organic compounds are well documented (1–3).

EQUATIONS

When chemical oxidant H_2O_2 is injected at concentrations of 10% to 35% into the subsurface, it decomposes readily into reactive hydroxyl radicals ($OH^\bullet$) and water. The hydroxyl radical ($OH^\bullet$) in the subsurface can rapidly mineralize hydrocarbon, solvent, and other contaminants to water and carbon dioxide. This reaction is enhanced in the presence of iron. Iron is naturally occurring in soil and groundwater or can be added during the injection process, if needed. The reaction is based on the principle of Fenton's Reaction where iron and hydrogen peroxide react to form hydroxyl radicals and other byproducts as shown in (1) (1–3).

$$\begin{gathered}
Fe^{2+} + H_2O_2 \rightarrow OH^\bullet + OH^- + Fe^{3+} \\
Fe^{3+} + H_2O_2 \rightarrow Fe^{2+} + HO_2/O_2{}^- + H^+ \\
Fe^{3+} + HO_2/O_2 \rightarrow Fe^{2+} + O_2 + H^+ \\
\text{(iron catalyst gets regenerated)} \\
OH^\bullet + H_2O_2 \rightarrow HO_2/O_2{}^- + H_2O \\
OH^\bullet + Fe^{2+} \rightarrow Fe^{3+} + OH^- \\
HO_2/O_2{}^- + Fe^{2+} + H^+ \rightarrow Fe^{3+} + H_2O_2 \qquad (1)
\end{gathered}$$

$OH^\bullet$ = hydroxyl radical

The process is self-replicating because the reaction of ferric iron with hydrogen peroxide to generate the perhydroxyl radical also occurs (10). Equation (2) is another way to view the reaction:

$$Fe^{3+} + H_2O_2 \rightarrow H^+ + {\bullet}OOH^- + Fe^{2+} \qquad (2)$$

The perhydroxyl radical is a less powerful oxidant than is the hydroxyl radical, but it does generate further ferrous ions that in turn stimulate further reaction with the hydrogen peroxide to produce more hydroxyl radicals (10).

Chlorinated solvents such as trichloroethylene (TCE) and tetrachloroethylene (PCE) have been the focus of *in situ* applications of Fenton's Reaction. The double bonds, C=C, that characterize chlorinated ethenes are more reactive than are the single C–C bonds of chlorinated ethanes. Therefore, PCE and TCE are more susceptible to chemical oxidation than is TCA. Although these chemicals are susceptible to chemical oxidation, relative resistance to oxidation goes from highest to lowest: PCE, TCE, vinyl chloride, phenanthrene, benzene, and hexane. The oxidation reaction for a common solvent, TCE, forms several unstable daughter products (epoxides), then breaks down to ketones and aldehydes, finally yielding carbon dioxide, water, and chloride ions (11). The oxidation of TCE is shown in (3):

$$4OH^\bullet + C_2HCl_3 \rightarrow 2CO_2{}^- + 3Cl + 5H^+ \qquad (3)$$

The hydroxyl radical that attacks the carbon–hydrogen bonds is capable of degrading many chlorinated solvents, chloroalkenes, esters, aromatics, pesticides, and other recalcitrant compounds such as MTBE, PCP, and PCB (2). The Fenton's chemistry reaction is highly complex. The iron cycles between the Fe(II) and Fe(III) oxidation states yield the hydroxyl radical and other byproducts (11).

Residual H_2O_2 not used in the oxidation process breaks down to water and oxygen in a matter of hours. In addition to the reaction described in (2), there are a large number of competing reactions including the free radical scavengers, most importantly, carbonate and bicarbonate alkalinity, that will greatly affect the overall reaction scheme. In addition, H_2O_2 can serve as an oxygen source for microbes in the subsurface to enhance biodegradation of contaminants.

IN SITU ISSUES

Fenton's Reaction has been effective in the relatively low concentrations in waste water treatment plants, but not in *in situ* applications. In this scenario, solid oxygen demand is limited in the treatment water and competing reactions are small by comparison with those in soils. Soil contains competing reactions that will react with the hydrogen peroxide, including organic carbon, unoxidized minerals, and biologically produced chemicals. Therefore Fenton's Reaction treatment plans in the field may take significantly more applications than the bench testing might indicate because of the competing reactions that occur in the soil and groundwater. More information about hydrogen peroxide decomposition in the presence of aquifer material is described in Miller and Valentine (12).

Although Fenton's chemistry has been documented for well over 100 years, it has been employee safety and handling issues that have kept large numbers of environmental contractors from using *in situ* chemical oxidation technology. Although this technology can be used safely, significant safety planning, worker training, personal protective equipment, on-site supervision, and monitoring must be an integral part of all oxidation projects. The main challenges for *in situ* applications are delivery of the oxidants, which are difficult to handle, and pH control of the subsurface environment where the reaction must occur. Since most soil has adequate concentrations of naturally occurring iron, addition of iron is not needed at many sites. The typical iron to hydrogen peroxide ratios is 1:5 to 10 wt/wt. Iron levels less than 25 to 50 mg/L can require excessive reaction times (10 to 24 hours) (13). Improper control of the Fenton's reaction will only generate oxygen and water, not the high intensity Fenton's oxidation chemistry.

DELIVERY OPTIONS

Delivery of the Fenton's Reaction chemistry requires close spacing of the injection ports/wells because of the rapid nature of the reactions. The liquids are generally pumped using pressures of 100 to 600 psi for probe rods or 1000 to 3000 psi using lances. Pouring hydrogen peroxide into wells or trenches may work for treating water in those areas, but because of the rapid reaction rates, pressure is needed to move the peroxide away from the injection location. The high pressure is also needed to ensure mixing in the subsurface and a reasonable radius of influence. Fenton's Reaction, although powerful, is not generally recommended or cost effective for low-concentration groundwater plumes where the concentrations of organics is less than 5 mg/L. Variations in the effective porosity, permeability, lithologic heterogeneities, BOD, COD, pH, and contaminant mass affect the outcome of *in situ* applications of Fenton's Reaction.

Hydrogen peroxide reacts in an optimal manner in lower pH settings, with lower alkalinity readings. In some cases, strong acids, most notably sulfuric acid, lower the pH. Trace chloride from chlorinated compounds will likely combine with sodium or calcium ions to form salts or with hydrogen to form weak acids. Careful evaluation of soil and water chemistry with a bench test with soil and water samples is recommended before the start of any injection process. Because of the rapid reaction time of the Fenton's Reaction, subsurface spacing of injection ports must be relatively close. The lower the effective porosity of the treatment zone, the closer the injection port spacing. Based on field experience, clays and silts, which are problematic to remediate *in situ*, typically require 0.6 to 1.0 m spacing, whereas injection ports for clean sand and gravels can be placed at 2.0 to 3.0 m spacing.

Chemical compatibility of the injection equipment components and safety procedures become critical with the injection of strong acids, bases, oxidants, and other chemicals. Although handling hydrogen peroxide and other oxidants requires significant safety training and planning, the oxidant is effective at remediation of a variety of organic contaminants and is relatively inexpensive. The reaction time for hydrogen peroxide in the subsurface is usually within seconds to minutes rising under ideal conditions to hours. A rise in temperature in the subsurface illustrates the exothermic nature of Fenton's Reaction process.

Based on field research, the optimum reaction temperature is relatively low, as measured on the reaction foam in the field using infrared thermal meters in 35 °C to 41 °C. With increases in temperature beyond about 57 °C, the peroxide becomes more volatile as it starts to produce a wispy white vapor. The gas is water vapor and carbon dioxide, the products of chemical oxidation. Subsurface reaction temperatures are measured with an infrared thermal meter. Reaction temperatures in the range of 82 °C to 93 °C are explosive and unsafe. Temperatures of subsurface chemical reactions can be monitored and lowered by adding water, lowering concentrations of the catalyst or oxidant, and reducing injection pressures. Effective porosity of the treatment zone may be reduced by the formation of metal oxide precipitates.

CASE STUDIES

Fenton's Reaction has been successful on a variety of sites throughout the United States since the early to mid-1990s. Reductions of organic contaminants such as DNAPLs in full-scale treatment projects are as high as 90% to 99%, depending on the contaminant, the subsurface variables, and the starting concentrations. Specific Fenton's Reaction case examples are included in a variety of publications, including U.S. EPA, (14), U.S. Navy (9), U.S. Navy (15), and Jacobs and Testa (16).

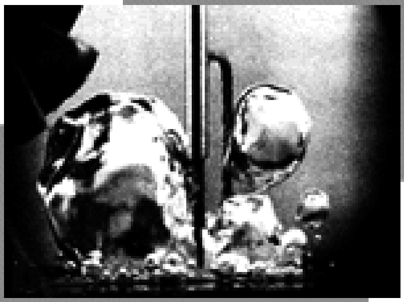
WHERE WATER FLOATS

NASA Marshall Space Flight Center



The **Fluid Physics Research Program** is implemented at the Lewis Research Center in Cleveland, Ohio and is managed by the Microgravity Research Program Office located at Marshall Space Flight Center in Huntsville, Alabama.

A fluid is any material that flows in response to an applied force, and assumes the shape of its container. Examples include liquids, gases, and granular systems such as soil and sand.

Fluid physics is vital to understanding, controlling, and improving all of our industrial and natural processes. The engines used to propel a car or an airplane, the shape of the wings of an airplane that allow it to fly, the operations of boilers that generate steam used to produce over 90% of the world's electric power, the understanding of how cholesterol is transported in our bloodstream and effects heart disease, and how pollutants are transported and dispersed in air and water are just a few examples of how fluid physics affects our everyday life and forms the very basis for an industrial society. Areas of NASA's research in fluid physics include the following:

Complex Fluids are fluids containing structures or aggregates on supermolecular scales; examples include

---

colloids, emulsions, liquid crystals, granular solids, and polymer solutions.

Multiphase Flow and Heat Transfer includes the study of processes such as boiling, condensation, flows and heat transfer in fluid-fluid and fluid-solid mixtures.

Interfacial Phenomena investigates the shape and dynamics of solid-liquid-gas interfaces such as during a coating process, the liquid-gas interface as in partially filled containers, and the effect of energy and mass transfer on these interfaces.

Dynamics and Instabilities deal with fluid flows and stability of thin and thick films, geological and biological flows, liquid bridges, drops and bubbles, and electrochemical and chemical transport. Pattern formation and turbulence are other interesting areas investigated under this topic.

INTRODUCTION

Water is an important solvent and is sometimes called the universal solvent (1). It dissolves, to the extent possible, the material with which it comes in contact. Salinity is a measure of various constituents dissolved in water, including solids, liquids, and gases. Total dissolved solids (TDS), another form of expressing the amount of dissolved ingredients in water, is the sum of total solids that have been dissolved in water [note that TDS at $180\,^{\circ}\mathrm{C} = \text{Sum of ions} + \mathrm{SiO_2} - 0.5082 \times \mathrm{mg/l\,HCO_3}$; (2)]. However, many references do not differentiate between TDS and salinity because the absolute majority of the dissolved constituents of water are usually the solids. Both parameters have units of mg/l or ppm. These two units, ppm and mg/l, are almost the same except for high salinity waters for which 1 mg/l = 1 ppm × density of water. The salinity of groundwater ranges from 25 mg/l in quartzite springs to more than 300,000 mg/l in brine (3), and the salinities of distilled water, River Murray in South Australia, seawater, and the Dead Sea are 0, 553, 35,000, and 385,000 mg/l, respectively (4).

Waters are classified into various types based on their salinity or TDS content. Two widely used classification systems are illustrated in Table 1. The Australian Water Resources Council (AWRC) (1976) (5) has devised a considerably different classification, shown in Table 2, which can be regarded as one of limited local use.

DEFINITION

Based on the two widely used classification systems above, freshwaters are those whose salinity or TDS is less than 1000 mg/l. Interestingly, freshwater has identical definitions in both systems; other water types, for example, brines, have slightly to considerably different meanings. Despite this equality, Manning (8) believes that criteria for terms such as fresh, when applied to water quality, are not universal. He writes (p. 221) “It depends on the individual tastes and on the purpose for the water. One person’s unacceptable saline water might be another’s only drinking water.”

In a generalized sense, freshwaters may be regarded as all waters in the world, excluding saline waters of ocean, seas, and saline lakes. Based on this, global freshwater resources are estimated at 36.02×10^6 km^3 accounting for about 2.6% of the total world water of 1.348×10^9 km^3 (9). If one adopts this generalization, then, rivers, freshwater lakes, most groundwaters, and soil moisture all are eligible to be categorized as freshwater resources.

The term “freshwater,” may be misleading. It may suggest that freshwaters are those that are suitable for drinking, but this is not the case. In other words, freshwater is an arbitrary chemical denomination and does not strictly imply suitability of this type of water for drinking. Various guidelines, such as those established by the United States, European Community, and World Health Organization, suggest a TDS of less than 500 mg/l to 1500 mg/l for drinking water, which does not completely conform with the TDS of freshwater. For instance, a particular type of freshwater may not be suitable for drinking because one or more of its constituents exceeds the desirable criteria. Water from an irrigation field,

Table 2. AWRC Classification of Water

Water Type	TDS
Fresh	<500 mg/l
Marginal	500–1,000
Brackish	1000–3000
Saline	>3000

Table 1. Water Types Based on TDS Value—(Different Classification Systems)

Water Type[a]	TDS mg/l[a]	Water Type[b]	TDS mg/l[b]
Fresh	0–1000	Fresh	0–1000
Brackish	1000–10,000	Slightly saline	1,000–3,000
Saline	10,000–100,000	Moderately saline	3,000–10,000
Brine	>100,000	Very saline	10,000–35,000
		Briny	>35,000

[a] *Source*: Reference 6, in Reference 3.
[b] *Source*: Reference 7—proposed by USGS.

for example, may be chemically classified as fresh, but due to its high nitrate, phosphate, or toxic components is more likely to be rejected as a source of drinking water. Similarly, water that flows through, or emerges from, geologic media containing sulfur deposits will not be suitable for drinking, though chemically fresh, because of its low pH value. Hundreds or thousands of similar cases can be described. However, in normal conditions and in the majority of cases, so-called freshwater meets drinking water standards and can be consumed.

SOME GENERAL POINTS ABOUT FRESHWATER

1. All types of wet atmospheric precipitations such as rain, snow, and hail turn into freshwater.
2. Surface waters are generally lower in TDS than groundwaters and, thus, are more likely to be classified as freshwater compared with groundwater. It is not incorrect to say that river waters are generally fresh.
3. Various groundwaters (excluding connate water, intruded sea water, magmatic and geothermal water, and water affected by salt leaching) generally have a TDS of less than 10,000 mg/l (10). Thus, they may or may not be fresh.
4. Generally the electrical conductivity (EC) of groundwater in hard rock regions is 120 μS/cm or less (11) and therefore, is fresh.
5. Water emanating from upland catchments and water of lowland rivers that have typical ECs less than 700 μS/cm(12) are fresh.
6. Igneous, volcanic, carbonate, and metamorphic rocks generally yield freshwater.
7. Freshwater may turn into other types of water (brackish, saline, etc) by various means, including human-induced pollution, sea/saltwater intrusions, overexploitation, and other natural causes.

Gases dissolved in water play an important role in solution chemistry and in biological processes in solutions. The story that we will present of dissolved gases in water is in some sense twofold. We begin with the more conventional description and a general discussion of gases dissolved in groundwater, in seawater, and in blood, and decompression sickness. We then give a short introduction to a new and rapidly developing scientific field within colloid and solution chemistry that has demonstrated a profound role for dissolved gas in, for example, colloidal interactions, hydrophobic interactions, conductance, surface tension, and bubble fusion. We argue strongly that different scientific disciplines that consider dissolved gases in very different ways can benefit tremendously from better knowledge of work in other disciplines.

DISSOLVED GASES IN GROUNDWATER

Dissolved gases and dissolved organic matter (hydrophobic acids, bases, and neutrals) are ubiquitous in water. A large number of dissolved organic materials are composed of humic acids that are heterogeneous organic macromolecules. These have an important role in binding of metals and pesticides. Humic substance concentrations range from 20 μg/L in groundwaters to 30 mg/L in surface waters. Groundwater also contains dissolved gases due to exposure to the atmosphere, gas production reactions with minerals, and biological activity. These gases are certainly at least as important as dissolved matter. The most common gases are those that constitute the atmosphere; O_2, N_2, and CO_2. Methane, H_2S, N_2O, and other gases are also present in groundwater due to biogeochemical processes. Dissolved gases can have a tremendous impact. The presence of dissolved H_2S in water can, for example, give rise to the smell of rotten eggs, and above an H_2S concentration of 1 mg/L, the water is no longer suitable for consumption. Dissolved oxygen, on the other hand, is vital for biology. The concentration of dissolved oxygen (at 20 °C) at saturation is 9.1 mg/L. This is not that far above the minimum concentration of dissolved oxygen that can maintain aquatic life (which is around 5 mg/L). Aerobic bacteria can break down oxygen and leave an oxygen concentration close to this lower limit (it may even become too low to sustain aquatic life) (1). Another major dissolved gas is carbon dioxide. The total concentration of carbon oxides ($[CO_2(aq)] + [H_2CO_3] + [HCO_3^-] + [CO_3^{2-}]$) is around 2.3 mM in seawater, 0.1–5 mM in river water, 0.5–8 mM in groundwater, and 10–50 μM in rainwater (2).

DISSOLVED GASES IN THE OCEANS

A large number of measurements of the fluxes of gases between the atmosphere and the ocean have been carried out to determine gases dissolved in seawater (3,4). The first determination of N_2 dissolved in Atlantic seawater was performed in 1938 (5). A large number of methods have been used to measure dissolved gases in water (e.g., Winkler method, gasometric methods, mass spectroscopic methods (6), and gas chromatographic methods (4,7)). The mechanisms of gas exchange in the ocean are not entirely understood. Studies of gas exchange between air and water are often based on the simple theoretical surface film model developed by Liss and Slater (3). However, it is a complicated system and more recent attempts have been made to include different complications. Gas exchange depends, for example, on the partial pressure of a gas in air, its solubility coefficient, concentration in bulk surface water, wind velocity (8), temperature, salinity, molecular diffusivity, bubbles, and bubble size (9). Another complicating factor for oxygen and carbon dioxide dissolved in the ocean is that biological processes affect them. Oxygen profiles as a function of depth under the ocean surface are very different compared to the profile of N_2 (4) because O_2 is produced in the surface euphotic zone by photosynthesis and consumed by decomposition of organic matter in the aphotic zone.

The composition of gases in seawater (or in any other aqueous solution) under solution equilibria differ from their atmospheric composition. Dissolved gases that have been studied include carbon dioxide (CO_2), carbon monoxide (CO), nitrous oxide (N_2O), nitrogen (N_2), oxygen (O_2), methane (CH_4), sulfur dioxide (SO_2), dimethyl sulphide (DMS), and argon (Ar). Many of these gases are related to global warming, and there has been some discussion of the ocean as a source of methane to the atmosphere (4,10). Some of these dissolved gases are also contained in air bubbles. For example, Nakayama et al. (4) report values around 0.6 mM/kg for N_2, 0.35 mM/kg for O_2, and 16.5 μM/kg for Ar in the surface (0–50 m depth) region of the north Pacific Ocean and a mean value of 18.4 μmol/kg of dissolved air bubbles in the upper 30 m of water (4).

DISSOLVED GASES IN BIOLOGICAL SYSTEMS

Dissolved gases are very important in biological systems, and all forms of life visible to the human eye require oxygen. Hemoglobin is an important transport protein embedded in the cell membrane of the red blood cell. Its main function is to collect oxygen in the lungs, where it is abundant, and deliver it to the tissues around the body. O_2 that is used by most organisms is converted to CO_2. The carbon dioxide that diffuses in the blood is mainly in the form of dissolved CO_2 because conversion to carbonic acid is a comparably slow process. Long before this conversion takes place, it has usually diffused into the red cell. Once inside, conversion to carbonic acid takes place well buffered by the hemoglobin in the cell wall. While O_2 is delivered to the tissues, CO_2 is absorbed and transported out of the system (11).

Large volumes of gas dissolve in the tissues of divers. Gases such as nitrogen and helium are not metabolized by our bodies and need to be eliminated during slow decompression. Gradual decompression for several days is needed following extended human dives to pressures above 20 atm to avoid excessive gas supersaturation and bubble formation that may lead to decompression sickness (12,13). An interesting biochemical method to tackle decompression sickness has been investigated in experiments on rats. Suspensions of the human colonic microbe *Methanobrevibacter smithii* were introduced into the rats. This microbe that converts 4 mol of H_2 and 1 mol carbon dioxide (which is a gas that is abundant in tissues) to 1 mol methane and water, significantly reduces the risk of decompression sickness in rats (12). Decompression sickness begins at a much lower gas pressure than traditionally anticipated (less than 2 atm). The most likely explanation for this has only recently emerged and is discussed in the following section.

THE ROLE OF DISSOLVED GASES IN COLLOID SCIENCE AND BIOCHEMISTRY

Literature has accumulated during the last decade in physical chemistry journals focusing on the effects of dissolved gases on, for example, bubble fusion (14), emulsion stability (15,16), colloid interactions (17), hydrophobic forces (18,19), and optical cavitation (20). Bubble fusion depends strongly on salt concentration and ionic species but obviously also on the amount of dissolved gas (14). A mechanism has been proposed for hydrophobic forces that are based on surface adsorption and nucleation of dissolved gases in water. Suggestions have been made that dissolved gas molecules can be involved in propagating perturbations induced by hydrophobic surfaces. This could possibly give rise to the extraordinarily long-range hydrophobic interaction observed. There is clear evidence that degassing a system can significantly reduce both the magnitude and range of the hydrophobic interaction. Bubble formation occurs much more readily near hydrophobic surfaces. We have plenty of hydrophobic surfaces in our bodies, which is highly relevant for the understanding of decompression sickness. It is a plausible explanation why decompression sickness begins at a much lower pressure than expected and why physical exertion before decompression can increase the severity. Exertion is likely to damage tissue mildly and increase the number of hydrophobic sites where such cavitation can occur (14). The interested reader is referred to the references suggested, but we would like to mention one very interesting proposal made by Karaman et al. (15). They argued, quite convincingly, that there might be an unanticipated role for dissolved gases in biochemistry. Chemical reactivity can depend on dissolved gas through enhanced radical production in microbubbles formed from gas aggregates. Experiments in molecular biology have revealed that negatively charged restriction enzymes lock onto negatively charged DNA and cut it at particular sequences. Enzymes and DNA have the same charge, so this cannot be explained in terms of electrostatics, and the source of the energy to drive the catalysis is not explained. If cavitation occurs on contact, free radical $OH^\bullet$ production follows, and the transfer of an electron to $Cl^\bullet$ does provide sufficient energy. Experiments reveal that above 0.2 M NaCl, where cavitation is inhibited, the enzyme loses its catalytic property entirely and reversibly. Below 0.2 M NaCl, the addition of vitamin C, a well-known free radical scavenger, totally inhibits the enzyme. Dissolved gas can play an important role in harnessing weak molecular forces cooperatively to influence vital biochemical reactions. Interestingly, the cutting efficiency of DNA by enzymes also depends on the choice of background salt following a so-called Hofmeister series (see article on the "Hofmeister Effect" in this volume), in particular on the supposedly irrelevant choice of negative co-ions (21). One can show that this experimental finding further strengthens the proposed mechanism for the activation energy.

THE ROLE OF DISSOLVED GASES IN SURFACE TENSION OF ELECTROLYTES

In the past, there has been a discussion of the ion specificity found for the surface tension of salt solution. In the air–water interfacial region (which is roughly the first 6 Å closest to the air–water interface), there is a gradual transition of the relative amount of water and dissolved gases. This means that an ion near the interface experiences a force that originates from the change in solvation energy when the ion moves into the surface region (with its increasing concentration of dissolved gas and decreasing concentration of water molecules). This is besides previously discussed image potentials and dispersion potentials (originating from the polarizability of ions). Inclusion of solvation energy effects acting on ions near the air–water interface gives exactly the right order of magnitude and the right ion specific sequence for the surface tension of different salt solutions (22). If one furthermore includes dispersion potentials acting on ions, one improves the result further. There are clearly other effects that influence the surface tension of salt solutions, but it is clear that solvation energy effects, related to the interfacial profiles of dissolved gases and water molecules, together with ionic dispersion potentials between ions and the interface, play vital parts. References and a discussion of ion specific effects can be found in the article "Hofmeister Effects" in this volume.

Some attempts have been made to model theoretically the influence of dissolved gases, but there is in most cases still a long way to go until it is firmly understood. But it is very clear from experiments that dissolved gases play a very important, sometimes vital, role in a large number of different chemical and biological systems in water.

HARD WATER

Gholam A. Kazemi
Shahrood University of
Technology
Shahrood, Iran

INTRODUCTION

In defining hard water, first it is necessary to describe hardness, a closely related chemical property of water.

Hardness is defined by some as a property of water that prevents lather formation with soap and produces scale in hot water systems (1); by others, in simpler terms, as the soap consuming capacity of water (2); and in broader terms, by Freeze and Cherry (3), as the "metallic ion content of water which reacts with sodium soaps to produce solid soaps or scummy residue and which reacts with negative ions, when the water is evaporated in boilers, to produce solid boiler scale."

The ions which result in, or produce, hardness include Mg^{+2}, Ca^{+2}, Sr^{+2}, Fe^{+2}, and Mn^{+2}, and to a lesser extent, Ba^{+2} and Zn^{+2} and other divalent ions. The first two are the most influential. There are different forms of hardness (4):

1. *Total hardness*: Ca and Mg expressed as $CaCO_3$
2. *Calcium hardness*: Ca expressed as $CaCO_3$
3. *Magnesium hardness*: Mg expressed as $CaCO_3$
4. *Temporary hardness*: Equals alkalinity, if alkalinity is less than total hardness
5. *Permanent hardness*: The amount of hardness greater than temporary hardness
6. *Noncarbonate hardness*: Permanent hardness

Of the six different forms of hardness, the most important and the one that is commonly known as hardness, is total hardness. It is calculated from the following simplified equation:

$$\text{Hardness} = 2.5\ \text{Ca} + 4.1\ \text{Mg} \quad \text{(units in mg/l)}$$

Note that there are equations to calculate each of the six different forms of hardness.
Example: The Ca and Mg concentrations in a water sample are 20 and 15 mg/l, respectively. What is its hardness?

$$\text{Hardness} = 2.5 \times 20 + 4.1 \times 15 = 111.5\ \text{mg/l}$$

As stated, each of the six forms of hardness can be calculated by analyzing a water sample for the relevant ion(s), followed by using the relevant equation. However, there are techniques for measuring total hardness directly such as (a) a standard solution of soap, that was in use for many years (2); and (b) Schwarzenbach et al.'s method of colorimetric titration (5), which is sometime referred to as the EDTA method.

The author believes that earlier, the measurement of hardness was a common and an inseparable practice in water analysis. To agree with this statement, one needs to look at a relatively old handbook and read, "The common denominator of the majority of water problems is hardness" (Ref. 2, p. 4.1, first published in 1979). Somehow, in contrast, recent hydrochemical analysis of water samples does not usually include a measurement of hardness. For instance, there is not a single report of hardness in the hundreds of hydrochemistry papers presented at the International Association of Hydrogeolgists (IAH) conferences in Prague (2003) and in Munich (2001) and in the recent past (1997–2001) annual symposia of the Geological Society of Iran. Other aspects of water chemistry and water biology, such as nutrients, heavy metals, bacteriological species, chlorinated hydrocarbons and many more contaminants have become so widespread and are considered more important and more dangerous than hardness. Rejection of water for drinking or other uses, these days, is many times more likely to be due to its harmful DDT level than because of its high hardness value. One other possible reason is that hardness and hard water topics are only important in a narrow field of water, e.g., hot water boilers.

The second point is that industrialization, urbanization, agricultural practices, and most environmentally unfriendly activities are not likely to result in an increase in the hardness of water resources. These activities do not usually generate hardness producing ions such as Ca^{+2} or Mg^{+2}, though, they may produce other trivial (in terms of hardness) ions such as Mn^{+2} and Fe^{+2}.

DEFINITION AND SPECIFICATIONS OF HARD WATER

Todd (6, p. 282) reports that Hippocrates (460–354 B.C.) was the first to use the term hard and soft for water when he, in his treatises on public hygiene, wrote "consider the waters which the inhabitants use, whether they be marshy and soft, or hard and running from elevated and rocky situations, and then if saltish and unfit for cooking... for water contributes much to health." However, it is probably safe to say that hard and soft water in Hippocrates' writings are likely to mean different things than what we today call hard and soft water.

The definition of hard water varies slightly among researchers. The most frequently used classification system for hardness is that of Sawyer and McCarty (7), presented in Table 1. There is another slightly different classification system by Hem (8), which is referred to in some publications as the classification of the U.S. Geological Survey (9).

Based on Table 1, hard water is defined as water whose hardness is about 120 to 300 mg $CaCO_3$/l. However, some researchers argue that there is no exact definition for determining hard or soft water, because it depends, at least partially, on what one is accustomed to (9). What is hard water for one person, may be moderately hard for another and vice versa. The very hard water category in Table 1 can be grouped into the hard water category as it has the specifications of hard water. It is, however, unclear to which category one can assign moderately hard water, should hard water and soft water be the only categories available.

Table 1. Different Types of Water Based on Hardness

Water Type	Hardness, mg $CaCO_3$/l	
Soft	below 75^a	Below 60^b
Moderately hard	75–150^a	60–120^b
Hard	150–300^a	120–180^b
Very hard	Over 300^a	Over 180^b

John C. Manning (9, p. 228), a very well known authority in the field of hydrology for his Manning's roughness coefficient, succinctly yet nicely describes the characteristics of hard water; "Really hard waters, are unmistakable. If you have ever stayed in a motel supplied with hard water and tried to take a shower with a tiny bar of soap many motels supply their guests, you know how frustrating it is to see the soap disappear before you are probably lathered and bathed. On the other hand most people like water with a little hardness. It usually tastes better, and it washes the soap off when you bathe. Very soft water feels slick on your body, as though the soap were still there. Water with a little hardness, which is to say with calcium and magnesium ions, is favored for irrigation, too, as it tends to maintain higher soil permeability and allow infiltration to take place."

The explanations given above can be summarized as "those waters that require considerable amounts of soap to produce a foam or lather and that also produce scale in hot water pipes, heaters, boilers, and other high water temperature units, are called hard water." By the end of this article, the author confesses that the reader may become confused as what is hard water and what is hardness.

The economic disadvantages of hard water include increased soap consumption and higher fuel costs for boilers due to poor heat conduction resulting from scale formation. The term scale describes a continuous, adherent layer of foreign material formed on the waterside of a surface through which heat is exchanged (5). The thermal conductivity of $CaCO_3$ scale is as low as 0.0022 cal/s.cm. °C, 418 times lower than that of copper which is 0.92 cal/s.cm. °C. Hence, precipitation of $CaCO_3$ due to use of hard water significantly reduces the thermal conductivity of boilers. As a result, guidelines have been produced to set the limit for hardness of waters used in various industries; a few are presented as examples in Table 2. In a similar fashion, 80 mg/l of hardness is set as the limit for domestic water (10).

It is generally accepted that there is no health hazard associated with hard water (1). However, a recent study in Taiwan (11) shows that there is a significant negative relationship between drinking water hardness and colon cancer mortality, an important finding for the Taiwanese water industry and human health. This is in line with Tebbutt's (1) report that there is some statistical evidence to suggest that artificially softened waters may increase the incidence of some forms of heart disease. All these confirm Muss's (12) observation that in the United States, death rates from heart and circulatory diseases are lower in states where public water supplies are harder.

Table 2. Recommended Hardness Limit for Industrial Process Water[a]

Use	Hardness Limit, mg $CaCO_3$/l
Carbonated beverages	200–250
Confectionery	75
Dairy	180
Food canning and freezing	25–400 (depends on the type of food)
Food equipment washing	10
Food processing, general	10–250
Laundering	0–50
Paper and pulp, fine	100 (Ca hardness, 50)
Paper, groundwood	200
Paper, kraft, bleached	100
Paper, kraft, unbleached	200
Paper, soda, and sulfate pulps	100

WHAT TO DO WITH HARD WATERS

When needed, there are a few methods to change a hard water to a soft water to suit the purpose, an exercise called water softening (1):

1. *Lime softening*: This method involves adding lime and is suitable for calcium hardness of the carbonate form. In a typical experiment, total hardness and carbonate hardness of 150 and 125 mg/l are reduced, after softening, to 65 and 40 mg/l, respectively.
2. *Lime—soda softening*: This technique involves adding soda ash (Na_2CO_3), and is suited to all forms of calcium hardness. In a typical experiment, total hardness and carbonate hardness of 200 and 100 mg/l are reduced, after softening, to 40 and 40 mg/l, respectively.
3. *Excess—lime softening*: This is suitable for magnesium carbonate hardness. Chlorination may be unnecessary after such softening, but carbonation is necessary.
4. *Excess—lime soda softening*: This method involves adding lime and soda ash. It is a complicated process which is suited to all forms of magnesium hardness and produces a large volume of sludge.
5. *Ion exchange*: This method takes place through three approaches: (a) zeolite, (b) hydrogen cycle cation exchangers, and (c) strong ion exchanger. The Na^+ ions of zeolites replace Ca^{+2} and Mg^{+2} ions in the water, a reaction like ion exchange between Na_2clay and water. A natural sodium cycle zeolite has an exchange capacity of about 200 gram equivalents/m^3. Hydrogen cycle cation exchangers exchange all cations for hydrogen and so, produce zero-hardness water. A strong anion exchanger removes all ions.

HARDNESS OF WATER—WORLDWIDE CASES

Limestone and dolostone aquifers that contain gypsum and anhydrite in their matrix may yield hard water, whose hardness is from 200–300 mg/l or more (10). Groundwaters are generally higher in hardness than surface waters (4). The hardness of groundwater in Akwa Ibom State, Nigeria, ranges from 1.2–65 mg/l (13). In the Jornada del Muetro Basin of New Mexico, the groundwater hardness reaches 260 mg/l (14). The hardness of shallow groundwater in Balatina and Arpineni in the Republic of Moldovia reaches 55.5 mg-ecv/l (15), and in the Damman

Aquifer of Bahrain, reaches 3115 mg/l and an average of 1296 mg/l (16). The Mississippi River at Vicksburg has a hardness of 172 mg/l (2).

AN ANALYSIS OF THE IMPACT OF WATER ON HEALTH AND AGING: IS ALL WATER THE SAME?

HOWARD REMINICK
Ohno Institute on Water and Health
Willoughby, Ohio

The human body was created to be in balance or return to balance. We call this homeostasis. Our body relies on its chemical processing plant to keep a metabolic balance. The body knows when it is being depleted of essential minerals and nutrients, which creates imbalance. When this happens, the body has to draw from its reserves. But this can only be temporary, until these reserves are replenished.

Our body knows when its energy level is low. If nothing is done, if we continue to ignore the body's call for help, we let our body begin on the path of its destruction. When the body is neglected, it becomes vulnerable to attack from invaders from the outside. It also is open to attack from the inside by free radicals. Bacteria, which are essential for our survival, suddenly turn on us and destroy us.

The body reacts to regain its balance by calling on the immune system. Sometimes it is too late if the body has been in a contaminated state too long, which can result from the poor quality of water we put in our body every day.

Water has the power to transfer information from cell to cell and bring back balance from imbalance. Water is vital to maintain life and organization of our cells. Organized cells are healthy, productive cells. To create harmony and balance, whether in our bodies or in the environment, water must also be balanced.

The body knows when it is drying out. The body can keep its ability to remain balanced only if it is given enough good water. Not just clean water, but water that can provide a good internal environment for the body to function and carry on its purpose to remain balanced or return to being balanced.

Water holds some of the most basic and, therefore, significant secrets of life. This is not a new idea. All ancient civilizations described this in their attempt to explain the structure of life. Even then as today, many believe that water within the cell has a "vital force." Cells are the fundamental units of life, so then they are responsible for all life processes and are the force that permeates all nature. If that force is available in any one substance, then it must be in water.

The earth is 70% water. Our body is 70% water. A cell is 70% water. DNA is 70% water. Is this just a coincidence? About 3 billion years ago, life was born in water. The first life form existed in pure, clean water. There is a direct connection between the quality, content and even the structure of the water in our body that can make the difference between sickness and health.

One of the most important books written, which explains the necessity of water for health is *Your Body's Many Cries For Water*, by F. Batmanghelidj, a medical doctor, who presents the most compete description, and further warns us that this relationship is not being addressed by general medical practice (1). He attributes the basis of all disease to dehydration and overly prescribed medications. He also warns that dehydration is a world epidemic, which can be controlled by attention to the body's hydration needs.

Understanding disease and aging begins with knowing what our body needs throughout its lifetime to maintain health and vitality. Premature aging can result from loss of water volume without adequate replacement or from contaminated water in our bodies. Because of environmental toxins and chemicals, food and water sources have been depleted of essential minerals. As a result, the body's chemistry becomes unbalanced, which creates a breakdown in the body's internal environment, making it susceptible to disease and rapid aging.

The body must receive at least 2.5 liters of water daily to replace loss. Although beverages such as coffee, tea, soda, and beer contain water, they do not count as hydration replacement. These beverages actually use water to be processed in our body, which increases dehydration. Only water can replace water in our body.

Symptoms of the body's deterioration begin to appear when the body loses 5% of its total water requirements. In a healthy, normal adult, this appears as fatigue and general discomfort. Although an adult can survive a 5% water loss, this can be fatal to an infant. In elderly persons, a 5% water loss may not be fatal, but the body chemistry becomes abnormal, especially the percent of electrolytes being overbalanced by sodium. Continuous water loss over time will speed up aging. Lost water must be replaced (Fig. 1).

Because water is an excellent solvent, vital nutrients are absorbed in the cells. The body must receive the best quality of water available to ensure that its internal environment is in the best operational state. This allows the body to be at its best to respond to distress and imbalance by making corrections, returning the body to homeostasis.

Every function such as digestion, absorption, elimination of waste products, and production of glucose to provide energy is maintained if the body has water that is not only pure, but bio-active. This bioactivity is created by magnetic influence throughout the body. Minerals absorbed in the body's water are carried throughout the body to become ionizing agents for all cells. The effect of biomagnetism on hemoglobin in the blood is critical. Hemoglobin consists of iron, which is the catalyst in its reaction to the body's biomagnetism in its role of stimulating nerve and muscle impulses.

It should now be evident that there are essential issues about the water in our body that must be considered if we are to remain as healthy as possible. First and foremost, all water is not the same. Although all water is H_2O, that is where it ends. And there is no way to fool the body. Water must be able to prevent toxins and chemical substances from accumulating and creating destructive influences in cells. Water must bring all minerals and nutrients required for metabolism into each cell and remove any substance that can damage the cell.

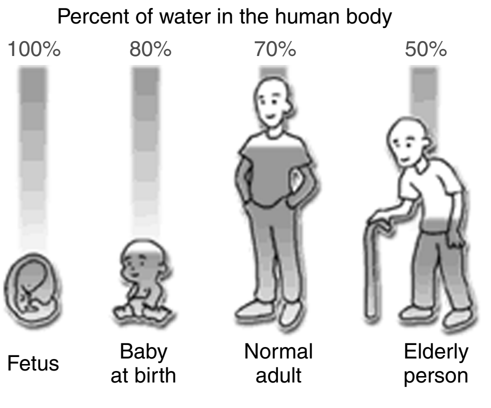

Figure 1. Percent of water in the human body.

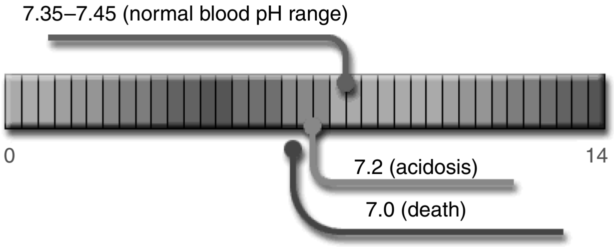

Figure 2. 7.35–7.45 (normal blood pH range).

Another critical need in the body is the pH balance of blood and body fluids. Normal blood pH has a very small window of normalcy (Fig. 2). It must range between 7.35 and 7.45. There must be an adequate amount of oxygen in the blood. Too little will diminish all organic function. Too much can cause oxidation, which is what happens when an apple is left exposed. Because of the ever-increasing levels of pollution and toxicity in our environment, which includes food and water supplies, our blood tends to be acidic.

THE INTERACTIVE EFFECT OF MAGNETIZATION AND WATER ON CELL BIOLOGY

Everything that happens in our bodies every day of our lives depends on the presence of magnetism. Magnetism in our body is created by the magnetic field, which dominates and controls the stability of our planet Earth. It also controls the stability of all life on Earth.

Does magnetization of the water do anything to change its basic physical properties? The answer is yes. The changes are very small but measurable. Magnetized water exhibits a change in the strength with which water molecules are able to bind with one another. Magnetized water can disrupt hydrogen bonding in water. Water, charged with magnetic energy, allows minerals and other organic substances to provide intermediate pathways of flow for magnetic energy to be directed to where it is needed in the body. The fact that magnetized water possesses altered binding forces between water molecules and various proteins, salts, and mineral substances appears to endow it with the ability to dissolve buildups of various types of salts and minerals.

There is a fascinating fact about the level of energy in moving water in our body and its effect on ionization. Because all living things are known to function largely by the influence of bio-magnetism, it seems reasonable to provide the body with water that is magnetically activated. Normally, water forms large molecular clusters, which slows movement and absorption into cells. This can be seen by microscopic analysis [most water molecules will aggregate around the rim of a slide (Figs. 3, 4, and 5). Naturally magnetized water will disperse throughout the slide, indicating free flow]. Because water molecules, which are not adequately magnetized, will lose order when they are not adequately magnetized, this can affect intracellular hydration.

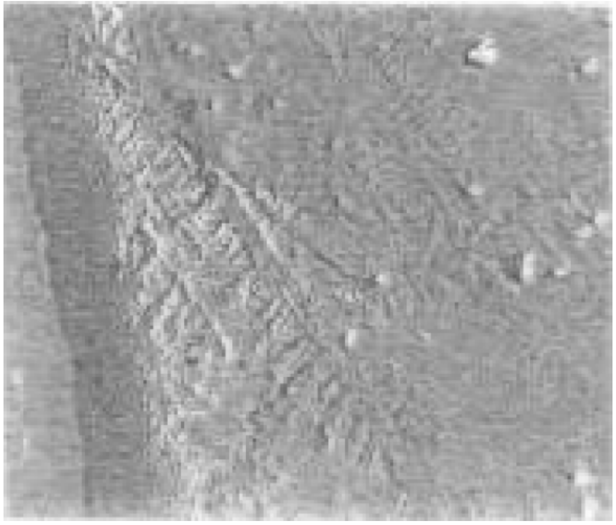

Figure 3. Microscopy photo of an unmagnetized water molecular structure. Note sparse formation of crystals and thick molecular clustering appearing as a mass and gathered at rim of slide.

Figure 4. Microscopy photo of naturally magnetized water. Note large number and density of crystals and individually fragmented molecules, remaining evenly dispersed on slide.

Water has long been known to be affected by magnetism. Magnetization can significantly reduce the surface tension of water and increase the pH, making it more alkaline. Water molecules are known to have a small interaction with magnetism, creating chains of organized molecules, which can influence the biochemistry of the water in the body. The intricate biological requirements needed to maintain electrochemical balance have been reported in books and journals about human physiology. Magnetically activated water may increase the percentage of intracellular hydration, which is a major factor in controlling the aging process and aging-related diseases.

RELATIONSHIP OF MAGNETISM TO CELL STABILITY

What is a living cell? It appears as one large molecule tied together by a matrix of water molecules. Like the atoms that compose them, they are tied together by ionic bonds, consisting of positive and negative charges on their outer surfaces. What creates these bonds?

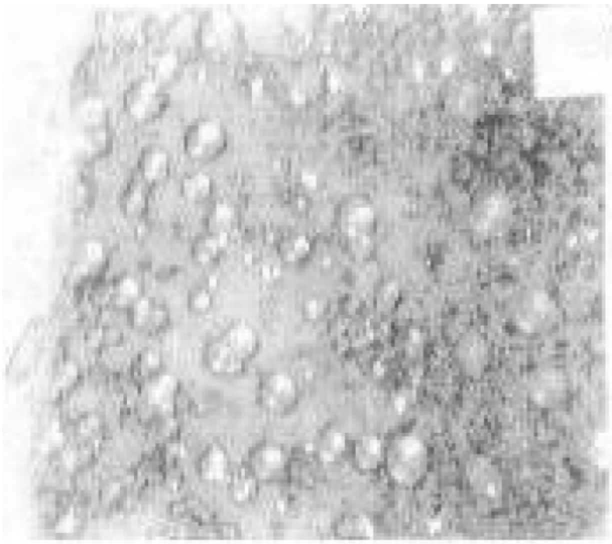

Figure 5. Microscopy photo showing detailed individual molecules of naturally magnetized water. They will not re-form in large clusters over time.

If salts like sodium chloride are added to water, the sodium and chloride ions (Na^+ and Cl^-) immediately become surrounded by water molecules to dissipate their charges. In doing so, adjacent water molecules take on the charges to form H_2ONa^+, which possesses the unique property of being able to transfer the small positively charged nucleus of one of its hydrogen atoms to a neighboring water molecule. Then the neighboring molecule becomes positively charged as H_3O^+, due to the extra hydrogen proton bonded to its oxygen atom. This charged molecule transfers one of its protons to another neighbor, cascading in a linear fashion to water molecules surrounding negatively charged ions. Thus, the stability of a particular molecule is the electromagnetic bond of energies between atoms.

Magnetism affects the electron stability of cells. Electrons of a cell are established in pairs. Think of an unstable element moving around the body, looking for an electron to make itself stable. It will steal an electron from wherever it can, at the expense of a stable cell, which needs paired electrons to remain stable. When a cell loses an electron from a pair, it will lose energy and die, sacrificing itself to the "thief," which is how bacteria and cancer strive. This is believed to be the activity creating free radicals, that is, strong, unstable magnetic activity as a result of a cell with electron imbalance aggressively seeking another electron, thereby creating imbalance in another cell.

One of the first things we learn about the complex molecules of living cells is the way in which their atoms are bonded together. Magnetism takes place when electrons orbit around their atoms. Electrons have a property called spin, which makes them act like miniature magnets with two opposite poles. If neighboring electrons spin so their poles are aligned in the same direction, they become magnetic. The electrons circling around atoms resist attempts to disturb their usual orbits, so they can create their own magnetic field.

The molecular parts which compose the cells of our bodies are much the same as those that composed the earliest forms of life on Earth. If we wish to comprehend the composition of life and its molecular roots and determine how these molecules move and flow in a spontaneous and miraculous fashion to sustain and perpetuate themselves, then, like nature, we must begin with water. Genetics defines which molecules are produced; water defines how they move and associate with each other.

Modern scientific technology has revealed the basis of molecular biology in the cell, its DNA, and how critical water is to its order. If DNA is dehydrated, like other bonding components of the cell, it loses its orderly, repeating structures and takes on more random shapes and forms. In other words, DNA loses its normal, functional properties.

It is now clear that all information needed to direct molecules into their functional shapes is contained in the molecules themselves in association with each other and the surrounding water medium. DNA, operating in harmony with water, determines shapes that are adopted as they are produced and move within the cell. It appears that DNA molecules themselves are the “code” and water the medium where the code is expressed.

As long as environment and temperature are maintained within the cell and there is adequate magnetization to keep cell biology functioning normally, then cellular reproduction, along with normal DNA coding, will continue. If, however, the content and effectiveness of the water inside and outside the cell contain destructive toxins, the degradation and deterioration of cells will increase quickly, resulting in rapid aging and disease.

THE EFFECT OF WATER ON CELLS

Fluid fluctuations affect blood volume and cellular function, which can be life threatening. When the amount of fluid within various cellular compartments is relatively constant, there is an exchange of solutes and water between compartments to maintain unique compositions. Individuals with more body fat have proportionately less total body water and are more susceptible to fluid imbalances that cause hydration.

The total body water percentage decreases with age, resulting in inadequate cellular hydration. Most critical is the decrease in intracellular fluid, which is due, in part, to increased fat and decreased muscle, and decreased ability to regulate the sodium and water balance. With age, kidney function becomes less efficient in producing urine, and responses for conserving sodium weaken.

There are two major issues about the water in our body that must be resolved if the body is to remain in a state of harmony and stability. First, the water must be able to prevent toxins and chemical substances from accumulating and creating destructive influences in the cells. Water must bring all minerals and nutrients required for metabolism into the cell and remove any substances that can damage the cell. Also, the cell wall must be protected from damage and invasion. Second, water is involved in every function of the body, so it must act as a conductor of electrochemical activity, such as neurotransmission, by moving water from one nerve cell to another smoothly and effectively.

When cells are studied under magnetic resonance imaging (MRI), water is observed to act very differently from when it is not exposed to a magnetic field. Molecules are re-formed in smaller clusters in a linear arrangement. The molecules are lined up and move in and out of the cells easily. In contrast, when water is photographed after removal from MRI exposure, molecules are randomly ordered and cluster with neighboring water molecules to form large, molecular clusters. (Interestingly, when cancer cells are studied under MRI influence, their water molecules are also organized and calm, in contrast to their aggressive, violent movement without MRI exposure.) However, naturally magnetized water remains organized in small clusters, whether exposed to MRI or not.

THE PASSAGE OF WATER IN AND OUT OF CELLS

Movement of water occurs because of hydrostatic pressure and osmosis in capillaries. As water flows from artery to vein, changes in pressure create movement across membranes. Any changes in pressure allow proteins, minerals, and other nutrients carried by the blood to escape into spaces between vessels and deprive the cells of vital needs to sustain life. In addition, when the water in the blood is acidic and contaminated with chemicals, it enters the cells and changes their structure, including changes in DNA, which is how disease begins and attacks structures in the body.

Osmosis is the diffusion of water across a membrane that permits the free passage of water but not solutes. Molecules of solutes (sugars, amino acids, and ions) dissolved in water are in constant motion, which creates diffusion, the random movement toward zones where the concentration of the molecules is lower. This tends to distribute molecules uniformly. Because of diffusion, both solvent (water) and solute molecules in a cell will move from areas where concentration is greater to an area where their concentration is less.

As water molecules continue to diffuse inward toward the area of lower concentration of unbound water molecules, pressure within the cell increases, which is called hydrostatic pressure. This is the force that must be applied to stop osmotic movement of water across a membrane. When two areas are separated by a membrane, what happens depends on whether the molecule can pass freely through the membrane; most solutes in cells cannot do so.

Solutes are water soluble and are kept within the cell. Water molecules, however, can diffuse across the membrane into the cell, thus diluting the high concentration of solutes within the cell so that it matches more closely the lower concentration in the solution outside the cell (extracellular matrix). Eventually, however, the cell will reach an equilibrium, and the osmotic force driving water inward is counterbalanced exactly by the hydrostatic pressure driving water out. As a result, the water and solute concentrations will be the same in both compartments.

The nature and proportion of solutes in the body's water determine its effectiveness in hydrating and detoxifying cells so that a homeostatic, internal environment can be maintained to ensure proper cell metabolism, which requires bioenergy. A key component in dispensing bioenergy is the interactive effect of water and biomagnetism. This interactive bioenergy is seen in the effectiveness of osmosis and the osmolarity of the water in the extracellular matrix, as well as in the cells. Through the influence of the body's bio-magnetism, greater penetration of ions through the cell membrane, transported by water, will increase the health and stability of cells.

Osmosis is created by a magnetic force in our body, which keeps the movement in balance. Osmotic activity occurs as a result of osmolarity, the total concentration of all solute particles in a solution. The extent to which water's concentration is decreased by solutes depends on the number, not the type, of solute particles in a solution, because one molecule or one ion of solute displaces one water molecule. Thus, a solution's osmolarity is a count of the number of solute particles (including ions) dissolved in one liter of water and is seen in the solution's ability to cause osmosis. The measurement used to describe the solute concentration of body fluids such as water is the milliosmol. The normal osmolality of body fluids should average around 270 milliosmoles.

Osmolarity controls the distribution and movement of water between body compartments. The osmolality of intracellular and extracellular fluid tends to equalize and, therefore, provides a measure of body fluid concentration and the body's hydration status. Osmolarity measures the effective change in pressure for water, assuming that all the solutes are impenetrable. When a solute is added to water, the volume is expanded and includes the original water plus the volume occupied by the solute particles. In measuring osmolarity, the volume of water is, therefore, reduced by an amount equal to the volume of added solute.

When equal volumes of solutions of different osmolarity are separated by a membrane that is permeable to all molecules in the system, net diffusion (tendency of the molecules or ions to scatter evenly) of both solute and water occurs, each moving down its own concentration gradient. A solution that changes the tone or shape of a cell by altering its internal water volume is described by its osmotic activity, or tonicity. Tonicity is the tendency of a solution to resist expansion of intracellular fluid volume.

Solutions with concentrations of nonpenetrating solutes equal to those found in cells are isotonic, or have the same tonicity. An isotonic solution has the same osmolality as the intracellular fluid (ICF) or the extracellular fluid (ECF), which is required to maintain normal cell metabolism. An example of an isotonic solution is 5% dextrose in water and a normal saline solution of 0.9% NaCl. This solution is isotonic because there is no net movement of the active particles in the solution into cells and the particles are not metabolized. Extracellular fluids and most intravenous solutions are isotonic.

Solutions that contain fewer nonpenetrating solutes are called hypotonic. Cells placed in hypotonic solutions plump up rapidly as water rushes into them. Distilled water represents the most extreme example of hypotonicity. Because it contains no solutes, distilled water pulls water into cells without proper resistance or osmotic pressure and causes them to swell or burst.

A hypertonic solution has a concentration greater than 285 to 294 milliosmoles. An example is a 3% saline solution. Water is pulled out of the cells so that the cells shrink. Tonicity is critical to cell metabolism when correcting water and solute imbalances by administering different types of replacement solutions, such as those used in IV therapy solutions.

Balanced osmolarity can be the difference between the life and death of an organism. An example is seawater, overbalanced with sodium ions, or distilled water, which can be deadly if infused because it has no osmolarity. If distilled water is present on both sides of a permeable membrane, no net osmosis occurs, even though water molecules continue to move in both directions through the membrane. If, however, the solute concentration on both sides of the membrane differs, water concentration differs as well, because as the solute concentration increases, water concentration decreases.

There is a consideration when determining osmotic activity. In living plant cells, as water diffuses into the cell, the point is reached where the hydrostatic pressure (the back pressure exerted by water against the membrane) within the cell is equal to its osmotic pressure (tendency to resist further net water entry). Generally, the higher the amount of nonpenetrable solutes within the cell, the higher the osmotic pressure and the greater the hydrostatic pressure that must be present to resist further net water entry. Osmotic pressure is also necessary to control water loss.

However, these pressure changes do not occur in living animal cells, which lack rigid walls and are surrounded only by flexible plasma membranes. Osmotic imbalances cause animal cells to swell or shrink, due to net water gain or loss, until the solute concentration on both sides of the plasma membrane is the same or the membrane is stretched to its limit. Many molecules, particularly intercellular proteins and selected ions, are prevented from diffusing through the plasma membrane. Any changes in their concentration produce changes in water concentration on the two sides of the membrane and result in net loss or gain of water by the cell.

THE EXTRACELL MATRIX AND WATER

Our cells are continuously bathed in an extracellular fluid called interstitial, found outside the cell. Because it contains such a large variety of ingredients, such as amino acids, sugars, fatty acids, vitamins, hormones, neurotransmitters, and salts, it is sometimes referred to as the "soup" that feeds the cells. It is also the dumping ground for waste products removed from the cells. To remain healthy, each cell must absorb substances from this "soup" in the exact amounts it needs at specific times and reject the rest.

The human body can maintain homeostasis only if the extracellular fluid (ECF) volume is closely regulated to maintain blood pressure and salt balance. Its osmolarity must be regulated to prevent swelling or shrinking of the cells. The maintenance of water balance is important in regulating ECF osmolarity. To maintain stability, the ECF must respond quickly to changes in volume and osmolarity (2).

In humans, kidneys can spare water by eliminating wastes in concentrated urine. This urinary concentration relies on water reabsorption driven by an osmotic gradient formed along the collecting ducts, consisting of NaCl and urea at similar osmolarities. Survival of renal cells is induced by NaCl, but not urea, because urea is a membrane-permeant solute. With excess saline in the tissues, there is a decrease in water excretion to bring the salt concentration back to normal, which allows the cell concentration to remain constant and prevent shrinking by fluid moving out of the cells to reach equilibrium within the cells.

The environment of a cell is directly affected by the environment outside the cell. Cells have a reciprocal relationship with their environment. The environment surrounding a cell consists of a structured, basic substance, called the extracellular matrix (ECM). This enormous space of connective tissues has a significant effect on determining genetic outcomes of the cell. Water is its primary regulation system. The ion composition of the elements in the extracellular space is activated in water.

Understanding how a cell maintains its integrity requires understanding the role of the extracellular matrix in the body in the health and longevity of its internal environment. Most body cells are in contact with a jelly-like substance composed of proteins and polysaccharides. These molecules are secreted by the cells into an organized mesh in the extracellular matrix, where they serve as a sort of glue that helps hold cells together. In reference to the cells, this can be viewed as the mortar between bricks of a wall. Depending on the time of day, this “mortar” can be gelatin-like or liquid because of the impact of the sympathetic and parasympathetic nervous systems, which perform different functions at different times of the day.

During the 12-hour “dumping cycle” (3:00 A.M. to 3:00 P.M.), controlled by the sympathetic nervous system, the “mortar” is gelatose to remove and retain wastes from cells and is acidic. During the 12-hour “feeding cycle” (3:00 P.M. to 3:00 A.M.), controlled by the parasympathetic nervous system, the “mortar” is liquid to transport nutrients to cells and is alkaline. It is the effect of magnetically activated water in the extracell matrix that assures an optimal delivery system and that these cycles function properly with pH balance (Fig. 6).

The ECM is the largest system in the body. It is virtually responsible for all vital functions that take place within the body. All cells depend on an intact ECM for their existence. It regulates the cell’s environment and is part of every aspect of the immune system because the lymphatic system is connected with it. It takes care of cell nutrition through internal circulation of water and

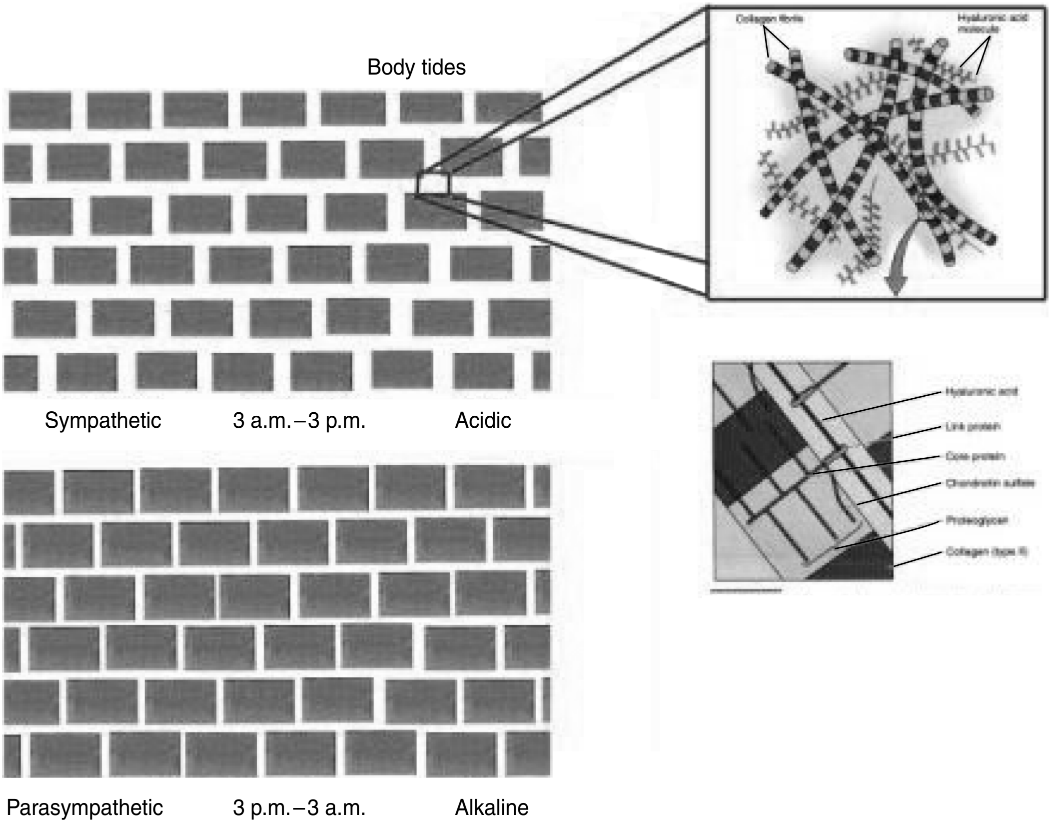

Figure 6. ECM Cycle.

removal of wastes. Disease originates in dysfunctions in this space, as it affects organs and other systems throughout the body.

More than having a supporting and space-filling function, the ECM provides regeneration for specific organ functions, as well as mediation of nerve and vascular functions. Everything that comes out of the blood takes a complicated route through the connective tissue to the cell and then into the lymphatic system. It is even more vital to the health of the human body because the nerves and blood vessels do not come into direct contact with the cells at any point; therefore, the ECM becomes the mediator for nervous and nutritional flow. As connective tissue is really a living part of the body, everything attributable to the life and health of the body, and all its basic functions, has to be attributed to the extracellular matrix.

The extracellular matrix provides the communication of connective tissue over the entire organism. The entire field of activity and information related to communication is the extracellular fluid. Connective tissue is found everywhere between the bloodstream and the principal structural parts. Everything that comes out of the blood takes a complicated route through the connective tissue to the primary, functioning cell and then into the lymphatic system, which is connected with it. It takes care of cell nutrition through internal circulation of water and the removal of wastes. It regulates the cell's environment and is part of every defense process.

The extracellular matrix is connected to the endocrine gland system via capillaries and the central nervous system via the peripheral nerve endings. Both systems are connected to each other in the brain stem, so superior regulatory centers can be influenced by the ECM. The advantage of the interconnection of these systems results in a significant increase in the performance capacity of the ECM, which can be attained only by highly functional, interconnected sets of systems, functioning as one.

When looking for the source of disease and aging, we must first look at the water in our bodies. I would like to repeat the statement that led me to search for the causes of aging diseases: If the body is composed of 70% water, then the condition of the water in our body can determine how well our body maintains its state of health. The structure of all living tissue is predominately water, a plain and simple substance. Knowing the importance of water in the body can help us learn how to keep the body from breaking down. Further, understanding that a living organism is composed mostly of water should help us better appreciate the need to supply our body with the best water possible.

The signature of life is found in the water we drink every day. A body can remain in a state of health only if it is given enough water, not just clean water, but water that has the structure, properties, and activity to provide a good internal environment for a body to function at its best. We become sick, not just from dehydration, but from the inadequacy of the water we drink. The question becomes, "is all water the same?" The answer is a definite no. Only water that is bioactive with magnetic energy can provide ideal hydration.

After years of investigation on the biological effects of magnetized water on human health, it became apparent that all magnetized water is not the same, nor does each behave the same in the body. Water that is magnetized with devices displays structural changes initially but will return to its original formation because every water source is unique; each has its own frequency, its own signal, due to its unique memory. Artificially altering water, therefore, will not create a permanent structural change. In all of our studies, only water that is naturally magnetized, which creates the water's memory, will perform as the optimal hydration source consistently and aid the body in maintaining a better internal environment, resulting in better health and more natural aging.

To learn more about the phenomenon of naturally magnetized water, go to http://www.ohno.org.

INTRODUCTION

This article should be studied in conjunction with the closely related articles on Deuterium and Isotope Fractionation. In some ways, it might have been slightly more appropriate if the Deuterium and Heavy Water articles were combined into one. For example, the whole introduction and some parts of the text of both articles overlap, making it more or less difficult to draw a sharp boundary between the two.

Each of the atoms of hydrogen and oxygen, which form the water molecule, has three isotopes; ^{1}H, ^{2}H (D), ^{3}H (T) for hydrogen and ^{16}O, ^{17}O, and ^{18}O for oxygen. The average terrestrial abundances of these isotopes are given in Table 1 (1).

The abundances of these isotopes in the hydrosphere, biosphere, and lithosphere and in different stages of the water cycle vary slightly from these figures.

Considering the six isotopes of hydrogen and oxygen, 18 combinations of H–O–H or "18 varieties of water" are possible (2,3). These and their respective molecular weights are shown in Table 2.

Table 1. Average (%) Terrestrial Abundances of Hydrogen and Oxygen Isotopes[a]

^{1}H (Proteum - stable)	99.985	^{16}O (stable)	99.762
^{2}H (Deuterium - stable)	0.015	^{17}O (stable)	0.038
^{3}H (Tritium -radioactive[b])	$< 10^{-14}$[c]	^{18}O (stable)	0.200

[a] Reference 1.
[b] $t_{1/2} = 12.3$ years
[c] Some references give 10^{-14}–10^{-16}.

Of the above eighteen varieties of waters, $^{1}H_2{}^{16}O$ has a mass of 18 and is the most common; it is generally known as "water" or sometime called ordinary or light water. Deuterium oxide ($D_2{}^{16}O$) has a mass of 20 and is known as "heavy water." Some references use the term "semiheavy water" for $HD^{16}O$. Washburn and Urey (4) were the first to enrich deuterium oxide in water in 1932. Some of the 18 varieties of water are extremely rare. An interesting, though trivial, point is that the molecular weight of the most common form of water $^{1}H_2{}^{16}O$ (18), equals the number of different varieties of water, 18.

CHARACTERISTICS OF HEAVY WATER

The physicochemical properties of heavy water and deuterium are compared with those of water and hydrogen in Table 3.

The extent of dissociation of heavy water is about half that of ordinary water:

$$D_2O \rightarrow D^+ + OD^-$$

and

$$H_2O \rightarrow H^+ + OH^-$$

Table 2. Eighteen Varieties of Water and Their Respective Masses

$H_2{}^{16}O$	18	$D_2{}^{16}O$	20	$T_2{}^{16}O$	22	$HD^{16}O$	19	$HT^{16}O$	20	$DT^{16}O$	21
$H_2{}^{17}O$	19	$D_2{}^{17}O$	21	$T_2{}^{17}O$	23	$HD^{17}O$	20	$HT^{17}O$	21	$DT^{17}O$	22
$H_2{}^{18}O$	20	$D_2{}^{18}O$	22	$T_2{}^{18}O$	24	$HD^{18}O$	21	$HT^{18}O$	22	$DT^{18}O$	23

Table 3. Physicochemical Properties of Heavy Water, Water, Deuterium, and Hydrogen[a]

Characteristics	Heavy water	Water	Deuterium	Hydrogen
Density at 25 °C (g/ml)	1.1045	0.99707		0.0899
Boiling point, °C	101.42	100	−249.55	−252.77
Freezing point, °C	3.8	0	−254.5	−259.2
Molecular volume at 20 °C	18.092	18.016		
Viscosity, poise at 20 °C	12.6	10.09

Critical pressure, atm			16.432	12.807
Evaporational enthalpy, kJ/mol	46.5	40.7		
Dielectric constant	78.25[b]	78.54[b]	1.277[c]	1.228[c]
Ionization potential, eV	12.6	12.6	15.46	15.427
Bond length at 298 K, Å	104.45	0.958 angle	0.7416	0.7461
Bond strength kJ/mol	—	Diatomic	443.546	436.002

[a] References 5–7. Note that in many references, the boiling and freezing points of H_2 and D_2 are given in K.
[b] At 20°K.
[c] At 25 °C.

This means that a bond to deuterium breaks 18 times more slowly than the same bond to hydrogen (6). This is the reason that the vapor pressure of heavy water is lower than that of ordinary water.

The amazing behavior of heavy water is its inertness in normal metabolic processes. For example, rats will die of thirst if given heavy water exclusively, and plants will not grow in pure heavy water (8). Experiments with mice showed that heavy water, due to a slightly different reaction rate compared to ordinary water, inhibits mitosis and causes progressive damage of tissues that need rapid regeneration. Human drinking of up to 25% heavy water is not harmful, but the main problem is consequent lack of enough ordinary water in the body. After several days of ingesting only heavy water, the body fluids contain about 50% heavy water, and at this point symptoms begin due to the decrease in cell division rates of rapidly dividing tissues, such as hair roots and stomach linings. Drinking heavy water may lead to the remission of aggressive cancer cell, but the, effect predicted is not great enough to make this a useful therapy (URL Ref. http://en2.wikipedia.org/wiki/Heavy_water#Toxicity).

In slight contrast to these publications, Kushner et al. (9) report that, so long as it has not been used in nuclear reactors, D_2O itself poses little risk to the environment because:

1. D_2O itself is not toxic to animals, except under exceptional and very improbable circumstances;
2. D_2O is nonradioactive; and
3. The amount of the ^3H, found in heavy water is very low, <6 kBq/kg D_2O (<0.15 μCi/kg D_2O), barely above background levels.

More information on the biological aspects of heavy water may be found in Katz (10). Dahl (11) provides good coverage of many aspects of heavy water, including discovery, uses, production techniques, its relationship to developments in nuclear physics and chemistry, social history, and a chronology of events relating to heavy water.

APPLICATIONS OF HEAVY WATER

Heavy water is used (1) as a neutron moderator, (2) to detect neutrinos, and (3) in the biology/biotechnology field. Biotechnological applications of heavy water are in the early stages of research and have not yet received widespread attention.

Neutron Moderator

The poem from James Young, prefacing this article, is directed toward this application of heavy water, its use in nuclear reactors. In nuclear reactors, an important factor in producing a chain reaction in uranium is the energy distribution of neutrons, which peaks near 1 MeV. To reduce the neutrons energies from 1 MeV to thermal energies (so they can react with the uranium in the reactor) would require at least 2000 collisions (with something else). The most common materials used to slow down neutron energy are heavy water and graphite (12). A huge nuclear reactor that uses heavy water as a moderator is CANDU in Canada (Fig. 1). The advantage of heavy water is that it has a low probability of absorbing neutrons. Ordinary water also acts as a moderator but because light water absorbs neutrons, reactors using light water must use enriched uranium rather than natural uranium; otherwise criticality is impossible. A nation that has a sufficiently powerful heavy water reactor can use it to turn uranium into bomb-usable plutonium, entirely bypassing uranium enrichment and all of the related technological infrastructure. Heavy water reactors have been used for this purpose by India, Israel, Pakistan, and North Korea. Due to its usefulness in nuclear

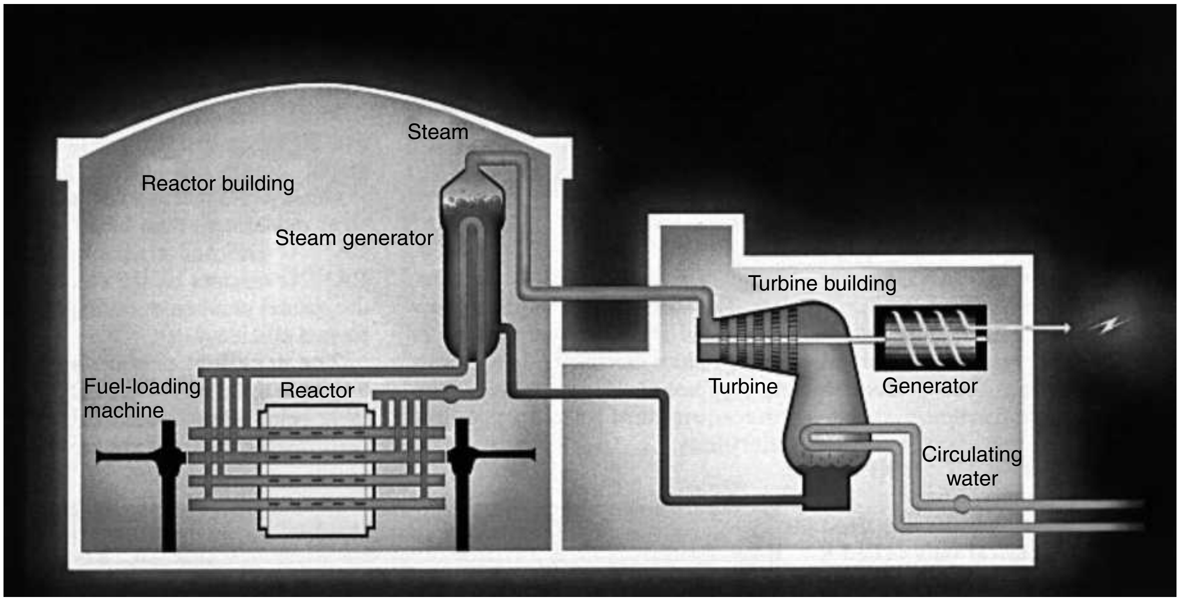

Figure 1. The layout of the CANDU heavy water reactor in Canada (URL Ref http://www.nucleartourist.com/type/candu.htm).

weapons programs, heavy water is subject to government control in several countries. In addition, heavy-water-moderated reactors can be used to make tritium (URL Ref. http://www.fas.org/nuke/intro/nuke/heavy.htm).

Neutrino Detector

The neutrino, discovered in 1956, is an elementary particle that has no charge, zero rest mass and travels at the speed of light (13). The detection of this particle is a difficult and complicated task. The Sudbury Neutrino Observatory (SNO), near Sudbury, Ontario, is a heavy-water Cherenkov detector that is designed to detect neutrinos produced by fusion reactions in the Sun. It is located 6800 feet underground in an old mine (to shield it from cosmic rays) and uses 1000 tonnes of heavy water on loan from Atomic Energy of Canada Limited (AECL), contained in a 12-meter diameter acrylic vessel. Neutrinos react with heavy water (D_2O) to produce flashes of light called Cherenkov radiation. This light is then detected by an array of 9600 photomultiplier tubes mounted on a snoball surrounding the heavy water vessel. The detector laboratory is extremely clean to reduce background signals from radioactive elements present in the mine dust which would otherwise hide the very weak signal from neutrinos (http://sps.la.asu.edu/~steve/paper/sno/node6.html).

Biological and Biotechnological Applications of Heavy Water

Kushner et al. (9) describe the potentially extensive use of heavy water and deuterated compounds in biotechnological applications. They report as follows:

1. Many microorganisms can grow in "pure" (99.6–99.8%) D_2O; usually, after a period of adaptation, they can produce a very large number of deuterated compounds that have many applications in optical technology, in deuterated drugs and fibers, etc.
2. Deuterated glycerol has interesting potential uses as a precursor of transparent plastics and other compounds and can be formed by *Dunaliella* spp, a salt-tolerant alga that grows in D_2O.
3. Heavy water has some direct therapeutic uses in both animals and humans. Nontoxic levels of heavy water, for instance, reduce induced hypertension and associated changes in rats.
4. Heavy water has been widely used in measuring body water space in children and in adults at various stages of nutrition and exercise.
5. Applications of deuterium in environmental studies are numerous. (These are dealt with in the Deuterium article.)

PRODUCTION OF HEAVY WATER

Heavy water occurs naturally in limited, yet precisely unknown, quantities. Production of heavy water includes separating these limited quantities (not actually making them) from other ordinary water molecules. In the hydrosphere, one in every 6700 molecules of water contains deuterium in its composition. If ^{16}O is the other atom of all of these "one in 6700" molecules, then the ratio of heavy water/water in the hydrosphere is 1/6700. This ratio, though most likely realistic, may be smaller because some of the oxygen atoms in water molecules that contain deuterium are ^{17}O and ^{18}O. In other words, not all deuterium isotopes join with ^{16}O to form heavy water; some are combined with ^{17}O and ^{18}O to form other varieties of water depicted in Table 2.

The discovery of deuterium in 1932 by Urey and his colleagues (14), may be considered the onset of the artificial production of heavy water. However, Gilreath (15, p. 61) in this regards, writes, "In 1933, G. N. Lewis and his collaborators at the University of California succeeded, by the continuous electrolysis of a very large amount of water obtained from an old commercial electrolytic cell, in preparing about 0.1 cc of water which contained practically only deuterium atoms of mass 2. The specific gravity of this water was about 10% greater than that of ordinary water which was in accordance with the molecular weight of D_2O." This paragraph may indicate that the *first drop* of heavy water was produced in 1933.

There are a few methods for artificially enriching the deuterium content of ordinary water and, thus, producing heavy water. These include distillation, electrolysis, and chemical exchange.

Distillation

The foundation of this method is based on the difference between the vapor pressures and boiling points of H and D. This was the principle used by Urey to discover deuterium. The most efficient process for enriching heavy water by this method uses a fractionating column in a continuous process, in which an upward-directed stream of vapor is kept in contact with a downward-directed stream of liquid; the two streams constantly exchange molecules. The molecules of H_2O have a relatively greater tendency to enter the vapor stream, and the molecules of D_2O enter the liquid (15). In 1943, the first plant based on distillation was built to produce heavy water for use as a moderator in nuclear reactors. However, the plant operated for less than a year only because (1) it was found that the chemical exchange method is more efficient and (2) it was learned that graphite is superior to D_2O as a moderator (15).

Electrolysis

The principle of this method, a common method for laboratory scale production of heavy water and described in many chemistry textbooks, is simple. Passage of an electric current through water leads to splitting water into hydrogen and oxygen. The deuterium atoms move more slowly because they are heavier and, so, it is possible to separate them. Finally, the resulting deuterium is reacted with oxygen to form heavy water. The electrolytic technique consists of up to seven stages, depending on the purity of heavy water required; the higher the purity of the required heavy water, the greater the number of stages of the process. This technique takes a vast amount of electrical energy. In a typical experiment, 2400 liters of ordinary water produce 83 ml of D_2O that is 99% pure (6).

Chemical Exchange

Minute differences between chemical properties and the reaction rates of hydrogen and deuterium form the foundation of this method. In this process, water flows from the top of a tower that contains a catalyst, downward to meet a mixture of steam and hydrogen moving upward. The catalyst promotes a rapid isotopic exchange reaction between the hydrogen and the water molecules in the steam; hence, there is a concentration of deuterium in the steam in the form of heavy water molecules. The flow of water from the top of tower causes condensation of the steam and, consequently, enrichment of deuterium in the outflow from the bottom of the tower. The outflow is then electrolyzed to increase its deuterium content and it is, then, repeatedly reprocessed in the system to achieve a high concentration of D_2O (15). The refined/advanced version of this method is now known as the Girdler Sulfide process (9—see the following section about the Bruce Heavy Water Plant for more information about this method).

WORLDWIDE PRODUCTION OF HEAVY WATER (THE FOLLOWING INFORMATION HAS BEEN GATHERED FROM WEB SITES)

As can be inferred from the previous explanations, a huge technical infrastructure is required to produce heavy water, and, thus, only a few countries such as Argentina, Canada, India, and Norway have the capacity to produce significant amounts.

The first commercial heavy water plant was the Norsk Hydro facility in Norway (built in 1934, capacity 12 metric tons per year); this is the plant which was attacked by the Allies to deny heavy water to Germany during World War II.

India is the world's second largest producer of heavy water through its Heavy Water Board of the Department of Energy (URL Ref: http://www.heavywaterboard.org), but accidents and shutdowns may have led to limitations on its production rate.

The Bruce Heavy Water Plant in Ontario, Canada (Fig. 2), built in 1979, has a capacity of 700 metric tons/year; it is the world's largest producer of D^2O (1979; 700 metric tons/year). It uses the Girdler Sulfide (GS) process which incorporates a double cascade in each step. In the upper ("cold," 30–40 °C) section, deuterium from hydrogen sulfide preferentially migrates into water. In the lower ("hot," 120–140 °C) section, deuterium preferentially migrates from water into hydrogen sulfide. An appropriate cascade arrangement actually accomplishes enrichment. In the first stage, the gas is enriched from 0.015% deuterium to 0.07%. The second column enriches this to 0.35%, and the third column achieves an enrichment between 10% and 30% deuterium. This product is sent to a distillation unit for finishing to 99.75% "reactor-grade" heavy water. Only about one-fifth of the deuterium in the plant feed water becomes heavy water product. The production of a single pound of heavy water requires 340,000 pounds of feed water. Heavy water produced by Bruce is used in CANDU reactors.

Figure 2. Bruce Heavy Water Plant in Ontario, Canada (Toronto Star, Online Edition, Dec. 2, 2003).

The Bruce Power Plant, which presently operates in the shutdown mode, was going to be decommissioned a few years ago, but its license was renewed in 2002 for 2 more years (Nuclear Energy Overview, 4 November 2002 cited in World Nuclear Association, WNA, News Briefing 02.45, 30 Oct to 5 Nov. 2002). The latest news headline about Bruce Power Plant, appeared in Toronto Star online edition, Dec. 2, 2003:

"Safety commission finds 'serious event' at Bruce

A defect in the backup shutdown system of a reactor at the Bruce B nuclear generating station went undetected for more than 3 weeks in December, according to a newly released report by the Canadian Nuclear Safety Commission."

There are a few website publications which claim that some countries, Iran, for example, are pursuing plans for heavy water reactors. One such report is that by J. Boureston and C. Mahaffey from Janes International Security which can be found at: http://www.janes.com/security/international_security/news/jir/jir031114_1_n.shtml. There are also locality maps of various heavy water reactors and production plants, photographs, statistics, and many other heavy-water-related publications available at various websites. A useful site is that of the Heavy Water Board of India at http://www.heavywaterboard.org.

HENRY'S LAW

ROGER C. VIADERO JR.
West Virginia University
Morgantown, West Virginia

OVERVIEW AND THEORY

William Henry (1774–1836) established the fundamental relationship to define the partitioning of a soluble (or partially soluble) chemical species between gas and liquid phases, at equilibrium, in a dilute aqueous solution. For the transfer of a chemical species, *C*, from the gas phase to the aqueous phase, presented schematically in Fig. 1, the following chemical reaction and dimensionless equilibrium constant, *k*, can be written for a dilute solution:

$$C_g \xleftrightarrow{k} C_{aq} \tag{1}$$

$$k = \frac{[C_{aq}]}{[C_g]} \tag{2}$$

where $[C_g]$ = gas phase concentration (mol/L) of *C* and $[C_{aq}]$ = aqueous phase concentration (mol/L) of *C*.

Upon recognizing that the molar concentration of a gas is related to the partial pressure of that gas via the ideal gas law presented in Eq. 3, the expression for the dimensionless equilibrium constant can be rewritten as in Eq. 4:

$$C_g = \frac{n}{V} = \frac{p_g}{RT} \tag{3}$$

$$k = \frac{[C_{aq}]}{[C_g]} = \frac{[C_{aq}],}{\dfrac{p_g}{RT}} \tag{4}$$

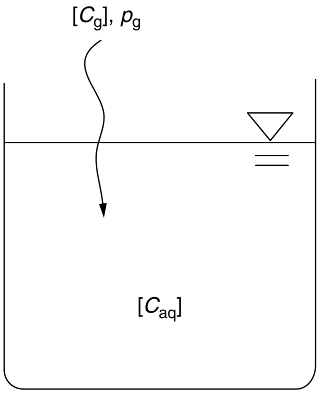

Figure 1. Transfer of chemical species *C* from the gas phase to the aqueous phase.

where n = number of moles of *C*, V = volume occupied by the gas (L), p_g = partial pressure of the gas (atm), R = ideal gas constant (0.082057 atm/L/K/mol) and T = temperature of the gas (K). By rearranging the relationship presented in Eq. 4, a familiar form of Henry's law is realized:

$$C_{aq} = k_H p_g \tag{5}$$

where k_H = Henry's law constant (mol/L/atm). The dimensionless equilibrium constants, *k*, and k_H, are related according to Eq. 6:

$$k_H = \frac{k}{RT} \tag{6}$$

Values of k_H for representative inorganic chemical species are presented in Table 1 (1,2). There are such a large number of volatile or semivolatile organic chemicals of environmental importance; readers are referred to the following representative supporting literature for detailed enumerations of Henry's law constants for organic species (3–10).

When using tabulated values of Henry's law constants or dimensionless equilibrium constants, care must be taken to examine the direction of transport being considered because the direction of reaction affects the units of k_H. For example, if the development of k_H presented above were reformulated for volatilization of *C* (from the aqueous to the gas phase), values of k_H would have units of atm L/mol and would thus be the inverse of the case developed above. The inconsistency encountered in the units of k_H is due partially to the

Table 1. k_H Values for Representative Inorganic Chemical Species[a]

Reaction	k_H (mol/L/atm)[b]
$CO(g) \leftrightarrow CO(aq)$	9.55×10^{-4}
$SO_2(g) \leftrightarrow SO_2\ (aq)$	1.23
$NH_3(g) \leftrightarrow NH_3\ (aq)$	57.5
$NO_2(g) \leftrightarrow NO_2\ (aq)$	1.00×10^{-2}
$O_3(g) \leftrightarrow O_3(aq)$	9.33×10^{-3}

difference in conventions used by engineers and chemists and general lack of consensus with regard to a standard for the direction of transport (1,11).

LIMITATIONS OF HENRY's LAW

Three main limitations must be considered when applying Henry's law: (1) the state of equilibrium, (2) the solute concentration, and (3) the veracity of using standard data for calculations in contaminated water systems. The application of Henry's law is limited to cases where chemical equilibrium has been reached in a dilute solution ($<1\%$ solute concentration). However, the concentrations of most water constituents are normally less than 1%, so the application of Henry's law is typically valid. Tabulated values of k_H are generally based on experiments using pure water. As a result, the application of such data to contaminated water systems can yield unpredictable results (1). Under such circumstances, experiments may be needed to determine the appropriate value of k_H for the contaminated solution. Similar care should be taken when working with solvent systems other than water (e.g., when determining the solubility of a gas in an organic solvent).

APPLICATION OF HENRY'S LAW

By evaluating the relative magnitude of k_H for particular species, it is possible to learn about the solubility and general tendency of those species to partition between water and air. For instance, in the transport of a soluble chemical species from the gas phase to the aqueous phase, a compound that has a high k_H would be more soluble than one that has a lower k_H and would partition into the water phase where it may be transported downgradient or adsorb onto solid surfaces. In contrast, a species that has a low k_H would be less water soluble and tend to remain in the gas phase.

The surface of the earth is dominated by an air/water interface, so the interaction between gas and aqueous phase chemicals is extremely important in understanding the origins, fate, and transport of water and dissolved contaminants through the hydrogeochemical cycle.

Consider a sample of pure water which is completely isolated from the atmosphere. At standard conditions, the pH of the water would be neutral (pH = 7). However, when the pure water is allowed to reach equilibrium with an atmosphere containing $CO_2(g)$, the following series of reactions occurs:

$$CO_2(g) \xleftrightarrow{k_H} CO_2(aq) \tag{7a}$$

$$CO_2(g) + H_2O \xleftrightarrow{k'_1} \Leftrightarrow H_2CO_3{}^* \tag{7b}$$

$$H_2CO_3{}^* \xleftrightarrow{k_1} H^+ + HCO_3{}^- \tag{7c}$$

$$HCO_3{}^- \xleftrightarrow{k_2} H^+ + CO_3{}^{2-} \tag{7d}$$

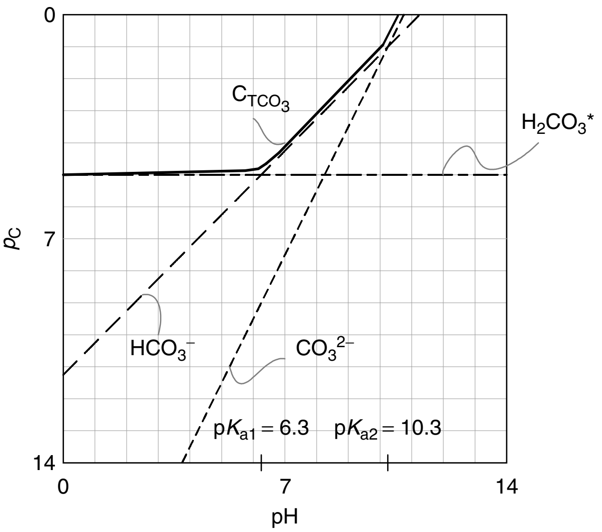

Figure 2. Plot of p_C versus pH for an aqueous system in equilibrium with atmospheric $CO_2(g)$ at standard conditions.

At standard conditions, the partial pressure of $CO_2(g)$ is 3.162×10^{-4} atm (12). $CO_2(aq)$ and carbonic acid, H_2CO_3, act as weak acids and the equilibrium pH of the water is ~5.6. In this case, the atmosphere serves as a constant source of CO_2, and the total concentration of carbonate species increases with pH as presented in Fig. 2, where

$$C_{T_{CO_3}} = [H_2CO_3{}^*] + [HCO_3^-] + [CO_3^{2-}] \tag{8}$$

Further, any change in the partial pressure of CO_2 would result in a corresponding shift in the equilibrium pH. Failure to account for the presence and effects of $CO_2(g)$ on the pH would result in an entirely incorrect interpretation of acid–base chemistry which would then adversely impact conclusions drawn relative to environmentally important chemical reactions (e.g., precipitation/dissolution reactions, complexation reactions, and oxidation/reduction reactions).

During the 1880s and 1890s, Franz Hofmeister (Professor of Pharmacology at the Charles University in Prague) and some of his coworkers demonstrated that salts with common cation (positive ion) but differing in anion (negative ion) have different effectiveness in stabilizing protein suspensions (1,2). They can be arranged in a sequence that seemed later to be universal. Reference (2) includes an English translation of two of Hofmeister's papers. As can be seen in Fig. 1, depending on the choice of salt, different concentrations are required to precipitate a certain concentration of proteins from whole egg white (3). Hofmeister effects, or Hofmeister sequences, refer to the relative effectiveness of anions or cations on a wide range of phenomena. They have remained unexplained by theories of physical chemistry until recently. But, as we will discuss later, some encouraging steps have recently been taken toward resolving the problem. Understanding Hofmeister effects is essential in understanding how different salt ions in water influence solution chemistry and are critical to biological processes that are ubiquitous.

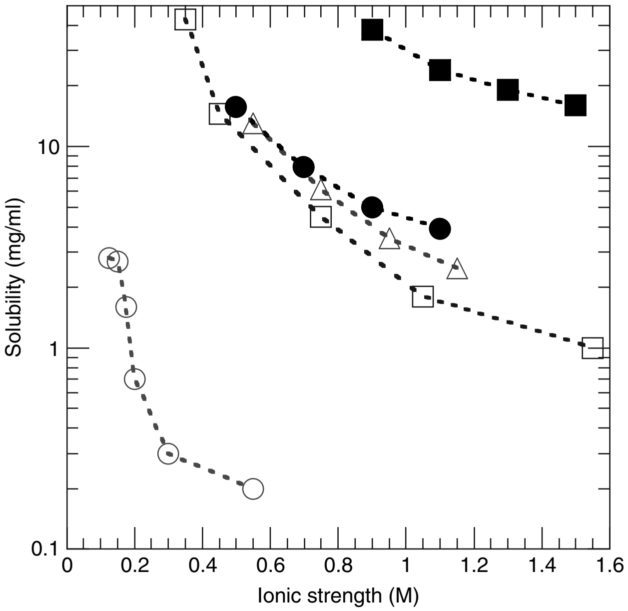

Figure 1. Variation, as a function of salt type, of hen-egg-white protein (lysozyme) solubility. Depending on the choice of salt, different concentrations are required to precipitate a certain concentration of proteins from whole egg white. Data taken from Ref. 3 are shown for NH_4OAC (filled squares), NH_4Cl (filled circles), KCl (open triangle), NaCl (open square), and KSCN (open circle).

Hofmeister effects have been observed in an enormous number of systems: solubility of salts; solubility of oxygen; surface tension of salt solutions (4); pH measurements (5); buffers; ion binding to micelles, proteins (6), and membranes; conformational changes of rhodopsin (membrane bound protein acting as light receptor) (7); transport across human red blood cells (8); molecular forces (9,10); and colloid stability. Another example is the cutting efficiency of DNA in buffered salt solutions that not only follows a Hofmeister series: A change in supposedly irrelevant choice of buffer has the ability to reverse the Hofmeister series (11). A corresponding change in buffer has recently been demonstrated to reverse, in the same way, the Hofmeister series in pH measurements. Even bacterial cell growth follows the Hofmeister series (12).

Understanding Hofmeister effects is especially important for biological and medical applications. Although many biochemical functions require specific ions at certain concentrations, too high concentrations of, for example, NaCl can have deleterious effects on enzymatic activities (13,14). One important biological example is the human red blood cell that is sensitive to salt. During gas exchange, involved in buffering of blood and in O_2 and CO_2 transport in blood, the chloride ion moves between the plasma and the red blood cell intracellular fluid (15). It is well known experimentally that transport of Cl^-, Na^+, K^+, and water molecules through the cell membrane, and the corresponding cell volume changes, depend strongly on the choice of background anions (8). The rate constant for chloride exchange is, e.g., lowered to 6.5% of its original value when 120 mM of the chloride ions are replaced with thiocyanate ions. The interactions of ions with cell membranes and with membrane bound proteins (hemoglobin) determine key regulatory mechanisms. Taboy et al. (16), investigating hemoglobin, found a larger redox potential in the presence of NO_3^- than in a Cl^- salt solution (with a maximum redox potential around a salt concentration of 0.2 M). This finding is interesting because it demonstrates that different anions have a different affinity for hemoglobin and may provide useful insights as to why the affinity of chloride ions is larger for deoxyhemoglobin than for oxyhemoglobin (17). This finding has important biological consequences, but the reasons have not been clear. Even though it is a different story, it is worth noticing that the difference between two typical Hofmeister anions, thiocyanate and chloride, has also been exploited in detoxification of anticancer agents (18).

These systematic Hofmeister series demonstrate that common underlying interactions are involved, which is encouraging and strongly suggests that general and truly predictive theories may not be far away. Clearly experiments and theory that explain these effects are valuable and can provide insights into the underlying mechanisms that control vital biological systems. Having explained why it is important to understand Hofmeister effects, we now proceed to discuss some recent theoretical attempts to understand it.

The traditional hand waving “explanation” for the Hofmeister effects has been that the ions exert their effects indirectly by changing the water structure. People have used words such as: “hard and soft ions,” “hydrophobic and hydrophilic ions,” “lyotropic series,” “chaotropic and cosmotropic ions,” “salting-in,” and “salting-out.” When words like these and simple theories have proven insufficient to accommodate experimental results, a large number of additional effects and interactions have been invoked (accompanied by numerous adjustable fitting parameters). Although “understanding” of experiments has occasionally been claimed, there has been no predictability.

Until recently, the theories used were mainly based on electrostatic interactions between charged particles. These theories failed to explain why a change from one monovalent salt to another (i.e., salts with the same charges) can have huge effects. The main attempts to explain Hofmeister phenomena involved extension of theory to allow different “hydrated ion sizes,” parameters that vary from one situation to another. However, such attempts do not work and Hofmeister series do not correlate directly with any additional physical or chemical parameter. The problem is that there must be a coupling, or cooperative effects, which are not so easy to characterize. An understanding has only recently emerged that the polarizability of ions, neglected in previous theories, plays an essential role. Polarizability is a quantity that measures the response of a particle to a perturbing electromagnetic field. Although two charged particles can interact via electrostatic forces, a quantum mechanical attraction also exists, the van der Waals force, between two charged neutral particles that is related to the polarizabilities of the two particles. This van der Waals force is also present for the interaction between charged particles but has usually been assumed to be negligibly small compared with the electrostatic force. Although electrostatic forces often dominate at low salt concentrations, van der Waal forces become important at high salt concentrations where the electrostatic forces are screened. Ninham et al. (19) demonstrated that van der Waals forces between ion and interface often dominate over electrostatic forces above and around the salt concentration we have in our blood (i.e., 0.15 molar salt), which is exactly the concentration regime where Hofmeister effects are observed. As can be seen in Fig. 2, ion-specific bubble fusion is, for instance, inhibited, following an abrupt transition with increased salt concentration, in sodium chloride solutions above the salt concentration we have in our blood (20). This is why ocean water is foamy, but fresh water is not. Today the salt concentration of the ocean is around 0.6 M, but the concentration in the Permian Sea was close to what we have in our blood, which means that even a small decrease in salt concentration would have had dramatic effects on bubble fusion. To have a sufficiently high salt concentration in the Permian Sea must have been a critical condition when early life emerged. A related topic is that the local salt concentration, e.g., in the Baltic Sea, may have dropped suddenly below the critical 0.15 M concentration after ice melted at the end of ice ages. A speculation on how this may have caused mass extinction of plankton can be found in the references (1).

At present, two parallel and complementary lines of work demonstrate that both surface effects and bulk effects are important for the understanding of Hofmeister effects. We will first briefly discuss surface related effects. The theoretical papers by Boström et al. have focused on surface phenomena, i.e., the van der Waals interaction between ions and interface. Boström et al. (21) demonstrated, e.g., that this is one important reason why the charge of lysozyme (hen-egg-white protein) at pH = 4.5 is higher in 0.1 M NaSCN than in 0.1 M NaCl. The negatively charged thiocyanate anions (SCN^-) are more attracted toward the protein, by larger van der Waals forces, than are the chloride ions. A higher local

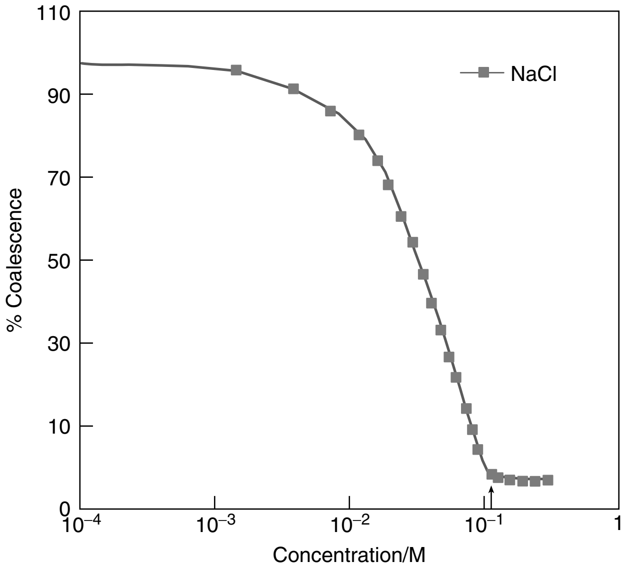

Figure 2. Effect of NaCl on bubble coalescence. The arrow indicates the concentration of NaCl in the extracellular fluid of humans. Bubble fusion is ion specific, and remarkably, with some salts, such as NaOAc, essentially no transition occurs as more salt is added to the solution. Data taken from Craig et al. (20).

anion concentration with SCN^- ions near the protein surface gives rise to a larger local concentration of hydronium ions (H_3O^+) at the protein surface, which in turn leads to more hydrogen ions being bound to the protein charge groups (i.e., a larger protein charge) in a thiocyanate (or iodide) salt compared with a chloride salt. Recent extension by Boström et al. of this theoretical work (investigating theoretically solutions with different buffers and proteins) has demonstrated that this also influences the ion-specific buffer capacity of a lysozyme solution at typical protein concentrations. Remarkably, in as far as both pH in solution and charge of hen-egg-white protein is concerned, one can often to a good approximation replace a certain concentration of NaCl with a smaller concentration of NaSCN and find the same final result. A similar result has been observed in experiments on enzymatic activity by P. Baudin et al. and in pH measurements in protein (cytochrome c) solutions by P. Baglioni et al. This kind of surface related effects has also offered a partial explanation (22) for the experimental observation by Bonneté et al. (6) that the interaction between two lysozyme proteins in salt solutions follows a Hofmeister series (the interaction is, e.g., more attractive in $NaNO_3$ solutions than in NaCl solutions).

The other line of work has focused on interactions in the bulk solution between ions and between ion and water molecules. It is important to stress that van der Waals forces are only one consequence of the ion polarizability. Other consequences are dipole-induced dipole and induced dipole-induced dipole forces between ions and between ions and water molecules. These forces have been in focus in molecular simulations. It has been repeatedly demonstrated that the static polarizability of ions must be included in computer molecular simulations to get reasonable results for the solvation energy of ions in water (23,24). This, however, is not the entire story. To get correct results for the activity coefficients (25) and solvation energies (26) of ions in water, strong evidence exists that one has to include the entire dynamic ionic polarizability. In several important contributions (27–29), attempts have been made to include forces that originate from the static polarizability correctly in computer simulations that include water molecules. These ion–ion and ion–water interactions are also important for the air–water interface. The air–water interface, and the surface tension of salt solutions, is more complicated than one might initially have guessed and not yet fully understood. Promising simulations (28) seem to give the right trend in Hofmeister sequence for the surface tension change with added salt. But these simulations give results that differ greatly from experimental surface tension changes with added salt. This is also true for pure water where simulations without fitting parameters give incorrect results for the surface tension and freezing temperature. One reason for these problems must be that simulations so far have not included many body dispersion forces properly. But simulations together with experiments are still useful tools for further understanding. As demonstrated by Jungwirth and Tobias (28), some highly polarizable anions, such as bromide, may, contrary to conventional wisdom (which is based on electrostatic theories), go to the air–water interface. It has also been demonstrated that one important effect is that the water molecules near an air–water interface are not isotropically ordered (28), which effectively gives an anisotropic film near the interface that strongly influences the interaction between ions and the air–water interface. These interactions (ion–ion, ion–water molecule, ion interface) influence each other in a self-consistent manner, which makes this a complicated but solvable problem. It is clearly important to take into account all of the complementary aspects discussed here for further progress. Our most recent results suggest a key role for interfacial dissolved gases, and the corresponding change in ion solvation energy, behind the observed surface tension changes (see article on Dissolved Gases). Theories, accompanied by refined simulations and experiments, are on the way that may substantially improve the understanding of the Hofmeister effect in the near future. It is also worth remarking that until now no theoretical work has included the effect of dissolved gasses properly. These gases are known to influence colloid interactions (30), bubble–bubble interaction (20), conductance, pH, and most likely the surface tension of salt solutions. It is not only CO_2 that is important but also other dissolved gasses. The interested reader can find more details about Hofmeister effects in different reviews (1,31–34).

CLATHRATE HYDRATES

Carolyn Ann Koh
E. Dendy Sloan
Colorado School of Mines
Golden, Colorado

DEFINITION OF CLATHRATE HYDRATES

Clathrate hydrates are crystalline inclusion compounds consisting of a network of polyhedral water cages (host), which enclathrate small hydrophobic molecules (guests; typically <0.9 nm). Clathrate hydrates can be described as solid solutions (1), such that the empty hydrate lattice is unstable with respect to ice. When guest molecules occupy the water cages, the hydrate lattice is stabilized by van der Waals interaction forces. Typically, a water cage has a maximum occupancy of one guest molecule.

Simple clathrate hydrates contain only one type of guest molecule within the hydrate lattice, while *binary clathrate hydrates* contain two different types of guest molecules. *Mixed clathrate hydrates* refer to hydrates containing two or more different guest species. When the guest species are gas molecules, such as methane, ethane, or carbon dioxide, clathrate hydrates are also called *gas hydrates*. It is not necessary for all the cages in these clathrate hydrate structures to be occupied; for example, methane hydrate can be prepared with 90% of the cages occupied by methane (2). The cage filling depends on pressure, temperature, and the nature of the guest species. Hence, these structures are often referred to as "nonstoichiometric compounds."

COMMON CLATHRATE HYDRATE STRUCTURES

The three most common types of clathrate hydrate structures are sI, sII, and sH hydrate. sI hydrate predominates in natural environments, while sII hydrate is found mainly in artificial environments (3). sH hydrate may occur in either environment but is less common than either sI or sII hydrate. These three structures have distinct crystallographic properties (see Table 1 and References 2 and 4 for further details). Both sI and sII hydrates have cubic crystal structures (Fig. 1), while sH hydrate has a hexagonal crystal structure. sI and sII hydrates contain two different types of water cages (Fig. 2). The water cages are described by the general notation X^n, where X is the number of sides of a cage face and n is the number of cage faces having these X sides. For example, the pentagonal dodecahedral 5^{12} water cage is composed of 12 *five*-membered water rings. A unit cell of sI hydrate contains two small (5^{12}) + six large tetracaidecahedral ($5^{12}6^2$) cages. A unit cell of sII hydrate contains six small (5^{12}) + eight large hexacaidecahedral ($5^{12}6^4$) cages (sII). A unit cell of sH hydrate is comprised of three types of water cages: three small (5^{12}) cages, two irregular dodecahedral ($4^35^66^3$) cages, and a single large icosahedral ($5^{12}6^8$) cage (Fig. 2).

The type of clathrate hydrate structure that forms depends on the size of the guest molecule; for example, CH_4 and CO_2 both form sI hydrate; C_3H_8 and C_4H_8O (tetrahydrofuran, THF) form sII hydrate; while a larger guest molecule such as methylcyclohexane in the presence of methane forms sH hydrate (2,4). Table 2 illustrates the range of different guest molecules that form sI, sII,

Table 1. Crystallographic Properties of the Common Clathrate Hydrate Structures

Property	sI	sII	sH
Space group	*Pm*3*n*	*Fd*3*m*	*P*6/*mmm*
Unit cell parameters (nm)	$a = 1.20$	$a = 1.70$	$a = 1.21$, $c = 1.01$
Average cavity radius (nm) [number of cavities per unit cell (cavity type)]	0.395[2(5^{12})](S) 0.433[6($5^{12}6^2$)](L)	0.391[16(5^{12})](S) 0.473[8($5^{12}6^4$)](L)	0.391[3(5^{12})](S) 0.406[2($4^35^66^3$)](S) 0.571[1($5^{12}6^8$)](L)
Symmetry of cages	$M\underline{3}$(S), $\underline{4}2m$(L)	3m (S), $\underline{4}3m$ (L)	Mmm(S), $\underline{6}m2$(S), 6/mmm(L)
Ratio of numbers of small/large cavities	0.33	2	5
Number of water molecules per unit cell	46	136	34
General unit cell formula	$X \cdot 5.75H_2O$	$X \cdot 17H_2O$	$5(X,Y) \cdot 34H_2O$

L, large cage; S, small cage; X,Y, guest molecules.

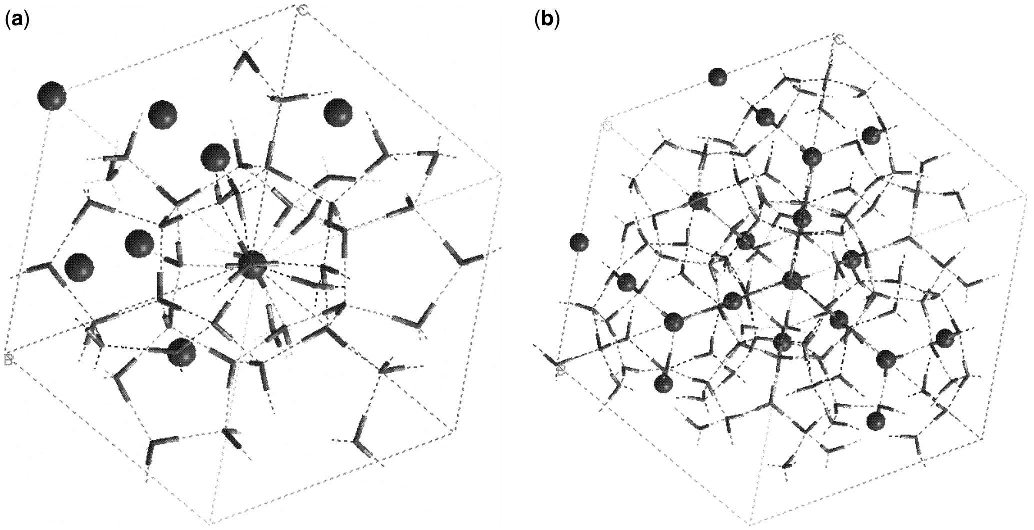

Figure 1. The partial unit cell structures of (**a**) sI hydrate and (**b**) sII hydrate. Dotted lines represent hydrogen bonds between water molecules. Spheres represent guest molecules.

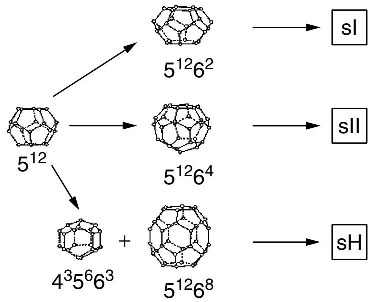

Figure 2. Water cages of sI, sII, and sH hydrates.

and sH hydrates. Typically, high pressure (3–11 MPa) and low temperature (275–285°K) conditions are required to stabilize gas hydrate systems. Table 2 gives the dissociation pressures of different clathrate hydrates and the occupancy of the corresponding hydrate guest molecules at around 277°K (the temperature at which most natural and industrial hydrates are found). Clathrate hydrates will be stable at 277°K and at a pressure above the dissociation pressure. Although CH_4 and C_2H_6 are both sI hydrate formers, a binary CH_4/C_2H_6 mixture can exhibit sI/sII transitions with varying pressure and/or composition. In contrast, a binary CH_4/CO_2 mixture (where both pure components are sI hydrate formers) forms only sI hydrate (Table 2).

NOVEL CLATHRATE HYDRATE STRUCTURES

Between the time that clathrate hydrates were first discovered in 1810 (6) and upto 1996, only three main structures were identified. Yet, within the last eight years (1997–2004), there have been a number of exciting reports of new clathrate hydrate structures. In addition to the discovery of multiple occupancies of the hydrate water cages, at least three new clathrate hydrate structures have been discovered. Some of these new structures are discussed next.

As mentioned earlier, typically only one guest molecule is accommodated within each clathrate hydrate cage. However, recent measurements and computer calculations have demonstrated that clathrate hydrate structures can consist of water cages containing more than one guest molecule. Specifically, neutron diffraction measurements show that double occupancy of the large cage of sII hydrate can occur for both nitrogen hydrate and oxygen hydrate at higher pressures (7). Similar conclusions have been derived from molecular dynamics computer calculations (8). Multiple cage occupancy has also been proposed in sI, sII, and sH argon hydrates from first principle and lattice dynamics calculations (9).

Multiple occupancy of the water cages in H_2 hydrate was discovered using neutron and X-ray diffraction and Raman spectroscopy by Mao et al. (10,11). H_2 molecules were reported to exhibit double and quadruple occupancy in the small and large cages of sII hydrate, respectively (10,11). However, recently Lokshin and coworkers in collaboration with the Mao group (10) reported that D_2 molecules only singly occupy the small cages of D_2 hydrate (12). This discovery that H_2 can form a clathrate hydrate is especially noteworthy since it was previously assumed that small molecules such as H_2 and He are too small to stabilize a clathrate hydrate structure. The pure H_2 hydrate structure is typically formed at very high pressures (near 1 GPa). However, the addition of a promoter molecule, for example, THF, to form a binary H_2/THF hydrate will stabilize H_2 within the sII framework at pressures two orders of magnitude lower than that in pure hydrogen hydrates (13).

A complex clathrate hydrate structure, 1.67 choline hydroxide-tetra-*n*-propylammonium fluoride·$30.33H_2O$, was identified in 1999 using single-crystal X-ray diffraction (14). A space group of *R*-3 was assigned to this structure. This new clathrate hydrate consists of alternating stacks of sH and sII hydrates. Unlike

Table 2. Different Hydrate Guest Molecules and Their Clathrate Hydrate Structures, Dissociation Pressures, and Water Cage Occupancy

Guest Molecule	Structure Formed	Occupancy of Water Cages[a]	P,kPa; T, K[b]
CH_4	sI	5^{12} (86%) and $5^{12}6^2$ (95%)	4170, 277.6
C_2H_6	sI	5^{12} (0.3%) and $5^{12}6^2$ (97%)	814, 277.6
CO_2	sI	5^{12} (70%) and $5^{12}6^2$ (98%)	3847, 277.6
C_3H_8	sII	$5^{12}6^4$ (~ 100%)	455, 277.8
C_2H_4O (EO)[c]	sI	$5^{12}6^2$ (~ 100%)	101.3, 284.2
C_4H_8O (THF)[c]	sII	$5^{12}6^4$ (~ 100%)	101.3, 277.5
CH_4+ C_2H_6	Binary sI/sII	sII−C_1: 5^{12} (79%), $5^{12}6^2$ (18%) sII−C_2: $5^{12}6^2$ (80%)	90.4% C_1: 2096, 277.6
		sI−C_1: 5^{12} (63%), $5^{12}6^2$ (3%) sI−C_2: 5^{12} (0.2%), $5^{12}6^2$ (97%)	56.4% C_1: 1564,[d] 277.6
CH_4+ CO_2	Binary sI	CH_4: 5^{12} (66%), $5^{12}6^2$ (41%) CO_2: 5^{12} (14%), $5^{12}6^2$ (55%)	66% C1: 2840, 277.0
Methylcyclohexane + CH_4	sH	5^{12} (CH_4), $4^35^66^3$ (CH_4), $5^{12}6^8$ (mch)	2137, 277.6
t-Butylmethyl ether + CH_4	sH	5^{12} (CH_4), $4^35^66^3$ (CH_4), $5^{12}6^8$ (*t*-btme)	2550, 277.5

[a] A Gibbs energy minimization program, CSMGem, has been used to estimate the occupancy of each water cage (5).

[b] Values are from experimental data extracted from Reference 4.

[d] Dissociation pressure calculated from CSMGem (5).

the common (sI, sII, and sH) hydrates, which contain hydrophobic guest molecules, the choline hydroxide guest in this complex structure exhibits both hydrophobic and hydrophilic modes of hydration. Choline hydroxide occupies the large cages ($5^{12}6^4$ and $5^{12}6^8$), displacing one of the host water molecules of the $5^{12}6^8$ cages. The tetra-*n*-propylammonium guest was reported to occupy fused supercages ($4^35^{30}6^3$ and 5^{36}). It was suggested that the closed-cage version of this structure could occur in natural and industrial environments with natural gas molecules as the guest species.

Contrary to previous reports of bromine forming a number of different hydrate structures, single-crystal X-ray diffraction measurements by Udachin et al. (15) showed that bromine hydrate only forms a tetragonal structure of space group $P4_2/mmm$ (cf. Ref. 16). The composition of bromine hydrate was found to be $Br_2 \cdot nH_2O$, where $n = 8.62–10.68$. The tetragonal framework is comprised of small 5^{12} cages and large $5^{12}6^2$ and $5^{12}6^3$ cages. The large cages are occupied by varying amounts of bromine molecules. The small cages were either vacant or partially occupied by O_2 or N_2 molecules, which were incorporated during crystallization of the bromine/water solution in air.

sT clathrate hydrate, a trigonal structure of space group $P321$, was discovered in 2001 (17). The structure was determined using single-crystal X-ray diffraction and NMR spectroscopy. All three types of large cages ($5^{12}6^3$, $5^{12}6^2$, and $4^15^{10}6^3$) in the structure are occupied by dimethyl ether guest molecules. The ratio of small to large cages is 0.25, which is significantly smaller than other known structures. As a consequence, this structure is most efficient at minimizing void space when the small cages are empty and has a higher density ($1.074\ g \cdot cm^{-3}$) than sII or sI hydrate. The authors suggest that this higher density may result in sT being favored over sI and sII for intermediate sized guests at high pressure. However, they also acknowledge that other factors need to be accounted for, such as the degree of ring strain of the four-membered water rings.

Methane hydrate has been shown from neutron and X-ray diffraction to undergo structural transformations to unconventional structures at elevated pressures (2,18,19). sI hydrate transforms to MH-II, a hexagonal structure, at around 1 GPa, which further transforms at around 2 GPa to an orthorhombic ice-filled structure MH-III. The ice-filled structure of methane hydrate was found to be stable up to 42 GPa (19).

Similarly, THF hydrate has been reported to undergo a structural transition from sII hydrate to an unusual structure at high pressure (0.8 GPa) (20). From neutron diffraction, the new high pressure phase of THF hydrate was assigned to an orthorhombic structure of space group *Pnma*. The water framework is reported to be formed exclusively from one type of 14-hedron cage, $4^45^46^6$. The unit cell stoichiometry of this new structure is $4(THF\text{-}d_8) \cdot 24D_2O$.

CLATHRATE HYDRATES IN NATURAL AND INDUSTRIAL ENVIRONMENTS

Clathrate hydrates, containing predominantly biogenic methane, occur naturally in ocean sediments and permafrost regions (2–4). The amount of carbon in these natural gas hydrate deposits is estimated to be twice that of combined fossil fuel reserves [1 m^3 of methane hydrate in which 90% of the cages are occupied contains the equivalent of 156 m^3 of methane under standard conditions (STP)]. Significant efforts have been made over recent years to evaluate the feasibility of recovering these natural gas hydrate deposits. Oceanic gas hydrate deposits are currently considered to be too disperse and expensive to warrant near-term exploration (3). Conversely, permafrost deposits have significantly higher hydrate concentrations than hydrates found in ocean sediments. As a consequence, pilot drilling and characterization are being performed in Alaska and Canada in the permafrost, and in Japan in the ocean (3). However, extensive research and development is still required before these natural gas hydrate deposits can be produced safely and economically.

Natural gas hydrates also occur in gas and oil subsea pipelines, when the fluid in the pipeline reaches the temperature and pressure conditions that are favorable for hydrate formation. This can result in blockage of the pipelines and, as a consequence, catastrophic economic loss and ecological and safety risks (2,4). The typical method used to prevent hydrate formation within subsea pipelines is to add a thermodynamic inhibitor, which shifts the hydrate formation conditions to lower temperatures and/or higher pressures (2,4).

However, in many deepwater production scenarios, thermodynamic inhibition can become uneconomical and even prohibitive due to the high concentrations required under these conditions. Therefore, new technologies are currently being developed to control hydrate formation within these deepwater pipelines. These new methods include:

1. The addition of low dosage hydrate inhibitors (LDHIs) that are effective at concentrations below about 1 vol%. There are two broad classes of LDHIs: kinetic hydrate inhibitors (KHIs) and antiagglomerant inhibitors (AAs). KHIs operate by delaying nucleation and/or crystal growth. AAs prevent hydrate crystals from agglomerating and forming a blockage by maintaining the hydrates in the form of a suspended slurry, which allows fluid flow to occur unimpeded.
2. “Cold flow,” whereby hydrates could be pumped through the pipeline without the need of inhibitors (21). Sintef-BP researchers have reported that the addition of water to a flow of dry hydrate results in the formation of further dry hydrate. It is suggested that this implies that if there is a cold flow of oil/gas containing dry hydrates, warm well streams containing water can then be added, with the water from the well being converted to dry hydrates.

Numerous technological applications have been proposed for clathrate hydrates. Highlights of some of these applications are given as follows. The discovery of the ability to store H_2 in a pure H_2 hydrate at high pressures by Mao et al. (10,11) and more recently within a binary H_2/THF hydrate at lower pressures (13) presents an innovative technology for hydrogen storage. This technology seems particularly feasible since the successful proof-of-concept that hydrogen can be stored at mild conditions (of T and P) within a binary clathrate hydrate lattice using promoter molecules (13). The advantage of using clathrate hydrate materials for hydrogen storage is that the hydrogen is stored in molecular form, without the need of a chemical reaction for its release (13). This increases the overall energy efficiency of the system. Furthermore, all stored H_2 should be completely released by decomposition of the hydrate at near-ambient temperature and pressure conditions. The storage of methane within a sI hydrate framework is also currently being evaluated as an alternative method to fuel ships or to transport stranded gas (3).

Methane hydrate has also been considered a potential source for climate change (3). The clathrate gun hypothesis (also known as the “late Quaternary climate change”) suggests that methane released from methane hydrate around 15,000 years ago caused immense global warming (22). However, this hypothesis remains controversial.

The use of gas hydrates for cool storage has been explored since the early 1980s (23). The R141b gas hydrate (sII hydrate) was selected as a cool-storage system, since the R141b refrigerant offers significant advantages over Freon hydrate formers, including a lower saturation pressure and lower cost. R141b hydrate can be formed under mild conditions of 0.1 MPa and around 278°K. A further potential application of clathrate hydrates is CO_2 sequestration. This would involve injecting liquid CO_2 (droplets) into the ocean at depths of greater than 500 m where a solid interface of CO_2 hydrate will form between CO_2 and water (24,25). Injecting CO_2 into deep marine sediments would not be expected to result in long-term effects to biological systems and could circumvent the problem of eventually releasing the disposed CO_2 into the atmosphere.

Other proposed applications of gas hydrates include a range of separation processes, such as the treatment of aqueous and gaseous pollutant streams [e.g., recovery of chlorinated hydrocarbons from contaminated groundwater (26) or carbon dioxide from flue gases (27), respectively], isotopic fractionation of oxygen and hydrogen (28), and marine desalination (29).

CONCLUSION

The increasing utilization of molecular tools, such as X-ray and neutron diffraction, Raman and NMR spectroscopy, and computer simulation calculations, is producing a wealth of new and interesting findings on the structural and dynamic properties of clathrate hydrates. Further understanding of the hydrate structural transitions occurring over a range of temperature, pressure, and composition and the kinetics of these transitions will be important in advancing the range of new technologies being developed based on clathrate hydrates. This new molecular-level insight of hydrate structure and dynamics could have implications in the broader fields of inclusion compounds and crystal growth processes.

HYDRATION

Carolyn Ann Koh
Colorado School of Mines
Golden, Colorado

DEFINITION OF HYDRATION

Hydration can be defined as the process by which water is added to produce a *hydrate*. The process is reversible, that is, water can be reextracted from the hydrate. A second meaning of *hydration* involves a *hydration reaction*. This is where water is permanently and chemically combined with a reactant in a way that it can no longer be reextracted. The second meaning of hydration will not be considered here.

Hydration to form a hydrate can occur when water (*solvent*) interacts with *solute* molecules to form a solution, which involves *hydrophobic hydration*. Hydrophobic hydration is the main focus here.

HYDRATION OF HYDROPHOBIC MOLECULES

Hydration of nonpolar molecules is usually associated with hydrophobic effects in which water cavities or hydration shells are formed. This is accompanied by a loss in entropy and aggregation of the nonpolar (hydrophobic) molecules. Hence, ordering of the water hydration shell around hydrophobic molecules has been attributed to “clathrate” behavior in which the water hydration shell is dominated by pentagons compared to bulk liquid water (1). However, thermodynamic studies (2) suggest that although there are larger numbers of pentagons in the solvation shell compared to the bulk, the hydration shell also contains significant numbers of hexagons and larger polygons. It was suggested that the existence of larger polygons in the hydration shell indicates that the clathrate analogy is too simple to explain water organization along hydrophobic surfaces (2).

The water hydration shell around nonpolar molecules, such as methane, has been studied before, during and after gas clathrate hydrate formation using neutron diffraction with H/D isotopic substitution coupled with empirical potential structure refinement (EPSR) computer simulations (3–5). Gas clathrate hydrates are crystalline inclusion compounds that are formed when water and nonpolar molecules, such as methane, come into contact at high pressure and low temperature (6). Figure 1 illustrates the expansion of the water hydration shell and increased ordering of the second hydration shell around methane after clathrate hydrate formation.

Hydrophobic behavior has been observed for a concentrated solution of 0.86 mole fraction of tertiary butanol in water (7). This behavior is generally seen in more dilute solutions. A solution of tertiary butanol in water presents

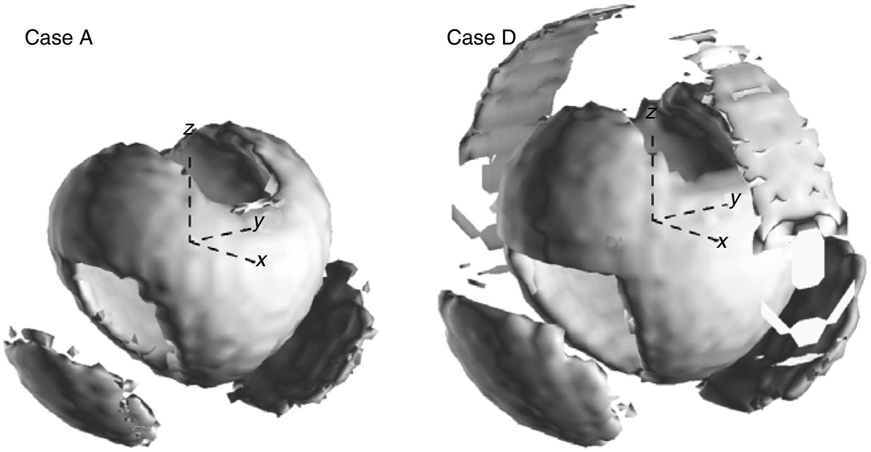

Figure 1. The hydration shell structure around methane: Case A, before hydrate formation (180 bar, 18 °C); case D, after hydrate formation (180 bar, 4 °C).

a classic example of an ampliphile–water solution. Neutron diffraction with H/D isotopic substitution coupled with EPSR computer simulations was used to examine the intermolecular correlations between alcohol and water molecules. The results revealed that "water pockets" are created within the concentrated alcohol–water solution, which reduce the degree of alcohol–alcohol direct hydrogen bonding. The pockets were found, on average, to contain between two and three water molecules. These water molecules exhibit a strong tendency to interact with the polar hydroxyl groups on the alcohol. As a result, the nonpolar groups became more tightly packed (i.e., exhibiting hydrophobic association) compared to that in the pure liquid alcohol. In the case of more dilute solutions of tertiary butanol in water (0.06 mole fraction of alcohol), the structural data do not support the conventional view that hydrophobic processes are dominated by perturbations of the first hydration shell. Conversely, significant changes are observed in the second hydration shell of water, with a "compression and tightening" of water molecules in the second shell (8).

A two-moment information theory was developed to describe the hydrophobic effect (9). This theory was shown to have a clear connection with the molecular principles of statistical thermodynamics. It was suggested that this theory could also be applied to describe hydrophobic effects on biopolymer structure in aqueous solution.

HYDRATION OF IONS

Concentrated solutions of sodium hydroxide in water have been studied using neutron diffraction with H/D isotopic substitution and EPSR computer simulations. The solute was found to affect the tetrahedral network of hydrogen-bonded water molecules (cf. when high pressure is applied to pure water). The results also indicated that there was a competition between the hydrogen-bonding interactions and Coulomb forces in determining the orientation of water molecules within the cation solvation shell (10).

The effect of adding sodium chloride as a salting-out agent to a dilute solution of tertiary butanol in water (0.02 mole fraction of alcohol) has also been studied using neutron diffraction (11). Contrary to previous understanding on salting-out (12), these measurements show that an anion bridge is formed between the polar ends of nearby alcohol molecules. Hence, there is significant enhancement of polar–polar interactions of the alcohol hydroxyl groups. As a result of the anion bridge formation, further hydrophobic interactions occur between the nonpolar/nonpolar groups.

CONCLUSION

Hydration of nonpolar molecules and salts and hydrophobic hydration have been studied in detail over the last couple of decades using computer simulation and theory. Recently, microscopic tools such as neutron diffraction with H/D isotopic substitution have been applied to study hydration of nonpolar molecules and salts. Neutron diffraction measurements coupled with molecular simulation provide a powerful tool to verify existing models of hydration of nonpolar molecules and salts, as well as combinations of these species.

THE MIRAGE OF THE H_2 ECONOMY

Reuel Shinnar
The City College of the CUNY
New York

In a recent paper (1), I analyzed the new “hydrogen economy” and explained why, for most uses, it makes no sense to convert fuels, electricity, or any other form of energy to hydrogen, only to use the hydrogen as a fuel for fuel cells. As H_2 is not a resource but an inefficient energy carrier, it would appear that the H_2 economy is just a mirage. If alternative energy sources are ever developed, an economy based on electricity would be cheaper (by a factor of three) and much easier to adopt than H_2. Oddly, I had covered the same topic twenty years ago in a paper that analyzed the hydrogen economy of the 1970s (2). Then, the investment in H_2 research was about 10 billion wasted dollars before it was phased out. In this column, I will try to explain why the scientific establishment engages in such obviously futile behavior and why this mirage attracts so many followers.

In the mid 1970s, I became aware of a strange phenomenon. Many leading scientific journals were suddenly giving enormous coverage to hydrogen, the fuel of the future; a new term, hydrogen economy, was born. International meetings attracted thousands of participants and the United States, Germany, and Japan funded the necessary development with vast resources. The central idea, put forward by the International Atomic Energy Research Center in Vienna, used a high-temperature nuclear reactor as the heat source. In this reactor, pressurized helium was used as the coolant. To generate electricity, the hot helium was first expanded through a turbine and then used for steam generation before being fed back to the reactor.

The “thermochemical cycle,” the name applied to this new process, does not include a turbine, and the heat from cooling the hot helium is used to drive a set of closed-cycle chemical reactions; the net result is that water is split into hydrogen and oxygen.

Following is a hypothetical example of such a reaction:

$$\mathrm{MeO + Heat \longrightarrow Me + 1/2O_2}$$
$$\mathrm{Me + H_2O \longrightarrow H_2 + MeO + Heat}$$

where Me is any metal. No such reaction was ever discovered, and all cycles proposed were quite complex. One does not need to be an experienced cost estimator to realize that such a cycle would be very expensive and have a low thermal efficiency.

The H_2 was supposed to be used to replace natural gas in existing pipelines. Several obvious questions were not asked:

1. A pipeline for methane cannot be used to transport H_2. To avoid leakage, one needs totally different valves and connectors. Furthermore, as the volume of H_2 is triple that of methane, one needs larger pipes and different compressors. Of course, the same factors would apply to the distribution of the gases to customers. None of the valves or controls would be tight enough, and all burners would have to be changed.
2. As nuclear reactors are available, why not use electricity instead of methane for most applications? Electricity is far more efficient than H_2 or methane (by a factor of two) for most uses. Let me illustrate. Today, in the United States and the world, a large amount of electricity is generated from natural gas. This electricity, on a BTU basis, costs by a factor of about 2.2 more than the natural gas feed. The fact that we do it obviously means that electricity is more valuable than natural gas. At the same price, it would have driven out natural gas. H_2 as a fuel has an even lower value than natural gas. If we now convert electricity to H_2, we again lose at least one-third of the energy. Thus, H_2 made from electricity has a value about four times lower than the electricity. This simple calculation illustrates the stupidity of the idea to convert nuclear or solar energy to hydrogen. At that time, no one was foolhardy enough to suggest using H_2 generated by a nuclear reactor as fuel for a fuel cell. Furthermore, an electricity distribution system is already in place and can grow with demand.
3. Why not make H_2 by electrolysis, a well-known process? Nobody asked why—in contradiction to our cumulative technical experience—a set of chemical reactions should generate a large increase in ΔT more cheaply or efficiently than electrolysis. The main item in the cost of electricity is the nuclear reactor, and if a thermochemical cycle is less efficient, it is inherently more expensive.
4. The cost of switching to hydrogen is astronomical. To produce the equivalent of one million BTU of hydrogen per day by electrolysis would require a 25-kilowatt nuclear reactor at an investment cost of \$150,000, which means that a standard nuclear reactor of one gigawatt costing \$6 billion will be able to supply 40,000 million BTU/day of H_2 the

equivalent of 6700 barrels of oils. Building the capacity for supplying a new pipeline that could carry 12% of the current U.S. capacity of natural gas would have to be built from the start at a cost of close to $1 trillion. For thermochemical cycles, the cost would be significantly higher. All of this must be invested before a pipeline can be started. The same energy needs could be supplied by electrical energy at only one-quarter the cost because electrical energy has a higher efficiency for almost all purposes. The investment for electricity can be spread over many years because a grid is already in existence. Furthermore, just the energy from the nuclear reactions would cost $50 per million BTU H_2.

5. The most dangerous of all fuels, pressurized H_2 ignites with an invisible flame. Its explosive limits are very wide, and its minimum ignition energy is ten times smaller than that of any other gaseous fuel. This problem occurs not only when H_2 is being distributed or used, but even more so when it is generated in a thermochemical cycle. When H_2 is produced by electrolysis, one can locate the plant far away from the nuclear reactor generating the electricity, which, however, is not true for helium, which must be pumped in such large quantities that it cannot be sent over long distances at reasonable cost. Society has accepted the risks of explosion in conventional fuels but tries to limit exposure. Thus, even a small propane storage tank may not be transported through a tunnel, but what level of risk from a potential explosion at a nuclear power plant complex is acceptable? None of these critical questions were asked then—nor are they being asked today.

These questions have been on my mind for a long time. In the “age of technology,” how could the scientific community have been misled by such obvious nonsense? And why had so many engineering firms and large companies come up with totally unrealistic cost estimates, at least by a magnitude too low, and thermal efficiency estimates that are unrealistically high?

The intellectual climate of the time can be illustrated by a small story. *Science* carried a six-page article, featured on the cover, about a new cycle developed by General Electric that promised to produce H_2 at $2.50/million BTU H_2 (at that time it would have cost $7.00/million BTU to produce H_2 from oil). For fun, I flow-sheeted the process and published the mass and heat balance in a letter to *Science* (3) suggesting that if GE can reduce costs to $2.50, they should forget about hydrogen and change the economy. By comparison, us poor chemical engineers could not achieve such results at a cost of $250/million BTU H_2. Three months later, I was invited to GE’s central laboratory where the Director of Chemical Research offered me a consulting job. The head of the lab was a chemist who had read about the need for a thermochemical cycle, and he actually developed the first one that worked. His engineers had given him this cost estimate. When my letter was published, he asked Corporate Engineering to make their own estimate and they confirmed my numbers. This story illustrates a key aspect of the hydrogen economy. Many excellent scientists lack the skills needed to deal with economics and costs. Later, I published another paper demonstrating, from elementary design principles, that any thermochemical process must, by necessity, cost much more than electrolysis (2).

It is true that many scientists could have erred because they were not knowledgeable about process economics. However, I also came to realize that other forces were driving the program. Although they are inherently safer, high-temperature nuclear reactors of the type required by thermochemical cycles were deemed less competitive and more costly than boiling water reactors, which created an opportunity for their developers to seek more government support. A large nuclear research community was hungry for grants and contracts.

Interestingly and unfortunately, the episode of the 1970s has been ignored or forgotten. However, before we place large national resources behind an effort to again deal with such major problems as renewable energy, global warming, and energy independence, we have to understand what went wrong the first time a so-called “hydrogen economy” was attempted.

The paper I just published is about the reincarnation of the hydrogen economy. This time, all the proposed processes are feasible, but the program itself seems to make even less sense. As before, the main emphasis is on the replacement of conventional fuels with a national distribution system of H_2 at a tremendous loss in efficiency in the production and transmission steps. As before, the same intractable safety and cost problems still persist.

Similar driving forces remain at work. Large research budgets are projected to find a use for a technology in which DOE has invested huge sums of money to little or no avail. This time, it is fuel cells powered by hydrogen, a technology that is good for space applications, where H_2 is used as a rocket fuel, and therefore available in small quantities, and other specialty applications, but useless for applications that couple H_2 generation with the generation of electricity. Such systems have half the efficiency of combined cycle turbines, cost over five times more (1,4), and create at least double the greenhouse emission, probably much more.

Today, there even is talk about switching cars from gasoline to H_2, which makes the transition problem even more difficult as the new supplying system cannot start locally, and this would also require the use of pressurized H_2 at 6000 psi, a pressure very seldom used in industry. Nobody mentions that in industry an H_2 tank with the capacity proposed for a family car requires storage in a special room with a blowout wall. Any technician approaching such a pressurized tank to check the valves swings a wooden broom to prevent being fried by an invisible flame which may come from a leaking valve, as above 1500 psi, an H_2 leak is self-igniting (1). For a gas station, a minimum-sized storage tank would have the explosive power of two thousand tons of TNT or two of the largest bombs used by the Air Force. A terrorist could just open a valve and detonate a small bomb after 20 seconds.

The most obvious fallacy of the new H_2 economy, however, is that it solves all of our problems (5,6). For those of us who accept the first and second laws of thermodynamics, it is obvious that the use of H_2 would increase the use of other energy resources. Arguments are made that, once we have a hydrogen distribution system, we could capture the CO_2 produced and sequester it. However, we have no idea how to sequester such vast amounts of CO_2 safely. A successful policy can only be formulated after all the elements are solved and a good deal is known about costs. At present, the United States releases 100 million tons of sequestered CO_2 back into the atmosphere each year.

In a system in which the basic science is known, costs are reduced by innovative ideas that develop during the implementation stage of a project rather than by more research. The cost of liquid natural gas plants and combined cycle power plants decreased in the last ten years by a factor of two even though the basic technology did not change because many were built to compete in the market. So, research, to be effective, needs to be coupled with a clear plan for implementation.

In order to promote the use of fuel cells or other new technologies, which are by one to two orders of magnitude more expensive than available technologies, the research community has invented the myth of "learning curves." In the last 40 years, computers became, through miniaturization, cheaper by several magnitudes, but this option does not apply to energy systems. In the last 20 years, the cost of solar cells was reduced by less than a factor of two despite a tremendous research budget. Better engineering and mass production can reduce the cost of most new technologies by a factor of two to three. However, this would require the building of large plants based on competitive bidding, not a new research breakthrough. Large research budgets over the past 40 years have not made the cost of fuel cells more competitive.

The alternative sources that really reduce CO_2 emissions include solar and nuclear energy and biomass. The use of H_2 just makes every one of these options several times more expensive. Solar and nuclear energy produce electricity, and, for most purposes, electricity is far more efficient to use than H_2. To provide electricity to the motor in a H_2 car requires three to four times the solar or nuclear capacity required for providing the electricity directly via a battery. Although we don't have good electric cars yet, Toyota has just come out with a hybrid car with a plug-in battery large enough for a 40-mile drive. Such a car could reduce total gasoline consumption by 80%, but electric cars would only reduce greenhouse emissions if the electricity were generated by solar energy. As for biomass, which is a valuable but limited future resource, conversion by fermentation to alcohol followed by conversion to gasoline or diesel is far cheaper and thermally more efficient than conversion to hydrogen.

In the early 1990s, an Israeli company, Luz (7), built solar electric power plants using a high-temperature heat transfer fluid, which included sufficient storage to supply Los Angeles with 300 megawatts of electricity on a reliable basis. The Luz plant had another major advantage; the design allowed for conventional fuel to be used as a backup because, even in the desert, 10% of the days may be rainy. To be profitable, all Luz needed was a 50% tax break on the investment. When Luz became large, the tax breaks were taken away. If Luz had been allowed to build a few gigawatts, the price would have come down and other companies would have come in; we might have had affordable solar energy today.

We have today the resources and the technology to do something useful about global warming if we really had the resolve. For example, for $50 billion a year over twenty years, we could replace 40% of coal power plants with solar power plants using proven technology; we just have to engineer them better and provide them with sufficient storage capacity. We are the only western nation who has enough sun and enough area for solar power. Alternatively, we could eliminate about 80% of our gasoline used for cars. We could easily afford to do both, but we have to realize that no research can make solar, nuclear, or other alternative energy competitive with cheap oil or gas.

Our society has solved far more difficult large-scale technical problems successfully, e.g., space travel and the most advanced defense weapons in the world. Applying our capabilities to global warming or to resource depletion to preserve a livable world to our grandchildren would require not only conviction but a strong political will to do so.

To give a recent example, thirty years ago, we faced the problem of increasing pollution from our coal power plants. We had the technology (scrubbers) to reduce the pollution substantially. It would have cost about $20–30 billion, but politics and the influence of senators from coal-producing states prevented the adoption of such a solution. Instead, we spent $20 billion on "clean coal" research programs that failed to produce results that could help solve this problem. However, the "clean coal" effort did provide large research budgets along with the illusion that we were accomplishing something. Thirty years later, the same plants are producing more electricity and consuming more coal—still poisoning the fish we eat with mercury, causing smog that blocks us from seeing the sky, destroying our forests, and, most importantly, impairing the health of all of us more than any other form of pollution.

The private car is another example of the obstacles that a serious national policy faces. In the 1970s, in response to the Arab oil embargo, oil price increases, and an alleged likelihood that the oil resource base would become depleted within the next several decades, Presidents Nixon, Ford, and Carter proposed new energy policy initiatives that included the goal of improving auto fuel economy. These initiatives resulted in the Corporate Average Fuel Economy standards (CAFÉ), which required that the fleet fuel economy of new light-duty vehicles (5500 lbs or less) reach 27.5 mpg by a certain, date a 30% reduction in gasoline demand. This standard limited the ability of the companies to produce large cars and stationwagons. The same provision set lower standards in mileage and emissions for light-duty trucks weighing less than 5500 lbs.

Nine years ago, the car industry realized that one could produce large cars (SUVs) that fit all the definitions of a light truck, such that one should be able to fold all seats to the floor to provide a major space occupying the car and several others. It was a great success. As light trucks convertible to luxury passenger cars do not count as passenger cars for the CAFE laws and are not considered in the fleet average, this allowed car companies again to produce gas guzzlers. Eight years later, 30% of the passenger cars sold in the United States are SUVs, and all the efficiency gains of 30 years have been wiped out.

As we face the potential of global warming and resource depletion that might endanger the future of our grandchildren, we escape our responsibilities by pretending that all problems can be solved better and at lower cost through the mirage of more research. Thus, the H_2 mirage allows car companies to continue to produce gas-guzzling, highly polluting SUVs while touting the glorious future, an "H_2" car that will miraculously be energy efficient and pollution-free. And, as in the 70s, thousands in the scientific and political communities are promoting this mirage to the public.

Thus, mirages like the "hydrogen economy" play an important psychological function in our society, and many in the technical community play along. The role engineers and scientists should be playing today is to educate the public and the politicians about the real options. We should be reminded of an old cartoon in the Pogo series that bears the caption "We have met the enemy and he is us."

HYDROGEN ION

Gholam A. Kazemi
Shahrood University of Technology
Shahrood, Iran

INTRODUCTION

This article includes an introduction to the ion and its properties followed by an overview of the characteristics of the hydrogen atom. The latter has been extracted mostly from Sienko and Plane (1). This article should be studied in conjunction with the pH and Hydronium Ion articles.

An ion in general terms can be any grouping of one or more atoms that carries a charge (1). The characteristics of an ion include:

1. the sign (type) of charge: positive (cation) or negative (anion);
2. the number of charges or valence (z): monovalent divalent, etc;
3. the ionic radius (*r*): the distance from the center of the nucleus to the outer shell of the atomic particle;
4. the ionic potential: *z/r*, the ratio of the charge of the ion to the ionic radius;
5. the electronegativity: the power of the ion to attract electrons;
6. the molar volume: the volume of one mole (cm^3/mol); and
7. the ionic conductance: the ability to carry electrical current.

When an ion is surrounded by many other ions/molecules such as in a solution, its other properties such as ionic strength and ion activity coefficient come to light. Ottonello (2) is a major reference where many properties of various ions are tabulated.

Hydrogen, the lightest of all gases, is colorless, odorless, and tasteless. Together with helium, it occupies the first period of the periodic chart of elements and is the most abundant element in the solar system. After helium, it has the second lowest boiling temperature of all elements (2). Because of its low boiling point, liquid hydrogen is used as a cryogenic fluid (to produce low temperatures), and because of its high heat of combustion (120 kJ/g), it is a valuable rocket fuel. Molecular hydrogen, H_2, can combine directly with most elements. Mixtures of H_2 and O_2 can be explosive. Much of the industrial consumption of hydrogen is in hydrogenation reactions, the addition of H_2 to other molecules. Water and power are required to produce hydrogen. In its compounds, hydrogen is found in three oxidation states, +1, −1, and 0. Hydrogen is such an important element that it has its own association. The National Hydrogen Association (WWW. Hydrogenus.org), for example, was formed in 1989 (in the U.S.) to act as a focal point in hydrogen related matters. Anyone interested in water related matters should know the important characteristics of hydrogen because of its place in the water molecule.

DEFINITION OF A HYDROGEN ION

A hydrogen ion, H^+, is a monovalent cation that occurs when a hydrogen atom loses its only electron:

$$H \longrightarrow H^+ + e^-$$

Therefore, the hydrogen ion has only one proton and no electron. This is why "proton" is another name for hydrogen ion. Some references state that there is no such ion as a hydrogen ion and what occurs, is actually a hydronium ion, H_3O^+, rather than a hydrogen ion (3). The hydride ion, H^-, occurs when a hydride such as NaH dissociates:

$$\mathrm{NaH} \longrightarrow \mathrm{Na}^+ + \mathrm{H}^-$$

In this reaction, the hydride ion radius is 1.46 Å. Molecular hydrogen is formed from the reaction of a hydride ion and a hydrogen ion (4):

$$\mathrm{H}^+ + \mathrm{H}^- \longrightarrow \mathrm{H}_2$$

${H_3}^+$ is an ion that is artificially generated by the interaction of H^+ and H_2. For instance, generation of ${H_3}^+$ is the most critical specification of the ion source in a mass spectrometer (5).

CHARACTERISTICS OF THE HYDROGEN ION

Some major characteristics of the hydrogen ion are presented in Table 1.

In chemistry and geochemistry, it is assumed that the standard heat capacity, C_p^0; standard partial molal Gibbs free energy from the elements, G_f^0; standard partial molal enthalpy of formation from the elements, H_f^0; standard partial molal entropy, S_0^p; and standard partial molal volume, V_p^0, of the hydrogen ion equal zero at all temperatures and pressures (2,7).

MEASUREMENT OF HYDROGEN ION CONCENTRATION

More than 100 years ago, Arrhenius suggested that acid properties are attributable to the presence of an easily detachable hydrogen ion, H^+ (1). Now, everyone knows that the concentration of hydrogen ion in any solution is a measure of the solution's acidity or pH ($\mathrm{pH} = -\log \mathrm{H}^+$). Thus, the measurement of H^+ concentration is better described in the pH article of the encyclopedia and is only briefly dealt with here.

The H^+ ion is the easiest ion concentration to measure. This is done using a hydrogen electrode, which is formed by bubbling H_2 over a platinum electrode surface (7). A variety of these electrodes are commercially available; Metrohm pH meter Model 744 and Orion pH meter Model 420A are examples. Measurement of pH cannot be more accurate than 0.02 pH units because the standard solutions or buffers which have been calibrated by the U.S. Bureau of Standards (NBS) have an absolute accuracy in the range of ±0.01 to 0.02 pH units (7). In field conditions, where disturbing factors are ample, the accuracy is usually ±0.05 pH units. Colorimetry is one older method of measuring H^+ concentration.

Table 1. Notable Characteristics of the Hydrogen Ion, H^{+a}

Type	Cation
Valence	1
Radius[b]	—
Ionic potential (IP)[c]	—
Electronegativity	2.2
Molar volume	0 (This is based on convention)
Ionic conductance	349.8 $\mathrm{cm}^2 \times (\mathrm{equiv}\Omega)^{-1}$
Charge to mass ratio (q/m)	9.6×10^7 C/kg

[a] References 4, 6, 7.

[b] It is difficult to define because the electron of the hydrogen atom has gone, and only the proton remains. So, there is no outer shell left to measure its distance to the proton.

[c] It cannot be calculated because there is no specified ionic radius.

Some Examples

Pure neutral water at 25 °C has a pH of 7, a H^+ concentration of 10^{-7} mg/l. A 1-molal solution of HCl will have an H^+ concentration of 1 and a 0.01-molal solution will have an H^+ concentration of 10^{-2} mg/l. The concentration of hydrogen ion in a 0.01-molal solution of a weak such as H_2CO_3 is only $10^{-4.2}$ mg/l, and it is $10^{-10.8}$ mg/l in an aqueous solution of pH 3.2.

Many authors prefer to use the term "hydrogen ion activity" rather than hydrogen ion concentration. The reason that the "pH" concept has been developed is the very low concentration of hydrogen ion and the difficulty in comprehending such low, sometime ambiguous, numbers. In solutions, the concentration of H^+ never reaches zero; there is no solution that is 100% basic or 100% acidic.

PRODUCTION OF HYDROGEN ION IN WATER

Hydrogen ion is produced in natural water from the three following main sources as well as from humic and fluvic acids, volcanic gases, acid rain, and short-chain organic acids present in some oil field brines (8).

1. Hydrolysis

$$\mathrm{H_2O} \longrightarrow \mathrm{H}^+ + \mathrm{OH}^-$$

As stated above, however, it might be more appropriate to write the previous equation in the form:

$$2\mathrm{H_2O} \longrightarrow \mathrm{H_3O}^+ + \mathrm{OH}^-$$

2. Dissociation

$$\mathrm{H_2CO_3} \longrightarrow \mathrm{H}^+ + {\mathrm{HCO_3}}^-$$

3. Oxidation

$$2\mathrm{FeS_2} + 7.5\mathrm{O_2} + 7\mathrm{H_2O} \longrightarrow 2\mathrm{Fe(OH)_3} + 8\mathrm{H}^+ + 4{\mathrm{SO_4}}^{2-}$$

IMPORTANCE OF THE HYDROGEN ION

Some of the important functions and behaviors of the hydrogen ion are described as following. Considering the huge and universal importance of H^+, these should be regarded only as examples.

1. The radius of the hydrogen ion is very close to the size of the neutron. This similarity is the principle used to design and develop compensated neutron

logs (CNL) and neutron probes. The former is used as an important tool for calculating the porosity of petroleum reservoirs and aquifers (9,10), and the latter is of extensive use in agricultural practices for measuring soil moisture (11).

2. The concentration of hydrogen ion, pH, is a master variable of the groundwater system because the hydrogen ion participates in many important chemical reactions such as (12):

   a: mineral dissolution—precipitation

   $$CaCO_3 + H^+ = Ca^{2+} + HCO_3{}^-$$

   b: aqueous complexation

   $$Fe^{3+} + H_2O = Fe\,(OH)^{2+} + H^+$$

   c: adsorption −desorption

   $$\equiv FeOH + Cu^+ = \equiv FeOCu + H^+$$

3. The hydrogen ion plays a major role in denitrification through which various forms of nitrogen in the soil revert to N_2 (6):

   $$4NO_3{}^- + 4H^+ \longrightarrow 2N_2 + 5O_2 + 2H_2O$$

   It also plays a major role in redox reactions and acid–base reactions.
4. In sanitary engineering and water treatment, pH is an important factor in chemical coagulation, disinfection, water softening, corrosion control, and biological processes (13).
5. The most remarkable function of hydrogen ion is its control of the acidity or alkalinity of solutions.

THE HYDRONIUM ION

Carl W. David
University of Connecticut
Storrs, Connecticut

Naked protons cannot exist in aqueous solution. Even when one writes

$$HCl(g) \rightarrow H^+(aq) + Cl^-(aq) \tag{1}$$

one knows that the $H^+(aq)$ is a representation of a significantly more complicated moiety (or, to be more precise, set of moieties). The simplest representation of $H^+(aq)$ is the hydronium ion (sometimes also referred to as the oxonium ion or the hydroxonium ion),

$H_3O^+(aq)$, but this is just the first in a series the next few members of which are $H_5O_2{}^+$, $H_7O_3{}^+$, $H_9O_4{}^+$, and in summary $(H_2O)_nH_3O^+$, the hydrated hydronium ions (Fig. 1).

The hydronium ion is isoelectronic with ammonia (NH_3) and therefore, ought to be pyramidal with the oxygen at the apex of the pyramid and the three protons disposed below, with symmetry C_{3v}. Like ammonia, it should invert, with the O[or N] passing through the plane of the three protons from one side to the other. In the planar transition state, when all four nuclei are coplanar, the symmetry should be D_{3h}. Also, like ammonia, there should be a barrier to this umbrella inversion; appropriate tunneling has been observed spectroscopically (ν_2). It is thought that the O–H distance is about 0.96 Å, and the H–O–H angle about 115°. The barrier to inversion, a saddle point on the energy hypersurface, is thought to be between 1 and 5 kcal/mol (Fig. 2).

The simplest occurrence of the hydronium ion can be seen in the gas phase water dimer, $(H_2O)_2$. The proton transfer reaction inside the dimer would be

$$H_2O\text{–}H_2O(g) \rightarrow H_3O^+(g) : OH^-(g) \tag{2}$$

forming an ion pair (Fig. 3).

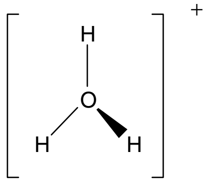

Figure 1. The hydronium cation.

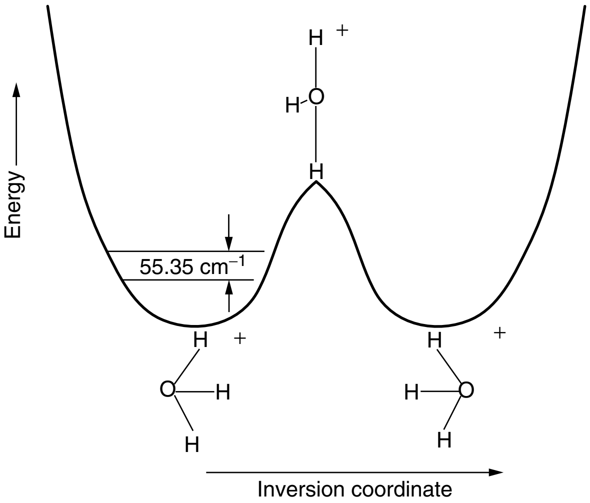

Figure 2. Potential energy surface for the hydronium ion's inversion coordinate.

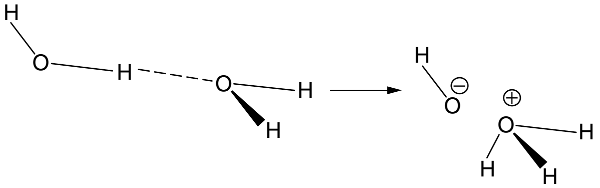

Figure 3. Dimer water forming an ion pair through proton transfer.

In the dimer, one molecule of water is a proton donor to the other (which is a proton acceptor). The former water is a Bronsted acid, the latter a Bronsted base. On the line of the hydrogen bond, $HO–H_{donor}$::::OH_2, the movement of the donor proton from one oxygen to another is equivalent to the proton transfer (above). The O–O distance in the dimer is about 3 Å, and the OH distances are about 1 Å, so the shift of 1 Å in a proton's position (between two oxygens) creates an OH^-:::H_3O^+ ion pair.

Hydrated versions of this ionization process illustrate that the actual process in liquid water is not cleanly definable. Figure 4 shows the results of three water molecules involved in ionization, whereas Fig. 5 shows the results with four water molecules.

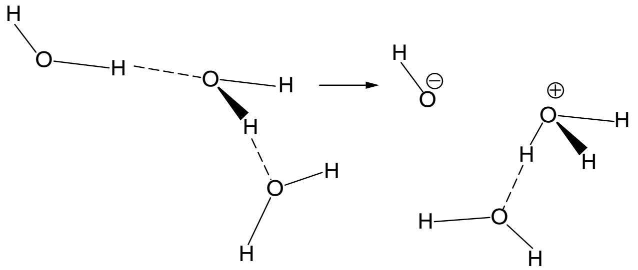

Figure 4. With three molecules of water, one can form a hydrated hydronium cation and a hydroxide anion.

Clearly, in liquid water, the hydroxide and hydronium ions are solvated but not statically enough to allow definition of a moiety.

In aqueous media, for the analog of the proton transfer reaction, one could write

$$2H_2O(l) \rightarrow H_3O^+(aq) + OH^-(aq) \tag{3}$$

the prototype of all acid–base chemistry in an aqueous medium.

In aqueous acidic media, the hydronium ion is rarely written. Instead, the older notation is employed. For instance, for acetic acid, CH_3COOH, one would write

$$CH_3COOH(aq) \Leftrightarrow H^+(aq) + CH_3COO^-(aq) \tag{4}$$

partial dissociation into a proton and a acetate anion, rather than the more accurate

$$H_2O(l) + CH_3COOH(aq) \Leftrightarrow H_3O^+(aq) + CH_3COO^-(aq) \tag{5}$$

The conductance properties of water are attributable in part to the hydronium cation and its peculiar properties. The Grotthuss mechanism for proton transfer in ice employs hydronium ions hydrogen bound to adjacent water molecules, in which, like the dimer, an excess proton migrates (or tunnels) from one oxygen to an adjacent one, moving only a tiny distance, whereupon the charge has shifted enormously (one O–O distance).

A similar mechanism for OH^-(aq) charge migration most likely also obtains. Here a water donor adjacent to the hydroxide anion shifts its donating proton to the hydroxide, thereby itself becoming a hydroxide anion (Fig. 6).

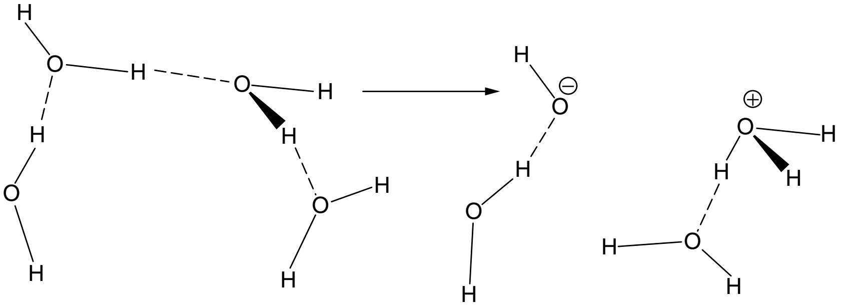

Figure 5. With four waters, hydrated hydroxide and hydrated hydronium ions are possible.

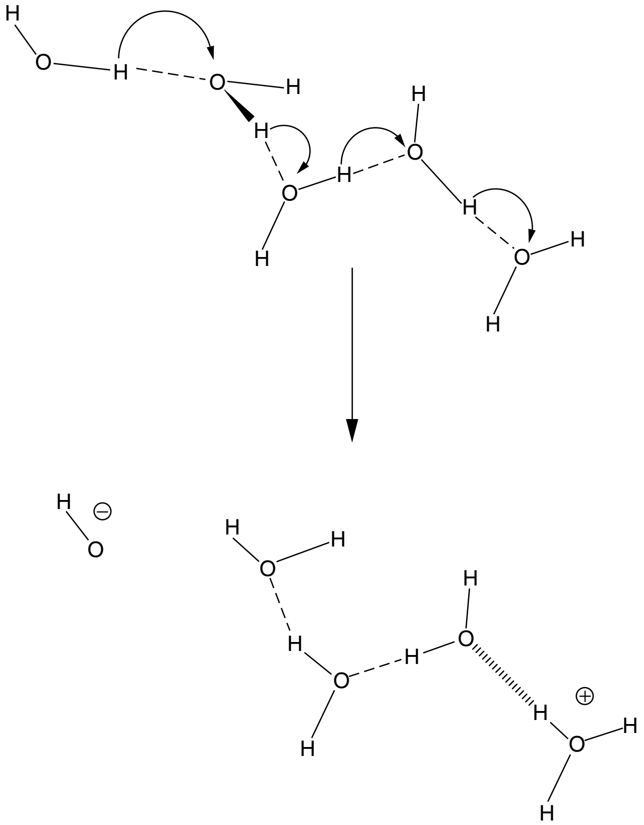

Figure 6. The Grotthuss mechanism for positive and negative charge creation and migration in aqueous solution.

INFILTRATION AND SOIL MOISTURE PROCESSES

Paul R. Houser

(from *The Handbook of Weather, Climate, and Water: Atmospheric Chemistry, Hydrology, and Societal Impacts*, Wiley 2003)

Infiltration is the process of water entry from surface sources such as rainfall, snowmelt, or irrigation into the soil. The infiltration process is a component in the overall unsaturated *redistribution* process (Fig. 1) (1) that results in *soil moisture* availability for use by vegetation transpiration, exfiltration (or evaporation) processes, chemical transport, and groundwater recharge. Soil moisture, in turn, controls the partitioning of subsequent precipitation into infiltration and runoff, and the partitioning of available energy between sensible and latent heat flux.

Because of the importance of soil moisture on multiple processes, its definition can be elusive (2); however, it is most often described as moisture in the unsaturated surface layers (first 1 to 2 m) of soil that can interact with the atmosphere through evapotranspiration and precipitation (3).

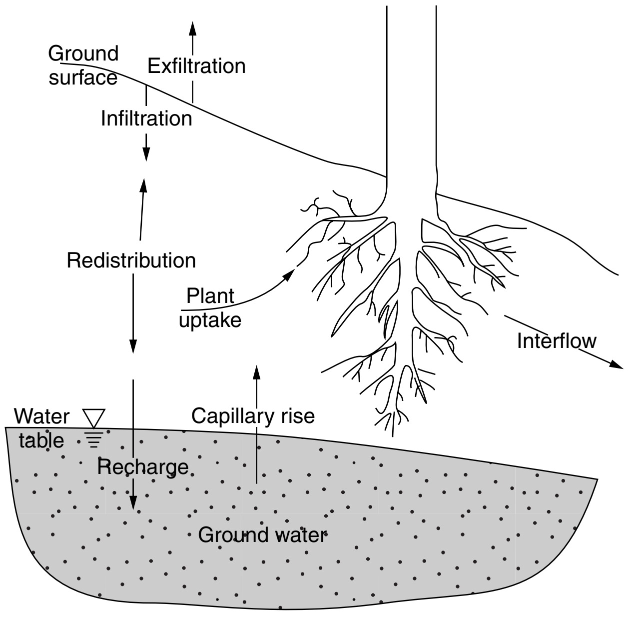

Figure 1. Unsaturated zone definition and active processes (1).

CONTROLS ON INFILTRATION AND SOIL MOISTURE

To characterize soil moisture and infiltration, the physical controls on these processes must be considered. The primary soil controls will be considered in this chapter; however, other factors such as soil chemistry, thickness, soil layering or horizons, and preferential flow paths, as well as vegetation cover, tillage, roughness, topography, temperature, and rainfall intensity also exert important controls (4).

A soil's particle size distribution has a large impact on its hydraulic properties. Soil particles less than 2 mm in diameter are divided into three texture groups (sand, silt, and clay) that help to classify broad soil types and soil water responses (Fig. 2) (5). The type of clay and the coarse material over 2 mm in diameter can also have a significant impact on soil water properties. An overview of methods for determining particle size properties is given by Gee and Bauder (6).

Bulk density, ρ_b (M/L^3) is the ratio of the weight of dry solids to the bulk volume of the soil, and *porosity*, ϕ (M^3/M^3), is the total volume occupied by pores per unit volume of soil:

$$\phi = \frac{V_a + V_w}{V_s} = 1 - \frac{\rho_b}{\rho_m} \tag{1}$$

where V_s (L^3) is the total volume of soil, V_a (L^3) is the volume of air, V_w (L^3) is the volume of water, and ρ_m (ML^{-3}) is the particle density (normally about 2.65 g/cm^3).

The volumetric water content, or soil moisture, θ (L^3 L^{-3}) is the ratio of water volume to soil volume:

$$\theta = \frac{V_w}{V_s} = \frac{W_w}{W_d}\frac{\rho_b}{\rho_w} \tag{2}$$

where W_w (M) is the weight of water, W_d (M) is the weight of dry soil, and ρ_w (M/L^3) is the density of water.

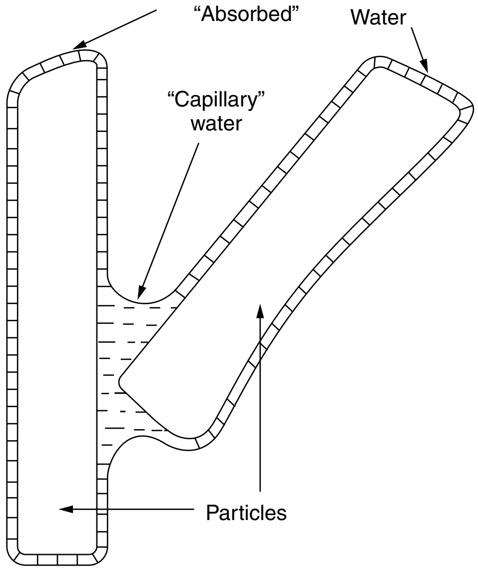

Figure 3. Capillarity and adsorption combine to produce suction (7).

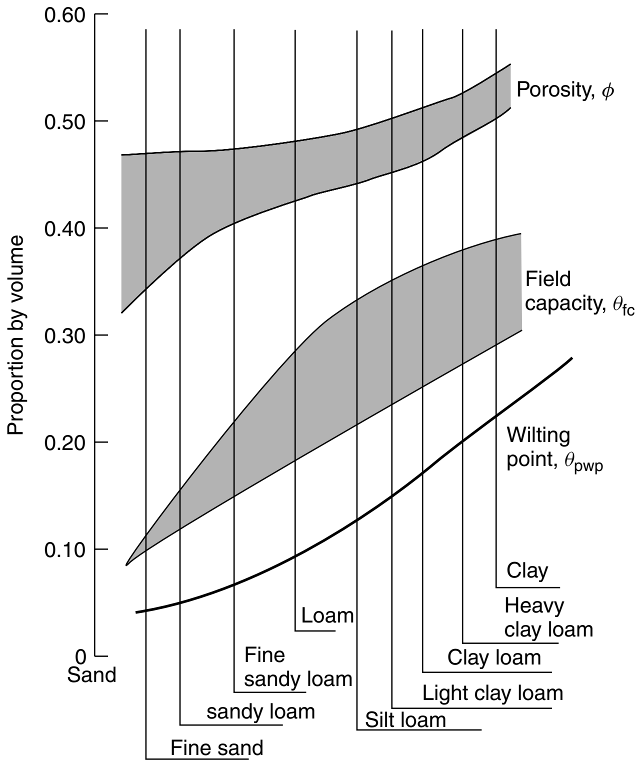

Figure 4. Water holding properties of various soils (8).

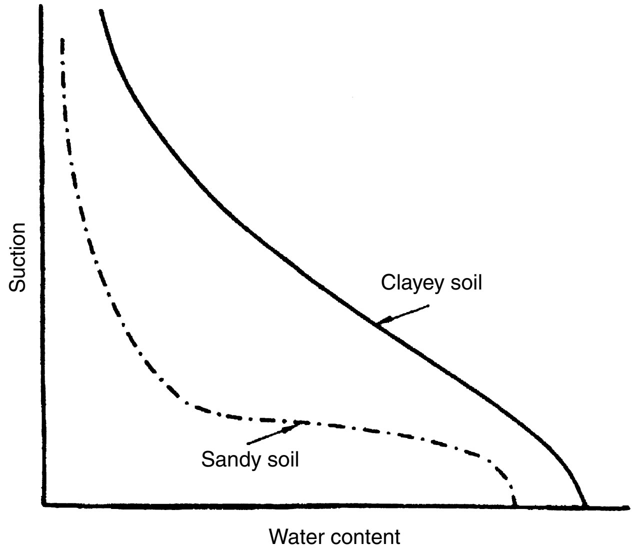

Figure 5. Effect of texture on water retention characteristics (9).

Soil moisture can vary in both time and space, with a theoretical range from 0 to φ, but for natural soils the range is significantly reduced due to isolated pore space and tightly held or "adsorbed" water (Fig. 3) (7). If a soil is saturated, then allowed to drain until the remaining water held by surface tension is in equilibrium with gravitational forces, it is at *field capacity*, θ_f. Vegetation can remove water from the soil until the *permanent wilting point*, θ_w, is reached. Therefore, the *available water content* for plant use, $\theta_a = \theta_f - \theta_w$. Typical ranges of porosity, field capacity, and wilting point for different soils are given in Fig. 4 (8).

In unsaturated soils, water is held in the soil against gravity by surface tension (Fig. 3). This tension, suction, or *matric potential*, ψ (L), increases as the radii of curvature of the meniscus or water content decreases (Fig. 5) (9). Matric potential is expressed in reference to atmospheric pressure, so for saturated soil $\psi = 0$ and for unsaturated soil $\psi < 0$.

The *hydraulic conductivity*, K (L/T), is a measure of the ability of the soil to transmit water that varies nonlinearly over a large range depending on both soil properties and water content (Fig. 6) (10). Many laboratory and field hydraulic conductivity measurement methods exist for

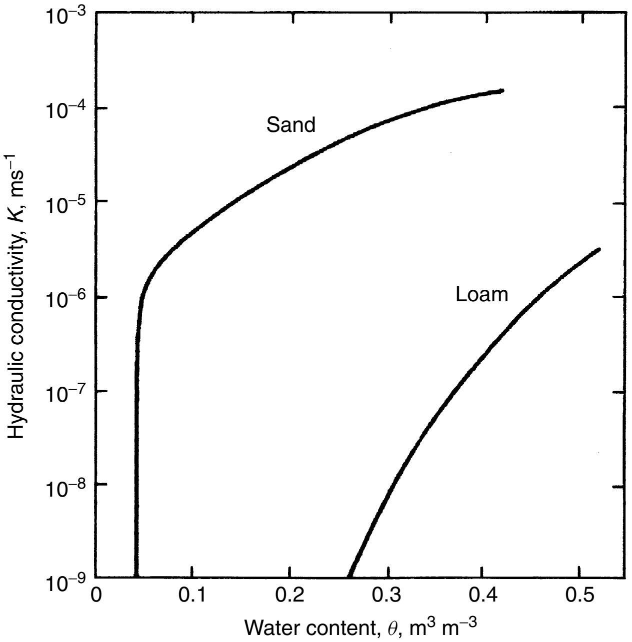

Figure 6. Effect of texture and soil moisture on hydraulic conductivity (10).

use with various soils; see Bouwer and Jackson (11) or Green et al. (12) for details.

Soil water content can significantly impact infiltration by (1) increasing the hydraulic conductivity, which increases infiltration, and (2) reducing the surface tension that draws moisture into the soil, which reduces infiltration. The net effect of these impacts depends on the water content itself, the water input rate, and duration and the distribution of hydraulic conductivity.

The *water retention characteristic* describes a soil's ability to store and release water and is defined by the relationship between soil moisture and the matric potential (Fig. 5). This is a power function relationship that has been described by Brooks and Corey (13) and Van Genuchten, (14) among others. The water tension characteristic is usually measured in air pressure chambers where the water content of a soil sample can be monitored over a wide pressure range (15).

The water retention relationship may actually change between drying and wetting due to the entrapment of air in soil pores (Fig. 7) (16). For practical applications, this effect, called *hysteresis*, is usually neglected (17).

PRINCIPLES OF SOIL WATER MOVEMENT

Through experiments on saturated water flow through sand beds, Darcy (18) found that the rate of flow, Q (L^3/T), through a cross-sectional area A (L^2), is directly proportional to head loss (e.g., water elevation difference), ΔH (L), and inversely to the flow path length, Δl (L):

$$Q = KA\frac{\Delta H}{\Delta l} \tag{3}$$

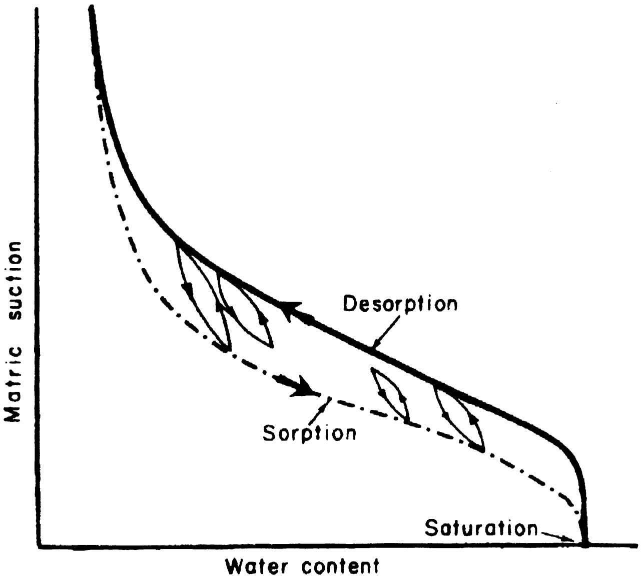

Figure 7. Changes in water retention characteristics between sorption and desorption (16).

Combining *Darcy's law* with the law of conservation of mass results in a description of unsaturated flow called *Richards equation* (19):

$$\frac{\partial\theta}{\partial t} = \frac{\partial}{\partial z}\left(\frac{K}{C}\frac{\partial\theta}{\partial z}\right) - \frac{\partial K}{\partial z} \tag{4}$$

where $C = -\partial\theta/\partial\psi$ is the water content change in a unit soil volume per unit matric potential, ψ change. The Richards equation is the basis for most simulations of infiltration and redistribution of water in unsaturated soil. Using some approximations, analytical solutions of the Richards equation are available (20,21) that show good agreement with observations (22). The Richards equation is based on saturated flow theory, and does not account for all of the processes active in natural systems, so it may not always perform well (23).

INFILTRATION ESTIMATION

Some basic principles that govern the movement of water into the soil can be used to predict infiltration. The *infiltration capacity*, f(L), is the maximum rate that a soil in a given condition can absorb water and generally decreases as soil moisture increases. If the *rainfall rate* is less than the infiltration capacity, then infiltration proceeds at the capacity rate. However, if the rainfall rate exceeds the infiltration capacity, then infiltration proceeds at the capacity rate, and the excess rainfall ponds on the surface or runs off. As the time from the onset of rainfall increases, infiltration rates decrease due to soil moisture increases, raindrop impact, and the clogging of soil pores, until a steady-state infiltration rate is reached (Fig. 8) (24). Existing infiltration models use empirical, approximate, or physical approaches to predict infiltration.(25)

Empirical. Empirical infiltration models generally utilize a mathematical function whose shape as a function of

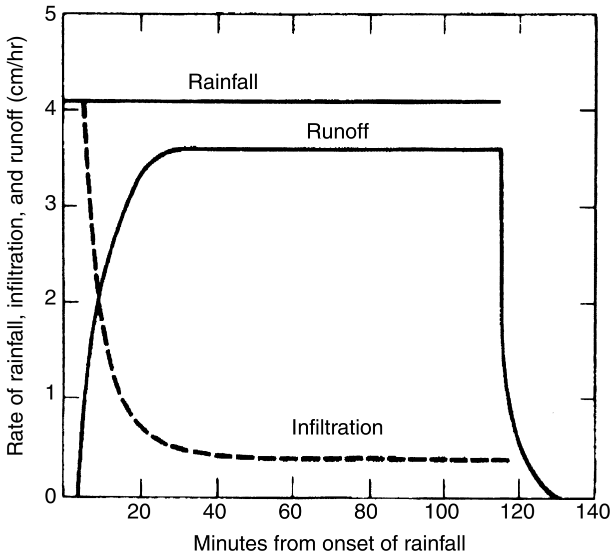

Figure 8. Idealized relationship between rainfall, infiltration, and runoff rates (24).

time, t, matches observations and then attempts a physical explanation of the process.

Kostiakov (26) proposed the simple infiltration rate, f(L/T) model:

$$f = \alpha\gamma t^{\alpha-1} \tag{5}$$

where α and γ are constants that have no particular meaning and must be evaluated by fitting the model to experimental data.

Horton's (27) infiltration model has been widely used in hydrologic simulation. It relates infiltration capacity to initial infiltration rate, and f_0, the constant infiltration rate at large times, f_c:

$$f = f_c + (f_0 - f_c)e^{-\beta t} \tag{6}$$

where β is a soil parameter describing the rate of decrease of infiltration.

Approximate. Analysis approximations to the Richards equation are possible if several simplifying assumptions are made. Most approximate infiltration models treat the soil as a semi-infinite medium, with the soil saturating above a wetting front.

Green and Ampt (28) assumed in a soil with constant hydraulic properties, the matric potential at the moving wetting front is constant, leading to a discontinuous change in soil moisture at the wetting front:

$$f = K\left[1 + \frac{(\varphi - \theta_i)S_f}{F}\right] \tag{7}$$

where S_f (L) is the effective suction at the wetting front, θ_i is the initial water content, and F (L) is the accumulated infiltration.

Phillip (29) proposed that the first two terms in a series of powers of $t^{1/2}$ could be used to approximate infiltration:

$$f = \tfrac{1}{2}St^{1/2} + A \tag{8}$$

where S is a parameter called sorptivity, t is time from ponding, and A is a constant that depends on soil properties. In this model, the infiltration rate approaches a constant equal to the hydraulic conductivity at the surface water content, and the wetting front advances without changing its shape and approaches a constant velocity.

Physical. Recent advances in numerical methods and computing has facilitated the practical application of the Richards equation to realistic flow problems. Such packages can simulate water infiltration and redistribution using the Richards equation and including precipitation, runoff, drainage, evaporation, and transpiration processes (30).

INFILTRATION MEASUREMENT

Infiltration rates can be measured at a point using a variety of methods described here, each appropriate for certain conditions. However, because of the large temporal and spatial variability of infiltration processes, catchment average infiltration rates may be desired, which can be obtained through the water balance analysis of rainfall–runoff observations (31).

Ring Infiltrometer. This simple method is most appropriate for flood irrigation or pond seepage infiltration. A cylindrical metal ring is sealed at the surface and flooded. Intake measurements are recorded until steady-state conditions are reached (32). If the effects of lateral flow are significant, then a double-ring infiltrometer can be used. Due to ponding conditions within the ring, observed infiltration rates are often higher than under natural conditions (33).

Sprinkler Infiltrometer. This method is appropriate for quantifying infiltration from rainfall. Artificial rainfall simulators are used to deliver a specified rainfall rate to a well-defined plot. Runoff from the plot is measured, allowing computation of the infiltration rate (34,35).

Tension Infiltrometer. The tension or disk infiltrometer employs a soil contact plate and a water column that is used to control the matric potential of the infiltrating water. By varying the tension, the effect of different size macropores can be determined (36,37).

Furrow Infiltrometer. This method is useful if information on infiltration of flowing water in irrigation furrows is desired. Either the water added to a small section of blocked off furrow to maintain a constant depth or the inflow—outflow of a furrow segment can be monitored to determine the infiltration characteristics of the system (38).

SOIL MOISTURE MEASUREMENT

Soil water content can be determined directly using gravimetric techniques or indirectly by inferring it from a property of the soil (39,40).

Gravimetric. The oven-drying soil moisture measurement technique is the standard for calibration of all other methods but is time consuming and destructive. The method involves obtaining a wet soil sample weight, drying the sample at 105 °C for 24 h, then obtaining the dry sample weight [see Eq. (2)].

Neutron Thermalization. High-energy neutrons are emitted by a radioactive source into the soil and are preferentially slowed by hydrogen atoms. The number of slow neutrons returning to the detector are a measure of soil moisture.

Gamma Attenuation. The attenuation in soil of gamma rays emitted from caesium-137 is directly related to soil density. If the soil's bulk density is assumed to be constant, then changes in attenuation reflect changes in soil moisture (41).

Time-Domain Reflectometry (TDR). TDR measures the soil's dielectric constant, which is directly related to soil moisture, by measuring the transmit time of a voltage pulse applied to a soil probe.

Tensiometric Techniques. This method measures the capillary or moisture potential through a liquid-filled porous cup connected to a vacuum gage. Conversion to soil moisture requires knowledge of the water retention characteristic.

Resistance. The electrical resistance or conductivity of a porous block (nylon, fiberglass, or gypsum) imbedded in the soil depends primarily on the water content of the block. However, because of salinity and temperature sensitivity, measurements of these sensors are of limited accuracy (42).

Heat Dissipation. Changes in the thermal conductivity of a porous block imbedded in the soil depend primarily on the water content of the block. The dissipation of a heat pulse applied to the block can be monitored using thermistors, then the soil water content can be determined from calibration information.

Remote Sensing. Soil moisture can be remotely sensed with just about any frequency where there is little atmospheric absorption (43). But, it is generally accepted that long wavelength, passive microwave sensors have the best chance of obtaining soil moisture measurements that contain little error introduced by vegetation and roughness and offer great potential to remotely sense soil moisture content with depth due to differential microwave absorption with varying dielectric constant (44).

SPATIAL AND TEMPORAL VARIABILITY

Natural soils exhibit considerable spatial heterogeneity in both the horizontal and vertical directions, and at all distance scales from the pore to the continent to a degree that it is difficult to capture this variability in routine measurements [45,46]. This large variations in soil properties, infiltration, and soil moisture over relatively small areas makes it difficult to transfer the understanding of processes developed at a point to catchment scales. Many hydrological models assume that a single spatially representative average soil property can be used to characterize catchment (or even larger) scale processes. It is clear from the nonlinear character of soil water processes that catchment average infiltration cannot be computed based on catchment average soil properties. It is also clear that the physical meaning of a soil property, say porosity, is relative to the volume over which it is averaged [47]. However, there is a need to understand and reduce this complexity for the purposes of prediction and management. Several approaches, including dividing the catchment into hydrologically similar subareas [48], various statistical approaches [49], and scaling and similarity theory [50,51] have made headway toward an understanding of infiltration and soil moisture spatial variability, but are not being widely used in practical applications.

One of the most important recent findings in this regard is the scale invariance of soil water movement(i.e., the Richards equation) remain uniform across spatial scales [52]. This new understanding of the underlying symmetry of the Richards equation may help to facilitate a workable scale invariant analytical soil water dynamical model.

Finally, there is acontinuing need for the observation of soil properties, soil moisture, and infiltration processes at multiple scales to facilitate understanding and prediction of these complex and socially significant processes. It is likely that remote sensing of soil moisture and other land surface factors will be instrumental in this respect.

ION EXCHANGE AND INORGANIC ADSORPTION

K. Kadirvelu
Jyotsna Goel
Centre for Fire, Explosives, and Environmental Safety
Timarpur, India

The presence of inorganic ions in water is of major concern for water quality because they can interfere with legitimate use of water for various applications. Inorganic ions, particularly heavy metals, are seriously questionable because of their toxicity and threat to human life and the environment.

Ion exchange and adsorption share so many common features in regard to removal of inorganic ions from water that they can be grouped together as unified processes for inorganic ion treatment. These processes involve the increase in concentration of a particular component at the surface or interface between two phases.

The objective of this article is to enumerate application of adsorption and ion exchange processes for inorganic ion removal from water. This article presents a review of potential adsorbents and ion exchangers for inorganic ion removal. It introduces important topics regarding inorganic ion removal by ion exchange and adsorption processes. Factors effecting metal removal are also presented and discussed in sections of the article. Research results from batch studies are presented to illustrate basic concepts. Accordingly, emphasis is placed on providing a review of adsorbents and ion exchangers available for inorganic ion removal.

ADSORPTION AND ION EXCHANGE: IN GENERAL

Adsorption involves, in general, the accumulation (or depletion) of solute molecules at an interface (including gas-liquid interfaces, as in foam fractionation, and liquid-liquid interfaces, as in detergency). Adsorbent surfaces are often physically and/or chemically heterogeneous, and bonding energies may very widely from one site to another. In discussing the fundamentals of adsorption, it is useful to distinguish between physical adsorption, involving only relatively weak intermolecular forces, and chemisorption, which involves, essentially, the formation of a chemical bond between the sorbate molecule and the surface of the adsorbent. The general features, which distinguish physical adsorption and chemisorption, are presented in Table 1.

Table 1. Distinction Between Physical Adsorption and Chemisorption (1)

Physical Adsorption	Chemical Adsorption
Low heat of adsorption (<2 or 3 times latent heat of evaporation.)	High heat of adsorption (> or 3 times latent heat of evaporation.)
Nonspecific.	Highly specific.
Monolayer or multilayer.	Monolayer only.
No dissociation of adsorbed species. Only significant at relatively low temperatures.	May involve dissociation. Possible over a wide range of temperature.
Rapid, nonactivated, reversible.	Activated, may be slow and irreversible.
No electron transfers, although polarization of sorbate may occur.	Electron transfer leading to bond formation between sorbate and surface.

Ion exchange is an effective means of removing heavy metals from wastewaters. It is a reversible chemical reaction, where the removal of heavy metals is accomplished by the exchange of ions on the resin for those in wastewater. In ion exchange, ions of positive charges (cations) and negative charges (anions) from the fluid (from aqueous solution) replace dissimilar ions of the same charge in solids. The ion exchanger contains permanently found functional groups of opposite charge-type. Cation exchangers generally contain bound sulfonic acid groups; less commonly, groups are carboxylic, phosphonic, and phosphinic, and so some resins involve quaternary ammonium groups (strongly basic) and amino groups (weakly basic).

Most ion exchangers in large-scale use are based on synthetic resins—either preformed and then chemically reacted as styrene or formed from active monomers. Natural zeolites were the first ion exchangers, and natural and synthetic zeolites are in use today.

Ion exchange may be thought of as a reversible reaction and of chemically equivalent quantities. A common example of ion exchange is the familiar water-softening reaction

$$\mathrm{Ca}^{++} + 2\mathrm{NaR} \Leftrightarrow \mathrm{CaR}_2 + 2\mathrm{Na}^{+} \quad (1)$$

where R represents a stationary univalent anionic site in the electrolyte network of the exchanger phase.

FACTORS AFFECTING INORGANIC IONS REMOVAL BY ADSORPTION

Factors affecting inorganic ion removal by adsorbent include (a) nature of the adsorbent (b) solution pH, (c) presence of foreign ions, and (d) temperature.

Nature of the Adsorbent

Surface Area and Pore Structure. Surface area with active functional groups is one of the principle characteristics affecting the adsorption capacity of an adsorbent. The adsorption capacity of a solid adsorbent is generally proportional to the specific surface area of the mass adsorbent; that is, the adsorption of certain solutes increases with an increasing surface area. Table 2 shows the physical properties of a few adsorbents that have been already employed for inorganic removal.

However, the specific surface area alone is frequently inadequate to explain the adsorption capacity of porous solids, such as activated carbons, for different solutes. In view of this, pore size distribution in activated carbon indicates that microspores contribute a major portion of the specific surface area.

Table 2. Properties of Adsorbents Employed for Inorganic Ion Removal (2–6)

Property	Calgon CAL	Coir-Pith Carbon	AC from *Arudo Donax*	AC Cloth	Carbon Aerogel
Surface area (m^2/g)	1100–1300	575	1142	1689	700
Porosity (%)	65.0	93.11	76.0	66.5	36.2
Micropore Volume (g/ml)	0.12	0.0913	0.47	0.964	0.10
Bulk density (g/ml)	0.56	0.12	0.5	0.13	0.644
Moisture content (%)	2.0	5.88	9.3	2.0	18.0
Ash content (%)	7.0	7.87	21.56	13.0	3.5

Depending on their preparation, active carbons also contain larger pores, known as macro and mesopores in the classification proposed by Dubinin (7) and now adopted by the International Union of Pure and Applied Chemistry (IUPAC) (8). The definition of the different types of pores is based on their width w, which represents the distance between the walls of a slit-shaped pore or the radius of a cylindrical pore. One distinguishes micropores, for which w does not exceed 2 nm; macropores, for which w exceeds about 50 nm; and mesopores of intermediate size (2.0–50 nm).

A linear relationship has also been demonstrated between the specific surface area and sorbate molecular size (9).

Chemistry of Adsorbent Surface. The nature and the presence of specific functional groups on the surface of the adsorbent impart certain characteristics that affect the adsorption process. It is now known that surface functional groups are formed during the carbon (adsorbent) activation process.

Attempts have been made to identify and estimate the surface oxygen chemical structures (functional groups) using several physical and chemical techniques, which include neutralization of acid and base (known as Boehm's method); desorption of the oxide layer; potentiometer, thermometric, and radiometric titrations; direct analysis of oxide layers by specific chemical reaction; Infrared (IR) spectroscopy; and X-ray photoelectron spectroscopy (XPS). The surface morphology and metal ion distribution adsorbent samples can be visualized via scanning electron microscopy (SEM). Figure 1 shows SEM micrograph for carbon aerogel equilibrated with Pb (II). SEM of activated carbon surfaces before and after the adsorbent was equilibrated with the metal ion solution clearly shows the presence of Pb (II) ions.

As a result of these investigations, various researchers have postulated the existence of functional groups, such as carboxyic, phenolic, lactonic, aldehydes, ketones, quinones, hydroquinone, anhydrides, and ethereal structures. Also, analysis of physicochemical properties of adsorbent ions provides a deep insight into adsorption mechanism involved during the adsorption process.

Solution pH

Extensive research investigations have been reported for adsorption of inorganic ions at different solution pH values (9–11). The dependence of adsorbent's adsorption capacity for inorganic ion removal from aqueous solution pH has been attributed to changes in surface chemical characteristics of adsorbent and species distribution of the inorganic ions varying with solution pH. In general, the cationic species removal will increase with increasing solution pH (Fig. 2), whereas in the case of inorganic ions present as anionic species, removal generally increases with decreasing pH, which is mainly because of electrostatic repulsion, which can be understood by removal of Cr (VI) by various adsorbents at lower pH range.

Specifically, pH affects the status of the outer hydration sheaths of the metal ion, metal speciation of inorganic ion in aqueous medium, complexation and solubility, and the electrochemical behavior of the carbon surface.

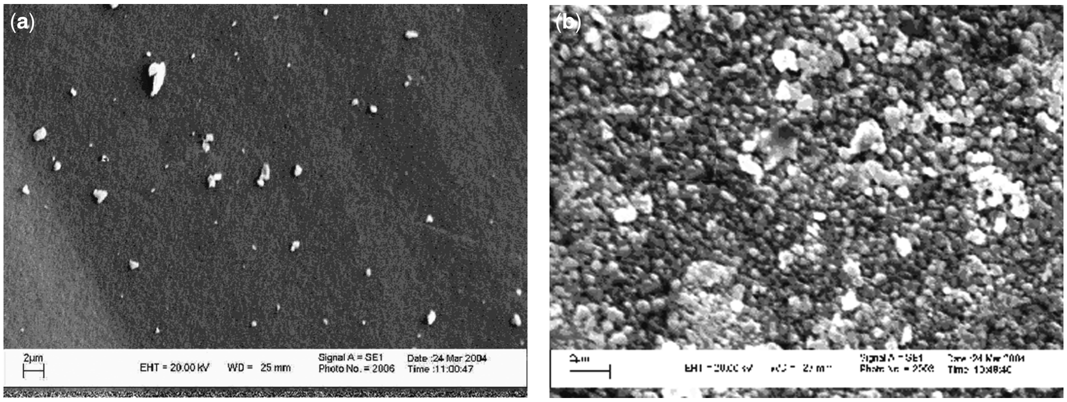

Figure 1. (**a**) SEM of carbon aerogel; (**b**) SEM of carbon aerogel loaded with lead.

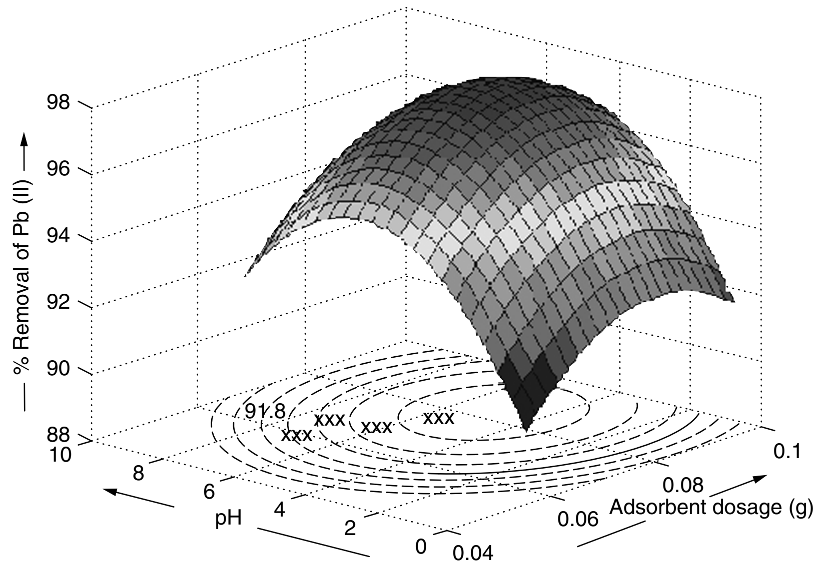

Figure 2. Plot for percent removal of Pb (II) versus pH and adsorbent dosage using carbon aerogel as adsorbent.

Figure 3 depicts possible inorganic ion removal mechanisms for carbon aerogel in relationship to pH, at which solution precipitation begins for Pb (II), Hg (II), and Ni (II). Figure 3 shows clearly that at any pH, the removal of metal ions is greater by adsorption in the presence of carbon aerogel than by precipitation in the absence of carbon. A rapid increase in percentage removal of metal ions is observed after pH 5.4 and 7.5 for Pb (II) and Ni (II), respectively, because of precipitation in the absence of carbon aerogel.

The adsorption of metal ions depends on both the nature of the adsorbent surface and the species distribution of the metal ions in the aqueous solution, which is, in turn, governed by solution pH. Removal noticed in a pH range of 3–5 for Pb (II) and Hg (II), because of their partial hydrolysis resulting in the formation of hydrolyzed metal ion species $[PbOH]^+$, $[HgOH]^+$ Pb $(OH)_2$, and Hg $(OH)_2$. In the case of Ni (II), the maximum adsorption range was shifted to 4–7, which may be because of formation of $[NiOH]^+$ and Ni $(OH)_2$ at these pH (12). Low solubilities of hydrolysis metal ion species may be another reason for maximum adsorption. At pH values below pH_{prec}, adsorption was hypothesized to be the primary removal mechanism. Also, it has been reported that metal removal by activated carbon was found to be inversely proportional to the solubility of the metal (13).

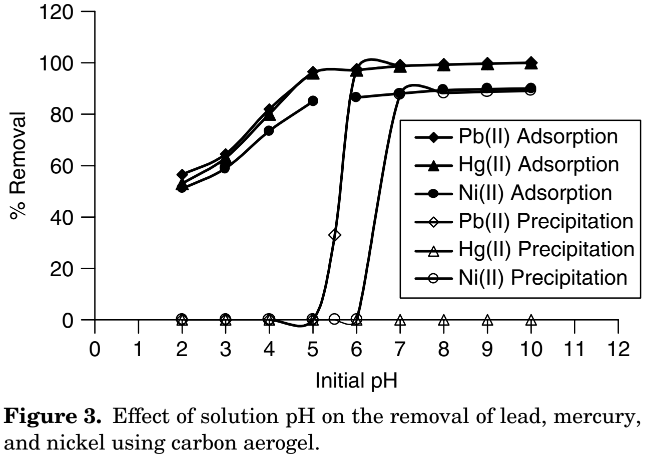

Figure 3. Effect of solution pH on the removal of lead, mercury, and nickel using carbon aerogel.

Namasivayam and Kadirvelu (14) reported an ion exchange phenomenon for Hg (II) removal by the formation of the following surface complexes when Hg (II) is present in the solution with the functional groups present on GAC (ACG-50).

$$2(C_XOH^+) + Hg^{2+} \longrightarrow (C_XO)_2Hg^{2+} + 2H^+ \qquad (2)$$

According to the surface complexation theory, Hg (II) removal increases as pH function increases can be explained on the basis of a decrease in adsorption competition between proton and metal ion species for the adsorbent surface sites by the decrease in positive surface charge, which results in a lesser columbic repulsion forward of the Hg (II) ion.

Presence of Foreign Ions

The presence of complexing ligands and competing adsorbates can alter metal removal from that observed in the mono-component system. The degree of competition is dependent on the type and concentration of competing ions, number of surface sites, and affinity of the surface for adsorbate and the ionic property of adsorbate. Presence of other cocations can influence the adsorption capacity of adsorbent with respect to one adsorbate. This phenomenon is illustrated in Fig. 4, where the adsorption equilibrium curve for Hg (II) removal by GAC is considerably effected by the presence of other metal ions like Cu (II) and Pb (II) (15,16). Similar results have been reported for the effect of EDTA on lead removal using GAC column studies (17).

Temperature Effect

As the process of adsorption is spontaneous, it is accompanied by a decrease in the system's free energy. A

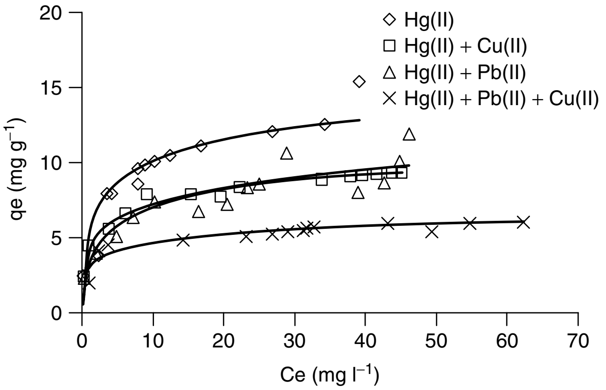

Figure 4. Equilibrium curve for Hg (II) ion in binary and tertiary system with Cu (II) and Pb (II) ions using GAC as adsorbent.

decrease in entropy always exists because of loss of degrees of freedom of the solute in passing from the dissolved state to the adsorbate state. It follows from the relationship

$$\Delta G = \Delta H - T\Delta S \tag{3}$$

that the adsorption process must always be exothermic; that is ΔH must have negative value regardless of the nature of interaction forces. An increase in temperature, therefore, will result in a reduction of the equilibrium adsorption capacity, whereas lower temperature will favor an increased capacity.

As reported by J. Goel et al. (6), according to the adsorption isotherm, the amount of Hg (II) by carbon aerogel increases with increasing temperature. Values of the thermodynamic parameters, such as ΔG^0, ΔH^0, and ΔS^0, describing mercury uptake by carbon aerogel were calculated using the following thermodynamic equations:

$$\Delta G^0 = -RT.\ln K \tag{4}$$

$$\Delta H^0 = [R \times T_1 \times T_2/(T_2 - T_1)] \times \text{Ln}\ (K_2/K_1) \tag{5}$$

$$\Delta S^0 = (\Delta H^0 - \Delta G^0)/T \tag{6}$$

where R is the gas constant and K, K_1, and K_2 are the equilibrium constant at temperature T, T_1, and T_2, respectively. The equilibrium constants was calculated from:

$$K = C_{\text{eq,s}}/C_{\text{eq,1}} \tag{7}$$

where $C_{\text{eq,s}}$ and $C_{\text{eq,1}}$ were the equilibrium concentration of Hg (II) in solution and on the adsorbent, respectively. Values found for ΔG^0, ΔH^0, and ΔS^0, as presented in Table 3, are indicative of the spontaneous nature of the uptake process.

The positive ΔH^0 value confirms the endothermic nature of the sorption process. As diffusion is an endothermic process, it would be expected that increased solution temperature would result in increased uptake of Hg (II) ions from aqueous solution.

Anoop Krishnan et al. (18) has reported that the endothermic nature of the adsorption process, where uptake of mercury on the bagasse piths activated carbon, is favored by increase in temperature. Panayotova (19) and Raji et al. (20) have also presented alike thermodynamics for the uptake of copper and mercury, respectively.

Table 3. Thermodynamic Parameters for the Mercury Adsorption on Carbon Aerogel

Temperature (K)	% Removal	ΔG^0 (J mol^{-1})	ΔH^0 (Jmol^{-1})	ΔS^0 (Jmol$^{-1}K^{-1}$)
293	60	−987.714	+25708.82	+91.11444

ADSORPTION MECHANISM—ION EXCHANGE PROCESS

With some of the adsorbents, like coir pith carbon, adsorption mechanisms have been explained based on the ion exchange model (12). A pure carbon surface is considered to be nonpolar, but in actual practice, some carbon−oxygen complexes C_x O, CO_x and C_xO_2 are usually present (21−23). The surface oxygen complexes hydrolyze water molecules as shown below:

$$C_xO + 2H_2O \longrightarrow C_xOH_2{}^{2+} + 2OH^- \tag{8}$$

$$CO_x + xH_2O \longrightarrow C(OH)^x + xOH^- \tag{9}$$

$$C_xO^2 + H_2O \longrightarrow C_xO^{2+} + 2OH^- \tag{10}$$

As the carbon is prepared with H_2SO_4, $(NH_4)_2S_2O_8$, and $NaHCO_3$, groups such as C_xONa^+, $C_xONa_2{}^{2+}$, C_xSO_3Na, and C_xONH_4 are also present. Na^+ in the above groups also exchange with H^+ in the medium as follows:

$$C_xONa^+ + H^+ \longrightarrow C_xOH^+ + Na^+ \tag{11}$$

$$C_xONa^+ + 2\ H^+ \longrightarrow C_xOH_2{}^{+2} + Na^+ \tag{12}$$

$$C_xONa_2{}^{2+} + H^+ \longrightarrow C_xOH_2{}^{+2} + 2\ Na^+ \tag{13}$$

$$CxSO_3Na + H^+ \longrightarrow C_xSO_3H + Na^+ \tag{14}$$

Excess of Na^+ was introduced into carbon where it was washed with $NaHCO_3$ to neutralize any free sulfuric acid (H_2SO_4) during the preparation of carbon. When metal ion is present in solution, its adsorption will free some H^+ and the pH increase will be lower than in the blank. At the same time, Na^+ will also be released according to reactions as given below:

$$2C_xOH^+ + M^{2+} \longrightarrow (C_xO)_2M^{2+} + 2H^+ \tag{15}$$

$$C_XOH_2{}^{2+} + M^{2+} \longrightarrow C_XOM^2 + 2H^+ \tag{16}$$

$$2C_xONa^+ + M^{2+} \longrightarrow (C_xO)_2M^{2+} + 2Na^+ \tag{17}$$

$$C_XONa_2{}^{2+} + M^{2+} \longrightarrow C_XOM^2 + 2Na^+ \tag{18}$$

$$2C_xSO_3H^+ + M^{2+} \longrightarrow (C_xSO_3)_2M^+ + 2H^+ \tag{19}$$

$$2C_xSO_3Na + M^{2+} \longrightarrow (C_xSO_3)M + 2Na^+ \tag{20}$$

which indicates that apart from exchange of H^+ ions on the adsorbent with M^{2+} ions, significant amount of Na^+ ions, which were present in the adsorbent, were also exchanged with M^{2+} ions.

ION EXCHANGERS FOR INORGANIC ION REMOVAL

By ion exchange, undesirable ions are replaced by others, which do not contribute to contamination of the environment. The method is technologically simple and enables efficient removal of even traces of impurities from solutions. Examples of selective removal of heavy metal ions by ion exchange are presented in Table 4. They include removal of Pb (II), Hg (II), Cd (II) Ni (II), V (IV, V), Cr (III, VI), Cu (II), and Zn (II) from water and industrial wastewaters by various means of modern type of ion exchangers.

By ion exchange, either all ions can be removed from a solution or substances are separated. Therefore, selective removal of ionic contamination and complete deionization can be distinguished. The choice between selective removal and complete deionization depends mainly on the composition of solution and on the extent of decontamination required.

Hg (II) ions sorption on the ion exchanger Imac TMR (Styrenedivinylbenzene Copolymer) can be described by means of the following reactions:

$$2\text{R–SH} + \text{Hg}^{2+} \longrightarrow \text{R–S–Hg–S–R} + 2\text{H}^{+} \qquad (21)$$

$$\text{RSH} + \text{HgCl}^{+} \longrightarrow \text{R–S–HgCl} + \text{H}^{+} \qquad (22)$$

where R is the styrenedivinylbenzene copolymer. After Hg (II) ions sorption, the ion exchanger Imac TMR can be regenerated by means of the concentrated hydrochloric acids.

Metal ions and other cationic impurities are removed on the cation exchanger, whereas chromates are removed on the anion exchangers:

$$\text{nRSO}_3\text{H} + \text{M}^{+} \longrightarrow \text{nRM}^{n+} + \text{nH}^{+} \qquad (23)$$

$$2\text{ROM} + \text{CrO}_4{}^{2-} \longrightarrow \text{R}_2\text{CrO}_4 + 2\text{OH}^{-} \qquad (24)$$

$$\text{R}_2\text{CrO}_4 + \text{CrO}_4{}^{2-} + \text{H}^{+} \longrightarrow \text{R}_2\text{Cr}_2\text{O}_7 + \text{OH}^{-} \qquad (25)$$

The NaOH solutions are applied for anion exchanger regeneration. Further developments of conventional ion exchangers, like polystyrenesulphonate cation exchangers and strongly basic anion exchangers, were aimed at large exchange capacity and better chemical, thermal, and mechanical stability. Kinetic capability of ion exchangers could be improved by means of macroporous ion exchangers developed in the 1970s. The range of application of the ion exchange method was remarkably extended, first by invention and application of new organic and inorganic ion exchangers.

ADSORBENTS FOR INORGANIC ION REMOVAL

Large numbers of adsorbents have been developed so far for the removal of inorganic ions, which primarily

Table 4. Selective Removal of Heavy Metal Ions by Ion Exchangers

Metal Ion	Ion Exchangers	Composition and Functional Groups
Pb (II)	Leawtit TP 207 (24)	Chelating ion exchanger with functional iminodiacetate group
	Ethanotricarboxylate, 1,1-ddicarboxylate-2-etanophosphonate (25)	Gel type Copolymer Of Vinyl benzene Chloride, Styrene and Divinyl Benzene
	Polyacrylamidoglycol Resin (26)	Amide, OH and carboxylic groups
	Clinoptilolite (27)	Aluminosilicate structure
Hg (II)	Imac TMR	Styrenedivinylbenzene Copolymer
	Varian BTAM (Nike), Varian BTKM, Varian BSM, Ionac SR-3 (28–31)	Containing nitrogen and sulphur functional group (22), Thiocarbamate group (23), Mercapathile group (24), Thiourea functional group (25)
	Dowex A-1 (32)	Iminodiacetate group
Cd (II)	Dowex 50 W-X4	Polystyrenesulphonic cation exchanger
	Diphonix (33)	Sulphonic groups and diphosphonic groups
	KB-2 and KB-2-12P (34)	Polyacrylate carboxylic cation exchangers
	Phillipsite and Chabazite (35)	Natural zeolite from volcanic rocks of Central Italy
Ni (II) and V (IV, V)	Wofatit CA-20 (36)	Macro porous carboxylic cation exchanger
	Chelex −100 (37)	Iminodiacaetae ion exchanger with Na/H/Ni in exchange system
	Sodium titnate, $Na_4Ti_9O_{20}$ (38)	Layered material with exchangeable Na ions in the titanium oxide layer.
Cr (III, VI)	Lewatit MP-500A (39)	Basic anion exchanger
	Amberlite IR-120 (40)	Polystyrenesulphone cation exchanger

Table 5. Summary Table of Maximum Reported Adsorption Capacities (mg/g)

Sorbent	Source	Cd (II)	Cr (III)	Cr (VI)	Hg (II)	Pb (II)
Bark	(41–44)	32	19.45		400	182
CPEI cotton	(45)				1000	
Chitin	Cr, Hg, Pb (46)	558	92		100	796
Chitosan	(47, 48)	16.50		57	1123	58
Clay	(49, 50)	28				116
Dead biomass	(51)			43.0		
Leaf mould	(46–52)				150	1587
Lignin	Cd, Cr, Hg and Pb (46)	87	17		632	1587
Modified wool	(53)	46.65				
Moss	(54, 55)	5.058	76	43.9	16.2	135
Peat	(54, 55)					
Sawdust	(56)			16.05		230

Peanut hull carbon	(64)	89.0			220.0	210.0
Furnace Sludge	(65)	7.4				68.0

include activated carbon prepared from a variety of materials of biological origin, industrial wastes, dead biomass, organic wastes, etc. Besides, several low-cost adsorbents such as chitin, chitosin, clay, fly ash, peat, moss, zeolites, xanthates, seaweed/algae/alginate, lignin, and bark/tannin-rich material have also been explored for heavy metal containing wastewaters (37–56). Table 5 presents some of the highest adsorption capacity reported for various low-cost adsorbents.

Although a significant number of low-cost adsorbent materials from sources, the commercial activated carbon (CAC) is still being used intensively to date. Based on its size and shape, activated carbon is classified as follows: Powder (PAC), granular (GAC), Fibre (ACF), and cloth (ACC). As a result of the different sources of raw materials, the extent of chemical activation, and the physicochemical characteristics, each type of activated carbon has its specific application with respect to physicochemical properties, as well as depending on the inherent advantage and disadvantages in wastewater treatment.

IRON

William R. Roy
Illinois State Geological Survey
Champaign, Illinois

CHEMISTRY OF IRON

The average concentration of iron in the earth's crust is about 5%, and it occurs in a wide variety of oxide, carbonate, silicate, and sulfide compounds either as metallic ores or in rock-forming minerals. Iron also occurs naturally in water from the dissolution of iron-containing minerals. Iron in water can occur in a dissolved form, a colloidal form that is combined with organic matter, and as suspended, iron-containing particles. Dissolved iron occurs in water in two oxidation states: ferrous iron, Fe (II), and ferric iron, Fe (III). In solution, iron can occur as a cation (Fe^{2+}) and in combination with other ions to form complexes and neutral ion pairs. Iron does not generally occur as the trivalent cation (Fe^{3+}) in significant concentrations in water. Trivalent iron generally exists in combination with other constituents. Depending on the occurrence of anions, such as sulfate, carbonate, and phosphate, and the pH and reduction-oxidation potential (E_h), the major iron species found in natural waters include a sulfate complex (${FeSO_4}^0$),

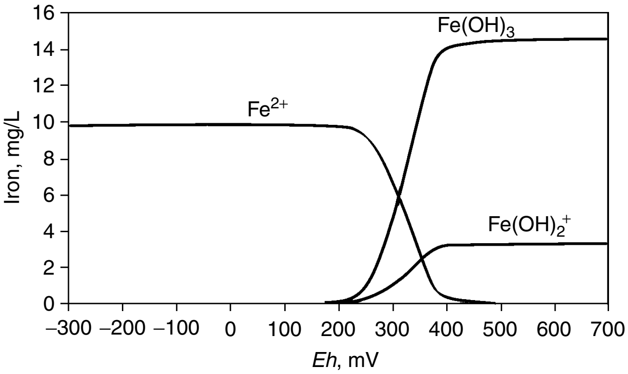

Figure 1. The distribution of 10 mg/L of iron in water at 15 °C and pH 7.0 as a function of oxidation-reduction potential (*Eh*).

a carbonate form [$Fe(HCO_3)_2$], phosphate complexes ($FeHPO_4{}^0$, $FeH_2PO_4{}^+$), and various hydroxide species such as $FeOH^+$, $Fe(OH)_2{}^+$, $Fe(OH)_3{}^0$, $Fe(OH)_4{}^-$, and $FeOH^{2+}$. The relative proportion of ferrous iron and ferric iron depends on the E_h of the water; ferrous iron is the dominant form in oxygen-poor water (reducing conditions). In oxygen-rich water (oxidizing conditions), ferric forms of iron dominate. For example, in a solution containing 10 mg/L of iron [Fig. 1], about 98% of the iron would occur as Fe^{2+} in a relatively reducing system. At an *Eh* greater (i.e., more oxidizing) than about 200 mV, ferrous iron is converted to the ferric forms $Fe(OH)_3{}^0$ and $Fe(OH)_2{}^+$. At an *Eh* of 700 mV, about 96% of the iron occurs in ferric forms. When a groundwater sample is collected, it may initially appear clear. However, if the sample is allowed to react with air and oxidize, the ferrous iron in the initially clear, reduced sample will be converted to ferric forms:

$$4Fe^{2+} + O_2 + 8OH^- + 2H_2O \rightleftharpoons 4Fe(OH)_3 \tag{1}$$

As a consequence, the sample may develop a reddish-brown color, and iron-containing particles may settle at the bottom of the container. The rate at which ferrous iron is oxidized depends on temperature, pH, and the amount of dissolved oxygen and iron.

Microorganisms can influence the oxidation state and distribution of iron in water. Iron can be used as an energy source via oxidation by microbial activity or reduced because iron can act as an electron acceptor. For example, *Crenothrix* and *Leptothrix* are diverse groups of iron-precipitating bacteria that are widely distributed in freshwater and soil. After ferrous iron is oxidized to the sparingly soluble ferric form, it may precipitate as ferric hydroxide. The bacterial cell sheaths can become coated with the precipitate, and the resulting gelatinous mass can clog water pipes and drains. There are bacteria and fungi that can reduce ferric iron. However, much less is known about iron-reducing microorganisms (1). The *Geobacter* are a group of bacteria that can reduce ferrous iron.

HEALTH AND REGULATORY ISSUES

Iron is not toxic in human consumption. Iron is an essential element for the formation of hemoglobin. The recommended dietary allowance for iron in healthy adults is 10 mg per day for men and 15 mg per day for premenopausal women (2). Dissolved iron in potable water is more of a nuisance than a potential heath issue. It can impart an unpleasant metallic taste to drinking water and alter the taste of food cooked in the water. The taste threshold for ferrous iron is about 0.1 mg/L. Concentrations exceeding 0.3 mg/L of iron can stain plumbing and clothing (3). The secondary maximum contaminant level for public water supplies is 0.3 mg/L, and 1.0 mg/L for freshwater aquatic life (4). However, bioassays by Roy et al. (5) suggested that concentrations less than 1.0 mg/L may be toxic to freshwater aquatic life.

LEVELS OF IRON IN WATER

The amount of dissolved iron in water depends on pH and *Eh*, but concentrations of less than 0.01 to 10 mg/L are typical for natural waters (6). Well-aerated surface water usually contains less than 0.05 mg iron/L. Iron concentrations in aquifers in Illinois have ranged from <0.05–21 mg/L (7). Iron in acid-mine drainage from coal mines has ranged from 10–5,625 mg/L (5,6).

SOLUBILITY OF IRON IN WATER

The amount of dissolved iron in water can be limited by the solubility of iron-containing solid phases. Schwab and Lindsay (8) concluded that when $pH + pE$ (pE is related to the redox potential *Eh* by $pE = (EhF)/(2.3RT)$ where $R =$ gas constant, $T =$ absolute temperature, and $F =$ Faraday constant) is less than 8.5, the concentration of ferrous iron in groundwater is limited by the solubility of siderite, $FeCO_3$:

$$Fe^{2+} + CO_3{}^{2-} \rightleftharpoons FeCO_3 \tag{2}$$

When $pE + pH$ is greater than 8.5, the solubility of ferrosic hydroxide, $Fe_3(OH)_8$, limits the amount of ferrous iron:

$$2Fe^{3+} + Fe^{2+} + 8H_2O \rightleftharpoons Fe_3(OH)_8 + 8H^+ \tag{3}$$

When the concentration of iron is greater than the solubility product of either siderite or ferrosic hydroxide, the iron precipitates, from solution. Ferrosic hydroxide is thermodynamically unstable, and other minerals may form, causing ferrosic hydroxide to dissolve. For example, amorphous ferric hydroxide, [$Fe(OH)_{3,a}$] and goethite (α-FeOOH) are less soluble than ferrosic hydroxide and given time, may control iron solubility. Moreover, amorphous ferric hydroxide can dehydrate (9) to form the more stable mineral hematite (Fe_2O_3):

$$2\,Fe(OH)_{3,a} \rightleftharpoons Fe_2O_3 + 3H_2O \tag{4}$$

The prevalent form of iron in surface water in the iron–carbon dioxide–water system can be illustrated by constructing a pH–pE stability diagram [Fig. 2]. This type of diagram illustrates which forms of iron are most thermodynamically stable at various values of pH

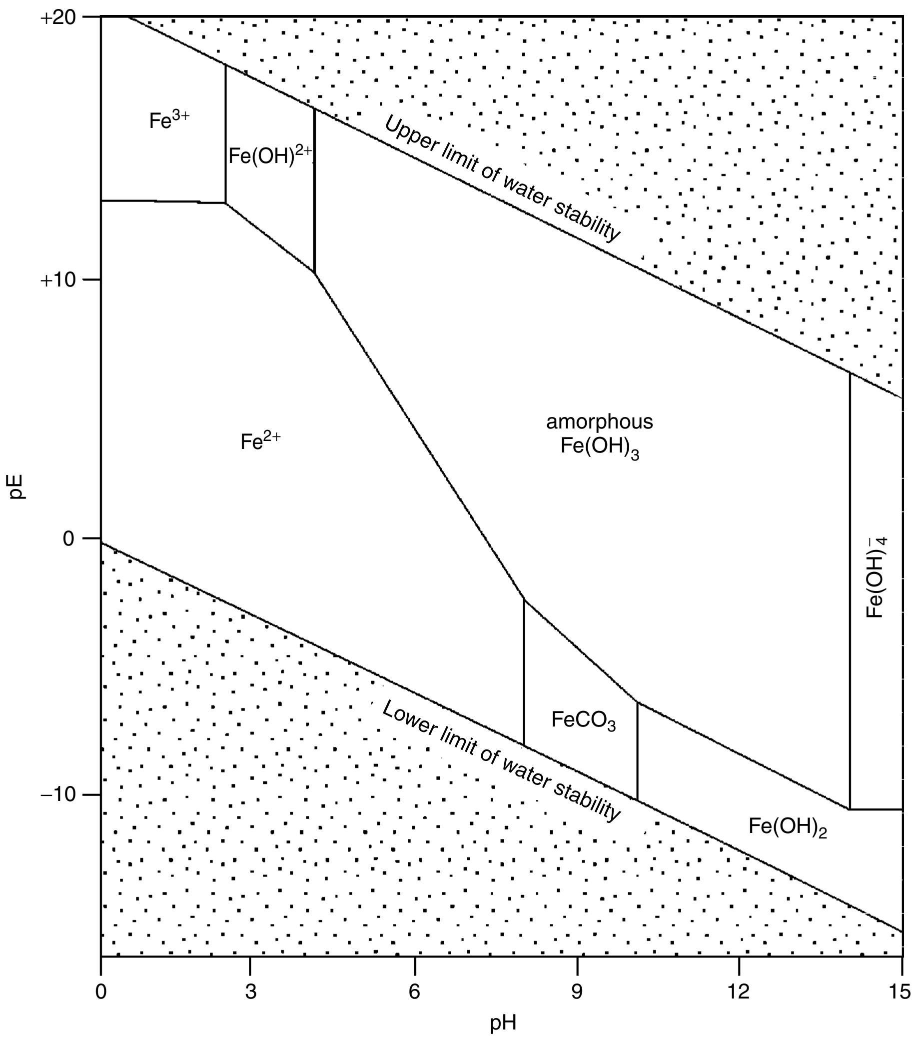

Figure 2. pE–pH diagram for the iron–carbon dioxide–water system at 25 °C and 1 atm (11).

and pE rather than at specific concentrations. Ferrous iron is the stable form in equilibrium with relatively acidic and reducing waters, whereas ferric iron, as both Fe^{3+} and FeOH^{2+}, is in equilibrium with acidic and oxidizing waters. In relatively less oxidizing and alkaline waters, the most thermodynamically stable forms may be amorphous iron hydroxide, siderite (FeCO$_3$), or solid ferrous hydroxide.

The concentration of iron in water may also be influenced by sorption–desorption interactions with mineral surfaces. Iron oxides and hydroxides have been studied as sorbents for other metals, but ionic iron is subject to the same electrostatic interactions that attract cations to clays and organic matter. Ferric iron can be sorbed by silica, clay minerals, and iron and manganese oxides (10). The sorption of ferrous iron has not been studied in detail.

METHODS FOR DETERMINING IRON

The amount of iron dissolved in water can be determined quantitatively by atomic absorption spectroscopy (AAS), atomic emission spectroscopy, and by colorimetric methods (12). In the AAS method, a water sample is aspirated into an air-acetylene flame and atomized. A monochromatic beam of light at a wavelength corresponding to iron is passed through the flame. The amount of light energy sorbed is proportional to the amount of iron present. When analyzed at a wavelength of 248.3 nm, the optimal concentration range for iron is about 0.3 to 10 mg/L.

Dissolved iron can be determined by argon-supported inductively coupled plasma (ICP) spectroscopy. In ICP, the liquid sample is aspirated into a high-temperature (6000–8000 K) flame, and atomic emission is measured to determine the concentration of the iron present. The concentration of iron is proportional to the intensity of the emissions. Iron has many such emission lines in its spectrum, but the wavelength of 259.94 nm is commonly used for concentrations ranging from about 0.007 to 100 mg/L.

Dissolved iron also can be determined by the phenanthroline method. In this method, iron in solution is reduced to the ferrous form, and then allowed to react with 1, 10-phenanthroline to form a reddish-orange product. The absorbance of the complex is measured in the range of 460–520 nm. Both AAS and ICP methods determine total iron, but the amount of ferric and ferrous iron can be determined separately by the phenanthroline method (13).

METHODS FOR REMOVING IRON FROM WATER

The presence of large concentrations of dissolved iron is a common water-quality problem, especially for groundwater (1). Methods for removing iron are summarized in Lehr et al. (3) and Vigneswaran and Visvanathan (2). The oxidation of soluble, ferrous iron into relatively insoluble ferric iron, followed by filtration of the suspended mass is common to many of the methods. Depending on its concentration in the untreated water, the oxidation of ferric iron can be promoted by aeration, catalytic oxidation with manganese oxides, and chlorination. Household water softeners are designed to remove calcium and magnesium from hard water using an ion exchange resin, but they can also remove dissolved iron. Lime softening of municipal water supplies can also promote the precipitation of ferric iron. The presence of iron-fixing bacteria may necessitate the use of relatively large amounts of bleach ("shot chlorination") to reduce the amount of iron in the final product.

ISOTOPES

Aldo Conti
Frascati (RM), Italy

Isotopes are atoms with the same atomic number, **Z**, but different atomic weight, **A**. Different isotopes, therefore, have the same chemical but different physical properties, such as melting and boiling point. The name isotope means "at the same place" and comes from the periodic table, where different isotopes of the same element are at the same place. The scientific way of labeling isotopes reflects this. They have the symbol of the corresponding element, but followed by a hyphen and the number of nucleons (neutrons and protons) of the isotope. So, C-12 is the normal carbon (six protons and six neutrons) and C-14 is a heavy unstable isotope (six protons and eight neutrons).

Isotopes of the same element share the same chemical properties because they depend only on the number of protons, Z. But different isotopes can have very different weights, which is particularly evident in hydrogen. Normal hydrogen has only one proton and no neutrons. Deuterium, or H-2, has one neutron and its weight is nearly twice that of hydrogen. Then, tritium, H-3, has two neutrons and is three times as heavy, which is the reason why, when deuterium combines with oxygen, the resulting molecule is called heavy water. Due to the extra weight of deuterium, heavy water boils at 101.42 °C (214.56 °F) and freezes at 3.81 °C (38.86 °F), at standard pressure. The difference in weight affects the speed of chemical reactions involving water. For this reason, heavy water is not really safe to drink. Experiments performed with mice have shown that large amounts of heavy water in the body can inhibit mitosis, which affects rapidly dividing tissues, such as the stomach lining.

Isotopes do not differ only in physical properties. The extra neutrons make some of the nuclei highly unstable, which is the reason that some isotopes are radioactive. A typical example is uranium. Its isotopes, such as U-235, decay radioactively following a long chain, which leads to lead. Some of this decay involves a neutron becoming a proton by emitting an electron. In this case, the nucleus becomes a new element, with the atomic number increased by one. The energy emitted during the decay can be harvested in nuclear plants or used destructively in atomic bombs.

The instability of their nuclei makes isotopes useful for many applications. A famous one is carbon dating. Carbon comes mainly in two isotopes, the normal C-12 and the heavy, unstable, C-14. When an organism grows, it uses them in the same proportion in which they are found in the environment. After the death of the organism, the ratio changes continuously, as the heavy C-14 decays. C-14 has a half life of 5730 years, which means that after this period half of it has gone. By this method, it is possible to date any biological remains or artifact up to about 50,000 years old. For older objects, the amount of C-14 becomes too small to be measured reliably. Isotopes are often used as labels. By replacing a stable atom in a molecule with an unstable radioactive isotope, it becomes possible to follow the chemical reactions the molecule undergoes. Our ability to detect radioactive isotopes makes them very useful in the fields of medicine and biology, where they are used as tracers.

ISOTOPE FRACTIONATION

Gholam A. Kazemi
Shahrood University of
Technology
Shahrood, Iran

INTRODUCTION

The following paragraph extracted from the major textbook by Bowen (1) describes fractionation as it is dealt with in general chemistry. The subsequent paragraph defines fractionation in general hydrochemistry. Then, isotope fractionation is discussed.

In general chemistry, fractionation is the separation of a mixture, usually of chemically related components, into fractions that possess different properties. A mixture of liquids having different boiling points, may be separated by collecting fractions that boil at different temperatures in a fractionating column. This is a long, vertical column containing plates or bubble caps attached to a still. As a consequence of internal reflux, a gradual separation occurs between high and low boiling point fractions of the liquid mixture.

In hydrochemistry, the fractionation factor is a ratio which shows the depletion or addition of ions in rainwater compared to seawater (2). In other words, the fractionation factor is the ratio of two ions in rainwater to the ratio of the same ions in seawater. For example, for Cl^- relative to Na^+, the fractionation factor F_{Na} is (2):

$$F_{\mathrm{Na}} = \frac{(\mathrm{Cl/Na})_{\mathrm{rainwater}}}{(\mathrm{Cl/Na})_{\mathrm{seawater}}}$$

In this equation, the units of concentration can be mg/l, mmol/l, meq/l, etc.

Example: What is the fractionation factor of Na for a rainwater sample whose chloride and sodium concentrations are 1 and 0.5 mg/l, respectively?

$$\mathrm{Cl/Na}_{\mathrm{rainwater\ sample}} = 1/0.5 = 2$$

$$\mathrm{Cl/Na}_{\mathrm{seawater}} = 1.81$$

$$F_{\mathrm{Na}} = \frac{(2)}{(1.81)} = 1.11$$

A fractionation factor greater than unity indicates that the rainwater sample is depleted (in comparison to seawater) in the ion in question. If it is less than unity, it shows the enrichment (in comparison to seawater) of the sample in the ion. Appelo and Postma (2) also propose the fractionation factor as a quantitative approach to find the activity of a single species that forms part of a given total concentration, for example, for HCO_3, $m_{HCO_3^-} = \alpha \times \Sigma CO_2$, where α is the fractionation factor. Some researchers use "enrichment factor (Ef)" in an equation slightly different from the fractionation factor to deduce source/s of solutes in atmospheric precipitation (3,4). If the Ef is greater than unity, the ion in question (in the sample) is derived partly or wholly from a source other than oceanic origin. If it is less than unity, the ion could have been derived wholly from oceanic sources:

$$\mathrm{Ef} = \| \frac{(\mathrm{Ion/Cl})_{\mathrm{sample}}}{(\mathrm{Ion/Cl})_{\mathrm{seawater}}}$$

In this example, the enrichment factor equals 0.91.

$$\mathrm{Ef} = \frac{(0.5)}{(0.55)} = 0.91$$

DEFINITION

Isotope fractionation is defined by Domenico and Shwartz (5) as a change in an isotopic ratio (for example, $^{18}O/^{16}O$) because of a chemical reaction (for example, water changes to water vapor). It is also defined by Coplen (6) as the fractionation or partitioning of isotopes by physical or chemical processes which is proportional to the differences in their masses. Coplen also classifies isotopic fractionation processes into two categories, chemical and physical isotopic fractionation processes: physical processes such as ultrafiltration or gaseous diffusion of ions or molecules. Chemical processes are those that lead to redistribution of the isotopes of an element among phases or chemical species and are divided into two broad categories equilibrium isotopic reactions and kinetic isotopic reactions (6).

Gilreath (7) in a simple yet valuable text describes the fundamentals of isotope fractionation in detail and refers to it as "isotope separation." Anyone intending to deal with isotope fractionation is advised to consult this text first. The point of primary importance is that fractionation of isotopes is important in the geologic environment *only* for elements of low atomic number. Bowen (1) describes three main processes which cause fractionation: (1) isotope exchange reactions; (2) unidirectional reactions; and (3) physical processes such as evaporation, condensation, crystallization, melting, adsorption, desorption, and diffusion. Isotopes may also be fractionated in the laboratory by a variety of means (URL Ref. http://www.c14dating.com/frac.html). One method that may result in considerable fractionation during isotopic analysis is the recently introduced technique of secondary-ion mass spectrometry (SIMS) (8).

The following are the factors that control the rate of isotope fractionation:

1. Fractionation is minimized when reactions are fast (9).
2. The higher the mass difference between various isotopes of the element, the more effective the fractionation process. Deuterium, for example, has the largest mass difference from common hydrogen compared to isotopes of other elements. Hence, it is subject to greater fractionation.

3. Isotope fractionation decreases as temperature increases—at finite temperatures, all isotopic species are well mixed (6).
4. Isotopic exchange between minerals and water in deep, basinal flow systems or in geothermal systems induced by high temperature helps the fractionation process to proceed (5).
5. In evaporation from a pond, fractionation is more efficient if the vapor produced is constantly removed, for example, by wind (10).

Fractionation Factor

The fractionation factor is the ratio of isotopes (for example, $^{18}O/^{16}O$) in a liquid phase to the same ratio in the vapor phase;

$$\alpha = \frac{(^{18}O/^{16}O)_{\text{liquid}}}{(^{18}O/^{16}O)_{\text{vapor}}} \tag{11}$$

or more clearly/generally defined by Haldorsen et al. (11) "as the increase or decrease of a given isotope in a substance that undergoes a phase change or simply in terms of delta notation:

$$\alpha = \frac{1000 + \delta^{18}O_{\text{liquid}}}{1000 + \delta^{18}O_{\text{vapor}}}$$

Example: In the condensation of water vapor to liquid, typical values of $\delta^{18}O$ for the liquid and vapor are, −5% and −14%, respectively. Therefore, the fractionation factor is,

$$\alpha = \frac{1000 + (-5)}{1000 + (-14)} = \frac{995}{986} = 1.0092$$

Each fractionating process results in a specific fractionation factor. For example, the oxygen fractionation factor in freezing differs from that from condensation. The former and the latter are 1.0111 and 1.003, respectively. This means that freezing is more effective than condensation for isotope fractionation; freezing leads to stronger fractionation than condensation.

Fractionation factors approach unity as temperature increases; when $\alpha = 1$, the isotope ratios become equal in both phases being considered, and hence no further isotopic fractionation can occur (1). Higher fractionation factors mean more effective fractionation processes.

Isotopic Fractionation Curve

A curve defines the equilibrium isotope fractionation between coexisting phases as a function of temperature (1). It usually takes the form of an exponentially decreasing curve; there is a negative correlation between isotope fractionation and temperature. The shape of this curve is different for different isotopes.

Fractionation of Various Environmental Isotopes

As can be inferred from the information provided so far, isotope fractionation is an extensive topic in chemistry/geochemistry and has been dealt with in detail in many references such as Bowen (1), Gat (12), Gilreath (7), and Ottonello (13); the last is a thorough mathematical treatment of the topic. Here, in the *Encyclopedia of Water*, the discussion of isotope fractionation is limited to the isotopes of hydrogen and oxygen, specifically, the atoms that form the water molecule, as well as other isotopes that are of frequent use in water related/hydrologic studies. The latter group includes isotopes of the elements C, N, Cl, S, Sr, and less used U, Th, and Si. These are, often, referred to as environmental isotopes (6). Some workers such as Haldorsen et al. (11) classify the environmental isotopes into two groups: hydrologic isotopes (O, D, T) and biochemical isotopes (C, N, S). Although this classification covers only a limited number of environmental isotopes, it is sound for fractionation. For the first group, the main fractionating processes are physical or chemical reactions, biological/bacteriological/microbial processes are dominant in the fractionation of the second group.

Before discussing all environmental isotopes one by one, it should be pointed out that in some cases, considerable isotope fractionation has led to the usefulness of those isotopes in hydrologic studies, for example, H and O isotopes (enrichment and depletion processes are the fundamentals for studying lake–groundwater interaction, recharge temperature, and many other applications). In contrast, in some other cases, lack of isotope fractionation has been helpful. Strontium isotopes, for example, are used to study the origin of solutes in the streams because they are not subjected to substantial fractionation.

H and O

Hydrogen and oxygen atoms have three isotopes each (see also Heavy Water and Deuterium articles): ^{1}H, ^{2}H, ^{3}H, and ^{16}O, ^{17}O, and ^{18}O. Water molecules containing the heavy isotopes are less likely to evaporate and more likely to condense than those containing lighter isotopes. Hence, when a body of water evaporates, the vapor phase is depleted and the residue, the liquid phase, is enriched in heavy isotopes, ^{2}H, ^{3}H, ^{17}O, and ^{18}O. During melting/freezing of water, heavy isotopes are slightly more inclined to freeze and less inclined to melt than lighter isotopes, making the melt water depleted in ^{18}O and deuterium compared to the snowpack. Ultrafiltration (passage of water through shale micropores) enriches the residue (not passed through water) in O and H isotopes (6), but transpiration is not a fractionating process. The principles of hydrogen isotope fractionation are the scientific foundation for producing heavy water, which is used in the nuclear industry.

The fractionation factor for deuterium is greater than that for oxygen-18 because of a larger difference between deuterium and hydrogen masses compared to the difference between ^{16}O and ^{18}O masses. The fractionation factors of these two elements at various temperatures are calculated via the following equations (1):
For oxygen,

$$1000 \ln (\alpha\ ^{18}O) = 2.644 - 3.026 \times 10^{3}/T + 1.534 \times 10^{6}/T^{2}$$

For hydrogen,

$$\ln (\alpha\ D) = 0.0771 + 13.436 \times 10^{3}/T^{2}$$

(note that the temperature is in K).

Example:
The fractionation factor for ^{18}O at 293.15 K (20 °C) is

$$\ln(\alpha\ ^{18}O) = (2.644 - 3.026 \times 10^3/293.15 + 1.534 \times 10^6/293.15^2)/1000 = 1.01000$$

The fractionation factor for ^{18}O during calcite precipitation from water is 1.0349, which means that calcite is 35% more enriched in ^{18}O relative to the water from which it precipitates. However, not all precipitated calcite is richer in ^{18}O compared to "parent water." For instance, if calcite precipitation is due to freezing, the ^{18}O content of calcite is lower (11).

C

Oxidation–reduction processes in which the heavier isotope is concentrated in the more oxidized forms are important in carbon fractionation. The most influential factor in carbon isotope fractionation is selective uptake of lighter CO_2 by plants. During photosynthesis, plants discriminate against the heavier isotopes of carbon; the isotope ^{13}C in organic matter (soil) is depleted by 1.8% compared to its natural ratios in the atmosphere. It is believed that all organisms discriminate against ^{14}C about twice as much as against ^{13}C and the ratio between the stable ^{12}C and ^{13}C atoms can be used to correct for the initial depletion of ^{14}C. The amount of isotope fractionation depends on the photosynthetic pathway used by the plant. Plants are divided into three categories in this regard (11). At high temperatures, equilibrium fractionation of isotopes may occur between CH_4 and CO_2, and this is sensitive to changes in pH, oxygen fugacity, and ionic strength as well as to changes in temperature (13). As an example, the fractionation factor for ^{13}C in $CaCO_3$ in equilibrium with CO_2 is 1.01074.

Cl

The author has not come across a remark in the literature about the occurrence of fractionation in chlorine isotopes. This may have happened because chloride is a highly mobile, soluble, and geochemically conservative (is not removed from solution by mineral interaction or secondary mineral formation) element and has a relatively high mass.

N

Fractionation of nitrogen isotopes occurs mostly through biological processes and some isotope exchange reactions. Kinetic isotope fractionation often dominates nitrogen reactions and because of this, during denitrification, $\delta^{15}N$ values of residual nitrate increase exponentially as concentrations decrease (6). Bowen (1) reports that conversion of ammonia to nitrate (nitrification) by nitrifying organisms produces isotope fractionation up to 20% and even greater values (up to 30%) are associated with denitrification.

S

Sulfur in near-surface environments frequently changes between the oxidized and the reduced forms, so it acquires a wide variety of $^{34}S/^{32}S$ ratios. Isotope fractionation occurs in many processes of the sulfur cycle. The principal reaction leading to the fractionation of sulfur isotopes in nature is the reduction of sulfate ion by anaerobic bacteria (13). Bacterial reactions are important because they are kinetic, fast, favor the lighter isotope, and result in depleting ^{34}S in natural biogenic H_2S and hence enrich the remaining sulfate (11). Brucher et al. (14) studied isotope fractionation during bacterial sulfate reduction and found that in addition to the variations in the rates of bacterial sulfate reduction, genetic and physiological differences between various genera of sulfate-reduction bacteria strongly influence isotope fractionation.

In the precipitation of sulfide minerals from solution, the fractionation and enrichment of ^{34}S depend on the relative bond strengths and the temperature of solution (13). Sulfide minerals in newly deposited sediment can be enriched in ^{32}S by about 50% compared with associated marine sulfate (1). The equilibrium isotope fractionation factor between SO_4^{2-} and H_2S is 1.074 and is 1.020 between water and dissolved sulfate at 88 °C (6). During dissolution of evaporites, the largest reservoir of sulfate, no sulfur fractionation takes place.

Sr

Because of its relatively high mass, no detectable isotope fractionation accompanies precipitation of Sr within minerals (6).

ARTIFICIAL ISOTOPE FRACTIONATION FOR "SEPARATION OF ISOTOPES"

The most interesting and applied part of the isotope fractionation topic is artificial separation ("fractionation") of isotopes, a subject that is scientifically simple, but, in engineering terms very complicated. Historically, the first successful attempt to separate isotopes was that by Aston (the inventor of the mass spectrograph and the Nobel prize winner in 1922) who separated neon into two fractions of different atomic weights by repeated diffusion. The topic gained importance with the discovery, in 1939, that ^{235}U is a fissionable material and in succeeding years that uranium-235 is the key material for producing nuclear weapons and power (7).

VARIOUS TECHNIQUES FOR SEPARATING ISOTOPES ARTIFICIALLY

As stated before, separating isotopes is an intensive complicated engineering task, and only a few countries have the capacity. Four principles that constitute the foundation of isotope separation should be considered when devising a separation process (7):

1. At a given temperature, gaseous molecules, regardless of mass, have the same average kinetic energy.

2. The gravitational or centrifugal forces acting on a particle of matter are directly proportional to its mass.
3. The electric or magnetic forces affecting ionized atoms or molecules follow Coulomb's laws for these forces.
4. Among the lighter elements, isotopic species may vary slightly in their chemical reactivities.

Considering these four principles, a variety of techniques have been developed for isotopic enrichment (7). Each of these techniques has advantages and disadvantages and is suitable for specific types of conditions and isotope(s).

1. The gaseous-diffusion method is used for separating and enriching uranium isotopes. The production plant which uses this technique is huge; the huge diffusion plant at Oak Ridge, USA, in operation from 1945, represents one of the greatest technical achievements in the history of humankind.
2. The electromagnetic method is suitable only where cheap electricity is available.
3. The thermal diffusion method is good for laboratory-scale production.
4. The centrifuge method was not developed into a large-scale production plant.
5. The electrolytic method is used only for separating hydrogen and deuterium.
6. The chemical exchange method is used mostly for separating C and N.
7. The distillation method is only for enriching deuterium.

A sideline and an interesting coincidence is that while this article was being written, the Board of Governors of International Atomic Energy Agency (IAEA) postponed its decision on Iran's (the home country of the author) uranium enrichment and nuclear program activities (CNN Online edition, Nov. 22, 2003). The uranium enrichment and nuclear activities program of Iran has been in the news headlines for quite a long time.

MARIOTTE BOTTLE—USE IN HYDROLOGY

Joseph Holden
University of Leeds
Leeds, United Kingdom

A Mariotte bottle is a device that allows constant flow of a fluid from a container, even when the fluid level in the container changes. It is named after Edme Mariotte (1620–1684), a French physicist, who, independently from Boyle, discovered the law that states that the volume of a gas varies inversely with its pressure. Mariotte bottles have a wide range of applications in engineering and science (such as fuel supply) and are used in a variety of hydrologic applications ranging from river discharge gauging to infiltration measurement.

Figure 1 shows the general design of a Mariotte bottle. It consists of a bottle that has an escape pipe or tap to allow fluid to exit and a vent tube to allow air to enter the bottle. The bottle is sealed so that the only location where air can enter is at that bottom of the vent tube, b. The fluid (such as water) exits through a tap (or any sort of escape tube) at c, at a rate that is controlled by the size of the escape tube and the head of water. The head of water, *h* will always be equal to the distance between the outlet tap and the bottom of the vent tube. Therefore, regardless of the water level inside the bottle, there will be a constant head of water.

If the vent tube is kept at a constant level, then as a result of the reduction of the fluid in the bottle, the air above it expands and its pressure drops. When the pressure of the air has dropped so that it plus the pressure of the water column from c to b (the vent tube opening) is less than the atmospheric pressure of the air outside the Mariotte bottle (and therefore also inside the vent tube), then air enters the Mariotte bottle at b and rises through the fluid. Therefore, the pressure at c will always be equal

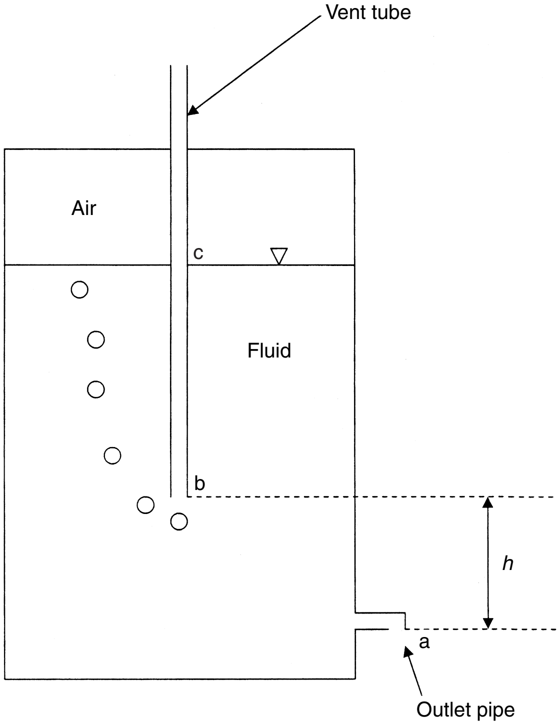

Figure 1. A Mariotte bottle.

to atmospheric which is also equal to the pressure at b. The excess pressure, under which the fluid is ejected, is the pressure of the fluid between the levels b and a. It remains constant until the fluid drops to the level of b, and the discharge from the escape pipe will remain constant until then. Thus, Mariotte bottles can be used wherever there is an application for a constant flow of water from a supply reservoir.

If the vent tube is raised to a greater height, the head will increase, and therefore, the rate of water flowing out of the bottle will increase. It is therefore possible to control the rate of water release from the bottle by controlling the head of water, and this is, in turn, controlled by the height of the base of the vent tube above the outlet at a. If the vent tube is moved down to the level of the escape opening, a, the flow stops because then the height of the column becomes zero. The discharge also ceases if the vent tube is sealed preventing air from entering the bottle.

There is a wide range of common hydrologic applications for Mariotte bottles. They are used frequently for adding a constant rate of solution (such as a dye or tracer) to watercourses. Most commonly this is for discharge gauging where, if a constant rate of solution (such as sodium chloride solution) is added to river, then the discharge of the river can be calculated based on the equation,

$$Q = q(C_i - C_d)/(C_d - C_b)$$

where Q is the river discharge, q is the rate of injection of tracer solution, C_i is the concentration of the tracer, C_b is the background concentration in the river, and C_d is the downstream sampled concentration of the tracer.

It is often useful to use a Mariotte bottle to supply a constant rate of water and also, if the bottle is graduated, then it can be used to determine how much water has been supplied during any given period. Frequently, Mariotte bottles are used in instruments designed to measure soil infiltration rates such as rain simulators or other types of infiltrometers where a constant rate of water supply to the soil surface might be required.

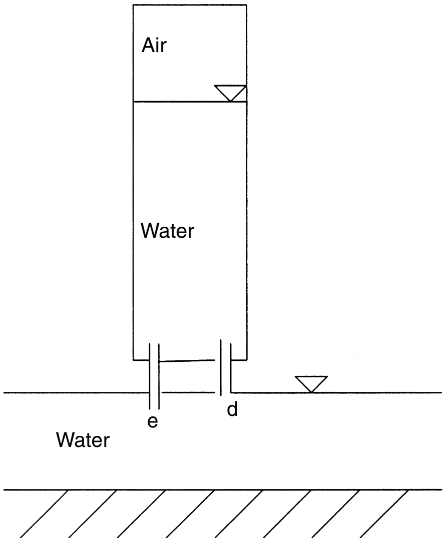

Figure 2. Mariotte bottle used to keep a constant water level above the ground surface.

In constant head infiltrometers (see entry for Infiltrometers), the Mariotte principle is used to ensure that there is a constant depth of ponded water above the soil surface. This is done by placing the vent tube for the Mariotte bottle at the same end of the bottle as the water exit pipe as in Fig. 2. Whenever the water level on the ground drops below the height of the base of the vent tube, d, air is allowed to enter the water supply bottle, and water can be released from e until the water level on the ground has risen back to the base of the vent tube. In this way, a constant height or head of water can be maintained on a soil surface. This principle can also be used for irrigation to maintain a constant surface water level or a constant groundwater level.

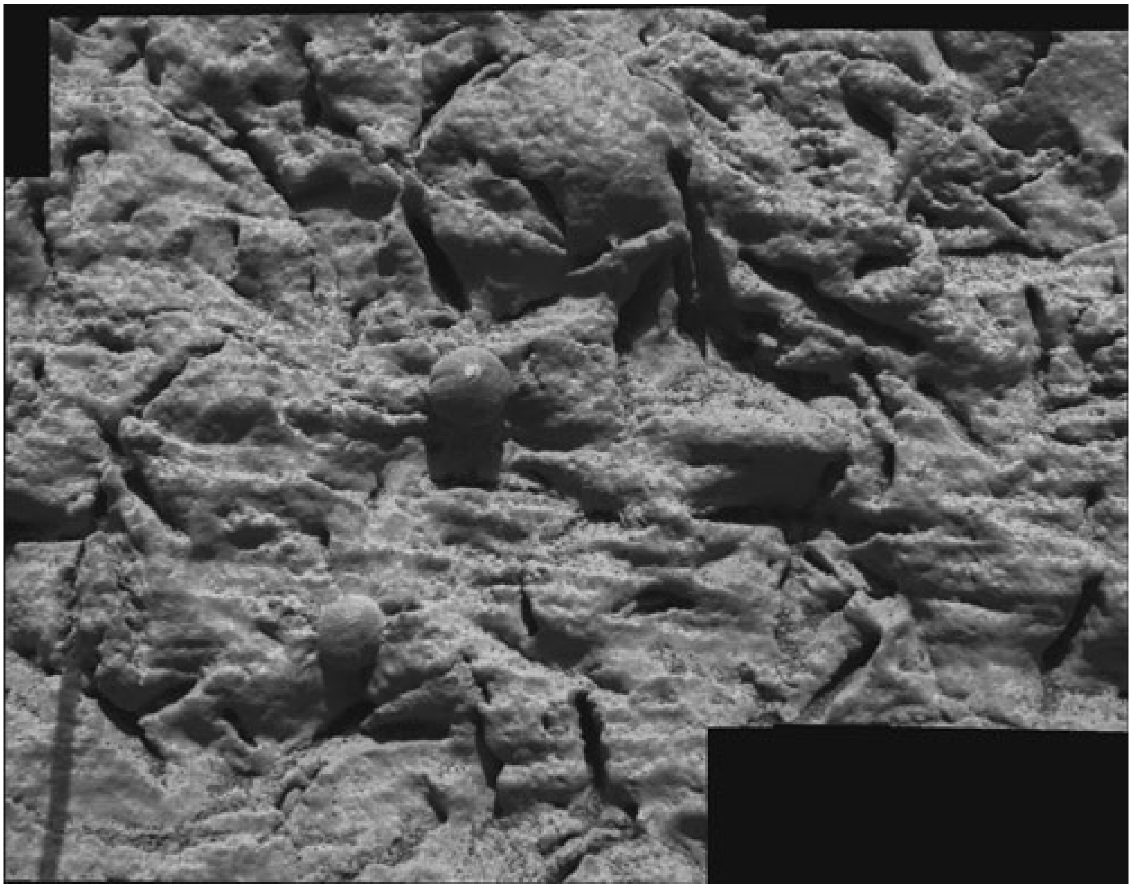
MARS EXPLORATION ROVER MISSION

Guy Webster
Jet Propulsion Laboratory
Pasadena, California

Donald Savage
NASA Headquarters
Washington

OPPORTUNITY ROVER FINDS STRONG EVIDENCE MERIDIANI PLANUM WAS WET

Scientists have concluded the part of Mars that NASA's Opportunity rover is exploring was soaking wet in the past.



This image, taken by Opportunity's microscopic imager, shows a portion of the rock outcrop at Meridiani Planum, Mars, dubbed "Guadalupe." View Opportunity images from this press release.

Evidence the rover found in a rock outcrop led scientists to the conclusion. Clues from the rocks' composition, such as the presence of sulfates, and the rocks' physical appearance, such as niches where crystals grew, helped make the case for a watery history.

"Liquid water once flowed through these rocks. It changed their texture, and it changed their chemistry," said Dr. Steve Squyres of Cornell University, Ithaca, N.Y., principal investigator for the science instruments on Opportunity and its twin, Spirit. "We've been able to read the tell-tale clues the water left behind, giving us confidence in that conclusion."

Dr. James Garvin, lead scientist for Mars and lunar exploration at NASA Headquarters, Washington, said, "NASA launched the Mars Exploration Rover mission specifically to check whether at least one part of Mars ever had a persistently wet environment that could possibly have been hospitable to life. Today we have strong evidence for an exciting answer: Yes."

Opportunity has more work ahead. It will try to determine whether, besides being exposed to water after they formed, the rocks may have originally been laid down by minerals precipitating out of solution at the bottom of a salty lake or sea.

The first views Opportunity sent of its landing site in Mars' Meridiani Planum region five weeks ago delighted researchers at NASA's Jet Propulsion Laboratory, Pasadena, Calif., because of the good fortune to have the spacecraft arrive next to an exposed slice of bedrock on the inner slope of a small crater.

The robotic field geologist has spent most of the past three weeks surveying the whole outcrop, and then turning back for close-up inspection of selected portions. The rover found a very high concentration of sulfur in the outcrop with its alpha particle X-ray spectrometer, which identifies chemical elements in a sample.

"The chemical form of this sulfur appears to be in magnesium, iron or other sulfate salts," said Dr. Benton Clark of Lockheed Martin Space Systems, Denver. "Elements that can form chloride or even bromide salts have also been detected."

At the same location, the rover's Mössbauer spectrometer, which identifies iron-bearing minerals, detected a hydrated iron sulfate mineral called jarosite. Germany provided both the alpha particle X-ray spectrometer and the Mössbauer spectrometer. Opportunity's miniature thermal emission spectrometer has also provided evidence for sulfates.

On Earth, rocks with as much salt as this Mars rock either have formed in water or, after formation, have been highly altered by long exposures to water. Jarosite may point to the rock's wet history having been in an acidic lake or an acidic hot springs environment.

The water evidence from the rocks' physical appearance comes in at least three categories, said Dr. John Grotzinger, sedimentary geologist from the Massachusetts Institute of Technology, Cambridge: indentations called "vugs," spherules and crossbedding.

Pictures from the rover's panoramic camera and microscopic imager reveal the target rock, dubbed "El Capitan," is thoroughly pocked with indentations about a centimeter (0.4 inch) long and one-fourth or less that wide, with apparently random orientations. This distinctive texture is familiar to geologists as the sites where crystals of salt minerals form within rocks that sit in briny water. When the crystals later disappear, either by erosion or by dissolving in less-salty water, the voids left behind are called vugs, and in this case they conform to the geometry of possible former evaporite minerals.

Round particles the size of BBs are embedded in the outcrop. From shape alone, these spherules might be formed from volcanic eruptions, from lofting of molten droplets by a meteor impact, or from accumulation of minerals coming out of solution inside a porous, water-soaked rock. Opportunity's observations that the spherules are not concentrated at particular layers in the outcrop weigh against a volcanic or impact origin, but do not completely rule out those origins.

Layers in the rock that lie at an angle to the main layers, a pattern called crossbedding, can result from the action of wind or water. Preliminary views by Opportunity hint the crossbedding bears hallmarks of water action, such as the small scale of the crossbedding and possible concave patterns formed by sinuous crestlines of underwater ridges.

The images obtained to date are not adequate for a definitive answer. So scientists plan to maneuver Opportunity closer to the features for a better look. "We have tantalizing clues, and we're planning to evaluate this possibility in the near future," Grotzinger said.

REMOVAL OF ORGANIC MICROPOLLUTANTS AND METAL IONS FROM AQUEOUS SOLUTIONS BY ACTIVATED CARBONS

Basu Saha
Loughborough University
Loughborough, United Kingdom

INTRODUCTION

World population growth has triggered agricultural and industrial growth for the sustenance of the day-to-day demands of the population. However, the increase in agricultural and industrial growth has also led to a corresponding growth in pollution related to the two activities. The use of pesticides to boost food production has caused increased contamination of drinking water, thus putting pressure on governments to invest in the provision of clean water. The same can also be said about the increase in industrial activities, which has seen, among many of the pollutants, the increase of heavy metals in the water bodies. Since the installation of water pollution control schemes are not profit-generating activities, there is a lot of ongoing research into finding efficient but inexpensive ways of separating pollutants from drinking water.

The ban on the use of atrazine for nonagricultural purposes in the United Kingdom in 1993 has resulted in the introduction of alternative herbicides. Among them is benazolin, which can be a potential groundwater pollutant owing to its high water solubility when compared with that of atrazine. A report compiled by the Environment Agency (1) revealed that, for the first time in England and Wales, benazolin has become one of the 10 most frequently occurring herbicides in surface water. The potential harmful effects of benazolin as a herbicide necessitates that it must be removed from water bodies if present at concentrations higher than that required by environmental regulations. However, conventional water treatment processes, such as filtration, disinfection, coagulation, and sedimentation, have been reported to be more effective in removing less water-soluble and easily degradable pesticides (2). Ozone technology is a potentially attractive technique in wastewater treatment. However, in some cases, the ozone degradation products can be equally harmful. Lambert et al. (3) have investigated degradation efficiency of benazolin and other herbicides using ozone and a combination of ozone and hydrogen peroxide. They realized that for benazolin, doses of 1.0 mg O_3/l, 2.0 mg O_3/l, and 3.1 mg O_3/l, degradation efficiencies of 55%, 68%, and 88% could be achieved, respectively. The combination of ozone and hydrogen peroxide further increased the degradation efficiency, but they recommended complementary techniques for other herbicides. Adsorption on activated carbon is one of the well-established and effective techniques for the removal of herbicides from water. The adsorptive efficiency of activated carbon is because of its well-developed internal pore structure, surface area, and surface reactivity. Typically, activated carbon consists of interwoven micropores, mesopores, and macropores, and these are responsible for the high surface area of the carbons. The existence of surface functional groups in an activated carbon matrix means that they can be manipulated by thermal or chemical treatments to produce adsorbents that are tailored for particular functions.

As wastewater streams consist of a mixture of pollutants that can generally be classified as organic and inorganic pollutants, tailoring an adsorbent to remove both classes of pollutants would give a significant process advantage. Among the inorganic pollutants, heavy metals form a major part in the classification. Heavy metals constitute a class of environmental pollutants that are of particular concern in the treatment of industrial wastewater because of their potential danger to humans and the environment. Therefore, they must be treated if present at concentrations higher than those specified by the environmental regulations.

Activated carbons have been proven to be an effective adsorbent for the removal of organic compounds from water (4,5). Research has also shown that they have a potential to remove heavy metals, especially in its modified state. For example, a number of authors have oxidized activated carbons to enhance sorption of heavy metals (6–9). The oxidation processes have mainly been by use of nitric acid, ozone, and air. The three methods have always produced the same results, that of producing weakly acidic functionality on the surface of the carbon. Saha et al. (10) compared the metal sorption capacity of a conventional carbon and its oxidized form. The adsorption of herbicides and trace metal ions onto activated carbon is discussed in this chapter. In particular, we discuss the effect of modification of activated carbon on the uptake of copper and benazolin. The effect of post-treatment of the oxidized carbons on the uptake of the target pollutants is also highlighted. The adsorbents were characterized in a bid to understand their chemical and physical properties, which gives a better understanding of the nature of the association of the target pollutants and the adsorbents.

BACKGROUND

Herbicides have undoubtedly contributed to the growth of agricultural productivity. For example, it has been reported that a \$4 billion U.S. investment in herbicide control saved \$16 billion U.S. in crops every year (11). However, the benefit realized from the use of herbicides does not factor in the negative effects they have on human health.

As a result of their negative impact on human health and the environment, stringent legislation has been imposed on the purity of drinking water. The European Union (E.U.) agreed to have the drinking water Directive Admissible Concentration for single herbicide or pesticide at a maximum of 0.1 μg/L. In Great Britain, the National Rivers Authority (12) showed that eulan and permethrin (mainly in effluents from the textile industry) had exceeded their Environmental Quality Standard (EQS) limits. Also, diazinon, a sheep dip insecticide, had also exceeded its EQS limits. One major concern was that the most commonly used, herbicides atrazine, diuron, bentazone, isoproturon, and mecoprop exceeded the standard 0.1 μg/L in surface waters, which has been and always will be a major concern simply because most groundwater sources used for drinking water have no treatment facilities designed to remove herbicides. Also, the most common water treatment processes, such as sedimentation, disinfection, coagulation, and filtration, can effectively remove only selected herbicides, especially those that have low solubility in water. On the other hand, advanced water treatment processes (mainly using adsorption onto activated carbon) have proved to be the most efficient and reliable method for the removal of aqueous dissolved organic herbicides. Hence, a lot of studies have gone into trying to improve the removal efficiency of the existing adsorbents. In improving the adsorption capacity of adsorbents, attention has been turned on to the number of variables that affect the adsorption capacity of the activated carbons.

As pollution in wastewater is because of a cocktail of pollutants, the use of activated carbon could be a viable way of simultaneously adsorbing pollutants of a different nature, which has a further advantage of cutting down on the number of wastewater processing units. Hence, the objective of this research is to investigate the effect of simultaneous adsorption of a heavy metal (copper) and a selected herbicide (benazolin) on as-received and surface-modified activated carbons. The adsorbents chosen for this work are as-received F400 supplied by Chemviron (USA) and various surface-modified samples of F400 that were prepared in the author's laboratory. Benazolin is highly soluble in water (solubility 600 mg/l) when compared with atrazine (solubility 33 mg/l). Properties, structural formula, and three-dimensional representation of benazolin are given in Table 1 and Fig. 1, respectively. Copper has been chosen as a representative of heavy metals. In order to understand the sorption mechanism of the target pollutants, physical and chemical characterization were performed for all the adsorbents. The other objective of the study is to investigate the mechanism of adsorption of the chosen pollutants. If the mechanism is fully understood, it is possible to produce tailor-made engineered adsorbents for various purposes in water treatment.

EXPERIMENTAL

Adsorbent Materials

A coal-based commercial granular activated carbon, F400 was used for surface modification with nitric acid. The

Table 1. Properties and Structural Formula of Benazolin

Herbicide	Chemical Formula	Structural Formula	Solubility in Water (mg/L)	pKa
Benazolin	$C_9H_6ClNO_3S$		600	3.04

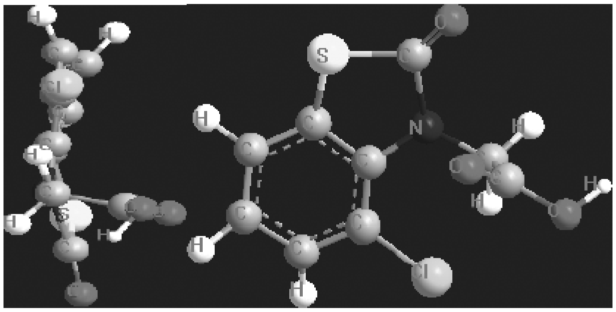

Figure 1. 3-D molecular representation of benazolin.

carbon sample was obtained from Chemviron (USA). Before the oxidation process, the carbon was washed in distilled water and dried at 383°K for 24 hours. The dried sample was then subjected to different modes of modification using part of a method described by Saha et al. (7) and Chingombe et al. (13).

Sample Preparation

A known amount of the washed and dried sample was introduced into the reaction vessel that contained nitric acid and distilled water at a ratio of 1:1 (v/v). The reaction mixture was heated to 363°K, and the reaction was allowed to continue for 6 hours with continued stirring. The reaction solution was removed and a fresh reaction mixture of nitric acid and water was introduced. The reaction was allowed to continue for an additional 3 hours under the same reaction conditions. The oxidized carbon was then washed with distilled water until no further change in pH could be detected.

The resultant water-washed samples (after oxidation) were divided into three portions. The first portion was denoted AC1, and this is a sample that was washed with water after the oxidation reaction. AC2 was a sample that was washed with 0.1 M sodium hydroxide to remove humic acids that were formed during the oxidation process. The washing was continued until no further coloration from the humic acids could be detected. Reconditioning of the sample to the hydrogen form was performed using 0.1 M hydrochloric acid, and further washing with distilled water was done until the pH of the supernatant solution stabilized to a pH of about 4.0. The conversion was deemed complete when the inlet and the outlet pH of the liquid flowing in the column were the same. The third sample, denoted AC3, was a result of heating the third portion of the oxidized sample at a temperature of 580°K under vacuum of 2 mmHg for 12 hours to remove humic acids.

ANALYSIS OF METAL ION AND HERBICIDE

Copper

The copper ion content was analyzed using a Varian SpectraAA-200 atomic absorption spectrophotometer (AAS). The AAS was set on the flame mode using air-acetylene mixture.

HPLC Analysis Method

As preconcentration of benazolin before analyzing on the HPLC was required, a trace analysis method had to be developed for the quantification of the herbicide. A Hewlette Packard 100 series HPLC consisting of a diode array detector, column thermostat, auto sampler, and a binary pump was used for analysis. Jones Chromatograph supplied a Genesis C18 silica column (4 μm, 150 × 3.0 mm) combined with a 1 cm Genesis guard column. The detector, flow rate, and injection volume were set at 222 nm, 0.88 ml/min, and 100 μl, respectively, and this gave the retention time of benazolin at 2.01 minutes. The column temperature was also set at 311°K. The eluent consisted of a solution of 40% acetonitrile and 60% buffer (10 mmol KH_2PO_4 at pH 3). The calibration curve for benazolin showed that correlations were linear over the range (0–8 ng/μl).

Solid phase extraction (SPE) technique was employed for the preconcentration of benazolin before analysis. The complete procedure for SPE is given in Table 2.

Table 2. Procedures for Solid Phase Extraction (SPE)

Conditioning	500 mg, s-triazine, 6 ml SPE columns were conditioned by passing 10 ml of HPLC-grade methanol followed by 10 ml of 2% MeOH in water under gravity.
Extraction	500 ml sample solution were passed through the column at a flow rate of 1 ml/min.
Elution	6 ml of acetonitrile was allowed to soak in the columns for 20 minutes before being passed through at approximately 0.5 ml/min and the eluent collected in 7 ml vials. The columns were then blown dry with nitrogen and the solvent was evaporated to dryness using a stream of nitrogen.
Reconstitution	500 μl of 40% acetonitrile, 60% 10 mmol KH_2PO_4 buffer at pH 3.0 was added to the vials to redissolve the analytes. The vials were shaken vigorously and their contents transferred to HPLC auto-sample vials.

CHARACTERIZATION OF ADSORBENTS

All samples were characterized to investigate the effect of the treatment and the chemical as well as the physical characteristics of these materials. The characterization included scanning electron micrographs (SEM), Brunauer-Emmett-Teller (BET) and Langmuir surface area measurements, pore size distribution, Fourier Transform Infra Red spectroscopy (FTIR) analysis, sodium capacity measurement, pH titration, zeta potential measurements, and X-ray photoelectron spectroscopy (XPS) analysis and elemental analysis. The detailed characterization procedure and the results have been reported by Chingombe et al. (13). The results indicated that a significant change occurred in the structure of the precursor by oxidation and subsequent treatments. Characterization of the adsorbents revealed that modification of the carbon by oxidation resulted in the introduction of weakly acidic functional groups, and the presence of such groups was confirmed by FTIR, pH titration, zeta potential measurements, and sodium capacity results. Sodium capacity was enhanced by a factor of up to 8 for the oxidized carbons compared with as-received samples.

Batch Adsorption Experiments

The sorption of copper on the F400 carbon range is shown in Fig. 2. The results clearly show that AC1 and AC2 have the same adsorptive capacity for copper when compared with AC3 and unoxidized F400. However, among the adsorbents employed, as-received F400 showed the least adsorptive capacity. The enhanced capacity observed on AC1, AC2, and AC3 could be as a result of the oxidation process, which generated carboxylic functional groups as evidenced in the FTIR spectra and the high sodium capacity of the above sorbents. These groups

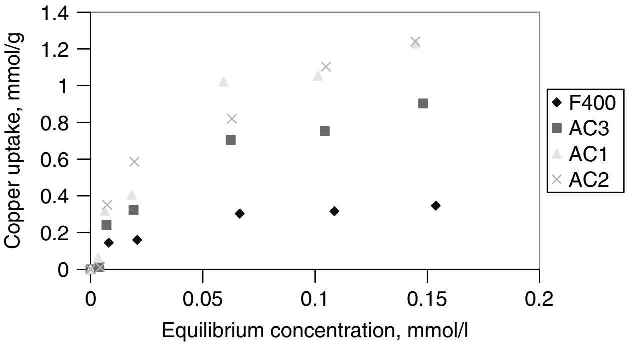

Figure 2. Equilibrium sorption results of copper on F400 and the oxidized carbons.

would be dissociated in aqueous solution, and they are responsible for copper sorption. The oxidized and heat-treated sample AC3 showed reduced capacity compared with AC1 and AC2, which could be because of the decomposition of the carboxylic acid groups during the heat treatment. Toledo-Bautista et al. (14) made similar observations when they adsorbed Cr(III) on a range of conventional and modified carbons.

The formation of metal surface complexes on the oxidized carbon involving cooperative action seems quite likely. Approximate calculation of oxygenated functional group density per unit area for F400(ox) yields a value of 0.02 functional groups per square angstrom. Given that the oxidized carbons evaluated in the present study possess a large proportion of pores in the region of 10–20 angstrom and the diameter of the hydrated metal ions is approximately 8 angstrom (15), it is reasonable to assume a cooperative binding mechanism (see Fig. 3).

Figure 4 shows the adsorption of benazolin on all the adsorbents under study. The results clearly show that benazolin adsorption on F400 is slightly higher than AC2 and reasonably higher than AC1 and AC3. However, AC1 and AC3 seem to have similar sorptive performance, whereas AC2 showed a higher performance than the other oxidized carbons, which can be expected because there was a significant loss in micropores for samples AC1 and AC3 as obtained by the pore size distribution analysis (13). It is generally accepted that sorption of an organic molecule takes place mainly in the micropore region of the adsorbents, because in this region, the contact points between the adsorbent and the molecules is higher than in mesopores and macropores. Also, it is reported that an overlap of potential forces exists in the micropores, which results in increased adsorption forces. Therefore, naturally, the capacity of AC1 and AC3 is expected to be low. Another factor in the difference between the adsorption capability of the adsorbents is the electrostatic interaction between the adsorbent and the adsorbate.

The zeta potential results show that the isoelectric point (IEP) of the oxidized carbons are significantly lower (1.5) than that of the conventional carbon (6.0) because of the introduction of weakly carboxylic acid groups with dissociation between pH 2 and 6. As the experiments are performed at pH 5, it would imply that the surface of the oxidized carbons is predominantly negative because of the dissociation of the carboxylic groups. Also, the pK_a value of benazolin (3.04) is lower than the pH of the solution experiment, and this condition would render mutual repulsion between the adsorbent and the adsorbate. Adsorption of benazolin is more favorable on F400 because of its high IEP. Streat and Horner (4), when comparing adsorption of some herbicides (including benazolin) on F400 and hypercross-linked polymers, realized that F400 outperformed the polymeric sorbents. They postulated

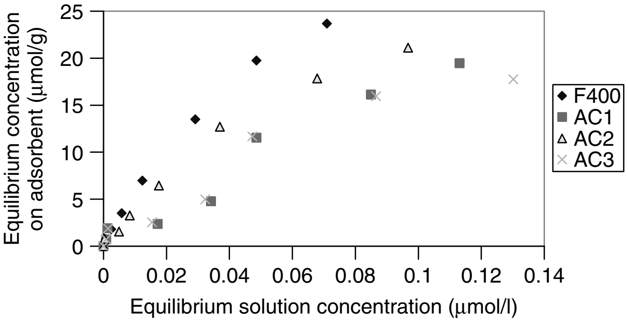

Figure 4. Adsorption of benazolin on F400 and the oxidized carbons.

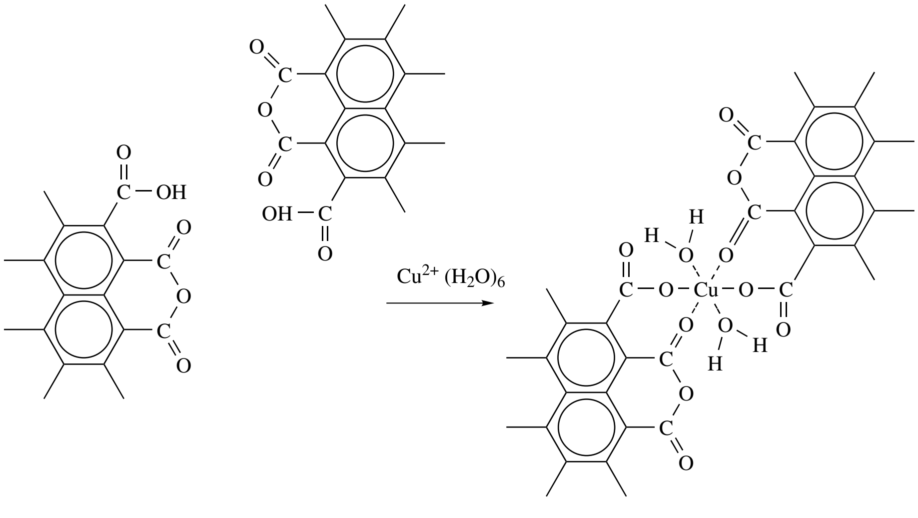

Figure 3. Postulated complexation reaction between copper (II) and oxidized carbon surface.

that adsorption of benazolin on F400 was through the dispersion interaction of the π electrons in the respective aromatic systems by a donor-acceptor mechanism. They further noted that the chloro (–Cl) group on benazolin is an electron-withdrawing group, therefore implying that a reduction of electron density occurs in the π ring system of the herbicide. Hence, benazolin would act as an electron acceptor in the donor-acceptor mechanism involving F400. This observation is consistent with investigations carried out by Radovic et al. (16) when they considered the adsorption of aromatics possessing electron-withdrawing and electron-donating functional groups on conventional and chemically modified activated carbons. Chemical modification involved samples that were subjected to nitration and others that were oxidized. Heat-treated carbons were also considered. They used nitrobenzene and aniline as the target adsorbates. Nitrobenzene contains nitro (–NO_2) group, which is known to be electron withdrawing, whereas aniline possesses an amino (–NH_2) group, which is electron donating. As nitration and oxidation reduces the π-electron density in the graphene layers of the carbon surface, which would in turn favor adsorption of aromatics with electron donor functional groups, it was realized that maximum adsorption uptake of aniline (with electron donor group) were attained on oxidized carbon surfaces. On the other hand, maximum adsorption uptake for nitrobenzene were found on heat-treated carbon surfaces (which possess higher π-electron density than the oxidized carbons). Hence, from the view point of Radovic et al. (16), it would be reasonable to postulate that benazolin adsorption is favored by adsorbents with high π-electron density. However, in the oxidized carbons employed in this work, such a mechanism would be highly unlikely because of the introduction of oxygen groups in the form of carboxylic acids. The carboxylic acid functional groups are electron withdrawing, and this condition reduces the π-electron density in the ring systems of the carbon. Therefore, the dispersion interaction between the herbicide and the oxidized carbon is reduced. Hence, unoxidized F400 would be expected to have a higher benazolin capacity than the oxidized carbons.

Figures 5 and 6 show the adsorption isotherms of benazolin in the presence of copper at 5 ppm and 10 ppm for unoxidized F400 and AC1 and AC3 samples, respectively. For both cases, it is apparent that benazolin uptake is distinctly affected in the presence of copper ions. Also, Fig. 7 shows the effect of the initial concentration of benazolin on the uptake of copper. The results clearly show that as the initial concentration of benazolin increases, a corresponding decrease occurs in the uptake of copper up to the point when the initial concentration of benazolin is at approximately 20 ppb, that is when the uptake of copper normalizes. The immediate conclusion that could be drawn from the two sets of results is that a competition exists for the same adsorption sites by copper and benazolin. As mentioned previously, the adsorption of benazolin is favored through electron donor-acceptor type of a mechanism, which involves π electron in the ring systems of the carbon. Biniak et al. (6) showed that copper ions had the capacity to interact with the π electron in the ring systems of the carbon. In their work, they employed XPS and FTIR to study the state of the copper adsorbed on different carbon surfaces. They investigated three types of modified activated carbons. One of the modified carbons was obtained by annealing a conventional carbon in a vacuum at 1000°K. This carbon had a low oxygen content of 2.72% compared with oxidized and ammonia-treated carbons, which had 10.10% and 6.20%, respectively. The annealed carbon was virtually devoid of acidic functional groups. XPS and FTIR results indicated that the dominant mechanisms of copper adsorption on heat-treated active carbons could be dipole-dipole (π-d) interactions between graphene layers and metal ionic species as well as spontaneous electrochemical reduction of copper ions. Hence, it is expected that benazolin and copper would compete for the same sites derived from the π electrons in the graphene layers of the modified adsorbents. However, conclusive evidence of

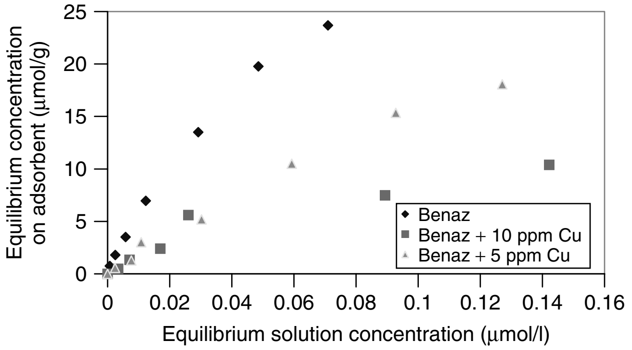

Figure 5. Simultaneous adsorption of copper and benazolin on F400.

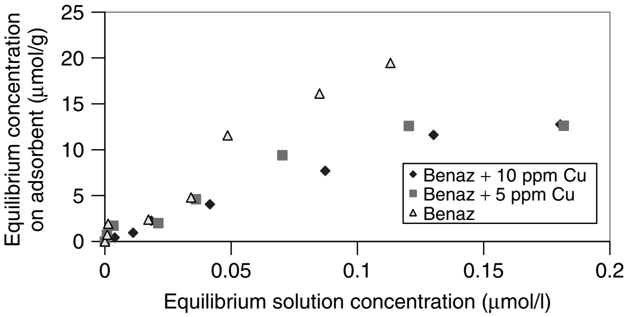

Figure 6. Simultaneous adsorption of copper and benazolin on AC1.

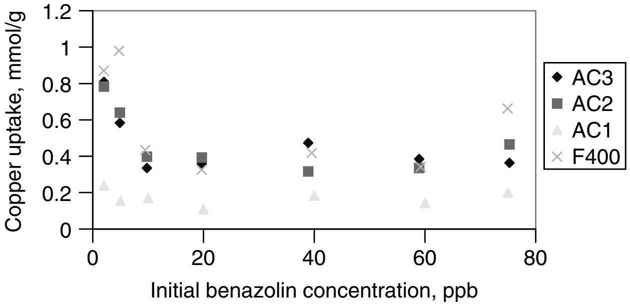

Figure 7. Effect of the initial concentration of benazolin on copper uptake.

such competition would only be proved by employing an annealed carbon adsorbent.

CONCLUSIONS

Oxidation of the conventional carbon and post-treatment of the resultant carbons had an influence on their uptake for copper and benazolin. Oxidation resulted in the introduction of weakly acidic carboxylic functionality, which markedly enhanced the uptake of copper ions. The isoelectric point (IEP) was also reduced as a result of oxidation. Oxidation of the carbon resulted in altered pore size distribution. Reduction in microporosity was observed, and it also explained the low uptake of benazolin by oxidized sample compared with as-received F400. However, post-treatment by washing with sodium hydroxide seemed to open up the pores for AC2 sample. Simultaneous adsorption of benazolin and copper showed that direct competition existed for the active sites, and possibly the two adsorbates targeted the π electron cloud on the graphene layers of the adsorbent. Copper uptake by the conventional and modified samples decreased in the presence of benazolin and vice versa. The decrease in metal uptake was dependent on the concentrations of metals in multicomponent aqueous solutions. The effect of copper on benazolin uptake was more pronounced than the effect of benazolin on copper uptake from water. Further work is necessary to fully understand the precise mechanisms of adsorption of complex aromatic molecules onto carbon, and this forms the basis of our continued work. Research is in progress in the author's laboratory to provide conclusive evidence on the interaction of these adsorbates with the modified carbon surface.

The environment is challenged by other micropollutants, namely polychlorinated hydrocarbons, organic oxygen compounds, surfactants, pesticides, aliphatic intermediates developing from the chemical industry, and, of course, endocrine disrupting compounds (EDCs). Further study of activated carbon continues to explore for potential solutions to these important problems.

Acknowledgments

I would like to express my sincere gratitude to Professor Michael Streat for his support, continuous encouragement, and advice for conducting the research in the area of adsorption and ion exchange and development of tailored sorbent materials for environmental remediation. I am indebted to Dr. Hadi Tai and Purazen Chingombe for their meticulous experimental work. Funding from European Community, EPSRC, Severn Trent Water Ltd., and Commonwealth Scholarship Commission is gratefully acknowledged.

MOLECULAR NETWORK DYNAMICS

D.L. Marrin
Hanalei, Hawaii

Perhaps the twentieth century's most startling discovery about liquid water is that it functions as a vast interconnected network, rather than as a random collection of independent molecules. Individual water molecules serve as network *elements*, which constitute the building blocks for the fundamental water network. Elements in the water network are connected to one another via magnetic-type linkages known as *hydrogen bonds*. In solid water (ice), each water molecule hydrogen bonds with all four of its nearest neighbors in forming a perfect *tetrahedron*, which is a three-sided pyramid comprising the most basic molecular geometry of water (see Fig. 1). As ice melts into liquid water, some of the hydrogen bonds between water molecules are broken (causing the tetrahedron to distort), whereas the remaining bonds transition to an ultra-dynamic state whereby they are switched as rapidly as a trillion times per second. The dynamics of this unique molecular network are believed to underlie many of water's anomalous properties.

NETWORK BEHAVIORS

This frantic switching of hydrogen bonds, which constitutes the underlying dynamism of water's molecular network, permits water to flow and to behave as a liquid even though it retains much of the molecular geometry of a solid. Physical chemists have long modeled liquid water as a space-filling network of individual water molecules, within

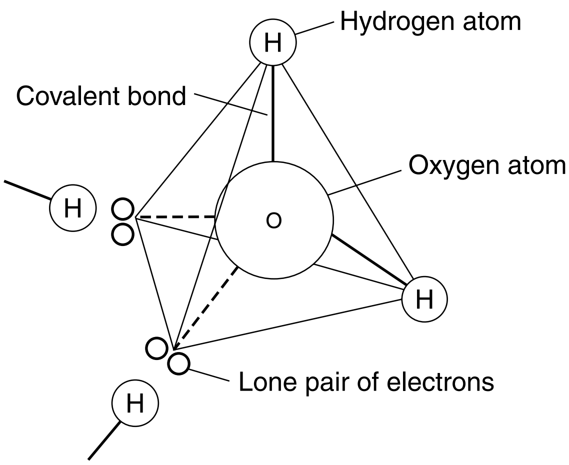

Figure 1. This diagram represents the simplest tetrahedral unit of water's H-bonded network (1). Two of the four hydrogen atoms comprising the tetrahedron are covalently bonded to the central oxygen atom (forming an individual H_2O molecule), whereas the remaining two hydrogen atoms (donated by each of two neighboring water molecules) are hydrogen bonded to the oxygen's lone pairs of electrons. Every water molecule in the network can act as both a hydrogen donor and a hydrogen acceptor in bonding with its nearest neighbors.

which all potential hydrogen bonds were described as either unbroken (ON) or broken (OFF) (2). More recently, scientists have characterized the shuffling (i.e., breaking and forming) of hydrogen bonds comprising liquid water's network as a nonlinear process and, consequently, have been unable to decipher the rules that govern the changing of molecular interconnections. This inability does not imply that the switching rules are haphazard—only that science's observational and mathematical techniques are currently overwhelmed by water's dynamism. Even scientists who study much simpler computer-generated systems have found it difficult to identify switching rules solely by analyzing network patterns and behaviors. Instead, researchers arbitrarily set the switching rules for these artificial systems and then observe corresponding network behaviors.

Whereas network hierarchies within liquid water have only recently been investigated, structural hierarchies are well described. Water exhibits structural self-organization on at least three distinct levels: molecules, clusters of molecules (e.g., hydration shells), and clusters of clusters (e.g., micelles). Self-organization implies that water molecules or molecular clusters arrange themselves into increasingly complex states. It is this self-organization that reportedly permits a network of simple interconnected elements, along with their switching rules, to display coherent behaviors (3). Although the primary water network is held together by short-range hydrogen bonds between neighboring molecules, it may either behave as an extensive system with global coherence or as individual smaller regions with local order (4). These two behaviors have been classically linked to network patterns displaying chaotic or disordered (i.e., bulk liquid water) and more ordered (i.e., water clusters) properties, respectively.

BIOLOGICAL STRUCTURE AND FUNCTION

Molecular biologists originally considered water to be merely an inert solvent within which biomolecules (e.g., proteins and nucleic acids) structured and activated themselves. More recently, water has been perceived as a key structural and functional component of many biomolecules, whose interaction with the surrounding environment is often mediated through *hydration shells*, which are immense water networks surrounding the biomolecules (5). Water releases its hydrogen bonds with biomolecular components so that protein or DNA assembly may begin. Conformational changes in the biomolecule then restructure both the internal (bound or integral) and external (hydrating) water that, in turn, facilitates more changes in the biomolecule. This iterative process appears to repeat until assembly and folding mechanisms yield a bioactive crystal.

In addition to the structural importance of water in biomolecules, the insertion and removal of water also has profound effects on their functioning. One of the most remarkable functions that proteins perform is that of a biochemical catalyst or *enzyme*, which permits chemical reactions to proceed at rates that are millions of times faster than would occur under ambient conditions. Water appears to play several roles in the functioning of enzymes. First, water molecules located at the interface of the protein-substrate complex often provide the free energy that actually binds the enzyme to its substrate. Second, water may be excluded from the active site until the moment of catalysis; at which time, it is allowed to enter the active site and reconfigure hydrogen bonds (permitting the reaction to proceed). Finally, the enzymes actually structure the water network or networks around them, thus enhancing the rate of catalysis (6).

In addition to its role as a structural component of biomolecule, water hydrates DNA as it would any other solute in an aqueous solution. It appears that water is most highly ordered adjacent to the DNA molecule and is less ordered with each successive hydration shell. This highly ordered water is sometimes referred to as *vicinal* or biological water (6). As was the case for proteins, each subunit of the DNA seems to have its own water network that interacts with other networks and, through successive hydration shells, with bulk water. If the geometry of the DNA molecule is contorted, the hydration shells and associated geometric clusters seem to be likewise affected. Similarly, the DNA molecule may contort in response to changes initiated by the water that hydrates it. The reasons for twisting and folding DNA molecules may include stuffing it into chromosomes or unraveling it during transcription and replication.

COMPLEX DYNAMICS

Scientists working with the pentagonal water cluster, which serves as a basic building block for many large hydration shells, observed that water's vibrational states are caused by a combination of bending and stretching motions of its bonds. Molecular vibrations are expressed in the units of cycles per second, or *hertz*. Although water's covalent bonds vibrate at about 10^{14} hertz (one-hundredth of a picosecond per cycle), its hydrogen bonds vibrate within the lower frequency range of 10^{12} to 10^{13} hertz (one-tenth to one picosecond per cycle). The time frames for one cycle of these bond vibrations are shorter than those measured for the exchange hydrogen bonds in water's bulk liquid network (more than one picosecond). One *picosecond* equals a time period of one-trillionth of a second (10^{-12} seconds). In addition to the dynamics associated with vibrating and exchanging bonds, water's molecular network performs several concurrent activities that have been clocked at both faster and slower rates.

As an example, *ultrafast vibrational energy* is transferred in water on timescales less than one-tenth of a picosecond (7). This ultrafast transfer could play a role in liquid water's transporting vibrational energy among certain solutes (e.g., proteins, DNA) and, perhaps, in transferring information within water's local network. Recent spectroscopy studies have suggested that liquid water's network may also function on timescales of less than a *femtosecond* (one-thousandth of a picosecond), which is at least 100 times faster than the ultrafast vibrational energy. Moreover, some of the studies indicate that most molecules in the liquid network form only two (rather than three or four) hydrogen bonds with their neighbors, perhaps creating long chains of molecules within a disordered cluster network (8). In contrast to these sub-picosecond dynamics, the reorientation of water molecules in a spatially restricted environment (e.g., the interface of a micelle) occurs on the much slower timescale of hundreds to thousands of picoseconds. Although further research is required to substantiate the recent observations, models describing both the structure and dynamics of water's molecular network are rapidly evolving.

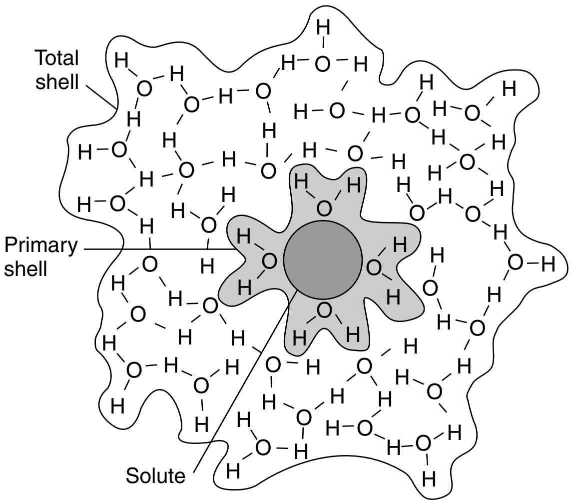

Figure 2. This diagram illustrates the primary and total hydration shells surrounding an ionic, or electrically charged, solute (1). In this case, a positively charged solute (e.g., a sodium ion in seawater) attracts the negatively charged oxygen atoms of surrounding water molecules. A solute's effect on the orientation of water molecules in the liquid network is greatest within the primary shell and diminishes as a function of distance from the hydrated ion. Theoretically, the total hydration shell includes all water molecules in the network that are affected by the solute.

SEAWATER

Thus far, the discussion of water's network has dealt with either pure water or dilute aqueous solutions in which solutes comprise only a small fraction (e.g., less than 0.1%) of the total solution. By contrast, the salts (ions) in seawater account for about 3.5% of the total solution. Unlike the structure of pure water's bulk phases and clusters, the molecular structure of seawater is poorly described as a result of difficulties associated with employing the investigative techniques that routinely probe the structure of pure water networks. Moreover, the high concentration of ions in seawater is hypothesized to significantly affect the water network. As the percentage of water molecules comprising hydration shells increases, the network structure of bulk water is compromised (see Fig. 2). A salting-out effect is observed at very high ion concentrations, when the interaction between water molecules and ions is sufficiently weakened to permit the formation of salt crystals.

The most pertinent changes in the molecular water network that have been observed or hypothesized in transitioning from dilute aqueous solutions to seawater include (1) the aforementioned ion–ion interactions, (2) overlapping hydration shells in which a single water molecule simultaneously hydrates more than one ion, and (3) varying orientations of the water molecules that comprise ion hydration shells (9). These factors are believed to profoundly affect the structure and dynamics of the water network comprising the world's oceans, which contain 97% of the planetary water. Perhaps scientists will better understand the oceans when the secrets of seawater's molecular network dynamics are more fully revealed.

IN SITU CHEMICAL MONITORING

Melissa A. Singer Pressman
Joseph H. Aldstadt, III
Genetic Technologies, Inc.
Testing Institute
Waukesha, Wisconsin

INTRODUCTION

For routine monitoring of environmental systems, *in situ* measurements offer several distinct advantages over laboratory analysis (1). *In situ* analysis allows much higher rates of sample throughput. As a result of the rapid dynamics of most environmental systems, it is important to collect frequent samples to prevent undersampling of the phenomena under study, which is essential to allow for a more accurate characterization of the true dynamics of the system and, therefore, a better understanding of the biogeochemical processes involved (2). Additionally, *in situ* analysis eliminates sample contamination that inevitably develops during the transport and storage of samples to the laboratory. Furthermore, current research efforts in several laboratories have demonstrated that relatively inexpensive monitors can be fielded that can self-calibrate, can be remotely controlled, and can provide reliable measurements in realistic environments (3). In particularly, it is the inability to provide high data quality at trace levels in complex matrices that has prevented *in situ* measurements from gaining more favor.

In situ monitors have been classified broadly as either "chemical sensors" or "chemical analyzers." Chemical sensors depend on diffusion to bring the analyte to the transducer surface. This type of sensor is mechanically simple, sensitive, and practical from the standpoint of low power requirements and small footprint, but often suffers from poor selectivity and the inability to self-calibrate. More importantly, sensors are based on reversible chemical reactions, i.e., the interaction of the analyte with the transducer surface, which makes it difficult for these sensors to detect environmentally relevant levels; that is, to detect trace levels of a chemical species, the equilibrium binding (formation) constants must be very large. For the reaction of analyte A with ligand B to form a complex AB, the rate equations are (3):

$$aA + bB \rightarrow ABrate = -(d/dt)\ [A] = -(d/dt)\ [B]$$
$$= k_1[A]^{\mathrm{a}}[B]^{\mathrm{b}}$$
$$xAB \rightarrow A + Brate = -(d/dt)\ [AB] = k_{-1}[AB]^{\mathrm{x}}$$

The equilibrium constant for the dissociation of the complex is equal to the ratio of the rate constants for the dissociation of the analyte-ligand complex and the formation of the complex, as shown in the following equation (3):

$$K_D = k_{-1}/k_1$$

If the complex dissociates slowly, the time required to return the signal to a steady baseline ("clear down" time) is introduced. One way to avoid this problem is to continuously renew the reagent at the sensor surface. This strategy depends on molecular diffusion to transport the analyte to and from the sensor surface; this type of sensor is called a "renewable reagent sensor" (4–6).

Chemical analyzers, on the other hand, depend on *active* transport of the analyte into and away from the monitor. Although analyzers lack the mechanical simplicity of sensors, the addition of valves and pumps in the design can more importantly provide a means by which to accommodate self-calibration of the monitor. The addition of these mechanical capabilities also allows for multistep, complex chemistries to be used as a way to increase sensitivity and selectivity of the monitor.

Continuous flow analysis (CFA) is a more general term than so-called "chemical analyzers," referring to any measurement process in which the concentration of an analyte is determined based on a steady flow of sample through the instrument (7). Nonchromatographic CFA-based measurement systems are widely used for industrial process control and environmental monitoring. As the instrument is often placed in a hostile environment in these types of applications, the relative simplicity of the CFA approach is attractive (8). Initial attempts to use CFA-based instruments were direct adaptations of benchtop (i.e., laboratory) CFA systems that were ruggedized (e.g., water-proofed) and taken to the sampling site (9). This approach was burdensome, expensive, and far from robust.

An example of an early effort of this type is illustrated by the work of Elliott et al. in using a segmented continuous flow analyzer, often called an "autoanalyzer," for shipboard chemical analyses (10). These researchers monitored nitrate concentrations in the Everglades using a commercially available autoanalyzer that they modified for the nitrate derivatization chemistry. In their design, air bubbles were created in-line to segment the liquid sample stream as a means to prevent uncontrolled dispersion

More recently, *in situ* CFA monitors have been developed that are not merely ruggedized bench-top instruments. One of the more interesting instruments, and the model which inspired this research, was described in work published in 1994 by Jannasch et al. at the Moss Landing Marine Laboratory in Monterey, CA (11). This group of chemical oceanographers was interested in accurately measuring nitrate ion in seawater with high sampling frequency. To accomplish this goal, they designed a CFA monitor "from the ground up" and incorporated several novel features. In doing so, they created a new paradigm in the science of chemical measurements.

In the system developed by Jannasch et al., a well-characterized, irreversible colorimetric method was used to measure nitrate. The dissolved nitrate was determined by reduction to nitrite in a neutrally buffered (imidazole) solution by an in-line copperized cadmium surface. The nitrite then merged with an incoming reagent stream containing sulfanilamide (*p*-aminobenzenesulfonamide or

PABSA) in acid to undergo reaction to form a diazonium ion. This species was then reacted with *N*-(1-naphthyl)ethylenediamine dihydrochloride (NED) to form an azo dye of high molar absorptivity that was detected by molecular absorbance spectroscopy.

The novel *in situ* monitor that the Moss Landing group developed used nonmechanical osmotic pumps to both deliver reagents to the system and to propel the continuous flow sample stream through the microscale manifold (~1 mm diameter conduits) (11). For the two reagent osmotic pumps (i.e., for PABSA and NED), the flow was driven by the osmotic pressure differential developed across the semipermeable membrane that separated a saturated brine solution from a solution with deionized water (12). The pressure created from the diffusion of deionized water across the semipermeable membranes resulted in compression of inner bags containing the reagents and their pulse-free delivery to the manifold (at ~4 μL per hr). For the sample pump, conventional osmotic pumps were modified by removing the inner bags and mounting the rigid permeable membranes in an enclosed container. Four of these modified osmotic pumps were then coupled to draw sample through the manifold at 12 μL per hr.

Microscale flow manifolds can be fabricated by "cold-forging" PVC: A wire bent in the desired flow microconduit configuration was pressed onto the surface of a flat-milled sheet of PVC. Following removal of the wire, ~0.5-mm diameter holes were drilled into the plate for connection of components. The optical system in the Moss Landing nitrate analyzer used a simple light-emitting diode (LED) source with photodiode detector, with data collected by a low-power programmable datalogger. The monitor exhibited a detection limit of 0.11 μM and a linear response to 20 μM nitrate. Measurements were taken every 2 min and the response time was ~30 min. Quality control samples were measured automatically every 48 hours. Jannasch et al. demonstrated the *in situ* monitor's stability by operating it continuously for month-long periods in large tanks at the Monterey Bay Aquarium.

The Moss Landing group's research incorporated several novel features—mainly the microscale flow design using nonmechanical osmotic pumps for reagent delivery and sample intake—into an *in situ* monitor capable of frequent and reliable measurements in environmentally complex samples. In addition, through the periodic addition of nitrate standards, the monitor automatically self-calibrated by correcting for baseline drift. Another advantage to this system was its flexibility; using different irreversible chemistries, the *in situ* monitor could be readily adapted to measure other analytes for optical detection and quantitation. A drawback of the system was that it detected relatively high levels of analyte (i.e., micromolar levels), albeit levels that are relevant to studying this important nutrient. Concerns over particles in the water eventually clogging the microconduit channels are less serious, because small particles (approx. <50 μm) cannot be drawn into the manifold at the low flow rates used.

In 1999, Byrne and coworkers at the University of South Florida developed a monitor based on long path-length absorbance spectroscopy (LPAS), which could be used for the determination of nitrate and several other biologically important chemicals in seawater at much lower levels. These workers used the same well-characterized chemistry as Jannasch et al., but they benefited from a 1-m liquid core waveguide as the absorbance flow cell. Another difference with the Byrne group's approach was in the use of mechanical (peristaltic) pumps instead of osmotic pumps—resulting in a five-fold increase in response time. This monitor was field tested recently in the Gulf of Mexico, and detection limits for nitrate were observed to be approximately 2 nM (13,14).

The next key development was reported recently by Worsfold and coworkers at the University of Plymouth. A portable *in situ* monitor for the determination of trace phosphate in surface waters was developed (15,16). This work demonstrated a monitor that was built with a forged plate similar in design to the work done by Jannasch et al. The phosphate monitor had a throughput of ~225 determination per hr and a detection limit of 0.15 μM with 2.0% RSD ($n = 9$) reported. This monitor was evaluated by mapping the phosphate concentration in Port Phillip Bay in Australia for a brief (2 hr) period. The agreement between determinations obtained using the *in situ* monitor and data obtained using manual sampling aboard the ship followed by laboratory analysis was within ±10%.

INSTRUMENT DEVELOPMENT FOR *IN SITU* MONITORING OF CR(VI)

For the *in situ* measurement of relatively low levels of important biological nutrients such as nitrate or phosphate, the work of the Jannasch, Byrne, and Worsfold groups (and others) was pioneering. However, clearly the next challenge in developing *in situ* monitoring instruments was the ability to measure relevant levels of trace metal ions in surface waters by the *in situ* approach. Hexavalent Cr was chosen as the target analyte because it is regulated at nanomolar levels (low parts per million) in surface waters. In addition, the metropolitan-industrial areas of southern Lake Michigan, specifically the Milwaukee Harbor area, contain industrial sources that generate a concentration of total Cr in surface water that ranges from 0.1 to greater than 100 μg/L (17). These reasons, coupled with the well-characterized spectrometric chemistry (18–21), made Cr a logical choice as a representative analyte to study for the development of an *in situ* monitor that measures trace metals in the environment.

A benchtop method for determining hexavalent chromium in high particulate-containing surface waters by sequential injection (SI) was developed (22). For utility in particulate-rich waters, the relative performance of two membrane-based methods for sampling was compared. The first membrane approach was based on a commercial design known as the "supported capillary membrane sampler (SCMS)" that uses tubular membranes; the second approach was based on a conventional parallel-plate dialyzer (PPD) design that uses planar membranes. The membranes were evaluated using the colorimetric method for the determination of hexavalent chromium by complexation with 1,5-diphenylcarbazide (DPC). Thin-walled (~200 μm) microporous (pore size ~0.2 μm) polypropylene membranes were equilibrated with DPC during each sampling period. Formation of the DPC-Cr(VI) complex allowed for efficient membrane transport; without the membrane, Cr(VI) transport decreased by ~90%. Factors optimized included reagent concentration, sampling time, flow rate, and spectrophotometric conditions. Optimal conditions for the reagents were 2.00 mM DPC and 0.100 M nitric acid, and sampling times of 600 s and 900 s for the planar and tubular designs, respectively. The planar (PPD) design increased the sensitivity relative to the tubular (SCMS) design by ~225%. The PPD-SI method was applied to the determination of dissolved Cr(VI) in high particulate-containing surface water samples. Figures-of-merit included a detection limit of <20 μg/L, precision of 1.1% relative standard deviation at 100 μg/L ($n = 4$), and selectivity for dissolved Cr(VI) in several surface water samples with high levels of particulate matter and potential interferences.

The optimized method conditions from the SI studies was then applied to the design, fabrication, and testing of an *in situ* remote monitor for the measurement of sub-part per million levels in surface waters (23,24). The monitor was based on a continuous flow analysis (CFA) design in which a narrow conduit (1.0 mm) manifold was hot-forged between Plexiglas plates. A miniature low-power peristaltic pump was used to draw sample (1.5 mL/hr) into the manifold where chromium (VI) in the sample was derivatized to its diphenylcarbazide complex. The absorbance of the complex was then measured in a light-emitting diode/photodiode detection cell. Solenoid-actuated osmotic pumps were used to introduce quality control standards at user-determined periodicities to achieve acceptable data quality. Figures-of-merit included a detection limit of 0.25 mg/L (7 min cycle time), precision of 2.5% relative standard deviation at 1 mg/L ($n = 3$), and selectivity for dissolved Cr(VI) in several surface water samples with moderate levels of particulate matter. Continuous testing of the monitor over a three-week period using Milwaukee Harbor water fortified with Cr(VI) yielded results that were in close agreement (±5%) with an ICP-MS reference method.

NITROGEN

Kenneth F. Steele
Kristofor R. Brye
University of Arkansas
Fayetteville, Arkansas

INTRODUCTION

Nitrogen (N) is ubiquitous in the environment and in the correct form is an essential nutrient for plants and animals. About 26.5% of Earth's nitrogen is in rocks and essentially all of the remainder (73%) is in the atmosphere as an inert monotomic gas (N_2) that comprises 78% of the atmosphere (1). Only a small amount of nitrogen is present in the hydrosphere and biosphere, but nitrogen is a crucial nutrient there. For nitrogen to be used by organisms, it must be in a usable form; it must be combined or "fixed" with oxygen or hydrogen. The most common fixed form of nitrogen in ground water is the anionic oxide—nitrate (NO_3^-), and the second most common form is the cationic form–ammonium (NH_4^+). Approximately 85% of the nitrogen in stream water is in the form of organic N and most of the rest (NO_3^- and NH_4^+) is derived from the decomposition of organic matter (2). N_2 is converted to organic nitrogen predominantly by microorganisms and certain plants. About 96% of the nitrogen in soil is bound in organic matter, and nitrate is a product of organic matter degradation (3). Nitrogen occurs in five oxidation states, −3, 0, +1, +3 and +5, that are primarily the result of bacteria-induced oxidation. The nitrogen species are listed in Table 1.

NITROGEN CYCLE

Fixation by plants can occur; leguminous plants convert N_2 to organic nitrogen compounds, but most plants cannot use N_2 directly. Most plants require atmospheric nitrogen converted to ammonium or nitrate ions (4). Organic nitrogen is not directly available to plant roots and has to be mineralized in the soil by a chain of microbial processes (Fig. 1). The release of ammonium and ammonia (total ammonia) from organic matter is referred to as mineralization (3) or ammonification. Total ammonia is readily oxidized to nitrate. The conversion of nitrogen gas to fixed form and from fixed form to nitrogen gas includes four main conversion reactions that form the essential parts of the nitrogen cycle (Fig. 1):

Table 1. Common Forms of Nitrogen in the Environment and Typical Concentrations of Nitrogen

Species	Oxidation State	Typical Source	Typical Concentration in Water as N
N_2	0	Atmosphere	14 mg/L
NO_3^-	+5	Oxidation of organic matter/ atmosphere	<0.6 mg/L background to 250 mg/L for contaminated sources
NO_2^-	+3	Intermediate form in nitrification, denitrification, and reduction of NO_3^-	<0.1 mg/L
NH_3	−3	Fixation of N_2	<0.01 mg/L
NH_4^+	−3	Ionization of NH_3	<0.01 mg/L
N_2O	+1	Reduction of NO_2^-	Negligible

1. fixation
2. ammonification
3. nitrification
4. denitrification

Fixation

For N_2 gas to be used by plants, it must first be fixed with hydrogen to form ammonium ions. Fixation is a microbial process, and even the few types of plants that can use N_2 directly are ultimately dependent on microbes also. For example, legumes can use N_2 because of the symbiotic relationship between the plant and *Rhizobium* bacteria that live in nodules in the plant roots. Other means of fixation include conversion of atmospheric N_2 to nitrate by lightning and industrial processes, such as the Haber–Bosch process for producing ammonia (NH_3 gas) (4).

Ammonification

Ammonification (also referred to as mineralization), the process of converting organic nitrogen (e.g., urea) to ammonium (Eq. 1), generally occurs during decomposition of animal and plant matter (4). Dissolution of ammonium carbonate releases ammonium ions:

$$\underset{\text{Urea}}{H_2NCONH_2} + 2H_2O \longrightarrow \underset{\text{Ammonium carbonate}}{(NH_4)_2CO_3} \qquad (1)$$

As indicated by Eqs. 2 and 3, the relationship between NH_3 and NH_4^+ is pH dependent. Under alkaline conditions (pH > 9), formation of NH_3 is favored due to neutralization of NH_4^+ by hydroxide (OH^-) (Eq. 2). In acid conditions (Eq. 3), ammonia gas is transformed into

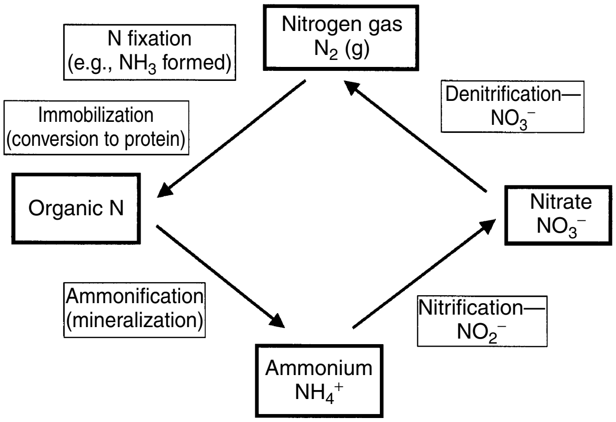

Figure 1. Simplified nitrogen cycle.

ammonium ions. For example, at 15 °C, ammonia gas makes up 0.027% of total ammonia ($NH_3 + NH_4^+$) at a pH of 6.0, but makes up 2.7% of total ammonia at a pH of 8.0. Although 2.7% is a small amount, it is a hundredfold increase of ammonia (5).

$$NH_3 + H_2O = NH_4^+ + OH^- \quad (2)$$

$$NH_3 + H^+ = NH_4^+ \quad (3)$$

Other factors that affect the concentration of NH_3 in water are temperature and ionic strength. The concentration of NH_3 increases as temperature increases and decreases as ionic strength increases. At 15 °C and pH 8.0, the percent NH_3 in solution is 2.7%, whereas, at 30 °C and pH 8.0, the concentration increases to 7.5% (5). The effect of ionic strength is minor for fresh to slightly saline waters.

Nitrification

Nitrification is the biological oxidation of ammonium ions to nitrite followed by conversion of nitrite to nitrate. Biological oxidation is carried out by *Nitrosomonas* and *Nitrobacter* bacteria (6,7) as shown in Eqs. 4 and 5. In addition to these two bacteria, (8) indicate that several different autotrophic organisms mediate nitrification:

$$2NH_4^+ + 3O_2 \xrightarrow[\text{bacteria}]{\textit{Nitrosomonas}} 2NO_2^-(\text{nitrite}) + 4H^+ + 2H_2O \quad (4)$$

$$2NO_2^- + O_2 \xrightarrow[\text{bacteria}]{\textit{Nitrobacter}} 2NO_3^-(\text{nitrate}) \quad (5)$$

Because oxidation of nitrite to nitrate is a rapid reaction and nitrite is metastable, nitrite is not abundant (Table 1) (9). Note that if both oxygen and nitrate are present in soil, bacteria preferentially use oxygen because it yields more energy (1). Therefore, nitrification typically occurs in oxic conditions, whereas denitrification occurs in anoxic conditions.

Denitrification

Denitrification is the biological reduction of nitrate to nitrogen gas by heterotrophic bacteria, such as *Pseudomonas denitrificans* and *Thiobacillus denitrificans* (8). These bacteria require organic carbon for energy (Equations 6 and 7).

$$NO_3^- + \text{organic carbon} \xrightarrow{\text{Heterotrophic bacteria}} NO_2^- \quad (6)$$

$$NO_2^- + \text{organic carbon} \xrightarrow{\text{Heterotrophic bacteria}} N_2 + CO_2 + H_2O \quad (7)$$

Because oxidation of organic carbon by oxygen yields more energy, generally the oxygen concentration must be very low (anoxic conditions) for nitrate to be used (4,6).

Analytical Terminology

Analytically, organic nitrogen (proteins, peptides, nucleic acid, urea, and other compounds) and ammonia are determined together and are referred to as “Kjeldjahl nitrogen,” a term that refers to the analytical method used. By expressing all nitrogen species as N, the concentrations of the various species can be added and subtracted. Organic N (−3 charge) is determined by analyzing ammonia by other methods and subtracting this value from the Kjeldhal nitrogen concentration (10).

Inorganic N is the sum of nitrate, nitrite, and total ammonia (ammonia plus ammonium). Some analytical methods determine the sum of nitrate and nitrite, but the results are sometimes incorrectly reported as nitrate because nitrite concentrations are considered very low. Total N is the sum of organic N and inorganic N.

AQUATIC NITROGEN

Despite the large proportion of nitrogen in the atmosphere, its abundance in water is low-measured as a few mg/L N, mostly in the inert form of nitrogen. Typically, the most environmentally important form of nitrogen is nitrate; however, dissolved organic nitrogen makes up the majority of total dissolved nitrogen in watersheds in New England (11). Note that for primary producers ammonium may be more available to organisms than nitrate (12). The various common species of nitrogen in the environment and the estimated concentration of each are presented in Table 1. Mueller and others (13) have demonstrated that background concentrations of nitrate as N are less that 0.6 mg/L.

Nitrogen species are subject to oxidation/reduction (redox) and reactions with hydrogen ions (pH). In Fig. 2, the NO_3^-/NO_2^- pe–pH boundary is dotted to indicate that NO_2^- is metastable. Nitrate, at a pe above the NO_3^-/NO_2^- boundary, is reduced at the NO_3^-/N_2 boundary to form nitrogen. Thus, there is little NO_3^- available to form NO_2^-. Because nitrite is a metastable species, it occurs only in low concentrations in natural waters where denitrification is occurring (9). Nitrate is present in the N_2 field, but under natural conditions, it is present in concentrations less than those of N_2. Ammonium ions are the dominant nitrogen species at low pe and pH. Ammonia is the dominant species above pH 9 (Fig. 2) and thus is not present in significant concentrations in natural waters; most natural waters have a pH range of 5–9. Dissolved organic N can also be relatively mobile.

Mobility

Nitrate is very soluble in water and because of its negative charge, is not adsorbed by humus or clay. Nitrate not taken up by plants can be transported from the upper soil zone to lower soil zones and eventually to groundwater. Ammonium ions are not nearly as mobile as nitrate ions, in part, because their positive charge allows their transport to be retarded by adsorption on humus and clay. In some situations, ammonium ions can be transported to deep soil horizons (3).

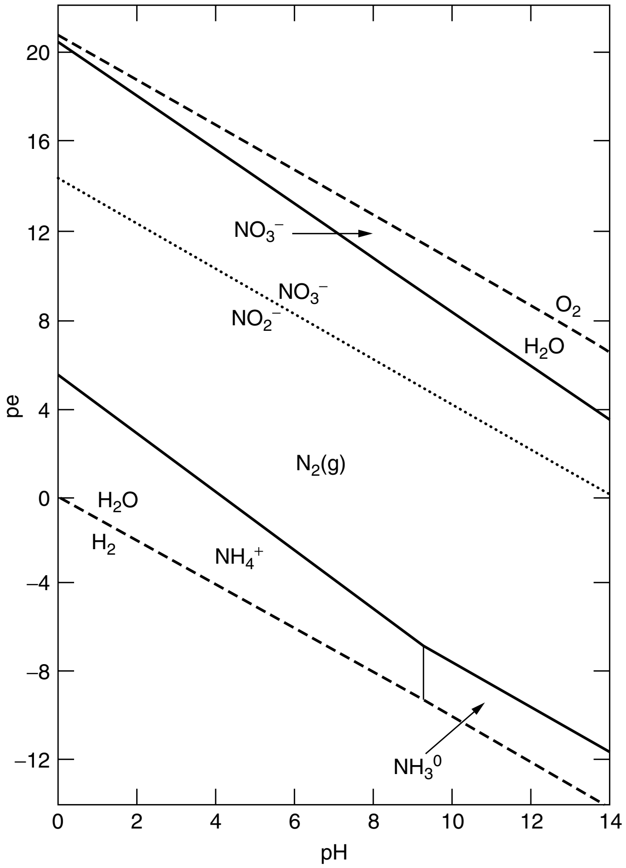

Figure 2. Stability fields for common nitrogen species in natural waters. The diagram is based on the following conditions: temperature of 25 °C, partial pressures of H_2 and O_2 are each 1 atmosphere, partial pressure of N_2 is 0.77 atmosphere, and total aqueous N concentration is 0.001 moles per liter.

Toxicity

Ammonia is a pungent, colorless gas that is very soluble in water and is toxic to fish at concentrations greater than 0.2 mg/L. Dissolved ammonia reacts with water to form ammonium ions, which are not nearly as toxic (1/50th) as the gas (3). The ammonia–ammonium equilibrium is controlled to a large extent by temperature and pH; only highly alkaline waters favor the formation of ammonia. The pH range of most natural waters is such that ammonium ions are dominant compared to ammonia gas (Fig. 2). The U.S. Environmental Protection Agency bases its ammonia criteria for water on a complex set of equations that include the effect of temperature and pH on ammonia concentration. The equations were developed to account for acute and chronic toxicity to particular types of fish. In addition, the criteria are based on specific periods of time and the frequency of exceeding these criteria (14).

Typically nitrate is toxic to warm-blooded animals only where large amounts of nitrite are formed by the reduction of nitrate. Nitrate can be reduced in the gastrointestinal tract to nitrite, especially in infants. Nitrite enters the bloodstream and reacts with hemoglobin to produce methemoglobin that reduces the number of hemoglobin cells available for oxygen exchange. These reactions can be life threatening for children less than 3 years old. Babies who consume water with nitrate concentrations as low as 1 mg/L as N risk methemoglobinia or "blue baby disease" because of the impairment of oxygen transport. There are also indications that nitrate (as related to nitroso compounds) may be associated with gastric cancer and perhaps liver and kidney cancer. The relative consumption of nitrate from water compared to consumption of dietary nitrate is a factor that concerns researchers attempting to determine the risk of cancer from water (15,16). The maximum concentration limit (MCL) of 10 mg/L N for nitrate in drinking water is based on minimizing methemoglobinia and is considered safe concerning cancer.

CONTAMINATION

The causes of pollution of water are divided into point sources and nonpoint sources. Nitrogen contamination of water is generally related to nitrate from sewage and septic systems (point sources) and from agricultural sources. The agricultural sources are commercial and animal manure fertilizers (nonpoint sources) (17,18) and from confined animal operations (point sources). Agriculture is generally considered the main source of nitrogen pollution of water (19). During rainstorms, streams often exhibit a dilution of nitrate concentration that indicates that most of the nitrate is transported to these streams by groundwater. Excessive nutrients in runoff can result in eutrophication of surface waters, for example, the Neuse River in North Carolina, U.S.A. (20). Best management practices have been developed to minimize the negative impacts of fertilizers (17).

ISOTOPES

There are two stable isotopes of nitrogen, ^{14}N and ^{15}N. Although the whole earth abundance of ^{14}N is 99.63‰ of total nitrogen, due to fractionation, the $^{15}N:^{14}N$ ratio is 0.003677 (21) in the atmosphere. Differences in the ratio of the two isotopes in the various nitrogen species are a result of the faster chemical reaction of the lighter isotope than the heavier isotope. Isotopic ratios of nitrogen are expressed as

$$\delta^{15}\mathrm{N} = [(R_{\mathrm{sample}}/R_{\mathrm{air}}) - 1] \times 1000$$

where R is the abundance ratio of ^{15}N to ^{14}N. The international standard for $\delta^{15}N$ is air, which by definition has a $\delta^{15}N$ of 0‰. Values greater than 0‰ indicate enrichment in ^{15}N, and values less than 0‰ indicate depletion of ^{15}N. Sources of nitrate have been determined using $\delta^{15}N$. The premise is that agricultural activity and sewage (including septic tank effluent) may have distinct $\delta^{15}N$ values. A definitive determination of source is sometimes thwarted by the possibility of overlapping $\delta^{15}N$ values between possible sources and changes in δ^{15} N due to volatilization of NH_3 from the soil and denitrification of nitrate in water. The origin of the nitrate in water can be found by using $\delta^{18}O$ to recognize different sources of nitrate and the influence of denitrification on δ^{15}N (21,22). A number of studies have had success using N and often O isotopes to determine the source of nitrate contamination (23,24).

OSMOSIS-DIFFUSION OF SOLVENT OR CAUSED BY DIFFUSION OF SOLUTES?

KARL ERIK ZACHARIASSEN
Norwegian University of
Science and Technology
Trondheim, Norway

Osmosis is the movement of water through a semipermeable membrane separating two solutions to the solution with the higher solute concentration. The membrane is semipermeable in the sense that it is permeable to water, but not to the solutes. The osmotic movement of water can be blocked by the application on the high concentration side of a hydrostatic pressure, which counteracts the so-called osmotic pressure that moves the water through the membrane.

The prevailing theory ascribes osmosis to a diffusion of water molecules through the membrane down a water concentration gradient across the membrane. The solutes are supposed to dilute the water, and the dilution will be strongest at the side with the highest solute concentration.

However, several investigators claim that this explanation fails to explain important characteristics of osmotic phenomena. Osmotic movement of water is considerably faster than should be expected from a diffusive movement of water. In addition, the water concentration of solutions of different solutes are not correlated with the osmotic activities of the solutions. Furthermore, the osmotic pressure is related to the total concentrations of dissolved particles, and van t'Hoff pointed out that the number of solute particles and the solution volume are related to the osmotic pressure in the same way as the number of molecules, pressure, and volume of a gas, i.e., osmotic phenomena, follow the universal gas laws. No theory has been proposed to explain the agreement between osmotic phenomena and gas laws on the basis of diffusion of water down a water concentration gradient.

In 1903, George Hulett (1) published a theory that explains the agreement between osmotic phenomena and gas laws and that is in agreement with the other observations on osmotic phenomena. Hulett emphasized that the solute particles diffuse inside solutions in the same way as gas molecules diffuse within the space in which the gas is distributed. In the same manner, as gas molecules create a pressure when they collide with the gas boundary, solute particles create a pressure when they collide with the boundary of the solution. Both for gases and solutions this pressure will tend to cause the volume to expand, which is easy for a gas if the boundaries can yield to the pressure and allow expansion of the volume. However, the water in which the solutes of a solution are distributed is essentially incompressible, and the expansive pressure created by the diffusing solutes cannot lead to an expansion unless more water can enter the solution and increase the solution volume. The semipermeable membrane of osmotic processes allows such an influx of water from a solution where a lower solute concentration creates a lower expanding pressure, whereas the solutes that create the pressure are prevented from passing. Water will subsequently move across the membrane until the pressures on both sides are equal.

According to the gas laws, an ideal 1 molar solution (1 mole of particles dissolved in a volume of 1 L), which is separated from pure water by a semipermeable, will create a pressure of 22.1 atm, which corresponds to a water column of impressive 224 m. It will have a melting point of $-1.86\,^{\circ}$C, and a solution with this osmotic concentration is said to be a 1 osmolar solution.

Proportionality exists among the osmolality, the osmotic pressure, and the melting point depression. This proportional relationship with osmotic pressure is also displayed by vapor pressure and boiling point elevation. Because of the exact proportionality that exists among these parameters, they are frequently referred to as the colligative parameters (from the Latin *colligare* = bind together).

A closer inspection of the relationship between mole-based concentration measures and the colligative properties reveals that it is the molal concentration that is most closely related to the colligative parameters. For this reason, some investigators prefer the term *osmolality*.

UNITS FOR OSMOTIC CONCENTRATIONS

Some confusion exists about the units for osmotic concentration. The officially approved unit for osmolality is Osmoles/kg water. Some investigators find that this unit is misleading, because it invites us to consider an Osmole as a defined amount of solute, which when diluted in 1 kg of water, gives an osmolality of 1 Osmole/kg water. Accordingly, when diluted in 2 kg of water, the same osmole of solutes should give an osmolality of 0.5 Osmole/kg water, but this is never the case. An Osmole is not a defined amount of solute, and the concept of osmolality has a meaning only for solutions. For this reason, some investigators use the unit Osm, where the letter m emphasizes the close relationship between osmotic and molal concentrations, which have m as the official unit.

To add to the confusion, the official unit for osmolality has led some authors to introduce Osmoles/L solution as a unit for osmolarity. However, the melting point is claimed to be $-1.86\,^{\circ}$C both for a 1 osmolal and for a 1 osmolar solution. Hence, the distinction between units for osmolality and osmolarity is merely semantic and of no practical consequence. Osmolality and osmolarity are different terms for the same thing, and furthermore, they are just quasi-measures for concentration. Solutions of different solutes with the same molar or molal concentrations all have different osmolalities, and for a given type of solute, no exact proportionality exists between molal concentrations on one side and colligative parameters on the other, which is at least in part because the amount of hydration water associated with each solute particle differs substantially from substance to substance, and for dissolved salts, the degree of dissociation varies from substance to substance and with their concentration.

Although osmolality is not a precise chemical concentration measure, it is a useful tool for comparing total solute concentrations of fluids in physiology, and it is a useful measure to control the chemical solute concentrations of body fluids and solutions.

PARTITIONING AND BIOAVAILABILITY

Jim Philp
Fiona Stainsby
Sandra Dunbar
Napier University
Edinburgh, Scotland, United Kingdom

INTRODUCTION

As soon as a chemical is spilled it becomes a pollutant, but the fate of that pollutant depends to a large degree on its chemistry, which determines how it will partition to various “compartments,” or phases, of the environment. This idea is enshrined in risk-based strategies for assessing contaminated land and water. In many cases a contaminant spill on land quickly becomes a water pollution issue, be it surface or groundwater. As many countries are heavily reliant on groundwater as a source of potable water, investigating the fate of pollutants is an essential prerequisite to any remedial action plan for contaminant cleanup.

Partitioning is governed by some fundamental properties of chemicals, but partitioning should be viewed in relation to the toxicity of the chemical in question and its degradability in the various environmental compartments. In this article, the important properties of chemicals that relate to partitioning are examined, and the theory is reinforced by example. The examples chosen are benzene, phenol, and some chlorinated phenols. All of these compounds are important industrial chemicals.

Bioavailability is a simple concept, but practically it is a complex issue that remains to be resolved. The bioavailability concept is also enshrined in the risk assessment approach to contaminated land and water. If a pollutant is present in soil or water in high concentration, but is not available to the biota, then surely it presents minimal risk. Regardless of the apparent simplicity of the concept, there is great urgency to find methods for quantifying bioavailability. Some approaches to solving this quandary are discussed.

PROPERTIES THAT DETERMINE PARTITIONING

The compartments of the environment relevant to partitioning are air, water, soil, and sediment and, through bioaccumulation/magnification through food chains, biota. Partitioning into the biota is beyond the scope of this article, and it will deal principally with partitioning to nonliving compartments. Figure 1 represents a common scenario in environmental remediation, contamination from old gas stations.

Vapor Pressure

This is the partial pressure of a chemical in a gas phase that is in equilibrium with the pure liquid or solid phase of the chemical. Vapor pressure is greatly influenced by temperature, and figures are usually quoted at a constant temperature (usually 20 °C or 25 °C). If the volume of the containing vessel is also known, the vapor pressure can be used to calculate the concentration of the chemical in the headspace of the vessel from the ideal gas law:

$$\frac{n}{V} = \frac{P}{RT} \tag{1}$$

where P = vapor pressure (atm)
V = volume
n = number of moles of the chemical
R = gas constant
T = absolute temperature

Another way to think of vapor pressure is that it is the pressure that a vapor exerts on the atmosphere: thus it will be clear that it is the driving force for volatilization. Vapor pressures of organic compounds are often compared to the vapor pressure of mercury (atmospheric pressure is 760 mmHg). Thus the vapor pressure of benzene is 87.2 mmHg at 25 °C. Volatilization potential can be misleading in the absence of information on the water solubility of the compound, however. A compound that has a low vapor pressure may still have a high tendency to "escape" if the water solubility is low. For example in Table 1, 2,4,6-trichlorophenol has a much lower vapor pressure than 3-chlorophenol, and yet its tendency to escape to air is higher. This can be explained when the water solubilities are compared: the much lower value for 2,4,6-trichlorophenol results in it having a Henry's constant about a magnitude order higher than 3-chlorophenol, even though its vapor pressure is much lower.

Henry's Law Constant

To study partition phenomena, then, Henry's law constant is more valuable than vapor pressure. Henry's law constant is the ratio of the equilibrium concentration of a compound in air and its equilibrium concentration in water. It can therefore be regarded as the partition coefficient between air and water, and is the best indicator of the tendency of a chemical to volatilize from water. Henry's law constant can be written as:

$$H = \frac{P}{S} \tag{2}$$

where H = Henry's law constant (atm-m^3/mol)
P = vapor pressure (atm)
S = water solubility (mol/m^3)

Water Solubility

This is of central importance to understanding partition phenomena in the environment. It is the maximum, or

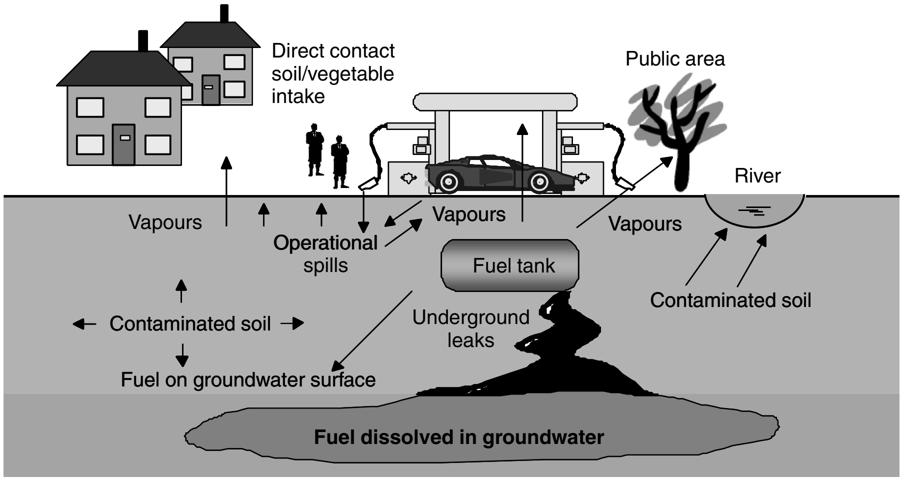

Figure 1. Partitioning of fuel as a contaminant from a gas station that has a leaking underground storage tank. Because fuels are multicomponent liquids, different components partition to different compartments of the environment.

saturation, concentration of a compound that dissolves in water. It also is significantly affected by temperature. As the water solubility of compounds is defined by a host of factors, comparisons should always be made at a constant temperature, usually 25 °C. In natural water systems, the concentration of pollutant chemicals is usually rather low, making this especially important.

Polarity refers to the extent to which charge is unevenly distributed within a molecule. Water itself is highly polar. Therefore charged or highly polar organic and inorganic molecules, hydrophilic molecules, are readily soluble in water. Conversely, nonpolar, hydrophobic molecules find solution in water a less energetically favorable state, and they have low water solubility. In the examples in Table 1, benzene has moderate water solubility, but the addition of the polar hydroxyl group makes phenol much more water soluble. The solubility of any solute in any solvent is mediated by forces of attraction; the main ones are:

- van der Waals forces;
- hydrogen bonding;
- dipole–dipole interactions.

The size and shape of a molecule is also critical in determining its overall water solubility. Large molecules tend to have lower water solubility because they have a higher molar volume. The addition of halogens to an organic molecule might be expected to increase the water solubility of the new molecule as halogens are electronegative (electron-withdrawing) species and would thus tend to increase the polarity of the molecule. However, in the increasingly chlorinated series of phenols in Table 1, this is not the case: increasing chlorination very markedly decreases the solubility of chlorophenols because the halogens increase the molecular volume of organic compounds (1).

Other chemical functional groups affect water solubility in rather specific ways. The presence of polar functional groups tends to increase the water solubility of molecules compared to unsubstituted hydrocarbons: alcohols, amines, ethers, ketones, and organic acids are good examples. Even with these examples, though, a general rule of increasing molecular size and decreasing water solubility still exists. The short-chain fatty acid acetic acid is much more water soluble than a long-chain fatty acid. The additions to the molecule are not more polar functional groups but simply more nonpolar $C–H_2$ groups that make the molecule larger but less polar.

The situation is further complicated by more specific chemical reactions. The chlorophenols in Table 1 illustrate this point. Chlorophenols behave as weak acids when dissolved in water due to the loss of a proton from the hydroxyl group to leave a phenoxide ion. The more chlorines that are added to the ring, the more electrons are withdrawn from the electron-rich phenoxide ion. This lowers the phenoxide negative charge and therefore lowers its ability to hold a proton. Thus the more chlorines on the ring, the more easily a proton is released, and the greater the acidity. The ionized form is usually several orders of magnitude more water soluble than the neutral un-ionized form. The relative proportion of each species is highly dependent on pH.

Log K_{ow}, a Measure of Hydrophobicity

Polarity and water solubility do not give direct measures of the hydrophobicity of a compound. A hydrophobic compound might be expected to dissolve in a lipophilic phase, and this is the basis for the octanol–water partition coefficient, K_{ow}. This is the ratio of a chemical's concentration, at equilibrium, when dissolved in octanol and in water, when both phases are saturated with each other.

This test was devised by the pharmaceutical industry to study partitioning of drugs as it roughly equates to the partitioning between water and body fat. It has proven very useful in predicting how chemicals partition in the environment. Large molecules of low polarity have a high K_{ow} and are more likely to partition to solids in the environment. Small, polar molecules dissolve in water rather than octanol, have a low K_{ow}, are much less likely to partition to solids in the environment, and so are more likely to remain in an aqueous phase:

$$K_{ow} = \frac{\begin{array}{c}\text{concentration of pollutant in}\\ \text{water-saturated octanol (mg/L)}\end{array}}{\begin{array}{c}\text{concentration of pollutant}\\ \text{in octanol-saturated water (mg/L)}\end{array}} \qquad (3)$$

The range of values for K_{ow} is very wide, and tabulated values are more often expressed as log K_{ow}. In the examples in Table 1, it can be seen that, as the molecule becomes larger through increasing chlorination, the water solubility decreases and log K_{ow} increases.

Log K_{oc}, Partitioning to Soil

The most basic statement of the composition of soil is that it contains sand, clay, organic matter, water, and air. Although typically the organic matter content of soil is in the range of 0.1 to 5%, this is where organic pollutants sorb, not to the soil as a whole. The soil adsorption coefficient, K_{oc}, takes account of this. For a liquid organic pollutant,

$$K_{oc}\ (\text{mL/g}) = \frac{\begin{array}{c}\text{mass of pollutant sorbed}\\ \text{to soil organic matter (mg/g)}\end{array}}{\begin{array}{c}\text{mass of pollutant in}\\ \text{the aqueous phase (mg/mL)}\end{array}} \qquad (4)$$

The range of values for K_{oc} is very wide, and therefore the use of log K_{oc} is preferred. The soil partition coefficient is greater, the more hydrophobic the pollutant. However, it has been measured for far fewer chemicals than K_{ow}. It might be expected to be a more realistic measure than K_{ow}, but as data are relatively rare for K_{oc}, a series of correlation equations has been developed that relate K_{oc} to K_{ow}. The increase in log K_{ow} seen in Table 1 as chlorination increases is mirrored by increasing log K_{oc}.

Fugacity

The term fugacity literally means the "tendency to flee," and refers to a molecule's driving force to escape from the compartment in which it currently exists. With knowledge of all of a chemical's partition coefficients, it is possible to predict its relative concentration in air, water, and soil at equilibrium. The gradient of fugacity between two compartments (e.g., soil and soil porewater) determines the potential for the chemical to move from one compartment to the other. Fugacity therefore has units of pressure, but this can be related to the chemical concentration through modeling, and thus the distribution through various compartments predicted (Table 1).

THE RELATIONSHIP TO TOXICITY AND BIODEGRADATION

Hydrophobicity and Toxicity

Particularly K_{ow} and log K_{ow} have become increasingly used as predictors of the behavior of pollutants in the environment. It has been correlated with toxicity. The most common mode of action regarding the toxicity of industrial pollutants is probably narcosis. Nonpolar narcosis results from the perturbation of cellular membranes (2) due to the entry of hydrophobic (lipid-soluble) molecules into the phospholipid bilayer of the membrane. Narcosis has been shown to be a nonspecific physiological effect which is independent of chemical structure, and log K_{ow} is highly correlated with nonpolar narcosis toxicity (3).

Phenols have greater toxicity than predicted by nonpolar narcosis (4). They act by polar narcosis, which probably results from a strong hydrogen-bonding group that makes the compound more polar. Nevertheless, there is still a strong correlation between the toxicity of these compounds and log K_{ow}. Pentachlorophenol has greater toxicity as a result of a further mechanism: its acidity makes it a weak acid respiratory uncoupler (WARU). Terada (5) noted that WARUs possess an acid-dissociable moiety (e.g., a hydroxyl group), a bulky hydrophobic moiety, such as an aromatic ring, and multiple electronegative groups, such as halogens. During weak acid uncoupling, ATP synthesis is inhibited with no effect on the respiratory chain (6) because electron transport and phosphorylation reactions are uncoupled from each other.

Hydrophobicity and Biodegradability

It is believed that only molecules of hydrocarbons that are dissolved in the aqueous phase are available for intracellular metabolism (7). The rate at which a particular organic compound dissolves in water is critical to both the toxicity and biodegradability of the compound as this governs the rate of transfer to the organism (in biodegradability, microorganisms are important). The rate of transfer is determined by the equilibrium and actual concentration in the bulk phase and the aqueous phase. This is central to the concept of bioavailability.

From the compounds in Table 1, the increasing degree of chlorination decreases the rate of biodegradation. Increasing chlorination also leads to a marked drop in water solubility and a corresponding increase in hydrophobicity, which influence biodegradability. The toxicity of the compound also adversely affects biodegradation. The interaction between toxicity and biodegradation is not well understood, but they are clearly linked and competing processes: at low concentrations, a compound may be biodegradable, but this is arrested at higher concentrations by toxicity. If the concentration is very low for biodegradation, then this may not be enough to support microbial growth and reproduction, the concept of threshold elaborated in detail by Alexander (8).

BIOAVAILABILITY

Bioavailability is a concept recently borrowed from nutrition to explain the behavior of chemical pollutants in the environment (9). There are several definitions in circulation. In its simplest form (10), bioavailability is defined as "the amount of contaminant present that can be readily taken up by microorganisms and degraded." But this ignores bioavailability to higher organisms. Another definition that takes account of this and alludes to the risk assessment practice (11) is "a measure of the potential of a chemical for entry into ecological or human receptors."

The bioavailability quandary mentioned previously has been accurately articulated by the International Union of Pure and Applied Chemistry (IUPAC).

> "In the IUPAC Conference of Pesticide Chemistry in London in 1998, there was a controversial discussion on the topic whether agrochemicals in the environment are really hazardous. The conventional wisdom is that chemicals in soil are available to microorganisms, plant roots, and soil fauna like earthworms and animals via dermal exposure. Then bioaccumulation through the food web may induce indirect exposure to higher organisms. National governments are simply reducing the threshold levels of chemicals in the environments for larger safety margins in their guidelines. However, the question raised at the Congress was that chemical residues in the environment are not always bioavailable, so that *the actual exposure of biota to chemicals is rather different from the amount (concentration) present in the environment* (authors' italics). In addition, the persistence and efficacy of agrochemicals are affected by their bioavailability in soil. There is a lack of comprehensive understanding of the bioavailability of chemicals with different chemical characteristics, such as non-polar organochlorines, polar agrochemicals and etc. Thus, there is a strong need to clarify the scientific basis for bioavailability: definition, estimation methods and affecting factors."

Measuring Bioavailability

Measuring or even estimating bioavailability is problematic as it is affected by many individual and interacting conditions relating to soil and water chemistry, pollutant chemistry and partitioning, and biological transformation and concentration factors (12). Moreover, the "aging" process brings about a time-dependent decrease in bioavailability as compounds become sequestered in soil over time by ill-understood mechanisms (13). The techniques currently being researched can be categorized broadly as direct or indirect and biological or chemical (14), although, as pointed out by these authors, only organisms can determine whether a chemical is bioavailable, so direct chemical methods are not possible.

Direct Biological Methods. These are techniques that measure the actual amount of a chemical taken up by a target organism, and this may ultimately be the most accurate measure of bioavailability, although it is by no means routine. For example, the determination of chemical levels in earthworms is relatively expensive and time-consuming. The great strength of these direct techniques, however, is that they integrate all the biotic and abiotic modifying factors of chemical bioavailability (14).

Indirect Biological Methods. It is possible to observe a response to a chemical in an organism without actually measuring the concentration of the chemical. A range of responses is possible, such as lethality, enzyme induction or inhibition, and reproductive effects. These are regarded as indirect biological methods because the effect may be quantifiable in the organism, but the chemical concentration remains unknown.

A promising, novel approach is the use of genetically modified microorganisms that can detect and quantify specific pollutants. This type of biosensor is based on the highly specific genetic control mechanisms used by microorganisms to ensure that specific proteins are expressed only when needed; for example, to detoxify a particular toxic substance. This control is exerted by inducible promoters, consisting of a specific DNA sequence upstream of the genes to be controlled and a DNA-binding protein that either activates or prevents transcription in response to the presence or absence of the target compound. Biosensors of this type are easily generated by fusing such a controllable promoter to a reporter gene that generates a detectable signal when the promoter is activated (15). The most popular reporter is the bacterial *lux* system that produces light (Fig. 2), because light can be easily quantified and, due to its rarity in biology, there is no interference from the background biochemistry of the host organism.

Such biosensors can be both highly specific and responsive to very low concentrations, and the microbial cell membrane makes this approach truly a measure of bioavailability. There are limitations to developing such biosensors for detecting organic pollutants as often the

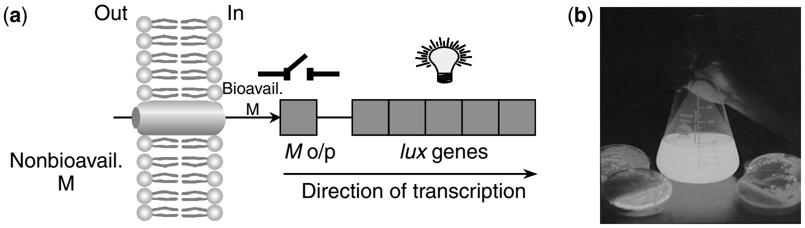

Figure 2. (**a**) Schematic of a genetically modified whole bacterial cell biosensor for detecting bioavailable metal. The metal may be expected to be transported into the bacterial cell via a specific transporter protein mediating uptake and efflux. If the metal is in a nonbioavailable form, for example, as a precipitate, it will not be transported. The interaction of the metal with the specific metal regulatory element initiates transcription resulting in synthesis of the luciferase enzyme and the production of light. (**b**) The naturally bioluminescent bacterium *Vibrio fischeri* producing light from colonies and liquid culture.

required specificity is lacking. For heavy metals, specificity may not be a problem. Nevertheless, careful selection of the host strain is required for a variety of reasons (16). Such biosensors offer the prospect of a much more routine measure of bioavailability.

Indirect Chemical Methods. Indirect chemical methods usually involve extracting a fraction of the chemical (metals or organics) from a soil; extractability is defined by the chemical itself, the nature of the extractant(s), and the experimental conditions applied. The origins of this approach are in sequential extraction procedures (17) that attempt to quantify the speciation of toxicants into those weakly bound and those strongly bound to the soil matrix. These tests often assume that the weakly bound toxicants are those that are more bioavailable, although evidence for this is incomplete. A recent advance in this technique is sequential accelerated solvent extraction (18) that reduces sample preparation time and maintains relatively constant extraction conditions. A technique under development is the use of selective supercritical fluid extraction (19).

A number of methods are based around the human gastrointestinal tract (the physiologically based extraction test, PBET; 20). To mimic human conditions, they incorporate gastric juices and enzymes, mix at 37 °C, and use soil residence times similar to those found in children after ingestion of food. Analysis of all solutions produced in the PBET extractions is completed by analytical chemistry techniques under matrix-matched conditions.

However sophisticated, any such technique is ultimately limited by the lack of an organism. There will be no universal chemical test for bioavailability as the phenomenon is organism- and even species-dependent (21).

PHYSICAL PROPERTIES

Kevin S. McLeary

STRUCTURE

Water is a molecule composed of two atoms of hydrogen bonded to an atom of oxygen. It has a volume of 2.97×10^{-11} μ^3 (29.7 Å^3) (1). As a result of the hybridization of the oxygen atom, the molecule is bent at an angle of 104.45°. Due to the nonlinear structure and to the difference in electronegativity between oxygen (3.44) and hydrogen (2.20), the molecule has a dipole moment of 1.85 Debye (2).

Water molecules are held together by intermolecular attractions. In water, the intermolecular attractions are hydrogen bonds. The negatively charged oxygen atom in one molecule of water is electrically attracted to the positively charged hydrogen atom of another molecule. Hydrogen bonding governs the structure of water up to the boiling point (2).

SPECIFIC WEIGHT (γ)

The specific weight of a substance is its weight per unit of volume. In U.S. Customary Units, it is often expressed as pounds-force per cubic foot (3). In SI units, it is often expressed in kN/m^3. Although a value of 62.4 pounds-force per cubic foot (9.81 kN/m^3) is commonly used for the majority of engineering purposes, the specific weight of water varies with temperature, from 62.42 pounds-force per cubic foot (9.805 kN/m^3) at 32 °F (0 °C) to 59.8 pounds-force per cubic foot (9.399 kN/m^3) at 212 °F (100 °C) (4). Table 1 shows the variability in the specific weight of water with temperature in U.S. Customary Units. Table 2 shows the variability in the specific weight of water with temperature in SI Units.

Specific weight is also a function of gravity, and it varies slightly with elevation. One cubic foot of water at 32 °F at sea level has a specific weight of 62.42 pounds-force per cubic foot (9.805 kN/m^3); the same volume of water at 10,000 feet above sea level has a specific weight of 62.36 pounds-force per cubic foot (9.796 kN/m^3). Because the earth is not a perfect sphere, but bulges at the equator, specific weight is also a weak function of latitude. However, these variations are small enough to warrant the use of a constant value of 62.4 pounds-force per cubic foot (9.81 kN/m^3) at all elevations and latitudes (4).

DENSITY (ρ)

The density of a fluid is defined either as its mass per unit of volume or as the ratio of its specific weight to the acceleration due to gravity. Density ranks among the most important hydraulic properties of water (1). It is a factor in the settling velocity of particles and in the filtration of water through a porous medium. A fluid's Reynolds number, the most important dimensionless number in hydraulics, is a direct function of density. The Reynolds number is used in calculating friction losses, pipe sizing, and pumping requirements

In U.S. Customary Units, density is expressed in slugs/ft^3, and in SI units, it is expressed in kg/m^3. Like specific weight, density varies with temperature. The density of pure water varies from 1.940 slugs/ft^3 (999.8 kg/m^3) at 32 °F (0 °C) to 1.860 slugs/ft^3 (958.4 kg/m^3) at 212 °F (100 °C). Tables 1 and 2 show the variation of density in U.S. Customary Units and SI units, respectively.

SPECIFIC GRAVITY

Specific gravity is defined as the ratio of the density of one fluid at a specified temperature to that of a reference fluid at a reference temperature. For liquids, the reference liquid is usually water, although varying reference temperatures have been used, for example, 39° and 68 °F (4° and 20 °C). Although specification of the reference temperature is required to ensure accuracy, it is often not given because the density of water varies by only 0.2% over the usual temperature range (5). The specific gravity of water is usually taken as 1.0.

ABSOLUTE (DYNAMIC) VISCOSITY (μ)

The viscosity of a fluid is expressed as a measure of the resistance to flow. Mathematically, it is defined as the ratio of the shear stress of a fluid to its velocity gradient or as the proportionality constant between the shear stress and the velocity gradient:

$$\frac{F}{A} = \mu \frac{dv}{dy} \tag{1}$$

Viscosity can be measured by taking two plates of area A, which are separated by a fluid whose thickness is y. The bottom plate is held stationary. The top plate is moved at a constant velocity v. The force required to maintain the constant velocity is measured and used to calculate the viscosity μ of the fluid.

The chief cause of viscosity in fluids is molecular cohesion. Molecular cohesion decreases as temperature is increased, therefore, viscosity also decreases as temperature increases. Changes in pressure do not affect viscosity (5). Impurities also exert little influence on viscosity (1). Tables 1 and 2 show the effect of temperature on viscosity.

KINEMATIC VISCOSITY (ν)

There are many times in fluid mechanics and hydraulics when the fluid's absolute viscosity is divided by its density. To ease calculations, this term has been defined as kinematic viscosity because it has kinematic units of length and time, ft^2/sec or m^2/s.

Both absolute viscosity and density are a function of temperature, so kinematic viscosity is also a function of temperature. Tables 1 and 2 show how kinematic viscosity varies with temperature.

[a] References 3 and 7.

[b] The modulus of elasticity is given at atmospheric pressure.

[c] Surface tension is given for water in contact with air.

SURFACE TENSION (σ)

Surface tension is caused by the attractive forces between molecules in a liquid. In a bulk liquid, each molecule is attracted to its neighboring molecules, and the total force on the molecule is zero. However, a molecule at the surface experiences an attraction to other molecules deeper in the liquid, but there are no molecules outside to balance these attractions. The molecule at the surface experiences a net attractive force toward the bulk liquid.

Surface tension is the amount of work necessary to increase the surface area of the liquid by one unit. It has units of force per unit area (ft-lb$_f$/ft^2, or lb$_f$/ft) and decreases as the temperature of the liquid increases. It is also a function of the gas contacting the liquid (5). Table 1 gives the variation of surface tension of water in contact with air as a function of temperature in U.S. Customary Units, and Table 2 shows the variation in SI units.

VAPOR PRESSURE (P_V)

Water is a collection of a large number of molecules in a liquid phase that move about at random. The molecules collide with each other and rebound in different directions. Each molecule moves with a certain velocity (energy). Molecules on the surface of a liquid moving away from the bulk liquid have no other molecule to collide with. If such a molecule has sufficient energy to escape the intermolecular attractions, it may escape the liquid into the vapor space above the liquid. It evaporates. Evaporated water molecules also move about at random. Some of the water vapor condenses into the liquid water phase.

If the water were placed in a closed container at a constant temperature and the air evacuated from the vapor space above the liquid, one could measure the pressure exerted by the water vapor. The pressure would increase until equilibrium is attained—when the rate of molecules evaporating and the rate of molecules condensing are equal. The pressure of the water vapor then is constant. This is the vapor pressure of the water for the given temperature. Table 1 gives the vapor pressure of water in psi. Table 2 gives the vapor pressure in kN/m^2.

MODULUS OF ELASTICITY (E)

Although water is usually considered incompressible, it is slightly compressible. The modulus of elasticity is defined as the increase in pressure that results in a specific percentage change in volume:

$$E = \frac{\Delta p}{\Delta V/V} \tag{2}$$

where Δp is the increase in pressure, ΔV is the resulting change in volume, and V is the original volume of water.

The modulus of elasticity has units of pressure and is a function of temperature. Tables 1 and 2 show the variation of the modulus of elasticity with temperature.

SPEED OF SOUND (C)

Sound is the propagation of a pressure wave through a material and is dependent on the material's modulus of elasticity and density. The speed of sound, c, in a liquid is given by

$$c = \sqrt{\frac{Eg_c}{\rho}} \tag{3}$$

The speed of sound in water is important in calculating the pressure increase due to water hammer. When the velocity in a pipe is decreased suddenly, the pipe experiences an increase in pressure. The increase in pressure, Δp, caused by a decrease in velocity of Δv, is

$$\Delta p = \frac{\rho c \Delta v}{g_c} \tag{4}$$

HEAT CAPACITY (C_P)

Heat capacity is defined as the amount of heat needed to raise the temperature of a given amount of substance by 1°. It is usually expressed in units of heat per unit of substance per degree. The term "heat capacity" is often used for this quantity of heat on a molar basis. If a mass basis is used, the term "specific heat" is frequently used.

The heat capacity of water is the basis of the unit of heat in both the English and SI systems. Therefore, the heat capacity (specific heat) of water is 1 Btu/pound-mass/°F in the English system and 1 cal/g/°C in the SI system.

Heat capacities of liquids are not functions of temperature, except at high reduced temperatures. (A reduced temperature is a thermodynamic quantity relating the temperature of a material to its critical temperature. The critical temperature for water is 647.1 K.) (6). At reduced temperatures exceeding 0.7–0.8, liquid heat capacities are large and are strong functions of temperature.

ENVIRONMENTAL PHOTOCHEMISTRY IN SURFACE WATERS

Mark A. Young
University of Iowa
Iowa City, Iowa

INTRODUCTION

Surface waters make up a large fraction of the available terrestrial surface area, accounting for over 70% of the total area with most of that consisting of ocean waters. A correspondingly large fraction of the incoming solar flux will impinge on natural waters, penetrating to a depth determined by the scattering and absorption properties of the water system. While most of the short wavelength solar radiation is attenuated in the atmosphere, mainly by absorbing species such as O_2 and O_3, the surface flux of energetic photons in the near-UV and visible remains appreciable. While water itself is not photoactive, the irradiated volume of typical surface waters contains a plethora of potential chromophores. The chromophoric material consists of dissolved species and suspended particulate matter that can have strong electronic absorptions that significantly overlap with the available solar flux. Absorption of solar photons can initiate a rich variety of photochemical processes with sufficient kinetic rates to manifest a substantial impact on the chemistry taking place in the aqueous environment. Photochemically driven chemistry, in turn, can have enormous implications for global geochemical cycles, climate, and biogenic processes, making photochemistry a critical consideration in the study of environmental processes.

BACKGROUND

Natural surface waters can be either saltwater (marine, or ocean, waters) or freshwater (continental waters). Within each of these reservoirs, widely varying environments are found: remote and coastal areas in the oceans, and rivers, lakes, streams, bogs/marshes on the continents, as well as interfacial environments, such as estuaries. In addition to differences in salinity and pH, there will be variations in the types and concentrations of chromophoric species residing in each reservoir. Potential chromophores include dissolved organic material (DOM), inorganic NO_x^- ions, metal complexes, anthropogenic pollutants, and colloidal matter consisting of crustal minerals and particulate organic material (POM). Organic chromophores may also adsorb on, or complex with, the surface of mineral colloids and participate in charge transfer processes. Likewise, metals can become incorporated into organic material. The distinction between dissolved and colloidal material is not sharp and often depends on the analytical procedure used to assay concentrations. The relative importance of the various chromophores will depend on the details of the aqueous environment. Chromophores can absorb solar photons and undergo photochemical transformation while yielding a variety of primary and secondary reactive species, as depicted schematically in Fig. 1. The photogenerated intermediates can, in turn, react with other species present in the water at rates that are often diffusion controlled to form final products. In some instances, the chromophore may be regenerated, resulting in a photocatalytic cycle that can be highly efficient (Fig. 1).

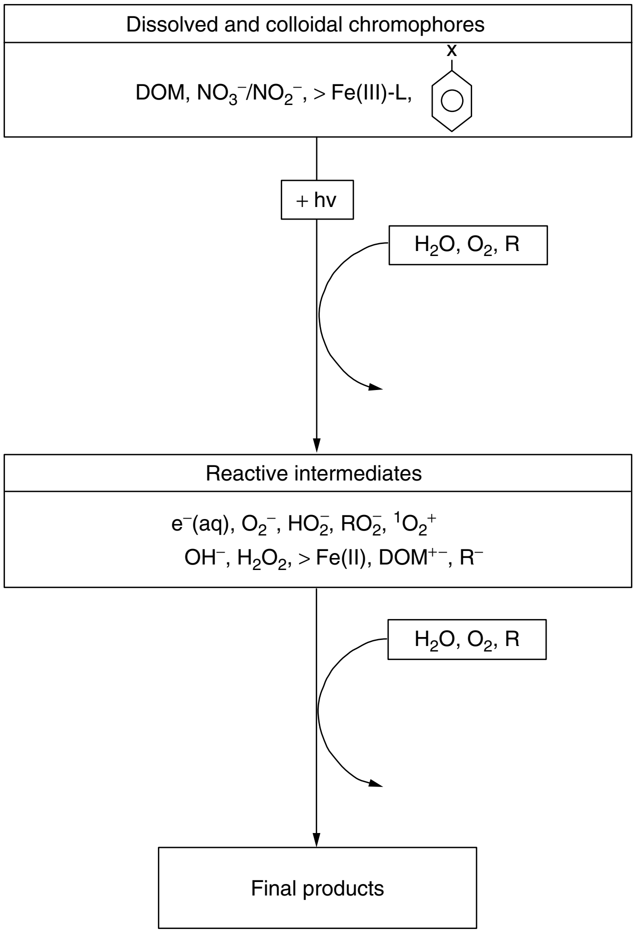

Figure 1. Schematic representation of photochemical processes in surface waters. Chromophores consist of DOM, nitrate/nitrite ions, dissolved and colloidal metal complexes [represented by Fe(III)], and anthropogenic pollutants (such as substituted aromatics). Reactive intermediates consist of solvated electrons, various radical species, both cationic and anionic, peroxides, and reduced metal centers.

Excitation of a chromophore can initiate a number of photophysical and photochemical processes that are outlined in the following equations:

$$S + h\nu \xrightarrow{J} S^* \quad \text{excitation;} \tag{1}$$

$$S^* \xrightarrow{k_L, k_I} S\ (+h\nu) \quad \text{luminescence, internal conversion, and intersystem crossing;} \tag{2}$$

$$S^* + Q \xrightarrow{k_Q} S + Q \quad \text{quenching;} \tag{3}$$

$$S^* \longrightarrow S^+ + e^- \quad \text{photoionization;} \tag{4}$$

$$S^* \xrightarrow[{[R]}]{k_R} P \quad \text{reaction;} \tag{5}$$

$$S^* + R \xrightarrow{k_{ET}} S + R^* \quad \text{energy transfer;} \tag{6}$$

$$S^* + R \xrightarrow{k_{CT}} S^{+/-} + R^{-/+} \quad \text{charge transfer.} \tag{7}$$

Photophysical processes, luminescence (fluorescence and phosphorescence), internal conversion, intersystem crossing—Eq. 2—and collisional quenching—Eq. 3—will return the chromophore to the electronic ground state and convert the photon energy to heat. The excited state may also ionize, Eq. 4, or react, Eq. 5, converting the photon energy into chemical potential. The reaction could be unimolecular, such as dissociation, or bimolecular in nature, involving other components of the water system. Products might include the reactive intermediates in Fig. 1, which can then participate in secondary chemistry. Energy transfer, or sensitization, Eq. 6, could also induce a concurrent change in the electronic spin state, yielding a reactive triplet excited state.

The photochemical sequence is initiated by absorption of a photon, Eq. 1, with a photolytic rate constant, J. From a simple consideration of Beer's Law, J is seen to depend on the incident solar flux, I, and the (molar, decadic) extinction coefficient of the chromophore, ε. The relative efficiency, or yield, of a reaction can be specified by the quantum yield, ϕ, which is the number of product species formed divided by the number of photons absorbed. The absorption coefficient and quantum yield are generally wavelength dependent. The flux depends on wavelength as well as the solar zenith angle and other factors, such as latitude, longitude, and meteorological conditions, such as cloud cover. The rate constant for a photoinduced process can then be written as an integral over the wavelength region of interest:

$$J = 2.303 \int \varepsilon(\lambda)\phi(\lambda)I(\lambda)d\lambda = 2.303 \sum_i \overline{\varepsilon}(\lambda_i)\overline{\phi}(\lambda_i)\overline{I}(\lambda_i)\Delta\lambda_i \tag{8}$$

The flux in this case is termed the spectral actinic flux and is a spherically averaged irradiance that takes into account radiation incident on the chromophore over 4π steradians. For practical purposes, the integral is often evaluated as a discrete sum over small wavelength intervals, as expressed in the last term of Eq. 8, where $\overline{\varepsilon}$, $\overline{\phi}$, and $\overline{I}$ represent average quantities over the interval $\Delta\lambda_i$ centered at λ_i.

The solar actinic flux at noon (zenith angle = 0°) for a northern latitude (47.4°N) is shown in Fig. 2. The flux is expressed in terms of the photon flux per unit wavelength interval with units of einstein $\cdot$ $m^{-2} \cdot s^{-1} \cdot nm^{-1}$, where an einstein corresponds to 1 mole of photons (Avogadros's number, $N_A = 6.022 \times 10^{23}$ mol^{-1}). The UV-B radiation (280–320 nm) is strongly attenuated by the ozone layer, effectively limiting the useful actinic flux to about 300 nm. Shorter wavelength radiation does reach the surface but at 293 nm, the flux has decreased by more than two orders of magnitude relative to 300 nm. UV-A (320–400 nm) is not strongly absorbed by ozone and the flux increases up to the maximum in the visible at approximately 575 nm. A photon has a molar energy of

$$\overline{E} = N_A \frac{hc}{\lambda} \text{ J} \cdot \text{einstein}^{-1} \tag{9}$$

A 300-nm photon has an energy of 399 kJ $\cdot$ einstein^{-1}, which is on the order of typical bond enthalpies (e.g., C–C, 348 kJ; O–O, 146 kJ; C–OH, 322 kJ; benzylic C–H, 368 kJ; phenolic O–H, 362 kJ; C–Cl, 342 kJ). Over the wavelength range of photochemical interest, 300–500 nm, Fig. 2 indicates that the noon-time flux to surface waters is about 4 einstein $\cdot$ $m^{-2} \cdot h^{-1}$. Typical penetration depths range from 1 to 20 m and so the molar rate of photon absorption is $0.2–4.2 \times 10^{-3}$ einstein$\cdot L^{-1} \cdot h^{-1}$. Dissolved organic carbon (DOC) is the major absorbing species in most natural waters (see Fig. 2) and has an approximate average concentration of 5 mg C$\cdot L^{-1}$. While highly diverse in nature, an average chromophore molecular weight of 120 g C$\cdot mol^{-1}$ (10 carbon atoms) can be assumed and so the absorber concentration is approximately 0.04 mM. The estimated photon absorption rate for a well mixed volume would correspond to an average excitation rate of 5–100 h^{-1}, meaning that a near-surface chromophore is excited approximately once each minute (2,3). Furthermore, it is estimated that the accumulated annual radiation dose is about 1300 times larger (2). Given the time scales for transport and chemistry in surface waters, it is clear that photochemically driven reactions will be an important component of chemical cycles in the hydrosphere (Fig. 2).

REACTIVE INTERMEDIATES

A variety of reactive intermediates have been identified from the irradiation of natural waters at relevant solar wavelengths (see Fig. 1). Selected properties for some of the important species are listed in Table 1, along with estimated steady-state concentrations in typical surface waters (generally corresponding to a noon-time solar flux). Under conditions of constant solar illumination, pseudo-first-order kinetics result and the steady-state concentration for an intermediate, $[I]_{SS}$, can be used in conjunction with the second-order rate constant, k, for a particular reaction to calculate the reaction half-life as

$$\tau = \frac{\ln 2}{k[I]_{SS}} \tag{10}$$

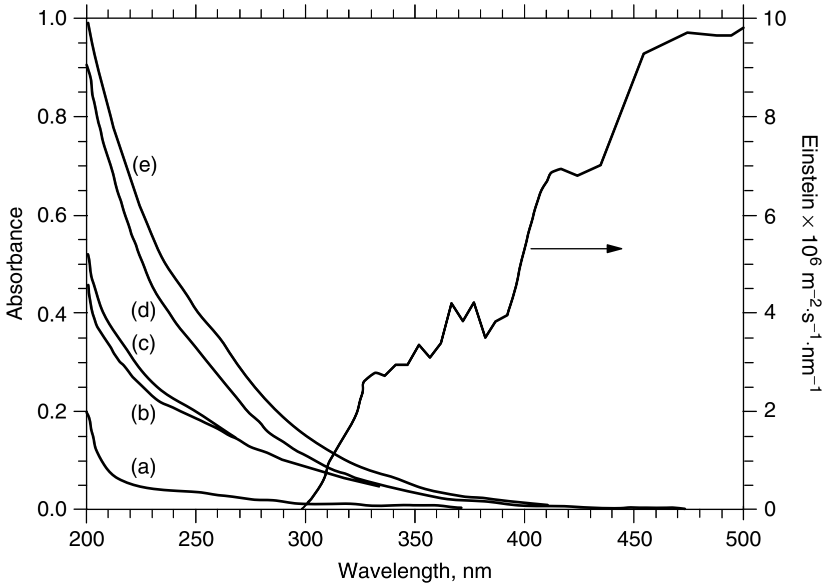

Figure 2. Left ordinate: Absorption spectra of surface water samples with varying concentrations and sources of DOC in mg C$\cdot L^{-1}$: (**a**) = 3.0, (**b**) = 7.8, (**c**) = 13.4, (**d**) = 13.4, (**e**) = 15.4. Path length is 1.0 cm. Data are adapted from Reference 7. Right ordinate: Solar actinic flux for noon-time sun (zenith angle = 0°) for a northern, midlatitude. Data is from Reference 1.

and, thus, estimate the importance of a given reaction pathway. For example, half-lives for reactions with phenol, a representative organic, aromatic compound, have been included in Table 1.

Primary transient species are produced rapidly, on the order of <1 ns. These transients can then react with other components in the aquatic environment to produce secondary products. Besides H_2O, one of the most important interactions involves dissolved oxygen, which, in well aerated surface waters, will be present in concentrations determined by Henry's Law,

$$[O_2] = K_H P_{O_2} \tag{11}$$

where $K_H = 1.3 \times 10^{-3}\ M^{-1} \cdot atm^{-1}$ is the Henry's Law constant (8). The mixing ratio of O_2 in the atmosphere is 21%, yielding a concentration of $[O_2] = 0.27$ mM at 298 K. Primary radicals will react with dissolved O_2 at diffusion controlled rates (diffusion controlled rate constant, $k_D \approx 7 \times 10^9\ M^{-1} \cdot s^{-1}$ at 298 K) corresponding to a time scale of $\approx 0.4\ \mu s$, which will limit the lifetime of many photogenerated transients (the "oxygen wall") (9).

e^-(aq)

Electrons generated from photoionization of DOM are rapidly solvated in aqueous environment to produce, e^-(aq). The solvated electron reacts with dissolved oxygen to form the superoxide,

$$e^-(aq) + O_2 \xrightarrow{k} O_2^- \tag{12}$$

where $k \approx 2 \times 10^{10}\ M^{-1} \cdot s^{-1}$ [which is larger than the diffusion limit due to a tunneling mechanism for e^-(aq) transport] (4,5). The time scale for Eq. 12 is on the order of 200 ns. The short lifetime coupled with measured typical production rates leads to a very small steady-state concentration of $[e^-(aq)]_{SS} \approx 10^{-17}$–$10^{-15}$ M (2,9). While reaction with e^-(aq) has been shown to degrade organic pollutants (2,10), it is unlikely to play an important role in photochemical processes in most surface waters.

O_2^-

Superoxide, O_2^-, can be formed from reaction with e^-(aq), as above, in charge transfer reactions with sufficiently reducing species, and via electron trapping at the surface of semiconductor colloids. Photolysis of DOM is a major source of superoxide but photolysis of trace metal complexes may also contribute to O_2^- formation (11). Superoxide is a mild reductant/oxidant (Table 1) and can participate in both one-electron oxidation and reduction reactions. The steady-state concentration is uncertain but from limited formation rate measurements, the concentration is $[O_2^-]_{SS} \approx 10^{-9}$–$10^{-7}$ *M* (9,10). The relatively high concentration suggests that superoxide may be important in photochemical degradation of various species (7). However, O_2^- is unstable in water with respect to disproportionation to form hydroperoxyl radical and hydrogen peroxide (3,12)

$$O_2^- + H^+ \overset{K}{\rightleftharpoons} HO_2 \quad \log K = -4.8 \tag{13}$$

$$HO_2/O_2^- + H^+ \longrightarrow H_2O_2 + O_2 \tag{14}$$

$RO_2^\bullet$

Peroxyl radicals can be formed from the photolysis of DOM and metal complexes. Formation rates for RO_2 species are thought to linearly scale with the DOM concentration in typical waters (2), but the reactivity of the radical is highly dependent on the type of humic substance involved, which is itself not well characterized. These uncertainties make it difficult to estimate a steady-state concentration for peroxyl radicals. HO_2 is a mild oxidant/reductant (Table 1) but DOM-derived peroxyl radicals exhibit significant

Table 1. Selected Properties of Some Important Reactive Intermediates in Aqueous Photochemistry[a]

	Radical				
Property	e^-(aq)	O_2^-	HO_2	OH	$^1O_2^*$
ΔG_f^0 (kJ·mol^{-1})	276[b]			13[b]	
ΔH_f^0 (kJ·mol^{-1})	277[b]	80[c]	138[c]	−7[b]	94.3[d]

reactivity with alkylphenols (13) and so may be an important reaction channel for some pollutants.

$^1O_2{}^*$

Singlet oxygen, $^1O_2{}^*$, is an electronically excited state of oxygen with 94.3 kJ of excess energy. Triplet excited ^{3}DOM*, generated by intersystem crossing from the initially excited singlet state, can sensitize the formation of $^1O_2{}^*$ through energy transfer, Eq. 6. Most of the singlet oxygen will be rapidly quenched back to the triplet ground state by H_2O ($\tau \approx 4$ μs) and only a fraction of the $^1O_2{}^*$ will be available for subsequent reaction (2). The production of $^1O_2{}^*$ generally scales with the amount of DOC and steady-state concentrations of $0.3–3.0 \times 10^{-14}$ M per mg·L^{-1} of DOC have been measured for typical surface waters (14). Singlet oxygen is a reactive electrophile, particularly toward cyclic 1,3 dienes, phenolate anions, and some polynuclear aromatics (2,14,15) and can play an important role in aqueous photochemistry.

OH

The hydroxyl radical is a powerful oxidant (Table 1) that exhibits high reactivity toward a range of organic species. It is mainly formed from photodissociation of $NO_3{}^-/NO_2{}^-$ but also via photolysis of metal-hydroxides, decomposition of H_2O_2, and DOM photochemistry. The hydroxyl radical is rapidly scavenged by DOM and the steady-state concentration of OH in surface waters is generally small, $[\mathrm{OH}]_{\mathrm{SS}} \approx 10^{-19}–10^{-17}$ M (9,10). The OH radical readily reacts with many organic species, via abstraction and addition to double bonds, but the low steady-state concentration suggests that hydroxyl will not be the dominant photooxidant for most surface waters. For example, a "typical" OH rate constant (4) is $5 \times 10^9\ \mathrm{M}^{-1} \cdot \mathrm{s}^{-1}$, corresponding to a reaction half-life of $\tau \approx 160$ d at the higher OH concentrations. However, for environments with a larger concentrations of $NO_x{}^-$ relative to DOC, hydroxyl radical reactions can be important pathways due to near diffusion-controlled OH rate constants (2).

H_2O_2

Hydrogen peroxide is a relatively stable, nonradical species produced from photochemical processes in natural surface waters. It is not a primary product but, rather, is generated in secondary reactions such as the disproportionation of superoxide, Eqs. 13 and 14. Hydrogen peroxide absorbs only weakly in the UV ($\varepsilon = 1\ \mathrm{M}^{-1} \cdot \mathrm{cm}^{-1}$ at 310 nm) (16), and decomposition to yield hydroxyl radicals may be dominated by biological mediation and redox cycles involving trace metals

$$H_2O_2 \longrightarrow 2OH \tag{15}$$

The slow decomposition of H_2O_2 leads to relatively high steady-state concentrations in surface waters, $[H_2O_2]_{\mathrm{SS}} = 10^{-8}–10^{-7}$ M (2,9).

CHROMOPHORES

$NO_3{}^-/NO_2{}^-$

Inorganic nitrate and nitrite ions are perhaps the most well defined and easily understood photoactive component of natural waters. Nitrate concentration in surface waters is on the order of 1 mg·L^{-1} although it may be substantially higher in waters subject to an influx of agricultural drainage due to the heavy use of nitrogen fertilizers. The absorption band maxima for nitrate and nitrite are at 302 nm ($\varepsilon = 3.1\ \mathrm{M}^{-1}\cdot\mathrm{cm}^{-1}$) and 352 nm ($\varepsilon = 9.6\ \mathrm{M}^{-1}\cdot\mathrm{cm}^{-1}$), respectively (17,18). Ultraviolet excitation of nitrite leads to photodissociation (18):

$$NO_2{}^- + h\nu \longrightarrow NO + {}^{\bullet}O^- \tag{16}$$

The $^{\bullet}O^-$ species, the conjugate base of hydroxyl radical, is rapidly protonated at pH < 12 [pK_a($^{\bullet}$OH) = 11.9] (4):

$${}^{\bullet}O^- + H^+ \longrightarrow {}^{\bullet}OH \tag{17}$$

The quantum yield for $^{\bullet}$OH production from nitrite varies from 0.015 to 0.08 over the wavelength range 298–371 nm (18,19). Photolysis of the nitrate ion yields either nitrite ion or nitrogen dioxide, which can then reform nitrate and nitrite:

$$NO_3{}^- + h\nu \longrightarrow NO_2{}^- + O \tag{18}$$

$$NO_3{}^- + h\nu \longrightarrow {}^{\bullet}NO_2 + {}^{\bullet}O^- \tag{19}$$

$$2{}^{\bullet}NO_2 + H_2O \longrightarrow NO_2{}^- + NO_3{}^- + 2H^+ \tag{20}$$

For wavelengths ≥290 nm, the quantum yield for formation of $^{\bullet}$OH from $NO_3{}^-$, via Eq. 19, is in the range of $9.2–17 \times 10^{-3}$ (17,18). Hydroxyl is a highly reactive radical and a strong oxidizing agent (see above). Various laboratory studies have shown that trace organic molecules, such as biologically refractory pollutants, are degraded by irradiation in the presence of nitrate/nitrite (17–19).

DOM

Dissolved organic matter (DOM) is a major and ubiquitous component of natural surface waters, having numerous sources such as soils, sediments, and aqueous biological activity (20). DOM concentrations are often expressed in terms of the dissolved organic carbon (DOC) fraction, which comprises about 60% of the total DOM. Continental waters have typical levels of 1–10 mg C·L^{-1} DOC, although some waters, bogs, marshes, and shallow streams, for instance, can have concentrations exceeding 50 mg C·L^{-1}. Marine DOC is about 1 mg C·L^{-1} and represents an enormous carbon reservoir, approximately equal in size to the CO_2 reservoir in the atmosphere (2). DOM is nominally defined as the organic content of water that passes through a filter of some pore size, 0.1–0.5 μm, and so will have a colloidal component. The DOC in surface waters can be divided into two fractions; a lower molecular weight nonhumic fraction and higher molecular weight humic component. The nonhumic fraction is about 10–60% of the DOC and is made up of small compounds of mainly biogenic origin, such as peptides, carbohydrates, fats, and chlorophyll, which are subject to rapid biological degradation. In addition, anthropogenically derived species, such as biocides (often halogenated compounds) and polycyclic aromatic hydrocarbons (PAHs, from combustion processes) are present. The higher molecular weight fraction (>300 Da), comprising 40–90% of the DOC, is termed humic matter (HM). Humic matter is a complex material composed of condensed biopolymers and is much more biologically refractory. HM is mildly acidic, has a significant aromatic content, and is highly functionalized with carboxyl, phenol, hydroxyl, carbonyl, ether, and ester functional groups present. HM can be further divided based on solubility properties into humic acids (HAs), which precipitate under acidic conditions, and fulvic acids (FAs), which are soluble at all pH values. FAs are more highly substituted and have a higher oxygen content than HAs and also have a lower average molecular weight.

DOM is a highly colored material with an absorption spectrum that overlaps significantly with the solar actinic flux (see Fig. 2). The UV absorption of surface waters has been found to be highly correlated with the DOC content (10,21,22). Studies have shown that photoexcited DOM can yield many of the radical species outlined in Fig. 1 and Table 1 through primary and secondary processes (9). The radical production rate varies with the character of the DOM and the concentration, as well as the location and type of surface water environment. One study found that coastal marine waters yielded radical production rates of $0.18–1.8\ \mu\text{M}\cdot\text{d}^{-1}$ in the summer due to irradiation of humic material in the surface layer (to a depth of 1.5 m) (23). The active spectral region was determined to be 300–385 nm, suggesting a quantum yield for radical production of $1–2 \times 10^{-3}$. Measurement of light absorption rates in highly colored, organic-rich waters that exhibit significant absorption at longer, visible wavelengths suggest the radical production rate will be orders of magnitude higher (9). These radicals dominate the photochemistry of most natural water samples, particularly in marine environments.

The DOM will be altered by photolysis, yielding a cationic radical product, for instance, but it can also be attacked by the photogenerated radicals. DOM decomposition can lead to photobleaching, allowing solar radiation to penetrate deeper into the water and impacting microbial photosynthesis. DOM is generally biologically refractory, resulting in long carbon reservoir residence times, estimated at 6000 years for deep ocean DOM (24). Photodecomposition of DOM may be an important removal pathway with significant implications for the global carbon cycle (9,15,24,25). The lower molecular weight degradation products are biologically labile and can provide a major fraction of the biological carbon uptake in certain surface waters (21,25).

Fe(III/II)

Iron is an abundant crustal metal and is one of the most important trace metals in natural water systems. The Fe-(hydrous)oxides (e.g., α-FeOOH, goethite; α-Fe_2O_3, hematite; γ-FeOOH, lepidocrocite; $Fe(OH)_3$, ferrihydrite) may be present as dissolved species but are predominantly in colloidal form. Iron has two common oxidation states, Fe(III) and Fe(II), and participates in redox reactions that are an important component of aqueous chemical cycles. Fe(III) can form strong complexes with naturally occurring organic ligands, such as polycarboxylate anions (e.g., oxalate, malonate, citrate), and humic and fulvic acids (11,26). Photoexcitation of a Fe(III) complex promotes a ligand to metal charge transfer process yielding a free, oxidized ligand and a reduced, Fe(II), center. Subsequent reactions generate reactive intermediates (11,12), as schematically depicted below for the oxalato ($C_2O_4{}^{2-}$) ligand:

$$>\text{Fe(III)}C_2O_4{}^- + h\nu \longrightarrow >\text{Fe(II)} + C_2O_4{}^- \tag{21}$$

$$C_2O_4{}^- \longrightarrow CO_2 + CO_2{}^- \tag{22}$$

$$CO_2{}^- + O_2 \longrightarrow CO_2 + O_2{}^- \tag{23}$$

$$>\text{Fe(II)} + O_2 \longrightarrow >\text{Fe(III)} + O_2{}^- \tag{24}$$

$$>\text{Fe(II)} + H_2O_2 \longrightarrow >\text{Fe(III)} + \text{OH} \tag{25}$$

where ">Fe(III/II)" represents either an iron colloid surface site or a dissolved species. The superoxide will form hydrogen peroxide and hydroperoxyl radicals, as discussed above. In colloidal material, the surface Fe(II) is generally oxidized back to Fe(III) by the ligand or O_2. However, due to weakened binding with neighbor atoms, the reduced species may also be released to the solution (3,26). The result is photodissolution of the mineral colloid and an increase in soluble iron species, facilitating redox reactions and promoting microbial activity.

ISOTOPE EXCHANGE IN GAS-WATER REACTIONS

Tom Wydrzynski

Canberra, Australia

INTRODUCTION

Molecular oxygen began to accumulate in Earth's atmosphere about 2.2–2.7 billion years ago, and it is widely accepted that it originated from the photosynthetic oxidation of water (1). The accumulation of O_2 in the atmosphere marked the most important event in the evolution of life on Earth as the atmosphere changed from a highly reducing to an oxidizing condition. All preexisting life forms had to either find an anaerobic ecological niche or adapt to the ever-increasing O_2 levels of the atmosphere.

Today on Earth, the photosynthetic O_2 generators are widely distributed on land and in the oceans in the form of plants, algae, and cyanobacteria. The current atmospheric pool of O_2 contains about 4×10^{19} mols and takes about 3.7 million years to turnover. The unique enzyme complex that produces the O_2 by photosynthetic organisms is called photosystem II (PSII), which acts as a water/plastoquinone oxido-reductase (2). PSII contains a special photochemical reaction center, which at excitation can generate strong oxidants that can be coupled to the splitting of two water molecules into O_2, four protons, and four electrons. The protein motif within PSII that catalyzes the water oxidation reaction contains a cluster of four Mn ions, a Ca ion, and a redox-active tyrosine and is often referred to as the O_2 evolving complex (OEC).

The oxidation of water by PSII is driven photochemically by the capture of light quanta (3,4). The chlorophyll binding proteins associated with peripheral regions of the PSII complex serve as light-harvesting antenna and direct spectrally diverse quanta to the special reaction center chlorophyll cluster called P680. At absorption of a light quantum, P680 generates an excited state with its pheophytin partner (P680-Pheo)*, which in turn is in equilibrium with the exciton in the antenna and the radical pair $P680^+$-$Pheo^-$. The time course for this reaction has been under some debate, but it is in the order of 3–20 ps. The primary charge separation is rapidly followed by a charge stabilization event, in which the electron is rapidly transferred to a tightly bound plastoquinone molecule, Q_A, in 300−500 ps, which results in the formation of $P680^+$-Pheo $Q_A{}^-$. The electron hole in $P680^+$ is subsequently filled with an electron derived from a redox-active tyrosine, Y_Z, located in the D1 protein subunit within some 40−380 ns, which results in the formation of $Y_Z{}^{ox}$ P680-Pheo $Q_A{}^-$. The electron at $Q_A{}^-$ is then transferred to a second bound plastoquinone molecule, Q_B, in 100−200 μs, whereas $Y_Z{}^{ox}$ is reduced by the Mn_4Ca cluster with S-state-dependent kinetics (see below) in the range of 30−1300 μs.

One key finding for understanding the water oxidation reaction is the observation that for dark-adapted, PSII-containing samples illuminated by a series of brief, saturating light flashes, O_2 is released with a damped periodicity of four. The peak O_2 yields occur on the third, seventh, eleventh, and so on flashes and eventually damp out after the third or fourth cycle (5, see Figs. 2B and 2C). The phenomenological model to explain this observation was developed by Kok et al. (6,7) and entails a cyclic reaction sequence in which the OEC traverses through five intermediate states called the S states. Beginning in S_0 and progressing to S_4, each S state is advanced by a single quantum event at P680. When it reaches S_4, O_2 is released within 1−2 ms, S_0 is regenerated, and the cycle begins anew (see Fig. 1).

The damping in the O_2 flash yield oscillations (which is caused by the desynchronization of the forward S state transitions within a given population of O_2 evolving centers) is explained by a certain probability for a "miss" (α) to occur during a flash in which an electron hole fails to accumulate in the OEC and, depending on the flash duration, by a certain probability for a "double hit" (β) to occur in which a double excitation event takes place. The maximum O_2 yield on the third flash is explained by the condition that the cycle initially starts in the S_1 state after complete dark-adaptation. The higher S states (S_2 and S_3) exhibit lifetimes of tens of seconds to several minutes, depending on the temperature, and deactivate to S_1 if not advanced by another incoming quantum, whereas the S_0 state slowly relaxes in the dark to the S_1 state (8). The S_4 state being metastable reacts immediately to produce O_2 and the S_0 state.

DURING WHICH STEP IN THE S STATE CYCLE DOES THE SUBSTRATE WATER BIND?

In the original Kok et al. hypothesis, it was implied that the two substrate water molecules entered the reaction sequence during the last step, just before O_2 release. Although this notion has been considered throughout the literature, the most recent models for the OEC generally predict that the substrate water binds to the catalytic site at the beginning of the S state cycle and that a concerted four-electron event occurs during the S_3 to S_4 to S_0 transition to create the O–O bond (9,10). However, definitive experimental evidence to show at which step in the S state cycle the substrate water binds and the O–O bond forms has until recently remained elusive.

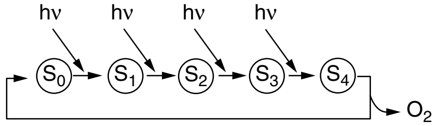

Figure 1. OEC Cycle.

The binding of the substrate water to the catalytic site can be probed by oxygen isotope exchange measurements between the solvent water and the photogenerated O_2 using mass spectrometry. Basically, the measurement involves the transfer of a photosynthetic sample into labeled water of known oxygen isotopic composition (i.e., ^{18}O-enriched water) and then determining the extent of isotopic incorporation into the photogenerated O_2.

In the first oxygen isotope exchange measurements (11−13), the fastest detectable rate of exchange was limited to ∼30 s, mainly because of the long stabilization time of the "open" chamber system that introduced isotopically labeled water to the sample. However, in the more recent measurements from our group, the stabilization time was greatly improved, by a factor of nearly 5000, through the introduction of a "closed" chamber system (14,15). The results from this experimental approach revealed for the first time that one substrate water molecule is bound to the catalytic site throughout the S-state cycle, whereas the second substrate water molecule is bound in at least the S_2 and S_3 states, and that the O–O bond indeed forms during the last step of the reaction sequence. This article documents the experimental approach and the arguments that come to these conclusions.

RAPID ^{18}O EXCHANGE MEASUREMENTS DURING PHOTOSYNTHETIC O_2 EVOLUTION

To probe the substrate water bound at the OEC, excess ^{18}O isotope (added as ^{18}O-labeled water) is introduced into the sample to set up a new isotopic distribution, because natural abundance ^{18}O in the solvent water is low at about 0.2%. The effect of the new isotopic distribution on the photogenerated O_2 can then be measured at m/e = 32, m/e = 34, and m/e = 36 with an in-line mass spectrometer (e.g., the VG Instruments IsoPrime stable isotope spectrometer Manchester UK) for the $^{16}O^{16}O$, $^{16}O^{18}O$, and $^{18}O^{18}O$ di-oxygen products, respectively. From these measurements, the extent of ^{18}O incorporation during the O_2 evolving process can be determined. Figure 2(a) shows the O_2 flash yields at these three masses for spinach thylakoid membrane samples after the injection of an aliquot of $H_2{}^{18}O$ (e.g., 98.5% enriched water from ISOTECH, Miamisberg, Ohio) that gives a final ^{18}O isotopic enrichment in the sample of $\varepsilon \sim 12\%$. In this case, after complete equilibration, the absolute yields (as determined by the extrapolated lines shown in the figure for the third flash) at the three masses follow closely the theoretical isotope equilibrium distribution: $32{:}34{:}36 = (1-\varepsilon)^2 : 2\varepsilon(1-\varepsilon) : \varepsilon^2 = 100\%$, which indicates that no major isotopic discrimination occurs during the O_2 evolving process, as shown earlier from steady-state measurements (16).

Figure 2(b) shows a plot of the normalized O_2 yields at m/e = 32 as a function of flash number. The oscillatory

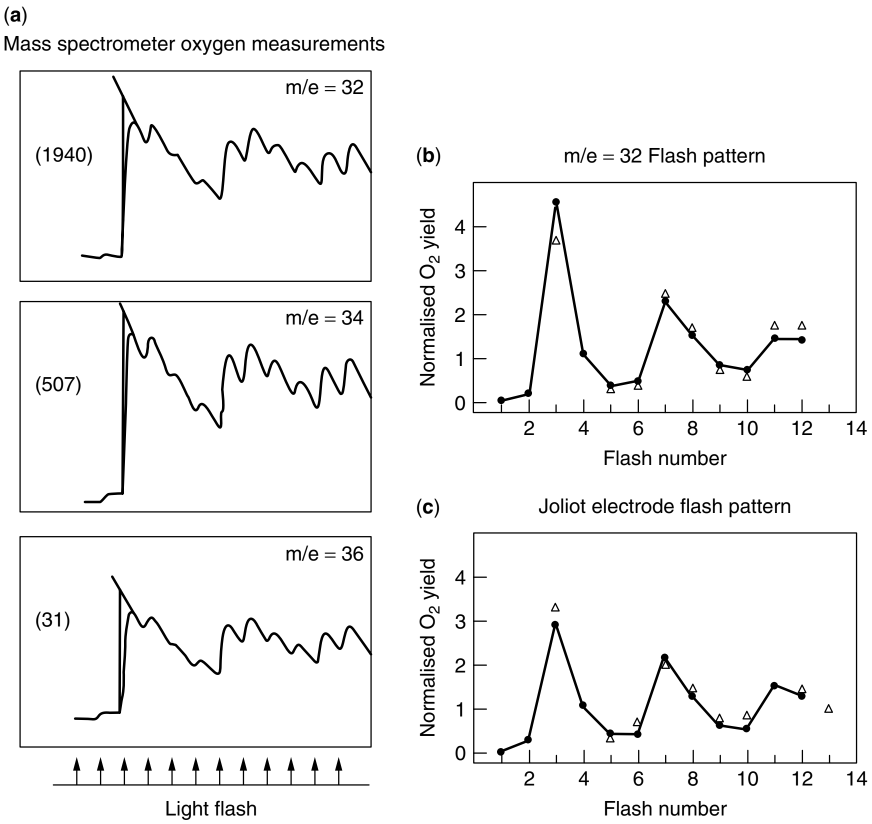

Figure 2.

pattern in the mass spectrometric measurements follows very closely the flash pattern in Fig. 2(c), which was obtained by the conventional amperometric method using a so-called Joliot-type oxygen electrode. Both types of measurements give rise to similar Kok et al. parameters, which indicates that the two techniques are measuring the same phenomenon.

To get information on the binding affinities of the substrate water in the OEC, the rate of isotope exchange between ^{18}O-labeled water and the photogenerated O_2 needs to be determined. To achieve this, our group designed a “closed” chamber system in which the sample volume is considerably reduced (160 μl) and a stirrer is incorporated to facilitate rapid mixing. By employing a solenoid-actuated Hamilton syringe, ^{18}O-labeled water can be rapidly injected and equilibrated with the sample within 6−8 ms. Thus, by measuring the extent of isotope incorporation as a function of the time after injection of the ^{18}O-labeled water, the rate of isotope exchange can be determined.

To evaluate the S-state dependence on the rate of isotope exchange, the “closed” chamber is optically coupled to a bank of three xenon flash lamps (e.g., FX-193 lamp, 4 μF @ 1 kV capacitor from EG & G, Salem, MA) via a 3-to-1 fiber optic to variously illuminate the sample with brief (FWHH ~8 μs), saturating light flashes. The samples are first given a series of activating flashes to preset the sample into a particular S state (see below). Then, after the rapid addition and equilibration of the ^{18}O-labeled water, a subsequent turnover flash sequence (spaced 5−10 ms apart, depending on S state, see below) is applied to photogenerate O_2. As the actual instrumental response time is relatively slow (being about 10 s because of the diffusion of the O_2 gas across a semipermeable membrane into the inlet line from the sample chamber), the flash spacings of a subsequent flash sequence that normalizes the oxygen signals are increased, typically to 20 s. As such, to retard the deactivation reactions of the higher S states during these flash spacings (see above), the temperature of the sample is reduced (usually to 10 °C), which is accomplished by enclosing the sample chamber in a cooling block. Details of the setup have been published earlier (63,64) and are given in Fig. 3.

S-STATE DEPENDENCE ON THE RATE OF ISOTOPE EXCHANGE BETWEEN ^{18}O-LABELED WATER AND THE PHOTOGENERATED O_2

To determine S-state dependence on the rate of isotope exchange, the mass measurements are made as a function of time between the addition and equilibration of ^{18}O-labeled water with the sample in a particular S-state and the first peak yield of the photogenerated O_2. Thus, for example, for the S_3 state, an S_1-enriched sample suspended in $H_2{}^{16}O$ is given two preflashes to advance the OEC into the S_3 state. $H_2{}^{18}O$ is then rapidly injected and followed by a variable delay time (Δt), which allows for the time-dependent isotopic exchange to occur between the solvent water and the substrate water. A single flash is then given, and the oxygen signals at m/e = 34 and m/e = 36 are measured. The oxygen signals are then collected on subsequent flashes (in which complete

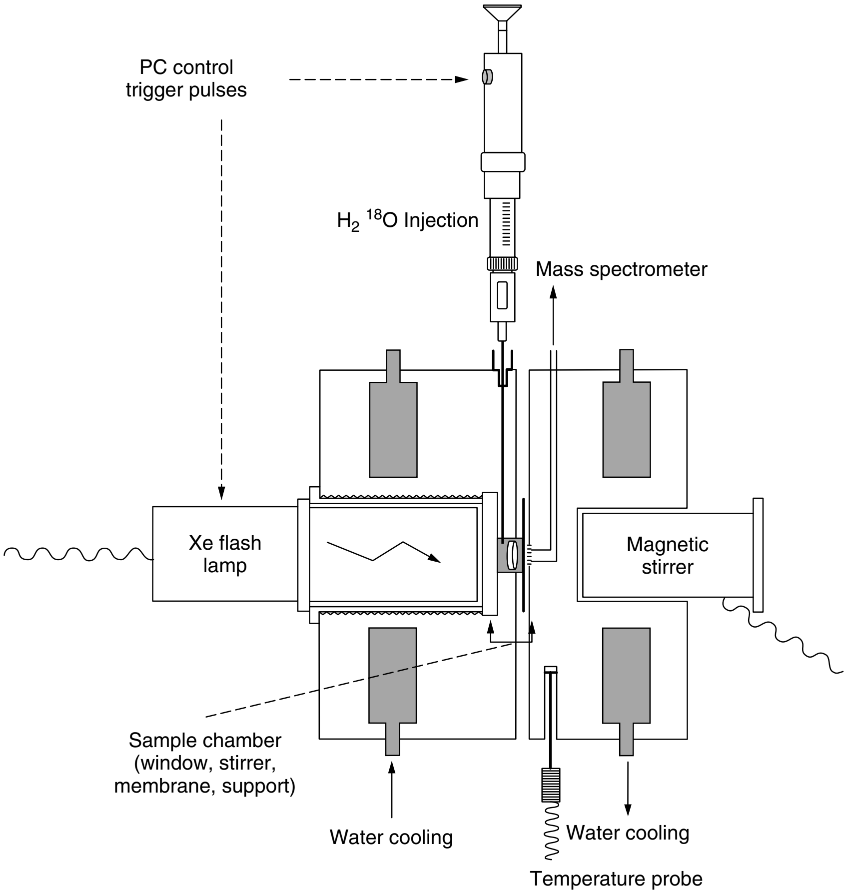

Figure 3.

exchange has occurred because of the 20 s flash spacings) to normalize the data among the different sample aliquots measured at different Δt values.

The complete ^{18}O exchange kinetics were determined for the different S states using the injection/flash protocols depicted in Fig. 4.

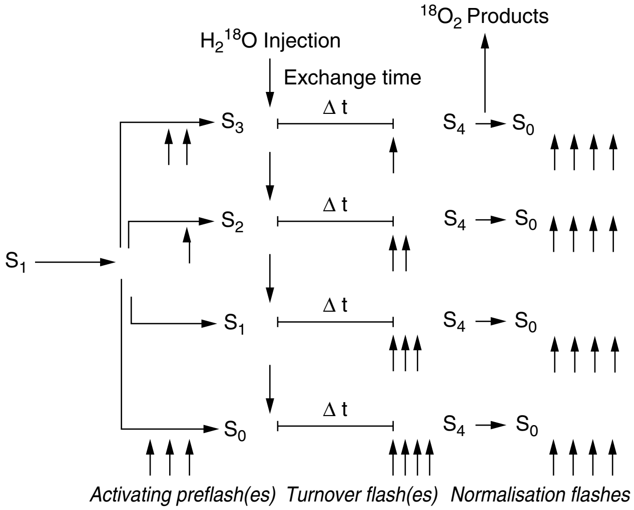

Figure 4.

The basic protocol involves the following procedure. Before loading, the samples are thawed in the dark at room temperature and given one saturating preflash followed by a 10-min dark period at room temperature to enrich the S_1 population. The S_1-enriched sample is then loaded into the sample chamber in the dark, equilibrated to 10 °C for 10–12 min, and then given several activating flashes (spaced 1 s apart). At a given S state, $H_2{}^{18}O$ is rapidly injected into the chamber ($t_{1/2\ (\mathrm{mixing})} \sim 4$ ms) and a variable delay time (4 ms $<$ Δt $<$200 s) is provided to allow the water bound in the OEC to exchange with the ^{18}O-enriched solvent water. After the delay time, several rapid turnover flashes (spaced at 5, 10, and 10 ms apart for S_2, S_1, and S_0 states, respectively) are then applied to advance the sample through to the S_3 to S_4 to S_0 transition, where the mass ratio of the photogenerated O_2 (Y_M) is determined. After this process, several normalization flashes (spaced 20 s apart) are given and their separate O_2 yields ($Y_{n(1\to4)}$) are measured. The Y_M is corrected for background O_2 contributions, double hits, and the injection response as described earlier (17,18) to give Y_C.

The resolvable ^{18}O exchange kinetics for spinach thylakoid samples as a function of the S-states are shown in Fig. 5. Here, the corrected, normalized yields of O_2 (Y_C) measured at m/e = 34 for the mixed labeled $^{16}O^{18}O$ product (left side of the figure) and at m/e = 36 for the double labeled $^{18}O^{18}O$ product (right side of the figure) are presented. Each point is a plot of Yc at a particular delay time (Δt) between the injection of $H_2{}^{18}O$ into the sample and the turnover flash sequences that photogenerated O_2. The m/e = 36 data exhibit only a single kinetic phase and are fit with a simple exponential function:

$$^{36}Y = (1 - \exp(-^{36}k\ t)) \tag{1}$$

In contrast, the m/e = 34 data on the left side in Fig. 5 reveals two distinct kinetic phases. The insets show expanded time ordinates for the fast phases. The two phases, however, are unequal in amplitude, with the fast phase constituting slightly more than half of the total signal. The basis for this difference in amplitude is well explained by the enrichment condition for two independent, exchanging sites. As the apparent kinetics of the two phases differ by at least a factor of 10, the fast phase of exchange is virtually complete before the slow phase begins. Thus, at short Δt only one substrate water molecule is exchanging at the catalytic site, which means at a typical ^{18}O enrichment of $\varepsilon = 12\%$, the mass distribution at 32:34:36 for the two oxygen isotopes will be 88:12:0. On the other hand, at longer Δt, when the second substrate water molecule is also exchanging, the mass distribution will be 77.44:21.12:1.44. Therefore, the relative contributions of the fast and slow phases will be unequal, with the fast phase representing ~57% (i.e., 12/21.12) of the total amplitude and the slow phase ~43%. The 0.57:0.43 distribution between the two phases is found consistently in the m/e = 34 data. Thus, the exchange kinetics in this case is fit exactly by the sum of two exponentials:

$$^{34}Y = 0.43(1 - \exp(-^{34}k_1\ t)) + 0.57(1 - \exp(-^{34}k_2\ t) \tag{2}$$

The solid lines in Fig. 5 represent the best fits to the data points based on Eqs 1 and 2 for the m/e = 36 and m/e = 34 data, respectively. The exchange rates from the corresponding kinetic fits at 10 °C are given in Table 1. The entire S-state results for the thylakoids have been presented earlier (17,18).

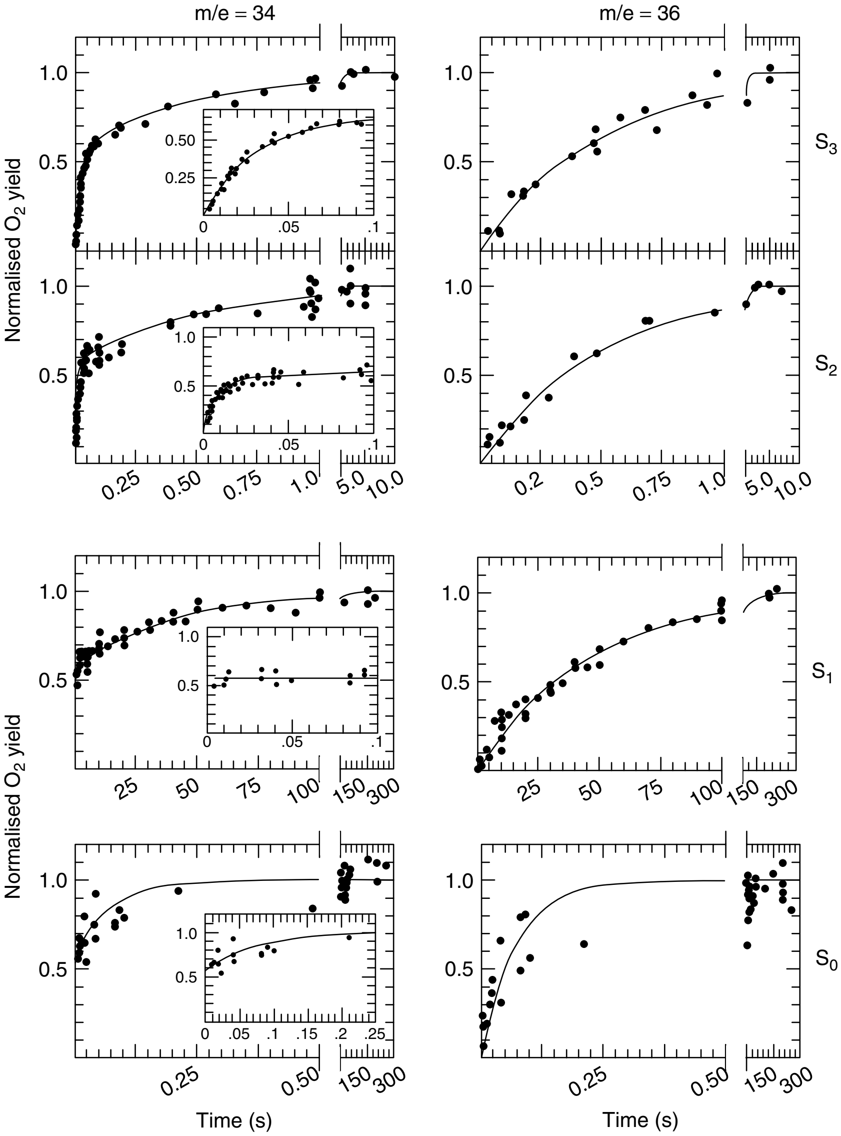

Figure 5.

Table 1. Rate Constants for the ^{18}O Exchange in Spinach Thylakoid Samples as a Function of the S States at 10 °C

S-State	^{36}k (s^{-1})	$^{34}k_1$ (s^{-1})	$^{34}k_2$ (s^{-1})
S_3	2.1 ± 0.2	1.9 ± 0.2	36.8 ± 1.9
S_2	2.2 ± 0.1	1.9 ± 0.3	120 ± 6
S_1	0.022 ± 0.002	0.021 ± 0.002	>175
S_0	18 ± 3	8 ± 2	>175

IMPLICATIONS OF SUBSTRATE WATER BINDING FOR THE MECHANISM OF O_2 EVOLUTION

Several striking features are found in the rate constants listed in Table 1. In each S state, the slow phase of exchange was resolvable, whereas the fast phase of exchange could be resolved only in the S_2 and S_3 states. For the S_0 and S_1 states, the fast phase of exchange is equal to or faster than the response time of the currently available experimental setup ($\sim 100 - 175\ s^{-1}$). Most importantly, the rate constants for the slow phase kinetics in the m/e = 34 data are virtually identical to the rate constants for the monophasic kinetics in the m/e = 36 data. This last result clearly indicates that the extent of ^{18}O incorporation into the photogenerated O_2 is limited throughout the S-state cycle by the substrate water molecule undergoing the slow isotope exchange process and that the biphasic behavior in the m/e = 34 data does not originate from PSII heterogeneity. Rather the two kinetic components in the m/e = 34 data reflect the binding of the substrate water at two separate sites.

The most relevant question to ask is at which S state does the substrate water bind. Based on the kinetic resolution of our current mass spectrometric setup, a measurable ^{18}O exchange kinetic will conclusively show the existence of bound water in a particular S state, which is justified by the observations that the O_2 release on the S_3 to S_4 to S_0 transition takes place in ~2 ms, whereas the rest of the S-state advancement from S_0 to S_3 takes at most another 1 ms (8). The catalytic site thus can make one complete turnover in ~3 ms. Therefore, any ^{18}O exchange that is slower than 3 ms would be indicative of bound water. From the rate constants for the slow phase of ^{18}O exchange listed in Table 1 for the m/e = 34 data, it is clear that one substrate water molecule is bound to the catalytic site through the S-state cycle. Interestingly, the results for the fast phase of exchange show that the second substrate water molecule is bound in at least the S_2 and S_3 states, but they are inconclusive for the S_0 and S_1 states because the fast exchange kinetics in these S states are not resolvable by our current setup (i.e., faster than 6–8 ms).

Even though the measurable exchange rates listed in Table 1 are slower than the total turnover time of the catalytic site, the magnitudes of these exchange rates in general are all remarkably fast, where the slowest exchange is measured in the S_1 state with $t_{1/2}$ ~50 s. Exchange rates in this magnitude range indicate relatively labile binding sites and can be interpreted for two overall mechanisms: (1) exchange of water bound to a metal site or (2) diffusional or isotope equilibration processes, where the solvent water must be translocated to the binding site across a physical barrier.

Rates of whole water exchange at a metal site can span a tremendous range (as much as 18 orders of magnitude), and examples for various transition metals have been summarized earlier (19–22). The most significant factors governing water exchange at a metal site are the charge and ionic radius of the metal center and any electronic occupancy of d orbitals. As a general rule, water exchange rates will decrease (by several orders of magnitude) as the metal center (M^n) is oxidized and charge is increased; i.e., k_{ex} (M^n-OH_2) > k_{ex} (M^{n+1}-OH_2). Furthermore, metal-bound water can undergo deprotonation in response to an increase in charge (and acidity) at the metal center. Thus, it may also be expected for water exchange to decrease at deprotonation for a given oxidation state; i.e., k_{ex} (M^n-OH_2) > k_{ex} (M^n-OH). In the case of the deprotonation of a neighboring ligand (L), the opposite effect may occur because the effective charge of the metal center is reduced, As such the rate of water exchange will tend to increase; i.e., k_{ex} (HL-M^n-OH_2) < (L-M^n-OH_2). The protonation state will thus be defined by the pK of the aquo metal complex.

Any number of possible intermediates in the water oxidation reaction can exist, and it is important to appreciate that the ^{18}O exchange measurements could reflect not only whole water and hydroxyl exchange but also the exchange of μ-oxo (–O–), peroxo (–O–O–), and oxo (=O) intermediates. Indeed various models in the literature on O_2 evolution invoke one or more of these intermediates (9,10). Although a dearth still exists in studies of ^{18}O exchange in model compounds, it is expected that the isotope exchange in μ-oxo (–O–), perxo (–O–O–), and oxo (=O) intermediates is much slower (in the order of hours to days) than whole water exchange because of tighter bonding and lack of protonation.

The other type of mechanism that could limit the ^{18}O exchange could be diffusion or isotope equilibration across a physical barrier. The catalytic site for O_2 evolution in PSII is located within the protein domain away from the solvent interface. In this situation, the structural barriers provided by the protein matrix may be mediated through specific water chains or water channels (23), something akin to what has been proposed for the cytochrome c oxidase (24,25). Such a water channel may provide an important function in optimizing O_2 formation by controlling the accessibility of the water substrates and O–O bond formation at the catalytic site, thereby minimizing side reactions that lead to the formation of reactive oxygen intermediates (23). The inability to resolve the fast phase of exchange in the S_0 and S_1, states (Table 1) could indicate that the second substrate water molecule only enters the reaction sequence at the S_2 state. However, such a possibility can only be clarified by resolution of the fast phase kinetics or by the progressive improvement in the resolution of crystal structure of PSII (26–28).

The S-state dependence of the ^{18}O exchange kinetics for the substrate water are clearly complex, but these results place limits on the types of mechanisms that may be involved in the oxidation of water during photosynthesis. Although the S-state-dependent changes in the kinetics may in the first instance be interpreted for metal-centered oxidations and/or substrate or other ligand protonation/deprotonation events, second-order effects mediated by the protein environment, such as H-bonding networks and structural conformations, will also have to be considered. To sort out the fine details, additional measurements will have to be made under different biochemical conditions and in mutants of the PSII. This work is currently in progress.

RADON IN WATER

Babs A. Makinde-Odusola
Riverside, California

Some groundwater contains the naturally occurring radioactive gas, radon-222 (radon). Radon dissolved in groundwater is released into indoor air when plumbed in water is agitated indoors. Radon released from domestic water typically contributes less than 2% of total indoor radon. This article describes the health risks from radon in domestic water and the efforts within the United States to regulate radon in drinking water. The U.S. National Research Council (NRC) found that the primary health risks from radon in domestic water are lung cancer and stomach cancer, primarily to ever-smokers. Radon concentration in air could reach levels considered unsafe for underground miners at some water treatment facilities that aerate water as part of the treatment process. Inhalation of radon gas and its progeny may result in lung cancer (inhalation risk). An estimated 11% of the health risk is from direct ingestion of radon dissolved in drinking water (ingestion risk). The NRC found that radon is a greater source of cancer risk than any other regulated chemical in drinking water. Some ecological studies contradict using the linear nonthreshold (LNT) model to assess the health risks from exposure to radon at low levels typical of indoor air. The U.S. Environmental Protection Agency (EPA) relied on the LNT model to assess health risks and propose standards and goal for radon in drinking water. Some water utilities could opt for treatment to comply with the radon in drinking water standard. Some other water utilities might avoid treatment by adopting a multimedia approach to radon mitigation. The multimedia approach could be more cost-effective and achieve greater health risk reduction. Noneconomic considerations may influence that decision. Health risk reduction and cost analyses (HRRCA) suggest that most of the benefits would accrue to ever-smokers and smaller water systems could incur most of the costs.

INTRODUCTION

Radon, in this article, refers to the specific isotope, radon-222, the daughter product of radium-226 and a member of the uranium-238 decay series. The decay scheme for uranium-238 is illustrated in Drago (1) and

NRC (2). Uranium is found in trace amount in soils everywhere. Radon escapes as a gas from soils into groundwater, indoor air, and outdoor (ambient) air. The U.S. Geological Survey (3) reported that soil air within the United States contains between 200 and 2,000 pCi/L ($1\ \text{pCi/L} = 37\ \text{Bq}\,\text{m}^{-3}$) of radon. Radon is a chemically inert, colorless, and odorless gas whose half-life is about 3.82 days. Radon emits alpha (α) particles as it decays to a series of solid short-lived radionucleotides, such as polonium-218 and lead-214. Those physical properties are important in understanding the health risks from exposure to radon and the mitigation of such risks.

The United Nations Scientific Committee on the Effects of Atomic Radiation (4) estimated that about 50% of the average annual effective dose from natural sources of ionizing radiation worldwide is from exposure to the alpha-particles produced by radon and its progeny. Potential contributors of radon to indoor air include soil gas, natural gas, building materials, and to a lesser extent—domestic water. Radon emanating from soils under homes is the primary source of radon in indoor air, which can range from <1 to 3,000 pCi/L (3).

Radon in drinking water is typically of concern to sources that rely on groundwater, where there had not been sufficient opportunity for significant decay nor release into the atmosphere before reaching indoor plumbing. A portion of the radon in plumbed water used indoors is released into the air, especially during agitation (e.g., laundering, dishwashing, humidifying, toilet flushing, etc.), which increments the level of radon in indoor air. The NRC (2) estimated that the average transfer coefficient is about 0.01% (1 in 10,000) of radon in water; that is 10,000 pCi/L of radon in water would increase the level of radon in indoor air by 1 pCi/L. The U.S. EPA (5) estimated that less than 2% of radon in indoor air emanates from domestic water. This author prefers to emphasize "domestic water" because of the widespread use of bottled water for drinking and because the NRC (2) found that the major part of the health risk is from inhalation of radon and its progeny.

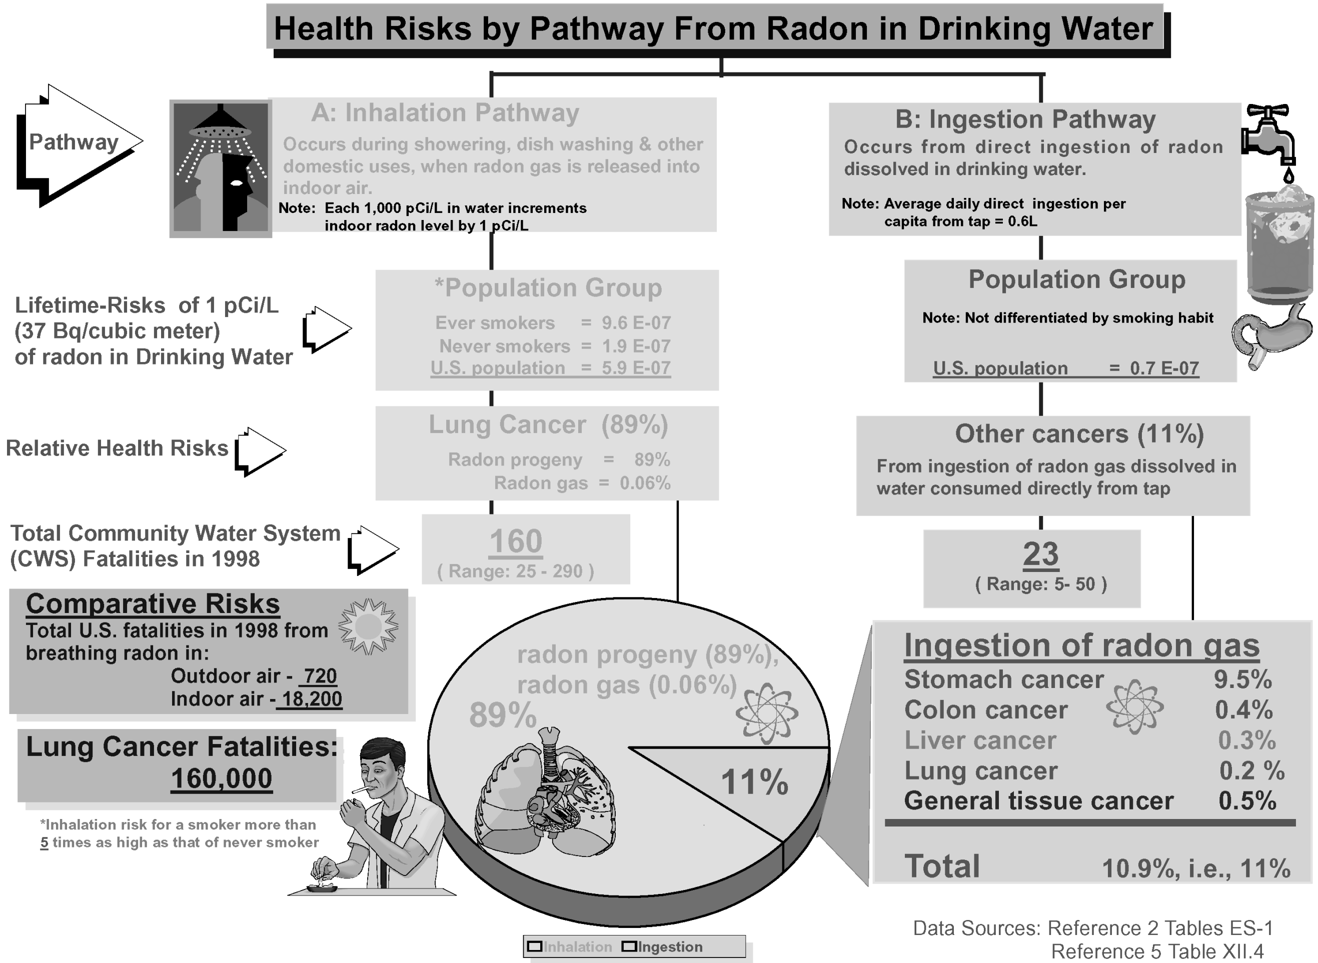
Some countries have policies to reduce public exposure to radon, especially in indoor environments. Cole (6) provides the historical development of radon risk policies in the United States. The U.S. Indoor Radon Abatement Act of 1988 established the goal of reducing indoor radon concentrations to natural ambient level. The NRC (2) estimated that the arithmetic national ambient average level of radon was 0.4 pCi/L. The U.S. EPA established a voluntary action level of 4 pCi/L for radon in indoor air. The indoor radon action level in other countries is as high as 27 pCi/L (7). Indoor radon guidelines are 22 pCi/L and 11 pCi/L in Canada and the European Union, respectively (7). The U.S. EPA (5) reported that more than 2500 lives were "saved" through the year 2000 since the inception of its voluntary indoor radon abatement program in 1986.

Many countries are developing policies to reduce exposure to radon in domestic water. The World Health Organization (WHO) is creating a database of national radon regulations [http://www.who.int/ionizing_radiation/env/radon/en/]. The rest of this article focuses on efforts within the United States. The NRC (2) found that radon is a greater source of cancer risk than any other regulated chemical in drinking water. Evaluating, and where necessary, mitigating the level of indoor radon is common during real estate transactions in the northeastern United States, even though compliance with the action level is voluntary. That practice could extend to testing for radon in privately owned wells after the EPA finalizes the maximum contaminant level (MCL) for radon in drinking water. Regulating radon in domestic water had been very controversial in the United States and dates back to 1986. In 1986, Congress directed the EPA to establish a mandatory standard for radon in drinking water as part of the amendments to the Safe Drinking Water Act (SDWA). The EPA (8) proposed the radon in drinking water rule using the risk management approach typically used for drinking water contaminants. Amendments to the SDWA in 1996 directed the EPA to withdraw the proposed rule of 1991 and repropose after an independent risk assessment by the NRC. The amendments include provisions for a multimedia approach to achieving an equal or greater level of health risk reduction. In 1999, the EPA (5) proposed 300 pCi/L and 4,000 pCi/L as the MCL and alternate MCL, respectively, for radon in drinking water. The EPA is expected to finalize the radon in drinking water rule after 2004. Key inputs and major milestones in developing the radon rule are illustrated in Fig. 1 of Article MW-66 (9).

OCCURRENCE OF RADON IN DOMESTIC WATER

Radon levels in water, like those in ambient air and indoor air, vary temporally and spatially. The EPA (5) analyzed data from the Safe Drinking Water Information System (SWDIS) to estimate the nationwide occurrence of radon in community water systems (CWS). The EPA (10) found geographic disparity in its occurrence. New England CWS had the highest arithmetic and geometric mean concentrations of 2933 pCi/L and 1214 pCi/L, respectively. Some privately owned wells, not monitored nor regulated by the EPA, might contain radon at much higher levels. The USGS (3) reported that the radon level in groundwater ranges from about 100 pCi/L to nearly 3,000,000 pCi/L. The EPA (5) estimated the population-weighted national average concentration of radon in CWS at 213 pCi/L, and a credible range of 213 to 240 pCi/L. In general, smaller CWS that rely on groundwater have the highest levels of radon. Radon levels exceeded 300 pCi/L at more than 51% and 16% of the CWS serving fewer than 100 people and 10,000 people, respectively (5). Radon levels exceeded 300 pCi/L and 4000 pCi/L in the domestic water of more than 16 million people and 77,000 people, respectively (5). The EPA (5) and NRC (2) have additional information on the occurrence and spatial distribution of radon in domestic water, indoor air, and ambient air. SWDIS would contain additional radon occurrence data when the radon rule is finalized and CWS begin compliance monitoring.

Radon levels at a particular well could fluctuate significantly. The EPA (5) proposed a monitoring regime that would require CWS using groundwater to monitor for radon initially at each entry point to the distribution system, quarterly for 1 year. Compliance would be based



Data Sources: Reference 2 Tables ES-1
Reference 5 Table XII.4

Figure 1. Estimated fatalities in the U.S. by pathway from radon in drinking water provided by CWS.

on the average of four consecutive quarterly samples. Zikovsky and Chah (11) found that concentrations of radon are lognormal in distribution and that the arithmetic mean of concentrations might create a false impression about exposure levels. The EPA (5) estimated that 26.8% of sources whose radon concentrations averaged between 200 and 300 pCi/L during the first four quarterly measurements would have long-term exceedances of 300 pCi/L. Field et al. (12) found higher levels of radon in domestic water at the point of use than prior to distribution because of increments from decay of the radium-226 deposits within the older portions of water distribution systems. The EPA (5) identified man-made sources of radon in groundwater to include releases from wastes from radium or thorium processing and from phosphate and uranium mining and milling operations.

RISK ASSESSMENT OF RADON IN DOMESTIC WATER

The health risks from radon in domestic water are primarily lung cancer and stomach cancer. Radon is a human carcinogen based on epidemiological studies of underground miners, cellular mutagenesis studies, and experimental research in animals (13). A linear nonthreshold (LNT) model is often used to assess the health risks of exposure to radon. The use of the LNT model to assess the health effects from exposure to radon at typical indoor concentrations is controversial. The National Council on Radiation Protection and Measurements (14) evaluated the evidence for and against the LNT dose–response hypothesis and found that the LNT model is more plausible. The NCRP (14) did not exclude other dose–response relationships because of growing evidence that adaptive responses, bystander effects, and other variables may modify the dose–response relationship. The NRC Committee on the Biological Effects of Ionizing Radiation (BEIR) VI did not exclude the possibility of a threshold relationship at the very low levels of radon exposure typically found in indoor air. The NRC (2) supported using the LNT relationship to derive quantitative estimates of cancer risks in the absence of credible evidence to the contrary. The NRC (2) recommended reconsideration of the LNT assumption when the "probability of an exposed cell becoming transformed" and the "latent period before malignant transformation is complete" are known. Lorimore et al. (15) observed the potential for interaction between irradiated and nonirradiated cells in the production of genetic damage and its significant implications for risk estimation. Brenner and Sachs (16) suggested that bystander effects from alpha-particle damage could cause downwardly curving dose–response relations and inverse dose-rate effects.

Parsons (17) presented a biological model of radiation hormesis that invalidated the LNT. Cohen (18) tested the LNT model by analyzing lung cancer mortality rates and average radon concentration in homes in 1601 U.S. counties while addressing problems typical of ecological studies. Cohen (18) found a "strong tendency for lung cancer rates to decrease with increasing radon exposure in sharp contrast to the increase" expected from the LNT model. The NRC (2) recommended investigating the significant negative trend of county lung cancer mortality with increasing home radon concentration established in the ecological study by Cohen (18). Puskin (19) found similar "strongly negative correlations for cancers strongly linked to cigarette smoking" but did not find "such correlations" for cancers not linked to smoking. Puskin (19) explained that the ecological correlation (18) "provides no substantial evidence for a protective effect of low level radon exposure." Van Pelt (2003) found that altitude (elevation) explains some of the inverse association between radon and lung cancer. Van Pelt (2003) postulated that the decrease in lung cancer is "caused by the carcinogenic effect of higher absolute oxygen concentration in the inspired air at lower."

The most direct way to assess the effects of radon in homes is through case-control studies (20). Krewski et al. (13) summarizes case-control studies of residential radon and lung cancer in North America. Field and Duport (21) presented points and counterpoints regarding lung cancer risks from exposure to residential radon. The NRC (2) reviewed available epidemiological studies of indoor radon and concluded "it is low and difficult, if not impossible to detect given the high background lung-cancer mortality in the populations studied."

Inhalation of radon gas, especially its progeny, causes lung cancer primarily among ever-smokers. BEIR VI (20) evaluated the risks of domestic radon to ever-smokers and never-smokers separately. CDC (22) defines ever-smokers as people who had smoked at least 100 cigarettes in their entire lifetimes. Alavanja (23) found many similarities between the pathologic lung-cancer mechanisms observed among those exposed to tobacco smoke and those exposed to radon gas.

NRC (2) conducted the most comprehensive review of the health risks of radon in domestic water. That review included epidemiological studies, BEIR studies, and earlier EPA (8,24) risk assessments. Both BEIR VI (20) and the NRC (2) reviewed the mechanistic information on alpha-particle-induced carcinogenesis. The NRC (2) postulated that the biological effects of exposure to radon at the low level of typical indoor air are initiated by the passage of single alpha-particles that have very high linear energy transfer (LET). Hei et al. (25) described the mutagenesis of a single alpha-particle in mammalian cells. Genes involved at low dose are different from those involved at higher doses and adaptive responses in cells exposed to low-level ionizing radiation allow the cells to better withstand a much higher dose later (priming effect) [http://www.llnl.gov/str/JulAug03/Wyrobek.html].

The NRC (2) developed a new model of ingested radon diffusion because its review of published ingestion risks found a wide range in the estimates. The uncertainties were mainly due to the assumed model of radon absorption in the gastrointestinal tract. The NRC (2) noted the lack of data on the extent to which radon diffuses through the stomach wall and recommended research to reduce the uncertainty regarding ingestion risks. Details of the mathematical models of radon diffusion in the stomach and the physiologically based pharmacokinetic (PBPK) model of radon behavior in the body can be found in the NRC (2). The NRC (2) estimated the ingestion risks using estimates of the amount of water ingested, the fraction of radon lost from water before ingestion, and calculations of the dose absorbed by tissues exposed. The NRC (2) estimated the confidence limits on the ingestion risk but noted, "the actual risk from ingested radon could be as low as zero depending on the validity of the LNT dose–response hypothesis." Yamaoka el al. (2004) found inhalation of radon gas from radon enriched water induced a small amount of active oxygen in the blood, decreased the levels of lipid peroxide and total cholesterol in the blood of osteoarthritis patients alleviating pain related to peroxidation reactions and immune depression.

Table 1 is a summary of the risks estimated by the NRC (2). Table 1 shows that males have higher lifetime risks than females and that the inhalation risk to ever-smokers is five times as high as those for never-smokers of either sex. Notice that the aggregate health risk to the general population is thrice as high as the risk for never-smokers due to the inclusion of ever-smokers. Figure 1 shows the relative distribution of cancer fatalities by exposure pathways. Notice in Fig.1 that 89% of the health risks are from inhalation of the radioactive by-products of radon released from water into indoor air. About 11% of the health risk is from direct ingestion of tap water (0.6 L/day directly from a tap). An earlier risk assessment by the EPA (5) estimated that the proportion of ingestion and inhalation risks were 53% and 47%, respectively.

Both the NRC (2) and the EPA (5) found that the hazards of exposure to radon during showering are likely to be small because the buildup of radon progeny is less than 4% of the maximum possible value during a typical shower that lasts 10 minutes. The NRC (2) found it highly unlikely that radon in drinking water has substantial teratologic or reproductive effects. The NRC (2) found that information was insufficient to determine radon risks to "sensitive" sub-populations, such as children. However, about 30% of fatal stomach cancers are attributed to exposure before age 10 (2). The NRC (2) suggested that there might be an opportunity interval for lung-cancer risk reduction from exposure during childhood. Bilban and Vaupotic (26) found higher chromosome aberrations in pupils at elementary schools that had high indoor radon levels. Fewer than 34% of lung cancer patients are diagnosed before age 65 (27).

Many researchers have estimated fatalities from radon in domestic water. Mills (28) estimated 60, 400, and 5000 annual fatalities from radon in surface water, public groundwater, and private wells sources, respectively. The NRC (2) used the risk estimates (Table 1) and information regarding the occurrence of radon in CWS, daily water

Table 1. Lifetime and Unit Risks Posed by Exposure to Radon in Drinking Water at 1 pCi/L (37 Bqm^{-3})[a]

	Lifetime Risk[b]			
Exposure Pathway	Male	Female	U.S. Population	Unit Risk U.S. Population
Inhalation (ever-smokers)	1.15×10^{-6}	7.40×10^{-7}	9.62×10^{-7}	1.31×10^{-8}
Inhalation (never-smokers)	2.18×10^{-7}	1.48×10^{-7}	1.85×10^{-7}	2.43×10^{-9}
Inhalation (population)	7.77×10^{-7}	4.44×10^{-7}	5.92×10^{-7}	7.90×10^{-9}
Ingestion* (population)	5.55×10^{-8}	8.51×10^{-8}	7×10^{-8}	9×10^{-10}
Total risk (inhalation and ingestion)	8.14×10^{-7}	5.18×10^{-7}	6.66×10^{-7}	8.89×10^{-9}
*Breakdown of Ingestion Risks				
Stomach			5.92×10^{-8}	
Colon			2.18×10^{-9}	
Liver			2.15×10^{-9}	
Lung			1.26×10^{-9}	
General tissue			2.92×10^{-9}	
Total ingestion			7×10^{-8}	

[a] Data sources: Reference 2, pp. 16, 17; Reference 5, Table X11.3.

[b] Annual unit risk can be obtained by dividing lifetime unit risks by the expected lifetime for each population category. Expected lifetime in years: Ever-smokers = 73.7; never-smokers = 76.1; combined population = 74.9.

Table 2. Health Risks from Radon in Drinking Water

a. Estimated Annual U.S. Fatalities Due to Radon in *Drinking Water

Health Risk	Source of Estimate	Central Estimate	Range
Lung cancer	NRC (2)	160	25–290
Lung cancer	EPA (5)	148	70–263
Stomach cancer	NRC (2)	23	5–50
Stomach cancer	EPA (5)	18	3–38

b. Occurrence of Lung Cancer due to Radon by Exposure Pathway

Pathway	Central Estimate	Range
Outdoor air (2)	720	120–300
Indoor air (5)	18200	3,000–33,000
*Drinking Water (2)	160	25–290
*Drinking Water (5)	148	70–263

c. Comparative Health Risks of Radon in *Drinking Water

	Annual Fatalities (Central Estimates)		
Health Risk	All Causes	*Drinking Water	% of All Causes Due to *Drinking Water
Lung cancer (2)	160,000	160	0.10%
Stomach cancer (2)	14,000	18	0.13%

Fatalities based on 1998 data.

*Potable water delivered by a community water system (CWS).

intake, and smoking patterns among several factors to derive estimates of cancer fatalities in the United States. Table 2 summarizes the estimated U.S. fatalities due to radon in domestic water relative to other sources. The NRC estimated that in 1998 radon from soil gas caused about 18,200 lung cancer fatalities in the United States. The NRC (2) also estimated that 160 lung cancer fatalities were due to radon in domestic water. Notice that an estimated 720 fatalities were from an unavoidable background level of radon in outdoor air. The NRC (2) estimated that 23 stomach cancer fatalities were from ingesting radon in drinking water. The EPA (5) estimated that radon in domestic water caused 148 lung cancer and 18 stomach cancer fatalities annually. The EPA (5) also estimated (screening level) that an additional 36 fatalities annually were from radon in water delivered outside residences, at schools, offices, etc.

RISK MANAGEMENT

The EPA (8) first proposed 300 pCi/L and 0 pCi/L as the maximum contaminant level (MCL) and MCL goal (MCLG), respectively, for radon in drinking water. Many criticized the proposed rule because it was not considered cost-effective. In addition, a multimedia approach could be more cost-effective and achieve greater health risk reduction. In 1996, as part of the amendments to the SDWA, Congress directed the EPA to withdraw the proposed rule and re-propose using an updated risk assessment provided by the NRC. Congress also directed the EPA to develop an alternate MCL (AMCL) and guidelines for multimedia mitigation (MMM) programs (MMMP). The NRC (2) defined the AMCL as the concentration of radon in water that would cause an increase of radon in indoor air that is no greater than the level of radon naturally present in outdoor air. The NRC (2) determined that the AMCL should be about 4000 pCi/L based on the national average outdoor air radon concentration of 0.4 pCi/L and the water to air transfer factor of 10,000. EPA is only to establish an AMCL if the MCL is more stringent than the water equivalent of the national average of radon in outdoor air.

The EPA (5) used NRC risk estimates (Table 1) to repropose the radon rule (MCL = 300 pCi/L; MCLG = 0 pCi/L, AMCL = 4000 pCi/L). CWS whose radon levels are within the range of the MCL and the AMCL have the option of complying with either the MCL or the less stringent AMCL. CWS that choose to comply with the AMCL must participate in an approved and verifiable MMMP that achieves at least an equivalent level of risk reduction as treatment to the MCL. CWS may opt to develop individual MMMP in accordance with EPA guidelines if the primacy state chooses not to develop an MMMP. The EPA (5) proposed four criteria required for approval of MMMP: involve the public in developing MMMP; include quantitative goals to measure the effectiveness of MMMP; include implementation plans, strategies and specific activities for achieving quantitative goals; and include plans for measuring and reporting results. Examples of MMMP include mitigation of radon levels in existing construction and use of radon-resistant techniques for new construction. CWS that choose the AMCL approach are not required to treat, but to participate in approved MMMP. The implemented MMMP might not reduce the ingestion risk, but reduce the inhalation risks, though not necessarily in the same community, nor in the same homes. Some CWS systems may opt to purchase water from other sources or consolidate with other CWS in lieu of treating or implementing the MMMP.

HEALTH RISK REDUCTION AND COST–BENEFIT ANALYSES (HRRCA)

Radon is the first drinking water contaminant for which the EPA (27) used the new cost–benefit analyses framework. The HRCCA (27) included detailed cost–benefit analyses by water system size for each considered MCL and MMMP adoption. In estimating benefits, the EPA (27) used the value of \$5.8 million (1997 dollars) as the value of statistical life (VSL) for each avoided cancer fatality and willingness to pay (WTP) of \$536,000 for nonfatal cancers. The EPA (5) estimated that the cost for MMMP is \$0.7 million per avoided lung cancer (the estimated average costs of indoor radon screening for all homes and mitigation cost for each home at or above the 4-pCi/L indoor air action level). The EPA (5) estimated annualized national costs at \$408 million and monetized annual benefits at \$362 million if 100% of impacted CWS choose to comply with the proposed MCL and assuming costs of capital of 7%. The estimated national annualized costs and monetized benefits are \$60 million and \$301 million, respectively, under a scenario that assumes that 95% of states implement MMMP and 90% of the CWS in each state comply with the AMCL. The EPA (5) prefers that states adopt the AMCL approach and develop MMMP but the NRC (2) noted that noneconomic considerations, such as equity, could be deciding factors in whether to undertake MMMP. The EPA (5) estimated that annual MCL compliance costs per household are about \$270 and \$10 for CWS serving 25 to 100 people and more than 100,000 respectively. The HRRCA shows that small CWS would incur most of the treatment costs but that the majority benefits would go to larger systems under the MCL approach. Some have argued that the EPA underestimated the costs of compliance and overstated the benefits. Costs could be higher because of unique local conditions and environmental permitting. Hahn and Burnett (29) found that the proposed radon rule was unjustifiable based on cost–benefit analyses.

TREATMENT TECHNOLOGIES

CWS may choose to comply with either the MCL or, under certain circumstances, with the AMCL. Treatment of radon in domestic water will reduce the health risks from both direct ingestion and inhalation through a decrement. Deb (30) reported on the decrements in indoor radon level after water treatment in three New Hampshire communities. Deb (30) found that significant reduction in the indoor radon level, occurred only in homes served by the CWS where water (radon concentration >20,000 pCi/L in water) was the major source of radon in indoor air.

The EPA (5) identified aeration as the best available technology (BAT) for removing radon from domestic water in large CWS. Article DW-32 (31) contains additional information regarding radon removal from drinking water. Aeration treatment methods such as a packed tower, diffused bubble, spray, slat tray, and cascade aeration are very efficient in removing radon from water because of the volatility of radon gas. Liquid-phase granular activated carbon (GAC) removes radon by adsorption but requires longer empty bed contact time (EBCT) ranging from 20 to 130 minutes, and its performance depends on water quality (1). The EPA (5) identified point-of-entry (POE) GAC as one of the affordable small systems compliance technologies (SSCTs). Drago (1) reported removal efficiencies of 20% to greater than 99% at 34 water treatment facilities and found that construction costs for either BAT are site specific. Either treatment technology requires disinfection after treatment, which EPA believes, will reduce the microbial risk and provide the additional benefit of complying with the proposed groundwater rule (32). The EPA (5,27) found that high levels of dissolved iron and manganese co-occurring with radon in water may complicate and increase radon treatment costs.

The EPA (5) reviewed the permitting and other environmental issues of either technology. Beta-gamma radiation from radon progeny might pose concern to GAC operators (1). A major concern of aeration technologies is off-gas emissions. Fisher et al. (33) found that radon concentration in air could reach levels considered unsafe for underground miners at some water treatment facilities that aerate water as part of the treatment process. The NRC (2) and EPA (5) recommended monitoring for radon in air around facilities treating groundwater for any contaminant and mitigation, if necessary, to reduce exposure. The EPA (5) modeled risks from potential air emissions of radon off-gas from aeration facilities based on data from 20 CWS whose radon levels ranged from 1000 pCi/L to 16,000 pCi/L. The EPA (5) estimated a maximum lifetime risk of 2×10^{-5} and a crude national estimate of 0.09 cancer fatalities per year if all CWS comply with the MCL. An air dispersion modeling study for the East Valley Water District, San Bernardino, California, suggests that the PTA (Packed Tower Aeration) downwind risk estimates could exceed the local regulatory risk threshold (34). The CDM (34) model predicted that a maximum individual cancer risk at some locations near the PTA could exceed 10^{-5} and 0.2 as the mean cancer burden for the service area. Preliminary design parameters for PTA to mitigate risks from radon emissions were not feasible from design/construct perspectives, for example, stack height up to 200 feet (34).

CONCLUSIONS

The preferred risk management model for radon in domestic water differs from those of other regulated drinking water contaminants because

- Amendments to the SDWA in 1996 require the EPA Administrator to take into account the costs and benefits of control programs for radon from other sources in setting the MCL.
- The major source of radon in indoor air is not regulated. Domestic water, which contributes on average less than 2% of radon in indoor air, would be regulated. Areas that have the highest indoor radon level may not coincide with service areas of CWS that have the highest level of radon in domestic water.
- The majority of health risks is not from direct ingestion of water, but rather from radon released during domestic use. Drinking water standards are usually set based on risks primarily due to ingestion.
- The majority of health risks are due to synergy with voluntary lifestyle choice—smoking. An ongoing public health antismoking campaign may result in significant reductions in the population of ever-smokers, thus reducing overall population unit risks. Though the EPA did not specifically categorize ever-smokers as a "sensitive subpopulation," their inclusion in risk analyses and benefit analyses significantly increased the benefits of adopting the rule.
- CWS may choose to comply with the AMCL rather than the MCL. In some scenarios, health benefits from risk reduction might accrue to communities outside the service area of the CWS. Health benefits might accrue to selected individuals rather than uniform risk reduction to all consumers.

Ayotte et al. (35) estimated that a 0.05% reduction in the prevalence of smoking would prevent as many deaths from lung cancer as mitigation of indoor radon. The NRC (2) noted "except in situations where concentrations of radon in water are very high, the reduction of radon in water will generally not make a substantial reduction in the total radon-related health risks to occupants of dwellings served by the water supply." The NRC (2) expressed similar concerns about the lack of data regarding the "overall effects of radon-resistant construction methods on reducing concentrations of radon in indoor air radon concentrations."

SILICA IN NATURAL WATERS

Robert Y. Ning
King Lee Technologies
San Diego, California

INTRODUCTION

Silica (1–4) and silicates (5–7) are generic names given to the family of silicon dioxide compounds derived from the dehydration–polymerization of silicic acid [$Si(OH)_4$]. Silicic acid, variously called orthosilicic acid, monosilicic acid, or silicic acid monomer, is a weak tetravalent acid that has pK_a values of 9.9, 11.8, and 12. Although silicic acid is prevalent in natural waters and is readily available from acidification of commercial crystalline sodium silicate or metasilicate (8), it has a great propensity to polymerize by dehydration to form Si–O–Si anhydride bonds:

$$\begin{aligned} \mathrm{n\,Si(OH)_4} &\longrightarrow \mathrm{(OH)_3Si{-}O{-}Si(OH)_3\ dimer} \\ &\longrightarrow \mathrm{Oligomers} \longrightarrow \mathrm{Colloidal\ polymers} \\ &\longrightarrow \mathrm{(SiO_2)_n} \end{aligned}$$

Thus silicon dioxide (SiO_2, silica) is the final and most stable product in normal conditions of silico-oxygen acid polymerization. The molecule of silica represented by the formula SiO_2 is polymeric and is more accurately represented by the formula $(SiO_2)_n$, where n is a large number.

The rate of silicic acid polymerization is strongly pH-dependent and is influenced by silicic acid concentration. It is very fast in neutral and slightly alkaline solutions, and extremely slow at low pH values of 2 to 3. Dilute polysilicate solutions that are undersaturated with respect to amorphous silica depolymerize to monosilicic acid.

Silicates imply more complex forms of silica in which silicic acid co-polymerizes with hydroxides of other metal elements covering almost the entire periodic table. This gives rise to the immense variety of rocks found on earth, which are copolymers of silicic acid in ultimate dehydrated forms. In solution, silicic acid readily reacts with alcohols and other hydroxyl-group containing organic compounds to form anhydrides. This provides for a great diversity of products and interactions in the biosphere.

CLASSIFICATION

Silica in natural waters can generally be classified in three categories: reactive soluble, nonreactive soluble (colloidal), and nonreactive insoluble (particulate). Reactivity refers to staining by molybdate reagent in the colorimetric assay of dissolved silica. The rate of this staining reaction is quantitatively reproducible only with low molecular weight polysilicic acids and varies inversely with the degree of polymerization of silicic acid (9). Monosilicic acid reacts with molybdic acid under assay conditions within 2 minutes, and disilicic acid reacts completely in about 10 minutes. Higher polysilicic acids require much longer times for substantial but incomplete reactions. After removal of suspended insoluble silica by filtration using typically a 0.45 micron filter, total dissolved silica (reactive + colloidal) can be measured by atomic emission or absorption spectroscopy. The colloidal silica value is the difference between the total and reactive silica. Normal detection limits of reactive silica in 25 mL samples are 0.1 mg/L. A greater sensitivity of 0.001 mg/L is possible in 100 mL sample sizes (9).

Agglomerated silica and silicates can reach a size, in solution, where they are no longer ions, but are actually colloidal particles that can remain in suspension indefinitely and are very difficult to remove by filtration.

GEOCHEMISTRY

Silica (SiO_2) in nature occurs in the crystalline forms of quartz, cristobalite, and tridymite, and also in the form of amorphous silica and glass. In number of atoms as well as weight, silicon is exceeded only by oxygen in the earth's crust. More than 95% of the volume of the earth's crust is composed of quartz and a small number of other rock-forming silicates.

Second only to carbon, silicon forms the largest number of compounds with other elements. The large number of carbon compounds is due to the fact that the bond energies of the C–C, C–O, and C–H bonds are of about equal magnitude, and they will therefore be formed with about the same probability. In contrast, the bond energy of the Si–O bond is considerably higher than that of the Si–H bond and more than twice that of the Si–Si bond. As a consequence, instead of the common C–C–C chains of carbon chemistry, chains of the type Si–O–Si–O are the skeletons of silicon chemistry (5).

Typical concentrations of dissolved silica in natural waters are:

Lakes	1–3 ppm
Major rivers	3–15 ppm
Seawater	1–10 ppm
Wells	2–60 ppm
Wells in volcanic and oil fields	50–300 ppm

In river and seawater, silica is not found exclusively in the colloidal state, but also in molecular solution, because its saturation concentrations are not attained. Despite the propensity for monosilicic acid to polymerize, it has been shown that silica in seawater is nearly exclusively in the monosilicic acid form in concentrations in the range of <0.006 to 10.1 ppm (11, 12). The concentration is low at the surface and increases with depth. Samples of lake and river water contain only monosilicic acid; there was no evidence of the presence of dimeric silicic acid (13). Silica in ground waters also appears to be in low molecular weight forms rather than the colloidal form (14). The concentration of particulate silica in seawaters of several oceans has been determined as 0.0006 to 0.43 ppm SiO_2 (12). It is thought that it is mainly of biogenic origin. Colloidal silica is depolymerized by seawater, which is considered at least one order of magnitude undersaturated with respect to amorphous silica.

DISSOLUTION OF SILICATE ROCKS

Pure silica such as quartz is completely dehydrated silicic acid. Depolymerization by rehydration as represented below represents dissolution to form soluble silicic acid:

$$SiO_2(s) + 2H_2O \longrightarrow Si(OH)_4$$

The dissolution rate depends on temperature and pH, it is minimum at pH = 2 to 3 and rises rising about 100-fold at pH = 11. Heat-accelerated hydrolysis would be expected in volcanic regions.

Silicic acid is also generated from the weathering of silicate rocks. Silicates are basically dehydrated forms of metal ion salts of silicic acid, which can be decomposed by carbonic acid. The following two reactions represent important dissolution processes of silicates (1):

$$2NaAlSi_3O_8 + 2CO_2 + 6H_2O \longrightarrow Al_2Si_4O_{10}(OH)_2 + 2Na^+ + 2HCO_3{}^- + 2Si(OH)_4$$

$$KMgFe_2AlSi_3O_{10}(OH)_2 + 1/2O_2 + 3CO_2 + 11H_2O \longrightarrow Al(OH)_3 + 2Fe(OH)_3 + K^+ + Mg^{2+} + 3HCO_3{}^- + 3Si(OH)_4$$

Field measurements of the weathering rate on a per square meter catchment area basis from different geographic areas are remarkably similar: 10^{-2} to 10^{-1} moles $m^{-2}yr^{-1}$. It is estimated that 10^5 m^2 surface area of mineral grains active in weathering is available per m^2 of geographic area and that only a few monolayers of rock silicates are dissolved per year (1). The silica concentrations on porewater increase continuously from the earth's surface to a depth of 3 meters. The silica concentration decreases slightly with depth either by precipitation or—under the influence of groundwater—by dilution. The total annual chemical load delivered from the continents to the oceans is estimated at 39.3×10^{14} g of which SiO_2 amounts to 4.26×10^{14} g (15).

DEPOSITION OF SILICA AND SILICATES

Most natural waters are undersaturated in amorphous silica and silicates, but unusual conditions found in geothermal waters (16) and industrial concentration or uses of waters do lead to deposition of silica and silicates. Biochemical extraction and deposition of silica by living organisms (see below) constitute a major deposition pathway.

Up to a pH of approximately 9, the solubility of amorphous silica (SiO_2) is relatively constant. It has been reported by various investigators as 100 to 150 ppm at 25 °C; the dissolved species is $Si(OH)_4$. Amorphous silica is metastable relative to quartz. The rate of crystallization of quartz is so slow at ordinary temperatures that the solubility of amorphous silica represents the upper limit of dissolved aqueous silica.

The precipitation of amorphous silica and silicates apparently proceeds in a series of steps. Polymerization by dehydration accompanied by cross-linking reactions and aggregation by van der Waal forces leads to negatively charged silica colloids. Further aggregation eventually leads to soft then hard gels.

At suitably high pHs, if $Fe(OH)_3$, $Al(OH)_3$, $Ca(OH)_2$, and $Mg(OH)_2$ are present, these hydroxides readily participate in the copolymerization resulting in the incorporation of Fe, Al, Ca, and Mg into complex anhydrous silicate structures. The strong tendency of magnesium hydroxide to react with silica, even in the monomeric state, is shown by the fact that the addition of 300 ppm of $Mg(OH)_2$ to water will reduce the soluble silica content from 42 to 0.1 ppm. The order of precipitability starting with the most readily precipitated metal is copper, zinc, manganese, cadmium, lead, nickel, silver, magnesium, and calcium. Metals that react in acidic solutions with silicates are Fe^{3+}, Co^{2+}, Zn^{2+}, and Cu^{2+} (4). Aluminum seems to occupy a unique position in combining with silica. Aluminosilicate gels (zeolites) can be prepared that have ion-exchange properties. A gel composition of $5SiO_2{:}Al_2O_3{:}Na_2O$ has an exchange capacity of 6% of its weight of CaO, and almost all of the sodium ions are exchangeable. Colloidal silica and silicates are active as flocculants and precipitate with other natural colloidal matter in rivers, lakes and the sea.

GEOCHEMICAL SILICA CYCLE

Geologically, the silica cycle is intimately associated with the carbonate cycle (see Carbonate in Natural Waters). The atmospheric CO_2 concentration of about 0.04% on a timescale of millions of years is controlled mainly by a combination of degassing from the earth's interior balanced by the uptake of carbon dioxide via the weathering of calcium and magnesium silicate minerals (17,18). The carbon dioxide in water as carbonic acid is converted to dissolved calcium and magnesium bicarbonate on land during weathering. This carbon form is stored in lakes and aquifers or is carried to the sea by rivers and precipitated there as calcium and magnesium carbonate minerals. The overall reactions shown here were first formulated by Urey (18) in 1952.

$$CO_2 + CaSiO_3 \Longleftrightarrow CaCO_3 + SiO_2$$
$$CO_2 + MgSiO_3 \Longleftrightarrow MgCO_3 + SiO_2$$

The reactions from left to right represent carbon dioxide absorption via weathering. The reactions from right to left represent degassing due to thermal decarbonation of carbonates after burial at sufficient depths in the earth's crust. Added to the Urey reactions should also be the organic carbon subcycle. It exerts an important additional control on the atmospheric carbon dioxide level. This involves the removal of carbon dioxide from the atmosphere through photosynthesis by organisms, the burial of organic matter in sediments, and the weathering of organic matter (or its thermal decomposition) which returns the carbon dioxide. The overall reaction is represented as:

$$6CO_2 + 6H_2O \Longleftrightarrow (CH_2O)_6 + 6O_2$$

Together, these reactions regulate carbon dioxide and silica on a geologic timescale.

BIOCHEMICAL ASPECTS

The importance of silicon for life on the earth results primarily from the fact that the fertility of soil relies in large part on the ability of clay minerals to absorb and release water and several cations that are indispensable for plant nutrition. This process is fundamental to the life of plants and based on them, to the life of those animals which in turn feed upon plants. Data on the physiology of silicon is limited, except that in a number of species, its presence is needed for normal growth.

Dissolved silica compounds play a substantial role in the cells of living organisms. Large amounts of silica are found in horsetail, rice, feather grass, reed and bamboo, where it contributes to the strength of the leaves and stems, and in the skeletons of diatoms which consist of very pure SiO_2. Silicon compounds are vital components in the metabolism of many bacteria, especially those that live in hot springs. The bacterium *Proteus mirabilis* even substitutes silicon for phosphorous in phospholipids. Silicon is also present as a trace element in higher animals and in humans, where it constitutes about 10 mg per kg live weight. It is essential in the cells of connective tissue and is involved in the biosynthesis of collagen, the substance that forms hair and nails, and in the formation of bony tissue.

The enrichment of silicon in mineralized tissues of unicellular organisms, such as diatoms and radiolaria, and a few metaozoa, such as sponges and gastropods is spectacular (19). The mineral phase is always amorphous silica in various stages of hydration as $SiO_2{\cdot}nH_2O$. Individual diatom populations require a certain level of monosilicic acid, and declining ambient silica concentrations in natural environments may influence the sequence of seasonal successions. The present day ocean contains a few ppm (parts per million) of dissolved silica; diatoms are often cited as the primary agent of silica removal from the world's ocean and keeping a low silicic acid level. Others favor inorganic extraction as the main regulating mechanism because common silicates take up dissolved silica from silica-rich seawater. The data suggest that the world ocean was low in silicon for most of its history.

SODIUM IN NATURAL WATERS

NITISH PRIYADARSHI
Ranchi University
Ranchi, Jharkhand, India

INTRODUCTION

Sodium is a light alkali metal which floats on water in its pure state. However, it is very chemically active and is rarely found in its pure state. All natural waters contain sodium; nearly all sodium compounds readily dissolve in water, and it naturally leaches from rocks and soils.

The sodium ion, the sixth most abundant metallic ion in the earth's crust, is a natural constituent of both food and water from several sources. Most water supplies contain less than 20 mg of sodium per liter, but in some countries, levels can exceed 250 mg/liter. Saline intrusion, mineral deposits, seawater spray, sewage effluents, industrial brines, chemicals used in paper processing, soap, glass, and glass-wool industries, food processing, slaughtering and meat packing industries and salt used in road deicing all contribute significant quantities of sodium to water. In addition, water treatment chemicals, such as sodium fluoride, sodium bicarbonate, and sodium hypochlorite can together result in sodium levels as high as 30 mg/liter. Domestic water softeners can give levels of over 300 mg/liter. A much more important source of sodium in fluvial waters is the input from leaching of halite from sedimentary or evaporite deposits. More than 40% of the sodium in fluvial waters comes from this source. Sodium is also derived from the weathering of silicate minerals, principally sodic plagioclase feldspar. This source accounts for more than 20% of the sodium in river water. It is also an important element in mica, amphibole, and pyroxene.

A Na^+ restricted diet is recommended to patients suffering from hypertension or congenital heart disease; in such cases, the intake of high Na^+ through drinking water may prove critical (1). The current drinking water standard for sodium is 20 milligrams per liter.

SODIUM IN NATURAL WATER

Groundwaters

The Na content of groundwaters is a function of (1) weathering of Na plagioclase from bedrock, followed by (2) exchange of Ca^{2+} for Na^+ on the surfaces of newly formed clay minerals. Feth et al. (2) considered the weathering reactions which supplies Na^+ to groundwater as:

$$\begin{aligned}&3Na_{0.66}Ca_{0.33}Al_{1.33}Si_{2.66}O_8 + 14H_2O + 4CO_2\\&\quad\rightarrow 2H_4Al_2Si_2O_9 + 2Na^+ + Ca^{2+} + 4H_4SiO_4 + 4HCO_3^-\\&\quad\text{(kaolinite)}\end{aligned}$$

and

$$\begin{aligned}&6Na_{0.66}Ca_{0.33}Al_{1.33}Si_{2.66}O_8 + 6CO_2 + 18H_2O\\&\quad\rightarrow 3Na_{0.66}Al_{2.66}Si_{3.33}O_{10}(OH)_2 + 2Ca^{2+} + 2Na^+\\&\qquad + 6H_4SiO_4 + 6HCO_3{}^-\text{(montmorillonite)}\end{aligned}$$

These theoretical calculations apply well to the actual minerals in the rocks and soils of the area studied (western U.S.)

Garrels (3) suggested that the Na^+ content of groundwater would rise due to weathering of plagioclase feldspars. If the system is closed, the waters eventually proceed through kaolinite stability. If calcite is precipitating, this montmorillonite will be sodic and hold the Na^+

content of the water relatively steady. If calcite is not precipitating, Ca^{2+} will be used by the montmorillonite, and the Na^+ content of the groundwater will continue to rise. Low concentrations of Na^+ ions are associated with the minerals, kaolinite and quartz (4).

Sathyanarayanan and Periakali (5), in their study of Na concentration in groundwater in Ultrabasic and Peninsular Gneissic Rocks of Tamil Nadu State of India, suggested that weathering of plagioclase feldspar and biotite in the Peninsular gneiss could be the source of Na in groundwater.

In short, the Na^+ content of groundwater is a function of weatherable minerals, pH, reaction time versus drainage time, the supply of Ca^{2+} to form Ca montmorillonite, sluggish drainage conditions, intensive irrigation practices, extensive use of chemical fertilizers, inadequate sanitary facilities, and precipitation dominance controlling water chemistry (6–9). In addition, groundwater can contain large amounts of Na^+ from the dissolution of evaporites, from saltwater intrusion, and smaller amounts from cyclic sea salts in original precipitation.

Rivers

The concentration of elements in river water varies with time at any single sampling site as a function of discharge, tributary supply, and groundwater discharge. In areas where rivers are draining evaporite deposits, the Na content can be very high. For example, streams in the Brazos River basin (Texas) have as much as 99,800 ppm Na and an average of 35,900 ppm (10).

The unweighted average Na content of 639 rivers and streams is 38.6 ± 5.9 ppm ($s/\sqrt{n}$). The range is 0.1 to 1.540 ppm, and the median is 6.1 ppm Na (11,12). The mean content may be used as a worldwide estimate, but the population is actually polymodal with a mean for humid and temperate weathering zones, a mean for arid climates, and an extremely high mean for rivers draining evaporite deposits (13). Comparison shows that river water and seawater are opposite in character for Na concentration. In seawater, Na>Mg>Ca; in average river water, Ca>Na>Mg (14). Livingstone's (11) weighted mean Na^+ content of world rivers was 6.3 ppm.

Lake Waters

The sodium content of lake water is a function of river and groundwater supply followed by increase due to evaporation where this process exceeds input. The evaporation may reach a stage of Na mineral precipitation, which occurs at a high level of Na^+.

Seawater

The sodium released into solution during weathering is transported by rivers to seas/oceans and represents a primary cyclic reservoir. Early knowledge of the average composition of seawater was provided by Dittmar in 1884; he carefully analyzed 77 water samples, representative of all oceans and taken both from the surface and from the depths. These samples had been collected on the voyage around the world of H.M.S. Challenger (1872–1876). He determined halides, sulfate, magnesium, calcium, and potassium. Sodium was calculated by difference by subtracting the sums of the chemical equivalents of the negative and positive ions. This procedure was followed because Dittmar was unable to achieve satisfactory direct determinations for sodium. He estimated 30.61% sodium in sea water.

In the valuable treatise, The Data of Geochemistry, (1924), F. W. Clarke calculated that the 300,000,000 cubic miles of oceanic waters owed their salinity to 4,800,000 cubic miles of dissolved salts which had been derived from the igneous rocks of the earth's crust. He confined his computations to the sodium (Na) percentages, reckoning an average of 1.14% in seawater and 2.90% of this element in igneous rocks. The average concentration of sodium in seawater is 1.1×10^7 g/L (14). Earlier, Goldberg (15) estimated 10,500 ppm Na^+ in seawater. Calculations of Garrels and Thompson (16) indicated that 99% of the Na in seawater exists as uncomplexed Na^+.

TREATMENT

Sodium may be removed from a water supply by ion exchange. The ion exchange resin in the water softener is enriched with calcium and removes the sodium from the water. Other demineralization techniques, such as reverse osmosis, distillation, electrodialysis and freeze–thaw processes, should be effective for removing sodium from water. If a large supply of water is required, it may be necessary, if feasible, to blend it with another water source low in sodium.

In addition to water treatment, another method of removing sodium from drinking water would require the construction or reconstruction of a water well. This frequently involves installing additional casing beyond the depth normally required by regulations.

SOFT WATER

Gholam A. Kazemi
Shahrood University of
Technology
Shahrood, Iran

INTRODUCTION

At the outset, it should be pointed out that soft and hard waters are two sides of a coin. Hence, the respective articles, this one and the Hard Water article are alike in many aspects. In defining soft water, it is necessary first to describe hardness, a closely related chemical property of water. Hardness is defined by some as a property of water that prevents lather formation with soap and produces scale in hot water systems, (1); by others, as the soap consuming capacity of water (2); and in broader terms by Freeze and Cherry (3), as the "metallic ion content of water which reacts with sodium soaps to produce solid soaps or scummy residue and which reacts with negative ions, when the water is evaporated in boilers, to produce solid boiler scale."

The ions which result in, or produce, hardness include Mg^{+2}, Ca^{+2}, Sr^{+2}, Fe^{+2}, and Mn^{+2}, and to a lesser extent, Ba^{+2} and Zn^{+2} and other divalent ions. The first two of these, are the most influential. There are different forms of hardness (4):

1. Total hardness: Ca and Mg expressed as $CaCO_3$
2. Calcium hardness: Ca expressed as $CaCO_3$
3. Magnesium hardness: Mg expressed as $CaCO_3$
4. Temporary hardness: Equals alkalinity, if alkalinity is less than total hardness
5. Permanent hardness: The amount of hardness greater than temporary hardness
6. Noncarbonate hardness: Permanent hardness

Of the six different forms of hardness, the most important and the one that is commonly known as hardness, is total hardness. It is calculated by the following simplified equation:

$$\text{Hardness} = 2.5\ \text{Ca} + 4.1\ \text{Mg (units in mg/l)}$$

Note that there are equations to calculate each of the six different forms of hardness.
Example: The Ca and Mg concentrations in a water sample are 20 and 15 mg/l, respectively. What is its hardness?

$$\text{Hardness} = 2.5 \times 20 + 4.1 \times 15 = 111.5\ \text{mg/l}$$

As stated, each of the six forms of hardness can be calculated by analyzing a water sample for the relevant ion(s), followed by using the relevant equation. However, there are techniques to measure total hardness directly such as (1) a standard solution of soap, that was in use for many years (2); and (2) Schwarzenbach et al's. method of colorimetric titration (5), which is sometime referred to as the EDTA method.

The author believes that earlier, measuring hardness was a common and an inseparable practice in water analysis. To agree with this statement, one needs to look at a relatively old handbook and read, "*The common denominator of the majority of water problems is hardness*" (2, p. 4.1, first published in 1979). Somehow, in contrast, recent hydrochemical analysis of water samples does not usually include a measurement of hardness. For instance, there is not a single report of hardness in the hundreds of hydrochemistry papers presented at the International Association of Hydrogeolgists (IAH) conferences in Prague (2003) and in Munich (2001) and in the recent past (1997–2001) annual symposia of the Geological Society of Iran. This occurred, perhaps, because other aspects of water chemistry and water biology, such as nutrients, heavy metals, bacteriological species, chlorinated hydrocarbons, and many contaminants have become so widespread that they are considered more important and more hazardous than hardness. This is to say that rejecting water for drinking or other uses, these days, is many times more likely to be due to its harmful DDT level than because of its high hardness value. One other possible reason is that hardness and soft water topics are important only in some narrow fields of water, e.g., hot water boilers.

The second point is that industrialization, urbanization, agricultural practices, and most environmentally unfriendly activities are not likely to result in an increase in the hardness of water resources because these activities do not usually generate hardness-producing ions such as Ca^{2+} or Mg^{2+}, though, they may produce other trivial (in terms of hardness) ions such as Mn^{2+} and Fe^{2+}.

The author, here, wishes to draw the reader's attention to one other point and pose a question as well. He believes that "softness" would have had an identical application and a similar meaning to hardness if it would have been there. Therefore, it is interesting to speculate as to what was the rationale for use of the term "hardness", not softness. One reason might be that hard water is generally easier to notice because of its unwanted and disappointing characteristics and our predecessors looked for something to describe it. In other words, the term hardness was created to explain easily noticeable hard water, not to describe soft water. This is why there is no such practice as water hardening, changing soft water to hard water, in contrast to the well-established exercise of water softening which changes hard waters to soft waters.

DEFINITION AND SPECIFICATIONS OF SOFT WATER

Todd (6, p. 282) reports that Hippocrates (460–354 B.C.) was the first to use the terms hard and soft for water, when in his treatises on public hygiene, he wrote, "consider the waters which the inhabitants use, whether they be marshy and soft, or hard and running from elevated and rocky situations, and then if saltish and unfit for cooking... for water contributes much to health." However, it is probably safe to say that hard and soft water in Hippocrates' writings, are likely to mean different things from what we today call hard and soft water.

The most frequently used classification system for water based on hardness is that of Sawyer and McCarty (7), presented in Table 1. There is another slightly different classification system by Hem (8), which is referred to in some publications as the classification of the U.S. Geological Survey (9).

The definition of soft water varies slightly among researchers. Based on Table 1, soft water is defined as water whose hardness is less than 60 or 75 mg $CaCO_3$/l. This means that waters with less than 15 mg Ca^{2+}/l and 10 mg Mg^{2+}/l are soft; higher concentrations in waters belong to the other categories such as hard water or very hard water. However, some researchers argue that there is no exact definition for determining soft or hard water because it depends, at least partially, on what one is accustomed to (9). What is soft water for one person, may be moderately hard for another and vice versa. The very hard water category in Table 1 can be grouped into the hard water category as it has the specifications of hard water. It is, however, unclear to which category one can assign moderately hard water, if hard water and soft water are the only categories available.

Table 1. Different Types of Water Based on Hardness

Water Type	Hardness mg $CaCO_3$/l	
Soft	below 75[a]	Below 60[b]
Moderately hard	75–150[a]	60–120[b]
Hard	150–300[a]	120–180[b]
Very hard	Over 300[a]	Over 180[b]

[a] Reference 7.

[b] Reference 8.

Manning (9), discredits soft water and states that very soft water when used for bathing feels slick on the body, as though the soap is still there. He also explains that most people prefer slightly hard water because of its taste and its ability to wash the soap off the body. Soft waters are not very good for irrigation either because they may lead to a lower infiltration rate compared with slightly hard water (9). In contrast to hard water, soft water produces a foam or lather easily but does not produce scale in hot water pipes, heaters, boilers, and other high water temperature units. Therefore, using soft water is an economically worthwhile practice because it leads to a decrease in soap consumption and lowers fuel costs for boilers due to good heat conduction.

The recommended water for domestic use should have a hardness of 80 mg/l; i.e., it should be soft (10). This is why water softening is a common practice where the water supply has a hardness greater than 80–100 mg/l (3). Soft water is also required for some industrial processes such as food equipment washing, confectionery, food canning and freezing, food processing, and laundering (6).

SOFT WATER AND HEALTH

There is a general perception among the public that soft water is healthier to drink. Studies, though not satisfactorily conclusive, suggest the opposite, especially with regard to artificially softened water. For instance, Tebbutt (1995) (1) reports that there is some statistical evidence to suggest that artificially softened waters may increase the incidence of some forms of heart disease. Also, a recent study in Taiwan (11) shows that there is a significant negative relationship between drinking water hardness and colon cancer mortality, a finding considered important for the Taiwanese water industry and human health. All these confirm Muss's (12) observation that in the United States, death rates from heart and circulatory diseases are lower in states where public water supplies are harder. Furthermore, artificially softened water may taste salty because its sodium content increases in the softening process.

AVAILABILITY OF NATURALLY SOFT WATER

Soft water may exist naturally or may be produced artificially, as stated before. Atmospheric precipitations (snow and rain) are soft waters. Similar to these are waters that emanate from upland catchments with an average total hardness of 10 mg/l (1). In contrast, most groundwaters, excluding those that occur in fractured igneous rocks, are hard. All ground water and surface water that pass through, or are in contact with, carbonate and other Ca–Mg bearing rocks are hard. Lowland rivers with a hardness of 200 mg/l (1) are also hard. Therefore, only a limited percentage of freshwater resources of the world, groundwaters and river waters, is soft.

Examples of naturally occurring soft waters include the Vilnius well fields groundwater (intermorainic and alluvial deposit aquifer), Vilnius District, Lithuania, that have unbelievably low hardness values of 3.9–8.5 mg/l (13), groundwater in Akwa Ibom State of Nigeria (fluvio-volcanic rocks) with a hardness of 1.2–65 mg/l (Akujieze, 2003) (14), and shallow basement groundwater of Lithembwe dambo, Malawi, with 1–14 mg/l of calcium and 1–7 mg/l of magnesium (15).

SOLUBILITY OF CHEMICALS IN WATER

CARL L. YAWS
PRASAD K. NARASIMHAN
HELEN H. LOU
Lamar University
Beaumont, Texas

RALPH W. PIKE
Louisiana State University
Baton Rouge, Louisiana

Correlations are presented for the solubility of chemicals in water. A wide variety of compounds are covered—alcohols, ketones, ethers, aldehydes, acids, acetates, amines, monochloroalkanes, and monobromoalkanes. The new correlation provides reliable solubility values down to very low concentrations (parts per million range). The correlation is based on the boiling point of the compound. The correlation and experimental data are in favorable agreement. The results are useful in process engineering for wastewater minimization.

IMPORTANCE OF WATER SOLUBILITY

The solubility of compounds in water is very important. This importance will increase in the future because of heath, safety, and environmental considerations. The following brief discussion illustrates the importance even at very low concentrations.

For health involving human exposure to substances in air, the threshold limit value (TLV) for *sec*-butanol in air is given as 100 ppm (parts per million, vol) by the Occupational Safety and Health Act (1). A concentration of only 0.0005 mol fraction of *sec*-butanol in water provides about 236 ppm of *sec*-butanol in air at the air–water interface. This concentration of 236 ppm in air exceeds the threshold limit value of 100 ppm.

For safety, the lower explosion limit (LEL) for *sec*-butanol in air is given as 1.7% by Yaws (2). A concentration of only 0.04 mol fraction of *sec*-butanol in water provides about 1.9% of *sec*-butanol in air at the air–water interface. This concentration of 1.9% in air exceeds the lower explosion limit of 1.7%.

For environmental, consider a spill of *sec*-butanol in contact with water. The water will become saturated with *sec*-butanol. At saturation, the solubility of *sec*-butanol in water is about 0.181 weight fraction or 0.0508 mol fraction (3). This concentration of only 0.0508 mol fraction at saturation will provide about 24,000 ppm or 2.5% of *sec*-butanol in air at the air–water interface. This concentration of 24,000 ppm or 2.4% greatly exceeds both the threshold limit value of 100 ppm and the lower explosion limit of 1.7%.

This brief discussion (using *sec*-butanol as an example) indicates that very low concentrations of a chemical in water can provide concentrations in air at the air–water interface that exceed the threshold limit value for human exposure and the lower explosion limit for flammability.

CORRELATION FOR WATER SOLUBILITY

In earlier work by Yaws and co-workers (2), the water solubility of hydrocarbons was correlated as a function of the boiling point of the compound. In this article, it was determined that the boiling point method is also applicable to the correlation of the water solubility of chemicals:

$$\log_{10}(S) = A + B\,T_B + C\,T_B^2 + D\,T_B^3 \qquad (1)$$

where S = solubility in water at 25 °C, ppm by weight,
T_B = boiling point of compound, K
A, B, C, and D = regression coefficients

Table 1. Solubility in Water^a

	$\log_{10} S = A + B\,T_B + C\,T_B^2 + D T_B^3$				(S, ppm(wt), T_B, K)			
Chemical Family	A	B	C	D	T_{BMIN}	T_{BMAX}	Formula	Example Compound
Alcohols	45.6398	−2.3859E−01	4.8739E−04	−3.7160E−07	370	620	$C_nH_{2n+2}O$	*n*-Pentanol
Ketones	45.2000	−2.3859E−01	4.8739E−04	−3.7160E−07	350	590	$C_nH_{2n}O$	Diethyl ketone
Ethers	11.4000	−2.2000E−02	0.0000E+00	0.0000E+00	300	560	$C_nH_{2n+2}O$	Dipropyl ether
Aldehydes	12.4200	−2.2000E−02	0.0000E+00	0.0000E+00	320	560	$C_nH_{2n}O$	1-Hexanal
Acids	14.3000	−2.2000E−02	0.0000E+00	0.0000E+00	440	560	$C_nH_{2n}O_2$	*n*-Hexanoic acid
Acetates	13.0000	−2.3382E−02	0.0000E+00	0.0000E+00	330	600	$C_nH_{2n}O_2$	Ethyl acetate
Primary amines	11.4300	−1.8000E−02	0.0000E+00	0.0000E+00	400	560	$C_nH_{2n+3}N$	*n*-Hexyl amine
Secondary amines	11.3600	−1.8000E−02	0.0000E+00	0.0000E+00	360	560	$C_nH_{2n+3}N$	Dipropyl amine
Tertiary amines	11.8200	−2.0000E−02	0.0000E+00	0.0000E+00	360	560	$C_nH_{2n+3}N$	Triethyl amine
Monochloroalkanes	−7.4500	1.0050E−01	−2.7288E−04	1.9987E−07	300	590	$C_nH_{2n+1}Cl$	2-Chlorobutane
Monobromoalkanes	−7.1700	1.0050E−01	−2.7288E−04	1.9987E−07	300	590	$C_nH_{2n+1}Br$	1-Bromobutane

^{a}S-solubility in water at 25 C, parts per million by weight, ppm(wt).
A, B, C, and D-regression coefficients.
T_B-boiling point temperature of compound, K.
T_{BMAX}-maximum temperature, K.
T_{BMIN}-minimum temperature, K.

The range of boiling point depends on the chemical family.

The coefficients (A, B, C, and D) are given in Table 1 for a wide variety of chemicals—alcohols, ketones, ethers, aldehydes, acids, acetates, amines, monochloroalkanes, and monobromoalkanes. The table also provides the boiling point range (T_{BMIN}, T_{BMAX}) for each chemical family. The correlation is applicable to compounds whose boiling points are in this range. The correlation should not be used for compounds whose boiling points are outside the boiling point range.

The coefficients were determined from regression of available data. In preparing the correlation, a literature search was conducted to identify data source publications (2–13). The excellent compilations by Horvath (5–6); Howard and Meylan (7); Mackay, Shiu, and Ma (9); Verschueren (11); Yalkowsky (3); and Yaws (2) were used extensively. The publications were screened and copies of appropriate data were made. These data were then keyed in to the computer to provide a database for which experimental data are available. The database also served as a basis to check the accuracy of the correlation.

Graphs of water solubility versus boiling point are shown in Figs. 1–11 for the chemical families. The graphs indicate favorable agreement of correlation values and experimental data.

For ketones, the graphs disclose that more data are available for alcohols. The graphs, also disclose that the data for ketones appear to be below and approximately parallel to the more extensive data for alcohols. This suggests that the solubility of ketones is lower and approximately parallel to the water solubility of alcohols.

For the other oxygenated compounds (ethers, aldehydes, acids, and acetates), the graphs disclose that the data for oxygenated compounds appear to be above and approximately parallel to the data for benzenes. This suggests that the solubility of oxygenated compounds is higher and approximately parallel to the water solubility of benzenes.

For the nitrogen compounds (primary amines, secondary amines, and tertiary amines), the graphs disclose

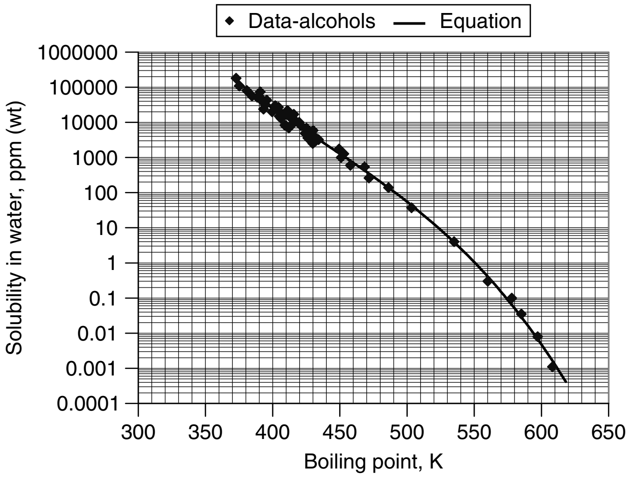

Figure 1. Solubility of alcohols in water.

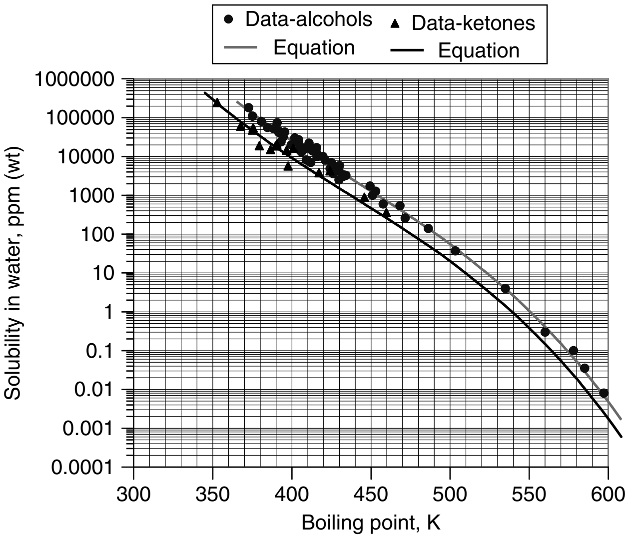

Figure 2. Solubility of ketones in water.

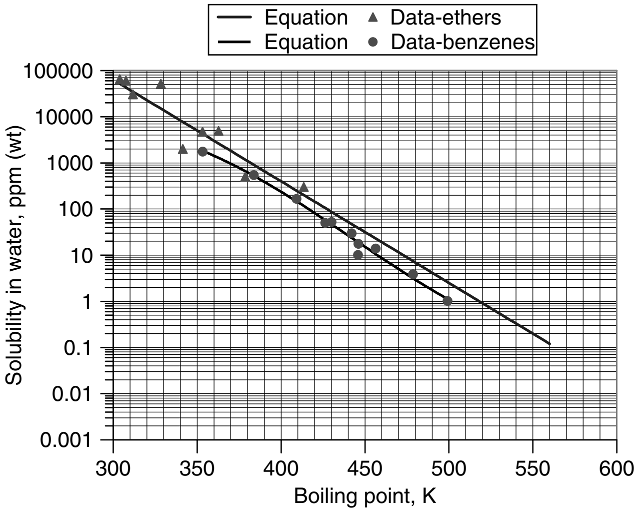

Figure 3. Solubility of ethers in water.

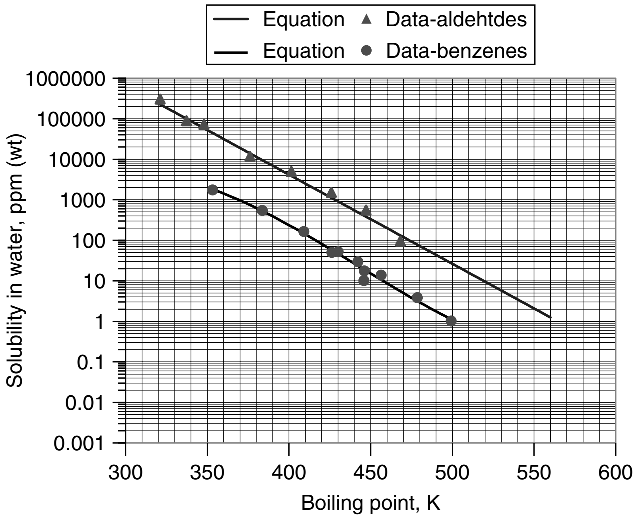

Figure 4. Solubility of aldehydes in water.

that the data for amines appear to be above and approximately parallel to the data for benzenes. This suggests that the solubility of amines is higher and approximately parallel to the water solubility of benzenes.

For monochloro and monobromoalkanes, the graphs disclose that the data appear to be lower and approximately parallel to the data for benzenes. This suggests that the solubility of monochloro- and monobromoalkanes is lower and approximately parallel to the water solubility of benzenes.

EXAMPLES

The correlations for water solubility are useful in engineering applications involving process wastewater. Examples are shown below.

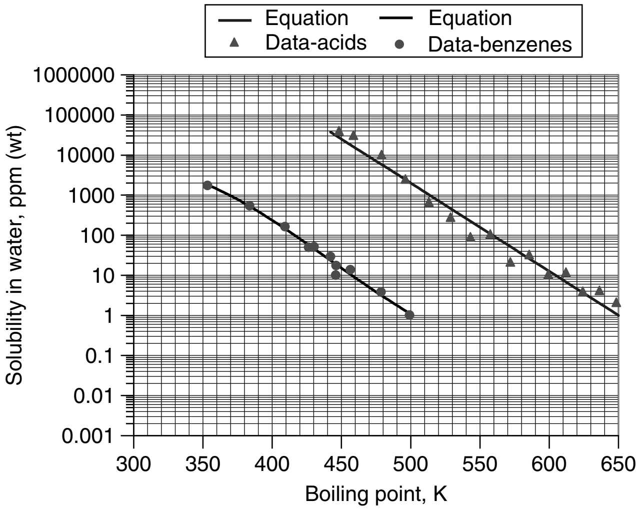

Figure 5. Solubility of acids in water.

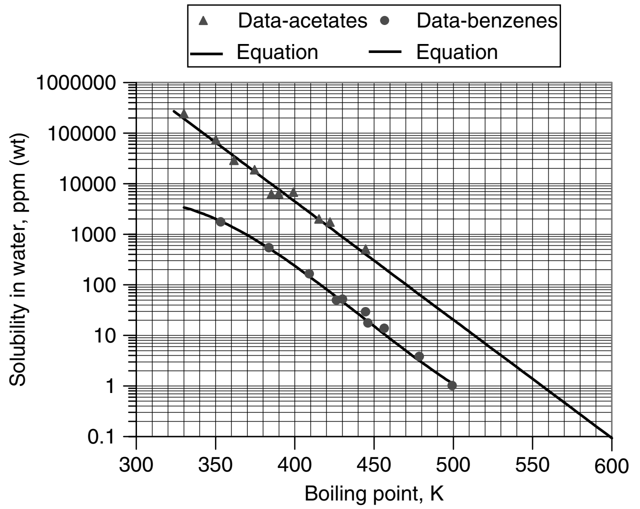

Figure 6. Solubility of acetates in water.

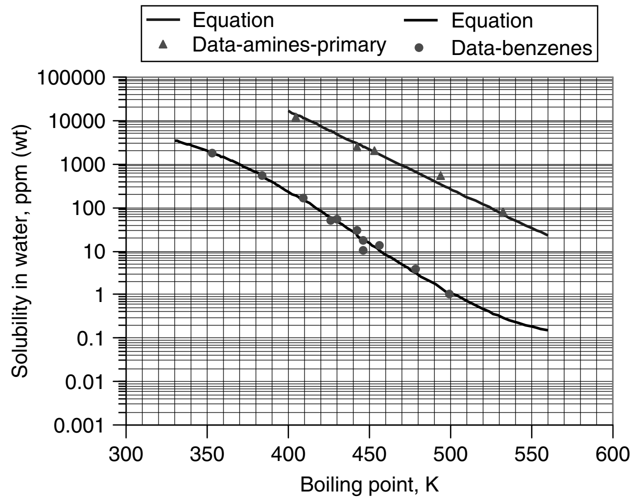

Figure 7. Solubility of primary amines in water.

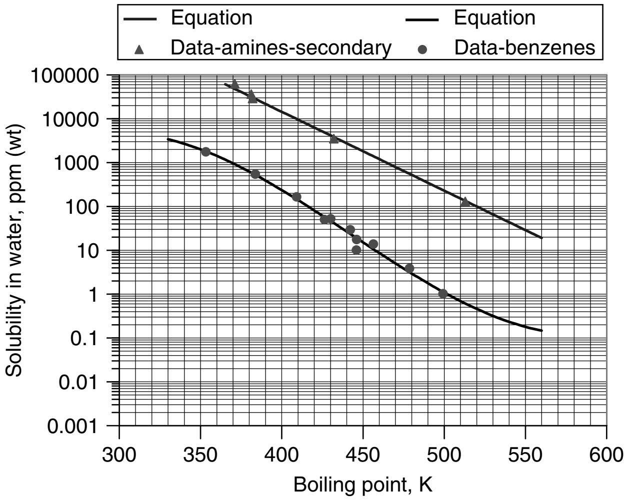

Figure 8. Solubility of secondary amines in water.

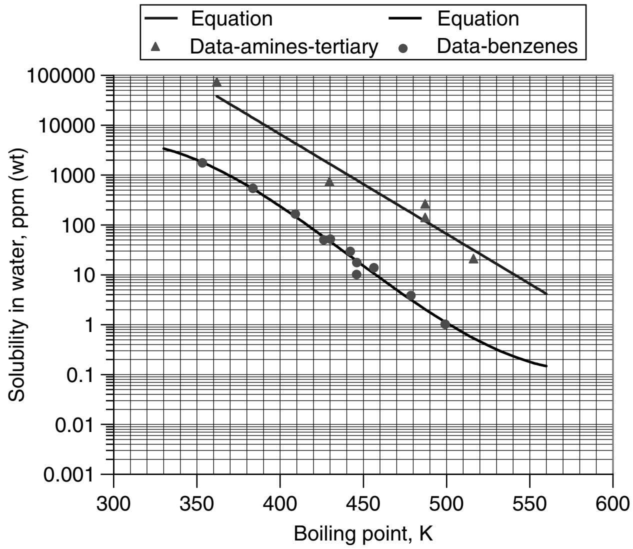

Figure 9. Solubility of tertiary amines in water.

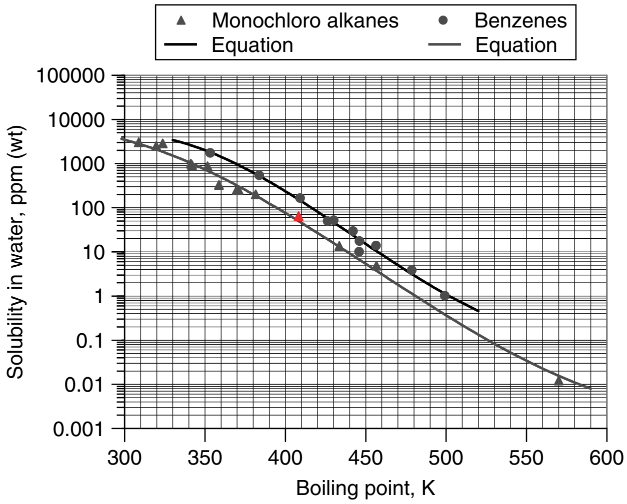

Figure 10. Solubility of monochloroalkanes in water.

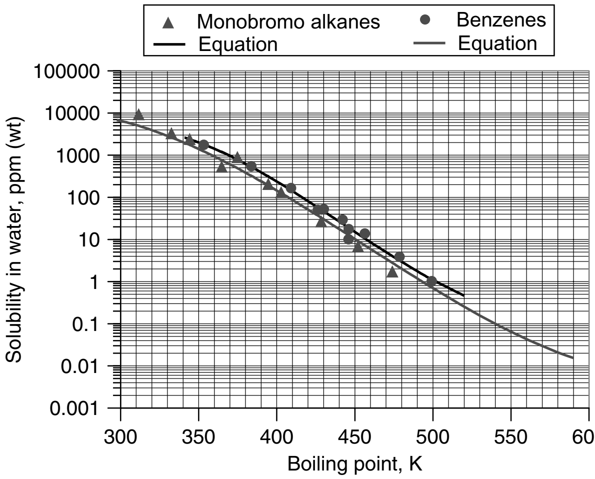

Figure 11. Solubility of monobromoalkanes in water.

Example. A chemical spill of dodecanol occurs into a body of water at ambient conditions. Estimate the concentration in the water at saturation.

The correlation for alcohols maybe used to determine the solubility in water. Substitution of the coefficients and boiling point of dodecanol in the correlation equation yields

$$
\begin{aligned}
\log_{10}(S) &= A + B\,T_B + C\,{T_B}^2 + D\,{T_B}^3 \\
&= 45.6398 - 2.3859\text{E}{-01}(535.00) \\
&\quad + 4.8739\text{E}{-04}(535.00)^2 - 3.7160\text{E}{-07}(535.00)^3 \\
\text{S} &= 3.93 \text{ ppm (wt)}.
\end{aligned}
$$

The calculated value and data compare favorably (3.93 vs. 4.00; deviation = 0.07/5 = 1.8%).

Example. A chemical spill of diethyl ketone occurs into a body of water at ambient conditions. Estimate the concentration in the water at saturation.

The correlation for ketones maybe used to determine the solubility in water. Substitution of the coefficients and boiling point of diethyl ketone in the correlation equation yields

$$
\begin{aligned}
\log_{10}(S) &= A + B\,T_B + C\,{T_B}^2 + D\,{T_B}^3 \\
&= 45.2000 - 2.3859\text{E}{-01}\ (375.14) \\
&\quad + 4.8739\text{E}{-04}(375.14)^2 - 3.7160\text{E}{-07}\ (375.14)^3 \\
\text{S} &= 45,257 \text{ ppm (wt)}.
\end{aligned}
$$

The calculated value and data compare favorably (45,257 vs. 48,235; deviation = 1,758/48,235 = 3.6%).

SOLUBILITY OF HYDROCARBONS IN SALT WATER

Carl L. Yaws
Prasad K. Narasimhan
Lamar University
Beaumont, Texas

INTRODUCTION

Physical and thermodynamic property data are required to design and operate industrial processes. In particular, the water solubility of hydrocarbons in the sea and ocean is becoming increasingly important because of more and more stringent regulations regarding the environment.

In this article, results are presented for the solubility of hydrocarbons in salt water. The results are applicable to the complete range of salt concentrations, including water without salt to water saturated with salt. The results are intended for use in engineering applications. As an example of such usage, solubility values from the correlation are useful in determining the distribution of a hydrocarbon spill upon contact with seawater. Solubility values at other salt concentrations may also be ascertained.

CORRELATION OF SALT WATER SOLUBILITY

The correlation of the solubility of hydrocarbons in salt water containing salt is based on a series expansion in salt concentration:

$$\log_{10} S = A + B\,X + C\,X^2 \tag{1}$$

where S = solubility in salt water at 25 °C, parts per million by weight, ppm(wt)
X = concentration of salt (NaCl) in water, parts per million by weight, ppm(wt)
$A, B,$ and C = regression coefficients

The coefficients (A, B, and C) are given in Table 1. The values in the table were determined from regression of the data sources (1–10) for water solubility. The compilations by Price (7) and Sutton and Calder (8) were especially helpful. The values presented are applicable to a wide variety of hydrocarbons (alkanes, cyclopentanes, cyclohexanes, benzenes (no and single substitution), and benzenes (double and triple substitution). The range of application for the correlations is about C_5 to C_{16} compounds.

Graphs of water solubility are shown in Figs. 1–3 for representative hydrocarbons (pentane, methylcyclopentane, and benzene). In the figures, solubility values are plotted at salt concentrations ranging from water without salt to water saturated with salt. The graphs discloses favorable agreement of correlation values and experimental data.

Examples

The correlations for solubility are useful in engineering applications involving hydrocarbons in contact with water containing salt. Examples are shown below.

Example 1. A chemical spill of n-pentane occurs in a body of saltwater [salt = 10,000 ppm(wt)] at ambient conditions. Estimate the concentration in the saltwater.

The values in Table 1 are used for the coefficients. Introducing the boiling point of n-pentane to calculate A and using the tabulated values for B and C provides

$$\begin{aligned} A &= -17.7916 + 1.7865\text{E}{-01}\, T_B - 5.0255\text{E}{-04}\\ &\quad {T_B}^2 + 4.1218\text{E}{-07}\, {T_B}^3\\ &= -17.7916 + 1.7865\text{E}{-01}(309.22)\\ &\quad - 5.0255\text{E}{-04}(309.22)^2 + 4.1218\text{E}{-07}(309.22)^3\\ &= 1.5850\\ B &= -4.5956\text{E}{-06}\\ C &= 2.2978\text{E}{-12} \end{aligned}$$

Substitution of these coefficients and the salt concentration in the correlation equation for solubility in saltwater yields

$$\begin{aligned} \log_{10} S &= A + B\,X + C\,X^2\\ &= 1.5850 - 4.5956\text{E}{-06}(10{,}000)\\ &\quad + 2.2978\text{E}{-12}(10{,}000)^2\\ &= 1.5393\\ S &= 34.62 \text{ ppm (wt)} \end{aligned}$$

Table 1. Solubility in Salt Water[a]

	$\log_{10} S = A + BX + CX^2$	S-solubility, ppm (wt), X(salt) – ppm(wt)	
Chemical Family	A, B, and C	Formula	Example Compound
Alkanes	$A = -17.7916 + 1.7865\text{E}{-01} T_B - 5.0255\text{E}{-04}\ T_B{}^2 + 4.1218\text{E}{-07}\ T_B{}^3$ $B = -4.5956\text{E}{-06}$ $C = 2.2978\text{E}{-12}$	C_nH_{2n+2}	n-pentane
Cyclopentanes	$A = 9.55 - 2.2987\text{E}{-02} T_B$ $B = -4.5987\text{E}{-06}$ $C = 2.2993\text{E}{-12}$	C_nH_{2n}	Methyl cyclopentane
Cyclohexanes	$A = 9.75 - 2.2987\text{E}{-02} T_B$ $B = -4.5987\text{E}{-06}$ $C = 2.2993\text{E}{-12}$	C_nH_{2n}	Cyclohexane
Benzenes (no and single substitution)	$A = 5.725 + 3.6778\text{E}{-03}\ T_B - 3.0346\text{E}{-05}\ T_B{}^2$ $B = -3.2714\text{E}{-06}$ $C = 1.6357\text{E}{-16}$	$C_{n+6}H_{2n+6}$	Benzene
Benzenes (double and triple substitution)	$A = 5.375 + 3.6778\text{E}{-03}\ T_B - 3.0346\text{E}{-05}\ T_B{}^2$ $B = -3.2714\text{E}{-06}$ $C = 1.6357\text{E}{-16}$	$C_{n+6}H_{2n+6}$	Benzene

[a] S-solubility in salt water at 25 C, parts per million by weight, ppm(wt).
X-salt (NaCl) concentration in water, ppm(wt).
Salt concentration range is $X = 0$ to 358,700 (saturated).
Salt in seawater is 34,472 ppm(wt).
A, B, and C—regression coefficients.
T_B—boiling point of compound, K.
T_{BMAX}—maximum temperature, $K = 560$.
T_{BMIN}—minimum temperature, $K = 300$.
Correlation should not be used for compounds having boiling points outside T_BMAX and T_BMIN.
Range of application for correlation is about C_5 to C_{16}.

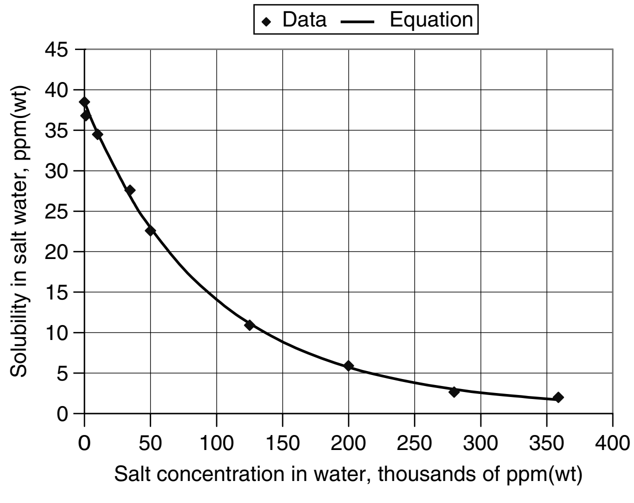

Figure 1. Solubility of n-pentane in salt water.

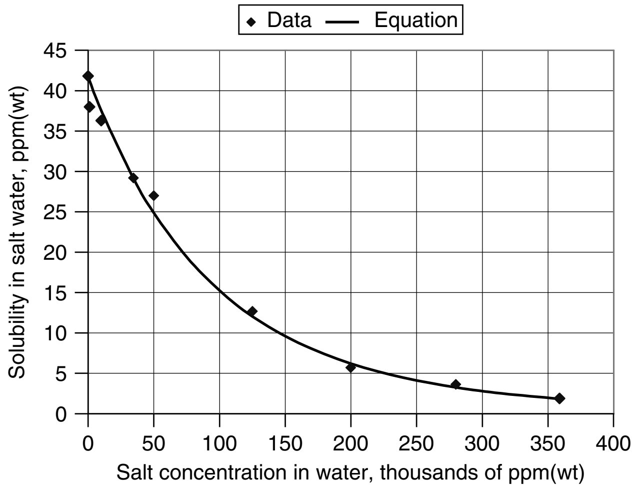

Figure 2. Solubility of methyl cyclopentane in salt water.

The calculated value and data compare favorably (34.62 vs. 34.50; deviation = 0.12/34.50 = 0.3%).

Example 2. A chemical spill of benzene occurs in seawater [salt = 34,472 ppm(wt)] at ambient conditions. Estimate the concentration in the seawater.

The values in Table 1 are used for the coefficients. Introducing the boiling point of benzene to calculate A and using the tabulated values for B and C provides

$$\begin{aligned} A &= 5.725 + 3.6778\text{E}{-03}\ T_B - 3.0346\text{E}{-05}\ T_B{}^2 \\ &= 5.725 + 3.6778\text{E}{-03}\ (353.31) \\ &\quad - 3.0346\text{E}{-05}\ (353.31)^2 \\ &= 3.2364 \end{aligned}$$

$$B = -3.2714\text{E}{-06}$$

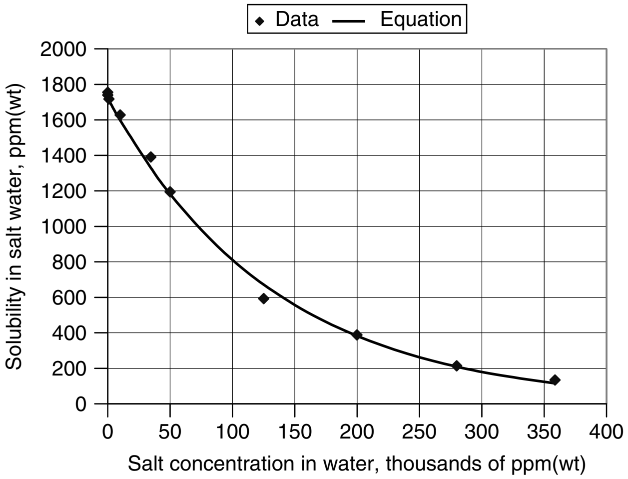

Figure 3. Solubility of benzene in salt water.

$C = 1.6357\text{E}{-16}$.

Substitution of these coefficients and the salt concentration in the correlation equation for solubility in saltwater yields

$$\begin{aligned}\log_{10} S &= A + B\,X + C\,X^2\\ &= 3.2364 - 3.2714\text{E}{-06}(34{,}472)\\ &\quad + 1.6357\text{E}{-16}(34{,}472)^2\\ &= 3.1236\\ S &= 1329.24 \text{ ppm (wt)}\end{aligned}$$

The calculated value and data compare favorably (1329.24 vs. 1391.00; deviation = 61.76/1391.00 = 4.4%).

SOLUBILITY OF HYDROCARBONS AND SULFUR COMPOUNDS IN WATER

Carl L. Yaws
Prasad K. Narasimhan
Helen H. Lou
Lamar University
Beaumont, Texas

Ralph W. Pike
Louisiana State University
Baton Rouge, Louisiana

Correlations are presented for the solubility of hydrocarbons and organic sulfur compounds in water. A wide variety of compounds are covered—alkanes, olefins, diolefins, acetylenes, cyclopentanes, cyclohexanes, benzenes, mercaptans, thiophenes, and sulfides. The new correlation provides reliable solubility values down to very low concentrations (parts per million range). The correlation is based on the boiling point of the compound. Correlation and experimental data are in favorable agreement. The results are useful in process engineering for wastewater minimization.

IMPORTANCE OF WATER SOLUBILITY

The solubility of compounds in water is very important. This importance will increase in the future because of heath, safety, and environmental considerations. The following brief discussion illustrates the importance even at very low concentrations.

For health involving human exposure to substances in air, the threshold limit value (TLV) for *n*-pentane in air is given as 600 ppm (parts per million, vol) by the Occupational Safety and Health Act (1). A concentration of only 0.0000001 mol fraction of *n*-pentane in water provides about 7000 ppm of *n*-pentane in air at the air–water interface. This concentration of 7000 ppm in air exceeds the threshold limit value of 600 ppm.

For safety, the lower explosion limit (LEL) for *n*-pentane in air is given as 1.4% by Yaws (2). A concentration of only 0.000001 mol fraction of *n*-pentane in water provides about 7% of *n*-pentane in air at the air–water interface. This concentration of 7% in air exceeds the lower explosion limit of 1.7%.

For environmental, consider a spill of *n*-pentane in contact with water. The water will become saturated. At saturation, the solubility of *n*-pentane in water is about 0.0000385 weight fraction or 0.00000916 mol fraction, as given by Yalkowsky (3). This concentration of only

0.00000916 mol fraction at saturation will provide about 644,000 ppm or 64.4% of n-pentane in air at the air–water interface. This concentration of 644,000 ppm or 64.46% greatly exceeds both the threshold limit value of 600 ppm and the lower explosion limit of 1.4%.

This brief discussion (using n-pentane as an example) indicates that very low concentrations (ppm or less) of compounds in water can provide concentrations in air at the air–water interface that exceed the threshold limit value for human exposure and the lower explosion limit for flammability.

CORRELATION FOR WATER SOLUBILITY

In earlier work by Yaws and coworkers (2), the water solubility of various chemical types was correlated as a function of the boiling point of the compound. In this article it was determined that the boiling point method is also applicable to correlation of the water solubility of hydrocarbons and organic sulfur compounds:

$$\log_{10}(S) = A + BT_B + CT_B^2 + DT_B^3 \qquad (1)$$

where S = solubility in water at 25 °C, ppm by weight,

T_B = boiling point of compound, K

$A, B, C,$ and D = regression coefficients

The range for boiling point is 298 K to about 560 K.

The coefficients (A, B, C, and D) are given in Table 1 for a wide variety of hydrocarbons and sulfur compounds—alkanes, olefins, diolefins, acetylenes, cyclopentanes, cyclohexanes, benzenes, mercaptans, thiophenes, and sulfides. The table also provides the boiling point range (T_{BMIN}, T_{BMAX}) for which the correlation is applicable. The correlation should not be used for compounds whose boiling points are outside the boiling point range.

The coefficients were determined from regression of available data. In preparing the correlation, a literature search was conducted to identify data source publications (2–10). The excellent compilations by Howard and Meylan (5); Mackay, Shiu, and Ma (6); Verschueren (8); Yalkowsky (3); and Yaws (2) were used extensively. The publications were screened and copies of appropriate data were made. These data were then keyed in to the computer to provide a database for which experimental data are available. The database also served as a basis to check the accuracy of the correlation.

Graphs of water solubility versus boiling point are shown in Figs. 1–8 for the compound families. The graphs indicate favorable agreement of correlation values and experimental data.

For olefins and diolefins, the graphs disclose that more data are available for alkanes. The graphs also disclose that the data for olefins and diolefins appear to be above and approximately parallel to the more extensive data for alkanes. This suggests that the solubility of olefins and diolefins is higher and approximately parallel to the water solubility of alkanes.

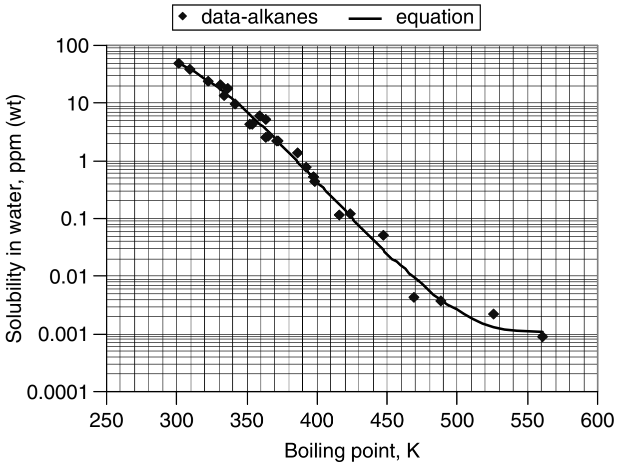

Figure 1. Solubility of alkanes in water.

Table 1. Solubility in Water[a]

$\log_{10} S = A + BT_B + CT_B^2 + DT_B^3$ (S - ppm(wt), $T_B - K$)

Chemical family	A	B	C	D	T_{BMIN}	T_{BMAX}	Formula	Example Compound
Alkanes	−17.6520	1.77811E−01	−5.00907E−04	4.11124E−07	298	560	C_nH_{2n+2}	n-Hexane
Olefins	−17.0300	1.77811E−01	−5.00907E−04	4.11124E−07	298	560	C_nH_{2n}	1-Hexene
Diolefins	−16.5610	1.77811E−01	−5.00907E−04	4.11124E−07	298	560	C_nH_{2n-2}	1,5-Hexadiene
Acetylenes	−15.8350	1.77811E−01	−5.00907E−04	4.11124E−07	298	560	$C_{n+2}H_{2n+2}$	1-Hexyne
Cyclohexanes	−16.7000	1.77811E−01	−5.00907E−04	4.11124E−07	298	560	C_nH_{2n}	Methyl cyclohexane
Cyclopentanes	−16.9000	1.77811E−01	−5.00907E−04	4.11124E−07	298	560	C_nH_{2n}	Methyl cyclopentane
Benzenes (single substitution)	−24.0080	2.21196E−01	−5.55632E−04	4.18830E−07	298	560	$C_{n+6}H_{2n+6}$	Toluene
Benzenes (multiple substitution)	−23.6500	2.21196E−01	−5.55632E−04	4.18830E−07	298	560	$C_{n+6}H_{2n+6}$	p-Xylene
Mercaptans	−6.9000	1.00500E−01	−2.72880E−04	1.99870E−07	298	560	$C_nH_{2n+2}S$	Propyl mercaptan
Thiophenes	−6.8500	1.00500E−01	−2.72880E−04	1.99870E−07	298	560	$C_nH_{2n-4}S$	2-Methyl thiophene
Sulfides	−6.5390	1.00500E−01	−2.72880E−04	1.99870E−07	298	560	$C_nH_{2n+2}S$	Ethyl methyl sulfide

[a] S = solubility in water at 25 C, parts per million by weight, ppm(wt).

$A, B, C,$ and D = regression coefficients.

T_B = boiling point of compound, K.

T_{BMAX}-maximum temperature, K.

T_{BMIN}-minimum temperature, K.

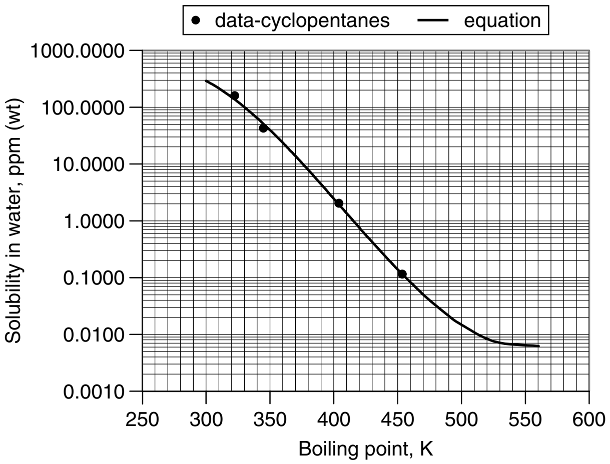

Figure 2. Solubility of cyclopentanes in water.

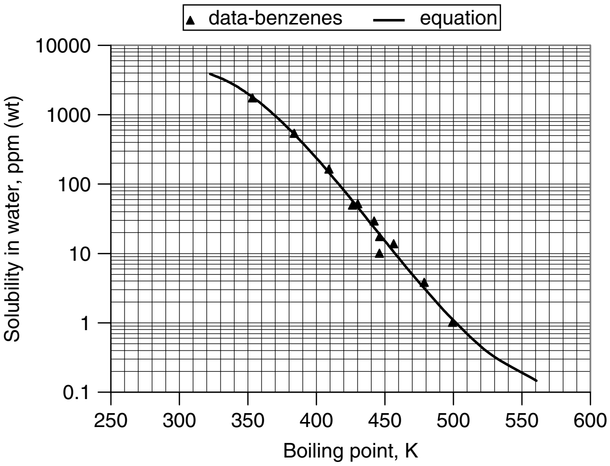

Figure 3. Solubility of benzenes in water.

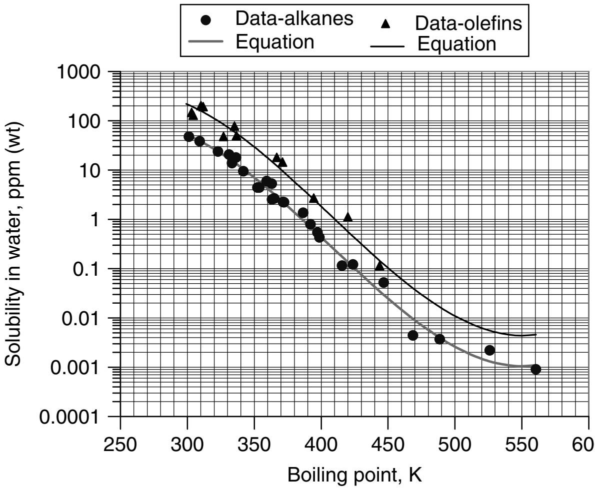

Figure 4. Solubility of olefins in water.

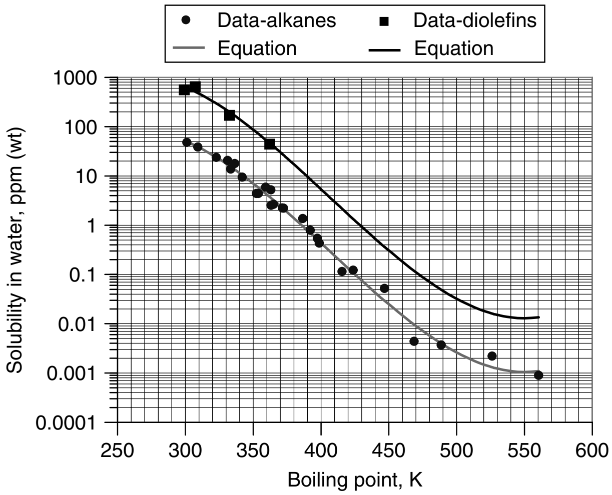

Figure 5. Solubility of diolefins in water.

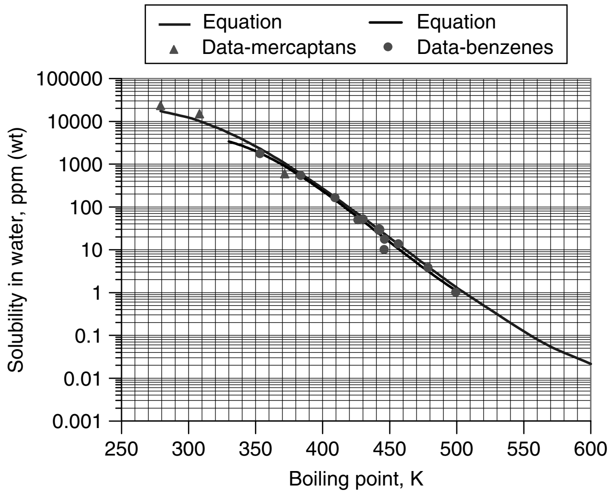

Figure 6. Solubility of mercaptans in water.

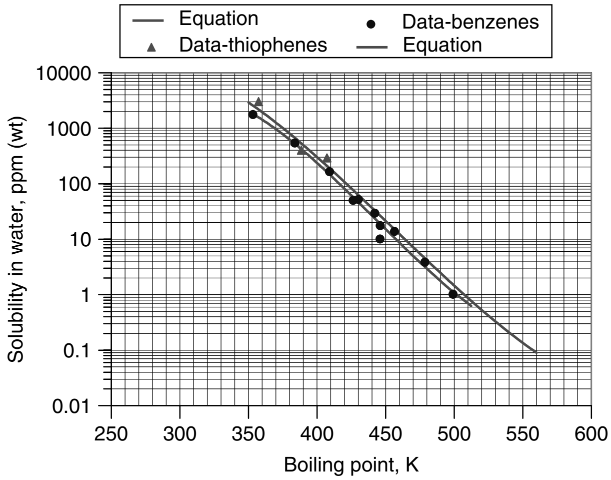

Figure 7. Solubility of thiophenes in water.

For sulfur compounds (mercaptans, thiopheolefins, and diolefins), the graphs disclose that more data are available for benzenes. The graphs also, disclose that the data for sulfur compounds appear to be slightly above and approximately parallel to the more extensive data for benzenes. This suggests that the solubility of sulfur

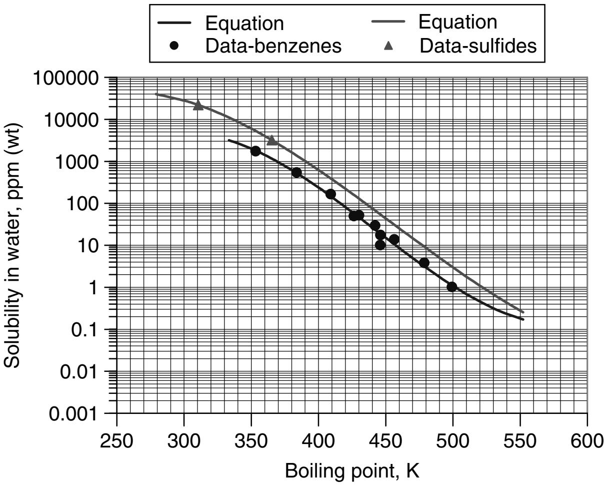

Figure 8. Solubility of sulfides in water.

compounds is higher and approximately parallel to the water solubility of benzenes.

Examples

The correlations for water solubility are useful in engineering applications involving process wastewater. Examples are shown below.

Example 1. A chemical spill of n-hexane occurs into a body of water at ambient conditions. Estimate the concentration in the water at saturation.

The correlation for alkanes maybe used to determine the solubility in water. Substitution of the coefficients and boiling point of n-hexane in the correlation equation yields:

$$\begin{aligned}\log_{10}(S) &= A + BT_B + CT_B{}^2 + DT_B{}^3 \\ &= -17.6520 + 1.77811\text{E}{-01}(341.88) \\ &\quad - 5.00907\text{E}{-04}(341.88)^2 \\ &\quad + 4.11124\text{E}{-07}(341.88)^3 \\ S &= 10.46 \text{ ppm (wt)}\end{aligned}$$

The calculated value and data compare favorably (10.46 vs 9.47; deviation = 0.99/9.47 = 10.4%).

Example 2. A chemical spill of toluene occurs into a body of water at ambient conditions. Estimate the concentration in the water at saturation.

The correlation for benzenes (single substitution) maybe used to determine the solubility in water. Substitution of the coefficients and boiling point of toluene in the correlation equation yields

$$\begin{aligned}\log_{10}(S) &= A + BT_B + CT_B{}^2 + DT_B{}^3 \\ &= -24.0080 + 2.21196\text{E}{-01} * (383.78) \\ &\quad - 5.55632\text{E}{-04} * (383.78)^2 \\ &\quad + 4.18830\text{E}{-07} * (383.78)^3 \\ S &= 524.68 \text{ ppm (wt)}\end{aligned}$$

The calculated value and data compare favorably (524.68 vs 542.4; deviation = 17.72/542.4 = 3.3%).

SORPTION KINETICS

Th.D. Karapantsios
M.X. Loukidou
K.A. Matis
Aristotle University
Thessaloniki, Greece

INTRODUCTION

Sorption is, by definition, a general term describing the attachment of charged species (such as toxic metal ions) from a solution to a coexisting solid surface. Sorption kinetics may be controlled by several independent processes that can act in series or in parallel (see Fig. 1). These processes fall in one of the following general categories:

1. bulk diffusion,
2. external mass transfer (film diffusion),

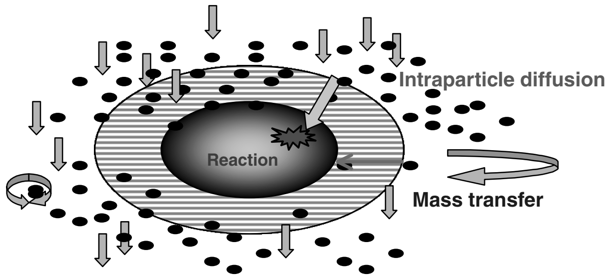

Figure 1. Illustration of the mechanism during sorption to describe suitably and model the respective process kinetics.

3. chemical reaction (chemisorption), and
4. intraparticle diffusion.

Kinetic analyses allow estimating sorption rates and also lead to suitable rate expressions characteristic of possible reaction mechanisms (1–3).

At sufficiently high agitation speed in a reaction vessel, the bulk diffusion step can be safely ignored because then sorption onto sorbent particles is decoupled from mass transfer in the bulk mixture. Apart from that, it is quite common that more than one process can contribute to system performance at the same time. In this case, the extensive interrelationships between the various equations make the overall kinetic model exceedingly complicated to evaluate. A rather simplifying approach to circumvent this problem is to assume that each one of the co-current processes dominate over the others (i.e., the rate-controlling step) at specific time regimes of the process and then study them independently (4); this approach was also adopted in this article.

Many studies engaged so far to examine sorption phenomena involved analysis of batch experiments where data were sampled at even time intervals over the entire course of the process. As a result, fast changing kinetic data characteristic of the phenomena just after the onset of sorption could not be accurately depicted on an adequately short timescale. Thus, a primary objective of this article is to investigate the kinetic mechanism of metal sorption on sorbent particles, putting more emphasis on samples collected at short times after the initiation of the process, where the major part of the adsorption occurs.

To identify the most appropriate mechanism for a process, several models must be checked for suitability and consistency in a broad range of system parameters. The model selection criteria proposed by Ho et al. (5) for sorption of pollutants in aqueous systems were used herein as a general guideline. According to this, several reaction-based and diffusion-based models were tested in simulating our data. The finally chosen kinetic models are those that fit the data closely and also represent reasonable sorption mechanisms.

EQUILIBRIUM AND KINETIC MODELING

An overall mass balance of the sorbate across the sorbent surface can be written as

$$X\,q_{\mathrm{t}} + C_{\mathrm{t}}^{s} = C_{\mathrm{o}} \Leftrightarrow q_{\mathrm{t}} = \frac{(C_{\mathrm{o}} - C_{\mathrm{t}}^{\mathrm{s}})}{X} \tag{1}$$

where q is the specific metal uptake (mg of metal per g of sorbent), C is the metal bulk concentration (mg/L) and X is the sorbent feed per unit volume of solution (g/L). Subscripts o and t denote conditions at the beginning and any other instant of the process, respectively. The superscript s denotes conditions at the sorbent interface. For adequately long adsorption times: $q_{\mathrm{t}} \approx q_{\mathrm{e}}$ and $C_{\mathrm{t}}^{\mathrm{s}} \approx C_{\mathrm{e}}^{\mathrm{s}} \approx C_{\mathrm{e}}$, where the subscript e denotes equilibrium conditions. The known Langmuir and Freundlich adsorption models have usually been employed to describe equilibrium metal uptake:

$$q_{\mathrm{e}} = \frac{q_{\max} b C_{\mathrm{e}}}{1 + bC_{\mathrm{e}}} \tag{2a}$$

$$q_{\mathrm{e}} = K_{\mathrm{F}} C_{\mathrm{e}}^{1/n} \tag{2b}$$

$q_{\max}$ (mg/g), b (L/mg), and K_{F} [mg [g (mg/L)$^{-1/\mathrm{n}}$]$^{-1}$] and n (dimensionless) are constants.

To compare measurements from various experiments for a kinetics investigation, it is necessary to introduce a dimensionless degree of conversion. Thus, by normalizing the remaining ion concentration, C_{t}, with respect to some reference value, an index of sorption is defined. Taking advantage of the values of C_{t} before the onset of sorption, C_{o}, and for completed sorption, $C_{\infty} = C_{\mathrm{e}}$, the following degree of conversion is proposed:

$$\alpha = \frac{C_{\mathrm{o}} - C_{\mathrm{t}}}{C_{\mathrm{o}} - C_{\mathrm{e}}} \tag{3}$$

Kinetic studies customarily use the basic conversion rate equation:

$$\frac{d\alpha}{dt} = k(T) f(\alpha) \tag{4}$$

where $f(\alpha)$ is a conversion-dependent function and k(T) is the reaction rate constant. Sorption in heterogeneous liquid–solid systems has usually been considered to follow Arrhenius kinetics, which means that the temperature dependence of the rate constant k may be described by the well-known expression:

$$k(T) = A \exp(-E/RT) \tag{5}$$

However, to apply the model in such systems, the morphology of the reactive surface and the final sorption capacity must not vary with temperature, conditions commonly overlooked by many workers (6).

The example used in this article deals with an investigation of the removal and depletion of cadmium and chromates from aqueous solutions by biosorption on *Aeromonas caviae* (the sorbent). This microorganism is often present in groundwater and generally in aquatic environments. Biosorption, the uptake of heavy metals by dead biomass, has gained credibility during recent years as it offers a technically feasible and economical approach (7–10); the latter author illustrated that adsorption is different from ion exchange. Below, evidence is also provided that the system examined is a complex process. More than one sorption model were often reported to describe a case study correctly (11). Attention should be paid to any possible experimental error.

The Langmuir isotherm equation was often found to fit quite satisfactorily the experimental data (12,13). Experimental adsorption isotherms of metal cations or oxyanions, obtained with different sorbent concentrations, temperatures, etc. are usually presented as figures and then, tables display the results of fitting the Langmuir and/or the Freundlich model to the data obtained; the values of the respective correlation coefficient (r^2), if high, are often used to demonstrate a satisfactory description. The assumptions involved in these models were well described, among others, by Volesky (9). The Langmuir isotherms obtained during the equilibrium study lend further support to the notion of a monolayer (14).

On the other hand, the Freundlich isotherm is heavily used in industry. This model is often accurate for higher concentrations, but is inaccurate at low concentrations due to its power-law nature. The equilibrium properties do not change proportionally with the sorbent addition, possibly due to an aggregation of solids at higher loads and hence reducing the effective adsorption area (15).

From the chemical reaction category (chemisorption), the best fit for the data sets of this study is achieved by second-order chemical reactions (16). The solution of the standard second-order reaction, based on constant stoichiometry of one metal ion per binding site, is (e.g., 4):

$$C_{\mathrm{t}} = \frac{C_{\mathrm{o}}}{1 - \dfrac{C_{\mathrm{o}}}{C_{\mathrm{e}}} \exp(-k_1 C_{\mathrm{e}} t)} \tag{6}$$

where k_1 is the reaction rate constant [L*(mg^{-1} of metal)*min^{-1}]. This adsorption model has been very effective in describing the kinetics of adsorption of gases on solids. Nevertheless, when the data were plotted, it was shown that Eq. 6 clearly fails to capture the steep concentration gradient of the early removal stage (16). This was a direct indication that adsorption on solids from a liquid phase is a process different from adsorption from a gas phase, where traditionally the remaining bulk concentration dictates the kinetics.

If the rate of sorption depends not on bulk concentration but on uptake by the sorbent, this can be described by the so-called Ritchie second-order equation according to which one metal ion occupies two binding sites (17):

$$q_{\mathrm{t}} = q_{\mathrm{e}} \left[1 - \left(\frac{1}{1 + k_2 t} \right) \right] \tag{7}$$

where k_2 is the reaction rate constant (min^{-1}). When in the above treatment, q_{e} does not dictate sorbate uptake, then a pseudo-second-order rate expression is more appropriate:

$$\frac{t}{q_{\mathrm{t}}} = \frac{1}{k_{\mathrm{m}} q_{\mathrm{m}}^2} + \frac{1}{q_{\mathrm{m}}} t \tag{8}$$

where k_{m} is the reaction rate constant [g of sorbent*(mg^{-1} of metal)*min^{-1}] and q_{m} is a numerically determined parameter which, under ideal second-order rate control, corresponds to q_{e}. In the literature (5), various other kinetic equations have been attempted: zero, first (forward or reversible)-order, Langmuir–Hinshelwood, and the Elovich-type.

Equations 7 and 8 provided quite a suitable description of data for advancing time (see Fig. 2). It is noteworthy that both models adequately capture the rapid rate of adsorption during the first minutes of the experiments. This implies that the metal uptake by the sorbent is a satisfactory rate-controlling parameter under a second-order reaction mechanism. The numerically best fit values of the rate parameters of these equations were displayed in a table (16). The predicted equilibrium sorption capacities were quite close to the experimental values for both models. Nevertheless, the rate constant of the pseudo-second-order model, k_{m}, is monotonically correlated with changes in the biomass load and in the bulk concentration, features that have been encountered in the past in biosorption (18).

In contrast, the rate constant of the Ritchie second-order equation, k_2, fluctuated, beyond any physical reasoning. In addition, Equation 8 exhibited better fitting statistics. Despite the goodness of fit for sorption at 40 and 60 °C, the reaction rate constant of both models varied randomly with temperature. Preliminary calculations,

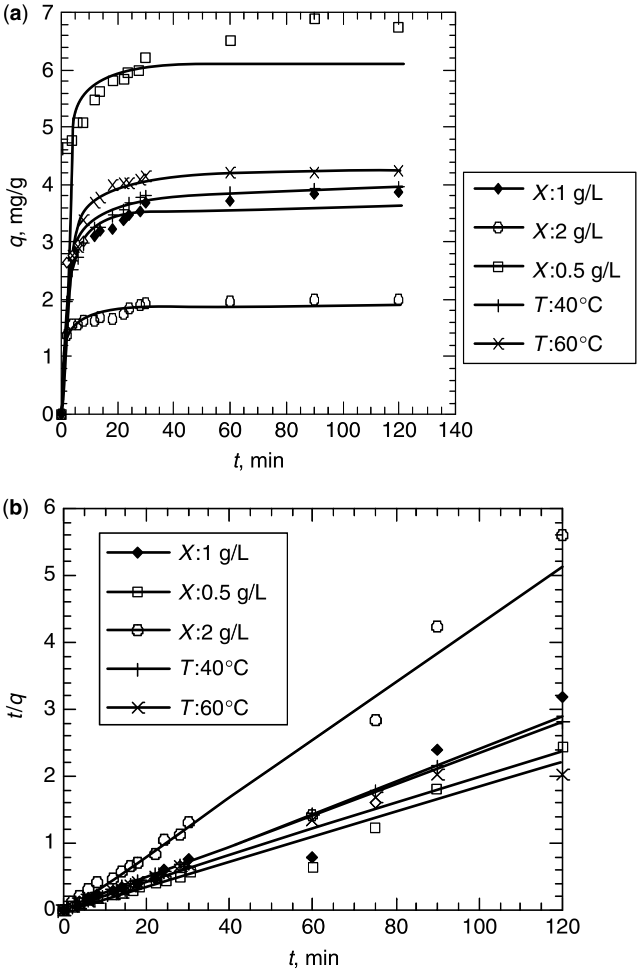

Figure 2. Comparison of experimental removal curves vs. theoretical predictions based on (**a**) the Ritchie second-order equation (at an initial cadmium concentration of 5 mg/L) and (**b**) the pseudo-second-order equation (at an initial cadmium concentration of 50 mg/L). Reprinted from Reference 16.

using the Arrhenius model between two temperatures every time, always gave activation energies below 10 kJ/mol, which is far less than expected for reaction-controlled sorption processes. The morphological changes in the biomass (sorbent) surface at different temperatures and the dependence of sorption capacity on temperature may be blamed for this irregularity.

DIFFUSION KINETICS AND MODELING

For intraparticle diffusion, Crank (19) proposed a model that takes into account the continuously decreasing bulk concentration due to sorbate removal. This gives rise to a time-dependent boundary condition for the concentration at the surface of the sorbent particle. The solution of the diffusion equation for such a boundary condition and a concentration independent diffusivity is

$$\alpha = 1 - 6\sum_{n=1}^{\infty} \frac{\exp(-\xi p_n^2 t)}{9\Lambda/(1-\Lambda) + (1-\Lambda)p_n^2} \tag{9}$$

where p_n is given by the nonzero roots of

$$\tan(p_n) = \frac{3p_n}{3 + p_n^2/(1-\Lambda)} \tag{10}$$

and $\Lambda \equiv (C_o - C_\infty)/C_o$ is the fraction of metal ultimately adsorbed by the sorbent.

Equation 9 can be solved numerically to determine ξ, the effective diffusional time constant, which for particle (also called micropore) diffusion control equals D_c/R_c^2; D_c and R_c are the intraparticle diffusion coefficient (m^2/s) and mean particle radius (m), respectively. The same expression is the solution of the diffusion equation for (macro)pore diffusion control but only where the equilibrium isotherm is linear ($q_e \approx K^*C_e$) for the concentration range under investigation. Then ξ equals $(D_p/R_p^2)/[1 + (1-\varepsilon_p)K/\varepsilon_p]$, where $\varepsilon_p D_p/[1 + (1-\varepsilon_p)K]$ is the effective macropore diffusivity, K is the equilibrium constant, ε_p is the void volume fraction, and R_p is the radius of the particle (14).

The experimental procedure in this article is based on measuring the remaining metal concentration in the bulk, so Λ is always above 0.5. For Λ greater than about 0.1, the effect of diminishing bulk concentration becomes significant, and under these conditions, the assumption of constant metal concentration at the surface of the sorbent leads to an erroneously high diffusivity. Provided that the concentration step employed in a sorption experiment corresponds to a linear section of the equilibrium isotherm, the constant K can be replaced by the local slope of the isotherm, dq_e/dC_e. This is approximately valid for the concentrations employed in this work, as can be seen from the experimental isotherms. Our interest is chiefly focused on the short time region ($\sqrt{D_{c,p}t/R_{c,p}^2} < 0.2$) where Eq. 9 converges slowly, so at least 200 terms are used in the summation to achieve satisfactory accuracy.

External mass transfer has been customarily analyzed in literature by adopting a pseudo-first-order reaction model (5,20). This approach assumes that the sorbate concentration at the sorbent surface is zero at all times. However, this is not true, particularly where a significant quantity of sorbate is adsorbed rapidly at the beginning of the process. A more realistic model should consider instead that a rapid equilibrium is established between the sorbate at the interface and that present on the sorbent surface (21), and this concept is adopted in this article.

If one combines the mass balance across the sorbent surface, Equation 1, the Langmuir adsorption isotherm, Equation 2a, and the rate of change equation in the bulk concentration, one ends up with (21)

$$\frac{dC_t}{dt} = -K_m S(C_t - C_t^s) \tag{11}$$

$$\frac{dC_t^s}{dt} = \left(\frac{K_m S}{Xq_{\max} b}\right)[(C_t - C_t^s)(1 + bC_t^s)^2] \tag{12}$$

where K_m is the external mass transfer coefficient (m/s) and S is the specific surface area of the sorbent particles per unit volume of the reactor (m^2/m^3). Using the following dimensionless variables: $C^* = C_t/C_o$, $C_s^* = C_t^s/C_o^s$, and $t^* = t/\tau$, where C_o^s is determined from Eqs. 1 and 2a and τ is the total adsorption time, Eqs. 11 and 12 convert to

$$\frac{dC^*}{dt^*} = -K_m S\tau(C^* - C_s^*) \tag{13}$$

$$\frac{dC_s^*}{dt^*} = \left(\frac{K_m S\tau}{Xq_{\max} b}\right)\left[(C^* - C_s^*)(1 + bC_o C_s^*)^2\right] \tag{14}$$

which is a system of two first-order ordinary differential equations that must be solved simultaneously. The initial conditions are $C^* = 1$ and $C_s^* = 0$ at $t^* = 0$. Note that normalizing C_t^s with respect to C_o^s —and not C_o, as Puranik et al. (21) did —and also t with respect to τ, improved the stability and convergence characteristics of the solution markedly due to comparable spreading of all variables over the computational domain.

Equations 9–10 and 13–14 are solved numerically to determine ξ and $K_m S$, respectively. The nonlinear numerical regression to fit experimental data to those equations is performed by the Levenberg–Marquardt method, which gradually shifts the search for the minimum of the sum of the errors squared (SSE), from the steepest descent to quadratic minimization—Gauss–Newton (22):

$$\mathrm{SSE} = \sum_i \left[\frac{(q_{exp,i} - q_{cal,i})^2}{q_{exp,i}^2}\right] \tag{15}$$

Figure 3a presents the results of fitting Eq. 9 to biosorption data obtained with different initial concentrations, solids loads, and temperatures. It is apparent that, despite some scatter in measurements, the finite volume diffusion model can fairly well describe the entire range of data, also including the steep concentration gradient at short times. The values of Λ, ξ, and the computed values of D_c were displayed in a table (14). Such behavior has been customary as a consequence of the decreasing slope of a nonlinear equilibrium curve, example, a Langmuir isotherm, which

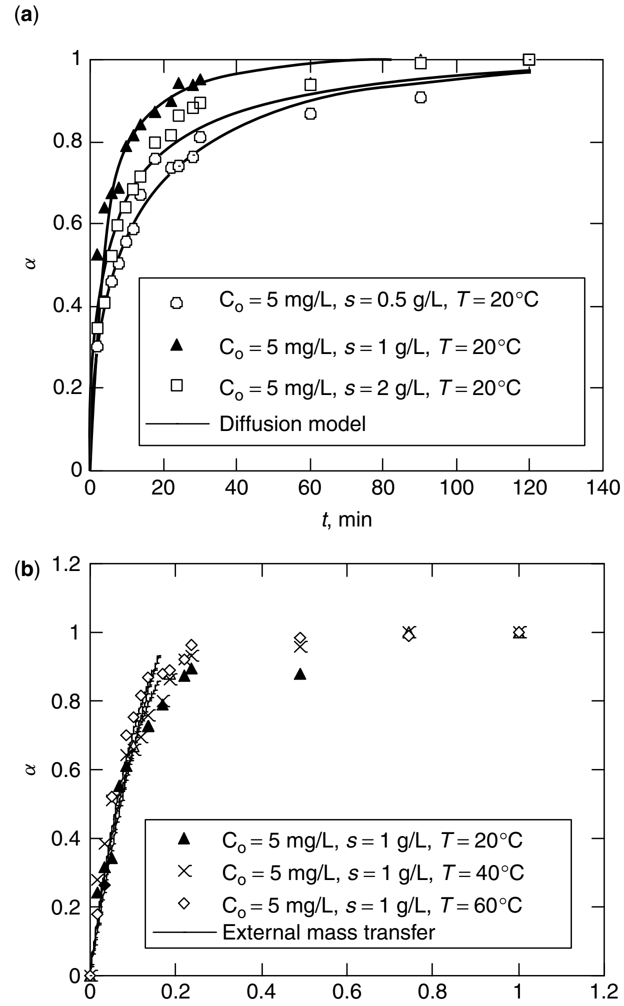

Figure 3. Experimental degree of conversion, α, vs. predictions based on the solution of (**a**) the diffusion equation, for various adsorbent loads and (**b**) the mass transfer equation, for various temperatures (both at an initial chromium concentration of 5 mg/L). Reprinted with permission from Reference 14; copyright (2004) American Chemical Society.

causes the diffusivity to increase rapidly as concentration increases (11).

A way to check further on the possibility of a pore diffusion-controlled mechanism is to perform desorption kinetic tests with adsorbent previously used for sorption. For a nonporous sorbent particle, transport of solute inside the particle may be neglected, and it can be assumed that biosorption occurs mainly at the particle surface. This idea can be effectively extended to cases of relatively large macropores, where the metal ions may have ready access to react with internal surface sites.

It was argued that, at the beginning of the process, chromium is sorbed according to quite a fast and highly favorable chemical mechanism, such as ion exchange, but soon external film diffusion comes into play (14). On this account, if one ignores the very first minute of sorption, the remaining curves were fitted pretty well by the model Eqs. 13 and 14. Figure 3b displays these results. Near the end of sorption (for α higher than 0.9), a much slower process, intraparticle diffusion, gradually becomes the rate-controlling step. Yet, this is a regime of no practical significance.

The computed mass transfer rate constant, K_mS, was presented in a table (14). As regards the effect of changing the solids load, it appears that K_mS is virtually not affected. To assess the statistical significance of the determination, a derivative time series analysis has been performed where $d\alpha/dt$ is plotted versus t and then, a Hanning low-pass filter was applied to flatten out the signal undulations until $d\alpha/dt$ versus α became a reasonably smooth curve (23). Next, the integrated smoothed signal $\alpha(t)$ was processed as before and resulted in K_mS values closely comparable to the values obtained from the unfiltered data, with no preferential trend in biomass load. This is an additional positive sign that external mass transfer may be the predominant mechanism of the sorption process after the initial fast chromium removal.

As a conclusion in the example thoroughly studied, we may say that the analysis conducted has not been capable of providing strong evidence in favor of any of the examined mechanisms because several diverse kinetic models were successful in fitting the experimental data. Perhaps, the questioning of surface kinetics by Levenspiel (24) is known, concluding that it is good enough to use the simplest available correlating rate expression.

NOMENCLATURE

q: specific metal uptake (mg/g)
C: metal bulk concentration (mg/L)
X: sorbent loading per unit volume of solution (g/L)
$q_{\max}$: Langmuir constant (mg/g)
b: Langmuir constant (L/mg)
K_F: Freundlich constant {mg [g (mg/L)$^{-1/n}$]$^{-1}$}
n: Freundlich constant (dimensionless)
E: apparent activation energy (J/mol)
A: preexponential factor (min^{-1})
n: apparent reaction order
R: gas constant (8.3136 J/mol/K)
T: temperature (K)
t: time (min)
k: rate constant
k_1: second-order chemical reaction rate constant [L*(mg^{-1} of metal)*min^{-1}]
k_2: second-order Ritchie reaction rate constant (min^{-1})
k_m: pseudo-second-order reaction rate constant [g of sorbent*(mg^{-1} of metal)*min^{-1}]
D_c: intraparticle diffusion coefficient (m^2/s)
R_c: mean particle radius (m)
R_p: radius of a particle
K_m: external mass transfer coefficient (m/s)
S: specific surface area of sorbent particles per unit volume of the reactor (m^2/m^3)

Greek Letters

α: degree of conversion
Λ: fraction of metal ultimately adsorbed by the sorbent

ξ: numerically determined parameter
ε_p: void volume fraction

SOUND IN WATER

D.L. Marrin
Hanalei, Hawaii

As sound travels through an elastic medium such as water, a wave is created that imparts energy to the individual molecules—causing them to compress and then to relax along the path of the wave. Because the medium is elastic, the distance separating individual water molecules is permitted to vary just slightly, so that the propagation of sound may be defined as a periodic variation in pressure that is transmitted via adjacent molecules. Sound emanating from a point source in water usually (but not always) results in a three-dimensional waveform that spreads spherically through the medium (1). Similarly, a planar source of sound in water can be considered multiple point sources that create a wave consisting of all the individual waves.

Sound waves are *longitudinal*, meaning that molecules (e.g., water or air) comprising the elastic medium move in a direction parallel to the propagating wave. Because water has a significantly higher density than air, water transmits sound more rapidly and efficiently than air. The water molecules oscillate, or move back and forth over a very short longitudinal distance; hence, sound waves are classified as *mechanical*. By contrast, light waves and microwaves are classified as *electromagnetic* and do not involve the movement of water molecules for propagation. The speed of sound in water is about 1500 meters per second or 3300 miles per hour (i.e., approximately five times greater than that in air), which varies slightly with temperature, pressure, and salinity.

FREQUENCY AND AMPLITUDE

The frequency of a sound wave is the number of waves that pass by a given point during a specified period of time. A single wave consists of a cycle that includes both compression (squeezing together) and rarefaction (rebounding apart); the distance over which a cycle is continually repeated is known as the wavelength. The period of time over which waves are normally counted is one second; therefore, sound frequencies are expressed as cycles per second or *hertz*. Whereas high-frequency sounds possess short wavelengths, low-frequency sounds possess long wavelengths. Frequency ranges and estimated intensity levels for common underwater sounds are listed in Table 1. Frequency-dependent differences in underwater sound attenuation result in low-pitched sounds that travel farther than high-pitched sounds generated at similar intensities.

The amplitude of a sound wave is the maximum longitudinal displacement (i.e., during one cycle of compression and rarefaction) of water molecules relative to their resting, or equilibrium, position. The intensity of a sound wave is proportional to its amplitude and is often quantified in units of *decibels*. The decibel scale is based on a ratio between the intensities (expressed as a power) of a measured sound and a reference sound that corresponds to a standard pressure. Many of the man-made sounds listed in Table 1 are actually more intense than naturally produced sounds, contributing, at least in part, to the controversy regarding the possible effects of anthropogenic noise on marine organisms. Sound intensities are commonly presented for a distance of only 1 meter from the source and, as such, are rarely indicative of ambient underwater noise (e.g., the cumulative intensity of sounds measured at greater distances from their respective sources).

FATE OF OCEANIC SOUND

The propagation of sounds in the ocean is a rather complex matter owing to differences in water density as a function of depth, latitude, seafloor topography, and many other factors. Changes in seawater temperature, salinity, and pressure contribute to changes in density that, in turn, affect sound waves traveling through the medium. Generally, sound is attenuated by *spreading* (proportional to distance), *reflection* (due to solid structures or boundaries between water of different densities), *scattering* (due to rough surfaces), *absorption* (conversion of acoustic to thermal energy), and *refraction* (deflection of sound waves from a straight path) (5). Ambient noise in a shipping channel can exceed that outside a channel by as much as 45 decibels (re 1 μPa), but noise in a channel is attenuated about 100 decibels from that measured directly beneath ships (2).

Due to the vertical stratification of oceans, sound behaves differently in turbulent shallow waters from the way it does in either more isothermal middepth waters or waters immediately overlying the bottom (see Table 2). Sound transmission at the surface is highly dependent on local conditions (e.g., wind, precipitation, swells, bubbles) and is usually restricted to low-frequency sounds. However, most of the ocean lies between shallow and bottom waters, creating a relatively thick layer that transmits a spectrum of sound waves that is far less attenuated than that in either shallower or deeper waters. Both humans and whales have taken advantage of this *sofar channel* to broadcast signals and songs, respectively, over vast oceanic distances (6). Sounds generated within the sofar channel itself or at shallower depths alongside seamounts are entrained and transmitted within this deep isothermal layer as a result of many contributing physical processes.

UNDERWATER DETECTION

Detecting and identifying an underwater sound from a particular source is often difficult due to the aforementioned effects of the environment and to the myriad of background noises from which any single sound must be distinguished. Sea sounds are detected by hydrophones (i.e., the underwater equivalent of a microphone) that are often positioned in specific arrays, thus permitting the relative position of a sound source to be determined. This type of *passive* detection may be used to locate oceanic precipitation, breaking surface waves, underwater explosions, undersea volcanoes, shipping traffic, and marine organisms that emit audible sounds (e.g., crustaceans, fishes, mammals) (7).

Active detection techniques, such as sonar, are routinely used to locate underwater objects because the objects themselves need not emit sound and because the results

Table 1. Approximate Ranges for the Frequencies and Intensity Levels of Common Underwater Sounds. Reported Ranges were Complied from Data Presented in Various Sources[a]

Sound Source	Frequency, Hertz	Intensity Level, Decibels re 1 μPa at 1 m[b]
Ship engines and propellers	10–5000	160–190
Navigation and profiling sonars	100–3000	180–230
Explosive devices/air guns	1000–17,000	190–260
Military surveillance sonars	1000–10,000	190–235
Icebreaking/drilling operations	20–1000	100–150
Whale songs and moans	10–8000	120–190
Dolphin clicks and whistles	500–25,000	100–180
Cetacean echolocation	10,000–150,000	130–230
Snapping shrimp colony	2000–15,000	180–190
Lightning strikes/undersea volcanoes/earthquakes	0.1–20,000	Up to 260

[a] Reference 2–4.

[b] Intensity levels are presented in units of decibels relative to a reference pressure of 1 micropascal at a distance of 1 meter from the sound source. Sound level attenuation is a function of distance from the source, frequency range, and various environmental factors.

Table 2. Approximate Depths and Representative Sound Speeds for Various Water Layers in the Ocean. Reported Ranges were Complied from Data Presented in Various Sources[a]

Vertical Zone	Depth, Meters	Speed, m/s	Comments
Overlying air	NA[b]	330	Significantly lower acoustic impedance than water; minimal transfer of sound energy
Surface water layer	0 to 50	1515	Influenced by weather (e.g., wind, rain, temp.) and turbulence that affect sound waves
Seasonal thermal layer	50 to 800	1485–1505	Sound channel (mostly for low frequencies); limited vertical thickness; refracts sound waves originating shallower and deeper
Deep isothermal layer	800 to 4000+[c]	1485–1525	Optimal sound channel (for all frequencies); extensive vertical thickness and horizontal extent; minimal sound attenuation
Bottom water layer	4000+ to seafloor[c]	1525	Influenced by seafloor topographic features that reflect and scatter sound waves
Underlying rock	NA[b]	2000–6000	Higher acoustic impedance than water; moderate transfer of sound energy

[a] References 2, 6, and 7.

[b] Not applicable.

[c] Indicates that the transition between deep isothermal layers and bottom water layers may exceed 4000 meters, depending on the exact location within an ocean basin.

are generally more interpretable. The most basic type of sonar is echolocation, whereby a sound pulse (acoustic energy) is introduced into the water. Depending on the sonic wavelength and the size of the objects, a portion of that acoustic energy is reflected back to the source (e.g., a ship) where it is detected, transduced, and analyzed. The distance, movement, size, and even shape of some objects may be determined using sophisticated sonars (e.g., Doppler, multibeam) and data analysis techniques (8). Several marine organisms—most notably cetaceans—are believed to use echolocation as a means of finding or assessing prey, predators, conspecifics, seabed features, and environmental conditions (2).

ULTRASOUND AND INFRASOUND

Most of the underwater sounds discussed thus far lie within the *sonic* range of humans (i.e., frequencies of 20 to 20,000 hertz), but water also transmits mechanical waves of *ultrasonic* (>20,000 hertz) and *infrasonic* (<20 hertz) frequencies. Dolphins emit whistles at frequencies as high as 30,000 hertz and complex echolocation clicks at frequencies exceeding 300,000 hertz (8). Obviously, the upper limit of hearing of dolphins far exceeds that of humans. In addition to marine organisms, ambient oceanic noise associated with bubbles (i.e., trapped gases), surface winds, waves, and sea spray can reach ultrasonic frequencies. Man-made ultrasounds include everything from complex signals for communication to guided waves for inspecting underwater pipelines (9).

The moans of baleen whales are the most common source of biologically produced infrasound, which has been documented down to about 10 hertz (8). By contrast, a number of geologic and meteorologic events (e.g., volcanoes, earthquakes, sea ice cracking, hurricanes) produce infrasonic waves that propagate through the ocean at frequencies of approximately 0.1 to 10 hertz. Even the breaking of large surf, either onto the shore or on the water itself, creates infrasound at frequencies of 1 to 5 hertz (10). Anthropogenic infrasound in the ocean is created primarily via shipping traffic, low-frequency active sonar (LFAS), and acoustic thermography. A thermography technique known as ATOC generates tones down to about 1 hertz, whereas LFAS sweeps multiple tones of 100 to 500 hertz across each other and produces resulting tones as low as 0.1 hertz (2). Both ATOC and LFAS generate peak intensity sounds that are greater than those of ships.

WATER ON THE SPACE STATION

Patrick L. Barry
Tony Phillips
NASA

Rationing and recycling will be an essential part of life on the International Space Station. In this article, Science@NASA explores where the crew will get their water and how they will (re)use it.

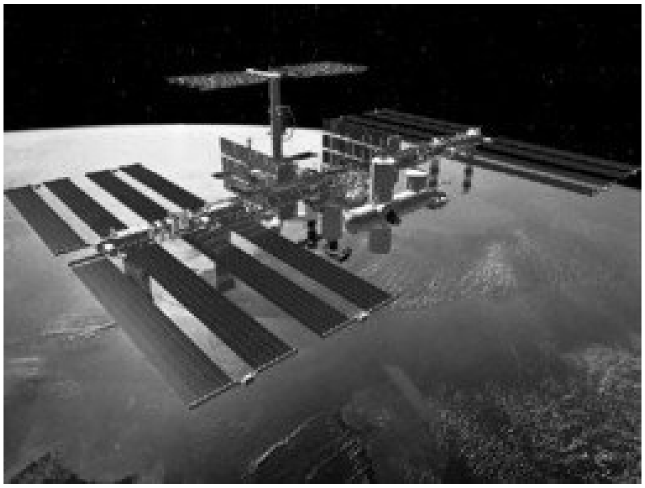
November 2, 2000—Future astronauts poised to blast off for an extended stay on the International Space Station (ISS) might first consider dashing to the restroom for a quick splash at the lavatory, or better yet, a luxurious hot shower. Once on board the ISS, spacefarers are in for a steady diet of sponge baths using water distilled from—among other places—their crewmates breath!

If you're squeamish, read no farther, because the crew will eventually include lab rodents—and they'll be breathing, too. All of the denizens of the space station lose water when they exhale or sweat. Such vapors add to the ambient cabin humidity, which is eventually condensed and returned to the general water supply.

Sometimes it's better *not* to think about where your next glass of water is coming from!

Rationing and recycling will be an essential part of daily life on the ISS. In orbit, where Earth's natural life support system is missing, the Space Station itself has to provide abundant power, clean water, and breathable air at the right temperature and humidity—24 hours a day, 7 days a week, indefinitely. Nothing can go to waste.

In this article, the first of a series about the practical challenges of living in space, *Science@NASA* will examine how the Space Station's **E**nvironmental **C**ontrol and **L**ife **S**upport **S**ystem (ECLSS), under continuing development at the Marshall Space Flight Center, will help astronauts use *and re-use* their precious supplies of water. Future installments will explore air management, thermal control and fire suppression—in short, all of the things that will make the Space Station comfortable and safe.



MAKING A SPLASH IN SPACE

Before recycling can begin, there has to be some water to start with.

"We have plenty of water on the Space Station now," says Jim Reuter, leader of the ECLSS group at the Marshall Space Flight Center. "The Russian module Zarya is packed with contingency water containers (CWCs) that were carried over from the Space Shuttle during assembly missions earlier this year. They look like duffle bags and each one holds about 90 lbs."

"But it's expensive to ferry water from Earth," he added. "We have to recycle. There's already a Russian-built water processor in orbit that collects humidity from the air. Here at Marshall we're building a regenerative system that will be able to recycle almost every drop of water on the station and support a crew of seven with minimal resupplies."

The ECLSS Water Recycling System (WRS), developed at the MSFC, will reclaim waste waters from the Space Shuttle's fuel cells, from urine, from oral hygiene and hand washing, and by condensing humidity from the air. Without such careful recycling 40,000 pounds per year of water from Earth would be required to resupply a minimum of four crewmembers for the life of the station.

Not even research animals are excused from the program.

"Lab animals on the ISS breath and urinate, too, and we plan to reclaim their waste products along with the

Shuttle pilot Terry Wilcutt with 7 contingency water containers destined for the space station Mir

---

crew's. A full complement of 72 rats would equal about one human in terms of water reclamation," says Layne Carter, a water-processing specialist at the MSFC.

It might sound disgusting, but water leaving the space station's purification machines will be cleaner than what most of us drink on Earth.

"The water that we generate is much cleaner than anything you'll ever get out of any tap in the United States," says Carter. "We certainly do a much more aggressive treatment process (than municipal waste water treatment plants). We have practically ultra-pure water by the time our water's finished."

MIMICKING MOTHER EARTH

On Earth, water that passes through animals' bodies is made fresh again by natural processes. Microbes in the soil break down urea and convert it to a form that plants can absorb and use to build new plant tissue. The granular soil also acts as a physical filter. Bits of clay cling to nutrients in urine electrostatically, purifying the water and providing nutrients for plants.

Water excreted by animals also evaporates into the atmosphere and rains back down to the Earth as fresh water—a natural form of distillation.

Water purification machines on the ISS partly mimic these processes, but they do not rely on microbes or any other living things.

"While you try to mimic what's happening on Earth—which is so complicated if you really think about it—we have to use systems that we can control 100 percent," said Monsi Roman, chief microbiologist for the ECLSS project at MSFC. ECLSS depends on machines—not microbes—because, "if a machine breaks, you can fix it."

The water purification machines on the ISS will cleanse wastewater in a three-step process.

The first step is a filter that removes particles and debris. Then the water passes through the "multi-filtration beds," which contain substances that remove organic and inorganic impurities. And finally, the "catalytic oxidation reactor" removes volatile organic compounds and kills bacteria and viruses.

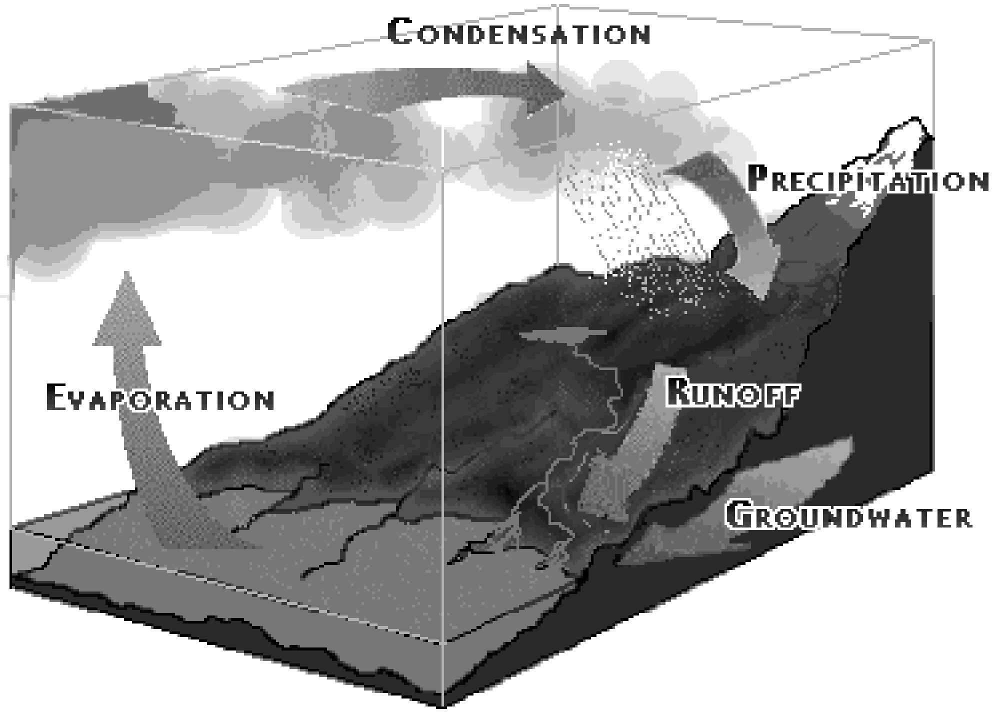
EVERY DROP COUNTS

Once the water is purified, astronauts will do everything possible to use it efficiently. "On the ground, people flick on the faucet and they probably waste a couple of liters of water just because it's free and the water pressure is high," notes Carter.

"On the ISS, the water pressure will be about half what you might experience in a typical household," Carter said. "We don't use faucets on the ISS, we use a wash cloth. It's much more efficient. If you're an astronaut, you'll wet the wash cloth with a spray nozzle and then use the cloth to wash your hands."

On the space station, people will wash their hands with less than one-tenth the water that people typically use on Earth. Instead of consuming 50 liters to take a shower, which is typical on Earth, denizens of the ISS will use less than 4 liters to bathe.

Even with intense conservation and recycling efforts, the Space Station will gradually lose water because of inefficiencies in the life support system.



When water evaporates from the ocean and surface waters, it leaves behind impurities. In the absence of air pollution, nearly pure water falls back to the ground as precipitation

"We will always need resupply, because none of the water reprocessing technology that is available right now for space flight ... is 100 percent efficient. So there's always some minimal loss," said Marybeth Edeen, deputy assistant manager of environmental control and life support at NASA's Johnson Space Center.

Water is lost by the Space Station in several ways: the water recycling systems produce a small amount of unusable brine; the oxygen-generating system consumes water; air that's lost in the air locks takes humidity with it; and the CO2 removal systems leach some water out of the air, to name a few.

Lost water will be replaced by carrying it over from the Shuttle or from the Russian Progress rocket. The Shuttle produces water as its fuel cells combine hydrogen and oxygen to create electricity, and the Progress rocket can be outfitted to carry large containers of water.

NASA scientists will continue to look for ways to improve the life support systems of the Space Station, reducing water losses and finding ways to reuse other waste products. If the water recycling systems can be improved to an efficiency of greater than about 95 percent, then the water contained in the Station's food supply would be enough to replace the lost water, Edeen said.

One of the "nodes" that will become a part of the Space Station. The ECLSS life support equipment will be housed in Node 3, which is scheduled to be attached to the station in October 2005

Sign up for our EXPRESS SCIENCE NEWS delivery

"It takes processes that are slightly more efficient than we have developed for the space station to do that," Edeen said. "Those are the next generation water processing systems. Those are being developed now, but they're not ready for space flight yet."

The ECLSS life support system will join the Space Station as part of Node 3, which is scheduled to launch in October 2005. Until then, the environment inside the ISS will be maintained primarily by life support systems on the Russian Zvezda Service Module.

STRONTIUM ISOTOPES IN WATER AND ROCK

Gholam A. Kazemi
Shahrood University of
Technology
Shahrood, Iran

INTRODUCTION

A brief summary of strontium and strontium isotopes, their concentrations in natural materials, and their evolution in the geologic system is given in the following paragraph. These introductory notes have been taken from a benchmark paper by Capo et al. (1). Anyone intending to deal with strontium isotopes should consult that paper as well as the paper by Clow et al., (2). Textbooks such as those by Faure (3) and Faure (4) provide excellent coverage of strontium isotopes in rocks. Being an encyclopedia of water, the emphasis here is more on strontium isotopes in water.

Strontium has four naturally occurring isotopes, whose approximate abundances are ^{84}Sr, 0.56%; ^{86}Sr, 9.87%; ^{87}Sr, 7.04%; and ^{88}Sr, 82.53%. All four isotopes are stable, although the fraction of ^{87}Sr varies due to radioactive decay of ^{87}Rb. The ionic radius of strontium (1.18 Å) is similar to that of calcium (1.00 Å), and, hence, Sr substitutes for Ca in minerals, including plagioclase feldspar, apatite, sulfates such as gypsum and anhydrite, and carbonates (calcite, dolomite, and especially aragonite). The average concentration of Sr in soils is 240 ppm but may fall below 10 ppm or exceed 1000 ppm in some cases. Weathering of bed rock or sediments can be a significant source of strontium in soil. Soil parent materials often have distinct Sr isotopic signatures. The average concentration of Sr in crustal rocks is 370 ppm but can vary from 1 ppm in some ultramafic rocks to several percent in some aragonitic corals. If Rb and Sr are incorporated into a mineral or rock at its formation and the system remains closed with respect to those elements, then the amount of ^{87}Sr increases over time as radioactive ^{87}Rb decays; the amounts of ^{84}Sr, ^{86}Sr, and ^{88}Sr remain constant. Therefore, older rocks in general have higher ^{87}Sr/^{86}Sr ratios than younger ones that have the same initial Rb/Sr ratio. Over geologic time, rocks of a given age, composed of minerals that have a high Rb/Sr ratio (e.g., granites in the continental crust), develop a higher ^{87}Sr/^{86}Sr than rocks that have a lower Rb/Sr ratio (e.g., oceanic basalts). Thus, ^{87}Sr/^{86}Sr ratios in geologic materials are indicators of both age and geochemical origin. The strontium in rocks is released by weathering, cycled through vegetation and animals, and eventually enters the oceans, primarily via rivers. Minerals within a crystalline rock or sediment generally have variable Rb/Sr ratios and therefore a range of ^{87}Sr/^{86}Sr ratios. River water has a Sr concentration that varies from ~6 to 800 ppb and averages ~60 ppb. The Sr concentration in seawater is about 8 ppm. Precipitation near ocean basins generally has a strontium isotopic composition similar to that of seawater (0.709). However, the concentration of Sr in rainfall is generally lower than that in seawater by several orders of magnitude (usually <1 ppb). Strontium leaves the oceans, the largest reservoir of dissolved Sr, primarily by deposition in marine carbonate. A small amount of Sr is also transferred directly from the oceans to the atmosphere and hence transferred to the continents in precipitation.

SR ISOTOPES IN WATER AND ROCK: SOURCES AND IMPORTANCE

The Sr isotopic ratio in natural water reflects the contribution made by various minerals as they dissolve in water. Rivers are the major provider of strontium to the oceans and define, to a great extent, the marine ^{87}Sr/^{86}Sr ratio. Strontium in rivers is mainly derived from two end members: limestone and evaporites as one end member (high Sr and low ^{87}Sr/^{86}Sr ratio of 0.706–0.709) and silicate rocks as the other end member that are low in Sr and have a higher ^{87}Sr/^{86}Sr ratio. Processes such as atmospheric deposition, cation exchange, and biological cycling, too, influence the Sr isotope ratio in water. However, unless there have been recent anthropogenic or natural disturbances, annual gains or losses of Sr from cation exchange and biological pool should be minimal.

Sr isotopes in water samples are used (1) as a chemical tracer to determine the sources of atmospheric contributions to soil cation reservoirs over time (1); (2) to determine the contribution of various components to the water balance of a lake (5); (3) to distinguish weathering reactions from cation exchange processes (6); (4) to investigate the origin of brine, brine migration, and the relationship between brine and diagenetic phases (7); (5) to characterize weathering reactions and identify sources of dissolved Ca in stream water (2); (6) as a tracer of cation sources in stream water (8); (7) to correlate and date marine sequences of late Neogene age (9); (8) to identify the origin of salts in groundwater (10); (9) to investigate the effect of carbonate dissolution on the chemical composition of groundwater (11); and (10) to indicate the influence of seawater on fresh groundwater (12).

Analysis of Sr Isotopes in a water sample

The strontium isotopes of a water sample are measured under clean laboratory conditions using a mass spectrometer, such as a Sector 54 type (13), a Finnigan Mat 261 multicollector model (2), or a VG354 thermal ionization brand (9). To analyze water for a Sr isotope ratio using a Sector 54 Type Mass Spectrometer, an initial aliquot of the sample is placed in a microwave oven to be evaporated to dryness. For water that has a total Sr content of more than 0.5 ppm, the aliquot is 2 mL, and evaporation time is about 1 hour; for water that has low concentrations such as rainwater, 500 mL is required which takes much longer to evaporate to dryness. Then 3 mL of 6 molar HCl is added to the residue to dissolve it and left to stabilize for a few hours. The following steps are then taken one after another (13):

1. Add 1 mL of 2.5 molar HCl, and evaporate to dryness by heating slowly.
2. Add 1 mL of 6 molar HCl, and leave to dissolve.
3. Transfer to centrifuge vessels, and centrifuge for around 5 minutes.
4. Pour 1 mL of the sample into the column (the column detail is AG W50-X 8).
5. Add 1 mL of 2.5 molar HCl to the column.
6. Add 1 mL of 2.5 molar HCl to the column.
7. add 1 +30 mL of 2.5 molar HCl to the column in two stages, respectively.
8. Add 10 mL of 2.5 molar HCl to the column.
9. Collect Sr by placing a container beneath the column and letting it drain.
10. Add 1 mL of HNO_3, and slowly heat to dryness.
11. Add 1 mL of HNO_3, and slowly heat to dryness.
12. Add 1 mL of Milli-Q water to the sample.
13. Place a small volume of the sample in the holding filament.
14. Heat sample slowly.
15. Add a small volume of phosphoric acid to the sample to facilitate ionization.
16. Heat the sample rapidly to a very high temperature (to burn) to remove any Rb.
17. Place the sample in the sample holder.
18. Transfer sample/s to the mass spectrometer.
19. Start running sample with mass spectrometer.

Analysis of Sr Isotopes in a rock sample

Rocks Other Than Limestone. To analyze a rock sample for Sr isotopes ratio using a Sector 54 Type Mass Spectrometer under clean laboratory condition, first it has to be ground to a 1 micron size. After grinding, for all rock types but limestone, the following steps should be undertaken one after another:

1. 0.1 gram of sample to accuracy of 0.0001 gram is selected.
2. 2 mL of HF acid and 10 drops of HNO_3 are added to each sample.
3. Samples are heated to dryness.
4. 2 mL of HF is again added to each sample.
5. 10 drops of $HClO_4$ are added to each sample, and sample is placed on a hot plate at 150 °C.
6. 5 drops of $HClO_4$ are added to each sample.
7. 5 more drops of $HClO_4$ are added to each sample.
8. Samples are placed on a hot plate at 180 °C.
9. Samples are then placed on a hot plate at 130 °C on the next day, and 1 mL 2.5 M HCl is added to each sample.
10. Samples are transferred to centrifuge tube to be centrifuged for 5 minutes.
11. From this step forward, all the steps are exactly the same as those for water samples from Step 5 onward.

Limestone. Due to its high solubility compared to other rock types, limestone is prepared for analysis using different techniques and the following steps:

1. 0.1 mg of sample is selected.
2. 1 mL of 1 M acetic acid is added to the sample.
3. 2 mL of 1 M acetic acid is added.
4. After reaction subsides, sample is centrifuged, and the residue is decanted to a clean beaker and heated to dryness at 150 °C.
5. 3 mL of 6.25 M HCl is added and evaporated to dryness, and 1 mL more is added again and heated to dryness.
6. 1 mL of 2.5 M HCl is added.
7. The sample is then loaded into columns (like other rock types).
8. The Sr is then collected and dried.
9. The columns are flushed and cleaned.
10. The dry sample (Sr) is again dissolved with 1 mL of 2.5 M HCl and loaded into the columns again. In contrast to the other samples, carbonates have a higher calcium content. Therefore, they need to be cleaned up twice before they are loaded into the mass spectrometer.
11. The rest of the procedure is like that for other rock types.

REPORTING THE RESULTS OF SR ISOTOPIC ANALYSIS

Before reporting the results of the strontium isotopic analysis, they should first be corrected for mass fractionation to $^{88}Sr/^{86}Sr = 8.37521$. Also, the value of isotopic ratio ($^{88}Sr/^{86}Sr$) of the NBS (National Bureau of Standards) 987 Sr metal used as a reference by the spectrometer should be included in the report. Measured strontium isotopic values are expressed as both ratios (ratio of ^{87}Sr to ^{86}Sr) and standard delta notation ($\delta^{87}Sr$) relative to NBS standard 987. To calculate $\delta^{87}Sr$, the following formula is used:

$$\delta^{87}\mathrm{Sr} = \left[\frac{(^{87}\mathrm{Sr}/^{86}\mathrm{Sr})\mathrm{sample}}{(^{87}\mathrm{Sr}/^{86}\mathrm{Sr})\mathrm{seawater}} - 1\right] \times 10^5$$

where $(^{87}Sr/^{86}Sr)_{sample}$ is the measured ratio of $^{87}Sr/^{86}Sr$ in a sample that has been normalized to $^{86}Sr/^{88}Sr = 0.1194$ and $(^{87}Sr/^{86}Sr)_{seawater}$ is the ratio of $^{87}Sr/^{86}Sr$ in modern seawater which is about 0.709172 (9). In most analysis, the precision of the $^{87}Sr/^{86}Sr$ ratios is ±0.0001 or better, and higher precision is of little value because seasonal variations in $^{87}Sr/^{86}Sr$ ratios in rivers are commonly in the third figure (14).

In a majority of cases, the Sr isotopic composition of a water or rock sample is a mixture of two or more end members. To calculate the relative proportion of each end member of a two component mixture, the following equation applies:

$$(^{87}\mathrm{Sr}/^{\mathrm{total}}\mathrm{Sr})_\mathrm{m} = x(^{87}\mathrm{Sr}/^{\mathrm{total}}\mathrm{Sr})_\mathrm{a} + (1-x)(^{87}\mathrm{Sr}/^{\mathrm{total}}\mathrm{Sr})_\mathrm{b} \tag{1}$$

where the subscript "m" is mixture, "a" is the first end member, "b" is the second end member, x is the proportion of end member a, and $(1-x)$ is the proportion of end member b. To solve this equation, $^{87}Sr/^{total}Sr$ can be calculated from the equation given by (Reference 2) as follows:

$$^{87}\mathrm{Sr}/^{\mathrm{total}}\mathrm{Sr} = (^{87}\mathrm{Sr}/^{86}\mathrm{Sr})/(3 +^{87}\mathrm{Sr}/^{86}\mathrm{Sr}) \tag{2}$$

Example (from Reference 13). In Table 1, the isotopic composition of groundwater (GW) is considered a mixture of soil and rainwater isotopic compositions. The relative proportion of Sr from rainfall and soil to groundwater in Piezometer 40, P40, is computed here. In Equation 1, "m" = groundwater; "a" = rainfall; and "b" = soil; x = proportion of end member a, rainfall; and $1-x$ = proportion of end member b, soil. To calculate the proportion of each end member, first the $^{87}Sr/^{total}Sr$ ratio (Eq. 2) must be computed:

$$\begin{aligned}
^{87}\mathrm{Sr}/^{\mathrm{total}}\mathrm{Sr}\text{ for rainfall} &= (0.7089)/(3+0.7089)\\
&= 0.191135\\
^{87}\mathrm{Sr}/^{\mathrm{total}}\mathrm{Sr}\text{ for soil} &= (0.72068)/(3+0.72068)\\
&= 0.19368\\
^{87}\mathrm{Sr}/^{\mathrm{total}}\mathrm{Sr}\text{ for groundwater} &= (0.7105)/(3+0.7105)\\
&= 0.191091
\end{aligned}$$

Substituting these values in Eq. 1, the relative contribution of rainfall to the Sr budget of groundwater in P40 is calculated as 86%, and only 14% of the Sr is from soils.

Case Studies

Kazemi (13) and Kazemi and Milne-Home (15), through a strontium isotope study of rainwater, surface water, groundwater (shallow and deep), soil, and rocks of a salinized watershed in Eastern Australia (Buckinbah Creek watershed) found that the ratio of $^{87}Sr/^{86}Sr$ of shallow groundwater was similar to that of soil and

Table 1. The ^{87}Sr/^{86}Sr of Various Materials in the Buckinbah Creek Watershed in Eastern Australia[a]

rainwater (Table 1). They showed that between 20 to 90% of the Sr budget of shallow groundwater and surface waters is derived from rainwater. They further concluded that the deep groundwater is the source of baseflow at the watershed outlet (due to identical ^{87}Sr/^{86}Sr ratios of deep groundwater and baseflow).

Hunt et al. (6) used water and strontium isotopes to investigate the hydrology of a natural and a constructed wetland. They showed that the porewater from the natural wetland had a ^{87}Sr content ranging from 0.00 to 0.86 per mil (^{87}Sr/^{86} Sr $= 0.71026$ to 0.71087) and the ^{87}Sr of pore water from the constructed wetland ranged from -2.35 to $+1.24$ per mil (^{87}Sr/^{86} Sr $= 0.70859$ to 0.71114). They attributed this difference to the presence of a thick peat layer in the natural wetland.

The ^{87}Sr/^{86}Sr ratio of 32 brine samples from the Upper Jurassic Smackover Formation in southern Arkansas was measured at 0.7071–0.7101, more radiogenic than the Sr in Late Jurassic seawater because of the contribution of Sr from detrital sources (7).

The linear negative correlation between the Sr and ^{87}Sr/^{86}Sr ratio (when plotted against each other) has been used by Faure (3), Dogramaci et al. (16), and Singh et al. (17) as proof of the mixing of two waterbodies. Similarly, the negative correlation between the molar ratio of Mg/Ca and Sr isotopes is an indication of the incongruent dissolution of calcitic minerals in the aquifer (11). Incongruent dissolution of carbonates occurs progressively through two mechanisms:

1. Dissolution of calcitic minerals, causing the addition of Sr to groundwater and modification of the ^{87}Sr/^{86}Sr ratio; and
2. Reprecipitation of calcitic minerals, thereby removing some of the Sr from the groundwater without changing the Sr isotope ratio, approaching eventually the ratio in calcitic minerals (11).

A large data set of Sr isotopic ratios of the rivers of the Ganges, Orinoco, and Amazon basins is found in Palmer and Edmond (14).

The study by Lyons et al. (18) focuses on the strontium isotopic signature of some streams and lakes in Antarctica. They found that the ratios of ^{87}Sr/^{86}Sr of Lake Fryxell, Lake Hoare, and Lake Bonney were 0.70895, 0.71057, and 0.71187–0.71204, respectively. They also found that in Lake Fryxell and Lake Hoare, the ^{87}Sr/^{86}Sr became less radiogenic with depth, whereas in Lake Bonney, the ratios increase slightly with depth.

Sr isotopes together with isotopes of Nd and Pb of Cenozoic basalts in eastern Australia were studied by Zhang et al. (19) to show that the isotopic signatures of the Pacific Ocean midoceanic ridge basalts (MORB) type characterize the lava-field basalts in southeastern Australia, whereas the mantle isotopic signatures of Indian Ocean MORB type characterize younger basalts from northeastern Australia.

TECHNETIUM IN WATER

Jay Clausen
AMEC Earth and
Environmental, Inc.
Westford, Massachusetts

INTRODUCTION

Technetium, element 43, was predicted on the basis of its location in the periodic table. Technetium was erroneously reported as having been discovered in 1925 by Noddack and Tacke (1), who called it masurium. However, Element 43 was actually discovered in Italy (2). It was found in a sample of molybdenum, which had been bombarded with deuterons in the University of California—Berkeley cyclotron by E. Lawrence and then sent to Perrier and Segre. Technetium was the first element to be produced artificially.

Twenty-two isotopes of technetium whose masses range from 90 to 111 are known, and all are radioactive (Table 1). Technetium has three long-lived radioactive isotopes: technetium-97 [^{97}Tc] (half-life {$T_{1/2}$} $= 2.6 \times 10^6$ years), ^{98}Tc ($T_{1/2} = 4.2 \times 10^6$ years), and ^{99}Tc ($T_{1/2} = 2.13 \times 10^5$ years). An important isotope is ^{95m}Tc ("m" stands for metastable state) [$T_{1/2} = 61$ days], which is used in tracer work. However, the most useful isotope of technetium is ^{99m}Tc ($T_{1/2} = 6.01$ hours), which is used in many medical radioisotope tests because of its short half-life, easy detection of the gamma ray it emits, and the ability of technetium to bind chemically to many biologically active molecules.

Technetium-99 is a weak, beta-emitting radionuclide, 0.292 million-electron volts (MeV), produced during nuclear fission, which decays to the stable isotope ruthenium-99. It has a specific activity of 3.78×10^{10} transmutations per minute per gram, which corresponds to 17 microcuries per milligram (μCi/mg) (4). Technetium metal is a silver-gray color, tarnishes slowly in the air, and has properties similar to those of rhenium. However, as mentioned earlier, technetium does not occur naturally.

However, ^{99}Tc in terrestrial material has been evaluated since its discovery. In 1961, ^{99}Tc was isolated and identified in African pitchblende (a uranium-rich ore) in extremely minute quantities (5). It was theorized that ^{99}Tc was produced as a result of the spontaneous fission of uranium-238 (^{238}U).

Technetium-99 is produced primarily through anthropogenic processes such as detonation of nuclear weapons, reprocessing of spent nuclear reactor fuel rods containing uranium, and disposal of nuclear waste. Reprocessing involves dissolving the spent nuclear fuel in acid to separate the potentially reusable components of the spent fuel

Table 1. Isotopes, Half-Lives, and Decay Processes for Technetium[a]

Nuclide	Half-Life[b]	Type of Decay	Nuclide	Half-Life	Type of Decay
^{91}Tc	3.2 m	β^+, γ	^{99}Tc	2.13×10^5 y	B$^-$
^{92}Tc	4.4 m	β^+, γ	^{100}Tc	15.8 s	B$^-, \gamma$
^{93m}Tc	43.5 m	ε, γ	^{101}Tc	14 m	B$^-, \gamma$
^{93}Tc	2.7 h	$\varepsilon, \beta^+, \gamma$	^{102m}Tc	4.3 m	B$^-, \gamma$
^{94}Tc	53 m	β^+, γ	^{102}Tc	6.3 m	B$^-, \gamma$
^{94}Tc	4.9 h	$\varepsilon, \beta^+, \gamma$	^{103}Tc	50 s	B$^-, \gamma$
^{95m}Tc	60 d	$\varepsilon, \beta^+, \gamma$	^{104}Tc	18.0 m	B$^-, \gamma$
^{95}Tc	20 h	ε, γ	^{105}Tc	7.6 m	B$^-, \gamma$

(the uranium and plutonium) from the waste component (the fission products). The fission products, which are of no use, must be disposed of properly. In a 1000-megawatt nuclear reactor (thermal fission yield of approximately 6%), approximately 28 g of ^{99}Tc is produced daily from the slow neutron-induced fission of ^{235}U or plutonium-239 [^{239} Pu] (6). The long half-life and mobility of ^{99}Tc makes it an important element to the nuclear fuel industry in terms of its potential environmental impact. This is a particular concern for designing underground nuclear waste storage facilities because ^{99}Tc is the most mobile of all radionuclides present.

There are no known uses of technetium other than ^{99m}Tc for medical purposes. Technetium has superconducting properties and is a good corrosion preventer (7). However, its unstable nature and production of radioactive particles negate its practical use.

ANALYSIS

Analysis for ^{99}Tc typically consists of methyl ethyl ketone (MEK) extraction followed by liquid scintillation counting using United States Environmental Protection Agency (USEPA) Method 900.0. The typical quantification limit is 1 becquerel per liter (Bq/L), which is equivalent to 25 picocuries per liter (pCi/L).

Chemistry

The oxidation states most commonly found for ^{99}Tc are Tc^0, Tc^{+4}, and Tc^{+7}. The most stable chemical species of ^{99}Tc in aqueous solutions is the pertechnetate anion, TcO_4^-, in the Tc^{+7} valence state, which is highly mobile and nonreactive (8–12). However, ^{99}Tc is very sensitive to changes in redox conditions (13). Under reducing conditions, ^{99}Tc can be precipitated by various cations to form anhydrous technetium dioxide, TcO_2, (as Tc^{+4}) or technetium heptoxide, Tc_2O_7, or other insoluble oxides and hydroxides such as Tc_2S_7 or TcS_2 or incorporated into minerals (14–17):

$$TcO_4^- + 4H^+ + 3e^- = TcO_2 + 2H_2O;\ E_0 = +0.738 \text{ volts} \tag{1}$$

In the presence of oxygen, the Tc^{+4} oxide or oxyhydroxide can be reoxidized (14,18):

$$[TcO_{2\,(s)} \text{ or } TcO(OH_{2\,(s)}] \rightarrow TcO_4^- \tag{2}$$

The pertechnetate anion also forms complexes with organic compounds containing –C –O and –COO functional groups, especially under reducing conditions. The thermodynamic data for technetium (Table 2) can be used to develop a phase diagram to identify which species are likely to be present at a given set of E_h and pH conditions (Fig. 1).

The pertechnetate ion is mobile under oxidizing conditions (Fig. 1). Bidoglio et al. (20,21) found in column experiments that the oxidized species persists, even under slightly reducing or anoxic conditions. Technetium can undergo a number of surface reactions on various minerals under reduced conditions.

Table 2. Thermodynamic Data for Technetium[a]

Species[b]	$\Delta G^0{}_f$ kcal/gfw[c]
$TcOH_{(s)}$	−56.1
$Tc(OH)_{2\ (s)}$	−110.2
$Tc_3O_{4\ (s)}$	−206.3
$TcO_{4\ (s)}{}^-$	−149.1
$TcS_{2\ (s)}$	−51.0
$TcO_{2\ (s)}$	−88.3

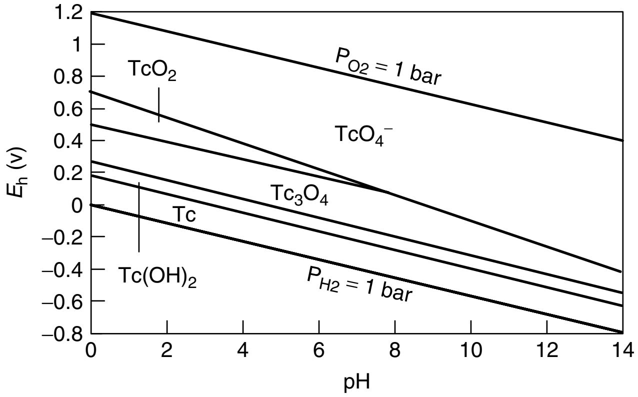

Figure 1. E_h-pH diagram for the Tc–O–H system at a concentration of 90 μg/L under standard temperature and pressure.

The solubility of sodium pertechnetate is reportedly 11 moles per liter [mol/L] (13). The solubility of ^{99}Tc in a reducing environment varies from 1.32×10^{-8} to 2.56×10^{-9} mol/L and is controlled by the Tc species present (14). Redox thus is a key variable affecting solubility (8). The solubility of technetium under reducing conditions in carbonate groundwater is pH dependent. At pH levels between 5 and 7.5, the solubility of Tc^{+4} is less than 10^{-8} mol/L. Pilkington (22) suggests that the solubility of TcO_2 is closer to 10^{-7} mol/L under reducing conditions. At higher pHs of 8 to 11, solubility increases, and the dominant ionic complex is $TcO(OH)_3CO^-{}_3$.

Equally important are the fate-and-transport properties of ^{99}Tc. Under aerobic soil conditions, ^{99}Tc behaves as an inert tracer and readily passes through soil unless there is a high content of organic matter or metal oxide (10,23–30). As Gu and Dowlen (31) report, this is not surprising because soil mineral surfaces are negatively charged as is TcO_4^- and therefore the two repel each other. Once introduced to surface water or groundwater, it can be transported significant distances due to its recalcitrant nature and lack of sorption. Given the concern over ^{99}Tc mobility, extensive studies have been conducted in various geologic media to assess suitable nuclear waste disposal storage facilities. Adsorption coefficients for various minerals are presented in Sheppard et al. (23), Wildung et al. (27), Palmer and Meyer (32), and

Strickert et al. (33). Sheppard et al. (23) indicate that soil redox conditions and organic matter content are the key variables influencing ^{99}Tc mobility in soil.

REGULATORY STANDARDS

The USEPA has set an effective dose equivalent of 4 millirem (mrem)/year for exposure, which they incorrectly calculated as 900 pCi/L (36 Bq/L). The correct activity equivalent to 4 mrem/year is 3790 pCi/L [152 Bq/L] (34). The U. S. Department of Energy (DOE) Order 5400.5 sets a permissible ingested-water limit of 100 mrem/year or 100,000 pCi/L (4000 Bq/L), whereas the U. S. Nuclear Regulatory Agency (NRC) has set a value of 50 mrem/year or 60,000 pCi/L (2400 Bq/L). The NRC has set the maximum activity of ^{99}Tc that can be released to a sanitary sewer at 500 mrem/year or 600,000 pCi/L (24,000 Bq/L). The proposed action level for groundwater cleanup at the Paducah Gaseous Diffusion Plant (PGDP) site is 25 pCi/L (1 Bq/L), which is the quantification limit.

Rainwater

Technetium has been released to the atmosphere in the form of Tc_2O_7 and $HTcO_4$ as a consequence of aboveground detonation of nuclear weapons through the fission of ^{235}U and ^{239}Pu. The nuclear industry also releases TcF_6 in addition to Tc_2O_7 and $HTcO_4$ during uranium enrichment. During a nuclear detonation, elemental ^{99}Tc burns to form Tc_2O_7, which upon cooling and contact with water vapor forms $HTcO_4$. The activity of ^{99}Tc measured in rainwater reportedly ranges from 8.2×10^{-8} to 1.0×10^{-6} μg/L (35,36). Work by Leon (37) and Attrep et al. (36) suggest the concentration of ^{99}Tc in rainwater has increased from the early 1960s through the 1980s. Both papers suggest that the source of this increase in ^{99}Tc in rainwater is from the reprocessing of spent nuclear fuel rather than nuclear weapons testing.

Surface Water

Technetium-99 is a surface water and groundwater contaminant at a number of DOE sites such as the PGDP in Paducah, Kentucky; the Portsmouth Gaseous Diffusion Plant in Piketon, Ohio; Oak Ridge National Laboratory Y-12 Plant, Savannah River Laboratory in Aiken, South Carolina; the Pacific Northwest National Laboratory 200 west area; and the Nevada Test Site (30,38–40).

Currently, the largest annual release of ^{99}Tc to the environment occurs at the two nuclear fuel-reprocessing facilities in Sellafield, United Kingdom. Technetium-99 laden effluent water from these facilities is discharged directly into the Irish Sea.

Contamination has been detected as far west as Svalbard and along the Norwegian coastline, distances of several hundred miles. The total discharge from these two plants amounts to between 70 and 90 tera (TBq)/year of ^{99}Tc (41).

Techentium-99 is reported in the Savannah River as a result of discharges from the U. S. Department of Energy Savannah River Plant located near Aiken, South Carolina (42,43). Technetium-99 is present at Oak Ridge National Laboratory where radioactive liquids generated from routine operations were disposed of in shallow waste pits (44). Nearby seeps have ^{99}Tc activity levels of up to 1185 pCi/L [3,200 Bq/L].

Blaylock and Frank (45) conducted a study in which TcO_4^- was added to a freshwater pond. Their study indicated that 84% of the TcO_4^- added remained in solution; very little was taken up by biota or by settling out into sediments. The vast majority of the ^{99}Tc was removed through drainage, indicating that the ultimate reservoir for technetium released into the environment is the ocean. Similarly, in a study of the Rhone River, it was found that the ^{99}Tc activity varied from 2.5 to 53×10^{-3} pCi/L (0.1 to 2.1×10^{-3} Bq/L) in seven samples collected in 1985 and 1986 (46).

Finally, significant quantities of ^{99}Tc laden effluent water were released to a settling lagoon as well as to several small streams surrounding the PGDP. Activity levels as high as 100,000 pCi/L (4000 Bq/L) were routinely released to surface water. Ferrous iron sulfate was used to precipitate metals in the lagoon before discharge into a nearby stream. The addition of this material shifted the redox state of the lagoon such that TcO_4^- was precipitated from solution. The likely form of the technetium precipitate was Tc_2S_7. In addition, the iron-rich clay and organic-rich stream sediments retained much of the ^{99}Tc, limiting its downgradient migration from the lagoon. Therefore, the ^{99}Tc migrated only several thousand feet from the point of release. However, downgradient of the site, groundwater discharges to the surface water streams and ^{99}Tc-rich water has been measured in several seeps (47).

Ground Water

The most extensive groundwater distribution of ^{99}Tc is at the PGDP where a 2-$\frac{1}{2}$ mile long plume of ^{99}Tc contaminated groundwater is commingled with the solvent trichloroethene. The ^{99}Tc was introduced to the site during the 1970s when fissioned uranium was reprocessed. ^{99}Tc became entrained in processing equipment at the PGDP, which was later cleaned with organic solvents and released to the environment. Gu et al. (48) determined conclusively that the species of ^{99}Tc mobile in groundwater at the PGDP was the pertechnetate anion, TcO_4^-. This later was supported through the development of phase diagrams using site-specific E_h and pH groundwater data (38,39). In addition, Gu and Dowlen (31) and Gu et al. (48) conclusively ruled out colloidal and natural organic matter facilitated transport as viable mechanisms of ^{99}Tc mobilization. Previous studies of PGDP, other sites, and laboratory studies assumed that TcO_4^- was the form of ^{99}Tc in most environmental settings. The estimated partitioning coefficient of ^{99}Tc exceeded 27,000 milliliter per gram [mL/g] (48). Technetium-99 activities as high as 179 Bq/L (4800 pCi/L) were observed in the groundwater plume (38,39). The estimated mass of ^{99}Tc dissolved in the groundwater plume was 4 to 6 lb, which equates to an activity of 1.0 to 1.6×10^{12} Bq/L (28 to 42×10^{12} pCi) of ^{99}Tc.

At the Hanford Site in Washington, ^{99}Tc has been found in groundwater in the Hanford 200 West Area where spent nuclear fuel was reprocessed and then the waste material was stored in underground tanks (30). Technetium-99 levels between 900 and 27,000 pCi/L (36 and 1080 Bq/L) have been found in groundwater.

Technetium-99 activity in shallow groundwater at the Portsmouth Gaseous Diffusion Plant has been observed at the 1000 pCi/L (40 Bq/L) level (49). The causes of contamination are similar to those discussed for the Paducah site. However, because the Portsmouth site received feed material from the Paducah site, the quantity of ^{99}Tc introduced into the site was much lower.

A unique study was conducted by the Lawrence Livermore National Laboratory at the Nevada Test site to assess the distribution of radionuclides in caverns produced by underground nuclear testing. The work by Buddemeier et al. (50) and Schroeder et al. (40) found that ^{99}Tc was present in groundwater associated with two separate nuclear weapons tests. The ^{99}Tc appeared to be associated and transported with colloidal material, but its mobility was reduced upon contact with zones of high levels of iron oxyhydroxides.

There are several known nongovernmental sites containing ^{99}Tc. One such facility is the Fields Brook National Priority Listed (NPL) site in Ashtabula, Ohio. The site was formerly a storage site for liquid waste, which contained ^{99}Tc as well as other radionuclides and solvents. Technetium-99 activities as high as 100,000 pCi/L (4000 Bq/L) have been detected in groundwater. A second site is the uranium fuel plant in Hematite, Montana. Recycled uranium, containing ^{99}Tc, was used to fabricate metallic fuel rods. Low-levels of ^{99}Tc have been observed in groundwater.

REMEDIATION

The technologies explored for remediating ^{99}Tc in water include ion exchange, liquid–liquid extraction, precipitation with various forms of iron, redox manipulation, the FORAGER sponge, granular activated carbon (GAC), and natural attenuation (10,16,18,31–33,48,51–65). The report by Bostick et al. (53) provides an excellent reference list of the many studies conducted on ^{99}Tc removal from aqueous waste streams. At the Portsmouth and Paducah Gaseous Diffusion plants, ion exchange is being used for treating ^{99}Tc-contaminated groundwater. Although, Gu et al. (31) found that GAC was superior to ion exchange due to its low cost, efficiency, and sorption capacity, GAC has not been employed at these sites.

CONCLUSION

Technetium is an element not typically found in nature and has environmental consequence at facilities that enrich or reprocess uranium fissioned material. These facilities are typically government operated. The high solubility of TcO_4^- and its stability across a wide spectrum of redox conditions enables the ion to be extremely mobile once introduced into water. As a consequence, at the few sites where ^{99}Tc has been introduced into the natural environment, it has produced very large plumes of contaminated surface and groundwater.

WATER—NATURE'S MAGICIAN

Environment Canada

Water is the solvent, the medium and the participant in most of the chemical reactions occurring in our environment.

Water is at once simple and complex. A water molecule itself is simple, made up of three atoms: two hydrogen and one oxygen, H_20. The configuration of these building blocks produces a molecule with almost magical properties.

WATER—VISIBLE AND INVISIBLE

On earth, water is found as a liquid, as a solid (ice) or as a gas (water vapour).

- Canada has about 7% of the world's renewable freshwater supply, compared with 18% for Brazil, 9% for China, and 8% for the United States.
- The ice we skate on in winter is water in its *solid* form. Unlike most substances, which are densest in their solid state, ice is less dense than water and thus floats. If this were not the case, lakes and rivers would freeze from the bottom up. Fish could not survive, and it is unlikely that rivers and lakes in northern countries would ever completely thaw.
- Water vapour forms a kind of global "blanket" which helps to keep the earth warm. Heat radiated from the sun-warmed surface of the earth is absorbed and held by the vapour.

WATER'S MAGICAL PROPERTIES

Water molecules are attracted to each other, creating *hydrogen bonds*. These strong bonds determine almost every physical property of water and many of its chemical properties too.

Boiling and Freezing

Pure water at sea level boils at 100 °C and freezes at 0 °C. At higher elevations (lower atmospheric pressures) water's boiling temperature decreases. This is why it takes longer to boil an egg at higher altitudes. The temperature does not get high enough to cook the egg properly. If a substance is dissolved in water, then the freezing point is lowered. That is why we spread salt on streets in winter to prevent ice formation.

Thermal Properties

Water absorbs or releases more heat than many substances for each degree of temperature increase or

---

This article is produced by Environment Canada and is reproduced with permission.

decrease. Because of this, it is widely used for cooling and for transferring heat in thermal and chemical processes.

Differences in temperature between lakes and rivers and the surrounding air may have a variety of effects. For example, local fog or mist is likely to occur if a lake cools the surrounding air enough to cause saturation; consequently small water droplets are suspended in the air

Large bodies of water, such as the oceans or the Great Lakes, have a profound influence on climate. They are the world's great heat reservoirs and heat exchangers and the source of much of the moisture that falls as rain and snow over adjacent land masses.

When water is colder than the air, precipitation is curbed, winds are reduced, and fog banks are formed.

Surface Tension

Surface tension is a measure of the strength of the water's surface film. The attraction between the water molecules creates a strong film, which among other common liquids is only surpassed by that of mercury.

This surface tension permits water to hold up substances heavier and denser than itself. A steel needle carefully placed on the surface of a glass of water will float. Some aquatic insects such as the water strider rely on surface tension to walk on water.

Surface tension is essential for the transfer of energy from wind to water to create waves. Waves are necessary for rapid oxygen diffusion in lakes and seas.

Molecules in Motion

Water molecules as well as binding to each other, bind to many other substances such as glass, cotton, plant tissues, and soils. This is called adhesion. For example, in a thin glass tube, when the molecules at the edge reach for and adhere to the molecules of glass just above them, they at the same time tow other water molecules along with them. The water surface, in turn, pulls the entire body of water to a new level until the downward force of gravity is too great to be overcome. This process is called *capillary action*.

Thus water readily wets many materials. Capillary action allows a paper towel or a sponge to be used to soak up spilled water. Without this property, the nutrients needed by plants and trees would remain in the soil.

The Universal Solvent

An extraordinary property of water is its ability to dissolve other substances. There is hardly a substance known which has not been identified in solution in the earth's waters. Were it not for the solvent property of water, life could not exist because water transfers nutrients vital to life in animals and plants.

A drop of rain water falling through the air dissolves atmospheric gases. When rain reaches the earth, it affects the quality of the land, lakes and rivers.

Did You Know

- Raindrops are not tear-shaped. Scientists, using high-speed cameras, have discovered that raindrops resemble the shape of a small hamburger bun.
- About 70% of the human body is water.
- Life on earth probably originated in water.
- More than half of the world's animal and plant species live in the water.
- Almost 75% of the earth is covered in water.
- The human body needs 2 liters of water a day in our climate; we can last only a few days without water.
- Most of our food is water: tomatoes (95%), spinach (91%), milk (90%), apples (85%), potatoes (80%), beef (61%), hot dogs (56%).

THE SUN-POWERED CYCLE

The endless circulation of water from the atmosphere to the earth and its return to the atmosphere through condensation, precipitation, evaporation and transpiration is called the hydrologic cycle.

Heating of the ocean water by the sun is the key process that keeps the hydrologic cycle in motion. Water evaporates, then falls as precipitation in the form of rain, hail, snow, sleet, drizzle or fog. On its way to earth some precipitation may evaporate or, when it falls over land, be intercepted by vegetation before reaching the ground. The cycle continues in three different ways:

- *Evaporation/Transpiration*— On average, as much as 40% of precipitation in Canada is evaporated or transpired.
- *Percolation Into the Ground*— Water moves downward through cracks and pores in soil and rocks to the water table. Water can move back up by capillary action or it can move vertically or horizontally under the earth's surface until it re-enters a surface water system.
- *Surface Runoff*— Water runs overland into nearby streams and lakes; the steeper the land and the less porous the soil, the greater the runoff. Overland flow is particularly visible in urban areas. Rivers join each other and eventually form one major river that carries all of the subbasins' runoff into the ocean.

Although the hydrologic cycle balances what goes up with what comes down, one phase of the cycle is "frozen" in the colder regions during the winter season. During the Canadian winter, for example, most of the precipitation is simply stored as snow or ice on the ground. Later, during the spring melt, huge quantities of water are released quickly, which results in heavy spring runoff and flooding.

Note: A resource guide, entitled Let's Not Take Water For Granted, is available to help classroom teachers of grades 5–7 use the information from the Water Fact Sheets.

FREEZING AND SUPERCOOLING OF WATER

Karl Erik Zachariassen
Norwegian University of
Science and Technology
Trondheim, Norway

Water in the crystalline solid state is known as ice, and for pure water at normal atmospheric pressure, ice is the physically stable form at temperatures below 0 °C.

Ice has a specific gravity of 0.92 g/ml, which is about 8% below the corresponding value of water, reflecting the fact that water expands by about 8% when it enters the solid state. The specific heat capacity of ice is 0.502 cal/g.deg, which is about half the corresponding value of water. The amount of heat liberated during the solidification (heat of fusion) is 79.71 cal/g.

The transition of water from the liquid to the solid state is known as freezing, and pure water has a so-called freezing point of 0 °C, which does not imply that pure water will freeze when cooled to this temperature. A small sample of pure water can be cooled to as much as −40 °C before it freezes spontaneously. For this reason, the term freezing point is misleading, and it is often replaced by the more precise terms *melting point* or *equilibrium freezing point*.

A substance that exists in the liquid state at a temperature below the equilibrium freezing point is said to be *supercooled* or *undercooled*, and the temperature where freezing is initiated is referred to as the *supercooling point* or the *temperature of crystallization*.

When a sample of supercooled water freezes, the released heat of fusion will immediately heat the system to the melting point. As a result of the high heat of fusion of water, the melting point temperature will be reached following the freezing of only a small fraction of the sample. From this point, the freezing can proceed only as fast as the released heat of fusion can be removed from the system. When pure water freezes, the temperature will remain at 0 °C until all water is frozen.

Initiation of freezing requires that the water sample contains an ice-like structure, which can act as a nucleus for ice formation, from which ice can grow. Liquid water is assumed to contain aggregates of water molecules organized in an ice-like pattern, but which usually are too unstable to act as nucleators. As the temperature drops, these aggregates become more stable and increase in size. On sufficient cooling, one of these aggregates will eventually reach the size critical for ice nucleation, and freezing will be initiated from this aggregate. When nucleation is initiated in this manner from the water molecules themselves, it is known as *homogeneous* nucleation.

Water samples often contain other substances that organize water molecules in an ice-like pattern and that cause freezing to be initiated at a higher temperature than would otherwise be the case. Such substances are known as *ice nucleators,* and freezing catalyzed by an ice nucleator is referred to as *heterogeneous freezing*. Ice nucleator activity is seen in various types of crystals and dust particles, and biological organisms may synthesize nucleating lipoproteins, which are physiologically important as ice nucleators, and which may have a high nucleating activity. Certain bacteria produce ice nucleators that can nucleate ice formations at above −1 °C.

FACTORS AFFECTING FREEZING

The equilibrium freezing point is influenced by factors such as solute concentration (Fig. 1) and hydrostatic pressure (Fig. 2). The osmolal melting point depression is 1.86 °C/Osm, whereas pressure depresses melting points by about 1 °C/100 bar.

The effect of these parameters on supercooling points depends on whether nucleation is homogeneous or heterogeneous. Homogeneous nucleation temperature is depressed 1.5–3 times more than melting points by increased osmolality and pressure, whereas, at least for the more active nucleators, nucleation temperature depression seems to be strictly equivalent to the corresponding melting point depression.

Nucleation temperature of purified water samples (no potent ice nucleators) also depends on sample volume as shown by Bigg in 1953 (1) (Fig. 3). When potent ice nucleators are present, the nucleation temperature depends only on the activity of the most active nucleator, and it does not matter if this nucleator occurs in a large or small water volume.

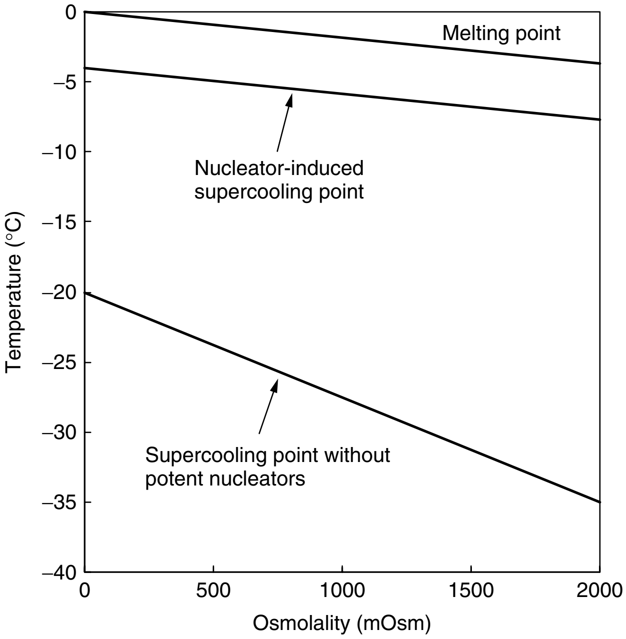

Figure 1.

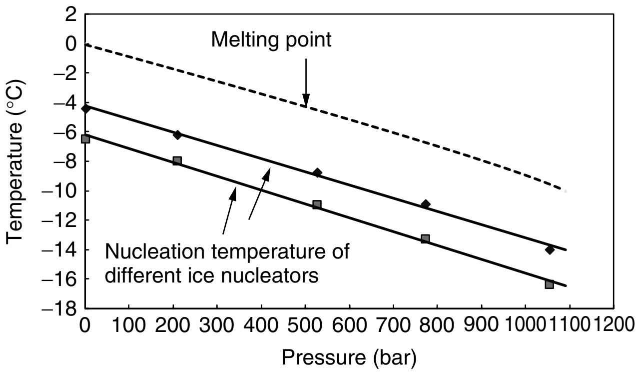

Figure 2.

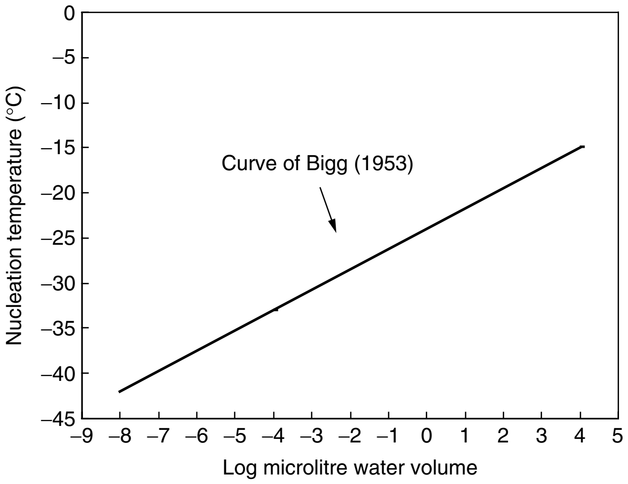

Figure 3.

FREEZING OF SOLUTIONS

When a solution freezes, the solutes are not incorporated in the ice structure, but remain in the liquid fraction surrounding the ice. Here, they become concentrated precisely until the solution reaches a melting point equal to the actual temperature. In this situation, vapor pressure equilibrium will exist between the solution and the ice, and no further freezing will occur until the released heat of fusion is removed from the system. As the heat is removed and the freezing proceeds, a gradual reduction of the temperature of the system will occur as the fluid fraction becomes more concentrated and the melting temperature of the fluid fraction drops. The solute concentration will increase until the eutectic point is reached. At the eutectic point, water and solutes freeze together.

CHEMICAL PRECIPITATION

Bradley A. Striebig
Gonzaga University
Spokane, Washington

Chemical precipitation is the removal of dissolved and suspended solids from aqueous solutions through chemical means. Chemical precipitation includes the removal of dissolved solids by altering the aqueous chemistry to make the dissolved solids less soluble. It also includes removing suspended solids by increasing their size in a process referred to as chemical flocculation. The larger the particle size of the suspended solids, the easier it is to remove them, usually through gravimetric settling in a process called clarification.

USES OF CHEMICAL PRECIPITATION

Chemical precipitation processes are utilized in water and wastewater treatment due to their effectiveness for pollutant removal with relatively low capital investment. The chemical reaction rates are typically very fast compared to biological reactions, so residence times in treatment processes or the reactor size may be significantly smaller than in other treatment techniques. Chemical precipitation processes can also process very toxic wastewaters. However, chemical precipitation processes often require the on-going addition of chemicals to control the pH and polymers to increase the size of the particles. The residuals collected from chemical precipitation processes may also be quite toxic and expensive to dispose of as sludge. Chemical precipitation is an effective tool for water treatment, and the most common uses are briefly described.

Industrial wastewaters often require pretreatment before being released to the sewer or receiving waters. High strength industrial wastewaters, such as those used in electroplating, contain high concentrations of dissolved metals. These metals can be removed from the wastewater by altering the pH of the water to reduce the solubility of the metal ions. The insoluble fractions of the metal ions form solid particles or precipitates, which are removed through filtration or gravimetric clarification. This allows industrial wastewaters to significantly reduce their metals concentrations in order to meet RCRA standards and also reduce the toxicity of the wastewater.

Municipal wastewaters may contain dissolved ions and a large amount of cell mass from biological treatment processes. The focus of chemical precipitation on municipal wastewaters is to remove the cell mass or suspended solids prior to and after biological treatment. The suspended solids are removed by adding chemical polymers, which attach to the existing suspended solids and help combine the individual particles into larger particles called flocs. This process, called coagulation, is accomplished by the chemical destabilization of particles and the subsequent aggregation. The process of gentle mixing and increasing the size of the suspended solids particles is called flocculation. The large floc particles are removed through gravimetric settling in a process called clarification. Thus a large fraction of the suspended solids and also the remaining BOD (in the form of cell mass) can be removed with the aid of chemical precipitation. Chemical precipitation is also commonly used when phosphorus removal is required at municipal wastewater treatment plants.

Industrial process water and recycled wastewater use chemical precipitation to remove hardness and dissolved salts from water. This allows a higher quality of water needed for specific industrial processes. The limits of hardness and salt removal are governed by the solubility of the dissolved ions in solution. Therefore, chemical precipitation has limited uses in industries that require highly purified water. However, chemical precipitation can be used as an inexpensive pretreatment step prior to ion exchange or reverse osmosis processes, which produce very high-quality water.

DISSOLVED SOLIDS

Dissolved solids are defined as the solid residuals in water that pass through a filter with a nominal pore size of 2.0 μm. These solids include dissolved ions and small colloidal solids. The dissolved ions in solution can be predicted based on the solubility product constant for the dissolved species. The solubility product constant, or solubility product, is an equilibrium constant that describes the reaction by which ions dissolve and solids precipitate:

$$A_zB_{y(s)} \rightleftharpoons zA^{y+} + yB^{z-}$$

For ions A and B, the generic equilibrium constant is

$$K_s = \frac{\{A^{y+}\}^z\{B^{z-}\}^y}{\{A_zB_y\}_{(s)}}$$

Many salts will form and precipitate as either hydroxides, with the hydroxide ion (OH^-), or carbonates, with the carbonate ion ($CO_3{}^{2-}$). The concentration of these ions can often be predicted through an equilibrium analysis with the aid of electron or pH diagrams. Since the activity of the solid substance is defined as 1, and the solubility product is a constant value, the activity of the anion of interest (A) can be predicted in the aqueous solution of interest. Solubility constants for a wide array of dissolved ions of interest in water and wastewater are found in the referenced literature (1–3).

In a dilute solution under ideal conditions the activity of the ions of interest can be closely approximated by their concentration:

$$\{A\} \approx [A]$$

However, many wastewaters have high concentrations of dissolved ions and do not behave ideally. An activity coefficient, γ_A, must be used to establish an accurate relationship between the activity of a compound in solution and the concentration:

$$\{A\} \approx \gamma_A[A]$$

The activity coefficient can be estimated from the ionic strength of the solution. The ionic strength is also commonly estimated from measurements of the total dissolved solids (TDS) and the electrical conductivity:

Langelier approximation $I = 2.5 \times 10^{-5}$ (TDS)[mg/L]
Russell approximation $I = 1.6 \times 10^{-5}$(conductivity) [μ mho]

One estimate of the activity coefficient is the Debye–Hückel limiting law for solutions with ionic strength less than 0.005 mol/L ($I < 0.005\,M$):

$$\gamma_A \cong -Az^2I^{1/2}$$

where A is a function of the dielectric constant of the solution. For water at 25 °C, $A = 0.51$. The term z is the ionic charge of the ion of interest. For more concentrated solutions ($I > 0.005\,M$), other estimates for the activity coefficient, such as the extended Debye–Hückel model and the Davies approximation can be used.

The potential to precipitate multiple ions from solution can be approximated from the activity of the ions in solution and the solubility product. Often, the pH of the solution is used as a “master variable.” Solids lines on a graph of this type indicate the solids equilibrium concentration. For most hydroxide species, a minimum soluble concentration appears between a pH of 8 and 12. Similar graphical representations can be made for sulfide and carbonate species. This minimum solubility can serve as a starting point for estimating and optimizing chemical precipitation of various ions in solution.

The removal of hexavalent chromium (Cr^{6+}) from solution is one illustration of the potential of chemical precipitation processes to reduce the toxicity of wastewater. Hexavalent chromium can be converted to the less toxic trivalent form by reaction at low pH with a reducing agent such as ferrous bisulfite. Figure 1 shows a solution containing hexavalent chromium, which when dissolved in water results in a yellow color. Figure 2 shows the change in color associated with the change in the oxidation state of the chromium from the 6+ state to the 3+ state. When the pH of the solution is raised to 8 or 9, the trivalent chrome becomes much less soluble in solution than the hexavalent form of chromium as shown in Fig. 3. The resulting solids precipitate out of solution to form a concentrated sludge as shown in Fig. 4.

SUSPENDED SOLIDS

Suspended solids are composed of floating matter, settleable matter, and large colloidal matter. This matter

Figure 1. Hexavalent chromium dissolved in water.

Figure 2. Reduction of hexavalent chromium to trivalent chromium.

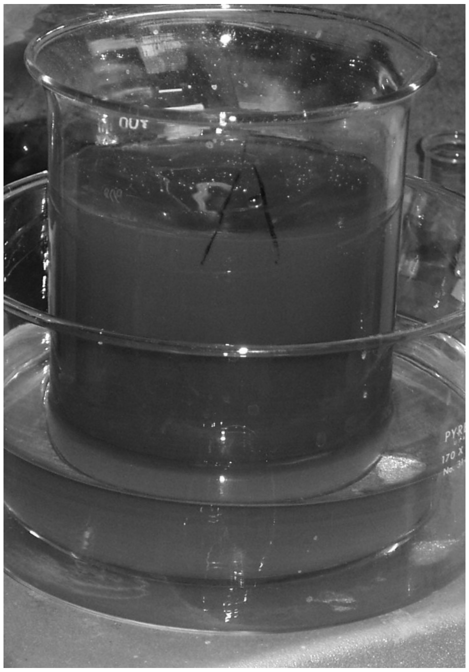

Figure 3. Formation of insoluble chromium oxide salts.

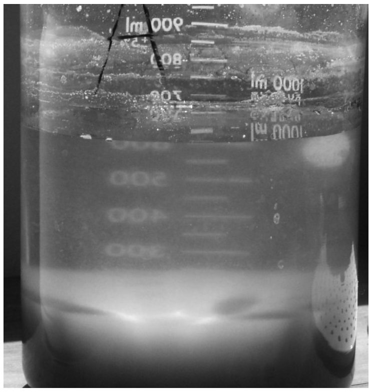

Figure 4. Precipitation of solid insoluble chromium into a sludge blanket.

may be organic or inorganic in nature. In municipal wastewater treatment plants, a significant fraction of the suspended solids consist of biological cell mass. The amount of suspended solids in water is an important parameter in determining water quality. Suspended solids are typically removed through a process of coagulation, flocculation, and gravimetric settling (or clarification). Chemical precipitation or coagulation of the suspended particles involves the destabilization of colloidal particles. Coagulation is usually followed by flocculation, which is the addition of a chemical, typically an organic polymer, to increase particle aggregation.

Suspended solids in water often have a charge that acts at the surface of the particle. Oil droplets, gas bubbles, and other inert substances may have a negative charge due to the preferential absorption of anions. Cellular materials such as microorganisms and proteins develop a charge through the ionization of carboxyl and amino acids functional groups. These charges create a force or zeta potential around the particles, which prevent them from increasing in size through aggregation as illustrated in Fig. 5. Coagulants are added to overcome these surface forces by the addition of potential determining ions or electrolytes. Once these charges have been neutralized, flocculants can be added to increase the speed of aggregation (Fig. 6).

Flocculant polymers that are anionic and nonionic become attached to the particles. These long particles increase the rate of aggregation and become intertwined

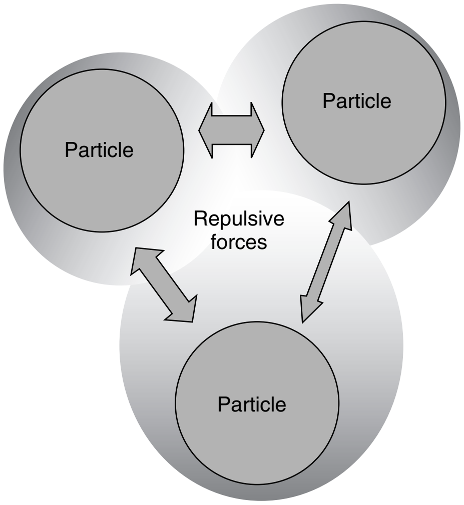

Figure 5. Repulsive forces acting on the surface of suspended particles.

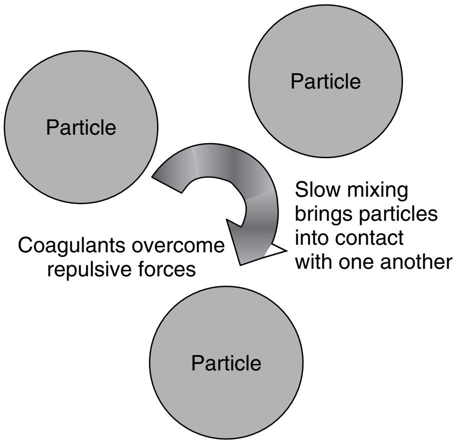

Figure 6. Chemical coagulants overcome repulsive forces and the solution is mixed.

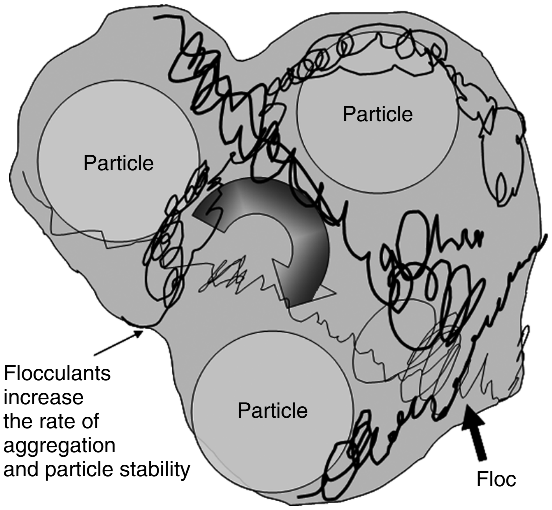

Figure 7. Flocculants increase the rate of aggregation to form large flocs.

during flocculation. This results in a significant increase in the particle size and mass (Fig. 7). The large particles called flocs are stabilized by the polymers, which prevent them from breaking up during the mixing process. The large flocs can then be removed with gravimetric settling in the clarification process. The resultant solids collected in the clarifier are the wastewater solids, or sludge.

Chemical precipitation by coagulation and flocculation has been used in the past to enhance removal of suspended solids and BOD. These processes are widely used to improve the performance of primary clarifiers, in basic physical–chemical processing of industrial wastewaters, for phosphorus removal, and for heavy metal removal.

ANTIMONY IN AQUATIC SYSTEMS

Montserrat Filella
University of Geneva
Geneva, Switzerland

INTRODUCTION

Antimony is a naturally occurring element. It belongs to group 15 of the periodic table of the elements. Antimony can exist in a variety of oxidation states (−III, 0, III, V) but it is mainly found in two oxidation states (III and V) in environmental, biological, and geochemical samples. Although antimony was already known to the ancients, it is still often overlooked, both as an element of environmental concern and as a subject for study, probably because of its lower abundance and the relative insolubility of most of its compounds. This is reflected in the poor standard of existing data on the behavior of antimony in natural waters. However, interest in the study of this element seems to be growing and an increasing number of papers on the subject are being published. A useful series of comprehensive reviews on antimony in the environment has recently been published (1,2).

Antimony has no known biological function and, like arsenic, is toxic. Trivalent species are reported to be more toxic than pentavalent forms (3). The U.S. Environmental Protection Agency (EPA) (4) and the Commission of the European Communities (5) both consider antimony and its compounds to be pollutants of prime interest. The U.S. EPA drinking water standards are: MCLG (maximum contaminant level goal) and MCL (maximum contaminant level), both 6 μg/L (6). The European Union's maximum admissible concentration of antimony in drinking water is 5 μg/L (7). Antimony is on the list of hazardous substances under the Basel convention on the restriction of the transfer of hazardous waste across borders (8).

ABUNDANCE

The relative abundance of antimony in different systems is shown in Table 1. According to Goldschmidt's classification, antimony is a strong chalcophile element of which the most common natural form is the sulfide mineral stibnite, Sb_2S_3. Antimony is occasionally found as a native metal or as an intermediate compound with arsenic. More than 113 different sulfide, antimonide, arsenide, and telluride minerals have been identified. Sulfosalts represent the most common antimony-bearing minerals, usually in some combination with silver, copper, arsenic, mercury, and lead. More than 35 oxide, hydroxide, and oxyhalide mineral species are known. Antimony is also found in seven silicate minerals, all of which are rare (9). Antimony is also a common component of coal and petroleum.

Antimony is present in the aquatic environment as a result of rock weathering, soil runoff, and anthropogenic activities. Typically, concentrations of dissolved antimony in unpolluted waters are less than 1 μg/L. The mean antimony concentration in surface marine waters is 184 ± 45 ng/L (1). However, in the proximity of anthropogenic sources, concentrations can reach up to 100 times natural levels.

Airborne supply to aquatic and terrestrial systems is important for the environmental fate of antimony in systems located far from direct sources of pollution. Atmospheric emission values for antimony are shown in Table 2. The values in this table should be viewed with some caution because the data used comes from relatively old studies. For instance, antimony production was considered to be only 80,000 metric tons/yr (142,000 metric tons in 2003) and, more importantly, the uses of antimony have changed significantly over the past few years. Pacyna and Pacyna (15) estimated natural and anthropogenic emissions into the atmosphere to be 2400 tons/yr and

Table 1. Antimony Geochemical Abundance

Material	Sb Abundance[a]

Source: Adapted from Reference 1.

1600 tons/yr, respectively. Very recently, Shotyk and co-workers (16) dismissed all previous values of natural antimony releases as being grossly overestimated. Based on antimony concentrations in ombrotrophic peat from Switzerland and Scotland, these authors suggested that 90–154 metric tons/yr would be more appropriate values.

USES

The first recorded use of antimony as a pigment to make mascara is found in an Egyptian papyrus dating from 1600 B.C. According to Emsley (17), the first uses of antimony date back even further; part of a 5000-year-old vase now in the Louvre is made of almost pure antimony. A peat core from an ombrotrophic Swiss bog revealed significant enrichments of antimony dating back to Roman times, which indicates that the anthropogenic fluxes of this element have exceeded natural fluxes for more than 2000 years. The present day enrichment factor (relative to the element/Sc ratios of typical crust rocks) is on the order of 70 times (as compared to 20 for As and 130 for Pb) (18). The chronology and intensity of the antimony enrichments in peat are similar in many ways to those of lead, which indicates that the extent of the human impact on the geochemical cycle of antimony is comparable to that of lead (16).

Table 2. Global Emissions[a] of Antimony into the Atmosphere, 10^3 metric tons/yr

Natural Sources	Sb Emission	Anthropogenic Sources	Sb Emission
Windborne dust (includes industrial sources of dust)	0.8	Energy production (coal, oil, gas)	1.3
Sea salt spray	0.6	Mining	0.1
Volcanic activity	0.7	Smelting and refining	1.4
Forest fires	0.2	Waste incineration	0.7
Biogenic sources	0.3		
Total	*2.6*	*Total*	*3.5*

[a] Adapted from Reference 1. Original estimations come from References 10–13. A completely different estimation, which is often cited in the literature, was published by Lantzy and Mackenzie in 1979 (14). They estimated natural and anthropogenic emissions of antimony into the atmosphere to be 0.98×10^3 metric tons/yr and 38×10^3 metric tons/yr, respectively.

The production and use of antimony have steadily increased. World reserves of antimony are in excess of 2 million tons and are located principally in China, South Africa, Bolivia, Russia, and Tajikistan (19). The world's mines produced 142,000 tons of antimony in 2003 (19). Table 3 shows the main uses of primary antimony in the United States in 2003, which can be seen as representative of the use of antimony across the developed world. Uses of antimony have changed over the years. Traditionally, it was used in lead–antimony alloys. Bulk-secondary antimony could be recovered as antimonial lead, most of which was regenerated and then consumed by the battery industry. Today, the main use of antimony is as Sb_2O_3 in flame-retardants, which have applications in, among others, children's clothing and toys and aircraft and automobile seat covers. Antimony trioxide cannot be recycled and is released into the environment.

ANTIMONY SOLUTION CHEMISTRY

Both Sb(III) and Sb(V) ions hydrolyze easily in aqueous solution, thus making it difficult to keep antimony ions stable in solution except in highly acidic media. Since most of the techniques used for the study of solution equilibria (solubility measurements, potentiometry, voltammetry, spectroscopy) necessitate the use of macroamounts of reactants, relatively little information is available on the chemical species of antimony that exist in aqueous solution, and on their stability constants in particular. Moreover, most of the published studies are relatively old. Only the system antimony–sulfur has been the object of recent studies, mainly in relation to the understanding of hydrothermal systems.

The following main points can be made regarding the antimony inorganic chemistry in solution (2): (1) According to thermodynamic data, antimony should exist as Sb(V) in oxic systems and as Sb(III) in anoxic ones. (2) At environmental concentration levels, at the pH range commonly found in natural waters and in the absence of sulfur, antimony exists as a soluble species regardless of its oxidation state. Antimony(V) is present as a negative species in solution [$Sb(OH)_6{}^-$, also represented as $SbO_3{}^-$] and Sb(III) as a neutral species [$Sb(OH)_3$, also often quoted as $HSbO_2$]. (3) It is not clear whether Sb(V) and Sb(III) form any chloride-containing species in seawater, but hydroxychloro species would be the most probable entities. (4) Antimony oxides exhibit low water solubility, which may affect the fate of antimony in soils and water, particularly since today antimony is mostly used as Sb_2O_3(s) in flame-retardant applications. Moreover, it is thought that, when released into the atmosphere as an aerosol, antimony is oxidized to antimony trioxide through reactions with atmospheric oxidants. (5) In anoxic systems, and in the presence of sulfur, antimony forms insoluble stibnite, Sb_2S_3(s), and soluble $SbS_2{}^{2-}$, depending on the pH. The formation of polymerized species at natural concentration levels (e.g., $Sb_2S_4{}^{2-}$, $Sb_2S_5{}^{4-}$, $Sb_4Sb_7{}^{2-}$) is not proved. The formation of an Sb(V)-containing species ($SbS_4{}^{3-}$) has been observed by EXAFS.

Eh–pH diagrams can illustrate the redox behavior of elements like antimony. Figure 1 shows one such diagram for the system Sb–S–H_2O at environmentally realistic concentrations of antimony and dissolved sulfur.

A comprehensive, thermodynamically consistent antimony database of equilibrium constants of antimony with inorganic ligands has recently been published (21).

Barely any data have been reported on Sb(V) binding by low molecular weight organic ligands. More extensive studies have been carried out on the binding of Sb(III), which behaves like a borderline metal. The extent of antimony binding by natural organic matter (NOM) is a point of some debate. A few studies report significant Sb–NOM interactions, but most do not, and observed environmental behavior seems to suggest that Sb–NOM interactions are not relevant in most aquatic systems.

Hydrous oxides of manganese and iron have been reported to significantly sorb Sb(III) but very few systematic studies have been carried out on antimony sorption by pure metal oxides. These oxides will also oxidize the trivalent antimony to pentavalent antimony. Several studies have found a correlation between the adsorption of antimony in soil and oxic sediments and the presence of manganese and iron oxides (22,23).

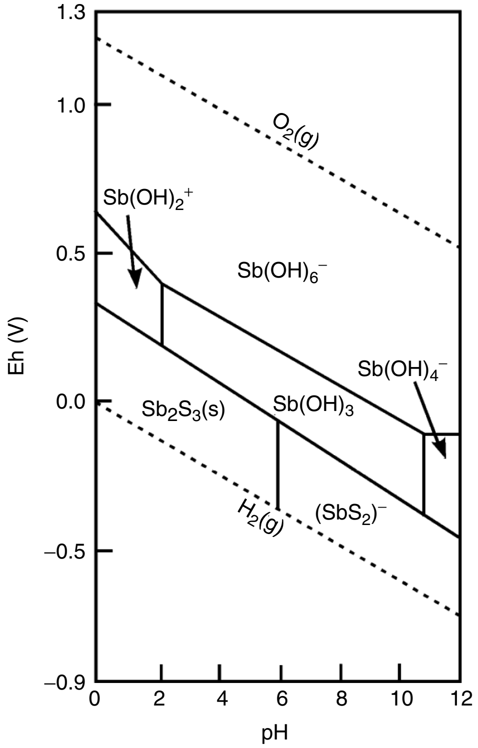

Figure 1. Eh–pH diagram of antimony in the Sb–S–H_2O system at a dissolved antimony concentration of 10^{-8} mol/L and a dissolved sulfur concentration of 10^{-3} mol/L. Adapted from Reference 2.

ANALYTICAL METHODS

The total concentrations of antimony in aqueous and solid environmental samples can readily be determined using current analytical techniques, primarily the result of the development of microwave digestion techniques for solid samples and NAA and plasma-based analyte detection systems. Both ICP-AES and ICP-MS techniques are in widespread use, although ICP-MS has less spectral interference and a lower detection limit (ng/L). An excellent critical review of the methodologies currently available for the environmental analysis of antimony has recently been published (24). However, determining antimony speciation still presents a significant analytical challenge (25). Recent data are almost exclusively based on hydride generation methods and often only oxidation state data are obtained. A lack of stability in the antimony species being investigated, particularly in trivalent forms, throughout the entire analytical process may result in an overestimation of pentavalent species concentrations.

Determining methylated antimony species is hampered by severe molecular rearrangements originating from the demethylation of trimethylantimony during the analysis. This problem has been the subject of extensive literary discussion but a solution has yet to be found (26).

ANTIMONY CONCENTRATIONS IN THE DIFFERENT AQUATIC COMPARTMENTS

The distribution and behavior of antimony in freshwater systems have not been studied extensively. Published concentrations range from a few nanograms/liter to a few micrograms/liter depending on location. They reflect the wide range of physical and chemical conditions existing in freshwater bodies and are very sensitive to the proximity of sources of pollution.

The concentration of antimony in ocean surface waters is about 200 ng/L. The behavior of antimony in the open seas is not considered to be highly reactive. According to some authors, it behaves as a conservative element and to others as a mildly scavenged element with surface (atmospheric) input. The comparison between antimony contents in deep waters of different oceans indicates that no antimony accumulation is produced during deep-water oceanic circulation (27). Antimony concentrations seem to reflect regional geochemical characteristics in coastal environments. Antimony behavior in estuaries varies somewhat according to the characteristics of the estuary. In some cases, it behaves conservatively and in others it shows a midestuary maximum. Behavior has even been seen to vary in the same estuary from one year to another.

Antimony concentrations in sediments are on the order of a few micrograms/gram of sediment and rarely exceed 1 mg/g. Higher concentrations are directly related to anthropogenic sources, mainly proximity to smelting plants and outfalls of sewage and fertilizer facilities.

ANTIMONY SPECIATION IN NATURAL WATERS

Today it is widely accepted that an understanding of biogeochemical processes requires knowledge of the chemical forms, or species, that are present in the natural environment. Despite this, the speciation of antimony in natural aquatic systems has yet to form the subject of many in-depth studies.

Dissolved Versus Particulate Fractions

Weak interaction between anionic species and suspended particles negatively charged in natural waters is to be expected and it is generally accepted that antimony is present as “dissolved” in aquatic systems. Experimental data (2) exist to support this. Fractionation of the so-called dissolved phase into several classes by ultrafiltration showed that most of the dissolved antimony is present in the smallest molecular weight region (2,28).

Redox

Antimony occurs in two oxidation states in natural waters and, thus, its behavior and toxicity can be affected by changes in the redox status of the aquatic environment. Antimony speciation studies have focused mainly on the separation and identification of Sb(III) and Sb(V) species.

Antimony (V) is the predominant species found in oxygenated systems but thermodynamically unstable Sb(III) has also been detected in different oxic marine water, fresh waters, groundwaters, and rain waters. This contrasts with thermodynamic equilibrium predictions, which suggest that Sb(V) concentration should exceed Sb(III) by several orders of magnitude. For thermodynamically unstable species to be present in water, mechanisms for their production and slow rates of interconversion must exist. The presence of Sb(III) has often been attributed to phytoplankton activity. However, although possible, a detailed analysis of published data has so far failed to produce conclusive proof to validate this hypothesis. Recently, the photochemical reduction of Sb(V) to Sb(III) has been suggested as an alternative to the phytoplankton source.

The true speciation of antimony under anoxic conditions remains unclear. According to thermodynamic calculations, in the absence of oxygen, antimony should only be present in the trivalent form. However, the occurrence of pentavalent forms of antimony has been reported in different anoxic systems. A variety of mechanisms have been suggested to explain these results, including delivery of Sb(V) on sinking detritus from oxic waters, formation of thiocomplexes by the pentavalent element, and advection of surface waters containing high concentrations of antimonate. All these mechanisms must be accompanied by relatively slow rates of reduction.

Methylated Species

Methylated species have been detected in surface seawaters, in estuaries, and in some rivers. They usually account for 10% or less of the total dissolved antimony. The monomethyl species is more abundant than the dimethyl form and close to the surface values tend to be higher. Monomethyl, dimethyl, trimethyl, and triethyl antimony derivatives have been detected in sediments from rivers and harbors. However, the identification of methylated antimony species has been questioned because some of these compounds undergo rearrangement reactions when subjected to the hydride generation procedures typically used for aquatic speciation.

The organoantimony compounds detected by Dodd et al. (26) in a freshwater plant (*Potamogetan pectinatus*) and a stibnolipid isolated from a marine diatom by Benson (29) are, as yet, the only organoantimony compounds with unequivocal biological origin to be detected in aquatic environments.

KINETIC ISSUES

As mentioned, the biogeochemical cycle of antimony is more complicated than equilibrium thermodynamic calculations predict (1). Several authors have cited the kinetic stabilization of thermodynamically unstable species to explain their presence in natural systems. Several processes may influence oxidation and reduction rates, including chemical and photochemical transformations and biological mediated reactions. It is well known that, when a redox process is accompanied by hydrolysis reactions, as is likely to be the case for antimony, the overall process can be much slower than expected. At present, kinetic information for redox reactions of antimony in natural waters is limited and rate constants are, for the most part, unknown. Cutter estimated an overall Sb(III) oxidation rate of 0.008 d^{-1} in the 65–85 m layer of the Black Sea from depth profiles (30). However, antimony residence times in seawater are probably longer because this rate included all forms of removal; that is, Sb(III) oxidation and also Sb(III) scavenging by sedimenting particles. Moreover, it was calculated at the oxic–suboxic interface of the Black Sea, where the presence of manganese and iron oxides is likely to increase the Sb(III) oxidation rate (31). Indeed, Belzile and co-workers (32), in a study on the oxidation of Sb(III) in the presence of natural and synthetic iron and manganese oxyhydroxides, showed that Sb(III) can be rapidly oxidized to Sb(V) by both compounds. Iron oxides also proved to play an important role in antimony redox chemistry in lake sediments (23). However, iron and manganese oxides are not likely to be present in oxic waters in significant quantities and thus are unlikely to influence antimony chemistry in oxic systems. It has recently been shown that Sb(III) oxidation by hydrogen peroxide and iodate is strongly pH dependent: the neutral $Sb(OH)_3$ species is unreactive to hydrogen peroxide and the presence of $Sb(OH)_4^-$ is needed for the oxidation to occur (33,34).

The addition of organic substances such as tartaric, lactic, citric, and ascorbic acids to natural or synthetic solutions has been shown to have a stabilizing effect on Sb(III). Solutions of Sb(III) prepared from potassium antimonyl tartrate have been reported to remain stable for long periods. The organic matter present in natural waters probably has a similar stabilizing effect. Ligand stabilization has been used to explain the apparent presence of Fe(II) in oxic solutions that contain relatively high levels of organic matter.

Little information is available on Sb(V) reduction kinetics in anoxic media. The reduction rate for Sb(V) in water at the bottom of the Black Sea was estimated to be 1.1×10^{-6} d^{-1} (35).

ANTIMONY AND AQUATIC BIOTA

Reported concentrations for antimony in fresh water and marine algae range from 0.02 to 1 μg/g dry weight (1). Although algae bioaccumulation and detoxifying mechanisms may play a key role in antimony redox speciation in natural waters, few studies have been carried out. Kantin (36) collected three marine algae near San Diego Bay in the United States and Sb(V) was the dominant species in all of them. Only *Sargassum* sp. contained up to 30% of Sb(III), thus demonstrating an ability to form reduced antimony species. Andreae and Froelich (37) analyzed the chemical speciation of antimony in phytoplankton (largely diatoms) from the eastern North Pacific and found that the trivalent species formed a significant part of the inorganic antimony. Both studies have since been used to justify the frequently cited biological origin of the Sb(III) found in oxic waters. Although no detailed studies exist, antimonate is expected to behave differently in bioavailability than arsenate and phosphate because of the weaker Lewis acidity and larger ionic radius of the antimonate ion in solution. More recently, the algae *Chlorella vulgaris*, isolated from an arsenic-polluted environment, excreted 40% Sb(V) and 60% Sb(III) on exposure to Sb(III), suggesting that a change in oxidation state is used by this alga as a detoxifying mechanism (38).

WATER LAW AND ECONOMICS

THE CLEAN WATER ACT

Timothy J. Ryan
Ohio University
Athens, Ohio

U.S. water legislation dates back to the late nineteenth century, when the 49th Congress enacted the Rivers and Harbors Act of 1886, which ultimately became the Rivers and Harbors Act of 1899. This law was designed to minimize obstructions in any navigable waterway in the United States, and it prohibited the deposit of any material on banks of navigable waters that would lead to the impeding of navigation. The law basically allowed for fines of $500 to $2,500 as well as imprisonment. Recognizing the continuing public health threat posed by water contamination, in 1948 Congress enacted the Federal Water Pollution Control Act (FWPCA) in order to "enhance the quality and value of our water resources and to establish a national policy for the prevention, control and abatement of water pollution." The original FWPCA aimed to establish programs that would improve sanitary conditions of both surface and groundwater while minimizing or eliminating the pollution of interstate waterways and tributaries. These goals thus differed from the original Rivers and Harbors Act's goals by adding pollution regulation in hopes of improving the public's water supply, habitats of aquatic life, and water for recreational, agricultural, and industrial uses. FWPCA and several subsequent amendments set out the basic legal authority for federal regulation of water quality to the present day.

The original FWPCA, or simply the "Act," was subjected to incremental but limited improvements that eventually resulted in a somewhat disparate collection of water-related requirements. Eleven reorganizations and restructurings of federal agency responsibilities compounded the difficulty of effectively implementing the law. For this reason, the 1972 amendments to the FWPCA restructured the authority for water pollution control and consolidated authority in the Administrator of the then newly formed United States Environmental Protection Agency (EPA). Formed in 1970 by President Nixon in response to the growing public demand for an overall healthier environment, the EPA was the first federal authority to implement pollution control programs for industry. Growing public awareness and concern for controlling water pollution throughout the mid-1970s led to amendments of the Act in 1977. As amended, this law became commonly known as the Clean Water Act (CWA).

The CWA, and it's associated rules found in Title 33 of the Code of Federal Regulations, established the basic priorities and structure for regulating pollution releases into the waters of the United States. The Act's major subchapters include six Titles: (I) Research and Related Programs, (II) Grants for Construction of Treatment Works, (III) Standards and Enforcement, (IV) Permits and Licenses, (V) General Provisions, and (VI) State Water Pollution Control Revolving Funds. The Act continued requirements to set water quality standards for all contaminants in surface waters and made it unlawful to discharge any pollutant from a single, or point, source into navigable waters, unless a permit was obtained under the Act. It also funded the construction of sewage treatment plants under the construction grants program and recognized the need for planning to address the critical problems posed by diffuse, or nonpoint, sources of pollution.

NATIONAL POLLUTANT DISCHARGE ELIMINATION SYSTEM

One of the most significant features of the Clean Water Act is the creation of a National Pollutant Discharge Elimination System (NPDES) under Section 402 of Title IV, Permits and Licensing. The NPDES prohibited industrial sources and publicly owned treatment works from discharging pollutants into navigable waters without a process review and permit. Under NPDES, all point source discharges of pollution into the waters of the United States are required to obtain a permit. Point source discharges come from "any discernible, confined, and discrete conveyance including but not limited to any pipe, ditch, channel, tunnel, conduit, well, discrete fissure, container, rolling stock, concentrated animal feeding operation, landfill leachate collection system, vessel or other floating craft from which pollutants are or may be discharged." The EPA Administrator may issue a permit for discharge on the condition that the discharge meets applicable requirements, which are detailed in the Act. Permitted discharges are only allowed insofar as federal effluent limitations and state water quality standards can continue to be met. The Act also provides that, given EPA approval, a state may administer its own permit program in lieu of the federal program so long as the state effort is deemed at least as effective as the federal controls.

NONPOINT SOURCE POLLUTION CONTROL

Since its use in 1972, the term "nonpoint source pollution" has been used in a variety of sometimes confusing contexts. Most simply, a nonpoint source is any source of pollution that is not otherwise legally considered as a point source. In 1987, Congress enacted Section 319 of Title III, Standards and Enforcement, of the Clean Water Act to establish a national program to control nonpoint sources of pollution. In its guidance for the program, the EPA rigorously defines nonpoint source pollution as that "... caused by rainfall or snowmelt moving over and through the ground and carrying natural

64. Vinyl chloride
65. Zinc and compounds

and human-made pollutants into lakes, rivers, streams, wetlands, estuaries, other coastal waters, and ground water. Atmospheric deposition and hydrologic modification are also sources of nonpoint pollution." A major source of typically nonpoint source pollution was recognized in urban stormwater. In response, and to address the specific concerns of contaminated stormwater runoff, the National Stormwater Program was established as part of the 1987 Clean Water Act amendments. Although stormwater is considered nonpoint source pollution, the hazardous constituents in the water may come from various points sources such as industry, sewers, or construction. Thus, the National Stormwater Program is controlled through NPDES, previously discussed.

EFFLUENT LIMITATIONS AND WATER QUALITY STANDARDS

In Section 401 of Title IV, Permits and Licensing, the Act prohibits the discharge of pollutants in excess of effluent limitations, and makes it unlawful to discharge radiological, chemical, or biological warfare agents; high-level radioactive waste; or any medical waste into navigable waters. Effluent limitations from point sources other than publicly owned treatment works (POTWs) must be treated using best practicable control technology, or BACT. The effluent limitations provide standards for a variety of pollutants and pollution sources, including but not limited to sources such as coal mining, landfills, construction, iron and steel manufacturing, meat products, pharmaceutical, paper products, and leather and tanning industry. Each source type has a different set of EPA effluent limitation standards to meet. Toxic pollutants defined in the Act (Table 1) require treatment using the best available technology that is economically achievable. If the source discharges into a POTW (e.g., via a connection to a sanitary sewer), it must comply with applicable pretreatment requirements as well as POTW expectations.

WATERSHED RESTORATION PLANS

Section 303(d) of Title III, Standards and Enforcement, of the Act requires that states and the EPA identify rivers, lakes, and coastal waters threatened or already impaired as a result of one or more specific pollutants. The states or EPA must develop "Total Maximum Daily Loads" (TDML) for every water body that has been placed on the EPA-designated threatened or impaired waters list. A TDML is thus a pollution cap or ceiling for the water body, and it has the functional effect of a cleanup plan. An associated plan for the affected water body then determines exactly how to attain that cap. The TMDL must specify problems, determine pollution reductions needed to solve the problems, identify pollution sources, and assign responsibilities for needed action. Also under Title III, various other specific and significant sources of pollution are regulated. Thermal discharges, marine sanitation devices, and oil and hazardous substance discharge are a few aspects of water pollution so regulated. As all of these sources have the potential to be hazardous polluters, the Act sets standards to which each must abide in different manners to ensure the quality of the water.

PLANS, GRANTS, AND FUNDING

The CWA both requires and assists in the development and implementation of waste treatment management plans and practices to achieve the water quality goals of the Act. Plans and practices must provide for treatment of waste prior to any discharge of pollutants into receiving waters, as well as the secure disposal of other pollution sources to avoid migration that could ultimately cause water or other environmental pollution. To accomplish these goals, Title II of the Act outlines a program of grants to states, municipalities, or other agencies for the construction of governmental water treatment facilities, or POTWs. Revisions of the Act in 1981 streamlined the municipal construction grants process, improving the capabilities of treatment plants built under the program. Additional changes in 1987 phased out the construction grants program but replaced it with the State Water Pollution Control Revolving Fund (found in Title VI of the Act), known within professional circles as the Clean Water State Revolving Fund. That funding strategy addressed water quality needs by building on EPA-State partnerships to identify and meet state and regional water quality issues.

KEY AMENDMENTS AND ASSOCIATED WATER PROTECTION LAWS

Safe Drinking Water Act

Over the years, many other environmentally related laws have changed or otherwise impacted parts of the CWA. The Safe Drinking Water Act (SDWA) was originally passed by Congress in 1974 to specifically protect the nation's public drinking water supply. The SDWA authorized the EPA to set national health-based standards for drinking water to protect against both naturally occurring as well as man-made contaminants that may be found in drinking water. These standards are divided into primary and secondary standards. Primary standards are set to protect the public's health, are legally enforceable, and apply to public water systems. Secondary standards are nonenforceable guidelines set to regulate contaminants in the drinking water that may cause negative cosmetic or aesthetic effects, such as tooth discoloration or bad odor. States may choose to adopt these secondary standards as enforceable regulations. The law was amended in 1986 and 1996 and requires various actions to protect drinking water sources, including rivers, lakes, reservoirs, springs, and groundwater.

Oil Pollution Act

As a response to the Exxon Valdez disaster of 1989, when a crude oil tanker ran into a reef on the coast of Alaska and spilled 10.8 million gallons of the oil into the Prince William Sound, Congress passed the Oil Pollution Act in 1990. This act amended the CWA to significantly raise the limits of liability to would-be polluters, and the amount of compensation that must me made to injured parties resulting from an oil spill.

Great Lakes Critical Programs Act

As a result of their immense size and value as a freshwater supply, state, federal, and international steps have been taken to protect the water quality of the Great Lakes. Title I of the Great Lakes Critical Programs Act of 1990, for example, put into place parts of the U.S.-Canadian Great Lakes Water Quality Agreement of 1978, wherein the two nations agreed to jointly reduce certain toxic pollutants entering these resources. That law required the EPA to establish water quality criteria for the Great Lakes for 29 toxic pollutants with a particular focus on persistent bioaccumulative toxics (such agents tend to occur in higher concentration in aquatic biota than in open waters). The criteria are intended to protect human health, aquatic life, and wildlife and include the first-ever EPA wildlife criteria to protect birds and mammals from long-term exposure to mercury, DDT, PCBs, and dioxin. It also required the EPA to help the states implement the criteria on a specific schedule.

With a growing world population and intense industrial demands on a finite water supply, regulations concerning U.S. water resources will continue to change and evolve with time. As the most prominent water quality law presently in effect, the CWA will continue to play a significant roll in the maintenance of water quality for future generations in the face of technological changes and demands.

CLEAN WATER ACT, WATER QUALITY CRITERIA/STANDARDS, TMDLS, AND WEIGHT-OF-EVIDENCE APPROACH FOR REGULATING WATER QUALITY

G. Fred Lee
Anne Jones-Lee
G. Fred Lee & Associates
El Macero, California

INTRODUCTION

The 1972 amendments to the Federal Water Pollution Control Act (Clean Water Act, CWA) established a regulatory framework to maintain and enhance water quality in waterbodies of the United States. The CWA specified that waterbodies were to be classified with respect to their beneficial uses, such as domestic water supply, propagation of fish and aquatic life, and recreation, and that the U.S. EPA was to develop national water quality criteria for chemical and other agents that would protect the designated beneficial uses of waterbodies. The numeric chemical-concentration-based national water quality criteria that it eventually developed were designed to be protective in any water under worst-case exposure conditions. The U.S. EPA criteria, in turn, were to be used by the states as the basis for water quality standards, the benchmark for control of beneficial use-impairment of waterbodies.

The way in which these CWA provisions have been implemented has been to require that a waterbody in which a water quality standard was exceeded be listed as a Clean Water Act section 303(d)-"impaired" waterbody. Such a listing requires that a program be initiated to control the sources of the constituents responsible for the water quality standard violation, which is done through a total maximum daily load (TMDL) assessment through which is determined a load that would not result in exceeding the standard; that load is then apportioned among those discharging the constituent.

Although this TMDL approach was originally adopted in 1972, it was not until the late 1990s that it began to be implemented to any significant extent. This implementation developed from environmental groups filing suit against the U.S. EPA for having failed to implement the TMDL provisions of the Clean Water Act. As part of settling the lawsuit, the U.S. EPA agreed to see to the implementation of TMDLs by the states. Considerable controversy, exists however, about the appropriateness of the TMDL process as it is typically being implemented for regulating water quality caused largely by the use of numeric U.S. EPA national water quality criteria and state standards equivalent to them as the benchmark for evaluation of water quality. Following is a synopsis of how this approach came to be established and issues that remain inadequately addressed in the pursuit of the goals of the CWA. Also described is a "best professional judgment" triad weight-of-evidence approach that provides a technically valid, cost-effective framework for assessing water quality/beneficial-use impairments and their remediation.

EARLY REGULATORY APPROACH—ISSUES STILL NEEDING ATTENTION

Lee (1) discussed several significant technical shortcomings inherent in the TMDL approach adopted by the U.S. EPA for regulating chemical constituents for the protection of water quality. For example, in the 1960s, when toxicity tests were starting to evaluate the toxicity of wastewater discharges, it was often found that a portion of the heavy metals in some discharges was in forms that did not cause toxicity. This finding was in accord with what would be expected based on the aquatic chemistry of heavy metals. It was recognized that heavy metals exist in a variety of chemical forms; given the chemical nature of the forms, it could be expected that not all of them would be equally available/toxic to aquatic life, although this distinction could not be made with chemical analytical techniques. This situation was sufficiently well known that by the early 1970s, the National Academies of Science and Engineering concluded, as part of their development of the *Blue Book of Water Quality Criteria* (2), that heavy metals in wastewater discharges could not be reliably regulated based on chemical concentrations. Rather, because of the numerous unquantifiable factors that control the manifestation of a chemical's toxicity, they recommended a toxicity test approach to determine the availability of the heavy metals, either alone or in combination with other metals or other substances, in a particular water. The National Academies of Science and Engineering Blue Book Criteria were adopted by the U.S. EPA (3) in its 1976 *Red Book Criteria*, which were the first official water quality criteria developed pursuant to the Clean Water Act.

In the early 1980s, however, the U.S. EPA abandoned the toxicity testing approach recommended by the National Academies of Science and Engineering. In its place, it adopted a policy of applying the numeric, worst-case, national water quality criteria (generally, chronic exposure, safe concentrations) to the concentrations of total recoverable metals (i.e., those forms that are measurable after strong acid digestion of the sample), rather than to the available forms, in water quality evaluation and regulation. That approach lead to overregulation of heavy metals because in some situations, substantial parts of the "total recoverable" heavy metals are nontoxic/unavailable.

Some relief from the overregulation of heavy metals was provided when application of the criteria was shifted from "total recoverable" forms to "ambient-water dissolved" forms of metals (4). The shift in focus at that time was not based on the finding of any new information because it had been well-established in the 1960s and 1970s that particulate forms of heavy metals in the water column were nontoxic. Focusing on dissolved forms of heavy metals corrected a long-standing problem in the implementation of the national water quality criteria into state water quality standards. That notwithstanding, the Agency has still not addressed its inappropriate application of water quality criteria for many other constituents, such as organics, to total concentrations rather than properly addressing contaminant availability.

Although deficiencies in the conventional application of the water quality criteria were generally recognized, they were not addressed by the U.S. EPA primarily because the regulations that were developed were not being enforced by either the U.S. EPA or many of the states. As a result, the promulgation took place of the National Toxics Rule in subsequent revisions of the Clean Water Act, through which Congress mandated that states either adopt the U.S. EPA criteria for toxics or have them imposed on them by the U.S. EPA. By the early 1990s, all states had adopted U.S. EPA criteria for “toxics.” California’s regulations adopting the U.S. EPA criteria as state standards, however, were soon judged invalid through court action because California state law also requires consideration of economic impact of water pollution control regulations. As the California State Water Resources Control Board did not comply with those state requirements, the courts determined that the regulations must be voided. Thus, for many years, California did not have water quality criteria/objectives for “toxics.” Finally, in 2000, the U.S. EPA Region 9 imposed what became known as the California Toxics Rule criteria (5). They are the U.S. EPA criteria for “toxics” that were originally adopted in the mid-1980s, or subsequent updates, such as the U.S. EPA (4,6–8). The most recent update of national water quality criteria occurred in 2002, when the U.S. EPA (9) developed its currently recommended national water quality criteria. The U.S. EPA requires that as states update their criteria, they incorporate the 2002 criteria as the state standards.

Lee et al. (10), Lee and Jones (11), and Lee and Jones-Lee (12) discussed alternative approaches for assessing and controlling the impact of contaminants on water quality that took better account of contaminant availability to affect water quality, thus directing the financial resources available first toward defining those constituents that adversely impact the beneficial uses of a waterbody and then toward controlling those constituents to the extent necessary to protect those uses.

PRIORITY POLLUTANT LIST

The 1972 Clean Water Act also mandated that the U.S. EPA develop a list of “priority pollutants” that was to include those chemicals found in water that should receive the highest attention for regulatory action. National water quality criteria were then to be developed for each of those chemicals to protect fish and aquatic life in all waters. Congress, however, did not fund the U.S. EPA adequately to carry out this mandate. Finally, when the U.S. EPA could not develop the list within the timeframe allowed, an environmental group filed suit to force the U.S. EPA to do so. In response to that suit, in the mid-1970s, the U.S. EPA’s attorneys and environmental group attorneys, with limited technical input and without public peer review, promulgated what is now known as the “Priority Pollutant” list.

Despite the intention to focus on water quality problems, in actuality, the “Priority Pollutant” list has proven to be detrimental to properly defining the constituents that are significantly adverse to the beneficial uses of waterbodies. The list was not properly peer-reviewed for its inclusion and prioritization of pollutants of real water quality significance. Instead, the list focused primarily on what are known as rodent carcinogens, i.e., those constituents that, at high concentrations over extended periods of exposure, cause cancer in rats, but do not necessarily have a great significance to water quality. Large amounts of public resources have been devoted to analyzing for and then developing control programs for many of the rodent carcinogens, especially the chlorinated solvents, while neglecting many pollutants of greater water quality significance.

In looking at this situation, Dr. Christian Daughton, Chief, Environmental Chemistry Branch, U.S. EPA National Exposure Research Laboratory, indicated that there are more than 22 million organic and inorganic substances, with nearly 6 million commercially available. The current water quality regulatory approach addresses fewer than 200 of those chemicals as potential water pollutants, i.e., the “priority pollutants.” He stated, “Regulated pollutants compose but a very small piece of the universe of chemical stressors to which organisms can be exposed on a continual basis” (13).

IMPLEMENTATION OF TMDLS

The establishment of TMDLs focuses on achieving water quality standards in receiving water. This focus led to a review of the TMDL-based water pollution control program by the National Research Council (NRC). The NRC’s review (14) discussed technical deficiencies in the U.S. EPA’s TMDL program. Waterbodies have been placed inappropriately on the Clean Water Act section 303(d) list of impaired waterbodies on the basis of unreliable evaluation. TMDL goals of achieving worst-case water quality standards for total concentrations are often inappropriate goals for solving real, significant, water quality/use-impairment problems in a technically valid, cost-effective manner. Most importantly, inadequate time and inadequate funding are available to support the development of TMDLs as they are being administered through the U.S. EPA and state regulatory agencies.

The first step toward establishing a more appropriate TMDL process should be an assessment of the appropriateness of the water quality standards that established the 303(d) listing and the standards that serve as TMDL goals to correct water quality impairment. As a considerable part of the TMDL program is directed toward sources such as agricultural runoff and urban runoff that frequently contain constituents that are, in substantial proportion, nontoxic, and unavailable, it is important that the U.S. EPA and the states refocus TMDL programs on controlling toxic, available forms, as opposed to total concentrations of constituents.

BPJ TRIAD WEIGHT-OF-EVIDENCE

Because of the technical inappropriateness and unreliability of using overly simplistic, even though administratively expedient, indicators of impact, increasing attention is being given to the use of a triad "weight-of-evidence" approach as a regulatory tool for water quality impact assessment and management. Although this approach has been configured in several ways with varying degrees of technical validity, a well-accepted, technically appropriate format is a "best professional judgment" (BPJ) evaluation of a triad of key parameters: aquatic life toxicity/bioaccumulation of the contaminant(s); aquatic organism assemblage information in the aquatic system of concern; and chemical kinetic/thermodynamic information pertaining to the contaminant(s) of interest and the aquatic system of concern. These components are described below.

Toxicity/Bioaccumulation

The availability of most chemical contaminants to aquatic life cannot be determined through chemical analysis; the availability can be affected by the character of the ambient water, the nature of the exposure conditions, and the sensitivity of the organisms of concern. Furthermore, routine chemical analysis does not cover all potential toxicants that may be present. Therefore, a key component of a BPJ weight-of-evidence evaluation for water quality impact assessment and management is aquatic life toxicity testing and/or bioaccumulation testing of aquatic organism tissue for potentially hazardous chemicals that are a threat to human health or higher trophic-level organisms that use aquatic life as food. The importance of using the BJP triad framework for the interpretation of the results of this testing is illustrated by the fact that, as discussed by Lee and Jones-Lee (15), finding aquatic life toxicity in laboratory tests of ambient water or sediment cannot be assumed to mean that that toxicity represents a significant impairment of the beneficial uses of the waterbody that is of concern to the public. It is not necessarily possible to equate laboratory-based water column or sediment toxicity with water quality impairment. For example, many sediments have natural toxicity because of low dissolved oxygen, ammonia, and hydrogen sulfide; yet the waterbodies associated with them have excellent fisheries and high water quality. The other aspects of the triad must be used with this information to make a best professional judgment regarding the significance of the toxicity and bioaccumulation information.

Organism Assemblage

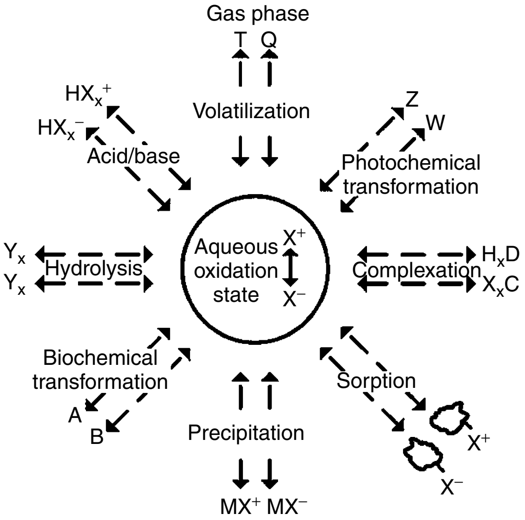
Organism assemblage information includes description of the numbers, types, and characteristics of aquatic life and, as appropriate, terrestrial organisms such as fish-eating birds, present at a potentially impacted site. Insight into whether water quality has been adversely affected can be gained from understanding how the organism assemblage at the location compares with that which might be expected to be supported there. However, a variety of physical (flow, temperature, sunlight, sediment, and habitat alteration, etc.), non-potential-pollutant chemical (TDS, nutrients, organic constituents, hardness, alkalinity, etc.), and biological (reproductive cycles, disease, predation, etc.) factors other than chemical potential pollutants can affect the numbers, types, and characteristics of aquatic life in a waterbody's water column or sediments. Therefore, it is critical that this information be considered in the context of a BPJ evaluation in assessing the water quality impacts of chemicals on the beneficial uses of a waterbody.

Chemical Information

Chemical concentration has been one of the most convenient, yet most misunderstood and misused, pieces of information in water quality evaluation and management. Unfortunately, chemical information and "chemistry" have often been considered to be a laundry list of total concentrations of a few regulated constituents having water quality standards, which are mechanically applied to discharges, ambient water, or sediment. This result occurs despite that for half a century, it has been known that the total concentration of a potentially toxic constituent in the water column and/or sediments is an unreliable basis for estimating the impacts of that contaminant on the beneficial uses of a waterbody. Thus, the administratively expedient application of such values directly can distort the significance of that chemical contaminant to water quality.

The reason the total concentration of a selected chemical is unreliable for assessing water quality/use-impairments is that many chemical constituents exist in aquatic systems in a variety of chemical forms, only some of which are toxic or available to affect aquatic life. The aquatic "chemistry," i.e., the kinetics (rates) and thermodynamics (positions of equilibrium) of reactions that a chemical can undergo in a natural water system, is illustrated in the aquatic chemistry "wheel" presented in Fig. 1.

As illustrated, chemicals can undergo oxidation/reduction, volatilization, photochemical, complexation, sorption/desorption, precipitation, hydrolysis, and acid/base reactions in natural water systems. Many reactions alter the availability of the chemical to affect aquatic life. Although measurement of the total concentration of a chemical includes essentially all of these forms, the amount of the "available" forms of the chemical present depends in part on the nature of the chemical and the types and amounts of materials in the water and/or sediment that act to "detoxify" the chemical, i.e., render it nontoxic or unavailable to affect aquatic life through these reactions. These types of materials include organic carbon, sulfides, carbonates, hydrous oxides, clay minerals, and others. The amount of available forms also depends on the rates of reaction, the extent to which these reactions occur, and the comparative availability among the forms.



- ➤ Distribution among species depends on kinetics & thermodynamics of reactions in the particular aquatic system
- ➤ Each chemical species has its own toxicity characteristics many forms are non-toxic

Figure 1. Aquatic chemistry of chemical constituents.

No simplistic method exists by which to reliably quantitatively account for these interactions by mathematical manipulation or chemical analysis. It is for this reason that chemical concentration information, especially total concentrations of chemicals, should not be used alone in assessing water quality or impairment of water quality. The disregard for the aquatic chemistry of contaminants and for the nature and duration of organism exposure in aquatic systems makes the application of worst-case, numeric water quality criteria typically overly restrictive for the protection of beneficial uses of waterbodies. Although chemical concentration information can raise issues to consider and sources that may be worthy of further investigation, it is unreliable for reaching a conclusion about "water quality" or beneficial use-impairment. It is for this reason that the aquatic toxicity/bioaccumulation and organism assemblage information are also critical parts of the triad evaluation, and the need for objective, technically informed, best professional judgment is clear.

CO-OCCURRENCE-BASED SEDIMENT QUALITY GUIDELINES: CAUTION

The issue of sediment quality criteria and guidelines warrants special attention in this discussion. Reliable evaluation and regulation of the impacts of contaminants in sediment systems is substantially more complex and more ill-defined than in ambient waters. Although it has been long understood that no relationship exists between the total concentrations of chemical contaminants in sediments and toxicity, bioaccumulation, or adverse impact on beneficial uses of a water, chemical concentration is simple and numeric, and lends itself to easy decision-making. In an attempt to make simple chemical analysis relevant, some have developed and advanced the use of co-occurrence-based "sediment quality guidelines" (16–18). A group of sediments was evaluated for having some type of biological impact. Then the concentrations of a few selected contaminants in those sediments that exhibit an "impact" were examined. Basically, then, for each contaminant, the lowest concentration associated with an "impacted" sediment was said to be adverse, a cause for concern in any sediment, and the basis for a "sediment quality guideline." No consideration was given to the actual cause of the "impact" reported, to the fact that total concentration is not related to impact, to several chemical and conditions that are well-understood to cause sediment toxicity, or to sediments having that or higher concentrations of the contaminant without exhibiting adverse impacts. The only basis for the so-called "guideline" concentration was the "co-occurrence" of the contaminant in the sediment with some biological impact attributed to that sediment. It is entirely expected that chemical constituents derived from urban industrial areas, although having biological effects, often occur in the presence of other constituents, which, although in nontoxic, unavailable forms, are present in elevated concentrations.

Co-occurrence-based approaches exemplify inappropriate use of chemical information in a water quality assessment but nonetheless are popularized because of their ease of application. As discussed by Lee and Jones-Lee (19–21), no cause-and-effect relationship is established in the co-occurrence-based values. Although so-called "correlations" exist between toxicity and a sediment quality guideline is exceeded, this is coincidental and unreliable for an assessment of the cause of the biological impacts. The fact that a chemical constituent exceeds a particular "sediment quality guideline" does not mean that that constituent is in any way related to biological effects, such as toxicity, bioaccumulation, and/or changes in organism assemblages. The actual cause of the biological response can readily be either a constituent(s) that is not measured or not considered in the scheme or a combination of constituents that, although measured, do not, individually or summed, exceed the "sediment quality guidelines." Thus, no expectation can exist that funds spent to achieve "sediment quality guideline" values will result in any improvement in sediment/water quality or that sediments targeted by the exceedance of guideline values are, in fact, of the greatest concern.

Some try to skirt the fundamental technical flaws in the approach by limiting its use to "screening" sediments. However, using a patently unreliable "screening" tool can do nothing but provide patently unreliable results, which will serve to misdirect concern, responsibility, and funds for remediation, and leave real problem areas unaddressed. Although sediments that exceed one or more "sediment quality guidelines" may, in fact, merit further investigation or remediation, the guideline values are meaningless for making that assessment; under no circumstances should anyone assume that the exceedance of a guideline value represents a cause-and-effect relationship that can determine the likely cause of a biological response. As discussed by O'Connor (22–24), O'Connor and Paul (25), O'Connor et al. (26), Engler (27), DiToro (28), Chapman (29), Burton (30), and Lee and Jones-Lee (15,19–21), the co-occurrence approaches are obviously technically invalid and unreliable for assessing cause-and-effect. A reliable evaluation and regulatory program must be based on reliable assessments of the cause of the adverse effect.

RECOMMENDED APPROACH FOR INCORPORATION OF CHEMICAL INFORMATION INTO A BPJ TRIAD WEIGHT-OF-EVIDENCE WATER QUALITY EVALUATION

The recommended approach for the use of chemical concentration information in a BPJ triad weight-of-evidence evaluation of the cause of a water quality impairment begins with the reliable definition of the water quality/use-impairment that is of concern. The existence of a contaminant in total concentrations greater than a worst-case-based standard/guideline is not, in itself, an adverse impact unless that contaminant is causing adverse impacts to the beneficial uses of the waterbody. Thus, for example, before measuring the concentrations of copper, lead, zinc, and cadmium that typically occur in street and highway stormwater runoff at concentrations above U.S. EPA worst-case-based water quality criteria and state water quality standards based on those criteria, the chemical impact evaluation approach determines whether the water or sediment of concern is toxic. Jones-Lee and Lee (31) describe an evaluation monitoring approach that has been developed to focus on chemical impacts rather than on chemical concentrations.

If toxicity is found in laboratory tests of a water or sediment, then an assessment should be made as to whether that toxicity translates to an adverse impact on the waterbody's beneficial uses, such as fisheries, survival or reproduction of desired aquatic life, and so on. It should not be assumed that toxicity measured in a standard toxicity test necessarily translates to a toxicity that is significantly altering the numbers, types, and characteristics of desirable forms of aquatic life in a waterbody. This fact is especially true for situations such as urban area and highway stormwater runoff, where there can be short-term pulses of toxicity associated with a runoff event that are not of sufficient magnitude or duration to exceed the critical magnitude/duration coupling needed to be adverse to important forms of aquatic life in a waterbody.

Figure 2 shows a typical relationship between duration of exposure and toxicity; as illustrated, the manifestation of a toxicity response to available forms of a contaminant depends on the duration of exposure. Elevated concentrations of a toxicant can be tolerated by aquatic life, provided that the duration of exposure of this toxicity is shorter than the critical, or threshold, toxicity/duration of exposure coupling for that contaminant and organism in the ambient water. Exposure durations of aquatic life can be affected by the intermittent nature of the introduction of the contaminant, the rate and nature of dilution in the ambient water, avoidance or attraction behavior of the organism, and so on.

If measured toxicity is determined to potentially affect the beneficial uses of the waterbody, then a toxicity identification evaluation (TIE) should be conducted to evaluate the cause of the toxicity (32–34). The TIE process defines the availability of contaminants present and can elucidate the potential availability of the toxicity-causing contaminant(s) from its various sources. This process, then, can direct control toward those sources that are contributing significantly to the toxicity. Not only is this approach more technically sound, but it also addresses the issue of potential impacts of unrecognized, unmeasured, and/or unregulated pollutants that has been the subject of increasing importance in water quality management.

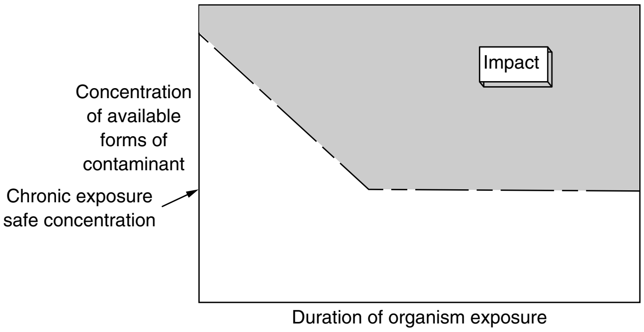


Figure 2. Critical concentration—duration of exposure relationship.

SUMMARY AND CONCLUSION

The federal Clean Water Act and amendments have directed the development of water quality criteria and standards and a framework for identifying and addressing beneficial use-impairments in the waters of the country. In the quest for administratively simple means by which to evaluate and regulate water quality and sediment quality, worst-case-based criteria and standards for a select group of chemicals have been developed. These are applied to the concentrations of contaminants in ambient waters as a means of judging water quality. This approach is known to be unreliable for evaluating or regulating water quality because it does not properly account for the beneficial uses of the water; the nature, behavior, and forms of chemical contaminants; or the unrecognized and unregulated pollutants.

The BPJ triad weight-of-evidence approach described herein provides a technically sound foundation and approach for assessing water quality impacts, causes of the impacts, and directions for controlling the impact. It is not as administratively expedient as simple comparison of chemical concentration data; however, that simplistic approach is not reliable for determining impairments or effecting control of real water quality problems. The BPJ triad weight-of-evidence approach requires the allocation of sufficient funds to determine the characteristics of the constituents/conditions of concern, with particular emphasis on properly defining toxicity and water quality cause-and-effect relationships. It also requires that individuals knowledgeable in aquatic chemistry, aquatic toxicology, and water quality provide guidance on, and appropriate interpretation of the results of, the kinds of chemical and toxicity studies that are needed to appropriately incorporate chemical information into assessing the water quality significance of chemical constituents in impacting the beneficial uses of a waterbody.

Numeric weight-of-evidence approaches in which arbitrary scale factors are assigned to each of the three components of the triad are technically invalid, because the scaling factors do not represent the relationship between a chemical constituent in a water or sediment and its impact on the water quality-beneficial uses of a waterbody.

Significant problems can occur with the use of the BPJ approach in incorporating chemical information into the triad. The use of total concentrations of constituents and/or the exceedance of a co-occurrence-based so-called sediment quality guideline is technically invalid. Such an approach can distort the triad water/sediment quality evaluation because it incorporates information into the triad that is not related to the impact of the chemicals on aquatic-life-related beneficial uses.

The BPJ weight-of-evidence approach should be based on the consensus of a panel of experts who, in a public, interactive, peer-review process, consider the information available, define what additional information is needed, and then render an opinion as to the integrated assessment of the information available on the significance of a particular chemical constituent in impacting the beneficial uses of a waterbody. The characteristics of the components of a BPJ weight-of-evidence approach that focuses on the appropriate use of chemical information are discussed further by Lee and Jones-Lee (35).

THE CONSTITUTION AND EARLY ATTEMPTS AT RATIONAL WATER PLANNING

Martin Reuss, Ph.D
Office of History Headquarters
U.S. Army Corps of Engineers

In the first decades of the American Republic, river and harbor bills met overwhelming resistance from the executive branch, mainly because of concerns over constitutionality, one more issue that reverberates through much of America's history. The specific points usually centered on presumed lack of constitutional authority to construct works of mainly local and even private benefit or works on rivers that were not clearly navigable. Pre-Civil War Presidents either practiced an inconsistent policy towards public works or became adamant opponents. Thomas Jefferson objected to federal involvement because it would empower the government at the expense of the common man, burden the taxpayer, lead to projects benefiting one location at the cost of another, and would enrich men at public expense. James Madison, who had been an early internal improvements advocate, on the evening before his departure from the White House vetoed the so-called Bonus Bill that would have provided funds for public works, declaring that the Constitution did not give Congress the power to appropriate money for or to construct public works without an "inadmissible latitude of construction." James Monroe at first thought that Congress could appropriate funds for public works but agreed with Madison that the federal government had no authority to construct the projects. Later, he determined that Congress might construct public works after all but only for those projects that were "national not state, general not local," a clarification that left the proverbial barn door open for defining local and general.

Andrew Jackson saw himself as a friend of internal improvements, but he feared the extension of federal power, sought a clarifying amendment on the appropriate national role in internal improvements, and admitted, like Monroe, that, while the federal government could appropriate money for truly national projects, it could not actually construct the projects itself. Strict constitutional constructionist James K. Polk vetoed every rivers and harbors bill sent to him. He even went to his office on the last day of his administration armed with a veto should Congress try to pass an internal improvements bill at the last moment. Abraham Lincoln, a young Whig congressman from Illinois, succinctly captured the problem in his denunciation of Polk's veto of the 1848 rivers and harbors act. "The just conclusion from all this is that, if the nation refuses to make improvements of the more general kind because their benefits might be somewhat local, a state may, for the same reason, refuse to make an improvement of a local kind because its benefits may be somewhat general. A state may well say to the nation, 'If you will do nothing for me I will

---

do nothing for you.'" In the following decade, Franklin Pierce vetoed five rivers and harbors bills on the grounds of unconstitutionality. As Civil War erupted in the land, the political and philosophical jousting over water projects remained as short of resolution as ever.

Given the fears, hopes, and questions facing the early American republic, it is little wonder that it saw no successful implementation of coordinated public works administration. Perhaps more surprising is that this became a permanent condition in the United States. Funding issues, sectional friction, and constitutional questions invariably posed insurmountable barriers. Prior to the Civil War, the federal government attempted twice to develop and implement a national program of public works. The first was the well-known Gallatin Plan. At the request of Congress, Secretary of Treasury Albert Gallatin proposed in 1808, an ambitious network of roads and canals connecting the Eastern seaboard with the interior and a coastwise water route to shorten distances between major Atlantic seaboard cities. Gallatin argued that the federal government should construct internal improvements that provide "annual additional income to the nation" but are beyond the capacity of private entrepreneurs to build. His formulation harkens back to Adam Smith's The Wealth of Nations and anticipates the term "National Economic Development " that appeared in twentieth century economic jargon. However, his effort fell victim to lack of funds (both private and public), New England opposition to the Jefferson Administration, and, finally, growing preoccupation with real and apparent British threats to the United States, which eventually resulted in war. It is also of more than passing interest that Gallatin himself agreed with President Jefferson that his plan could never be efficiently realized without a constitutional amendment.

The next great attempt occurred in 1824. President's Monroe's vacillation, the growing clout of new states interested in waterborne commerce, and a favorable Supreme Court ruling (Gibbons v. Ogden) that sanctioned federal control over interstate commerce, including rivers, based on the Commerce Clause of the Constitution, allowed passage of the General Survey Act in 1824, after weeks of acrimonious debate. The act carried largely because of support from the Middle Atlantic states (except Delaware) and the new states west of the Appalachians. It authorized the President to use the Army Engineers to survey (not build) roads and canals (not rivers) that may be deemed "of national importance in a commercial or military point of view, or necessary to the transportation of the public mail."

Once the bill passed, Secretary of War John C. Calhoun organized a Board of Engineers for Internal Improvements to determine which routes should be surveyed among the scores suggested. Like Gallatin's plan, this program could have become the beginning of a great nationwide, coordinated system of internal improvements. Instead, once projects were surveyed, they became subject to the same parochialism in Congress that had doomed earlier, similar ideas, and congressmen continued to introduce pet projects for funding despite a contrary recommendation from the army engineers or the absence of a survey altogether. Its planning role severely diminished, the Board of Engineers languished, and a reorganization of the Corps of Engineers in 1830 provided an excuse for its abolishment. Six years later, Congress repealed the General Survey Act, partially a response to the legislature's own abuse of the act, using Army Engineers to survey potential projects of clear local and even private interest. Thus began a contest between rational administration and congressional politics that has remained unresolved and contentious to the present.

ECONOMIC VALUE OF WATER: ESTIMATION

Jorge Ramírez-Vallejo
Harvard University
Cambridge, Massachusetts

> "Water has an economic value in all its competing uses and should be recognized as an economic good." The Dublin Statement, 1993.

MOTIVATION FOR VALUING WATER

The global awareness of the vital role water plays in sustainable national development is increasing. Water is vital for sustaining life on the earth. It is crucial for economic and social development, including energy production, agriculture, and domestic and industrial water supplies. Therefore, each unit of water should be used efficiently, equitably, and soundly. The economic value that water generates should be given due attention, when apportioning scarce water resources among competing uses.

Water is often regarded as a naturally occurring, freely available commodity. However, its supply, especially in an unpolluted state, is often limited compared to the demands placed upon it. Hence, water is both a constraint on and an essential input of economic activity, and decisions are required to allocate it among competing uses. Considerable resources are committed to delivering required standards of water services in adequate quantities and qualities. In addition, water-related environmental qualities, such as those associated with wetland regimes, are recognized as valuable to society. These characteristics of water imply that it can be regarded as an economic commodity—an economic good—whose use can be guided by economic principles (1).

Water, as other resources, has value whenever users are willing to pay a price for it rather than do without. The economic value and economic benefit of water can be considered synonymous. The benefits from this resource are derived from various uses. First, we find benefits of water from personal drinking, cooking, and sanitation, and from that those contribute to productive activities on farms and in businesses and industries. These uses are called *consumptive* uses. Second, there are *in-stream* water benefits from other uses such as hydroelectric power generation and waterways transportation. These uses are called *nonconsumptive* uses. The third type of value of water comes from the economic benefits that water has in recreation, aesthetics, and fish and wildlife habitat. As income and leisure time grow, these benefits are becoming more and more important. Fourth, there are the economic benefits of waste disposal using water as a sink for carrying away a wide range of residuals from the processes of human production and consumption. Water is used then to dilute them and in some instances to transform them into less undesirable form. Fifth, we find the *dis-values* of water that come from floods and negative water quality impacts. Finally, we have the *nonuse* value of water that comes from people who are willing to pay for environmental services that might neither be used nor experienced in the future.

Economic valuation is a process of expressing preferences in a money metric. But, why bother valuing water anyway? This is the obvious question that comes to mind when approaching this subject. The key answer to this question is simple but fundamental: for the future well-being of humanity. The longer we ignore or distort water's value, the more overused and misallocated the resource becomes. Without price signals or other indicators of value to help guide policy, we tend to manage the resource blindly.

Estimates of the economic value are key for management decisions on allocation. Economic valuation is also important because it aids in determining if people want proposed projects and helps in estimating the degree to which they are willing to pay for benefits. When public budgets are constrained, this information becomes important for making sound investment decisions. For policy decisions, water values are also important to set the levels that the various users should pay for this resource.

Estimating the economic value of water helps in decisions for optimal allocation of the resource among various uses. Limited supply and increasing demand for water are common around the world. Under these circumstances, the economic value of water for each of its competing uses helps the decision maker decide how much water to allocate to each sector or use, and also helps determine the use of water in time, how much to use now and how much to save for the future.

In 1992, experts from 100 countries, intergovernmental organizations, and NGOs gathered in Dublin for the International Conference on Water and the Environment. The conference influenced preparations for the UN Conference on Environment and Development, held later that year in Rio de Janeiro.[1] Its brief concluding statement remains an authoritative affirmation of the water policy agenda; it contained four "guiding principles." The most important principle from this statement that has generated a great deal of controversy has to do with the consideration that water has an economic value in all its competing uses and should be recognized as an economic good. However, the statement recognizes the basic right of all human beings to have access to clean water and sanitation at an affordable price (see Appendix 1).

ECONOMIC CONCEPTS

To understand better the methodologies for estimating the economic value of water described below, it is important to review two key economic concepts (2).

The Demand Curve and the Price Elasticity of Water Demand

When we talk about willingness to pay for value, we mean the maximum amount that a individual is willing to pay for a product. This is the sum of the product price (P) and the consumer surplus. If we wish to estimate the maximum that the individual is willing to pay for a proposed change, we should estimate the demand curve.

A consumer's willingness to pay for an increment of supply is the corresponding area under the demand curve (price vs. quantity), although the amount the consumer actually pays for the increment is the water price times the quantity. The difference between these two values is what it is called the consumer surplus (the benefit for the consumer that he/she did not pay for it).

Assuming that the price elasticity of demand (ε) is known, is constant over the relevant range, and is not equal to one, and second, that the relevant initial price P_1 and quantity Q_1 can be specified, then the area under the curve (i.e., the desired measure of value—denoted V) for a change in quantity Q_1 to Q_2 is given by

$$V = [(P_1{Q_1}^{1/\varepsilon})/(1 - 1/\varepsilon)][(Q_1/Q_1^{1/\varepsilon}) - (Q_2/Q_2^{1/\varepsilon})]$$

This expression represents the value of an increment of quantity Q to the final user. This incremental value will provide a measure of benefits to compare with costs in an investment project evaluation.

---

[1] Awareness of the seriousness of water problems has evolved gradually over the years, and important recommendations have been formulated since the United Nations Water Conference in Mar del Plata (Argentina) in 1977. Other events that have focused on water issues include the 1992 International Conference on Water and the Environment, convened by the World Meteorological Organization (WMO) in Dublin, Ireland, and the 1992 United Nations Conference on Environment and Development (UNCED) in Rio de Janeiro. The Ministerial Conference on Drinking Water and Environmental Sanitation held in Noordwijk in March 1994 adopted an action program. In 1994, the United Nations Commission on Sustainable Development requested a comprehensive assessment of the world's freshwater resources, including projections of future needs the results of the study were considered by the 1997 special session of the UN General Assembly reviewing the implementation of Agenda 21.

Estimates of price elasticities of water demand have shown that water use is consistently price-inelastic when there is no substitute, whereas residual use (i.e., watering the garden) is more elastic and differs significantly across geographical regions and between climate seasons (i.e., winter–summer, rainy–dry) (3).

The price responsiveness of water demand reflects the heterogeneity of demand components. A small portion of the demand is for uses for which there are no substitutes and that are of great necessity to the consumer; other uses are of lesser value and have ready substitutes.

Treatment of Time

The rate of conversion of value between time periods is called the rate of time of preference. Defining the best long-term management of the resource requires balancing the needs of the present and those of the future. Using a discount rate that adequately considers the value of goods or services for future generations creates this balance. A high discount rate implicitly places a low value on water's value to future generations. A low discount rate implies the opposite.

Another issue related to time is the difference between long-run and short-run values of water. The distinction between these two relates to the fixity of certain inputs necessary to make water available for consumption, such as supply infrastructure. Other things remaining constant, we would expect that values estimated for short-run contexts would be larger than values for the long run. Price elasticity of demand is less in the short run than in the long run when adjustments to shortages and infrastructure can be made. Accordingly, willingness to pay in the short run is usually higher than in the long run.

ESTIMATION METHODOLOGIES

The principles for valuing natural assets such as energy and mineral deposits, forests, and aquifers were set forth more than 60 years ago, but the principles for measuring consumptive value of water for household use were set forth a century ago.

Water services in many situations are difficult to value because much of the information needed for valuation is not readily available. When markets exist, they automatically generate useful information, but unfortunately, most of the services provided by water are not traded on markets. Therefore, one has to rely on techniques to value nonmarket goods.

Economists have developed indirect methods (e.g., hedonic price models, travel cost method, averting behavior), which infer values from other behaviors associated with the good. The strengths of indirect methods come from the fact that they rely on observed behaviors of producers and consumers. Examples are the market price as result of human behavior (demand and supply) as a function of the quality of the water nearby. Recent summaries of indirect approaches can be found in Braden and Kolstad (4), Mendelsohn and Markstrom (5), Smith (6,7), and Freeman (8).

The valuation method must be well matched to the context and the water function or service of interest. It is hard to generalize in the abstract about the validity and reliability of specific valuation approaches. The validity of the methodology used depends on the valuation context and the type of service that are of interest. Different approaches are needed to value different services. A valuation framework takes into account how time, institutions, water quality and quantity, hydrologic factors, and services interact to affect the resource's value.

One of the major challenges in valuing water resources is how to integrate the hydrologic and physical components into a valuation scheme. Valuation of the extractive and onsite services of water requires understanding the hydrology and ecology of the water source. Hydrologic information includes variables such as rainfall, runoff, infiltration, water balance, depth to groundwater, aquifer characteristics, and water quality.

DIRECT VALUATION APPROACHES

Market Prices

When market prices exist, the equilibrium price represents the willingness of potential buyers to pay for the good or service of water. In other words, when water has a market and it can be bought and sold, then the economic value of water is its price. However, in some cases due to government intervention such as subsidies or market failures, these prices are distorted and need to be adjusted to obtain the real economic value of the resource.

Transactions between a buyer and a seller are increasingly observed when water rights are defined and other conditions exist that make the water market function. Easter and Hearne (9) and Rosegrant and Binswanger (10) describe examples of water rights markets. If there is a market for perpetual water rights, the value of water can be estimated by using the perpetuity formula $V = A/r$ where r is the interest rate (discount rate), V the value of the perpetual water right, and A the value of water.

Contingent Valuation Method

Economic value is not a fixed, inherent attribute of a good or service but rather depends on time, circumstances, and individual preferences. One technique that attempts to measure total value is the contingent valuation method (CVM). CVM values are elicited directly from individuals via interviews or questionnaires in the form of statements of maximum willingness to pay (WTP) or minimum willingness to accept compensation (WTA) for hypothetical changes in environmental goods, such as water quantity or quality. However, there are numerous methodological controversies associated with the application of CVM, including the way the hypothetical water change (in quantity or quality) is to be specified, the elicitation format for asking valuation questions, the appropriate measure to be elicited, and various types of response biases. CVM provides reliable estimates of value when an individual has a close connection to the resource being valued.

This methodology is used when no value measures can be derived from observing individual choices through a market, such as water quality issues. This approach can potentially measure the economic benefits (or damages) of a wide assortment of beneficial (or adverse) effects in a way that is consistent with economic theory (11).

The CVM method is an ex-ante technique that can be used to measure the value of water without the need for observable behavior (data). In addition, this is the only method (direct or indirect) that measures existent or bequest values (use and nonuse values). It is an expensive method because of the need to carry out a survey, and there are concerns about its use for nonuse value applications.

Using this approach, respondents of surveys are offered conditions simulating a hypothetical market in which they are asked to express willingness to pay for existing or potential environmental conditions not registered on any market. The contingent valuation method (CVM) derives estimates for social benefits attributable to water, when considered a public or nonmarket good. This method is used frequently for projects or programs that affect water quality. The procedural steps for applying the CVM are as follows (12):

The first component describes the setting under which the respondent is to imagine herself/himself. Second are the choice questions, which will be used to infer values of the amenity or policy change. The third element asks questions about the respondent to identify demand shift variables such as age, education, income, and gender. For the forms of questions used and the way to design the survey instrument in CVM studies, see Mitchell and Carson (11) and Cummings et al. (12).

The CVM approach, given its hypothetical attributes, is susceptible to various sources of errors or biases. Some of them are (1) the questionnaire scenario can encourage strategic behavior, (2) the compliance bias or a tendency to fit the responses to the perceived preferences of the interviewer, (3) the possibility that the scenario provides implied values cues to the respondent, and (4) scenario misspecification when the respondent fails to understand the scenario intended by the researcher. These biases demand a careful questionnaire design.

The willingness to pay is estimated by using the following expression:

$$\mathrm{WTP} = f(\Delta Q_j, \Delta P_j, \Delta \mathrm{SP}_j/I_j, H_j)$$

where ΔQ_j defines a specific change in water quality, ΔP_j represents the change in price of water from primary supplies, ΔSP_j represents the change in price of substitute sources of water, I_j represents household income for individual j net of taxes, and Hj represents various nonincome characteristics of individual j's household.

INDIRECT VALUATION APPROACHES

Derived Demand

Water demand (households, farms, etc.) tends to be very site-specific and is influenced by a range of natural and socioeconomic factors. The demand relationship is represented algebraically by the familiar function,

$$Q_w = Q_w(P_w, P_a, P; Y; \mathbf{Z})$$

where Q_w refers to the individual's level of water consumption in a specified time period, P_w refers to the price of water, P_a denotes the price of an alternative water source, P refers to an average price index representing all other goods and services, Y is the consumer's income, and $\mathbf{Z}$ is a vector representing other factors such as climate and consumer preferences (13). This demand curve is usually estimated by using cross-sectional observations (data taken for the same time period) from a sample of water service agencies which exhibit a range of water rates and often variation in other factors influencing demand, such as income, rainfall, and temperature. The general approach is to apply regression analysis to estimate the parameters of the demand equation, parameters that allow us to estimate the price elasticity of demand.

The gross value of water is derived by integrating (area under the curve) the inverse of the econometrically derived demand function, $P(Q_w)$, over the appropriate increment in quantity. If the demand function was estimated for tap water and one is looking for the consumer demand function for raw water for intersectional allocation, then an additional step is necessary. The costs of capturing, transporting, treating, and storing water must be deducted from the estimated willingness to pay for tap water. When tap water (domestic) is priced to recover fully the costs of supplying it, the average revenue can be subtracted from the value of water estimated before. See Booker and Young (14) for an application of this point.

The derived demand approach is usually used to estimate the value of water in the municipal environment. Its main advantages are that it is based on observable data from firms/households using water and is relatively inexpensive. However, using this approach, it is not possible to measure the nonuse value of water and, sometimes, understates the willingness to pay for the resource (2).

The approach described above does not capture the benefit of loss in value due to the reliability dimension (the probability of having an interrupted service). Some other methodologies such as the contingent valuation method have been used in the past to estimate the reliability attribute of water supply. See, for example, Carson (15), Altaf et al. (16), and Howe and Smith (17).

Valuing Water as an Intermediate Good

Water is commonly used for producing goods; it is not a final product itself. Agricultural irrigation, industry, and hydroelectric or thermal power generation are examples of these uses. For intermediate goods, the theory of producer's demand for inputs provides the conceptual basis for valuing the economic value of water (18). The producer's demand for an input is its value as a marginal product (VMP); therefore measuring the economic value of water requires an approximation of the VMP. Three methods of valuing water as an intermediate good are in common use: the residual approach, the hedonic approach, and the alternative cost approach.

The Residual Approach. The "residual" method is the most frequently used approach for estimating the price of intermediate goods, particularly of irrigation water. Under this method, the incremental contribution of each input in the production process is determined. If appropriate prices can be assigned by market forces to all inputs but one, water, for example, the remainder of total value of product is imputed to the remaining residual input. In algebraic terms,

$$P_w = [\text{TVP}y - [(P_k Q_k) + (P_l Q_l) + (P_R Q_R)]]/Q_w$$

where P_w and Q_w are the price and quantity of water, respectively, TVP_y is the total value product, and the parenthesis terms are the price multiplied by the quantity of each of the other inputs in the production process (K, L, R).

This technique is extremely sensitive to small variations in the assumptions about the nature of the production function and about prices. Biases can be introduced by any of several types of errors and omissions. Therefore, this approach is most suitable when water contributes significantly to the value of the output (agricultural production, hydropower generation).

Sometimes, mathematical programming (optimization) models are used to estimate the value of water using the residual approach. These models are built to obtain the optimum allocation of water and other resources (inputs) so as to maximize profits, subject to constraints on resource availability and institutional capacity (19). Mathematical programming is advantageous when a wide range of technological options is to be studied.

The Alternative Cost Approach. This method is also appropriate for measuring the value of water when water is an intermediate good. The technique is attractive under the assumption that, if a given project of specified output costs less than the next best public or private project which can achieve the same output, then the cost of the next best project can be assigned as the benefit to the public project in consideration. This approach has been employed for valuing of water in municipal, industrial, hydroelectric, and thermal electric power projects. Steiner (20) remains the primary authority on this approach. See also Herfindahl and Kneese (21).

Averting Behavior Model

Using this method, water value is estimated by the actions taken to avoid or reduce damage from exposure to water contaminants, such as changing daily routines to avoid exposure. However, averting expenditures and true reduction of pollution differ because such expenditures do not measure all the costs related to pollution that affect the consumer's utility. Therefore, the ability of this valuation approach to provide a lower bound to willingness to pay depends on various assumptions. A list of these conditions is explained in detailed in the literature (22).

The averting behavior technique is based on observable data from actual behavior and choices and is relatively inexpensive. It provides a lower bound of the willingness to pay if certain assumptions are met. However, its estimates do not capture full losses from environmental degradation, and several key assumptions must be met to obtain reliable estimates. It is usually used for expost analysis and is limited to current situations; as in the derived-demand approach, it does not estimate nonuse values.

Hedonic Price Model

This pricing method is based on the premise that people value a good because of the attributes of that good rather than the good itself. These models encompass both land (housing) price models and wage models that account for variations due to environmental attributes. Therefore, by regressing housing prices to the attributes of a house and site, including environmental characteristics, one obtains the marginal value of the characteristic q. In the estimating equation,

$$P = F(\mathbf{S}, \mathbf{N}, \mathbf{Q}) + \varepsilon$$

P is the sale price of the asset, $\mathbf{S}$ is a vector of structural characteristics, $\mathbf{N}$ is a vector of neighborhood characteristics, $\mathbf{Q}$ represents the environmental attribute(s) of interest, F is a function to be estimated by multiple-regression methods, and ε is an error term. $\partial P/\partial Q$ is the marginal value of the characteristic q or the amount of value gained or lost due to a defined change in the environment.

Estimating the economic value of environmental resources by hedonic methods is quite difficult in practice, and the technique is subject to serious limitations (8). First, a large enough sample might be difficult to obtain. Second, if water resources are already in public ownership, market transactions may not be available. Third, sometimes the effect of an environmental attribute or characteristic of price may be small and hard to detect statistically or to disentangle from the effects of all other variables. See a detailed description and examples in Palmquist (23) and McConnell (24).

Travel Cost Method

The travel cost is the most widely used example of the observed indirect methods. It involves two steps: the first is to estimate the individual recreationist's demand for the resource, and the second is to derive statistically the relevant aggregate resource demand curve. Travel cost methods encompass a variety of models, ranging from the simple single-site travel cost model to regional and generalized models that incorporate quality indexes and account for substitution across sites. The basic premise behind these models is that the travel cost incurred in traveling to a site can be regarded as the price of access to the site. Therefore, under some assumptions, it is possible to derive the demand for visits to a site as a function of the price of admission, which is set equivalent to the cost of travel to the site.

This method is based on observable data from actual behavior and choices and is relatively inexpensive. However, sometimes is not easy to observe consumer behavior regarding the choice of recreation sites, and it is limited to the water uses that include travel such as recreation. It does not measure nonuse values.

The major drawback is that sometimes it is difficult to isolate the contribution of water to the attractiveness of a site. In other words, there are some other attributes that contribute to the total site value and are difficult to isolate. Another problem in using this approach is to decide what to include when estimating the cost of travel (cost of gas, oil, tires, etc), and whether or not the opportunity cost of the recreationist's time should be included in the estimate. A detailed explanation of this approach and real world examples are in Walsh (25), McConnell (24), Freeman (8), and Fletcher et al. (26).

Benefit Transfer and Meta-Analysis

The process of benefit transfer consists of adapting estimates relating to sites that have been studied to sites lacking such studies. It is an approach that consists of pooling data from already completed studies and then applying multiple regression analysis using explanatory variables that are site specific and methodology specific. For a detailed description, see Walsh et al. (27). A similar approach but using research findings is called meta-analysis; it has been used for estimating the benefits of natural resources. See, for example, Smith and Kaoru (28).

AN APPLICATION OF VALUATION

Quality of Water

Valuing the quality of water usually requires establishing its relationship to the health conditions of its users. In the past, various methodologies have been used to measure the economic value of changes in health benefits or risks from a change in water quality levels. For this purpose, they have used various tools or techniques such as water demand functions, averting or defensive expenditures, changes in production costs, the hedonic price method, or stated preference methods such as the contingent valuation method or conjoint analysis (29).

Another service supported by water quality is the provision of drinking water for livestock and irrigation. A change in the quality of water used for these purposes may result in a change in the value of livestock or crops, a change in agricultural production costs, or a change in human health or health risks by increasing or decreasing the trace chemicals found on plants ingested by people. The change in the value of crops can be estimated using a market demand function. The change in production costs can be estimated using cost functions. For changes in human health and health risks, one could use the damage avoided approach and stated preference methods. Similar methods should be used for the eventual changes in the value of crops from a commercial fish harvest, commercial hunting harvest, or commercial plant harvest.

A change in surface or groundwater quality can also have an impact on the quantity or quality of recreational services such as fishing, hunting, or just enjoying the scenery. Potential techniques for valuing these effects include the travel cost method and stated preference methods.

On the other hand, the effects of changes in nonuse or passive use services are some of the most difficult effect to value monetarily. A change in nonuse or passive use services results in a direct change in personal utility or satisfaction that may be reflected in the decision on consumption of water. The most viable techniques for measuring these effects are stated preference methods (11,15).

A comprehensive, rigorous and useful discussion of the theory and practice of valuing environmental resources is given in Freeman (8). See also Anderson and Bishop (30), Bentkover et al (31), Johansson (32), Braden and Kolstad (4), and Pearce and Warford (33).

APPENDIX 1. THE DUBLIN STATEMENT

In commending this Dublin Statement to the world leaders assembled at the United Nations Conference on Environment and Development (UNCED) in Rio de Janeiro in June 1992, the Conference participants urge all governments to study carefully the specific activities and means of implementation recommended in the Conference Report, and to translate those recommendations into urgent action programmes for water and sustainable development.

Guiding Principles

Concerted action is needed to reverse the present trends of overconsumption, pollution, and rising threats from drought and floods. The Conference Report sets out recommendations for action at local, national and international levels, based on four guiding principles.

Principle No. 1. Fresh water is a finite and vulnerable resource, essential to sustain life, development and the environment

Since water sustains life, effective management of water resources demands a holistic approach, linking social and economic development with protection of natural ecosystems. Effective management links land and water uses across the whole of a catchment area or groundwater aquifer.

Principle No. 2. Water development and management should be based on a participatory approach, involving users, planners and policy-makers at all levels

The participatory approach involves raising awareness of the importance of water among policy-makers and the general public. It means that decisions are taken at the lowest appropriate level, with full public consultation and involvement of users in the planning and implementation of water projects.

Principle No. 3. Women play a central part in the provision, management and safeguarding of water

This pivotal role of women as providers and users of water and guardians of the living environment has seldom been reflected in institutional arrangements for the development and management of water resources. Acceptance and implementation of this principle requires positive policies to address women's specific needs and to equip and empower women to participate at all levels in water resources programmes, including decision-making and implementation, in ways defined by them.

Principle No. 4. Water has an economic value in all its competing uses and should be recognized as an economic good

Within this principle, it is vital to recognize first the basic right of all human beings to have access to clean water and sanitation at an affordable price. Past failure to recognize the economic value of water has led to wasteful and environmentally damaging uses of the resource. Managing water as an economic good is an important way of achieving efficient and equitable use, and of encouraging conservation and protection of water resources.

Acknowledgments

It must be acknowledged that this chapter owes a great deal in both substance and form to the paper written by Robert A Young

in 1996 for the World Bank based on the pioneering work by him and S. Lee Gray in 1972 (1,34).

WATER SUPPLY PLANNING—FEDERAL

David L. Feldman
University of Tennessee
Knoxville, Tennessee

The U.S. government has been engaged in water supply planning for domestic, agricultural, commercial, and industrial needs from its inception. Planning was initially undertaken for inland navigation and flood control. Later, primacy was given to irrigation, municipal needs, and hydroelectricity. The Army Corps of Engineers, the largest and most important federal water supply planning entity, was initially given responsibility for all these efforts. In 1902, the Bureau of Reclamation (BOR) was established and given principal responsibility for water supply projects in the West.

GENERAL PLANNING ISSUES

Federal water supply planning has been characterized by recurring policy debates on four issues:

- the value of *structural* measures (e.g., dams, impoundments) versus *nonstructural* measures such as conservation and demand-side management;
- the primacy to be accorded the *philosophies and missions* of competing agencies (e.g., the Corps, BOR) in the planning process;
- the advantages of *comprehensive, conjoint coordination* by a single entity (e.g., Interior Department, Water Resources Council), facilitated by state cost-sharing; and
- the appropriate role of *public participation*, particularly inclusion of environmental NGOs in plan formulation.

These issues have frequently arisen in discussions over specific plans. In the 1940s, for example, the Pick–Sloan Missouri River project, one of the largest federal water supply planning efforts, was conceived as a compromise between the Corps and BOR, which shared responsibility for water supply in the upper Missouri basin though they had different priorities. The BOR envisioned irrigation as the primary objective of main-stem dam construction, and the Corps gave primacy to flood control and hydropower. When these agencies failed to reconcile priorities, Congress opted to allow each to develop separate plans which would later be integrated by a series of review boards charged with managing and overseeing reservoir operations (1).

HISTORY OF FEDERAL WATER SUPPLY PLANNING EFFORTS

For much of the nineteenth century, water supply planning meant the development by states and communities of engineering-based solutions to meet specific stakeholder objectives such as flood control, municipal supply, or water treatment (2). During the twentieth century planning embraced "multiple objectives" undertaken by *all* levels of government. It is now generally conceived as a comprehensive effort to harmonize environmental, economic, financial, and other concerns (3).

Five distinct periods in the evolution of federal water supply planning are discernible: (1) a formative period consisting of federal intervention in water supply in response to specific regional needs; (2) a federal–state cooperative planning era, following the Civil War, whose focus was mostly navigational improvements; (3) a "multiprogram" era, beginning in the 1930s, characterized by establishment of national priorities; (4) an effort to "federalize" water supply planning through greater presidential-level coordination; and (5) a new federal–state partnership coupled with greater sensitivity to environmental protection and restoration needs.

Formative Developments

The earliest federal water supply planning efforts coincided with exploratory surveys of the intermountain West. Led in many cases by Army engineers, one of these expeditions was intended to identify and trace the origins and suitability for development of water supply sources. The journeys of Lewis and Clark (1804–05) and Zebulon Pike (1806–07) in the upper Missouri and Arkansas River basins, respectively, are the best known of these; Stephen H. Long's Central Rocky Mountain-Yellowstone expedition (1819–20) also surveyed regional water resources.

In 1824, the Corps was officially designated as the steward of the nation's water resources. Between this time and the Civil War, the Corps identified mill sites and needs for navigational improvements and engaged in channel widening and other flood hazard mitigation activities (4,5). These efforts generally produced site-specific solutions to local problems. Despite fierce engineering debates, particularly over proposals to harness the Mississippi River for navigation and flood prevention (6), they failed to set broad, consistent development priorities.

The Advent of Federal–State Cooperative Planning

The origins of a more comprehensive approach to water supply planning may be traced to 1879, when explorer and geographer John Wesley Powell decried the system of Western water law, charging that by encouraging the first users of a river to lay claim to its entire flow (the law of prior appropriation), harm is imposed on other users and the in-stream environment. As first director of the U.S. Geological Survey, Powell proposed dividing the West's arid lands into irrigation districts where each farmer was allotted 80 acres. These districts would be drawn to conform to watershed topography, and drainage basins would serve as state boundaries (7,8).

Powell's proposals discouraged Western migration and drew the ire of Congress and Western land development interests. Ironically, this adverse reaction partly hastened federal efforts to initiate large-scale reclamation projects designed, principally, to support Western agriculture.

These projects would be justified (and subsidized) by their flood control and hydroelectric power benefits—a pattern which would characterize federal water supply planning until the late twentieth century. In exchange for broad political support, a reciprocal system of large-scale, publically financed water projects was eventually provided to Eastern states, principally for navigation, power, and flood abatement (9–13).

In 1879 the Mississippi River Commission (MRC) was also established, one of the first efforts to coordinate federal–state water supply planning efforts in a single basin. MRC was formed to deepen and widen the river's navigable channel and provide flood abatement. Limited efforts to accelerate intergovernmental coordination efforts elsewhere occurred under the presidency of Theodore Roosevelt who "was interested in securing state cooperation and assistance in his program" to develop comprehensive management of the nation's rivers (14). However, these efforts were largely unidirectional in their scope: federal construction agencies that had greater fiscal and technical resources continued to make most decisions. Another goal of Teddy Roosevelt—reducing the power of private interests to exploit the development of water resources for their own gain—was not seriously tackled until the 1930s.

Multiprogram Planning and the Great Depression

The first multipurpose federal water supply planning efforts began when the Tennessee Valley Authority (TVA) was established in 1933. The TVA was granted broad power over a seven-state area to engage in regional water supply planning, flood control, hydropower production, navigation, and economic development. In President Franklin Roosevelt's words, it was to be a "... corporation clothed with the power of government but possessed with the flexibility and initiative of private enterprise" (15). Local entities were incorporated into its economic development programs, and long-term political alliances were built to ensure programmatic and funding stability. Most importantly, TVA "supplanted" other federal water resource agencies in its operating region, and the absence of large private power companies also helped it achieve comprehensive breadth (16).

The political conditions that permitted TVA to do all these things were uniquely characteristic of American politics during the 1930s. Some contend that these conditions may no longer exist, exemplified by the fact that later federal efforts to develop TVA-like entities in the Missouri and Columbia basins failed to gain support in Congress and among local elites (13,15). In short, no TVA-like entity has been replicated anywhere else in the United States.

In other regions, FDR's Interior Secretary Harold Ickes formed basin study groups with formal staffs, planning funds, and some powers of program review during this period. These groups had little formal access to Congress and lacked the ability to initiate new projects or overrule decisions of established water agencies regarding what they often deemed as uneconomical or environmentally damaging policies. They also had no control over planning objectives, which continued to be left to the Corps and other "construction agencies" (17).

A parallel, noteworthy development in this period was the federal interstate compact. The Colorado River Compact, one of the oldest of these, allocates both claimed and unused waters in a seven-state basin based on future needs and water-use priorities. The compact entered into force in 1922, but Arizona, due to resentment over what it considered to be an inequitable division of its share of the lower Colorado, refused to ratify it until 1944. When it did so, it tried to use its ratification to leverage federal funds to build the long-coveted Central Arizona Project, designed to divert Colorado River water to Phoenix, Tucson, and surrounding rural communities via aqueduct (18–20).

Although interstate compacts vary in intent, scope of activity, and structure, all derive their legal authority from the compact clause of the U.S. Constitution (Art. I, Sec. 10, clause 3) which mandates Congress's consent when states enter into binding agreements with one another. This endows them with rights to embrace public as well as private facilities and projects within their jurisdiction. It also binds the actions of signatory states *and* federal agencies and authorizes allocation of interstate waters in accordance with the doctrine of equitable apportionment (i.e., in ways that do not disturb or impair rights awarded to parties under Supreme Court decree without their consent). In effect, their decisions have the force of national law.

During the 1960s, in response to deteriorating water quality and droughts in the Northeast, compact commissions were established for the Delaware (DRBC), Susquehanna (SRBC), and Potomac River (PRBC) basins. These were empowered to allocate interstate waters (including groundwater and interbasin diversions), regulate water quality, and manage interstate bridges and ports. The DRBC, as a forerunner of this model, included numerous federal partners such as Interior Department and Corps of Engineers officials (21,22).

Since 1997, most compacts have continued to function without federal appropriations as a result of Congressional adoption of Heritage Foundation recommendations which urged that Congress "defund" programs whose benefits were viewed as more regional than national in scope. The DRBC and SRBC have sustained themselves without federal appropriations, and Congress has not withdrawn from any compact. Also in 1997, the DRBC's Executive Director advised officials of Alabama, Florida, and Georgia during formulation of two new compacts in that region (the ACF-ACT compacts), and the DRBC and SRBC were explicitly adopted as models by these compacts' framers (21).

"Federalizing" Water Supply Planning: The Water Resources Council and Other Efforts

In the early 1960s, Congress embarked on an effort to provide greater coordination of water supply planning. The Water Resources Council (WRC) was established in 1961 to hasten a more holistic approach to planning by encouraging interagency cooperation and integrating water quality and quantity concerns. It was initially composed of representatives from the Departments of Agriculture, Army, Commerce, and Interior.

In 1965, WRC was empowered by the Water Resources Planning Act (PL 89-80) to engage in comprehensive water supply planning by "maintain(ing) a continuing study of the nation's water and related land resources and to prepare periodic assessments to determine the adequacy of these resources to meet present and future requirements" (23). The Act encouraged states to establish "Title II" river basin commissions charged with integrating and harmonizing state assessments of water supply problems and encouraging regional supply planning. These were staffed by state *and* federal representatives.

The WRC employed competitive planning grants to states and river basin commissions for gathering basic data on water; identifying problems; and developing long-term ("level B") plans for "comprehensive, coordinated management of water resources." The commissions also tried to coordinate the efforts of the Corps of Engineers, BOR, and other federal agencies to provide assistance to states and communities in drawing up these plans. The WRC conducted two national assessments in 1968 and 1978. Both comprehensively depicted the nation's current and projected water needs; analyzed water-related problems from national, regional, and major river basin vantage points; and provided a wealth of data on water quality, quantity, and land use trends and problems (23,24).

As long as the WRC's efforts remained confined to preparing broad sets of recommendations for others to weigh and adopt, they generated little controversy and even less public attention. In the mid-1970s, however, WRC was charged by the Office of Management and Budget with developing "principles and standards" to be applied to evaluation of water projects, as well as cost-share guidance. The WRC was also granted power to discourage projects of dubious economic value or potentially adverse environmental impact. Controversy came to a head during the presidency of Jimmy Carter (1977–1981) who actively sought to diminish Congress's tradition of "pork barrel" water projects, charging that they were wasteful of public expenditures, economically unjustifiable, and in many cases, ecologically harmful. Criticism grew in Congress that WRC was exercising an "anti-dam" agenda through budget-cutting and impoundments to eliminate locally popular, necessary projects (25).

As a result of these criticisms and its eventual demise in 1981 under President Reagan, WRC is regarded as a failure. Critics charge that WRC did not ensure meaningful citizen participation at the inception of federal agency planning; overcome disagreements among states, communities, and other traditional beneficiaries of "pork-barrel" projects; or overcome the perception that its planning efforts were perceived as imposed from above. Moreover, it failed to find "an appropriate ideological basis for policy" (26,27).

Mention should also be made of the U.S. National Water Commission (NWC, 1967–1973), which grew out of controversies in the 1960s surrounding proposals to dam the lower Colorado River. Its chief legacy was the attempt to place fiscal discipline upon federal water supply efforts and to identify ways to better coordinate federal agency water supply planning and pollution control activities (28,29). NWC did succeed in placing species diversity, riverine protection, and other environmental issues on a policy footing equal to traditional economic development drivers of federal water supply planning. Moreover, the NWC's final report provided a "penetrating critique of water resources decision making" (29, pp. 4–24). Its recommendations to improve groundwater management, liberalize in-stream flow protection, urge greater wastewater reuse, and increase agricultural water efficiency remain part of many recent water planning efforts.

The 'New' Paradigm: Federal–State Partnership and Environmental Sensitivity

Since the 1980s, a "new" paradigm for federal water supply planning has evolved that is characterized by greater stakeholder participation in formulating policy alternatives; environmentally sound, socially just water resources management; reliance upon drainage basins as planning units; and greater state–federal cost sharing (30). This paradigm, advocates believe, promotes a management approach more accountable to *varied* interests, amenable to "regionally and locally tailored solutions" (29), and protective of fish and wildlife. Eroding federal interest in water supply, exemplified by Congress' 1997 'zeroing-out' of funding for river basin commissions and a general decline in support for new water projects, has helped legitimize this new paradigm (31–33).

In 1980, Congress passed the *Pacific Northwest Electric Power Planning and Conservation Act* [16 U.S.C. § 839b(h)]. The Act's purpose was to restore salmon spawning runs on the Columbia and Snake Rivers by making salmon a "coequal partner" with hydroelectric power in the operation of the Columbia Basin's 150 + dams (34). The Act also established the Northwest Power Planning Council (NPPC), a multistate, multiagency partnership comprised of the Bonneville Power Authority (BPA), the Pacific Northwest Electric Power and Conservation Council, and governor-appointed representatives from Washington, Oregon, Idaho, and Montana. NPPC has encouraged cooperation among utility systems, conservation and efficient power use, greater involvement of state and local governments in regional power planning, and oversight of electric power system planning and regional fish and wildlife recovery. NPPC is developing a long-range plan to ensure low-cost power for the region while protecting and rebuilding fishery and wildlife populations depleted by hydropower development.

Because NPPC represents a bold step toward adopting this "new" paradigm, its efforts have been heralded as an innovative means of bringing stakeholders together. Its activities have even led to creation of a regional "water budget" designed both to protect fisheries and provide for other services (more than 4 million acre-feet for salmon, seasonally allocated on the Columbia and Snake Rivers), and the set aside of 44,000 river miles of prime fish and wildlife habitat from new hydropower development.

Although it had an enormous effect on regional electric policies and regional approaches to fish and wildlife protection and restoration, NPPC has not prevented several species of Snake River salmon from being listed under the *Endangered Species Act*. By 1990, annual fish runs had been reduced from an estimated 10–16 million to fewer than 3 million, despite more than $100 million in expenditures on environmental improvements at dams and decreased hydropower production. By 1995, many West Coast salmonid species had been driven to extinction, and others remain at risk of extinction. Adding to its problems, in 1994, the Ninth Circuit Court of Appeals rejected NPPC's initial Salmon Strategy and criticized the council's "sacrificing the Act's fish and wildlife goals" (35, p. 190). NPPC has promulgated a new plan to provide for endangered salmon recovery as well as to ensure protection of other fish species.

Although not formally a "compact," NPPC does have compact-like powers to develop plans and meld the operations of state and federal water supply entities. The various water budgets and operational and engineering changes developed on the riverine system are products, in part, of data management tools refined in the light of experience. Eleven state and federal agencies, 13 Native American tribes, eight utilities, and numerous fish, forest, and environmental groups are among the stakeholders involved in restoring the Columbia River system.

Despite its mixed record, NPPC has forced environmental issues onto the agenda of water and power agencies in the Pacific Northwest. As one observer has stated, ecological imperatives, aesthetics, and demands for equity "have given rise to a greater consciousness of the ethical implications of water use" (36). Moreover, unlike previous federal efforts, NPPC has encouraged extensive public involvement and planning for long-term threats by incorporating local community and tribal concerns (35,36). Clearly, NPPC is a major departure from previous federal water supply planning efforts. It may also be a window into the future.

CONCLUSIONS: WHITHER FEDERAL WATER SUPPLY PLANNING?

Federal water supply planning efforts began as attempts to promote support for regional power, reclamation, or flood control projects; or to thwart the influence of private interests who wanted to develop such projects. For most of their history, these efforts limited public involvement to a "consultative" role; failed to provide adequate interagency coordination; and, sometimes fell short of being truly comprehensive.

We now know that effective federal water supply planning requires the ability to overcome agency "turf wars" by pursuing objectives defined by regional stakeholders; supplant authority vested in several agencies (e.g., TVA), and comprehensively manage several water supply needs simultaneously (e.g., DRBC and SRBC have mandates over water quality *and* supply). The record of federal planning further suggests that effective efforts are those perceived as economical and efficient, and thus able to generate public support for projects and programs (37). Finally, they must encourage collaboration among those stakeholders most directly affected by water supply problems. Collaboration overcomes resistance to change, facilitates new opportunities for funding, and stimulates resilient policy ideas (38). Today, public involvement is an essential part of all water supply planning efforts in the United States. As we enter a new millennium, questions that remain to be answered include, how do we determine the objectives of future plans, and what should the federal role be in their implementation?

FLOOD CONTROL ACT OF 1944

ARTHUR M. HOLST
Philadelphia Water Department
Philadelphia, Pennsylvania

The Flood Control Act of 1944, enacted on December 22 of that year, established federal policy regarding jurisdiction over rivers and other bodies of water, specifically watersheds. The act states that all water-related construction and navigation projects will be approved only if they substantially improve navigational capacity and do not excessively interfere with standard water usage. The plan was proposed to prevent flooding and to allow more irrigation, easier navigation, increased river-related recreation, and the production of hydroelectric power. The Army Corp of Engineers was designated to oversee these tasks.

A major component of the Flood Control Act of 1944 is known as the Pick–Sloan plan. Named after its two creators, Glenn Sloan and Lewis Pick, members of the Army Corps of Engineers, this plan authorized the construction of six dams in three states on the Missouri River. The plan created the largest reservoir in North America. Prior to the 1940s, national water navigation and flood control projects were run by four different agencies that had little or no communication and planning among them: the Army Corps of Engineers, the Federal Power Commission, the Reclamation Bureau, and the Soil Conservation Service. As a result of massive and catastrophic flooding that occurred in 1936, all this changed. In March of that year, flooding killed 107 people and caused $270,000,000 of damage. The United States had never before had very many flood control projects; after these floods, it became clear that this needed to change. The federal government responded by passing the 1936 Flood Control Act and 8 years later, the Flood Control Act of 1944.

The Flood Control Act has 15 sections. The first section is composed of rules for water-related planning submissions to Congress, specifically, that they must not interfere with established water uses. These include domestic and municipal use, as well as irrigation and industrial uses. It also asserts the importance of state involvement in projects and plans that will affect them, as determined by the Chief Engineer of the Army Corps.

The second section explains that flood control includes channel and drainage improvements. This section also states that river improvement for flood control is under the War Department (now the Department of Defense) as directed by the Secretary of War (now the Secretary of Defense), and supervised by the Chief Engineer of the Army Corps. Watershed alteration, erosion prevention, and water flow control projects, on the other hand, are stated to be under the control of the Department of Agriculture, as directed by the Secretary of Agriculture. These jurisdictions are subject to change only by Acts of Congress.

The third section deals with the 1936 Flood Control Act. It says that section 3 of that Act still applies to all projects. It also allows a 5-year period in which local interests working on water-related projects can secure whatever local cooperation the Secretary of War deems necessary.

Section 4 authorizes the Chief Engineer of the Army Corps to operate and maintain reservoir facilities in the United States. The Secretary of War is authorized to lease reservoir land but must give preference to federal, state, and local government. The Secretary must also make reservoir areas available to the general public for recreational purposes, as adjudged consistent with the public interest.

Section 5 instructs the Secretary of War to deliver to the Secretary of the Interior all energy produced at reservoirs that is not required for their operation. The Secretary of the Interior is instructed to dispense this energy to the public at low rates and is allowed to build or acquire transmission lines and other facilities with money from Congress only if necessary.

The sixth section of the Act authorizes the Secretary of War to sell surplus reservoir water for reasonable prices, so long as this does not negatively affect standard water uses.

Section 7 instructs the Secretary of War to regulate the usage of reservoir storage intended for navigation and flood control. This section does not generally apply to the Tennessee Valley Authority.

Section 8 states that the Secretary of War may, on advisement of the Secretary of the Interior, allow the use of water for irrigation. The Secretary of the Interior is then authorized to construct and maintain whatever structures are necessary for irrigation. However, the Secretary is allowed to undertake such projects only after receiving Congressional authorization. This section does not apply to dams and reservoirs built for irrigation prior to 1944 by the Army Corps of Engineers.

Section 9 of the Flood Control Act of 1944 refers to specific flood control projects and allocates $200,000,000 for those projects; specifically, the Missouri River project.

The tenth section details many other projects which are authorized by the Act and affect the following areas: the Lake Champlain Basin, the Blackstone River Basin, the Connecticut River Basin, the Thames River Basin, the Housatonic River Basin, the Susquehanna River Basin, the Roanoke River Basin, the Edisto River Basin, the Savannah River Basin, the Mobile River Basin, the Alabama-Coosa River Basin, the Lower Mississippi River, the Red-Ouachita River Basin, the Arkansas River Basin, the White River Basin, the Upper Mississippi River Basin, the Red River of the North Basin, the Missouri River Basin, the Ohio River Basin, the Great Lakes Basin, the Colorado River Basin (Texas), the Brazos River Basin, the Rio Grande Basin, the Great Salt Basin, the Colorado River Basin, the San Diego River Basin, the Ventura River Basin, the Santa Ana River Basin, the Los Angeles-San Gabriel Basin and Ballona Creek, the Pajaro River Basin, the Sacramento-San Joaquin River Basin, the San Joaquin River, the Napa River Basin, the Coquille River Basin, the Nehalem River Basin, the Willamette River Basin, the Columbia River Basin, the Willapa River Basin, the Chehalis River Basin, and the Territory of Hawaii.

Section 11 lists many more areas for which the Secretary of War is instructed to oversee preliminary studies of flood control and other plans. These plans are not to be undertaken until authorized by law.

Section 12 appropriates $950,000,000 for all of these projects. It also appropriates $10,000,000 to the Departments of Agriculture and War for any preliminary studies of flood control improvements, $1,500,000 to the Federal Power Commission for these studies, and a $500,000 emergency fund for emergency flood prevention.

Section 13 authorized various projects to reduce soil erosion and to improve water flow and runoff in these areas: the Los Angeles River Basin, the Santa Ynez River Basin, the Trinity River Basin (Texas), the Little Tallahatchie River Watershed, the Yazoo River Watershed, the Coosa River Watershed, the Little Sioux River Watershed, the Potomac River Watershed, the Buffalo Creek Watershed, the Colorado River Watershed (Texas), and the Washita River Watershed.

Section 14 of the Act deals with the balance of some $10,000,000 appropriated by an earlier act. It is to be used for the work detailed in section 13 of the Flood Control Act of 1944, and no more than 20% is to be spent on any one project.

The 15th and final section of the Act amends an earlier act approved in 1938. It allows the Secretary of War to undertake emergency measures to avert dangerous, destructive, and/or fatal flooding, based on codicil that he may not spend more than $100,000 in any fiscal year.

This Act permanently altered the manner in which water issues are handled in the United States and has saved billions of dollars in property damage by averting flooding.

GREAT LAKES GOVERNORS' AGREEMENT

Frederic Lasserre
Laval University
Quebec City, Quebec, Canada

Several institutions govern the use of the Great Lakes water and try to coordinate the actions undertaken by national governments (the United States and Canada) as well as state and provincial actions. Some of these institutions are old; some are much more recent and stem from political concerns regarding the quality of the water in the Great Lakes, as well as potential diversions that would have taken large quantities out of the basin.

THE GREAT LAKES GOVERNANCE

The International Joint Commission (IJC) prevents and resolves disputes between the United States of America and Canada under the 1909 Boundary Waters Treaty and "pursues the common good" of both countries as an "independent and objective advisor" to the two governments (1). Transportation was one of the main concerns of water management at the time: there was no water quantity problem, nor was there much talk of large variations in Great Lakes levels that could hamper human or industrial consumption. The negotiators wanted to ensure that water would always be sufficient to allow for the safe passage of ships through locks. Article III of the Treaty states that "no further or other uses or obstructions or diversions, whether temporary or permanent, of boundary waters on either side of the line, affecting the natural level or flow of boundary waters on the other side of the line shall be made, except by authority of the United States or the Dominion of Canada within their respective jurisdictions, and with the approval, as hereinafter provided, of a joint commission, to be known as the International Joint Commission." The IJC is, therefore, as its name underlines, an international institution between two sovereign States.

In particular, the Commission rules upon applications for approval of projects affecting boundary or transboundary waters and may regulate the operation of these projects; it assists the two countries in protecting the transboundary environment, including the implementation of the Great Lakes Water Quality Agreement (1972, renewed in 1978) and improving transboundary air quality, and it alerts the governments to emerging issues along the boundary that may give rise to bilateral disputes. The IJC, in particular, in its *Final Report on Protection of the Waters of the Great Lakes* (2000), recommended that Canadian and U.S. federal, provincial, and state governments should not permit diversion of water from the Great Lakes Basin unless the proponent can demonstrate that the removal would not endanger the integrity of the Great Lakes ecosystem (2).

The Great Lakes Commission (GLC) is the only regional organization whose statutory mandate is to represent the eight Great Lakes states on a variety of environmental and economic issues. It was created in 1955 and was granted Congressional consent in 1968. The Great Lakes Commission is now a binational agency: its members include the eight Great Lakes states—Illinois, Indiana, Michigan, Minnesota, New York, Ohio, Pennsylvania, and Wisconsin; the Canadian provinces of Ontario and Québec have had associate member status since 1999.

The Commission is dedicated to managing the waterbody of the Great Lakes: it promotes the orderly, integrated and comprehensive development, use, and conservation of the water and related natural resources of the Great Lakes Basin and St. Lawrence River. Each jurisdiction appoints a delegation of three to five members comprised of senior agency officials, legislators, or appointees of the governor or premier.

The Commission works actively at the member states' civil servant level. It is responsible for sharing information among members, coordinating state and provincial positions on issues of regional concern, and advocating those positions on which the members agree (3).

The GLC was set up by the member states as the St. Lawrence Seaway construction was well under way. The concern of the states was, at the time, to coordinate their views on ways to manage the economic, ecological, and social impacts of the increasing commercial traffic that would result from opening the Seaway in 1959.

The Council of Great Lakes Governors (CGLG), created in 1983, is a partnership of the Governors of the eight Great Lakes states. It has no legal basis. It is a pressure group that coordinates actions among the member states. It is, therefore, an institution separate from the Great Lakes Commission. Besides, the GLC is more technical, the CGLG more political in its aims and functioning. In recent years, the Canadian premiers of Ontario and Quebec have joined with the Council of Governors in sharing their views on the Great Lakes region.

The CGLG is not limited to Great Lakes water management. For instance, the CGLG coordinated negotiations among member states. The resulting 1988 Economic Development Agreement provides for coordinating the commercial promotion and trade missions of the member states abroad.

The central issue of common concern to all of the Governors was protecting and managing the waters of the Great Lakes. As the primary source of freshwater for the region as well as a trade route that connects the region to the world through the St. Lawrence Seaway, proper management of the lakes is crucial to the health of the residents of the Great Lakes region as well as to the continued growth of the region's economy. Consequently, coordinating Great Lakes regional water policy was the original impetus for creating the Council (4).

A MAJOR IMPETUS: PREVENTING DIVERSION FROM THE GREAT LAKES

The Advent of the Great Lakes Charter

Water pollution was one concern, and the Governors tackled the issue of improving Great Lakes water quality. In 1986, the Governors signed the Toxic Substances Control Agreement (TSCA) that provides for developing programs for companies to adopt pollution-prevention devices.

Diversion control and basin water integrity were another major concern. Governmental archives from the early 1980s attest to western United States lobbying for diversion of Great Lakes water to quench their lack of water. Great Lakes states wanted to resist these projects, both for environmental reasons as well as for political reasons: why would the Great Lakes states give to California an added value at a time when so many firms were leaving the area and moved away to the West Coast (5). The Great Lakes Charter stemmed from this growing concern that Great Lakes water could be diverted to water-scarce regions of the United States, the Midwest, and the West especially. States and provinces from the Great Lakes Basin had discussed their fears of diversion schemes at Mackinac Island (Michigan) in 1982 and at Indianapolis (Indiana) in 1983. The Great Lakes Charter, signed in 1985 by the eight Great Lakes Governors and the premiers of Ontario and Quebec, is the final resolution of a process set up after the Indianapolis meeting. The Charter created a notice and consultation process for Great Lakes diversions. The signatories agreed that no Great Lakes state or province would proceed with any new or increased diversion or consumptive use of Great Lakes water of more than five million gallons per day without notifying, consulting, and seeking the consent of all affected Great Lakes states and provinces. It also calls for coordinating water policies among member states and exchanging hydrologic data.

The Great Lakes states also lobbied the federal government that was in the process of designing a new law governing water use in the United States. The subsequent Water Resources Development Act of 1986 (WRDA) prohibits "any diversion of Great Lakes water by any State, federal agency, or private entity for use outside the Great Lakes basin unless such diversion is approved by the Governor of each of the Great Lakes States." It also prohibits any Federal agency from studying the transfer of Great Lakes water for use outside the Great Lakes Basin, unless done under the auspices of the IJC. To ensure compliance with a 1967 Supreme Court (modified in 1980) consent decree, the Act also appropriates federal resources to monitor and measure Lake Michigan's water flow into the Chicago River.

The Council coordinates the authority granted to the Governors under the Water Resources Development Act of 1986 (WRDA). The Act requires the Governors' unanimous approval on any proposed out-of-basin diversion of water from the Great Lakes Basin.

In 1997, the Great Lakes states entered into a Memorandum of Understanding on the Lake Michigan diversion, concluding a lengthy mediation process on the matter of Illinois' diversion of Lake Michigan water at Chicago. Under the U.S. Supreme Court decrees (1967 and 1980), Illinois was limited to 3,200 cfs each year. Illinois had exceeded that limit by nearly 15%. Illinois will further reduce its annual diversion during the following 14 years to restore to Lake Michigan the excess amount of water it has withdrawn since 1980 and construct new lakefront structures that do not allow leakage. All eight Great Lakes states and the U.S. federal government participated in the discussions. The Province of Ontario, as well as the City of Chicago and the Army Corps of Engineers, were also involved as observers or by providing technical support.

Diversions Are Still Feared: Banning Water Exports?

Diversion projects are far from being outmoded, despite the conclusion set forth by many observers that bulk water is, for now, too expensive to move over large distances. Large and small diversion schemes are still pushed by pressure groups. For instance, in the spring of 1998, the Province of Ontario approved a permit for the Nova Group of Sault Saint Marie Ontario that would have allowed the Nova Group to remove 60 million gallons per year from Lake Superior that would then be sold in Asia. In direct response to concerns expressed by the Great Lakes Governors via the Council, the Ontario government rescinded the permit. The accompanying public uproar led to the previously mentioned review of the issue of bulk removals by the International Joint Commission (IJC) in 2000. The Governors, through the Council, were represented on the study team that advised the IJC on these issues. Again in November 2002, Milwaukee mayor, John Norquist, denounced a diversion project to bring water to far western suburbs, outside the Great Lakes Basin.

So as to address a growing public concern that large water diversion schemes could someday be implemented, despite the Charter and the WRDA, the Council of Great Lakes Governors convened in 1999 and agreed there was a political need to reinforce the provisions of the Charter by

- forging a new, more binding agreement to manage the Great Lakes waters;
- creating a new standard requiring an improvement to the water and water-dependent natural resources of the Great Lakes before allowing new water uses;
- pledging to obtain better information so that the water is managed rationally; and
- lowering the trigger level for diversions that need to be approved under the Charter.

The Great Lakes Governors and the premiers of Ontario and Quebec signed the Great Lakes Charter Annex on June 18, 2001 in Niagara Falls, New York. The Annex, an amendment to the Great Lakes Charter of 1985, provides a blueprint for creating a new set of binding agreements among the states and provinces on the effective management of Great Lakes water resources. It also outlines a series of principles for reviewing water withdrawals from the Great Lakes Basin that is grounded in protecting, conserving, restoring, and improving the Great Lakes ecosystem. The new agreement must be set up by the member States before 2004 and then ratified at the two national levels of Canada and the United States to prevent any attempt to divert water from the Great Lakes Basin. A particular emphasis was placed in the Annex on the need to close loopholes that legal experts claim have arisen for water exports under the North American Free Trade Agreement and the General Agreement on Trade and Tariffs.

The history of the Great Lakes agreements attests to the evolution of the concerns regarding the largest body of freshwater. From a very transportation-oriented perspective, as embodied in the 1909 Boundary Waters Treaty, the focus evolved to pondering the possible impacts of the opening of the St. Lawrence Seaway in 1955, by the Great Lakes Commission, to emphasis placed on water quality and quantity, by the Great Lakes Charter of 1985. The advocacy of a major water diversion by western states pressure groups and recent strong variations in the Great Lakes levels stirred an important public controversy that led the Great Lakes Basin state and province leaders to sign the Annex in 2001 to ban all large water diversion out of the basin, thus implementing recommendations already made by the IJC in 2000.

U.S./CANADIAN BOUNDARY WATERS TREATY AND THE GREAT LAKES WATER QUALITY AGREEMENT

David W. Yoskowitz
Texas A&M University—
Corpus Christi
Laredo, Texas

The United States and Canada established the International Joint Commission (IJC) to take on certain responsibilities for transboundary bodies of water. The United States also has a similar arrangement with Mexico known as the International Boundary Water Commission (IBWC). Note that the task of the IBWC by comparison is not as involved because it has only two rivers in its jurisdiction, whereas the IJC has more than 200 transborder rivers (1), plus lakes and common aquifers.

FORM

The IJC was created as a result of the Boundary Waters Treaty of 1909 between the United States and Great Britain because it still controlled Canadian foreign policy. The pressure for a treaty came from within as populations of communities on both sides of the border began to grow and demands on water increased along with it. Initially, obstacles had to be overcome in the legal wording of the document because the two countries look at boundary waters differently. Americans tend to look at boundary water resources from the point of view of equity and equitable utilization, in which rights and obligations of the individual water user are recognized. Canadians, on the other hand, see water issues in terms of equality and the rights and responsibilities of the two states.

Institutionally, it was the early irrigation congresses and conferences of the 1890s that ultimately promoted movement toward considering bilateral agreements and treaties and, as a result, the creation of the IJC (2).

The treaty begins with assurance that navigation along common bodies of water shall remain open, and no country may impose excessive tools on the other for use of canals, locks, etc. Until power production and irrigation became important uses of water near the turn of the century, international water law had focused on navigation rights. A strong impetus for a treaty was to secure navigation rights, although it was less important during negotiation than other boundary water issues (3).

The first time the IJC is mentioned in the Treaty Relating to Boundary Water Between the United States and Canada is in Article III with regard to the authority to approve/disapprove obstructions or diversions of boundary water that affect the natural level or flow of the water on the other side of the line, but it is not until Article VII that establishes the IJC with six commissioners, three from each side, appointed by their respective governments. Its jurisdiction covers all cases involving use, obstruction, or diversion for which approval is required as mentioned in the treaty (3). A majority is required to make a decision, and, if evenly split, separate reports will be made to the respective governments and settled through diplomatic channels (4).

Each country was assured equal and similar rights in the use of the water, but there was an order of precedence:

1. uses for domestic and sanitary purposes; then
2. uses for navigation, including the service of canals for navigation; then
3. uses for power and irrigation.

These reflect the interests of the time and thus are dated because they do not reflect more current interests in fisheries, recreation, wildlife, and the environment in general (3). What makes the IJC important are the investigative powers that were accorded to them in Article IX, which states that, "The IJC is authorized in each case so referred to examine into and report upon the facts and circumstances of the particular questions referred" (4). Reports issued by the IJC are not to be considered decisions, as was made very clear in the treaty, and therefore the governments could ultimately ignore the IJC as they saw fit.

FUNCTION

The Boundary Water Treaty put the IJC into action using some broad guidelines but has changed since its inception at the beginning of the century. Along the northern border, the questions have moved from quantity to quality, and the IJC has a leading role in the answers. The governments have delegated new responsibilities to the IJC based on its track record and reputation for impartiality (3). An existing problem is that the commission has no follow-up implementation authority, which gives it largely an advisory role.

Several categories of management issues/problems dominate the work that the IJC becomes involved in, including upstream–downstream conflicts, common pool resources, and integrated river basin developments (5). Work on these issues can take the form of either an approval or reference. Approval is required if an application is made that falls under the scope of either Article III or IV of the Treaty (3), and usually consists of constructing dams, hydropower projects, or diverting flows. The IJC appoints a technical advisory board of members from each country to conduct the investigative work on whether to approve/disapprove a project. References, on the other hand, take much more time and involve constant monitoring of whatever issue has been referred to the commission. Advisory boards are set up in much the same way as they are in the approval category (3).

The strength of the commission lies in several areas where it could become an instrument for boundary environmental protection and management: (a) The IJC performs administrative and quasi-judicial tasks handling a range of issues; (b) There is experience and legitimacy in dealing with boundary issues on an impartial basis; (c) The IJC is an arbitrator of fact; (d) It is a mediator of policy; (e) Top water managers in each country meet regularly under the IJC umbrella, which has created an informal network of contact among government officials and experts (6).

GREAT LAKES WATER QUALITY AGREEMENT AND THE IJC

The Agreement, first signed in 1972 and renewed in 1978, expresses the commitment of each country to restore and maintain the chemical, physical, and biological integrity of the Great Lakes Basin ecosystem and includes a number of objectives and guidelines to achieve these goals. It reaffirms the rights and obligation of Canada and the United States under the Boundary Waters Treaty.

In 1987, a Protocol was signed amending the 1978 Agreement. The amendments aim to strengthen the programs, practices, and technology described in the 1978 Agreement and to increase accountability for implementing them. Timetables are set for implementing specific programs.

The parties will meet biennially to discuss progress and report periodically to the Commission. New annexes address atmospheric deposition of toxic pollutants, contaminated sediments, groundwater, and nonpoint sources of pollution. Annexes are also added to incorporate the development and implementation of remedial action plans for areas of concern and lakewide management plans to control critical pollutants.

The IJC monitors and assesses progress under the Agreement and advises each government on matters related to the quality of the boundary waters of the Great Lakes system. The Agreement also calls on the IJC to assist the United States and Canada with joint programs under the Agreement and provides for two binational boards—the Great Lakes Water Quality Board and the Great Lakes Science Advisory Board—to advise the Commission.

The general objectives of the agreement, expressed in Article III of the Agreement (7), are to keep the waters:

(a) free from substances that directly or indirectly enter the waters as a result of human activity and that will settle to form putrescent or otherwise objectionable sludge deposits, or that will adversely affect aquatic life or waterfowl;

(b) free from floating materials such as debris, oil, scum, and other immiscible substances resulting from human activities in amounts that are unsightly or deleterious;

(c) free from materials and heat directly or indirectly entering the water as a result of human activity that alone, or in combination with other materials, will produce color, odor, taste, or other conditions in such a degree as to interfere with beneficial uses;

(d) free from materials and heat directly or indirectly entering the water as a result of human activity that alone, or in combination with other materials, will produce conditions that are toxic or harmful to human, animal, or aquatic life; and

(e) free from nutrients directly or indirectly entering the waters as a result of human activity in amounts that create growths of aquatic life that interfere with beneficial uses.

GREAT LAKES WATER QUALITY INITIATIVE

Elsie F. Millano
ERM, Inc.
Vernon Hills, Illinois

GENERAL DESCRIPTION

The Great Lakes Water Quality Initiative (the "Initiative") is a program to improve the quality of the waters in the

Great Lakes system. The Great Lakes consist of (1) Lake Ontario, Lake Erie, Lake Huron (including Lake Saint Clair), Lake Michigan, and Lake Superior; and (2) their connecting channels, including the Saint Mary's River, the Saint Clair River, the Detroit River, the Niagara River, and the Saint Lawrence River to the Canadian border. The Great Lakes system includes all streams, rivers, lakes, and other bodies of water within the drainage basin of the Great Lakes within the United States. The effort was undertaken by the U.S. Environmental Protection Agency (U.S. EPA) and the eight Great Lakes U.S. states (Illinois, Indiana, Michigan, Minnesota, Ohio, Pennsylvania, New York, and Wisconsin), supported by the U.S. Fish and Wildlife Service, the National Park Service, environmental groups, municipalities, industry, and academia.

The main objective of the Initiative is to reduce the discharge of bioaccumulative compounds of concern (BCCs) into the Great Lakes system. The first phase of the Initiative consisted of the development of a consistent set of water quality criteria to be applied throughout the Great Lakes system by the Great Lakes States and by any Indian Tribes that have jurisdiction over portions of the Great Lakes system.

The Initiative participants collected available scientific information on persistent toxic chemicals in the Great Lakes system, reviewed and evaluated the data and the different regulations and procedures to establish water quality criteria of the participant states and developed the water quality criteria and procedures issued in 1995 as the Water Quality Guidance for the Great Lakes System (the "Guidance").

The second phase of the Initiative, called the Great Lakes Toxic Reduction Effort (GLTRE), is under development. The GLTRE focuses on reducing BCCs contributed to the Great Lakes system by nonpoint sources.

HISTORY

In the spring of 1989, the Council of Great Lakes Governors unanimously agreed to participate in the Initiative with the U.S. EPA, to establish consistent water quality criteria throughout the Great Lakes system. The Initiative was a response by the United States to continuous contamination of the Great Lakes system by persistent and bioaccumulative toxic (PBT) pollutants (such as polychlorinated biphenyls, dioxins, DDT, DDE, and mercury), despite efforts to bring the Great Lakes system back into health that date back to 1972, when Canada and the United States signed the Great Lakes Water Quality Agreement (GLWQA).

At the time of the 1972 GLWQA, algae growth and reduced dissolved oxygen concentration were reducing the fish population in the Great Lakes system. The 1972 GLWQA specified (1) objectives to reduce the discharge of pollutants that caused nuisance conditions (color, odor, floating oil and scum, aquatic weeds, and algae) and of substances toxic to human, animal, or aquatic life; and (2) numerical targets for reducing loadings of phosphorus into the lower Great Lakes (i.e., Lake Erie and Lake Ontario). The 1972 GLWQA also contained measures to reduce the loading of phosphorus, including effluent limits on all major municipal sewage treatment facilities, limitations on the phosphorus content in household detergents, and reduction in nonpoint source runoff loadings.

During the 1970s, the passage of the Clean Water Act in the United States and similar efforts in Canada reduced the discharge of untreated municipal and industrial wastewaters and provided funding for further evaluating the effects of pollutants on the Great Lakes system. The additional research indicated that PBT substances were responsible for the declining population and accumulation of pollutants in several species of animals, including bald eagles, minks, herring gulls, double-crested cormorants, common and Caspian terns, ospreys, and lake trout among others.

As a result, the 1978 revisions to the GLWQA established a policy calling for virtual elimination of the discharge of PBT substances. In addition, the 1978 GLWQA specified modified phosphorus target loadings for the lower Great Lakes and new phosphorus target loadings for the upper Great Lakes.

In the 1980s, scientists detected effects of PBT substances on humans, consisting of neurological effects on infants whose mothers had eaten Lake Michigan fish contaminated with PBT substances during their pregnancies. In 1987, Canada and the United States amended the GLWQA by Protocol to require the development of (1) Lakewide Management Plans (LaMPs) to control and reduce PBT substances and (2) Remedial Action Plans (RAPs) for 43 recognized local areas of concern in the lakes (now 42, one of them was delisted as such an area in 1994) affected by PBT substances. The 1987 amendments called for greater coordination among different jurisdictional authorities to allow the success of the LaMPs and RAPs, plus more focused attention on PBT substance pollution from land runoff, contaminated sediment, airborne toxic substances, and contaminated groundwater.

As previously indicated, one of the objectives of the Initiative was to develop water quality guidance for BCCs in the Great Lakes system to ensure consistency in requirements among the Great Lakes states. In 1990, the U.S. Congress approved an amendment to the Clean Water Act that required the U.S. EPA to publish water quality guidance for the Great Lakes system in accordance with the 1987 GLWQA and to perform other key activities in the 1987 GLWQA, imposed statutory deadlines for implementing the water quality guidance once issued, and provided funding for programs to meet the 1987 GLWQA requirements. The Water Quality Guidance for the Great Lakes System (the "Guidance") was issued by the U.S. EPA in March 1995 and supplemented in November 2000. The Guidance uses the term BCC to refer to PBT substances. The GLTRE is currently focusing on the other aspects of the 1987 GLWQA.

WATER QUALITY GUIDANCE FOR THE GREAT LAKES SYSTEM

Under United States regulations, each state or Indian tribe has the right to set water quality criteria for the waters under their jurisdiction. These criteria are, in turn, used by each state or Indian tribe to develop water quality standard-based discharge limits for wastewater effluents under the National Pollutant Discharge Elimination System (NPDES). The issuance of the Guidance ensures that all point source discharges to the Great Lakes system will meet a set of consistently developed criteria.

General Description

The proposed regulation was issued in 1993. The final Guidance, which was issued in March 1995 and then supplemented in November 2000, contains

- water quality criteria for a set of 29 chemical constituents to protect aquatic life, human health, and/or wildlife;
- procedures to develop water quality criteria for additional pollutants;
- an antidegradation policy to be adopted, at a minimum, for BCCs;
- a ban on mixing zones for BCCs; and
- procedures to implement the water quality criteria guidance.

Mixing zones, which are established by each state on a point-source basis, allow discharge of compounds at concentrations higher than the surface waterbody standard as long as the concentration in the water near or outside the boundary of the mixing zone meets the water quality criteria.

The March 1995 Guidance contained all five elements listed above, but the ban on mixing zones was vacated in June 1997 by the U.S. Court of Appeals in the District of Columbia and reinstated in November 2000 with modifications. The final Guidance is codified at Part 132 of Title 40 of the Code of Federal Regulations, and includes the six tables and the six appendixes shown in Table 1. The implementation procedures included in Appendix F are listed in Table 2.

Table 1. Attachments to the Water Quality Initiative Regulation

Attachment	Description
Table 1	Acute Water Quality Criteria for Protection of Aquatic Life in Ambient Water
Table 2	Chronic Water Quality Criteria for Protection of Aquatic Life in Ambient Water
Table 3	Water Quality Criteria for Protection of Human Health
Table 4	Water Quality Criteria for Protection of Wildlife
Table 5	Pollutants Subject to Federal, State, and Tribal Requirements
Table 6	Pollutants of Initial Focus in the Great Lakes Water Quality Initiative
Appendix A	Methodologies for Development of Aquatic Life Criteria and Values
Appendix B	Methodology for Deriving Bioaccumulation Factors
Appendix C	Methodologies for Development of Human Health Criteria and Values
Appendix D	Methodology for the Development of Wildlife Criteria
Appendix E	Antidegradation Policy
Appendix F	Implementation Procedures

The Guidance required the Great Lakes states to adopt and submit to the U.S. EPA for review, within two years of publication of the final Guidance (i.e., March 23, 1997), minimum water quality standards, antidegradation policies, and implementation procedure regulations in compliance with the corresponding Guidance procedures. To date, all states have submitted their proposed regulations and obtained either approval or partial approval of their submittals. When an element of a state's submittal was inconsistent with the Guidance, the U.S. EPA disapproved that element of the submittal and established that the specific state has to meet the Guidance's requirements for that specific element.

Water Quality Criteria

Table 3 presents the 29 chemical constituents for which water quality criteria were issued, along with an indication of whether each compound is a BCC and what population is covered by the water quality criteria. The Guidance includes water quality criteria for

- protecting aquatic life on an acute and chronic basis;
- protecting human health from drinking water and eating fish, or from recreationally using the Great Lakes waters; and
- protecting wildlife against ingestion of aquatic life containing the indicated chemical constituents.

Tables 4 through 7 reproduce the Guidance's water quality criteria, and Table 8 presents the pollutants of initial focus in the Guidance. Only chemical constituents for which sufficient information was available to determine a water quality standard based on requirements included in the Guidance appear in Tables 4 through 7; those chemical constituents include only nine of the 22 BCCs shown in Section A of Table 8.

Table 2. List of Implementation Procedures

Procedure #	Description
1	Site-Specific Modification to Criteria and Values
2	Variances from Water Quality Standards for Point Sources
3	Total Maximum Daily Loads, Wasteload Allocations for Point Sources, Load Allocations for Nonpoint Sources, Wasteload Allocations in the Absence of a TMDL, and Preliminary Wasteload Allocations for Purposes of Determining the Need for Water Quality Based Effluent Limits
4	Additivity
5	Reasonable Potential to Exceed Water Quality Standards
6	Whole Effluent Toxicity Requirements
7	Loading Limits
8	Water Quality-Based Effluent Limitations Below the Quantification Level
9	Compliance Schedules

Table 3. Summary of the Parameters for which a Water Quality Criterion/Standard is Presented in Part 132

Parameter	BCC?	Acute Aquatic Life	Chronic Aquatic Life	Human Health	Wildlife
Arsenic (III)		XX	XX		
Benzene				XX	
Cadmium		XX	XX		
Chlordane	Yes			XX	
Chlorobenzene				XX	
Chromium (III)		XX	XX		
Chromium (VI)		XX	XX		
Copper		XX	XX		
Cyanide		XX	XX		
Cyanides				XX	
DDT				XX	
DDT and metabolites	Yes				XX
Dieldrin	Yes	XX	XX	XX	
2,4-Dimethylphenol				XX	
2,4-Dinitrophenol				XX	
Endrin		XX	XX		
Hexachlorobenzene	Yes			XX	
Hexachloroethane				XX	
Lindane	Yes	XX		XX	
Mercury (II)	Mercury	XX	XX		
Mercury (including methylmercury)	Mercury			XX	XX
Methylene chloride				XX	
Nickel		XX	XX		
Parathion		XX	XX		
PCBs (class)	Yes			XX	XX
Pentachlorophenol		XX	XX		
Selenium		XX	XX		
2,3,7,8-TCDD	Yes			XX	XX
Toluene				XX	
Toxaphene	Yes			XX	
Trichloroethylene				XX	
Zinc		XX	XX		

Key:
BCC = Bioaccumulative chemical of concern
DDD = 1, 1-Dichloro-2,2-bis(p-chlorophenyl)ethane
DDE = 1, 1-Dichloro-2,2-bis(p-chlorophenyl)ethylene
DDT = 1, 1, 1-Trichloro-2,2-bis(p-chlorophenyl)ethane
TCDD = Tetrachlorodibenzo-p-dioxin
Notes:
The concentration of 2,3,7,8-TCDD in the wastewater discharge to be compared with the effluent standards for the protection of human health must be calculated by determining the equivalent toxicity of all dioxins and furans.
DDT's metabolites include DDD and DDE.

The Guidance establishes that water quality criteria for protecting aquatic life, human health, and wildlife for pollutants not included in Tables 4 through 7 must be developed by each state using the procedures in Appendixes A, C, and D of the Guidance. In addition, water quality criteria for the chemical constituents or parameters listed in Table 9 can be established on a state-specific basis, which may or may not be in accordance with the procedures in the Guidance.

Antidegradation Policy

The antidegradation policy consists of the following provisions:

- applies, at a minimum, to BCCs;
- includes an antidegradation standard that requires maintaining the water quality necessary to protect existing uses;
- allows the identification of high-quality waters for individual pollutants;
- provides procedures for implementing the antidegradation standard;
- describes the information required for demonstrations to lower water quality; and
- presents the procedures to be followed to evaluate demonstrations to lower water quality and issue decisions on lowering water quality; these demonstrations are subject to public participation and intergovernmental coordination.

Mixing Zones Ban

With respect to the ban on mixing zones for BCCs, the Guidance establishes the following requirements:

- elimination of the use of mixing zones for the BCCs shown in Section A of Table 8 for new dischargers;

- phasing out of mixing zones for BCCs discharged by existing facilities by November 15, 2010; and
- allowing an exception to the mixing zone ban for dischargers that (1) have discharges at higher concentrations of BCCs than specified in the Guidance as a result of water conservation measures that produce an overall reduction of the mass of BCCs discharged, or (2) treat their discharge using the best possible technology and would suffer unreasonable economic effects if further control measures were taken.

GREAT LAKES TOXIC REDUCTION EFFORT

The GLTRE is evaluating nonpoint sources, wet-weather point sources, and atmospheric deposition to determine the need for additional controls on the discharge of BCCs from these sources. Some of the issues being evaluated or to be evaluated include

- additional regulation of BCCs under the Clean Air Act;
- spill prevention planning;
- reduction of BCC discharge from hazardous waste sites being remediated under the Resource Conservation and Recovery Act and the Comprehensive Environmental Response, Compensation, and Liability Act;
- improved pesticide registration procedures;
- additional regulation of combined sewer overflows and stormwater outfalls (wet-weather sources);
- public education on the dangers of BCCs;
- improved reporting of BCCs under the Toxic Release Inventory; and
- procedures to apply the National Contaminated Sediment Management Strategy in the Great Lakes Basin.

Table 4. Acute Water Quality Criteria for Protection of Aquatic Life in Ambient Water[1]

Part	Chemical	CMC (μg/L)	Conversion Factor (CF)
(a)	Arsenic (III)	$339.8^{a,b}$	1.000
	Chromium (VI)	$16.02^{a,b}$	0.982
	Cyanide	22^{c}	n/a
	Dieldrin	0.24^{d}	n/a
	Endrin	0.086^{d}	n/a
	Lindane	0.95^{d}	n/a
	Mercury (II)	$1.694^{a,b}$	0.85
	Parathion	0.065^{d}	n/a
	Selenium	$19.34^{a,b}$	0.922

Part	Chemical	m(A)	b(A)	Conversion Factor (CF)
(b)	Cadmium^{e,f}	1.128	−3.6867	0.85
	Chromium (III)^{e,f}	0.819	+3.7256	0.316
	Copper^{e,f}	0.9422	−1.700	0.960
	Nickel^{e,f}	0.846	+2.255	0.998
	Pentachlorophenol^{g}	1.005	−4.869	n/a
	Zinc^{e,f}	0.8473	+0.884	0.978

Key:
The term “n/a” means not applicable.
The term “ln” represents the natural logarithm function.[2]
The term “exp” represents the base e exponential function.
CMC is Criterion Maximum Concentration.
CMC(tr) is the CMC expressed as total recoverable.
CMC(d) is the CMC expressed as a dissolved concentration.
CMC(t) is the CMC expressed as a total concentration.

Notes:
[a] $\mathrm{CMC} = \mathrm{CMC(tr)}$
[b] $\mathrm{CMC(d)} = [\mathrm{CMC(tr)}]^{*}\mathrm{CF}$. The CMC(d) shall be rounded to two significant digits.
[c] CMC should be considered free cyanide as CN.
[d] $\mathrm{CMC} = \mathrm{CMC(t)}$
[e] $\mathrm{CMC(tr)} = \exp\{m(A)^{*}[\ln(\mathrm{hardness})] + b(A)\}$
[f] $\mathrm{CMC(d)} = [\mathrm{CMC(tr)}]^{*}\mathrm{CF}$. The CMC(d) shall be rounded to two significant digits.
[g] $\mathrm{CMC(t)} = \exp m(A)^{*}[(\mathrm{pH}) + b(A)]$. The CMC(t) shall be rounded to two significant digits.

Table 5. Chronic Water Quality Criteria for Protection of Aquatic Life in Ambient Water[3]

Part	Chemical	CCC (μg/L)	Conversion Factor (CF)
(a)	Arsenic (III)	$147.9^{a,b}$	1.000
	Chromium (VI)	$10.98^{a,b}$	0.962
	Cyanide	5.2^{c}	n/a
	Dieldrin	0.056^{d}	n/a
	Endrin	0.036^{d}	n/a
	Mercury (II)	$0.9081^{a,b}$	0.85
	Parathion	0.013^{d}	n/a
	Selenium	$5^{a,b}$	0.922

Part	Chemical	m(C)	b(C)	Conversion Factor (CF)
(b)	Cadmium^{e,f}	0.7852	−2.715	0.85
	Chromium (III)^{e,f}	0.819	+0.6848	0.860
	Copper^{e,f}	0.8545	−1.702	0.960
	Nickel^{e,f}	0.846	+0.0584	0.997
	Pentachlorophenol^{g}	1.005	−5.134	n/a
	Zinc^{e,f}	0.8473	+0.884	0.986

Key:
The term “n/a’” means not applicable.
The term “exp” represents the base e exponential function.
The term “ln” represents the natural logarithm function.[4]
CCC is Criterion Continuous Concentration.
CCC(tr) is the CCC expressed as total recoverable.
CCC(d) is the CCC expressed as a dissolved concentration.
CCC(t) is the CCC expressed as a total concentration.

Notes:
[a] $\mathrm{CCC} = \mathrm{CCC(tr)}$.
[b] $\mathrm{CCC(d)} = [\mathrm{CCC(tr)}]^{*}\mathrm{CF}$. The CCC(d) shall be rounded to two significant digits.
[c] CCC should be considered free cyanide as CN.
[d] $\mathrm{CCC} = \mathrm{CCC(t)}$.
[e] $\mathrm{CCC(tr)} = \exp\{m(C)^{*}[\ln(\mathrm{hardness})] + b(C)\}$.
[f] $\mathrm{CCC(d)} = [\mathrm{CCC(tr)}]^{*}(\mathrm{CF})$. The CCC(d) shall be rounded to two significant digits.
[g] $\mathrm{CMC(t)} = \exp\{m(A)^{*}(\mathrm{pH}) + b(A)\}$. The CMC(t) shall be rounded to two significant digits.

[1] EPA recommends that metals criteria be expressed as dissolved concentrations.
[2] Not included in the regulation.
[3] EPA recommends that metals criteria be expressed as dissolved concentrations.
[4] Not included in the regulation.

Table 6. Water Quality Criteria for Protection of Human Health

	HNV (μg/L)		HCV (μg/L)	
Chemical	Drinking	Non-Drinking	Drinking	Non-Drinking
Benzene	1.9E1	5.1E2	1.2E1	3.1E2
Chlordane	1.4E−3	1.4E−3	2.5E−4	2.5E−4
Chlorobenzene	4.7E2	3.2E3		
Cyanides	6.0E2	4.8E4		
DDT	2.0E−3	2.0E−3	1.5E−4	1.5E−4
Dieldrin	4.1E−4	4.1E−4	6.5E−6	6.5E−6
2,4-Dimethylphenol	4.5E2	8.7E3		
2,4-Dinitrophenol	5.5E1	2.8E3		
Hexachlorobenzene	4.6E−2	4.6E−2	4.5E−4	4.5E−4
Hexachloroethane	6.0	7.6	5.3	6.7
Lindane	4.7E−1	5.0E−1		
Mercury (including methylmercury)	1.8E−3	1.8E−3		
Methylene chloride	1.6E3	9.0E4	4.7E1	2.6E3
PCBs (class)			3.9E−6	3.9E−6
2,3,7,8-TCDD	6.7E−8	6.7E−8	8.6E−9	8.6E−9
Toluene	5.6E3	5.1E4		
Toxaphene			6.8E−5	6.8E−5
Trichloroethylene			2.9E1	3.7E2

Key:
DDT = 1, 1, 1-Trichloro-2,2-bis(p-chlorophenyl)ethane
HNV = Human non-cancer value
HCV = Human cancer value
PCBs = Polychlorinated biphenyls
TCDD = Tetrachlorodibenzo-p-dioxin.

Table 7. Water Quality Criteria for Protection of Wildlife

Chemical	Criteria (μg/L)
DDT and metabolites	1.1E−5
Mercury (including methylmercury)	1.3E−3
PCBs (class)	7.4E−5
2,3,7,8-TCDD	3.1E−9

Key:
DDD = 1, 1-Dichloro-2,2-bis(p-chlorophenyl)ethane
DDE = 1, 1-Dichloro-2,2-bis(p-chlorophenyl)ethylene
DDT = 1, 1, 1-Trichloro-2,2-bis(p-chlorophenyl)ethane
PCBs = Polychlorinated biphenyls
TCDD = Tetrachlorodibenzo-p-dioxin
Note:
DDT and metabolites include DDD and DDE.

In addition to the GLTRE efforts to control BCCs, each of the Great Lakes states has prepared a Lake Management Plan (LaMP) under the binational GLWQA, which will evaluate current sources of BCCs and recommend enhancements to any media-specific program that would result in improved quality of the Great Lakes.

Table 8. Pollutants of Initial Focus in the Great Lakes Water Quality Initiative

Section A. Pollutants that Are Bioaccumulative Chemicals of Concern

Chlordane
4,4′-DDD; p,p′-DDD; 4,4′-TDE; p,p′-TDE
4,4′-DDE; p,p′-DDE
4,4′-DDT; p,p′-DDT
Dieldrin
Hexachlorobenzene
Hexachlorobutadiene; hexachloro-1, 3-butadiene
Hexachlorocyclohexanes; BHCs
alpha-Hexachlorocyclohexane; alpha-BHC
beta-Hexachlorocyclohexane; beta-BHC
delta-Hexachlorocyclohexane; delta-BHC
Lindane; gamma-hexachlorocyclohexane; gamma-BHC
Mercury
Mirex
Octachlorostyrene
PCBs; polychlorinated biphenyls
Pentachlorobenzene
Photomirex
2,3,7,8-TCDD; dioxin
1,2,3,4-Tetrachlorobenzene
1,2,4,5-Tetrachlorobenzene
Toxaphene

Section B. Pollutants that Are Not Bioaccumulative Chemicals of Concern

Acenaphthene
Acenaphthylene
Acrolein; 2-propenal
Acrylonitrile
Aldrin
Aluminum
Anthracene
Antimony
Arsenic
Asbestos
1,2-Benzanthracene; benz[a]anthracene
Benzene
Benzidine
Benzo[a]pyrene; 3,4-benzopyrene
3,4-Benzofluoranthene; benzo[b]fluoranthene
11,12-Benzofluoranthene; benzo[k]fluoranthene
1,12-Benzoperylene; benzo[ghi]perylene
Beryllium
bis(2-Chloroethoxy) methane
Bis(2-chloroethyl) ether
bis(2-Chloroisopropyl) ether
Bromoform; tribromomethane
4-Bromophenyl phenyl ether
Butyl benzyl phthalate
Cadmium
Carbon tetrachloride; tetrachloromethane
Chlorobenzene
p-Chloro-m-cresol; 4-chloro-3-methylphenol
Chlorodibromomethane
Chloroethane
2-Chloroethyl vinyl ether
Chloroform; trichloromethane
2-Chloronaphthalene
2-Chlorophenol
4-Chlorophenyl phenyl ether
Chlorpyrifos
Chromium
Chrysene

Table 8. (*continued*)

Copper	Cyanide
2,4-D; 2,4-Dichlorophenoxyacetic acid	DEHP; di(2-ethylhexyl) phthalate
Diazinon	1,2:5,6-Dibenzanthracene; dibenz[a,h]anthracene
Dibutyl phthalate; di-n-butyl phthalate	1,2-Dichlorobenzene
1,3-Dichlorobenzene	1,4-Dichlorobenzene
3,3′-Dichlorobenzidine	Dichlorobromomethane; bromodichloromethane
1,1-Dichloroethane	1,2-Dichloroethane
1,1-Dichloroethylene; vinylidene chloride	1,2-trans-Dichloroethylene
2,4-Dichlorophenol	1,2-Dichloropropane
1,3-Dichloropropene; 1,3-dichloropropylene	Diethyl phthalate
2,4-Dimethylphenol; 2,4-xylenol	Dimethyl phthalate
4,6-Dinitro-o-cresol; 2-methyl-4,6-dinitrophenol	2,4-Dinitrophenol
2,4-Dinitrotoluene	2,6-Dinitrotoluene
Dioctyl phthalate; di-n-octyl phthalate	1,2-Diphenylhydrazine
Endosulfan; thiodan	alpha-Endosulfan
beta-Endosulfan	Endosulfan sulfate
Endrin	Endrin aldehyde
Ethylbenzene	Fluoranthene
Fluorene; 9H-fluorene	Fluoride
Guthion	Heptachlor
Heptachlor epoxide	Hexachlorocyclopentadiene
Hexachloroethane	Indeno[1,2,3-cd]pyrene; 2,3-o-phenylene pyrene
Isophorone	Lead
Malathion	Methoxychlor
Methyl bromide; bromomethane	Methyl chloride; chloromethane
Methylene chloride; dichloromethane	Naphthalene
Nickel	Nitrobenzene
2-Nitrophenol	4-Nitrophenol
n-Nitrosodimethylamine	n-Nitrosodiphenylamine
n-Nitrosodipropylamine; n-nitrosodi-n-propylamine	Parathion
Pentachlorophenol	Phenanthrene
Phenol	Iron
Pyrene	Selenium
Silver	1,1,2,2-Tetrachloroethane
Tetrachloroethylene	Thallium
Toluene; methylbenzene	1,2,4-Trichlorobenzene
1,1,1-Trichloroethane	1,1,2-Trichloroethane
Trichloroethylene; trichloroethene	2,4,6-Trichlorophenol
Vinyl chloride; chloroethylene; chloroethene	Zinc

Key:
DDD = 1, 1-Dichloro-2,2-bis(p-chlorophenyl)ethane
DDE = 1, 1-Dichloro-2,2-bis(p-chlorophenyl)ethylene
DDT = 1, 1, 1-Trichloro-2,2-bis(p-chlorophenyl)ethane
TCDD = Tetrachlorodibenzo-p-dioxin
TDE = DDD

QUANTITATIVE GROUNDWATER LAW

Marshall Lawson
Land Conservation Legal Services, LLC
Columbia, South Carolina

INTRODUCTION

From ancient times, the law looked upon surface water and groundwater as separate resources, requiring separate rules for ownership and use. Whereas surface water was considered a public good to be shared among competing users, groundwater was equated with private property to be appropriated by the landowner at will.[1]

---

[1] Compare Dig. 43.12.3 (Paulus, Ad Sabinum 16) ("Rivers which flow [perennially] are public, and their banks are also public.");

The separate classification and treatment of groundwater can be attributed, in part, to a primitive understanding of hydrogeology; a mathematical description of groundwater storage and movement was not formulated until the midnineteenth century and not widely disseminated until the late twentieth century.[2] Without an understanding of aquifer characteristics, legal authorities lacked a basis for developing sophisticated groundwater allocation rules. The occurrence and nature of groundwater was, to them, too "... uncertain ...[to] subject it to the regulations of law...".[3]

Hand in glove with a nascent understanding of hydrogeology was the propensity of nineteenth century English jurists and commentators to follow the perceived equities of Roman water law as "indirect authority" for English water law.[4] The English Reasonable Use Rule, for example, embodies the Roman concept of limited property rights in public surface waters.[5] Likewise, the Roman classification of groundwater as private property free from any equitable rules of sharing appeared well over a millennium latter in English and American common law as Absolute Dominion or the Rule of Capture.[6]

The most important reason, however, for the development of separate legal rules for surface and groundwater centered not upon science or legal history but technology. Prior to the invention of the deep-well turbine pump in the last decade of the nineteenth century, groundwater could not commonly be exploited at rates sufficient to encroach upon the property rights of neighboring landowners. Consequently, there was little need to impose legal restraints on groundwater use.[7] The advent of submersible pumps and power drilling equipment, however, made it possible to develop aquifers at sufficient pumping rates to cause widespread injury to the environment and other property owners in the form of diminished stream flow, saltwater intrusion, land subsidence, well interference, and groundwater mining.[8] Technology had effectively made the once functional Rule of Capture obsolete in theory, if not in practice.

As groundwater conflicts became more common, American courts attempted to mitigate the harsh Rule of Capture by adopting various equitable rules of allocation, starting with the Reasonable Use Doctrine in 1862 followed by the Correlative Rights Doctrine in 1903 and The Restatement (Second) of Torts rule in 1979.[9] In reality, the rough justice dispensed by courts under these doctrines did little to protect groundwater supplies from being diminished or extinguished by competing users, and aquifers remained theoretically susceptible to complete dewatering by overlying property owners.

In response to the failure of the common law to manage groundwater use effectively, many Eastern states enacted legislation modifying common law rights in the use of groundwater. The legislation varies widely in scope and criteria but centers upon the requirement of an administrative permit to pump groundwater above certain predetermined thresholds.[10]

In contrast to the various quasi-riparian rules governing groundwater use in states west of the Mississippi River, a distinctly American system of water use, called the Prior Appropriation Doctrine, arose in the arid West. The system allocates water rights based upon priority of beneficial use and irrespective of contiguous (or in the case of groundwater, overlying) land ownership.

Appropriation proved more suited to the climate and geology of the arid West than riparianism. The central tenets of the riparian doctrine, that water rights accrue

only to contiguous or overlying landowners and are primarily limited to on-tract use, proved impracticable in the West where the federal government owned much of the land, water resources were scarce, and mining and agriculture practices required off-stream water use. Furthermore, the subjective allocation criteria of the various riparian doctrines proved ill suited for managing scarcity.

ORIGIN AND NATURE OF PROPERTY RIGHTS IN GROUNDWATER

Property rights in water, including groundwater, have a long pedigree in European jurisprudence. Roman law is the oldest legal system to which the roots of European water law can be traced with any certainty and, as discussed above, Roman jurists considered groundwater an integral part of the land.[11] As such, the landowner enjoyed a property right in the groundwater itself (res) as well as an unfettered right of use (usufruct).[12] English and American courts firmly embraced this concept of groundwater as an absolute property right in the nineteenth century.[13] Although many U.S. courts and legislatures now define groundwater as a public resource, most, if not all, jurisdictions still acknowledge (at least tacitly) a usufructuary right of the landowner to use the groundwater underlying his property.[14]

As a form of property, regulation of groundwater use is theoretically subject to challenge as a "taking" of private property without compensation in violation of the Takings Clause of the United States Constitution.[15] At least one court has stricken modification of water rights as a violation of the Takings Clause,[16] but the decision is very much an anomaly. Other courts addressing the issue have upheld groundwater regulation in the face of takings clause challenges on one of the following grounds: (1) Permitting has not deprived a landowner of all economic use of his property right and is, therefore, not a compensable taking. (2) Landowners enjoy no constitutionally protected right in groundwater until they actually begin pumping. (3) The regulation is a valid exercise of the sovereign's police power.[17] States have broad police power under the Constitution to regulate for the public health, safety, morals, and general welfare. The sovereign's exercise of this power may not require compensation for diminished property rights resulting from regulation, as long as such regulation is not arbitrary or irrational.[18]

At least one authority would add another defense to takings clause challenges to groundwater regulation. Because the overlying landowner's right to use water under various riparian doctrines is "subject to complete destruction by a more powerful pumper, [the] ... landowner's expectation of exclusive use of groundwater [is] close to illusory."[19] Stated another way, riparian law (or quasi-riparian law for groundwater) holds that groundwater is private property but effectively treats it as common property by failing to provide a mechanism for quantifying and protecting the water right.

On the other hand, it could be argued that permitting systems for groundwater use, depending upon the terms of the permit, might actually strengthen the claim of a landowner to a property right in the use of groundwater. Consistent with this argument, a permit holder could defend his right to pump against future permit holders if such pumping reduced his own allotted yield.[20]

Regardless of the court's willingness to uphold groundwater-use regulation, it should not be assumed that courts or groundwater-use statutes have abolished private property rights in the use of groundwater. Even the Regulated Riparian Model Water Code, which proposes comprehensive regulation of water resources, makes clear that the administrative permit process does not usurp

common law rights in water and that "the new system is a regulation rather than a taking of the older riparian rights."[21]

LEGAL CLASSIFICATIONS OF GROUNDWATER

The common law historically distinguished not only between groundwater and surface water, but also distinguished between two types of groundwater: (1) that found flowing in underground streams; and (2) so-called "percolating" groundwater, or that which did not "flow" but rather "oozed" through the void spaces within the aquifer skeleton. Courts generally assign the law of surface streams to the former, and groundwater law to the latter.[22]

As mentioned above, this dual classification arose initially because "percolating" groundwater was envisioned as too "occult in its occurrence and movement" for courts to attach formalistic rules to its use.[23] In addition, courts labored under the false assumption that a large portion of groundwater occurs as an underground analog to surface streams, and, therefore, both flow regimes should be governed by the same principles. In reality, "percolating" groundwater, like stream water, flows in an ascertainable direction and rate, albeit through an aquifer matrix and at orders of magnitude slower than surface water. Furthermore, the occurrence of groundwater as underground streams is extremely rare and confined to karstic terrains or lava flows.[24]

In acknowledgment of the hydraulic interconnection between groundwater flow and stream flow, some modern courts recognize a third legal category of groundwater, the "subflow" of surface streams. The subflow of surface streams, like water flowing in underground streams, was generally made subject to the same law that applied to surface water.[25]

Finally, statutes in a number of jurisdictions exempt certain kinds of groundwater from ordinary groundwater law. For example, groundwater pumped from a mine to allow continued mineral extraction may be exempt from regulation applied to other groundwater. Another category of groundwater often exempted from regulation as groundwater is water hot enough to have value as a geothermal resource. Water extracted from the ground as a by-product of oil and gas development may also be separately treated by statute.[26]

LEGAL RULES FOR GROUNDWATER USE

Federal Legislation

The United States has no single rule governing groundwater use. Although the federal government regulates a wide range of groundwater pollution sources, it has, thus far, left formulation of quantitative groundwater law to the states, which have in turn adopted their own unique rules and statutes governing groundwater use.[27]

State Groundwater Law

Common Law (Quasi-Riparian Doctrines). Four distinct allocation doctrines for groundwater use apply east of the Mississippi and in a handful of Western states. These doctrines are best described as quasi-riparian because the property right in the groundwater vests with ownership of overlying land. They are (1) the "English rule" of Capture or Absolute Ownership, (2) the "American rule" of Reasonable Use, (3) the "Correlative Rights Rule" of shared access, and (4) the Restatement of the Law of Torts (2d, Tent. Draft 17, § 858A).[28]

A definitive and accurate appraisal of states adhering to a particular groundwater doctrine is problematic due to the blurring of the various rules in case law; an absence of decisional law in some states; and administrative overlays on the common law that modify, in various degrees, common law rights in groundwater.

In general terms, Absolute Ownership survives in only a few jurisdictions.[29] Most Eastern states employ some variation of the Reasonable Use Rule.[30] Several states follow some variation of the Correlative Rights Rule originating in California.[31] The Restatement approach has found little favor and has been adopted in only a handful of states.[32]

Absolute Ownership (Capture). Under this doctrine, also known as the English Rule of Capture, landowners are allowed to withdraw all the water they wish for whatever

[32] SAX, supra note 8, at 366.

purpose on or off the owner's land. The owner could even waste the water, thereby injuring a neighbor, but still face no liability.[33]

American Reasonable Use. Reasonable Use, also known as the American Rule, found favor with American courts as a modification of Absolute Dominion. In effect, Reasonable Use is equivalent to an equitable servitude upon the property right in groundwater requiring that (1) groundwater use be reasonable and (2) such use must be confined to the overlying tract of land.[34]

The term "Reasonable" varied among jurisdictions but generally meant "A waste of water or a wasteful use of water was unreasonable only if it caused harm, and any nonwasteful use of water that caused harm was, nevertheless, reasonable if it was made on or in connection with the overlying land."[35] The doctrine does not articulate a rule of allocation, but some courts imply a rule of sharing that makes the practical application of the doctrine difficult to differentiate from the Correlative Rights Doctrine.[36]

Correlative Rights ("California Rule"). This doctrine, first articulated by the California Supreme Court, requires a sharing of available water equitably among overlying landowners. They share the resource in times of scarcity proportionate either to their aerial land ownership or actual historic use.[37] Even if the water is used beneficially on the overlying land, landowners cannot infringe upon the rights of others by exceeding their proportionate shares.[38]

Off-tract uses are subordinate and are legally protected only in the event "surplus" water is available, that is, if recharge exceeds withdrawals.

If no competition for water exists, then Correlative Rights are synonymous with Reasonable Use.[39]

Restatement (Second) of Torts (Reasonable Use). Although the Restatement rule is similar to reasonable use, it draws no distinction between on-tract and off-tract use. It also differs from Reasonable Use by establishing criteria for liability. A landowner who pumps groundwater from his land and uses it for a beneficial purpose is liable for interference with other's groundwater use if

1. the withdrawal causes unreasonable harm through lowering of the water table;
2. the groundwater occurs in a distinct underground stream;
3. the withdrawal of water has a substantial effect upon a stream, river, or lake.[40]

Priority System (Prior Appropriation). In the West, a uniquely American water use rule called the Prior Appropriation Doctrine gradually supplanted riparian principles for both surface and groundwater. In contrast to riparian doctrines, the acquisition of water rights does not depend upon the ownership of contiguous or overlying land. Water rights vest by appropriating the water and putting it to beneficial use and accrue on a first in time, first in right, basis. Furthermore, water rights are quantified, can be lost through nonuse, and are transferable, as long as other water rights holders suffer no harm.

Prior appropriation developed in the mining camps of the Sierra Nevada during the California gold rush of the 1840s. As discussed before, the nature of mining operations and federal ownership of western lands were incompatible with the riparian doctrine for three reasons: (1) Under the riparian system, water rights accrued only to the owners of land. The miners, however, did not own the land they mined; it belonged to the federal government; (2) Mining operations were often conducted remotely from waterbodies requiring off-stream diversions that violated riparian prohibitions of off-tract transfers of water.[41] (3) In contrast to riparian doctrines, Appropriation provided quantifiable water rights that were enforceable and transferable. These attributes fostered predictability of planning and investment.[42]

Appropriation arose first as a common law doctrine, effectively ratifying water use practices in the mining camps. Over time, the doctrine was codified and even incorporated into some state's constitutions.[43] Most Western states have extended some version of the Prior Appropriation Doctrine, to groundwater, by statute, making it the primary doctrine for groundwater use in the West.[44]

The Appropriation rules for groundwater are essentially the same as those for surface water. In case of a dispute, priority of use is the determining factor in allocating water among competing users; junior claimants may have their supply of groundwater diminished or eliminated by senior claimants in times of scarcity.[45] The realities of hydrogeology, including the time lag between the start of pumping and deleterious effects on water levels, can make

application of the doctrine difficult to enforce in the case of groundwater.[46]

Active Management and Regulation of Groundwater

Permit Statutes ("Regulated Riparianism")[47]. Although some Eastern states enacted groundwater statutes more than a century ago, such legislation did not become common until the second half of the twentieth century. As of 1996, eighteen states had enacted regulated riparian systems for surface water sources, generally including underground water resources as well. Two other states apply a regulated riparian system only to underground water sources.[48]

The common characteristic of such legislation is the requirement of a permit to withdraw groundwater based upon reasonableness of use.[49] An administrative agency is responsible for both the decision to grant or deny a permit and, at least initially, dispute resolution.[50]

These statutes were not originally introduced as a radical revision of the water law of a particular state but emerged gradually through a process of discrete initiatives in the form of well-spacing regulations, prohibitions of wasteful pumping, or licensing of major withdrawals. In several states, it remains unclear whether the law would be better described as basically riparian rights with limited legislative alterations or as comprehensive regulatory schemes referred to as "regulated riparianism."[51]

Supply Side (Conjunctive Use) Management. The Orange County (California) water district (OCWD) takes a novel approach to groundwater allocation. Instead of imposing restrictions on pumping, the district focuses on maintaining groundwater supplies by recharging aquifers with imported surface water. No attempt is made to limit groundwater pumping directly or prevent waste. In fact, OCWD is forbidden from directly limiting the amount of groundwater an individual user may withdraw, although it may discourage use by levying a "basin equity assessment" against pumpers who withdraw more than a percentage of groundwater set by the district. In addition, the OCWD does not attempt to manage groundwater withdrawals to prevent or minimize well interference.[52]

The drawbacks to this type of management model include dependence upon imported recharge water and the cost of transmission and recharge facilities. These costs, however, are largely offset by maintaining a stock of relatively cheap local water in the form of groundwater storage.[53]

NATURE OF GROUNDWATER DISPUTES

Most groundwater disputes are the product of a race-to-pump mentality referred to as "the tragedy of the commons."[54] When many users tap the same aquifer, it becomes a common property resource. Without social or legal limits on water use from the common aquifer, there is no incentive to conserve because the conserver does not enjoy an exclusive right to the water that is saved.[55] For example, under the Reasonable Use Doctrine, two neighboring landowners are free to withdraw all the groundwater they can put to beneficial use upon their own land. The reasonableness of the use is judged solely as it relates to the purpose of such use and not its effect upon others or the sustainability of the resource.[56]

The race-to-pump has produced widespread declines in potentiometric surfaces and in severe cases, groundwater mining[57] that, in turn, led to well interference, land subsidence, saltwater intrusion,[58] and diminished stream flow. Unwise groundwater use may even threaten endangered species by desiccating springs.[59] In addition to environmental damage, these phenomena impose additional costs upon water users, ranging from a few thousand dollars incurred by individual well owners for well deepening and increased electrical costs to millions of dollars to provide alternative water supplies for municipal systems threatened by saltwater intrusion.[60]

Groundwater disputes may involve adjudication of the denial for new permits to pump groundwater or limitations and conditions upon existing permits.[61] In the case of property damages from groundwater use, courts may apply groundwater law (common law or a statute on point) or even tort law (e.g., nuisance or negligence theories) to the facts of a case to determine pumping rights or fix remedies in the form of an injunction or money damages.[62]

Plaintiffs may be private citizens, corporations, or public entities such as municipalities seeking to define, expand, or defend rights to groundwater. Depending on the jurisdiction, groundwater disputes, not resolved by administrative processes, may be appealed to higher state courts.

In addition to state common law and administrative law, federal law may come into play if groundwater use affects federal water rights claims,[63] impacts a federal statute, such as The Endangered Species Act,[64] or when groundwater use has an interstate dimension such as transportation of groundwater across state lines.[65]

LEGAL REFORM

Until recently, American groundwater law has been a hodgepodge of outdated common law doctrines that lacked an effective mechanism for allocating supplies on a sustainable basis and dealt only with disputes after the fact, during litigation. The need for reform prompted proposals for statutory models that can be roughly divided between emerging market-based approaches based upon the movement of water to higher value uses,[66] on the one hand, and command and control regulatory schemes restricting water use, on the other.[67]

Regulatory proponents believe that agency experts are the best suited to allocate the limited supplies in a sustainable fashion. In their eyes, market-based approaches to natural resource management inevitably lead to competitors vying to monopolize water rights and, thus, deprive others of access to water supplies.

Market proponents, on the other hand, argue that administrative control does not end competition for water but only shifts competition from the market to the political arena thereby promoting uncertainty that tends to work against meaningful conservation.[68] They also decry the assumption long held by legal authorities that control of the production of water, like alcohol, must somehow be tied to the end use of the product and not related to the valuation of the marketplace.[69] The more economical and less environmentally harmful choice to them is a system of tradable property rights in groundwater based upon either a share system or a seniority system.[70] This type of system would allow water to seek its highest value use, benefiting both buyers and sellers and minimizing government regulation with its attendant costs.

Others would like to see a combination of the two models, market incentives with government oversight to protect outside parties and the general public from harmful side effects.[71] Such oversight could include zoning restrictions, assignment of quota rights in common pools, and the right to receive money damages for economic harm to individual water users.[72]

CONCLUSION

Although groundwater law has progressed beyond the ancient Rule of Capture in most jurisdictions, it remains far from the nimble and pristine law required for the wise management of groundwater resources. Effective groundwater law of the future must focus on sustainable use of the resource within the context of both local and regional hydrogeologic realities, a formidable task, given the complexities of hydrogeology and political impediments to meaningful legal reform.

The law should encourage efficient water use by providing quantifiable and transferable property rights in water, and government should play the role of gatekeeper in maintaining environmental integrity and access to water for newcomers. Above all, water should no longer be regarded as so plentiful that it is regarded as a free good or so precious that it can be assigned no value. Where demand exceeds thresholds the environment can safely bear, as in mining or saltwater intrusion, consumers should pay for the realistic cost of alternative water supplies. Realistic water pricing combined with sound laws incorporating the appropriate mix of market incentives and regulation would foster both conservation and the beneficial transfer of water from areas of abundance to areas of scarcity.

Regardless of the mix of regulation and economic incentives, wise use of groundwater in the future will

ISLAMIC WATER LAWS

Islam covers all aspects of human life. It regulates the relationships among God (Allah), man, and nature. It is based on the recognition of the Creator and of human submission to His will. Muslims believe that everything originates from the One God and everyone is responsible to Him. According to Islam, Allah created nature for the benefit of humans. The relationship between humans and nature is based on harmony; humans are urged to explore and use natural resources in a sustainable manner.

Water is considered one of the most profound elements in Islam. Water is also necessary for cleaning one's home and personal effects, as well as for general hygiene. It is indispensable to agriculture and industry: *He it is who sends down water from the sky. With it, we bring forth plants of every kind* (6:99). It cannot be denied that all human beings rely on water for life and good health, but for Muslims, water is first and foremost, a social good in Islam. It is also regarded as a blessing from Allah that gives and sustains all life in this world. Furthermore, the word "water" appears sixty-three times in the holy book of Muslims, Al-Quran. This indicator shows the importance of water in our daily life.

Before the coming of the Prophet Muhammad, there were no standard water regulations in the Arab world. The only guide concerning water laws was through customs practiced by tribes. There are four fundamentals in Islamic law, the first three can be considered the roots of Muslim dogma. The first is the Holy *Quran*, the divine revelation from Allah to humans through the Prophet Muhammad. It consists of 114 suras (chapters) and 6666 words. It also considered the basis for all legislation.

Second are the *Sunna* and the *Hadith*, which represent the sum total of habits or general pattern of life of the Prophet Mohammad, inclusive of his word, acts, and tacit approval. Third, is the *Ijma*, which means the universal consensus of opinion of the nations or Muslim community. And finally, *Qiyas* or deduction by legal analogy. It consists of the following precedents in deciding new cases, which have not been discussed or found before.

WATER RIGHTS IN ISLAM

In Islam, water is considered a gift from God, so no individual literally owns it. Humans act as the stewards of water as well as other resources that belong to the community. The environment is protected from humans by specifics injunctions against upsetting its natural order through pollution or other activities. This is to ensure that Allah's gifts are available to all living things in the present and future.

Although humans are the most favored creation, we are also responsible for ensuring that water is available to all living things. Allah commands believers to "*make not mischief on earth*." (2:11); this means that we cannot spoil or degrade natural resources. The prophet Mohammad, very sensibly, forbade urination into stagnant water and advised guarding against this practice. This shows how Islam has underlined that water sources should be guarded from any contempt that can pollute it. This opens the door for penalties or punishment in modern legislation for those who disobey. Apart from that, waterside co-owners who enjoy the right to use water should care for and maintain water sources. They have to bear the burden of maintenance and cleaning operations. The expenses can be taken from taxes or special funds for that purpose.

Muslims believe that ensuring social justice is the cornerstone of Islam. The recognition of water as a vital resource, to which everyone has the right to a fair share, is emphasized by the following hadith, which effectively makes water a community resource to which all, rich or poor, have a right: "*Muslims have a common share in three things, pasture, water, and fire*", as narrated by Abu Daud.

Apart from that, animals cannot be allowed to die of thirst, and the water that remains after humans quench their thirst must be given to them. The immense value of giving water to any creature is reflected by the following hadith: "*A prostitute was forgiven by Allah because she took off her shoe and tying it with her head cover and drew out some water from a well to be given to a panting dog passing by that was about to die of thirst. So Allah forgave her because of that*," as narrated by Al-Bukhari.

The Al-Quran notes that the gift of water is for flora as well: "*vegetation of all kinds*" (6:99) is nourished by rainwater that Allah sends down. This verse supports the statement that water is made available by Allah so that all life should receive support according to its needs, including humans, animals, and plants. As in Islam, humankind has the first right to resources that Allah has provided for its creation. It is well accepted by Islamic scholars (1) that the priority rights of the use of water are first the right of humans to quench their thirst; second, the right of cattle and household animals; and third the right of irrigation.

Nevertheless most Islamic scholars have concluded that individuals or groups have the right to use, sell, and recover the value added costs of water. These judgments are based totally on two hadiths: the first, about Othman, the third caliph, who purchased a well at Ruma (a place near Medina), proves that wells can be owned and traded (2) and secondly, as Prophet Muhammad said, "*It is better to go to the wood and cut and sell lumber to feed himself than to beg people for help*," narrated by Muslims. This implies that common property resources such as wood and water can be sold and traded (3).

In his time, the Prophet Muhammad discouraged the selling of water and even forbade the sale of excess water. As noted, he also encouraged Othman to buy the well at Ruma and give away its water free. These examples reflect the prophet's desire for the poor and weak to have access to water. Apart from that, he encouraged people to work for a living, even by taking wood (a free natural resource) and selling it; a number of Islamic scholars believe it should also be applied to water, where we have the right to use, trade, and sell.

As narrated by Abu Hurairah, Allah's Apostle, said, *"No doubt, you had better gather a bundle of wood and carry it on your back (and earn your living thereby) rather than ask somebody who may give you or not*." Obviously, water in its natural state, such as a river or a lake, cannot be bought or sold. However, most prominent Muslim scholars agreed that if infrastructure and knowledge have been invested to withdraw it, for instance, a treatment and distribution system to convey it to people's homes, then the water utility has the right to recover its costs.

To prevent anyone new from diminishing the water flow, Islam has underlined a principle that entitles canals or wells or and any other sources of water that entail the ownership of a certain amount of adjacent land. This is known as *harim* or forbidden area. In this area, there should be no development such as land or tree cutting; it should remain as it is. Most schools of thought in Islam proclaim that no uniform size for a *harim* can be fixed and that the rules sanctioned by local customs must be adhered to, even in a region of 3 meters for a small well up to 100 meters for a spring.

Irrigation Regulations

The general principles of irrigation are that no one may alter an established irrigation system. Water may be drawn in any way, provided this does not entail any derogation of the lawful owner's rights and privileges. The assent of the waterside dwellers must be obtained, and the irrigation rights of other parties must be considered. Lower lying plots of ground are supposed to receive water from natural flows from upstream plots. The owner of the lower plot may not erect any barrier likely to obstruct the natural flow of water. Likewise, the owner of the upper plot may not do anything likely to harm the lower plot (5).

As narrated by Abdullah bin Az-Zubair,

> *An Ansari man quarreled with Az-Zubair in the presence of the Prophet about the Harra Canals which were used for irrigating date palms. The Ansari man said to Az-Zubair, "Let the water pass," but Az-Zubair refused to do so. So, the case was brought before the Prophet who said to Az-Zubair, "O Zubair! Irrigate (your land) and then let the water pass to your neighbor." On that the Ansari got angry and said to the Prophet, "Is it because he (i.e., Zubair) is your aunt's son?" On that the color of the face of Allah's Apostle changed (because of anger) and he said, "O Zubair! Irrigate (your land) and then withhold the water till it reaches the walls between the pits round the trees." Zubair said, "By Allah, I think that the following verse was revealed on this occasion": "But no, by your Lord they can have No faith until they make you judge in all disputes between them."* (4.65)

In addition Islam proclaims water conservation, and it is considered a fixed concept of Islamic teaching. A Muslim is ordered to be economical with water even if he is taking his water from a fast flowing river. The Prophet Muhammad teaches us not to overdo even in worshipping Allah; for instance, he uses only a handful of water in taking his ablution. Further more, as narrated by Anas, The Prophet used to take a bath with one Saor up to five Mudds (1 Sa' is equal to 4 Mudds) of water and used to perform an ablution with one Mudd of water. As in bathing, he also used a single pot of water. As narrated by 'Aisha (one of his wives), The Prophet and I used to take a bath from a single pot called a 'Faraq.

CONCLUSION

lslam is the religion of all times and places. It is a perfect system of temporal values. By practicing its laws, Muslims all over the world attain spirituality and also the pinnacle of all other glories. It was proven that the religious precepts of Islam do not represent an obstacle for efficient management of water resources; on the contrary, proper use of Islamic principles could significantly enhance water management practices in the countries concerned.

Before it came to mean simply law, the Arabic word *sharia* denoted the law of water (1). Therefore, it is not surprising that a detailed examination of the Quran and the Hadith shows that Islam makes a remarkable number of specific statements about water management. It is because Islam rose and developed in a desert area where water resources were extremely important and always considered sacred. It is also connected with the nature of Islam as a monotheistic religion that sought to regulate the behavior of humans according to the commands of Allah.

Actually, there is no major contradiction between what Islam says about the laws of water and the emerging international consensus on the issue. Islamic water laws are not that unique; some of the same principles could be derived by studying other faiths, their holy books, and the lives of their prophets. The major differences existed and were practiced more than 1400 years ago; they have proven adequate, applicable, and practical in our daily life. It was noted that Islam is very flexible and can accommodate all concerns regarding natural resource management, including water. Furthermore, Islamic principles for water management are completely compatible with the Dublin International Conference on Water and Environment and other accepted principles. In addition, Islam considers the protection of biological biodiversity, as well as water quantity and quality.

TRANSBOUNDARY WATERS IN LATIN AMERICA: CONFLICTS AND COLLABORATION

Scott Whiteford
Alicia Jimenez
Michigan State University
East Lansing, Michigan

Tensions over freshwater resources may become more frequent as pressures on water resources grow due to increasing water scarcity, degrading water quality, rapid population growth, unilateral water development, and uneven levels of economic development. As water resources become increasingly overallocated and used, the potential for conflict between nations with competing priorities and management strategies grows. Despite many obstacles, several international organizations are proposing that instead of being zones of conflict, shared water resources can provide a basis for cooperation and benefit-sharing, provided that threats to international waters are recognized and collaborative structures created. In the largest study of transnational water conflict and cooperation, it was found that cooperative interactions between riparian states over the past fifty years have outnumbered conflictive interactions by more than two to one (1).

Acknowledging the benefits of cooperative water management frameworks, policy makers have developed guiding principles and laws for international freshwater management. On a smaller scale, regional bodies and individual governments have developed protocols and treaties governing the management and protection of specific international water bodies (2).

In the Americas, there are approximately 70 international basins shared by Latin American countries (32 in North America and 38 in South America). Of those, 15 of the North American international basins and six of the South American international basins are governed by international treaties (2). These treaties refer to agreements where there is a concern with water as a scarce or consumable resource, a quantity to be managed, or an ecosystem to be improved or maintained (see Table 1).

Although treaties and agreements of cooperation exist, countries of the Americas face a great challenge in collaborating to achieve sustainable development on both sides of their borders. This is particularly important where the actions of one nation can directly or indirectly affect the well-being of its neighbors. Frequently, projects that threaten water quality are located near international borders and create winner–loser confrontations. These situations generate serious international conflicts, sometimes violent, which may extend for years. To resolve these types of prolonged conflicts, collaborative agreements are negotiated which facilitate shared water and land management. This article presents examples of conflicting situations and cooperative efforts among Latin American countries in North America, Central America, and South America. This article examines key examples of binational development that has threatened the quality of water used by two nations and created binational conflict and negotiation.

NORTH AMERICA: MEXICO–U.S. BORDER

In the U.S.–Mexico border region, water scarcity is a growing problem heightened by drought, rapid population growth, tourism, urbanization, and agriculture. The border extends almost 2000 miles and includes multiple watersheds, diverse ecological zones, political units, and a range of economic activities. The two nations have developed a set of institutions to manage water conflict which we do not examine in this article. At the end of this section, we present a list of significant binational disputes and negotiations.

The following is a brief overview of one of major conflicts between the United States and Mexico, the conflict over water quality at the lower end of the Colorado River. Because Mexico is down stream on the Colorado River, which provides much of the water for the western United States, the quality and quality of water flowing from the United States to Mexico has been the subject of dispute and international litigation. See Table 1 for the many treaties written to govern the border water resources between these countries. Although both countries have developed institutions to negotiate the disputes over water rights and responsibilities, the challenge is almost overwhelming, given that the two countries have very different water laws, national institutions, and constituencies (3).

Water conflicts over water quality in the border region arose because of the salinity from drainage water coming into the Colorado from irrigated fields in the United States and then taken from the Colorado for irrigation in the Mexicali Valley (Mexico). This valley is located on the western area of the United States- Mexico border and is one of the richest agricultural zones in North America. The valley draws water from the Colorado River and also from the Mexicali-Mesa de Andrade aquifer that transcends both regions and which is also subject to international dispute. Until recently, the Mexican government has had the dominant role in managing water for both drinking and irrigation in Mexicali Valley; nonetheless, people in Mexicali mobilized for their water rights and put pressure on their local and national governments to negotiate with the United States to protect surface water. The negotiations led to the introduction of water quality control that resolved the crisis. Nevertheless, Mexican farmers are periodically plagued by discharges of poor quality water (3).

Water of the Colorado River is governed by international agreements, but this is not the case for groundwater which was not a source of conflict until the end of the twentieth century. It was assumed to be in great supply and of high quality, but conflicts have arisen with the paving of the irrigation canals on the American side of the border that had been recharging the aquifer pumped by farms on the Mexican side of the border. The quality of the water in the aquifer is also being questioned after recent studies that showed high levels of pesticides and salts. Binational efforts to resolve the groundwater conflicts are beginning, but cooperation between the two countries over groundwater is still being negotiated. Groundwater is not the only transnational water problem being negotiated between the United States and Mexico. Other issues include conflicts over water of the Rio Bravo/Rio Grande; pollution of the Rio Bravo, Tijuana, and Nogales by urban and industrial water; and the construction of radioactive waste dumps

Table 1. Transboundary Water Treaties in the Americas

NORTH AMERICA[b]

Basin	Total Area	Date	Treaty Basin	Signatories	Treaty Name
Artibonite	8,800 km^2	02-20-1979	Frontier or shared waters	Dominican Republic; Haiti	Treaty of peace, friendship, and arbitration between both countries.

[b] Includes Central America and the Caribbean.

in Sierra Blanca, Texas; Ruidoso, New Mexico, a toxic waste incinerator in Ciudad Juarez; and several toxic waste dumps in the border region of south Texas. All of these projects threaten the border environment. Meanwhile treatment plants have been built along the border. Major sources of pollution such as the Rio Nuevo, that flows from Mexicali to the Salton Sea in California, are now being treated and are returning a much better quality of water to the stream. Conflicts, negotiations, and cooperation will continue to be the pattern along this border for years.

CENTRAL AMERICA

Despite the importance of transnational rivers in Central America, they have not been the subject of extensive diplomacy. Dam construction projects on the Usumancinta, Salinas, and Pasión Rivers on the Mexico-Guatemala border have generated both conflicts and cooperation. The Mexican and Guatemala governments have signed a memorandum of energy cooperation which has created great concern among people who live in communities along the rivers and are afraid of being displaced by their governments by the construction of new and bigger dams (4). Community leaders have protested the lack of information about future construction plans, especially in the context of the Plan Puebla-Panama. The Plan Puebla-Panama implementation, begun in 2001, framed economic integration and sustainable development for Central America and the southern states of Mexico (5). Funding from the World Bank and the Inter-American Development Bank for the projects includes building dams on the border rivers. In response to such controversial plans, 98 nongovernmental organizations (NGOs) from 21 countries of the Americas and Europe and affected communities have created a regional movement against dams (6). The concern is focused on forced relocation of communities, the destruction of valuable archaeological sites, and loss of biodiversity (4).

Other major transboundary rivers in Central America include the Rio Hondo between Mexico and Belize and the San Juan River that divides Costa Rica and the San Juan. Heavy use of pesticides in Belizean agriculture that are killing fish and impacting coral reefs are creating concern on the Mexican side of the river. Another type of transboundary river problem, navigation rights, is reflected in a dispute between Costa Rica and Nicaragua over the San Juan River. The conflict started in 1998, when Arnoldo Aleman, a former Nicaraguan president used police to impose navigation fees on Costa Rican citizens using the river on the Nicaraguan side. It was only by the intervention of the Costa Rican government that the fees were dropped, much to the relief of people living on both sides of the river (7).

SOUTH AMERICA

Transboundary water management in South America is very challenging. The region includes one of the largest river basins in the world, the Amazon River Basin. The region, known as Amazonia, includes more than 8000 km of borders, including eight South American countries. Its enormous natural, cultural, biological, hydrological, mineral, forest, and medical resource richness has made it an object of intensive exploitation that has endangered the natural balance and health of the basin.

Another important international basin is the Orinoco, located in the south part of this basin where Venezuela and Guyana are located. The Orinoco is affected by gold mining. In 1995, more than one million liters of cyanide waste were spilled in the Omai and Esequibo Rivers in Guyana. The impact of these activities and the contamination of the zone's hydrologic network affect at least 25% of the basin's indigenous population, including the following ethnic groups: Pemon, Yanomami, Piaroa, Guahibo, Yekwana, and 17 other indigenous peoples. There are no treaties or agreements of cooperation on water quality between the countries that share this basin.

In addition to the Amazon, other rivers in South America play an important role in linking as well as dividing countries in northern South America. The Meta River that divides Colombia and Venezuela has supported transportation of produce for centuries (8). Sediments, caused by watershed degradation, create serious difficulties for transportation on the Meta River reducing its capacity for transportation. With funding from the Inter-American Development Bank, a binational dredging project of the Meta River has begun to increase trade by reducing transportation cost, but the project has been opposed by many stakeholders and conservation groups on the grounds that no impact studies were carried out and local populations had little input to the project.

Sovereignty and control over who uses rivers (sailing rights) may be a source of conflict and/or cooperation. Sailing rights in waters controlled by multiple countries are a challenge for integration. An example of this is the Orinoco-Amazonas fluvial interconnection project, which has been promoted by Venezuela's and Brazil's presidents, but integrating the Colombia has been difficult. Colombia wants free sailing rights on the Orinoco, without the approval of Venezuela and Brazil, to facilitate transportation and trade. The Orinoco–Meta integration is important for Colombia because it would provide a corridor between the Pacific and Atlantic Oceans. Both Venezuela and Brazil are reluctant to give Colombia free access and have recommended doing the fluvial interconnection gradually and in specific phases. To open the waterway to commercial vessels will require considerable dredging and construction in Colombia and cooperation from its neighbors (9).

La Plata Basin, which is shared by five countries, Brazil, Argentina, Paraguay, Bolivia, and Uruguay, is also under threat. The Pilcomayo river, part of this basin shared by Argentina, Bolivia, and Paraguay, has been contaminated periodically with arsenic, cadmium, and lead caused by spills of toxic waste containers from Bolivian mining. In the trinational zone, the Pilcomayo is an important source of water for indigenous peoples, agriculture, and its unique wildlife. There are several cooperative agreements for the water management of this river (see Table 1).

The process to build a hydro-via, a water highway, using the Parana and Paraguay Rivers is in its final discussion phase (10). The Paraguay-Parana River Hydro-Via is a plan of the five governments of the La Plata Basin to build 2100 miles of river and canal systems navigable by large barges. The project would significantly reduce the transportation costs of commodities within and beyond the region. For example, it would reduce the cost of transportation of soybeans exported to Europe from South America by half. However, the project was halted in 1997 due to the Rios Vivos Coalition's efforts to demonstrate the irreversible effects on this unique ecosystem, the Pantanal. The Pantanal is the world's largest tropical wetland ecosystem formed by the Parana-Paraguay rivers (11).

The Pantanal is an ecological wonder shared by Bolivia, Brazil, and Paraguay. The ecosystem of the region is based on seasonal flooding of the major rivers, including the transborder rivers; yet there is no trinational agreement to protect the ecosystem and the people who depend upon it. This unique region has serious problems caused by deforestation, expansion of agriculture, contamination of the water by pesticides and derivatives of combustible alcohol production, and illegal hunting of endangered species. There has been an increase in natural habitat loss and a decline in the quality of life

South America has major several shared hydroelectrical dams; over the Parana River are two: Yacyretá (Argentina and Paraguay) and the biggest dam in the world, Itaipú (Brazil and Paraguay). Another is Salto Grande, shared by Argentina and Uruguay over the Uruguay River (10). Five more international dams on the Uruguay and Parana border rivers have been under study.

The Yacyreta binational dam has had great impact on native and rural populations, forcing them to move away from their homes and farms. This mobilization has affected the health of these populations, increasing their risk of contracting malaria and other tropical diseases. The Itapu dam has also had massive social and environmental impacts. One of the most significant impacts has changed the weather of the region periodically creating semihurricane conditions. The building of dams and sharing of electricity reflect a high level of cooperation between the countries that share borders.

South America economic integration and the new infrastructure, including highways and hydroelectric dams in the southern region of South America, have also generated conflicts over transboundary waters. One criticism of the integration process is the lack of wide stakeholder participation and the lack of information to the civil society about these efforts. The projects mentioned before, the Meta River canalization, the Orinoco–Amazonas fluvial interconnection, the Venezuelan–Brazilian electrical interconnection, and the South Cone projects, among others, are usually perceived as local or isolated national efforts, without taking into account their continental scope. In addition, according to Arocha (12), most of the new infrastructural projects will produce considerable disturbances in the natural and social environment, and most likely, the indigenous population will be affected the most.

Several organizations, such as the United Nations Global Environment Facility (GEF) propose a comprehensive, ecosystem-based approach to managing transboundary waters and their drainage basins; these are often called “international water projects”(1). The goal of these organizations is to build transboundary collaboration projects to help each of the countries use the full range of technical, economic, financial, regulatory, and institutional measures needed to operationalize sustainable use strategies for transboundary waterbodies and contributing basins.

One example of a GEF international water project in Latin America is the Bermejo River Basin of Bolivia and Argentina. The GEF became interested in this basin because it has excessive levels of sediment, important transboundary biodiversity, and a binational commission for developing of the basin. One of the objectives of GEF was the involvement of stakeholder groups in the basin to determine their sustainable development future. They facilitated participatory transboundary diagnostic analysis (TDA), a scientific-based assessment of the key transboundary problems and their root causes. Originally, 16 dams were proposed for hydropower production in the basin. This was quite controversial. However, through public participation in the project, the binational commission that was created to develop hydropower transformed itself into a force to consider sustainable development options. Three dams will still be pursued, but the focus on the transboundary environment, strategic processes for participation, and practical measures consistent with sustainable development helped overcome initial transboundary concerns and NGO opposition (1).

The future of transnational rivers in Latin America and their role in enhancing sustainable development depends on binational collaboration. The watershed and basin agreements in place have generally facilitated negotiation and found solutions of mutual benefit. In other transborder water situations, mutually agreed upon conflict resolution mechanisms and management plans have yet to be developed. Until these agreements are in place, binational management will continue to generate conflict. At stake is the development of some of the most important yet vulnerable areas on the continents. Fortunately, progress is being made on almost every border.

UNITED STATES-MEXICO BORDER WATERS: CONVENTIONS, TREATIES, AND INSTITUTIONS

Nancy A. Lowery
San Diego, California

SELECTED TREATIES AND CONVENTIONS

Cooperation over shared United States–Mexico waters dates back to the *Treaty of Peace, Friendship, Limits, and Settlements*, know as the Treaty of Guadalupe Hidalgo, signed in 1848. This treaty established the international boundary from the Gulf of Mexico along the Rio Grande to El Paso, Texas, then west to the Pacific Ocean just south of San Diego Harbor, a stretch of 3141 km. For 2001 km of that border, the Rio Grande serves as the boundary line. This is a long and complex boundary with topography ranging from coastal plains to mountain ranges and high desert. The climate is predominately semiarid to arid, has two major watersheds, the Rio Grande (called the Rio Bravo in Mexico) and the Colorado River, many smaller watersheds, and numerous groundwater basins. This was a treaty of intent, not of specifics. The treaty did not deal with details of the boundary line, management of water between the two countries, fluctuation of the river courses, water quality, or groundwater resources. Subsequent agreements would have to deal with these issues.

The introduction of the railroad and irrigated agriculture in the late 1800s spurred settlement, which required that questions left unanswered by the 1848 Treaty be resolved or at least addressed. Therefore several conventions were enacted to solve disputes over the boundary line, establish surveys, and fix boundary monuments to officially demarcate the border (1). These include the *Gadsden Treaty of December 30, 1853* and the *Convention of July 29, 1882* (2).

Changes in the course of the Rio Grande and Colorado rivers and the resulting fluctuations in the international boundary were dealt with by the *Convention of November 12, 1884*. This agreement established rules for maintaining the boundary line, given changes in the riverbed. The *Convention to Avoid the Difficulties Occasioned by the Reason of the Changes which Take Place in the Beds of the Rio Grande and Colorado River*, March 1, 1889, established a binational commission, the International Boundary Commission (IBC). The IBC's role was to apply the 1884 Convention rules and handle disputes related to boundary waters. The IBC had both a United States and a Mexican Section; each had a separate commissioner appointed by the federal governments of the respective countries.

None of these previously mentioned agreements dealt with the apportionment of waters between the two countries. By the end of the nineteenth century, however, allocation issues could no longer be ignored. The growth of irrigated agriculture on the upstream reaches of the Rio Grande meant that in low flow years, farmers on the Mexican side of the border did not receive sufficient water to irrigate crops. By the 1890s, Mexico was pressing for a solution to this problem, especially where agricultural pressures were at their greatest, which was in the section of the Rio Grande that forms the border between New Mexico, Texas, and Chihuahua.

To alleviate stress in that region, the May 12, 1906 *Convention Providing for the Equitable Distribution of the Waters of the Rio Grande for Irrigation Purposes* allocated the waters of the Rio Grande above Ft. Quitman, Texas, between the United States and Mexico. It guaranteed Mexico 74 Mm^3 (60,000 acre-feet) to be delivered at a point just above Ciudad Juárez, Chihuahua, in accordance with a monthly schedule. In exchange for that delivery, Mexico waived any additional claims to the waters from the upper stretch of the river to Ft. Quitman, Texas.

All water allocated under the 1906 Convention is for irrigation; none is set aside for municipal or industrial uses or for instream flows. As water demand has changed, this allocation structure has had ramifications for the region. The Convention also did not deal with water quality issues or apportion groundwater supplies. It did, however, provide for drought or catastrophic conditions. Stating that should it be impossible to deliver the quantity of water promised due to severe drought or destruction of the delivery system, Mexico's supply would be diminished in the same proportion as the supply delivered to U.S. irrigators.

In 1933, the two governments enacted the *Convention for the Rectification of the Rio Grande (Rio Bravo del Norte) in the El Paso–Juárez Valley*. This convention established the Rio Grande Rectification Project to manage the river in the increasingly developed Mesilla–El Paso–Juárez Valleys for flood control and delivery of treaty waters. It provided for joint construction, operation, and maintenance, by the IBC, of the facilities needed for these purposes, which entailed straightening a 155-mile stretch of the river and was the first joint construction treaty between the United States and Mexico.

Continued border growth in the early 1900s caused the lower Rio Grande basin and the Colorado River to experience water demand pressures similar to those that had been felt in the upper Rio Grande basin 50 years earlier, which led to the 1944 *Treaty Relating to the Utilization of Waters of the Colorado and Tijuana Rivers and of the Rio Grande*, considered the most important United States–Mexico water treaty. This treaty expanded the scope of cooperation between the two countries to include issues related to border sanitation and, more importantly, provided the legal framework for resolving water disputes between the two countries. It replaced the IBC with the International Boundary and Water Commission (IBWC), called the Comision Internacional de Limites y Aguas (CILA) in Mexico.

The new IBWC had expanded scope and authority in line with the expanded scope of the 1944 Treaty. It has the status of an international body, has two Commissioners, appointed by the presidents of each country, and permanent offices in El Paso, Texas, and Juárez, Chihuahua. It operates under the Departments of State of each country and has the authority and responsibility to negotiate and carry out agreements between the two countries regarding border water and sanitation, as outlined in the treaties. These agreements are called Minutes. Once approved by the United States and Mexican governments, Minutes are binding on those governments. As of March 2004, there are 311 Minutes (3). The Minute process has been an effective means to address serious border water issues, such as salinity, untreated effluent discharges, and drought mitigation, without having to renegotiate existing treaties or negotiate new ones.

Additionally, the 1944 Treaty (4) sets out, in Article 3, priorities for the joint use of the international waters, which would be used if the Commission were asked to make a determination of priorities. In order of preferential use, they are

- domestic and municipal uses,
- agriculture and stock raising,
- electric power,

- other industrial uses,
- navigation,
- fishing and hunting, and
- any other beneficial uses that may be determined by the Commission.

The 1944 Treaty also apportioned the shared surface waters, not already divided, between the two countries. Waters of the Rio Grande–Rio Bravo from Fort Quitman to the Gulf of Mexico are apportioned in the following manner:

Mexico has the right to:

- all of the waters reaching the main channel of the Rio Grande from the San Juan and Alamo Rivers, including the return flows from the lands irrigated from those two rivers;
- two-thirds of the flow of the main channel of the Rio Grande measured from the Conchos, San Diego, San Rodrigo, Escondido, and Salados Rivers and the Las Vacas Arroyo, subject to the U.S. right to an average 431,721,000 cubic meters (350,000 af/yr) in cycles of 5 consecutive years; and
- one-half of all other flows in the main channel of the Rio Grande downstream from Ft. Quitman not specifically allocated under this Treaty to either of the two countries.

The United States has the right to:

- all of the waters reaching the main channel of the Rio Grande from the Pecos and Devils Rivers; Goodenough Spring; and Alamito, Terlingua, San Felipe, and Pinto Creeks;
- one-third of the flow reaching the main channel of the river from the Conchos, San Diego, San Rodrigo, Escondido, and Salados Rivers and the Las Vacas Arroyo, providing that this third shall not be less than 431,721,000 cubic meters annually (350,000 af/yr) as an average amount in cycles of 5 consecutive years; and
- one-half of all other flows in the main channel of the Rio Grande downstream from Ft. Quitman not specifically allocated under this Treaty to either of the two countries.

In the case of the Colorado River, under the 1944 Treaty, Mexico is to receive 1,850,234,000 cubic meters annually (1.5 million af/yr), to be delivered in accordance with schedules provided in advance by Mexico. Mexico is also assigned any surplus waters not necessary for uses in the United States arriving at the Mexican point of diversion. The total annual amount of water delivered to Mexico is not to exceed 2,096,931,000 cubic meters (1.7 million af/yr).

The amount of Colorado River water allocated to the United States is not specifically mentioned in the 1944 Treaty. Those allocations are set out in the *Colorado River Compact of 1922*. The compact allocates 18,495,000,000 m^3 year (15 million acre-feet) to the compact States of Arizona, California, Colorado, Nevada, New Mexico, Utah, and Wyoming. The Compact, which came into effect before the 1944 Treaty, maintains in Article III that if the need arises for waters of the Colorado to be delivered to Mexico, than Mexico's share would come from excess flows. If surplus waters are unavailable, then the deficit in flows is to be shared equally by the states. Because of water variability and increasing urban and agricultural reliance on the Colorado River, supplying the allocated waters has become a problem (5). The 18.5 Bm^3 allocated under the Compact and the 1.8 Bm^3 assigned under the Treaty are higher than the annual average flow of the river, which is approximately 16.6 Bm^3 or 13.5 million acre feet (6).

In allocating Tijuana River waters, provisions for distribution are not laid out. The 1944 Treaty recommends, however, that the Commission investigate all means for equitable distribution of the waters between the two countries. This investigation and all other exploration of border surface water issues would be carried out by the newly formed IBWC.

Finally, the 1944 Treaty allows for the construction of dams, delivery structures, and flood control structures that are necessary to fulfill treaty obligations. It determined that these structures would be jointly constructed, maintained, and operated, and the costs to each country would be equal to the benefits provided. Since 1944, the IBWC has been responsible for constructing, maintaining, and operating two large dams and storage reservoirs, Falcon and Amistad, numerous diversion and delivery structures, international wastewater treatment plants, and a surface water salinity treatment plant.

On August 29, 1963 the two governments signed the *Convention for the Solution of the Problem of the Chamizal* to resolve a 100-year-old boundary and land dispute between the United States and Mexico. The Rio Grande channel in the area of El Paso, Texas, and Juárez, Chihuahua, had shifted periodically over the centuries, causing approximately 600 acres to move back and forth between the north and the south banks of the river. The Convention settled this dispute by repositioning and stabilizing 4.4 miles of the river, which transferred 437.18 acres from the United States to Mexico.

In 1970, the *Treaty to Resolve Pending Boundary Difference and Maintain the Rio Grande and the Colorado River as the International Boundary between the United States and Mexico* was enacted. This Treaty provides for the maintenance of the boundary line due to shifting river courses, erosion, or other changes in the channel. It also resolved all pending boundary disputes between the two countries. The IBWC is responsible for carrying out the provisions of the Treaty.

SELECTED BINATIONAL AGREEMENTS

There are several other agreements that were signed by the United States and Mexico that are relevant to managing water in the border region. These include the La Paz Agreement and the side agreements of the *North American Free Trade Agreement*.

The *Agreement between the United States of America and the United Mexican States on Cooperation for the*

Protection and Improvement of the Environment in the Border Area (La Paz Agreement) was signed on August 14, 1983. The La Paz Agreement is the framework for cooperation between the United States and Mexico on protecting, improving, and conserving the environment in a 100-kilometer area on either side of the border. This Agreement deals with issues of water, soil, and air pollution and provides for a system of emergency notification.

Five technical annexes were established to deal with specific projects of environmental concern, two of which are water related. Annex I, *Solution of the Border Sanitation Problem at San Diego, California and Tijuana, Baja California*, and Annex II, *Regarding Pollution of the Environment along the Inland International Boundary by Discharges of Hazardous Substances*, were both enacted in 1985. The framework set up by the La Paz Agreement paved the way for future environmental cooperation between the two countries. The 1992–1994 Integrated Border Environment Program (IBEP), the Border XXI Program, and the Border 2012 Program were developed in conformance with the *La Paz Agreement*.

The *North American Free Trade Agreement* (NAFTA) among Canada, United States, and Mexico became effective on January 1, 2004. NAFTA uniquely included side agreements on the environment. These agreements established a Commission on Environmental Cooperation (CEC) among the three signatories. CEC's role is to protect the environmental regulations of each country and to allow individuals and governments to file complaints with the Commission if they believe environmental laws are not being enforced.

The NAFTA side agreements also established the Border Environment Cooperation Commission (BECC) and the North American Development Bank (NADBank). BECC and NADBank are international organizations whose goal is to protect and improve the environment of the United States–Mexico border. BECC's mandate is to certify water, wastewater, and solid waste projects within the border zone. This area is defined using the La Paz Agreement boundaries of 100 kilometers on either side of the border. Certification is based on a set of engineering standards and economic and environmental sustainability concepts. NADBank's role as a development bank is to fund projects certified by BECC. Both of these institutions have played an integral role in water and sanitation infrastructure and management in the border region; due to the certification process, projects cannot be built without BECC approval.

CURRENT SITUATION

The complex set of Treaties, Convention, Compacts, and side agreements that laid the foundation for water allocation and management in the United States–Mexico borderlands have served the region well. Rapid growth, however, has placed stress on both the resource and the legal and institutional structures used to govern it. Most, if not all, border water resources are plagued by increased demand and diminishing supply. In 2000, the border population was approximately 11.8 million (7), primarily living in 14 sets of twin cities stretched out along the border. Based on annual growth rates of between 3% and 5%, that population is expected to reach 19.4 million by 2020 (8).

Current water management on the U.S.–Mexico border, therefore, is defined by three realities: first, seasonal and annual variability of water supply; second, overallocation of that supply; and third, increased competition for the resource due to burgeoning growth and changing priorities. Demand in the early and mid-1900s was sufficiently low that, except in times of severe drought, supply was adequate to meet demand. Growth and changing demand patterns have altered the balance and strained the institutional mechanisms that regulate and manage shared waters. Issues of how to deal with persistent drought, the allocation and joint management of groundwater basins, and environmental concerns surrounding degraded and endangered habitat and species have stretched the limits of the treaties and their institutions. The current debate centers around the question of whether the treaties in force have the flexibility to deal with emerging issues, whether they should be significantly altered, or if new treaties should be enacted (9–12).

NEGOTIATING BETWEEN AUTHORITY AND POLLUTERS: AN APPROACH TO MANAGING WATER QUALITY

Petr Šauer
Antonín Dvořák
University of Economics
Prague, Czech Republic

INTRODUCTION

Water pollution reduction is one of the most complicated challenges of environmental policy. Water quality engineers are able to offer many technical solutions. Some are based on “end-of-pipe” technologies; some represent “cleaner production” solutions. Solutions exist that are already economically efficient for the polluters. Many cleaner production projects are of this type. However, many projects exist that bring net control costs for the polluters, so the polluters do not have an economic interest in them. As these projects can still be efficient from the social point of view (if negative externalities would be internalized), it is important to change the institutional framework of environmental policy. The best institutions are those that not only satisfy ecological efficiency but also support economically efficient solutions, or at least cost-effective solutions, to the given problem. Our contribution is to present a relatively new approach that could lead to cost-effective solutions of water pollution reduction problems. It is based on voluntary negotiations between an authority and polluters where economic tools of environmental policy (environmental fees and subsidies) are used at the same time. The principle of the approach is explained in the and an illustration of an economic laboratory experiment follows.

PRINCIPLE OF THE APPROACH DESCRIBED

The suggested approach is based on (mostly multiple rounds) negotiations between an authority of environmental policy and economic subjects—polluters. The binding agreements are the results of the negotiations. The agreements contain: (final) commitments of the polluters to reduce pollution, commitments of the authority to contribute negotiated financial resources to pollution reduction projects, and a set of consequences in the case of noncompliance with the agreement conditions. If the water pollution charges are introduced, then there must be a commitment of the polluters to pay it, unless the charge has not been already introduced by a law, i.e., the charge already exists. NGO’s and various independent experts (like public health experts, ecologists, environmental engineers) can also take part in this procedure.

The positions and performance of the parties taking part in the negotiations are as follows [for the formalized procedure see (1)]:

The polluters have technical solutions (projects) that can reduce their pollution. They know the true information about their net costs of environmental protection but keep it confidential, which creates a so-called information asymmetry between the polluters and the authority. The fact that the polluters can keep the private information confidential and still achieve a cost-effective outcome seems to be one of the important privileges of the approach. During the negotiation process, they apply their own strategies to their benefits maximization when requesting (financial) contributions from the authority and offering water pollution reduction in the single rounds of the negotiations.

The authority has some available information about contributions of individual polluters to the pollution in the region, but it is unfamiliar with the true net costs of environmental protection of polluters and about their criteria of economic efficiency. The authority uses traditional economic tools in the process of the negotiation. The rate of payments for pollution is set. The rate of this payment can also be negotiable in more advanced models of the concept. The authority collects revenues from these payments in a fund and negotiates financial contributions from the fund with the polluters. During the process of negotiations, it maximizes various environmental effects per one unit of the financial contribution, which leads to the cost-effective solutions. Various methods and approaches for a quantification of indicators of these environmental effects can be used, such as risk assessment, multicriteria analyses, etc. Three different sets of environmental indicators could be used in the process: first, charging for the pollution; second, setting priorities for the financial support from the fund, and third, the final control of the concluded agreements. The authority can use various strategies from a spectrum defined by marginal strategies as follows: the first strategy leads to a uniform contribution from the fund per one unit of the positive environmental effect; the second strategy tries to reflect different net costs of environmental protection of the individual polluters.

LABORATORY ECONOMIC EXPERIMENT ILLUSTRATION

Let us illustrate the approach to a laboratory economic experiment. An ideal case of (politically) required water pollution reduction in a river basin was based on both environmental and economic data taken from various projects realized in practice in the Czech Republic. We considered pollution based on chemical oxygen demand (3,700 t/year), dissolved substances (790 t/year), insolved substances (1,320 t/year), phosphorous (18 t/year), and nitrogen (140 t/year). To put it more simply, the pollution was recalculated by using coefficients of harmfulness of the single pollutant. The resulted pollution was 1,454,000 units/year.

15 major polluters exist in the region. Their contribution to the pollution was transferred to the recalculated

units as follows: textile company (A; 30,760), stone manufacturing (B; 5,760), heating station (C; 7,750), pigments manufacturing (D; 4,500), heating station (E; 14), photo-developing (F; 50), metal surface remanufacturing (G; 10,800), textile (H; 102,560), food production (I; 365,200), food production (J; 157,890), waterworks (K; 176,750), municipality I (L; 54,605), municipality II (M; 99,500), municipality III (N; 105,250), and municipality IV (O; 43,790). These polluters contribute, in total, 1,165,108 units, which is approximately 80% of total water pollution in the basin.

The environmental goal for the region was to reduce pollution from all sources at least by about one-third and to reduce pollution from the major sources by about one-half.

The laboratory experiment was conducted by Czech students of Environmental Economics and Policy Specialization at the University of Economics in Prague. The students played roles of managers of polluting entities. The teacher played the role of the authority. Charges that are paid according to Czech law (2) on pollution of surface water were used as a rate of payment for single pollutants to create revenues in the fund.

The negotiating in this experiment took three rounds. Six hypothetical agreements between the authority and the polluters were concluded at the end of the last round: I (pollution reduction 280,700 units), B (5,760), J (151,975), N (89,448), K (88,750), G (7,200). The agreed pollution reduction was 623,833 units in total, which represents about 54% of total pollution from major sources and about 43% of total pollution in the region. When repeating the experiment with teachers of economics, the agreements were concluded with a similar set of polluters C, G, I, J, B, and K. The pollution reduction was, in this case, 535,825 units [for the other experiment see (1)]. The theoretical (computed) pollution reduction satisfying the cost-effectiveness rule was 536,523 units, i.e., very close to the results of both experiments. Also, the subsidies agreed at the end of the experiments were very close to the theoretical (computed) ones: Computed subsidies were 55,799 monetary units. Students agreed with 52,650 and teachers concluded the agreements with the total subsidies at 54,780 monetary units.

Other experiments testing the described approach were conducted using ideal data. Also, in these cases, the experimental outcomes were very close to the computed ones.

In the next step, we used the same data for experimenting with the tradable pollution permit system. We were interested what the result would be if the same (water) pollution reduction target were achieved via trading the permits. In all laboratory experiments, the set of polluters who concluded the agreements with the authority and the set of polluters who sold the permits were about the same. Moreover, the price per one unit of permit was very close to the subsidy per one unit of reduced pollution.

CONCLUSIONS

It would be possible to discuss several practical applications of the approach. It could be used as a model for negotiations between a state environmental protection authority (regulator) and multiple polluters, as described above.

An environmental protection fund could be established and privately owned by the polluters that voluntarily want to solve a pollution reduction problem in a region and want to use the negotiation approach to avoid negative state authority action. The concept could be applied within a single corporation having multiple sources of pollution for solving the "principal-agents" problem where manager's and owner's utility functions are different.

A special application might be to organize a voluntary, experimental workshop of selected polluters and/or experts. Some information that might be useful for environmental policy decision-making, like a rough estimation of the environmental pollution charges, could be generated at the workshop (to receive information that is important).

The approach can also help with an efficient initial distribution of tradable water pollution rights. Moreover, it could contribute to resolving complicated situations (characterized by many pollutants, synergic effects, etc.) before the rights are allocated for limited number of the pollutants.

WATER RESOURCE ORGANIZATIONS

Peter E. Black
SUNY ESF
Syracuse, New York

Water management organizations evolved at local, regional, state, and federal levels. They were created, in large part, during the twentieth century, exhibit different degrees of formality and authority, and exist for different purposes, serving different groups consisting of individual qualified members and/or of the public at large. The organizations fill specific missions, roles, and meet demands of members and official segments of society. Knowing their missions and responsibilities makes it easier to seek information or how to influence their responsibilities.

INTRODUCTION

Organizations may be classified in a variety of ways. The water and related land resources agencies lend themselves to classification by mission (or responsibility), level of government, and legal status. Other water organizations may be national in scope but voluntary in membership, responsible for licensed professional activity, or open to all who subscribe to the group's philosophy. Any nongovernmental organization may be chartered under the laws of a state and may be incorporated for protection from liability actions. Some organizations may be tax-exempt, depending on their political nature and/or activity. Organizations may be temporary if their missions are limited; others may experience a shift in mission as their goals are achieved, or the membership finds them no longer relevant.

GOVERNMENTAL ORGANIZATIONS

Federal Agencies

Federal agencies derive their authority from the U.S. Constitution. State agencies, of course, derive theirs from their constitutions, which were approved by the U.S. Congress at the time of statehood, or were subsequently created by state legislatures. All the organizations' chartering legislation is subject to judicial review to ensure constitutionality. For example, the 1911 Weeks Forest Purchase Act (36 Stat 961) asserts in its opening statement of purpose of "the purchase of forest lands necessary to protection of the flow of navigable streams," the federal government may buy abandoned forest lands for inclusion in the National Forest system. Those fourteen words (in quotes) are sufficient to establish the constitutionality of the Act because the Constitution confers the right to regulate navigation on the federal government [Article I, Section 8 (3)]. The principal federal agencies charged with water and related land management are arranged by primary function(s) in Tables 1a to 1e (abstracted from Table 3.1 in Reference 1). Many agencies have other functions as well.

State Agencies

The states usually have a series of departments involved with forests, water, lands, fish and wildlife, and parks and recreation. The specific names and combinations of responsibilities are quite variable but tend to follow some typical patterns and in several different ways administer those permits and programs that federal agencies may have delegated to lower levels either because the states refused to be regulated by the federal government, they wished to have greater control over the regulations, or the federal government had neither the time nor funding to execute the mandated responsibility ("unfunded mandate").

Typically, the states create state-wide agencies such as departments of natural resources or environmental conservation, fish and wildlife, parks and recreation, agriculture and markets, and so forth. These deal with *intrastate* policies and management, regulation, granting of permits, and occasionally research and inventory. For point source pollution control permits under the control of the (federal) Environmental Protection Agency, the latter may have delegated responsibility for issuing National Pollution Discharge Elimination System (NPDES) to the state agency, in which case they are called SPDES permits. Continuing coordination between the state issuing authority and the EPA is part of these cooperative efforts. Some of the agencies may also be involved as partners with similar agencies in other states.

States may create *interstate* organizations to work with neighboring states by authority of the United States Constitution [Commerce Clause, Article I, Section 10 (3)]. These are interstate compacts that may exist for any of several reasons. Most interstate compacts administer interstate rivers and harbors. The managing organization is known as a *commission* (as opposed to a *committee*, which is usually informal. The Commissioner of the appropriate state department may serve—by appointment of the governor—as the representative of the state to an interstate commission.

Local Agencies

States may extend the constitutional right to local government to create agencies such as districts. These are extensions of state government that have the power to set boundaries, hold referenda, tax those holding real property within the district boundaries, enter into contracts, and incur indebtedness. There is a wide variety of districts; many exist for water management, including soil and water conservation districts, flood control districts, conservancy districts, drainage districts, and so on (in addition to the typical neighborhood highway districts, lighting, fire fighting, and school districts).

Typically, local organizations are formal or informal. The former include the *districts* (described above), and the latter are *associations*. Associations are not legal extensions of state government. Without formal boundaries, they may have members who agree to pay dues and may live anywhere. Usually, some common long- or short-term interest is the glue that holds the association together. Currently, there are thousands of watershed initiatives, associations that have a wide variety of collective names. They are watershed, river basin, or lake associations, councils, committees, land trusts, and so forth. They may, of course, be incorporated. Districts are often identified by other descriptive names, such as Resource Conservation Districts, Soil Conservation Districts, Conservation Districts, Natural Resource Districts, and Land Conservation Districts (as is pointed out on the NACD website http://www.nacdnet.org/). In some of the states that have strong county governments, the districts are organized on the basis of and coincident with the boundaries of the county; in others, the district is based on natural drainage.

Table 1a. Federal Land and Water Management Agencies

Agency	Date	Department	Mission, Responsibility
Bureau of Indian Affairs	1824	War, Interior	Manage forest, range and water resources; education, advocacy
Forest Service	1905	Interior, Agriculture	National forests, research, state and private forestry, and international forestry
National Park Service	1916	Interior	Preservation for science and recreation
Fish and Wildlife Service	1940	Interior	Wildlife refuge administration
Bureau of Land Management	1946	Interior	Renewable and mineral resources on public lands

Table 1b. Federal Construction and Operating Agencies

Agency	Date	Department	Mission, Responsibility
Corps of Engineers	1774	Continental Congress, War, Defense	Survey, rivers and harbors, navigation, flood control, water supply, water supply and recreation, dam safety, wetland permits, and aquatic ecosystem restoration
Bureau of Reclamation	1902	Interior	Irrigation and dams therefore
Natural Resources Conservation Service (nee Soil Conservation Service)	1933	Agriculture (Interior for a few years)	Soil and water conservation, upstream flood control, wetlands, education and information; administration of principal agricultural conservation programs; disaster response
Tennessee Valley Authority	1933	Independent	Hydropower development, flood control, economic improvement

Table 1c. Federal Regulation and Enforcement Agencies

Agency	Date	Department	Mission, Responsibility
Interstate Commerce Commission	1887	Independent	Carrier rules and regulation; sets interstate freight rates and routes
Federal Power Commission	1920	Independent	Licenses hydropower sites on navigable streams, public lands
Flood Insurance Administration	1968	Housing and Urban Development	National Flood Insurance Program
Environmental Protection Agency	1970	Independent	Pollution control permits, abatement, research/grant programs

Table 1d. Federal Research and Inventory Agencies

Agency	Date	Department	Mission, Responsibility
Geological Survey	1879	Interior	Mapping, hydrologic data collection, publication, and research; benchmark watershed program
National Weather Service (nee Weather Bureau)	1890	Signal Corps, Agriculture, Commerce, NOAA	Weather data collection, research, and publication; flood and fire weather forecasting
Agricultural Research Service	1953	Agriculture	Soil–water–vegetation research
Office of Water Research and Technology	1964	Interior, now abolished	Promotion, coordination, and funding for water resources research
National Oceanic and Atmospheric Administration	1970	Commerce	Explores, maps, and charts oceans, atmosphere, and space

Table 1e. Federal Coordination and Study Agencies

Agency	Date	Department	Mission, Responsibility
Senate Select Committee on Water Resources	1959–1961	Congress	Federal investigation of all water resource issues
Water Resources Council	1965–1981	Independent (now nonfunded)	Coordination of federal activities, flood control regulations, principles and standards for evaluation of water and related land resources projects and programs
National Water Commission	1968–1973	Independent	Nonfederal study of all water resource programs issues
Council on Environmental Quality	1970	President	Policy, research, advice to President and reports to Congress and the Public
National Study Commission	1972–1977	Independent	Charged to report on necessary adjustments to Clean Water Act halfway to 1983 and 1985 goals

PROFESSIONAL ORGANIZATIONS

There are numerous professional societies (sometimes confusingly referred to as associations) that serve the particular profession, such as architects, engineers, fishery biologists, foresters, geologists, geophysicists, hydrologists, landscape architects, limnologists, oceanographers, public administrators, range managers, soil scientists, surveyors, water works managers, well drillers, wetland managers, wildlife managers, and so forth. Many of these organizations serve, wholly or in part, important professions in water resource activities. Many have both technical and public-oriented publications that might be of interest to the lay public. Annual national and regional or state meetings are also often open to the public in whole or in part. Usually, putting the organization's initials (or full name) into the website URL line will provide the home webpage. Many water resources organizations may be found listed under links at the American Water Resources Association (http://www.awra.org), the principal interdisciplinary professional water resources organization in the United States, at the Environmental Protection Agency (http://www.epa.gov/), or at the website of the Conservation Technical Information Center (http://www.ctic.purdue.edu/CTIC/CTIC.html).

NONGOVERNMENTAL ORGANIZATIONS

Nongovernmental organizations are most often referred to collectively as "NGOs." The number continues to grow. Many of these may also be found at the websites of organizations cited above, by online search, or in the publications of the organizations.

During the past two decades (approximately), water resources management decisions have been effected by partnerships made up of mandated national, state, and local agencies in concert with business, interested individuals, and NGOs. Successful partnerships operate at all levels, with large or small numbers of participants, with and without government sanction, and over time with a shifting membership reflecting past accomplishments and initial goal achievement. Partnerships represent the finest in problem solving challenges and are truly democracy in action.

Partnerships require that all stakeholders[1] have an opportunity to take part in the process; that the participants respond to questions such as "What are our common goals?", "What can we do together better than separately?", "On what do we disagree?", and "Can we agree on an initial objective?"; that no one participant exercises fiscal, organizational, political, or social control over the process or the outcome; that participants treat one another with cordiality and respect; and that there be some identifiable constraint on the challenge, usually for water resources challenges, geographical, but also possibly economic, legal, or disaster or other crisis.

SUMMARY

Historical, legal, and cultural events during the last 200 years combine with the individual personalities of leaders and public citizens to leave a massive array of legislation, government agencies, and nongovernmental organizations all charged with or assuming responsibilities for some part of the water resources of the United States. Knowing the authority, extent of influence, nature, and relationships among the organizations is essential for sound water resources management. But, it does not guarantee it: only when people take on the responsibility of participating in the important water resources decision-making process will the vital water resources be effectively managed for a sustainable future. Partnerships are important players in the continuing policy and management decisions over water and related land resources.

A BRIEF HISTORY OF THE WATER POLLUTION CONTROL ACT IN THE U.S.

David L. Russell
Global Environmental
Operations, Inc.
Lilburn, Georgia

The Rivers and Harbors Act of 1899 was the earliest piece of federal water pollution control legislation in the United States. It regulated the dumping of garbage into rivers and harbors from ships. The act was only moderately successful in its application, but it became important in the 1970s when the EPA used it to regulate discharges into navigable waters.

ORSANCO

The earliest significant start for water pollution control legislation in the United States began with the formation of the Ohio River Sanitary Commission (ORSANCO) in the 1940s. It was formed as a result of efforts by individuals

---

[1] This interesting term is currently used to identify those with a vested interest. However, that is the precise opposite of the original use of the term to identify the person in a poker game who held the bet funds—the stake—while the game was played out, in other words, it was the person who had *no* vested interest!)

from the U.S. Public Health Service (USPHS) and many of the state Departments of Health. The ORSANCO compact culminated more than 10 years of work to promote public health and reduce the incidence of waterborne disease in communities along the Ohio River. ORSANCO started as an initial effort among four states, and by 1940, the compact had six states. In 1948, the seventh and eighth states signed the compact on the same day that President Harry Truman signed the first comprehensive water pollution control legislation that directed the U.S. Public Health Service to control water pollution to promote public health.

The Public Health Service already had authority, but was reluctant to use it for water pollution control unless there was a specific prominent incident. The real power to control pollution still lay with the states.

By contrast, ORSANCO was effective because the control came from within the states as a cooperative agreement among the Departments of Health. ORSANCO was instrumental in issuing the first set of coordinated standards—the first water treatment design code manual—in 1954. ORSANCO was also effective in coordinating the development of antipollution lawsuits and still is an effective voice in the Ohio River region when it speaks for the state governments. ORSANCO has legal authority to compel individual polluters in any of the compact states to reduce their discharge of pollutants, or even to cease the discharge completely and can, if it chooses, override individual state governments.

The ORSANCO compact is still in force and has remained unchanged for 50 years. The fundamental tenet of the compact is that the discharge from one state shall not be injurious to the public health and well-being of the residents of another state.

It is important to point out that developments in water chemistry, analytical technology, and fundamental research, along with political developments, accompanied the growth and expansion of ORSANCO. Many of these developments were independent, but it was the driving interest in water pollution control and industrial wastes that created the climate for research and development to bloom. Many of the earliest names in the history of water pollution control were involved with ORSANCO as well. Harold Streeter, who is one of the formulators of the Streeter–Phelps equations (which underlie much of river modeling) was an early Commissioner of ORSANCO. State Commissioners on the ORSANCO Board of Governors (from their respective State Health Departments) include Clarence Klassen (Illinois), Blutcher Poole (Indiana), and Fred Waring (Ohio). One of many early workers in the State of Indiania was Dr. Don Bloodgood at Purdue University, who created the Purdue Industrial Waste Conference in 1946. That conference was made possible through the encouragement of some of the ORSANCO Commissioners and was instrumental as a showcase in promoting nationally prominent water pollution control research until its incorporation into the Water Environment Federation Industrial Wastes Program in 2000.

WATER POLLUTION CONTROL ACT OF 1948

In 1948, the Water Pollution Control Act (Ch. 758; P.L. 845) authorized the Public Health Service to prepare comprehensive programs for eliminating or reducing the pollution of interstate waters and tributaries and improving the sanitary condition of surface and underground waters. Under the plan, water conservation and improvement was to be emphasized. The original statute also authorized the Federal Works Administrator under the U.S. Public Health Service to assist states, municipalities, and interstate agencies in constructing treatment plants to prevent discharges of inadequately treated sewage and other wastes into interstate waters or tributaries. More information is available at http://laws.fws.gov/lawsdigest/fwatrpo.html.

Controlling pollution and industrial waste gradually became more important, and the original act was amended to authorize additional water quality programs, standards, and procedures to govern allowable discharges as well as funding for construction grants or general program funding. The authority of the original act was extended several times, through appropriations up to 1956 by Ch. 927; P.L. 579.

Progress to the Mid-1960s

The Federal Water Pollution Control Act Amendments of 1961 (P.L. 87-88) stipulated that, during the planning for any reservoir, federal agencies consider storage to regulate stream flow for water quality control, but the act was placed under section 33 U.S.C. 1252 (transportation) of the U.S. Code. This later provided impetus for the U.S. Army Corps of Engineers and the U.S. Coast Guard to have authority for “transportation related” oil spills and what later became National Pollution Control Discharge Permit issuance. Under the 1961 amendments, the Department of Health, Education, and Welfare was directed to undertake research and determine the effect of pollutants and treatment methods and assess water quality in the Great Lakes. The Secretary of HEW was authorized to take “appropriate measures to ward off pollution of interstate navigable waterways if requested by a state (33 U.S.C. 1254(f)). Few requests were issued under the legislation.

The Department of Heath, Education, and Welfare was also ordered to report to Congress by 1964 on the effects of pollution on U.S. estuaries and the economic impacts of pollution control. HEW was also told to develop recommendations for further actions that would lead to a comprehensive national policy and define the roles of federal, state, and local governments. The interests of Mexico and Canada were initially considered but only as they related to damage from pollution of boundary waters (the Great Lakes and St. Lawrence Seaway, and the Rio Grande River). Congress prohibited the discharge of oil into U.S. waterways under 33USC 466 (transportation legislation).

Congress decided to provide some form of funding to states and cities to construct sewage treatment plants. This Construction Grants Program was initially a relatively modest effort through most of the 1960s, and it was capped until late in the decade at a maximum grant of 33% of the cost of interceptor sewers and treatment works.

PL-660

Public Law 660 was the beginning of a comprehensive pollution control effort. Prior to PL-660, the Public Health Service (Commission Corps) officers were largely responsible for water pollution control. The law that was passed in the early 1960s made several important changes in the funding of water pollution control programs. A new organization, called the Federal Water Pollution Control Agency, was created under the administration of the Department of Interior. The FWPCA also had responsibility for pollution control in Alaska (P.L. 86-70) and an expanded role in construction grants (P.L. 86-624).

The Silent Spring, the Age of Aquarius, and the Vietnam War

The publication of Rachel Carson's *The Silent Spring* in 1967 and the dawning of the "Age of Aquarius,"—the coming of age of the children born after World War II—led to a major departure from the once quiet role of the federal government in pollution control. In the United States, the Vietnam War was a time of domestic turbulence and significant social and political protest. The statements of young radicals ("Don't trust anyone over the age of 30") and a growing dissatisfaction with the progress in solving the war led to social protest and dissatisfaction with other areas of government as well. "Make Love not War" and the countercultural exploration of new religions and ideas, especially those from India, quickly led to the incorporation of the concept of "Mother Earth" and a "Gaia" movement. Among the tenets of this movement were the concepts that the earth was a living sentient being, that all industry was bad and full of polluters, and that all pollution was bad and should be stopped at any cost. During this era, the first ecoterrorists became active in driving spikes in trees to be logged so that they would ruin the timber cutting and debarking machines. Other actions and rhetoric were also significant in defining and shaping the environmental movement.

The Silent Spring presented a graphic description and made a persuasive case for the ecological damage from the indiscriminate use of pesticides, principally DDT. When the book reached bestseller status and was condensed in Reader's Digest, it struck a resonant chord among disaffected youth. When combined with the societal revolution, it quickly led to the inauguration of the first "Earth Day" in 1970. Later, researchers accused Carlson of sloppy and inaccurate research and presentation of a poor case for action, but her literary talents and public opinion silenced the critics.

The Clean Water Restoration Act of 1966, P.L. 89-753, authorized the Departments of Interior and Agriculture and the Water Resources Council to study the effects of pollution, including sedimentation, on fish and wildlife, sport and commercial fishing, recreation, water supply and power, and other specified uses in the estuaries and estuarine zones of the United States.

By 1969, the United Nations entered the political fray about the environment, when the Secretary General (U Thant) predicted Armageddon from environmental causes. He was asking whether mankind could survive another 10 years without immediate and decisive actions to control pollution. Predictably, he condemned the United States as the principal culprit in creating this forthcoming environmental disaster (which it may have been) and demanded that the United States take unilateral action to control pollution. He conveniently ignored the pollution arising from the rest of the world and the benefits from their industrial activity.

In the United States, Congress created the National Environmental Policy Act in 1969 and submitted it to President Nixon for signature. The NEPA was hailed as a new direction for the federal government because, for the first time, certain specific federal actions were to become subject to environmental review and the issuance of an "environmental impact statement." According to President Nixon, this heralded, "a new decade of environmental awareness."

On December 2, President Nixon signed Reorganization Plan Number 3, which created a new cabinet-level federal agency, the Environmental Protection Agency. The plan disbanded the Federal Water Quality Administration and stripped the Department of Interior of environmental enforcement responsibilities and programs. It also demoted the role of the Public Health Service and the Corps of Engineers in managing and controlling air pollution and water pollution, respectively.

It should be noted that at that time, many of the industries located on major waterways, such as the Ohio River, were required to obtain operating discharge permits issued by the Corps of Engineers. Municipalities were, depending on size, operating with state permission and permits. The federal program was much better administered than state programs. Funding for construction of wastewater treatment facilities by municipalities was coordinated through the states, and federal monies for construction grants to municipalities were rapidly increasing to 66% of the cost of those facilities that the states had prioritized.

Other actions in 1970 under PL 91-224 included

1. the development of a National Contingency Plan for preventing discharge of oil to the seas;
2. the development of regulations for determining harmful quantities of oil discharged to U.S. waters;
3. state certification that such discharge will not violate applicable water quality standards;
4. development of performance standards for marine sanitation devices;
5. demonstration projects to control acid or other mine water pollution;
6. control of water pollution within the watersheds of the Great Lakes; and
7. required federal facilities to operate in compliance with applicable water quality standards.

PL 92-500

The passage of PL 92-500 is often considered a major landmark in defining national policy for environmental protection. The reason often cited is the stated goals of the law: to make the waters of the United States *fishable* and *swimmable* by 1985. The law also had several other important provisions in addition to dramatic increases in funding for sewage treatment works.

The financial incentive for municipalities was increased to between 85% and 95% of the applicable construction costs and was supported by a very large pool of money. The consequence of this funding was that the qualified and unqualified began designing and building wastewater treatment works at an enormous rate—so fast that the personnel required for planning, project review, and construction oversight were overwhelmed by applications. Moreover, the incentive for oversight was reduced because the municipalities had only 5% to 15% of the actual cost at risk and the administration of the federal Construction Grants Program was primarily financial, not technical. As a result, a large number of new facilities were built, many of them far in excess of the needs of the communities.

By 1982, the EPA had issued a manual citing the most common mistakes in designing facilities. This manual detailed the most common failures in designing facilities, and, by its very existence, was a ringing condemnation of the many failures of oversight of the Construction Grants Program. Many of the mistakes cited by the EPA were elementary and illustrated a degree of incompetence of many of the design professionals and failure of the regulatory community to exercise adequate planning and oversight. Planning and oversight takes qualified manpower and time and cannot be rushed.

The Construction Grants Program was a well-intentioned failure in a number of other aspects as well. First, it added a significant level of complexity and paperwork requirements to the construction program that increased engineering, administrative, and total project costs. The requirement for Davis–Bacon Act compliance, which mandates that the highest prevailing wage rate would be paid and that union labor would be used whenever and wherever possible, effectively eliminated any potential savings from the use of nonunion labor and discouraged many cost-efficient improvements.

The second item that caused the greatest percentage of failures was directed at the engineering specifications. The EPA required that the project engineer must provide three specifications for each major piece of equipment in a project and that those items would be competitively bid without regard to the quality, only the price. The result was often a direct and dramatic deterioration in the quality of equipment purchased. The equipment was often selected by the contractor who had the option to appeal to the EPA on the basis of potential savings for the project. Many projects became contractor's auctions where the final project bore only a slight resemblance to the engineer's original specifications. The result was that equipment compatibility and reliability issues often arose during construction but were often sidestepped or overlooked because of the insistence on obtaining the lowest costs.

One final impact of the Construction Grants Program under PL 92-500 was the restructuring of the U.S. wastewater treatment industry. The emphasis on equipment price caused severe competition among wastewater treatment equipment manufacturers and reduced profit margins. As a result, companies cut back on research, and that had a 10 to 20-year impact on the wastewater treatment industry. From about 1975 to 1995, new products were being developed and introduced by non-U.S. sources.

Other requirements of PL-92-500 required the Federal Power Commission not to license hydroelectric power projects unless stream flow and water quality objectives could be met; proposed a range of national objectives for water quality designed to restore and maintain the chemical, physical, and biological integrity of the national waterways (33 USC 1252); and required reissuance of permits for pollution control discharges.

This last item was the item that created the National Pollution Discharge Elimination System (NPDES) permit system. The legislation also established minimum standards and requirements and provided funding for states to assume control over their own water quality management programs, once they had demonstrated their compliance with minimum federal standards set by the EPA.

In addition, PL 92-500 significantly expanded provisions related to pollutant discharges by requiring point-source effluent limitations consistent with state water quality standards, enabled the State issuance of water quality standards, and provided initial methodology for identifying and evaluating nonpoint-source pollution. Authority was also provided for developing water quality inventories and toxic and pretreatment effluent standards.

Other provisions clarified and established liability for discharges of oil and hazardous substances, provided for federal oversight and backup responsibility for oil spill cleanup operations, and authorized the Corps of Engineers to issue permits for discharging dredged or fill material into navigable waters at specified disposal sites (Section 404-33 U.S.C. 1344). However, the EPA could block the use of a disposal site based on water quality issues related to the discharge from the site and potential deleterious effects on municipal water supplies, fisheries, wildlife, or other water quality uses.

1977 Amendments

The Clean Water Act was further amended in 1977 (P.L. 95-217) to provide additional requirements for the following: "Best Management Practices" Program as part of the statewide planning program (33 U.S.C. 1288); provision for the Fish and Wildlife Service to provide technical assistance for developing "best management practices;" authorization for the Department of the Interior to complete the National Wetlands Inventory by December 31, 1981; and additional regulations and de minimis standards for the Corps of Engineers to issue general permits for dredging and filling waters and wetlands. These exemptions included normal farming, silviculture, and ranching (33 U.S.C. 1344(f)), and general activities below certain sizes.

1987 Amendments

The Water Quality Act of 1987 (P.L. 100-4) amended the Clean Water Act to provide (1) continuation of the Chesapeake Bay Program and an office dealing with pollution of the bay; (2) establishment of a Great Lakes

National Program Office within EPA and a Great Lakes Research Office within NOAA; (3) a requirement that EPA, the Fish and Wildlife Service, and NOAA conduct research on the harmful effects of pollutants in the Great Lakes, emphasizing the bioaccumulation of these pollutants in aquatic species; (4) require states to develop strategies for cleanup of toxics in waters where the application of "best available technology" (BAT) discharge standards will not meet state Water Quality Standards; (5) an increase in the penalties for violations of Section 404 (Dredge and Fill) permits; and (6) additional state reporting on lake water quality and methods to reduce the adverse impact of excess acidity.

A $15 million funding package has been provided to demonstrate methods to reduce the acidity of lakes (often found in coal and surface mining areas), and a $400 million program has been authorized for states to implement a nonpoint pollution source (agricultural and other areas) control program with EPA oversight. Estuaries of national significance are also to be nominated under this program, and plans must be developed to protect and restore those estuaries and to protect their chemical and biological status.

THE NATIONAL POLLUTION DISCHARGE ELIMINATION SYSTEM

Rolf R. von Oppenfeld
The TESTLaw Practice Group
Phoenix, Arizona

INTRODUCTION

The Clean Water Act (CWA) authorizes the United States Environmental Protection Agency (EPA) to regulate water pollution discharges to federally regulated surface waters via a permitting process. All facilities that discharge pollutants from a point source into waters of the United States must obtain a National Pollution Discharge Elimination System (NPDES) permit from the EPA or an authorized state [42 U.S.C. §§ 1311(a), 1342; 40 C.F.R. § 122.1(b)]. Permits typically allow the permittee to discharge specified pollutants from designated outfalls. See the NPDES program homepage at http://www.epa.gov/npdes/. The NPDES program generally imposes technology-based standards and water-quality-based effluent limits on point source discharges of pollutants to surface waters, although less stringent requirements presently apply to stormwater runoff discharges.

Currently, 46 states and territories are authorized (have primacy) under Section §r402(b) of the CWA to administer the NPDES program. The EPA regions are the lead permitting authority in the other states and territories. State NPDES programs must use federal standards as a baseline; however, states may impose stricter requirements [40 C.F.R. § 123.1(I)]. State-issued permits are also subject to review by the EPA [33 U.S.C. § 1342(d)]. The EPA may make comments, objections, or recommendations to the state. If the state does not change the permit to address the EPA's concerns, the EPA may assume control of the permitting process for that facility. [33 U.S.C. § 1342(d)(4)]. The EPA may also retract program approval from states not administering the program in accordance with federal law [33 U.S.C. § 1342(c)(2)]. When the EPA region is the permitting authority in the state, the state must certify that an authorized discharge will comply with the state water quality standards [33 U.S.C. § 1341(a)].

TYPES OF PERMITS

A NPDES permit is a license to discharge a specified amount of a pollutant or pollutants into a specified receiving water under certain conditions. The NPDES permits establish effluent limitations [33 U.S.C. § 1362(11)]. However, NPDES permits also contain monitoring and reporting requirements, a duty to properly operate and maintain systems, upset and bypass provisions, recordkeeping, and inspection and entry requirements [40 C.F.R. § 122.41]. The source of much information concerning NPDES permits is contained in EPA's *Permit Writers' Manual* located online at http://cfpub1.epa.gov/npdes/writermanual.cfm.

There are two basic types of permits: the individual and general permit. NPDES permits are issued for fixed terms, not to exceed 5 years [33 U.S.C. § 1342(b)(1)(B); 40 C.F.R. § 122.46]. Individual permittees generally must apply for renewal 180 days before the permit expires. EPA has made electronic copies of NPDES permits for major facilities available online at http://www.epa.gov/NPDES/permitdocuments/.

General Permits

The permitting agency develops and issues a general permit. A general permit typically covers multiple facilities within a specified category, industry, or area. General permits are cost-effective and efficient because the agency can authorize discharges from a large number of facilities with numerous common criteria under one blanket permit. Facilities covered by a general permit "self-regulate," although the permitting agency will periodically inspect or investigate potential noncompliances. The procedures for using general permits and the general conditions that apply to all general permits can be found at 40 C.F.R. § 122.28. Most stormwater dischargers may apply for a general permit by filing a Notice of Intent (NOI) pursuant to a federal or state stormwater general permit. Many states also issue general NPDES permits for certain process wastewater discharges generally considered of minimal impact.

Individual Permits

A discharging facility must be covered by an individual permit if it does not qualify for coverage under a general permit. The authorized permitting agency prepares an individual permit for a specific facility. A permittee first provides the required information on an individual permit application.

Once the permit writer determines that the application is complete, the technical review starts. Effluent limitations are determined, and a preliminary permit containing these limits is prepared. (Id). The agency publishes public notice of the draft permit. Typically, the public notice allows for 30 days of public comment. Based on this information, the agency will issue or deny a permit (40 C.F.R. § 122.5).

DISCHARGE LIMITATIONS

Effluent limitations are established in a two-step approach consisting of technology-based and quality-based standards. First, dischargers are required to use treatments that are technologically and economically feasible for the particular industry. Additionally, dischargers may be required to use more stringent treatments to achieve certain water quality goals for the particular waterbody. Limits can be expressed as mass limits, concentration limits, visual observations, monitoring requirements, testing requirements, parameter limits, flow, pH range, or temperature limits. The limits can be imposed as maximum limitations and monthly average limitations.

Technology-Based Effluent Limitations (TBEL)

The NPDES permit system sets technology-based levels of allowable discharges, determined by a series of minimum technology-based national effluent standards for various industrial discharge categories. If no categorical technology-based standards apply, the standards are determined by the permit writer's best professional judgment (BPJ) of the appropriate technology-based reduction. See 40 C.F.R. Part 400 et seq.

TBELs are national effluent guidelines that establish limitations for all types of discharges within a specific industry, such as direct and indirect dischargers, existing and new sources, and specific discharges, including process water, cooling water, and sanitary wastewater. EPA has issued approximately 50 industrial category effluent guidelines (40 C.F.R. §§ 405–471). Guidelines are available online at http://www.epa.gov/docs/epacfr40/chapt-I.info/subch.N.htm.

The CWA created a two-step approach for dealing with the reduction of water pollution through TBELs. The first phase required industrial dischargers to meet pollution control through the best practicable control technology currently available (BPT) [33 U.S.C. § 1311(b)(1)(A)]. The second level of pollution control required using the best available technology economically achievable (BAT) [33 U.S.C. § 1311(b)(2)(A)]. BAT applies to nonconventional pollutants, whereas best conventional pollutant control technology (BCT), which is more lenient, applies to conventional pollutants, as explained below. However, BPT/BAT/BCT standards do not apply to new sources, only to existing sources. New Source dischargers must meet New Source Performance Standards (NSPS), based on the best available demonstrated control technology (BADCT) (33 U.S.C. § 1316). Also, industrial indirect dischargers that discharge to a publicly owned treatment works (POTWs) are not regulated by TBELs but are instead subject to the Pretreatment Program under 33 U.S.C. § 1317(b).

BPT Standard. The BPT standard collectively examines an industry category to determine the types of treatment facilities used in that industry. The EPA looks at the better run facilities and estimates the level of pollution control achieved through the typical technology. The EPA compares the cost of applying the technology to the entire industry with the effluent reduction benefits. See 52 Fed. Reg. 42522 (Nov. 5, 1987). This analysis yields a pollution control level demonstrating the average of the best achieved pollution reduction.

BAT Standard. BAT controls represent the maximum feasible pollutant reduction. EPA considers the technology currently used in that industry and also pilot data and technology used in other comparable industries. BAT does not require the use of a cost–benefit analysis, but the standard must be economically achievable. The BAT standard was designed to apply to toxic and nonconventional pollutants.

BCT Standard. BCT standards require industries to meet a cost-reasonableness test for the discharge of conventional pollutants, such as BOD, TSS, fecal coliform, pH, and oil and grease [51 Fed. Reg. 24973 (July 9, 1986)]. The cost-reasonableness test compares the reasonableness of the cost of the reduction in discharge levels of conventional pollutants to the cost of achieving that reduction. Conventional pollutants are subject to BCT, which are no more stringent than the BPT standard, rather than the more stringent BAT standard [33 U.S.C. § 1311(b)(2)(e)].

NSPS. New sources must comply with the stricter New Source Performance Standards, thus making the definition of a new source highly disputed. The EPA employs the substantial independence test to determine whether construction is leading to a new source or a modification of an existing facility [40 C.F.R. § 122.29(b)(1)(iii)]. This test looks at the degree to which the new unit functions independently of the existing facility, the degree of integration, and the extent to which the new unit is engaged in the same general type of activity as the existing source [49 Fed. Reg. 37998, 38043 (Sept. 26, 1984)].

NSPS are generally more stringent than those for existing sources; ideally, new sources should be built with state-of-the-art treatment technology. Requiring existing sources to retrofit under NSPS would be unreasonable. The major benefit to classification as a new source is that any new source constructed to meet NSPS may not be subjected to more stringent standards for 10 years after the date construction is complete or for the period of depreciation under the Internal Revenue Code, whichever is shorter (33 U.S.C. § 1316). However, the 10-year protection applies only to TBELs, not to WQBELs. At the end of the 10-year period, immediate compliance with the standards in effect at that time is required [33 U.S.C. § 1316(d)].

Best Professional Judgment. When TBELs have not been established for a particular industry sector or where there is a concern over a particular parameter (e.g., the permit writer thinks a receiving water is too polluted), permit writers will apply best professional judgment (BPJ) to establish permit limitations [40 C.F.R. § 125.3(e)]. The permit writer may consider data from the facility itself, from similar industries having similar waste treatment, or potentially applicable technology from an industry outside of the immediate industrial group. See 40 C.F.R. §§ 122.44(a), 125.3(c)(2).

Variances From TBELs. A qualified permittee may obtain a variance or modification from its permit's TBELs. One type of variance is a fundamentally different factors (FDF) variance [33 U.S.C. § 1311(n); 40 C.F.R. §§ 125.30–32]. The discharger must demonstrate that the factors applicable to its facility are fundamentally different from those considered for developing the effluent guidelines for its industrial category (40 C.F.R. Part 125). A variance is not issued merely because the cost of compliance would cause the facility to close. (Id). The applicant must also demonstrate that an objection was raised based on the FDF during effluent guidelines development or show why it was not. (Id).

The EPA may also modify BAT requirements or pretreatment requirements affecting nonconventional and nontoxic pollutants if the economic capability of the discharger requires less stringent limits [33 U.S.C. § 1311(g)]. The permitting agency may grant a variance from BAT for several nonconventional, nontoxic pollutants, such as ammonia, chlorine, color, iron and total phenols, where applicable BATs are unnecessarily stringent. (Id). Both the variance and the modification are granted on a permit specific basis.

Water-Quality-Based Effluent Limitations (WQBEL)

WQBELs are imposed where TBELs are insufficient to ensure water quality. WQBELs rely on the state water quality standards (WQS), and consist of two elements: (1) designated use classification and (2) criteria that are used to protect the designated uses. Surface water quality standards have become increasingly stringent during the last decade. Consequently, the WQBELs required in a NPDES permit for a particular pollutant are often more stringent than the corresponding technology-based effluent limitations.

Water Quality Standards. Water quality standards (WQS) are numeric standards developed for each stretch of a waterbody based on the designated uses. All states must classify their waters according to intended uses, for example, public drinking water, propagation of fish and wildlife, recreation, industrial, agricultural, and other uses [33 U.S.C. § 1313(c)(2)]. The WQS must also attain the CWA's goal of fishable or swimmable, if possible, and must maintain both the current and designated uses under the antidegradation policy, unless the state can demonstrate that it is unattainable or infeasible [40 C.F.R. §§ 131.10(g), 131.12].

Water quality criteria describe the physical, chemical, and biological characteristics of waters necessary to attain the designated uses. The EPA has developed numeric surface water quality criteria for over 150 pollutants [33 U.S.C. § 1314(a)(1); 63 Fed. Reg. 67547 (Dec. 7, 1998)]. Each navigable water is assigned such criteria to ensure that the water can support its designated use.

When the permitting agency determines that a discharge causes, has the reasonable potential to cause, or contributes to an in-stream excursion above the allowable ambient concentration of state numeric criteria within a state water quality standard for an individual pollutant, the NPDES permit must contain effluent limits for that pollutant [40 C.F.R. § 122.44(d)].

Toxicity-Based Limitations. Effluent limitations are sometimes based upon Whole Effluent Toxicity (WET), when it becomes difficult to set individual WQBELs [40 C.F.R. § 122.44(d)(1)(ii), (iii) and (iv)]. When the permitting agency determines that a discharge causes, has the reasonable potential to cause, or contributes to an in-stream excursion of pollutants in amounts or combinations that are *toxic* to humans, animals, plants, or other organisms, the permit must contain effluent limits for WET. WET limitations are incorporated into the NPDES permit and require the permittee to perform toxicity testing on the effluent. Toxicity tests expose various aquatic species to one or more concentrations of effluent in the laboratory to determine the short-term and long-term effects of exposure. Most permits issued since the release of EPA's WET Guidance Document require conducting toxicity tests regularly, such as monthly or quarterly [40 C.F.R. § 136, 65 Fed. Reg. 46457 (July 28, 2000)].

STORMWATER DISCHARGES

Regulation of stormwater runoff has presented challenges because stormwater runoff comes from diverse sources. EPA estimates that about 30% of known pollution to the nation's surface waters results from stormwater runoff. In 1987, Congress required EPA to establish regulations and issue permits for stormwater discharges. "Stormwater" includes stormwater runoff, snowmelt runoff, and surface runoff and drainage [40 C.F.R. § 122.26(b)(13)]. Stormwater does not include street wash water or infiltration, water that enters a sewer system below ground through defective pipes, pipe joints, connections or manholes. Discharges to retention basins that do not flow into waters of the United States or flow to POTWs also do not require stormwater permits.

The stormwater program has been implemented in two parts: Phase I and Phase II. The federal NPDES stormwater program relies on three types of permits: (1) The Construction General Permit, (2) The Multi -Sector General Permit, and (3) The Individual Permit. State agencies with primacy generally have analogous permits. More information on the federal stormwater program is available at http://cfpub.epa.gov/npdes/home.cfm?programid=6.

The Phase I Program

Phase I regulations cover separate municipal storm sewer systems (MS4s) serving populations over 100,000. Discharges into MS4s are treated as discharges to waters of the United States and require a NPDES permit (40 C.F.R. § 122.26). A MS4 is a conveyance or system of gutters, ditches, man-made channels or storm drains, owned by a state, county, municipality, or other public entity, designed or used for conveying stormwater, and is not a combined sewer or part of a POTW [40 C.F.R. § 122.26(b)(8)].

Phase I also regulates discharges from "areas associated with industrial activities" in 11 categories listed at 40 C.F.R. § 122.26(b)(14). The term "areas associated with industrial activities" covers discharges from any point source used for collecting and conveying stormwater, which is directly related to manufacturing, processing, or material storage at industrial facilities [55 Fed. Reg. 48007-15 (Nov. 16, 1990)]. The regulations break this definition down into two parts: what types of facilities have "industrial activity" based on their facility's Standard Industrial Classification (SIC) and what portions of the facilities include industrial activity. The portions of the facilities that include industrial activity include industrial plant yards, material handling sites, refuse sites, shipping and receiving areas, manufacturing buildings, raw material storage areas, etc. [40 C.F.R. § 122.26(b)]. Discharges from areas separate from the industrial activities, such as office buildings and parking lots and discharges from facilities engaged in wholesale, retail, service, or commercial activities are not included. [55 Fed. Reg. 48007 (Nov 16, 1990)]. Facilities covered by Phase I must apply for an NPDES permit, unless otherwise exempt.

Exemptions are provided until March 10, 2003 for industrial activities operated by municipalities with populations less than 100,000. See 64 Fed. Reg. 68722 (Dec. 8, 1999). Light industrial facilities (SIC codes 20–39 and part of 42) with "no exposure" of industrial activities or materials to stormwater are exempt under Phase I.

Permits for MS4s can be issued either for a particular system or on a jurisdiction-wide basis. MS4 permits must control pollution to the maximum extent practicable (MEP) [33 U.S.C. § 1342(p)(3)(B)(iii)]. The MS4 permit must also contain a requirement that prohibits nonstormwater discharges into the system's storm sewers.

Entities regulated under Phase I must obtain coverage under either an Individual Permit or a General Permit. Regulated entities must also implement stormwater pollution prevention plans (SWPPPs) or stormwater management programs; both require BMPs that effectively reduce or prevent the discharge of pollutants to receiving waters.

The Phase II Program

On December 8, 1999, the EPA published the NPDES stormwater management program Phase II Final Rule [64 Fed. Reg. 68722 (Dec. 8, 1999)]. Facility operators covered under Phase II must apply for permit coverage by March 10, 2003, except for oil and gas small construction activities which must apply by March 10, 2005 [67 Fed. Reg. 79828 (Dec. 30, 2002)].

The Phase II rule subjects two new groups of permittees to stormwater management: operators of small MS4s in urbanized areas and small construction activities that disturb 1–5 acres of land. The nonexposure exemption has been extended to include all industrial activities other than construction activities. The Phase II rule impacts about 5000 municipalities and federal systems such as military bases and prisons. Regulated operators must implement stormwater discharge best management practices (BMPs) that reduce or prevent the discharge of pollutants to receiving waters.

Stormwater Discharges Associated with Industrial Activities

Phase I contains a permitting component for industrial stormwater. The operations of industrial facilities that are within the 11 categories of "stormwater discharges associated with industrial activity" [located at 40 C.F.R. § 122.26(b)(14)(i)-(xi)] that either discharge to a MS4 or directly into waters of the United States must receive a NPDES industrial stormwater permit. Operators of industrial facilities can generally obtain either a general or individual permit to satisfy the NPDES stormwater permit requirement.

Conditional No Exposure Exclusion

"No exposure" means that all industrial materials or activities are protected by storms resistant sheltering to prevent exposure to rain, snow, snowmelt, or runoff. Certified facilities are not required to obtain a stormwater permit. Applicants must submit the "No Exposure Certification Form" every 5 years.

The no-exposure certification form is nontransferable. All new owners or operators must complete, sign, and submit a new form to claim the no-exposure exclusion. Upon submission of the new owners' form, the permitting agency may inspect the facility to verify the claim. A facility owner or operator who fails to maintain nonexposure status could be liable for an unauthorized discharge of stormwater. Under Phase II regulations, all industrial activities, except for construction, are eligible for exclusion.

The Multi-Sector General Permit

The Multi-Sector General Permit (MSGP) is designed to regulate certain stormwater discharges from nonconstruction industrial activities [63 Fed. Reg. 52430 (Sept. 30, 1998)]. The MSGP is one large permit subdivided into 29 separate sectors based on the SIC system and/or narrative descriptions. If a facility has operations that can be described by more than one sector, then it must comply with all pertinent requirements.

Facilities eligible for MSGP coverage must file a notice of intent (NOI). The NOI is essentially a promise that the applicant will comply with all MSGP conditions. The applicant must also prepare and implement a Storm Water Pollution Prevention Plan (SWPPP) prior to the submission of the NOI. The applicant can look at the MSGP for guidance on what to include in the SWPPP.

The SWPPP must create a Pollution Prevention Team comprised of individuals who develop and implement the SWPPP. The SWPPP must include a map of the facility, an assessment of the potential sources of stormwater pollution at the facility, and a list of BMPs. Generic BMPs include "good housekeeping," preventive maintenance, spill prevention and response, employee training, record keeping, nonstormwater discharge evaluation, erosion control measures, and stormwater management measures, as appropriate. Comprehensive site inspection/compliance evaluations are required.

Stormwater discharges subject to an existing NPDES permit cannot be covered under the MSGP until the existing permit expires. If the existing permit contains numeric standards that are more stringent than those required in the MSGP, the MSGP will not be available when the existing NPDES permit expires.

Stormwater Discharges Associated with Construction

Operators of both large and small construction activities must obtain a NPDES construction permit if the activity disturbs more than 1 acre or is part of a larger common plan of development or sale that will disturb more than 1 acre and the discharge is to a water of the United States or a MS4. The EPA requires that construction activities obtain a general permit. Effective on July 1, 2003, a new federal construction general permit is applicable to both large and small construction sites [68 Fed. Reg. 39087 (July 1, 2003)]. States with primacy have developed their own construction general permits.

There are two waivers available for small construction sites. The first waiver is the rainfall erosivity factor (R). The construction site operator must determine that the R in the reused universal soil loss equation is less than five. The second waiver is available operators in nonimpaired waters or who certify that stormwater controls are not needed, based on a total daily maximum allowance.

Separate Municipal Storm Sewer Systems (MS4)

Operators of large, medium, and regulated small MS4s must obtain NPDES permits to discharge pollutants and must develop stormwater management programs to prevent harmful pollutants from entering MS4s by stormwater runoff. Medium and large operators must submit permit applications under Phase I. Regulated small MS4s can choose among an individual permit, a general permit, or a modification of an existing Phase I MS4 individual permit. See Phase II Guidance, EPA 833-R-00-002 p. 4-1.

A "large MS4" is any MS4 located in an incorporated place or county with a population of 250,000 or greater, as of the 1990 Census. A "medium MS4" is any MS4 located in an incorporated place or county with a population from 100,000–249,999, as of the 1990 Census (40 C.F.R. Part 122 App. F, G, H). Many MS4s in areas of less than 100,000 population were individually brought into the Phase I program by NPDES. These regulated MS4s are not required to develop a Phase II program. See EPA Phase II Guidance, EPA 833-R-00-002, p. 4-2.

The Phase II program requires that certain small MS4s obtain a NPDES permit. A "small MS4" is any MS4 not already regulated under the Phase I definition of "small," including federally owned systems, such as military bases and veterans hospitals. See Phase II Guidance at p. 4-3. Small MS4s can be regulated if the small MS4 is wholly or partially located within an urbanized area, as defined by the 2000 U.S. Census, designated by NPDES, or designated by the permitting agency [40 C.F.R. § 122.32(a)(1), (2)]. Phase II requires that the permitting agency develop and apply designation criteria to all small MS4s located outside of an urbanized area that serves a population of at least 10,000 and a population density of at least 1,000 people per square mile.

Some MS4s receive a "physically interconnected" designation. Physically interconnected means that one MS4 is connected to a second in a way that facilitates direct discharges into the second system (Phase II Guidance, EPA 833-R-00-002 at p. 4-3-5). The permitting agency must designate most small MS4s located outside of an urbanized area that contributes substantially to pollutant loadings of a physically interconnected MS4 permitted by the permitting agency. The NPDES permitting authority may waive the coverage requirement in limited circumstances. See Phase II Guidance at p. 4-10, 11. Phase II allows operators of regulated small MS4s to choose from three permit options, the general permit, an individual permit, or a modification of an existing individual permit. The permitting agency reserves the right to determine which options are available to a regulated small MS4.

LEGAL PROTECTION FOR IN-STREAM FLOW

Melinda R. Kassen
Trout Unlimited, Colorado
Water Project
Boulder, Colorado

Water is precious. Human society needs water for drinking, other municipal uses, crops, and stock watering, as well as for industrial, aesthetic, and recreational purposes. But water left flowing through the landscape also has value, as it sustains every component of an ecosystem.

Water in rivers and lakes creates aesthetic value, as well as habitat for thousands of water-dependent species. Such species include aquatic species—fish, insects, amphibians, and plant life—as well as the land-based animals that eat them. Water flowing in a natural hydrograph helps maintain water quality. In addition, flowing rivers and streams can provide significant recreational amenities that feed local economies from fishing and boating or secondary activities such as hiking and bird-watching.

For most of recorded history, there has been enough water to supply humanity's needs without worrying about how removing water from streams for human use might affect other water-dependent species. However, because of significant human population growth, enhanced appreciation for the importance of protecting natural ecosystems, and increased concern about sustainability, societies have begun to provide legal protection to water left in a stream for the benefit of both water-dependent species and the people who use and enjoy the natural environment. These concerns have surfaced more in the western part of the United States than in the east, but concerns now arise even in less water-short areas.

Moreover, in view of a recent United Nations statement that one out of three people globally will face a water shortage by the year 2025, making water the commodity likely to cause controversy during the twenty-first century as oil did in the twentieth, understanding competing water uses and values is critical throughout the world.[1]

STATE PROTECTION OF IN-STREAM VALUES—WESTERN STATES[2]

In the United States, states, rather than the federal government, have primary authority over water allocation. Those states west of the 100th meridian are, for the most part, arid or semiarid. Since early in their settlement, they have found a need to reconcile disputes between water users; each of these states follows the doctrine of prior appropriation to allocate water among competing users.[3] Each state's system is unique, but their systems share many features. Most importantly, these systems define the value of water in terms of its use, and until late in the twentieth century, this meant use out of the stream. The prior appropriation system did not recognize any value for leaving water in a stream. Because the prior appropriation system functions as a seniority system, where the earliest user of a river retains always the first right of use, the system has created a challenge today for states and others seeking to protect remaining in-stream values, where water is "unused" except in sustaining the environment or by recreationists in a non-consumptive manner. Because water allocation is primarily a function of state law, the means to protect in-stream values must also be found primarily in the systems states use to allocate quantities of water to various uses.

All but three western states (New Mexico, North Dakota, and Oklahoma) provide some in-stream flow protection.[4] States use three different types of programs: legislatively established in-stream flows, agency actions to create or enforce in-stream flow rights, and private or market mechanisms to protect in-stream flows.

States vary in the methodology they use to quantify in-stream flow protection levels. Some, like the Tennant and R2Cross methods, look at a few simple variables, such as maximum flows, velocity, depth and wetted perimeter, and input them into a model that calculates minimum flows. States whose programs protect only minimum flows, such as Colorado and Wyoming, use these methods.[5] Others, like instream flow incremental methodology (IFIM) or physical habitat simulation system (PHABSIM), model the habitat requirements for aquatic species. Finally, there is the indicators of hydrologic alterations model developed by The Nature Conservancy; this model yields results that more closely mimic a natural hydrograph.

State Legislative Actions

In Montana, Kansas, and Idaho, the legislatures establish or approve agency recommendations for in-stream rights. Montana created a dozen such rights for blue-ribbon trout streams in a one-time effort in 1969.[6] Idaho has legislated nine stream flows or lake levels,[7] and Kansas has adopted statutory protection for 32 watercourses.[8] In addition, in 2000, Montana closed the Bitterroot entirely to new appropriations to protect the recreation and farm based economy of the area, both of which need water flowing downstream.[9]

State Agency Actions

Many Western states allow only state agencies to hold in-stream flows. Even so, neither Kansas nor Texas has recognized any in-stream flow rights; Nebraska has fewer than five. Pursuant to his statutory authority,[10] the Wyoming state engineer has approved 13 applications for new water rights from the state Game and Fish Commission to protect in-stream flows, but has only adjudicated two; adjudication is a prerequisite for enforcement. Sixty-nine applications await decision. Montana gives any state or federal agency the ability to apply for an in-stream reservation of up to 50% of a stream's average annual flow, and Montana's Department of Fish, Wildlife, and Parks now holds in-stream flow reservations on the main-stem Missouri and Yellowstone Rivers.[11]

Colorado and Oregon have the most extensive programs for in-stream protection.[12] In Oregon's program, the responsible state agency limits other diversions based on in-stream levels established for more than 1400 stream reaches.[13] On the streams where these levels exist, it is virtually impossible to obtain a new diversionary right; moreover, Oregon actively enforces its rights. In Colorado, where all water rights are a matter of court decree, the state, which has the exclusive authority to hold in-stream protection flows, has applied for and obtained more than 1350 water rights since 1973.[14] Unlike the situation in Oregon, however, Colorado's in-stream flow decrees do not automatically stop additional future development. Because Colorado also has no field personnel to monitor its rights and few gauges to measure their flows, Colorado has only once made one "call" on the river to demand that

[14] These rights protect 8100 miles of more than 107,000 miles of state streams.

junior appropriators' diversions be curtailed to satisfy the Board's in-stream right. Instead, Colorado objects to applications for changes of water rights that might adversely affect the state's in-stream flow and negotiates court settlements that rely on others to monitor the state's rights. In both states, only the state agency owner of the right may enforce the rights with a call; members of the public must rely on the agencies.

Idaho has had a minimum stream flow statute on the books since 1937.[15] However, the program does not allow for new in-stream flow protective rights on streams that are otherwise fully appropriated—and most Idaho streams have long been overappropriated, so the statute provides little protection. Instead of obtaining water rights, the Idaho's Department of Water Resources has protected about 100 streams by adopting recommendations in its state water resources plan for minimum stream flow reservations for recreation or natural resources.[16]

The State of Washington follows a similar strategy. In 19 of its 62 water resources inventory areas, as well as the Columbia River, the state has adopted in-stream resource protection programs that establish minimum stream flows.[17] The state conditions later-issued water rights on meeting these flows. In addition, the state agency responsible for water rights has closed portions of the Yakima River Basin to further groundwater appropriations (at least pending further study) to keep some of this basin's water in-stream.[18]

Most states whose agencies have the power to protect in-stream flows acted only after 1970—in a region where traditional water rights date back to the mid-nineteenth century. Given that the prior appropriation doctrine values water rights based on their seniority and given that a senior user may dry up a stream entirely before junior users are entitled to any water, the junior nature of states' in-stream flows still leave agencies unable to protect—let alone restore—healthy stream flows. For example, Colorado has fewer than 15 rights whose priorities date earlier than 1973; in a state where most rivers were overappropriated at the beginning of the twentieth century, these rights can protect against additional future depletions but do little to restore already damaged fisheries to health. The state acquired its few, highly valuable senior rights by donation from cities seeking to protect streamfront amenities, and in one case, from a private conservation group. Wyoming also has the authority to acquire traditional existing rights by transfer or gift and change these rights to instream flow purposes,[19] but the state has never done so.

Some state agencies allowed to hold in-stream rights may not make new appropriations for such rights but may only change existing rights or acquire previously consumptive rights by donation. This is true in Utah, where the Division of Wildlife Resources holds five in-stream flow rights.[20] California and Arizona agencies may also accept such transfers.

Finally, some states can protect in-stream flows by denying other new diversionary applications. A statute directs the Utah state engineer to ensure that no new diversion will "unreasonably affect public recreation or the natural stream environment."[21] However, the state engineer has never relied exclusively, or even primarily, on this provision to deny a new or changed application for a water right. Oregon also has a "public interest" test, and though the state has never denied a new permit based on this test, Oregon has adopted rules pursuant to this provision that make it difficult to obtain a new water development permit where there are sensitive stocks of fish.[22]

Public Trust Doctrine

The public trust doctrine also plays a role in protecting in-stream water resources. Evolved from the laws of the Roman Empire, this doctrine holds that a state holds certain resources in trust for the benefit of society at large because of their public values. The ancient Romans applied the doctrine to the ownership of navigable rivers and harbors, which were held in trust by the state to protect the public's interest in commerce, navigation, and fishing. This concept was subsequently adopted by the English courts and applied to lands beneath tidal waterways.

In this country, states assumed this trust responsibility, including the ability to forbid private ownership of public trust resources. For example, the U.S. Supreme Court read the public trust to require automatic state ownership of submerged lands beneath navigable waters.[23] The Court then added that the states could not sell trust lands if the transfer would unduly burden public fishing, navigation, and commercial rights.[24] Because the public trust doctrine is primarily an aspect of state law, its application varies widely between states. Whereas the Colorado courts have never recognized the public trust doctrine as applied to water resources, California has used the doctrine aggressively to protect both lands and waters. The California Supreme Court found that its state water agency, the State Water Resources Control Board, had to consider public trust values in permitting new water withdrawals and also in reviewing existing withdrawals.[25] Thus, Los Angeles had to curtail existing diversions by one-third from tributaries of Mono Lake until the lake level recovered to a certain elevation.

Private and Market-Based Efforts

In some states, private entities can augment state programs that protect in-stream flows. The states of

Oregon and Washington have nonprofit water trusts that purchase mostly small quantities of water in the tributaries of targeted river basins dedicated to in-stream flow protection. In most cases, these purchases are for short periods of time. For example, although the Oregon Water Trust, has made more than one dozen permanent acquisitions (where it transfers the rights to the state), most are short-term leases, from 1–10 years. Still, the Trust has brokered more than 50 deals protecting 450 river miles. In addition, the Trust is helping irrigators take advantage of Oregon's conserved water program, which allows a water user who conserves water to use 75% of that water, provided that the user turns 25% back to the stream.[26]

Montana's program allows government agencies or nonprofit entities to lease water that is currently put to beneficial use through a diversion for in-stream flow protection for up to 30 years.[27] The state agency for fish, wildlife, and parks has entered into 10 leases under this provision. Trout Unlimited, a private conservation organization, has entered into fewer than 10, but at least one of TU's leases put 200 cfs into the Madison River, a quantity of substantial and significant magnitude. Montana also allows private water users to change a traditional diversionary right temporarily for in-stream purposes.[28] The change can last 10 years for a direct flow right and up to 30 years for water coming out of storage. Only one water diverter has sought (and been granted) a temporary change, as of 2001.

Alaska, Arizona, Nevada, and California also allow individuals to hold in-stream rights permanently. Anyone may transfer existing rights to in-stream reservations in Alaska,[29] although these reservations must undergo review every 10 years, a hurdle no other water right must jump. Two government agencies have obtained such rights, and several private entities have pending applications.

Under its statute,[30] Arizona has received 85 applications for new in-stream flow rights from individuals, environmental groups, and several federal agencies. Of these, the state has permitted 25 and perfected another 23 (after the applicants demonstrated actual use for 3 years). In addition, in 1997, the state used its Water Protection Fund to purchase unused Central Arizona Project water to sustain riparian habitat.

In California, an individual may not make a new appropriation for an in-stream flow right but may convert an existing diversionary right to in-stream protection; however, in 2001, 8 years after passage of this statutory provision, the Water Resources Control Board had yet to grant a single in-stream permit.

At least one federal agency has obtained a new in-stream flow water right in Nevada.[31] In addition, since 1988, Nevada has allowed the transfer of existing water rights to in-stream use. Both government agencies and private organizations have done so; in one case off-stream rights were transferred to protect streams on the Stillwater Wildlife Refuge.

South Dakota has no express statutory authority for in-stream flows, but the state Supreme Court has held that diversion of water was not necessary to achieve a beneficial use of water under state law.[32] As a result, the state has awarded several in-stream water rights, two new rights to a state agency, one to a federal agency and a change to a private company. In 2001, there were two additional applications pending.

Conclusion

Most states have some power to maintain, if not restore, healthy stream flows, but few have made such protection a priority. Western states water law systems simply do not make in-stream flow protection easy, and at the same time the region must accommodate significant growth. Given the limitations described above (little enforcement, seniority, or measurement), many state programs provide more of an illusion of protection than real water in-stream.

STATE PROTECTION OF IN-STREAM VALUES—EASTERN STATES

The wetter United States east of the Mississippi River follows a system of water allocation different from that of Western states. In the East, the riparian doctrine prevails, under which riparian landowners, those adjacent to a waterbody, have a right to use a portion of the flow of the stream or lake.[33] Although originally, a riparian water user could not diminish the natural flow of the stream,[34] today, holders of riparian rights can consumptively use water—even outside the watershed—if the use is "reasonable."[35] Today, urban, industrial, and agricultural demands have increased to the point that water resources are sometimes scarce in riparian jurisdictions.

To protect the public's interest in a reliable water supply, many riparian states require even landowners to obtain permits before using any water. Essentially, permits serve as a means for a state to quantify existing water uses and give the permit holder a right to use a quantity of water permanently or for a limited time. The permit requirement limits the number and size of water rights that come with riparian property ownership.

Most riparian states recognize water as a public resource and have taken steps to protect public recreational, environmental, and aesthetic values. Thus, these states have passed statutes to protect stream flows. In addition, many of these states have established minimum stream flows, lake levels, and groundwater levels or delegated the authority to set these levels to a state agency.

For example, Florida has authorized its Water Management Districts to set seasonal minimum flow levels for both surface and groundwater.[36] "Minimum flow" is "...the limit at which further withdrawals would be significantly harmful to the water resources or [area] ecology."[37] Further diversions may not occur below the established minimum. When existing flows or levels do fall below or are projected to do so within 20 years, the state must implement a "recovery or prevention strategy."[38]

New Hampshire's Rivers Management and Protection Program takes a different approach.[39] There, the state develops "river corridor management plans" to maintain in-stream flows along designated rivers after someone nominates the river for protection. Once accepted, the nomination must undergo court review and legislative approval. The rules to implement this program establish a general standard of in-stream flow protection for all designated rivers.[40]

FEDERAL LAW PROTECTION OF IN-STREAM VALUES

State law is the primary vehicle for water allocation decisions, but the federal government also plays a role. This is true in part because the federal government is a major landowner, particularly in the West. In addition, the federal Bureau of Reclamation owns and operates a massive system of water projects that controls the flows on many Western rivers. Finally, the nation's web of environment and natural resources law intersects with the goal of river protection.

Federal lands reserved for specific purposes, such as national parks, monuments, forests, and refuges, almost always need water. At the beginning of the twentieth century, the U.S. Supreme Court held that in reserving lands, Congress had implicitly reserved as well the water to fulfill the purpose of the reservation and also that the water right's priority date would be the date of the initial Congressional reservation, not the later year in which the federal government sought to quantify its right.[41] In 1954, Congress passed the McCarran Amendment, a statute directing the federal agencies to obtain these reserved water rights through the individual state systems of water allocation.[42]

Only in the 1970s did federal agencies begin in earnest to enter state systems to obtain and quantify their rights. Unfortunately, given the Western states' system of prior appropriation, the time lag between the date the federal land was reserved and the year when the federal government sought to confirm its water rights has proved devastating to this federal effort. Much of the West was unsettled in the early twentieth century; since that time, large cities have grown, farming has continued to divert 80–90% of the water used, and new industrial needs for water have been created—from heap leach mining to oil shale extraction to ski area snowmaking. These intervening water users are unwilling to remain passive when the federal government seeks to jump the seniority line and gain water rights for its lands.

As a result, almost all adjudications of reserved rights have been controversial. In most cases involving national forest lands, the Forest Service has failed to obtain meaningful protection for the rivers crossing its lands, even though its mandate includes the command to provide favorable flows.[43] The National Park Service and U.S. Fish and Wildlife Service on behalf, respectively, of national parks and the wildlife refuge system have fared marginally better; yet even these agencies have failed frequently to obtain protective flows. In Colorado, the Park Service failed to obtain a right to protect the rivers within Dinosaur National Monument.[44] More recently, the Idaho Supreme Court denied the U.S. Fish and Wildlife Service a reserved right for the Deer Flat National Wildlife Refuge made up a series of islands in the Snake River.[45]

Some federal agencies also use administrative mechanisms to protect stream flows when making permitting or licensing decisions. Thus, wholly outside state water allocation systems, federal agencies impose bypass flows to fulfill requirements that derive from federal laws, such as the Federal Power Act, the Clean Water Act, and the Federal Land Management and Policy Act, as well as the agencies' authorizing statutes, for example, the Forest Service Organic Act. In part because the use of this authority has sometimes limited validly issued state water rights, agency exercise of this authority has proved highly controversial and is thus used sparingly, if at all.

The Clean Water Act provides two mechanisms for protecting in-stream values to any state willing to use them. First is the state water quality certification program.[46] Under its provisions, a state must certify that a federally permitted or licensed project will meet state water quality standards. Pursuant to this authority, the State of Washington imposed substantial flow restrictions on a hydropower facility on the Olympic peninsula; in 1994, the U.S. Supreme Court upheld these restrictions.[47] Second is the total maximum daily load (TMDL) program" which arguably provides states a mechanism to protect flows through water quality regulation.[48] Here, states must list streams whose water quality is impaired.[49] Then, states must establish TMDLs that will bring the streams back into compliance. Recently, the EPA determined that the federal government cannot impose flow-based conditions in TMDLs, yet the states, which have primary

[49] 33 USC §1333(d).

responsibility for this program, can. Montana, for example, has adopted a flow-based TMDL for an impaired stream, a tributary of the Yellowstone River.[50]

The Endangered Species Act (ESA) provides federal agencies another handle for restoring stream flows when such flows are necessary to avoid jeopardizing an endangered or threatened species' existence. Again, the use of this authority is highly controversial. In one recent case, a federal court upheld the U.S. Forest Service's imposition of a bypass flow to protect an endangered species as consistent with both the ESA and the Forest Service's own Organic Act.[51] Some water users who have received less water from federal projects as a result of actions taken under the ESA have begun to challenge these federal actions as "takings" of their property rights without compensation, in violation of the 5th amendment to the U.S. Constitution.[52] In the summer of 2001, such a curtailment occurred to benefit both endangered salmon and lake fish sacred to the Klamath tribe that has resulted in a firestorm of litigation and proposed legislation.

On the other hand, ESA mandates have forced some creative responses. The Middle Rio Grande Conservancy District, embroiled in litigation over recovery of the silvery minnow, created a water bank to allow users to lease surplus water, at least some of which may go to keep critical Rio Grande reaches wet. New Mexico and the federal government have also reached an agreement to operate federal reservoirs in the Rio Grande basin to release stored water for in-stream flows to maintain minnow habitat. An even larger effort is beginning in California. There, parties trying to address endangered species concerns in the San Francisco Bay Delta created the Environmental Mitigation Bank to trade water to benefit the ecosystem.[53]

Finally, due to the existence of major federal water storage projects throughout the West, interests have pressured the federal agencies—owners of these projects—to change their operation. Primarily to benefit endangered species, but also to enhance recreation and other values, reoperation of federally owned or licensed storage and hydropower facilities can enhance river flows in a way that restores, or at least maintains, aquatic species. This has occurred to benefit endangered species in the Rio Grande, the Klamath, and the Columbia Rivers, along with many lesser known systems where endangered species live. Through the "CalFed" project, California reoperations have benefited people as well as endangered species.

CONCLUSION

State water law systems grew out of a nineteenth century worldview that believed that all resources are endless. Therefore, it is not a surprise that governments struggle today to protect in-stream values. But, because of the pressures exerted on the system as a result of modern environmental values, decision-makers are seeking ways to ensure that at least some of the country's waterways maintain healthy flows.

WATER QUALITY

U.S. Geological Survey

APPLICABLE STATUTES

Clean Water Act (PL 92–500; 33 U.S.C. 1251 et seq.)

Safe Drinking Water Act (PL 93–523; 42 U.S.C. 300f-j-26)

CLEAN WATER ACT, AS AMENDED (PL 92–500; 33 U.S.C. 1251 ET SEQ)

Purpose

Also known as the Federal Water Pollution Control Act, it is the objective of the Clean Water Act (CWA) "to restore and maintain the chemical, physical, and biological integrity of the Nation's waters". Seven goals and policies are declared in order to meet this objective. One goal was to reach zero discharge of pollutants by 1985. Others include providing funding for the construction of publicly owned treatment works (POTWs), creating a nonpoint source pollution program, and generally, and making the waters of the U.S. "fishable and swimmable". Although not specifically stated in this declaration, the CWA contains the nation's most noteworthy wetlands legislation.

MAJOR PROVISIONS BY SECTION

201–209 (33 U.S.C. 1281–1289)—Grants for Construction of Treatment Works.

These sections originally provided federal grants for the construction of wastewater treatment plants. The program has been phased out by the 1987 amendments in favor of a revolving loan fund.

301 (33 U.S.C. 1311)—Effluent Limitations

The discharge of any pollutant into the nation's waters except for discharges in compliance with the CWA is prohibited, according to this section. Limitations are placed on existing sources which vary according to the nature of the pollutant discharged and to where the outfall is directed.

302 (33 U.S.C. 1312)—Water Quality Related Effluent Limitations

Point sources which interfere with the attainment or maintenance of desired water quality are subject to the imposition of more stringent effluent limitations.

303 (33 U.S.C. 1313)—Water Quality Standards and Implementation Plans

Water quality-based regulatory controls on dischargers known as Water Quality Standards (WQS) are required by states to protect designated uses of water bodies. Technological capability is not a consideration in setting WQS.

304 (33 U.S.C. 1314)—Information and Guidelines

This section requires the EPA to develop water quality criteria and guidelines for effluent limitations, pretreatment programs, and administration of the National Pollutant Discharge Elimination System (NPDES) program.

306 (33 U.S.C. 1316)—National Standards of Performance

A list of categories of effluent sources is presented which specifies that each of the industries listed must conform to technology-based new source performance standards. The standards are to demonstrate the best demonstrated control technology.

307 (33 U.S.C. 1317)—Toxic and Pretreatment Effluent Standards

This requires that industries discharging toxic pollutants meet effluent limits that employ the best available technology economically achievable. Part (b) mandates the establishment of pretreatment standards while part {c} looks at new sources of pollutants into publicly owned treatment works (POTWs).

309 (33 U.S.C. 1319)—Enforcement

Enforcement by the states, as well as compliance orders, and administrative, civil, and criminal penalties are authorized.

311 (33 U.S.C. 1321)—Oil and Hazardous Substance Liability

The Congressional declaration of policy against discharges of oil or hazardous substances in harmful quantities into waters and adjoining shorelines is presented. A spill prevention, control, and countermeasure plan is to be developed by all facilities that handle, transport, and store oil. Any spill or discharge of a harmful quantity of oil must be reported to the National Response Center. Strict liability is assigned to owners or operators of facilities from which oil discharges occur.

319 (33 U.S.C. 1329)—Nonpoint Source Management Programs

This section requires that states identify waters that are not able to meet WQS because of nonpoint sources. The activities responsible for the pollution are to be identified and a management plan is to be created to help correct the nonpoint source problem.

401 (33 U.S.C. 1341)—Certification

Any applicant for a Federal license or permit to conduct any activity which may result in any discharge into the navigable waters, shall provide the licensing or permitting agency a certification from the State in which the discharge will originate.

402 (33 U.S.C. 1342)—National Pollutant Discharge Elimination System

One of the most critical parts of the CWA is the establishment of the National Pollutant Discharge Elimination System which translates standards into enforceable limitations. This program may be administered by the EPA or states under EPA-delegated authority. After an opportunity for public hearing, a permit may be issued for the point source discharge of any pollutant, or combination of pollutants.

404 (33 U.S.C. 1344)—Permits for Dredged or Fill Material

This is the major wetlands provision of the CWA, and largely, in environmental law. The basic gist of this section is that a permit is required from the U.S. Army Corps of Engineers for the disposal of dredged or filled materials into navigable waters, notably wetlands, with EPA concurrence, and notice and opportunity for public hearings.

505 (33 U.S.C. 1365)—Citizen Suits

Any citizen is given the right to file suit against any person in violation of an effluent standard or against EPA for failure to perform nondiscretionary duties.

PERTINENT REGULATIONS

- **33 CFR Part 320—General Regulatory Policies, Army Corps of Engineers**
  The Corps issues permits under several different acts, the CWA being only one of them. The Corps must issue permits for discharges to insure that they comply with the applicable limitations and WQS. Section 320.4 describes the general policies that the Corps will follow in reviewing all Department of the Army permits. Such permits are to consider public interest, effect on wetlands, fish and wildlife, water quality, property ownership, energy conservation, navigation, environmental benefits, and economics, among other things. The pertains particularly to dredge and fill permits covered under 404 of the CWA.
- **33 CFR Part 323, Permits for Discharges of Dredged or Fill Material into Waters of the United States, Army Corps of Engineers**
  Contains definitions and special policies, practices and procedures to be followed by the Corps in connection with review of permit applications for the discharge of dredged or fill materials under 404 of CWA. Permits issued under 404 are required

for the discharge of dredged or fill materials not exempted by 323.4 of this part or permitted by 33 CFR Part 330. Please refer to 323.4 for a detailed listing of exemptions.

- **33 CFR Part 325—Processing of Department of the Army Permits, Army Corps of Engineers**
  Contains general processing procedures for all Department of the Army permits. Attention is given to dredge and fill activities in 325.1(d)(3) & (4). Federal agencies that initiate or authorize proposed actions that include dredge or fill discharge operations must ensure that the appropriate permits are obtained. In states with approved programs, permit application is done through the appropriate State agency.
- **40 CFR Part 110—Discharge of Oil, EPA**
  This section reiterates the mandate of 311(b)(3) of the CWA. It generally prohibits the discharge of oil into navigable waters in such quantities as may be harmful.
- **40 CFR Part 112—Oil Pollution Prevention, EPA**
  This requires that owners or operators of non-transportation related onshore and offshore facilities engaged in any type of oil and gas operation prepare a Spill Prevention Control and Countermeasure Plan, and provide guidelines for preparation of the plan. Such a plan may be required of an applicant for USGS approval of any oil and gas activities.
- **40 CFR Part 122—EPA Administered Permit Programs: The National Discharge Elimination System, EPA**
  Contains definitions and basic permitting requirements for EPA-administered NPDES programs under 318, 402, and 405 of the CWA. Permit applications and special NPDES program requirements are discussed in Subpart B. This is followed by permit conditions in subpart C. Subpart D covers the transfer, modification, revocation and reissuance, and termination of permits. Federal agencies that initiate or authorize proposed actions that include point source operations must ensure that the appropriate permits are obtained. In states with approved programs, permit application is done through the appropriate State agency.
- **40 CFR Part 123—State Program Requirements, EPA**
  Describes the general requirements and additional requirements for states and the EPA to obtain and give approval, revision, and withdrawal of state NPDES programs. State program information shall be made available to EPA upon request. EPA also has the right to review proposed general permits for 90 days.
- **40 CFR Part 125—Criteria and Standards for the National Pollutant Discharge Elimination System, EPA**
  This section prescribes criteria and standards for various requirements imposed as conditions for NPDES permit approval. Some of the criteria expanded upon are those presented for the imposition of technology-based treatment requirements in permits as given under 301(b) and 402(a)(1), those for modifying secondary treatment requirements under 301(h), those for Best Management Practices authorized under 304(e), and those applying to ocean dumping, in Subparts A, G, K, & M, respectively.
- **40 CFR Part 129—Toxic Pollutant Effluent Standards, EPA**
  This section designates toxic pollutant effluent standards and applies to owners or operators of specified facilities discharging into navigable waters. Section 129.4 listed the pollutants to be regulated. Each owner/operator is given 60 days to notify the Regional Administrator of any listed pollutant that is discharged. Much of the regulation gives specific information on each of the toxic pollutants.
- **40 CFR Part 130—Water Quality Planning and Management, EPA**
  Section 303 of the CWA gives the authority for promulgation of water quality standards (WQS) by states. Here, policies are established for water quality planning, management, and implementations of 303. The Water Quality Management process from the CWA provides the authority for a “consistent national approach for maintaining, improving and protecting water quality while allowing States to implement the most effective individual programs”. After WQS are set by each state, implementation of the standards may be achieved by issuing permits, building publicly-owned treatment works, or instituting Best Management Practices (BMP) through a water quality management plan. Total maximum daily loads (TMDL) and individual water quality-based effluent limitations are discussed in 130.7. States are required to submit water quality reports to the Regional Administrator in accordance with 305(b) of the CWA (130.8). Final points of the regulation cover state submittals to EPA and program management.
- **40 CFR Part 131—Water Quality Standards, EPA**
  While Part 130 of this title works with water quality management, this section deals with water quality standards (WQS). It is stated that a WQS defines the water quality goals of a water body by designating the uses to be made of the water and by setting criteria necessary to protect the uses. WQS should be set to provide for the protection of fish, shellfish, wildlife, water recreation, and the use and value of public water supplies, agricultural, industrial, and other purposes. The procedures are presented for developing, reviewing, revising and approving WQS by the states and EPA. In 131.12, states are ordered to develop statewide antidegradation policies. WQS shall be reviews at least every three years by the states.
- **40 CFR Part 230—Section 404 (b)(1) Guidelines for Specification of Disposal Sites for Dredged or Fill Material, EPA**

These guidelines were written to restore and maintain the chemical, physical, and biological integrity of the U.S. through the control of discharges of dredged or fill material, with the guiding principle that degradation of sites may represent an irreversible loss of valuable aquatic resources. In Subpart B, it is stated that "no discharge of dredged or fill material shall be permitted if there is a practicable alternative to the proposed discharge which would have less adverse impact on the aquatic ecosystem". The permitting authority must determine the potential effects of dredging or filling activities on the components of the aquatic environment.

- **40 CFR Part 231—Section 404(c)Procedures, EPA**
  Contains procedures for EPA in exercising its authority to veto the specification by the Army Corps of Engineers or by a State of a disposal site for a 404 permit.
- **40 CFR Parts 401-471—Effluent Guidelines and Standards, EPA**
  Prescribes effluent limitations and pretreatment and performance standards, categorized by industries, that must be complied with as conditions for NPDES permit approval. Part 401 gives general provisions and Part 403 covers general pretreatment regulations for existing and new pollution sources. The remaining parts are industry-specific. Of particular interest to the USGS are:

  40 CFR Part 434—Coal Mining Point Source Category
  40 CFR Part 435—Offshore Segment of the Oil and Gas Extraction Point Source Category
  40 CFR Part 436—Mineral Mining and Processing Point Source Category
  40 CFR Part 440—Ore Mining and Dressing Point Source Category

- **518 DM 1—Comprehensive Waste Management, Department of the Interior**
  This chapter defines waste to include solid and hazardous waste, hazardous materials, and hazardous substances. Departmental policies, responsibilities, and functions regarding waste management are presented, with an aim towards prevention of hazardous waste generation. The use of sound waste management practices is mandated.

SAFE DRINKING WATER ACT (PL 93–523; 42 U.S.C. 300F—J-10)

Purpose

In 1974, the Safe Drinking Water Act (SDWA) was enacted with the general intent to protect the quality of drinking water the public receives from public water systems. To accomplish this, the SDWA focuses on two approaches. The first is to assure the quality of drinking water coming from the tap. The other approach is to prevent the contamination of groundwater that may be a source for drinking water.

MAJOR PROVISIONS BY SECTION

§1412 (42 U.S.C. 300g-1)—National Drinking Water Regulations

The EPA is required to promulgate national drinking water regulations, known as Maximum Contaminant Level Goals (MCLGs) and Maximum Contaminant Levels (MCLs) for public water systems. These standards specify minimum levels of drinking water quality and are to be issued for any contaminant that is known or anticipated to have any adverse effect on health.

§1413 (42 U.S.C. 300g-2)—State Primary Enforcement Responsibility; Regulations; Notice of Hearing; Publication in Federal Register; Applications

States are given the authorization to assume primary enforcement of the Act.

§1415–1416 (42 U.S.C. 300g-4 & 5)—Variances—Exemptions

The conditions are offered in which states may issue variances and exemptions.

§1417 (42 U.S.C. 300g-6)—Prohibition on Use of Lead Pipes, Solder, or Flux

Any use of lead in pipes, solder, or flux in public water systems where the water is intended for human consumption is prohibited.

§1422 (42 U.S.C. 300h-1)—State Primary Enforcement Responsibility

This section requires the establishment of state underground injection control programs so as to protect current and potential underground sources of drinking water from contamination.

§1424 (42 U.S.C. 300h-3)—Interim Regulation of Underground Injections

This declares that Federal agencies shall make no commitment of Federal assistance to actions that will contaminate an aquifer designated as the sole or principal drinking-water source for an area which, if contaminated, would create a significant hazard to the public health.

§1428 (42 U.S.C. 300h-7)—State Programs to Establish Wellhead Protection Area

States are given the authority to develop wellhead protection programs that address the kinds of activities that might be conducted in proximity to wells, particularly seeking to limit activities that might pose threats to the well fields.

§1431 (42 U.S.C. 300i)—Emergency Powers

If there is an imminent and substantial endangerment to public health through drinking water, EPA is given emergency powers to act against contamination.

§1445 (42 U.S.C. 300j-4)—Records and Inspection

The EPA is to promulgate regulations requiring drinking water monitoring. This section also mandates that EPA establish record keeping requirements.

§1448 (42 U.S.C. 300j-7)—Judicial Review

The D.C. Circuit is given the jurisdiction of judicial review of national primary drinking water regulations. The U.C. Courts of Appeal are given jurisdiction for any other EPA action when the petitioner resides or transacts business in that particular region.

§1449 (42 U.S.C. 300j-8)—Citizen's Civil Action

This section gives citizens the right to file suit to enforce any mandatory provisions of the SDWA.

Part F—Additional Requirements to Regulate the Safety of Drinking Water

§1461–1465 (42 U.S.C. 300j-21 to 26)

These particular sections codify the Lead Contamination Act of 1988. This requires that any lead-lined tanks of drinking water coolers be recalled.

PERTINENT REGULATIONS

- **40 CFR Part 141—National Primary Drinking Water Regulations, EPA**
  One of the most significant provisions of the SDWA is the establishment of National Primary Drinking Water Regulations. The regulations are given life here, with the establishment of maximum contaminant levels (MCLs) for inorganic and organic constituents, Subpart B and maximum contaminant level goals (MCLGs), Subpart F. Much attention is given to the monitoring and analytical requirements for the regulated water quality parameters, Subpart C. Filtration and disinfection are given much the same kind of thorough treatment. Also included are sections covering control of lead and copper, muse of non-centralized treatment devices and treatment techniques.
- **40 CFR Part 142—National Primary Drinking Water Regulations Implementation, EPA**
  With only a few exceptions, this part applies to the public water system in each state. States are given primary enforcement responsibility, given that the state has an EPA-approved program. If a state wishes to revise its program, it may do so if it follows the requirements given in 142.12. All states with enforcement responsibility are required to submit to the EPA Administrator a report containing various components dealing with national primary drinking water regulations. Variances and exemptions to the primary regulations may be granted by either the states of the Administrator. Another section (142.60) discusses best available technologies for a list of contaminants as they pertain to national primary drinking water regulations.
- **40 CFR Part 143—National Secondary Drinking Water Regulations, EPA**
  While Part 141 of this title is concerned with primary drinking water regulations, this part deals with national secondary drinking water regulations. Secondary regulations control contaminants that primarily affect the aesthetic qualities of drinking water. Levels are given for selected contaminants and it is explained that states may establish higher or lower levels depending on special conditions with that state, given that public health and welfare are not adversely affected. Section 143.4 gives monitoring requirements, stating that monitoring should occur no less frequently than the schedule used for the National Interim Primary Drinking Water Regulations.
- **40 CFR Part 144—Underground Injection Control Program, EPA**
  This regulation stems from Part C of the SDWA which allows for the establishment of an Underground Injection Control (UIC) program in each state. General program requirements are given in Subpart B. These requirements address prohibition of unauthorized injection, prohibition of movement of fluid into underground sources of drinking water, prohibition of Class IV wells and requirements for wells injecting hazardous waste. In 144.16 of this subpart, direction is given for cases when injection does not occur into, through, or above an underground source of drinking water. Subpart C takes a look at authorization of underground injection by rule where each class of wells is given particular authorization requirements. Authorization is also available by permit, and this is the topic of Subpart D. Going hand-in-hand with Subpart D is Subpart E, which discusses permit conditions. Finally, in Subpart F, financial responsibility for hazardous waste injection wells is described.
- **40 CFR Part 146—Underground Injection Control Program: Criteria and Standards, EPA**
  By working closely with Part 144 of this title, this part sets forth the technical criteria and standards for the Underground Injection Control Programs. Criteria are given for exempted aquifers, which include aquifers used as an "underground source of drinking water". Injection wells are then classified as Class I–V, based on the material injected. The following subparts (B–G) then outline, in detail, the criteria for each class of injection wells.
- **40 CFR Part 149—Sole Source Aquifers, EPA**
  Pursuant to 1427 of the SDWA, this regulation was written to provide criteria for identifying critical aquifer protection areas. Section 149.3 refers to a Critical Aquifer Protection Area as one which was designated as a sole or principal source aquifer prior to June 19, 1986 for which an area wide ground-water

quality protection plan was approved. The second definition entails major recharge areas of a sole or principal source aquifer designated before June 19, 1988. Edwards Underground Reservoir, of the San Antonio area, is given attention in Subpart B.

- **Environmental Statement Memorandum No. ESM94-5—Environmental Impacts on Groundwater, Department of Interior**
  Implements CEQ memorandum issued on November 19, 1976, concerning 1424(e) of the Safe Drinking Water Act. EISs will analyze impacts on the quantity and quality of ground water with specific emphasis on drinking-water sources. For proposed actions which may affect ground water, early consultation is to be initiated with the appropriate District Hydrologist, Water Resources Division (WRD). If it is possible that the proposed action may affect an aquifer which has been designated or is being petitioned for designation for special protection, early consultation should be initiated with the Regional EPA Administrator.
- **516 DM 2 Appendix 2 (2.2), Department of Interior**
  Environmental documents (EA, EIS, FONSI) must be prepared for actions which may adversely affect such unique geographic characteristics as sole or principal source drinking-water aquifers.
- **518 DM 1—Comprehensive Waste Management, Department of the Interior**
  This chapter defines waste to include solid and hazardous waste, hazardous materials, and hazardous substances. Departmental policies, responsibilities, and functions regarding waste management are presented, with an aim towards prevention of hazardous waste generation. The use of sound waste management practices is mandated.

DEFINITIONS

Best Management Practices (BMP)

Schedules of activities, prohibitions of practices, maintenance procedures, and other management practices to prevent or reduce the pollution of “waters of the United States”. (40 CFR Part 122.2)

Contaminant

Any physical, chemical, biological, or radiological substance or matter in water.(SDWA, 1401(6))

Discharge of a Pollutant

Any addition of any pollutant to navigable waters from any point source. (CWA, 502(12)(A))

Exemption

A document for water systems having technical and financial difficulty meeting national primary drinking water regulations effective for one year granted by EPA “due to compelling factors”.

Maximum Contaminant Level (MCL)

The maximum permissible level of a contaminant in water which is delivered to any user of a public water system. (SDWA, 1401(3))

Maximum Contaminant Level Goal (MCLG)

The level at which no known or anticipated adverse effects on the health of persons occur and which allows an adequate margin of safety.

National Pollutant Discharge Elimination System (NPDES)

The national program for issuing, modifying, revoking and reissuing, terminating, monitoring and enforcing permits, and imposing and enforcing pretreatment requirements, under sections 307, 402, 318, and 405 of CWA. (40 CFR Part 122.2)

Navigable Waters

Waters of the United States, including the territorial seas. (CWA, 502(7))

Person

An individual, corporation, partnership, association, state, municipality, commission, or political subdivision of a State, or any interstate body. (CWA, 502(5))

Point Source

Any discernible, confined and discrete conveyance, including but not limited to any pipe, ditch, channel, tunnel, conduit, well, discrete fissure, container, rolling stock, concentrated animal feeding operation, or vessel, or other floating craft, from which pollutants are or may be discharged. This term does not include agricultural stormwater discharges and return flows from irrigated agriculture. (CWA, 502(14))

Pollutant

Dredged spoil, solid waste, incinerator residue, filter backwash, sewage, garbage, sewage sludge, munitions, chemical wastes, biological materials, radioactive materials (except those regulated under the Atomic Energy Act of 1954), heat, wrecked or discarded equipment, rock, sand, cellar dirt and industrial, municipal, and agricultural waste discharged into water. It does not mean: (a) sewage from vessels; or (b) water, gas, or other material which is injected into a well to facilitate production of oil or gas, or water derived in association with oil and gas production and disposed of in a well, if the well used either to facilitate production or for disposal purposes is approved by authority of the State in which the well is located, and if the State determines that the injection or disposal will not result in the degradation of ground or surface water sources. (CWA, 502(6))

Public Water System

A system for the provision to the public of piped water for human consumption, if such system has at least fifteen service connections or regularly serves at least twenty-five individuals. (SDWA, 1401(4))

Publicly Owned Treatment Works (POTW)

Any device or system used in the treatment of municipal sewage or industrial wastes of a liquid nature which is owned by a "State" or "municipality". This definition includes sewer, pipes, or other conveyances only if they convey wastewater to a POTW providing treatment. (40 CFR Part 122.2)

Recharge Zone

The area through which water enters a sole or principal source aquifer.

Significant Hazard to Public Health

Any level of contaminant which causes or may cause the aquifer to exceed any maximum contaminant level set forth in any promulgated National Primary Drinking Water Standard at any point where the water may be used for drinking purposes or which may otherwise adversely affect the health of persons, or which may require a public water system to install additional treatment to prevent such adverse effect.

Sole or Principal Source Aquifer

An aquifer which supplies 50 percent or more of the drinking water for an area.

Streamflow Source Zone

The upstream headwaters area which drains into an aquifer recharge zone.

Toxic Pollutants

Those pollutants…which after discharge and upon exposure, ingestion, inhalation or assimilation into any organism…,will, on the basis of the information available to the Administrator, cause death, disease, behavioral abnormalities, cancer, genetic mutations, physiological malfunctions or physical deformations, in such organisms or their offspring. (CWA, 502(13))

Variance

A document for water systems having technical and financial difficulty meeting national primary drinking water regulations which postpones compliance when the issuing of which "will not result in an unreasonable risk to health".

Waters of the United States

a) all waters which are currently used, were used in the past, or may be susceptible to use in interstate or foreign commerce, including all waters which are subject to the ebb and flow of the tide; b) all interstate waters, including interstate "wetlands"; c) all other waters such as interstate lakes, rivers, streams…, mudflats, sandflats, "wetlands", sloughs, prarie potholes, wet meadows, playa lakes, or natural ponds the use, degradation, or destruction of which would affect…interstate or foreign commerce…(40 CFR Part 122.2)

Wetlands

Those areas that are inundated or saturated by surface or groundwater at a frequency and duration sufficient to support…a prevalence of vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs, and similar areas. (40 CFR Part 122.2)

APPLICABLE ACTIONS

Clean Water Act

NPDES permits are required for the discharge of pollutants from any point source into waters of the U.S. [40 CFR 122.51(c)]

Section 404 permits are required for the discharge of dredged or fill material into waters of the U.S. (33 CFR 323.3)

Safe Drinking Water Act

Any action which may result in degradation of groundwater quality and/or pose a hazard to public health.

SUMMARY OF IMPLEMENTATION PROCEDURES

Clean Water Act

The procedures for determination of potential water quality impact from USGS activities and the need for various permits are extremely complicated and require close coordination with the Environmental Affairs Office, USGS, with regional offices of the EPA and the Army Corps of Engineers, and with state water pollution control agencies.

Safe Drinking Water Act (Consult ESM 94-5 for details)

1. In all cases where a project may involve ground water, one or more aquifers, or a recharge area, consultation with the appropriate District Hydrologist, WRD, should be initiated early in the planning stages.
2. Where a project may have any possibility of direct or indirect contamination of a sole or principal source aquifer, a recharge zone for such an aquifer, or a related streamflow source zone that has been designated or for which a petition for designation is being processed, early consultation should be initiated with the Regional Administrator, EPA.
3. If a project-related ground water impact is possible, an environmental assessment should be prepared. If an EIS is to be prepared, a copy of the Notice of Intent should be sent to the appropriate EPA Regional Administrator and he/she should review the draft EIS.

4. Final plans for projects having a potential for adverse impacts should incorporate appropriate mitigation measures.

INTERFACE BETWEEN FEDERAL WATER QUALITY REGULATION AND STATE ALLOCATION OF WATER QUANTITY

Melinda R. Kassen
Trout Unlimited, Colorado
Water Project
Boulder, Colorado

Healthy rivers and lakes require both clean and flowing water. In the United States, however, there are two separate and distinct systems for regulating water quality and water allocation, i.e., the amount of water taken out of a waterbody for beneficial use and, as a result, the amount of water left in the waterbody for environmental, aesthetic, or recreational purposes. States have the primary authority to allocate quantities of water for various users. Thus, state allocation decisions affect how much water flows in rivers and streams. At the same time, federal law—the Clean Water Act—regulates water quality, although the Act gives the states certain responsibilities and allows the Federal Government to delegate other responsibilities to the states, albeit in both cases with federal oversight. Because a river has aspects of both flow and quality; however, actions taken pursuant to either quality or quantity regulation can affect regulatory actions in the other system. Such instances of overlap create substantial friction both between levels of government and between the governments and those using or enjoying the nation's waters.

WATER QUANTITY

The 50 states each have developed their own systems of water allocation. However, the states in the western half of the country generally follow the system of prior appropriation, whereas the states in the wetter eastern half generally follow the riparian system of water allocation. Even federal agencies must procure their water rights through the state allocation systems.

In the temperate east of the country, states follow the riparian doctrine for water allocation. This common-law doctrine, imported from England with the first European settlers to North America, allows landowners bordering a river to take what water they need for use on their land—reasonable use—so long as such use does not impair others' use on the same river. Increasingly, riparian states are refining their doctrines and adopted statutory frameworks, including water use permits. Both common-law riparianism and the statutory variants provide that one owner's use should not adversely affect the water quality to the point where another riparian user cannot make reasonable use of the river. If such a situation develops, the injured riparian user can seek to enjoin the offending action and/or compensation for damages.

West of the 100th Meridian where natural precipitation is half or less than what is available further east (as well as in Alaska and Hawaii), states follow the doctrine of prior appropriation. Prior appropriation allows anyone to divert water from a river for beneficial use in priority. The priority system assigns water users seniority based on when they first started using the water; the "first in time, first in right" precept means that the most senior appropriator gets to fulfill his or her entire right before the next appropriator can take any water out of the stream.

Many western states do not have any public interest, environmental, or other balancing tests that prevent appropriators from drying up streams entirely. Although most western states do have some type of "instream flow" protection programs, these programs were typically added into the system within the past few decades and do not disturb existing diversionary rights.

WATER QUALITY

Before 1965, states had exclusive authority to regulate water quality except to the extent that the U.S. Army Corps of Engineers may have affected water quality through its regulation of navigable waters under the 1899 Rivers and Harbor Act. Even the 1965 federal legislation did not create federal legislative authority. So, it was not until 1972 that Congress passed the Federal Water Pollution Control Act, which, for the first time, created a federal floor for water quality protection and two mandatory permit programs. The goals of the Act were no less than to "restore and maintain the chemical, physical and biological integrity of the Nation's waters" and eliminate all discharges of pollutants into the nation's waters by 1985. [33 U.S.C. §1251 (2002)].

The Act, later amended and retitled the Clean Water Act, retained the preexisting scheme, albeit substantially strengthened, for states to adopt their own water quality standards—composed of the uses and chemical quality for all their water bodies—however, now subject to approval by the federal Environmental Protection Agency (EPA). In addition, federal agencies, or delegated state agencies, issued discharge permits to ensure compliance with the water quality standards. Finally, where a waterbody does not meet the water quality standards that the state has adopted for it, the Clean Water Act requires the state to list this waterbody as impaired and then to establish a "Total Maximum Daily Load" (TMDL) of pollutants that, once achieved, will result in the waterbody meeting its standards. This latter program is similar to the standards-setting program in that the states have primary authority for listing and setting TMDLs, but the EPA must ultimately approve the state's actions, and if the state's actions are insufficient to meet federal law, then EPA establishes the TMDLs.

The Clean Water Act creates two different permitting programs. The first, the National Pollutant Discharge Elimination System (NPDES), requires entities, including many industries but also municipal wastewater treatment facilities, discharging pollutants to a waterbody through a discrete conveyance or point source, often a pipe, to obtain a permit. This permit imposes "end of the pipe" effluent limits to ensure compliance with two distinct sets of requirements—the state-adopted water quality standards for the receiving water and a federally determined set of best-available technologies, established on an industry-by-industry basis. The second permit program regulates those who discharge dredged or fill material into waters of the United States, including wetlands tributary to rivers, lakes, and estuaries. Such permits must again protect the receiving water's water quality standards and must ensure that the discharge of dredged or fill materials does not have an "unacceptable adverse effect" on either municipal water supplies or the environment. Although Congress gave federal agencies the initial authority to administer both permit programs, the Act also encouraged states to seek delegation of the programs. Most states administer their own NPDES permit programs, rather than the EPA; only a handful of states have chosen to seek delegation of the permit program for dredged and fill materials from the U.S. Army Corps of Engineers. With regard to both types of permits, states must certify that the discharge, as ultimately regulated, will meet the state's water quality standards. In fact, states must certify compliance with water quality standards for all federal permits that affect water quality, even those not issued pursuant to the Clean Water Act, for example, hydropower licenses that the Federal Energy Regulatory Commission issues.

The Clean Water Act creates many additional programs and includes significant sources of federal funding to enable the states to meet their regulatory responsibility, and to enable municipalities to achieve the necessary levels of sewage treatment. In addition, 30 years after passage of the Act, most waters that remain impaired are so as a result of "non-point sources" of pollutants, for which the Clean Water Act does not require permits. These sources include runoff from farms, construction sites, and abandoned mines. Although the Clean Water Act did not mandate controls for these sources of contamination, it includes programs to encourage their voluntary cleanup.

INTEGRATION

In water rights adjudications and permit proceedings, in most western states, the decision maker has only a limited ability to consider water quality. At one extreme, California has fully integrated water quality protection into water rights decisions, such that the state agency responsible for granting water rights has in a few instances required a diverter to leave water instream for water quality protection. In addition, since 1983, California implements its common-law public trust doctrine to require water quality protection in the context of water diversions. Thus, the California Supreme Court found that the California Water Resources Board had an affirmative duty to protect Mono Lake's water quality and environment from adverse effects caused by diversions by the City of Los Angeles, although the court still recognized a need to balance water rights with environmental protection and did not limit existing diversions [*National Audubon Society v. Superior Court*, 658 P.2d 709 (Cal. 1983)]. Other states such as Colorado and Idaho have explicitly rejected this approach, whereas still others, e.g., Oklahoma and Nebraska, simply have not articulated a position in the decades since the Mono Lake ruling.

In fact, in most other states, the water quality protections embedded in water rights and permit proceedings are limited. Only 7 of the 17 western states have either statutory or public interest requirements to protect a senior diverter's water quality from injury as a result of changes to existing water rights.

Most states require a new diverter to protect water quality at least to the point that the quality is sufficient for a senior diverter's purposes. However, in Colorado, a senior water user cannot seek protection from a lessening of water quality because of new diversions, or changes to existing diversions, although that user is entitled to have water quality maintained when there is an exchange of water on the river, i.e., when the senior is receiving water from a different source because of changes elsewhere in the system. Thus, senior diverters on the Arkansas River were denied relief as a result of a change to water rights that resulted in water formerly used for irrigation on the plains being diverted in the headwaters out of the basin entirely, even though the change substantially reduced the water quality of the flows remaining the basin.

Although 1970s era slogan proclaimed that, "Dilution is not the solution to pollution," entities discharging pollutants to a stream pursuant to a Clean Water Act permit have also sought protection from changes to water rights that would remove dilution flows. In Colorado, at least, this effort has not been successful. Thus, the courts denied relief to a discharging industry that objected to a change of water rights that would have removed stream flow such that the discharger would have faced significant additional water treatment costs to be able to meet its permit limits. The court remarked on the subservient nature of water quality regulation to the water rights allocation system, which did not allow consideration of water quality, or injury to a discharger, as opposed to another water user, in determining whether to grant a water right [*City of Thornton v. Bijou Irrigation Co.*, 926 P.2d 1, 90–94 (Colo. 1996)].

On the water quality front, even as it adopted a federal regulatory scheme for water quality protection, Congress was mindful of the states' role in water allocation. Thus, the 1972 law includes a section that its provisions not "be construed as impairing or in any manner affecting any right or jurisdiction of the States with respect to the waters . . . of such States" [33 U.S.C. §1370(2) (2002)]. Yet, by 1977, after 5 years of Clean Water Act implementation, some western water user interests had become alarmed as to the potential for Clean Water Act regulation to "interfere" with the exercise of water rights. Congress added an additional provision to the Act, as part of a broad package of amendments, that no regulatory actions it authorized should "supercede, abrogate or impair" the exercise of state water rights [33 U.S.C. §1251(g)(2002)]. However, for several reasons, including that this language is a goal and that legitimate water quality regulation may affect water rights, the Courts have upheld water quality regulation to occur that appears at least to affect individual water users. For example, a farmer could not discharge dredged and fill material without a permit, even though he was doing so to better use his water rights [*United States v. Akers*, 785 F.2d 814 (9th Cir. 1986)]. And, a state could impose conditions in a water certification for a federal permit that had the effect of limiting the amount of water the permittee could use [*PUD No. 1 of Jefferson County v. Wash. Dep't of Ecology*, 114 S.Ct. 1900 (1994); *see also Public Util. Dist. No.1 of Pend Oreille County v. Wash. Dep't of Ecology*, 51 P.3d 744 (Wash. 2002)]. Finally, an entity seeking to build a new dam must obtain a Clean Water Act dredge and fill permit even if that entity already has a state water right to build the dam [*Riverside Irrigation Dist. v. Andrews*, 758 F.2d 508 (10th Cir. 1985)]. In making these findings, the courts repeatedly have held that legitimate regulation under the Clean Water Act may proceed even if there are indirect effects on the exercise of a water right.

In contrast to the courts' rulings, state legislatures have often taken action expressly to exempt water rights holders from regulation under state Clean Water Act programs. Thus, Colorado adopted the federal Act's language regarding not to "supercede, abrogate or impair," but not in the goals section of the Act; rather the provision is part of the state Water Quality Control Act's implementation [Colo. Rev. Stat. §25-8-104 (2004)]. Similarly, after the U.S. and state Supreme Court rulings in Washington confirming the state water quality agency authority to impose minimum stream flows that might affect the yield of water rights through water quality certifications, the state legislature adopted statutory amendments forbidding the state agency from adversely affecting water rights in water quality regulation [Wash. Rev. Code §90-48-422 (2004)].

A recent set of cases that illustrate the potential tension between water quality regulation and state water allocation laws involve artificial transfers of water, i.e., the man-induced movement of water from one waterbody to another. In each case, an entity was moving water from a contaminated watershed to a relatively cleaner waterbody through a conveyance—via a snowmaking system at a ski area, a municipal drinking water collection system, and a flood control system. Three U.S. courts of Appeal ruled that the discharger had to obtain an NPDES permit, because there was a discharge of pollutants from a point source to waters of the United States. The U.S. Supreme Court considered one of these cases in 2004 but did not reach the ultimate issue, although the Court did hold that the transferring water from one distinct water to another through a pipe did constitute a point source subject to permitting, even though the discharger was not, itself, "adding" pollutants to the water being transported [*South Florida Water Mgmt. Dist. v. Miccosukee Tribe of Indians*, 124 S.Ct. 1537, 1543 (2004)]. In other words, it was enough that the water being discharged was polluted already and was being discharged to a cleaner system.

As all three of the cases developed east of the Mississippi, the dischargers did not argue that they had water rights that allowed them to operate their systems free from Clean Water Act regulation, but many western states and water users weighed in to make that point. In fact, diverters have argued that requiring all transbasin diversions of water to operate only under an NPDES permit would overwhelm the states' permitting systems and adversely affect the use of state water rights. Those in support of requiring such permits have suggested that many of these diversions with discharges could be accomplished under states' general permitting programs in a way that would not be onerous. Only one state, Pennsylvania, has historically required permits for these kinds of discharges.

There are other places in the Clean Water Act program where water rights issues collide with water quality regulation. The Clean Water Act requires states to establish water quality standards, including use designations and numeric or narrative criteria for individual pollutants (33 U.S.C. §1313). To the extent that the exercise of water rights has affected what uses a waterbody can attain, because of the loss of dilution flow or fundamental changes in the natural system because of a dam, diversion, or artificial increase in the quantity of water coursing through the channel, states wrestle with how to accommodate human activity while encouraging operations that will maintain the Clean Water Act's "fishable/swimmable" goal for water quality.

In the program that requires states to list waters that remain impaired after all permitted discharges have permits [33 U.S.C. 1313(d)] EPA has interpreted the Clean Water Act not to require listing for impairment because of pollution, the definition of which includes hydrologic modifications such as dams and diversions that allow parties to exercise their water rights [64 Fed. Reg. 46011 (August 23, 1999); 65 Fed. Reg. 43586, 43592 (July 13, 2000)]. The problem is that the exercise of water rights that result in changes to the flow regime can lead both to impairment and to certain pollutant levels above the adopted standards. Examples include excessive temperatures, sediment, and nutrient levels. As temperature, sediment, and nutrients are pollutants, there have been listings, for example, in the Yakima River Basin in Washington State, where the underlying issue is most likely a change in the flow regime as a result of the exercise of water rights. So as not to challenge the exercise of water rights, other states, including California, New Mexico, and Washington, try to solve high temperatures with requirements to plant shade trees along a river's banks. See, e.g., http://www.ecy.wa.gov/programs/wq/tmdl/-watershed/index.html. However, EPA has rejected state proposals to solve impairment with flow enhancement programs. See http://www.-deq.state.mt.us/wqinfo/TMDL/approvalLtrs/Approval_BigCreekYelBasin.pdf.

Thus, state resistance to integrating water quality regulation, a federal mandate, with state water allocation systems has hampered protection of the environment as well as protection of the water quality necessary to sustain competing water uses. However, fears regarding the costs associated with water users having to protect the environment have kept most state legislatures from adopting statutes that integrate water quality protection into their water allocation systems in a way that would impose additional burdens on water development.

REGULATORY ISSUES AND REMEDIATION: RISK, COSTS, AND BENEFITS

David B. Vance
ARCADIS

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

Major regulatory changes have occurred over the past decade regarding enforcement and cleanup standards. These changes have occurred in part, because of the realization that enormous financial and human resources were being spent on the remediation of properties with low concentrations of residual fuel hydrocarbon (primarily gasoline and diesel) contamination with low impact to human receptors. A major report from a national laboratory in 1995 changed the regulatory approach to focus attention on the risk benefits and exposure pathways associated with subsurface fuel contamination. Risked based decision making takes into account the risk, costs, and benefits when evaluating regulatory approaches to remediation

INTRODUCTION

A Lawerence Livermore National Laboratory (LLNL) report (1) found that once fuel leak sources have been removed, petroleum hydrocarbon contamination generally does not spread far from the leak sites. Given time, naturally occurring indigenous microbes in the soil and water usually break down most of the contamination before drinking water sources are impacted. The report noted that only 136 sites of the 28,051 evaluated (<0.5 of 1%) affected drinking water supply wells. The LLNL study concluded that at many low-risk sites, active cleanup could be stopped and natural attenuation by naturally occurring biological and geochemical methods would reduce the contamination over time (1).

The LLNL study was important at the time. About 1200 out of 20,000 leaking underground fuel sites were examined in detail. It appeared that in most cases, the length of the hydrocarbon plumes was limited to several hundred feet and less than 50 feet vertically. Natural bioattenuation, abiotic degradation, and diffusion processes stabilized or attenuated these plumes over time (2). LLNL concluded that the threat to human health and long-term effects on the environment caused by petroleum hydrocarbon contamination may have been vastly overestimated. Water supplies can generally be purchased for about \$50 to \$200 per acre foot, or even \$1000 per acre foot at the most expensive price. Cleanups of petroleum contamination of groundwater were costing up to \$600,000 per acre feet to reclaim groundwater and to meet cleanup goals (2).

Critics to the LLNL report noted that LLNL had huge environmental cleanups to contend with, so their recommendations may have been politically motivated, none of the actual data discussed in the LLNL report were included in the report for examination, the report relies on written and verbal communications and papers supplied by the petroleum industry, and no public health professionals from CAL EPA, the Department of Health Services (DHS), or other agencies were solicited for their recommendations or review (3).

Even with the controversy, the LLNL report did focus public policy discussion on how clean is clean and what financial and human resources are worth using to clean up hydrocarbon contamination. These discussions led to consideration of risked based cleanup standards.

Changing from enforcement driven by arbitrary cleanup standards to action (or no action) driven by health-based risk assessments in conjunction with a cost/benefit analysis. The current debate includes the application of this concept at the highest level for the promulgation of new regulations or modification of existing regulations. However, the more powerful application of the new regulatory paradigm is on a site-specific basis. The purpose of risked based regulatory decision making is to examine the components of the site-specific risk/benefit/cost process. The following discussion is predicated on two basic assumptions: First, if a release of contaminants has occurred at a site, the source of that release will be abated. Second, free product hydrocarbons are not allowed to remain on or near the water table.

These actions quickly limit the potential size of a contaminant plume, minimize further migration of the core of that plume, and recover contaminants as free product versus dissolved phase. All of which offer significant cost savings in the remediation effort. A health-based risk assessment determines what concentration of contaminant represents an acceptable risk level. The cost side of the process is driven by the effort required to achieve that risk-determined contaminant concentration. Health-based risk assessment can be a complex process. However, it has two key technical components: first, is the dose/response relationship of a chemical and second, is the pathway through which that chemical can ultimately enter a human body. A third nontechnical issue is how accepting the public is of the process, particularly those exposed to the risk. Dose/response relationships are categorized into two broad areas: noncarcinogenic and carcinogenic.

Noncarcinogenic responses are generally characterized by a threshold dose. The threshold represents a level of exposure to a contaminant that can be tolerated by a person with no adverse effects until the protective mechanisms of the person are overwhelmed. As individual levels of tolerance vary, threshold determination can be controversial.

Carcinogenic responses are assumed to have no threshold. This assumption means that some finite cancer risk exists no matter how small the dose.

The primary routes of exposure to groundwater are ingestion, inhalation of vapors during bathing or showering, and dermal exposure during bathing or showering. Direct ingestion is straightforward, and inhalation and dermal adsorption are dependent on physical properties of the contaminant such as vapor pressure and partition coefficients.

The public perception of risk is contradictory. Significant risk to which a person will voluntarily expose themselves, such as driving, improper diet, or smoking are of concern, but deemed acceptable. In contrast, much smaller risks associated with environmental impairment that is imposed, and not voluntarily engaged, often generate alarm at any level above zero risk. This issue can only be resolved by education to each person's aggregate risk during their lifetime from many sources with a view toward the benefits each receives from our industrial society. This should be an important part of the current risk versus cost and benefit debate.

In a practical sense, the most effective method of controlling the risk from contaminated groundwater is simply to not use it, which in many situations may be the most viable alternative. However, our groundwater resources are finite and are diminishing in quality with time. One solution that is likely to become more common is surface treatment to remove contaminants. The most cost-effective goals are to maintain as much of our groundwater as possible in pristine condition and the timely restoration of contaminated aquifers to acceptable conditions.

Cost effectiveness enters from establishing a health-based contaminant concentration that is considered acceptable and expending the minimum effort sufficient to ensure that level is maintained. Whenever possible, natural attenuation should be used for the final clean up of the core and the dilute distal portions of the plume.

Groundwater recovery or *in situ* treatment should be designed with three goals in mind:

1. Control and treat the core of the plume in which the dissolved concentrations exceed the capacity of the aquifer to naturally attenuate in a timely fashion.
2. If required, recover groundwater at a rate just sufficient to achieve the above goal.
3. Design a system that takes into account the heterogeneity of the aquifer matrix.

A fine-grained matrix will in general take a significant amount of time to remediate because the overall mass transport rates the matrix will support are low and the amount of adsorbed contaminant is high. However, groundwater recovery rates or *in situ* remediation systems need only be sufficient to meet the low mass transfer requirements. On the other hand, the migration distances are likely to be minimal.

The worst case exists in aquifers that contain strata of fine-grained material mixed with highly permeable continuous layers. Pumping rates must be high to obtain hydraulic control, but treatment durations are extended because of the slow leaching of adsorbed contaminants from fine-grained material. In aquifers of this type with pronounced hydraulic gradients and subsequent high groundwater flow rates, it may be necessary to allow much of the contamination to spread through the aquifer such that concentrations will be at levels amenable to natural attenuation. A health-based risk assessment will be key in this scenario, which in essence uses an extensive portion of the aquifer matrix as a chemical/biological reactor for contaminant destruction.

For permeable heterogenetic aquifers with small hydraulic gradients and low groundwater flow rates, it will be more economical to run a groundwater recovery system or an *in situ* treatment system for short durations on a periodic basis. The core of the process is the diffusion of contaminants from fine-grained units into the more highly permeable portions of the aquifer. This contaminated pore volume is then treated to restore the contaminant concentrations to low levels providing a concentration gradient that drives the diffusion process. Initial capital costs must be met, but operation and maintenance costs will be significantly decreased over the life of the project.

If natural attenuation processes stop on a site because of a lack of a suitable electron acceptor, such as oxygen for aerobic bioremediation, other methods are available to enhance site conditions and to continue with the natural attenuation approach. The consumption of any available oxygen within the core of a hydrocarbon plume is quite common. In these cases, even the nitrate and sulfate concentrations may be low within the core of the plume because of the microbial consumption of these alternative electron acceptors. For these projects that are too high in concentration to close, but too low for active and aggressive remediation methods, enhanced bioremediation holds promise of lowering concentrations to regulatory acceptable levels, wherein natural attenuation can be used. More detailed information about natural and enhanced bioremediation methods can be found in Suthersan (4).

Risk-based decision making and natural attenuation has undergone changes over the past several years. Risk-based corrective action (RBCA) is a U.S. Environmental Protection Agency (EPA) cleanup process designed to protect human health and the environment while allowing for practical and cost-effective site-specific remedial measures. RBCA has an expanded use of natural attenuation as a cleanup option.

Some regulatory agencies are moving toward the use of risk-based screening levels and decision making. This approach uses lookup tables of conservative, risk-based screening levels (RBSLs) for over 100 chemicals commonly found in impacted soil and groundwater at sites where releases of hazardous substances have occurred. The approach is intended to help expedite the preparation of environmental risk assessments at sites where impacted soil and groundwater has been identified. As an alternative to preparing a formal risk assessment, soil and groundwater data collected at a site can be directly compared with the RBSLs and the need for additional work can be evaluated. It is anticipated that documents like these will be especially beneficial for use at small- to medium-sized sites, where the preparation of a more formal risk assessment may not be warranted or feasible because of time and cost constraints (5).

This new regulatory approach will rationalize the process of environmental restoration. Regulators, industry, and the public will benefit. For it to succeed, we all must understand and accept reasonable levels of risk. Cost effectiveness will hinge on the understanding and exploitation of site-specific aquifer characteristics, and acceptance of cleanup time frames that allow for the use of natural attenuation.

THE SAFE DRINKING WATER ACT

Rolf R. von Oppenfeld
The TESTLaw Practice Group
Phoenix, Arizona

OVERVIEW OF THE SAFE DRINKING WATER ACT

The Safe Drinking Water Act (SDWA) was enacted in 1974 and subsequently amended in 1986 and 1996 to protect the public from risks posed by drinking water contamination. The Act required the Environmental Protection Agency (EPA) to establish standards or treatment techniques for contaminants that could adversely affect human health, establish requirements for monitoring the quality of drinking water supplies and for ensuring the proper operation and maintenance of water systems, and protect groundwater from subsurface injection of polluting liquids. EPA posted a general guide to the SDWA provisions at http://www.epa.gov/OGWDW/SDWAsumm.html and posted its general approach for implementing the provisions at http://www.OGWDW/sdwa/sdwa.html.

The 1996 Amendments are important because Congress gave the EPA greater flexibility under the SDWA and emphasized the cost/benefit analytical approach to regulation. For an overview of the program, see the Office of Groundwater and Drinkingwater at http://www.epa.gov/safewater.html. The SDWA regulations can be found at 40 C.F.R. Parts 141–149 and may be accessed on the internet at http://www.water.access.gpo.gov/nara/cfr or http://epa.gov/OGWDW.regs. html. Inquiries about the regulations can also be directed to the Safe Drinking Water Hotline at 1-800-426-4791.

The EPA has delegated primary compliance and enforcement responsibility for the SDWA program to qualifying states. A detailed description of state primacy requirements can be found at http://www.epa.gov/safewater/pws/primacy.html. If states fail to ensure proper standards, the EPA may bring independent enforcement against violators through the Act's federal enforcement procedures. With respect to the regulated community, the SWDA focuses on operators of public water systems (PWSs) and on persons engaged in underground injections of fluids into wells.

Regulation of Public Water Systems

The SDWA regulates public water systems (PWSs) that provide water for human consumption through pipes or other constructed conveyances and regularly provide service to more than 25 persons or have 15 or more service connections [42 U.S.C. § 300f(4)(A)]. The EPA separates PWSs into the following categories:

1. community water systems and
2. noncommunity water systems that may be either
   a. nontransient, or
   b. transient.

Community water systems (CWSs) supply at least 15 service connections used by year-round residents or regularly serve at least 25 year-round residents [42 U.S.C. § 300f(15)]. Of approximately 180,000 water systems in the United States, only 55,000 are considered CWSs. They range from large municipal systems that serve millions of people to small systems that serve fewer than 100 people. CWSs can be publicly owned systems, including systems owned and operated by municipalities, townships, counties, water districts, and water authorities; privately owned systems that may be owned and operated by groups ranging from investor-owned water companies to homeowners associations; or ancillary systems that provide water as an ancillary function of their principal business or enterprise. Ancillary systems primarily service mobile home parks and a variety of institutional water providers.

Noncommunity PWSs are those systems that are not community water systems [42 U.S.C. § 300f(16)]. Examples of noncommunity PWSs include small systems in recreational areas and transient situations. Noncommunity systems may not have year-round residents but would have at least 15 service connections used by travelers or intermittent users for at least 60 days a year or serve an average of 25 individuals for at least 60 days a year. Specific examples of noncommunity systems include restaurants, campgrounds, motels, schools, and factories with their own wells or other water supply.

Nontransient, noncommunity water systems (NTNCWS) regularly serve at least 25 of the same people for 6 months of the year (Id). Schools and factories that serve water to 25 or more of the same people for 6 or more months of the year are nontransient, noncommunity water systems. All remaining water systems are classified as transient noncommunity systems (TNCWS). TNCWSs do not serve the same people on a day-to-day basis. In fiscal year 2000, there were more than 54,000 CWSs, more than 20,000 NTNCWS, and more than 93,000 TNCWS.

Certain PWSs are excluded from coverage and need not comply with SDWA regulations (42 U.S.C. § 300g). Excluded PWSs

1. consist only of distribution and storage facilities (have no collection and treatment facilities);
2. obtain all their water from a regulated PWS (but are not owned or operated by that PWS);
3. do not sell water; and
4. are not interstate carriers of passengers (Id).

This exclusion means that facilities such as hotels, factories, schools, and other businesses are not subject to SDWA regulation merely because they operate a storage tank and act as conduits from a PWS to consumers. However, the exclusion does not apply to private facilities that maintain their own wells or water supply. The EPA provides guidance for its definition of PWSs at http://www.epa/gov/OGWDW/guide/define.html.

SDWA DRINKING WATER STANDARDS AND GOALS

The SDWA authorizes the EPA to set drinking water standards called National Primary Drinking Water Regulations (NPDWRs). The EPA's NPDWRs are located at 40 C.F.R. Parts 141 and 142. NPDWRs are designed to protect consumers against the adverse effects caused by contaminants in drinking water. The SDWA requires that the EPA publish NPDWRs for contaminants that may have an adverse affect on human health, occur, or are likely to occur in PWSs at harmful levels and where the health risk can be reduced by regulation.

The 1996 Amendments made dramatic changes in the SDWA implementation process. Congress required the EPA to consider the following criteria when setting future drinking water standards and goals:

1. use of best available, peer-reviewed science [42 U.S.C. § 300g-1(b)(3)(A)(i)];
2. the assessment of health effects of populations at greater risk [42 U.S.C. § 300g-1(b)(3)(C)(i)(V)];
3. a list of treatment technologies for small systems, considering the quality of source water [42 U.S.C. § 300g-1(b)(4)(E)(ii)];
4. an assessment of the incremental costs and benefits of each alternative MCL considered [42 U.S.C. § 300g-1(b)(3)(C)(i)(IV)].

Maximum Contaminant Levels (MCLs)

A NPDWR must specify either a maximum contaminant level (MCL) or a treatment technique [42 U.S.C. §§ 300f(1), 300g-1(a)(3)]. The EPA is authorized to promulgate a NPDWR "that requires the use of a treatment technique in lieu of establishing a MCL," if the EPA finds that "it is not economically or technologically feasible to ascertain the level of contaminant" [42 U.S.C. § 300f(1)(C)]. Two significant NPDWRs that rely on treatment techniques are the Surface Water Treatment Rule and the Lead and Copper Rule.

MCLs are enforceable standards and represent the maximum permissible level of a contaminant in water delivered to any use of a PWS (40 CFR § 141.2). MCLs must be set as close to the maximum containment level goals as feasible. "Feasible" means using the best technology, treatment techniques, or other means which the administrator finds available after considering costs [42 U.S.C. § 300g-1(b)(4)(D)]. There are limits, however, to the use of cost considerations. First, the costs considered must be limited to those likely to be incurred [42 U.S.C. § 300g-1(b)(3)(C)]. Second, no consideration of costs is allowed to establish a MCL for "contaminants that are disinfectants or disinfection byproducts, or to establish a maximum contaminant level or treatment technique requirement for controlling *Cryptosporidium*" [42 U.S.C. § 300g-1(b)(6)(C)].

Under certain conditions, MCLs may be set at a level different from the feasible level. A variation is allowed where the means employed to achieve the feasible level of one contaminant would increase concentrations of other contaminants that pose a threat to human health. A level other than the feasible level may also be set when the means of reaching the feasible level for one contaminant interferes with the treatment processes necessary to comply with other NPDWRs. In these situations, the MCL or treatment process specified must "minimize the overall risk of adverse health effects" [42 U.S.C. § 300g-1(b)(5)(B)(i)].

The EPA must publish findings based on a scientific risk assessment of the probable health benefits and probable costs of each alternative MCL under consideration [42 U.S.C. § 300g-1(b)(3)(C)]. The published findings should be based on all of the following:

1. The EPA must use the best available, peer-reviewed science and studies.
2. Data must be collected by accepted methods.
3. Information on health effects must be presented by the EPA in an objective, comprehensive, and understandable manner.
4. Analysis for MCLs must show the quantifiable and nonquantifiable health risk reduction benefits, costs, and any increased health risk of compliance with the MCL.
5. For treatment techniques, analysis must show the health risk benefits and costs likely to result from compliance and alternative treatment techniques.
6. Valid approaches for measuring benefits must be identified.

If the EPA determines that the costs of a promulgated MCL outweigh the benefits, the EPA may promulgate a new MCL [42 U.S.C. § 300g-1(b)(6)]. The choice of treatment technique is left to the PWS, but the EPA must list available technology and methods to meet the MCL [42 U.S.C. § 300g-1(b)(4)(E)]. In addition, this list must include affordable methods for small

PWSs (Id). The EPA maintains a list of MCLs at http://www.epa.gov/safewater/mcl.html.

Judicial Review of MCLs

Section 1448(a) of the SDWA provides for judicial review of EPA's MCLGs and MCLs [42 U.S.C. § 300j-7(a)]. Only the U.S. Court of Appeals for the District of Columbia may review MCL determinations. A petition for review must be filed within 45 days, starting on the date of the promulgation of the regulation, unless solely based on grounds occurring after expiration of the 45-day period. There is no judicial review of a regulation in any enforcement proceeding (Id). Judicial review of MCLs is conducted under a narrow standard of review. The Court of Appeals will reverse only if an EPA action is arbitrary, capricious, an abuse of discretion, or not in accordance with the law. The EPA is given great deference because of the level of technical expertise it uses to evaluate complex scientific data.

The Drinking Water Contaminant Candidate List

In 1996, Congress set its most recent schedule for setting standards for drinking water contaminants. See 42 U.S.C. § 300g-1(b)(1)(B). First, the EPA was required to publish a list of contaminants that are not subject to any proposed or promulgated NPDWR, that are known or anticipated to occur in PWSs, and that *may* require regulation under the SDWA. The EPA was required to publish a Drinking Water Contaminant Candidate List (CCL) in February 1998 and every 5 years thereafter. The list must be published only after consultation with the scientific community and public comment. Following publication of the list, the EPA must determine which of the listed contaminants to regulate. The determination must be completed every 5 years for at least five listed contaminants.

Unregulated Contaminant Monitoring Regulations

The 1996 amendments also required EPA to develop a program to monitor unregulated contaminants and publish a list of monitored contaminants [42 U.S.C. § 300j-4(a)(2)]. In response, the EPA promulgated the Unregulated Contaminant Monitoring Regulations (UCMR) [64 Fed. Reg. 50556 (Sept. 17, 1999)]. The UCMR works in conjunction with the CCL. The EPA can use the data generated through the UCMR to prioritize contaminants on the CCL and help determine which contaminants to regulate. Several states may also petition to have certain contaminants monitored under the UCMR [42 U.S.C. § 300j-4(a)(2)(B)]. The UCMR covers all CWS and NTNCWS that serve more than 10,000 customers. An additional, 800 systems serving under 10,000 customers were randomly selected to test for unregulated contaminants.

The UCMR created three lists of contaminants for monitoring. Substances were placed on lists depending on their known environmental occurrence and the ability to test analytically for them. List 1, the "Assessment Monitoring" list, contains those substances known to occur in more than two states or more than 10 PWSs, and for which monitoring methods were available. See 40 C.F.R. § 141.40 Table 1. EPA has little monitoring data for List 2, the "Screening Survey," and List 3, the "Pre-Screen Testing List."

Chemical Monitoring Reform (CMR)

To reduce unnecessary monitoring and reporting requirements, the 1996 Amendments contained a provision for modifying NPDWR monitoring requirements. This CMR provision streamlined drinking water monitoring requirements for 64 chemicals that may occur in the *source water* of PWSs. For a system to qualify for alternative monitoring, it must demonstrate that a contaminant is not present in its water supply or if it is present, that it is reliably and consistently below the MCL. If the contaminant is later detected at or above the MCL, then the system must eliminate the contamination, or it must monitor as required under the NPDWR.

Secondary Regulations

Section 1412(c) of the SDWA also authorizes the EPA to promulgate National Secondary Drinking Water Regulations (NSDWRs) [42 U.S.C. § 300g-1(c)]. A NSDWR is "a regulation which applies to PWSs and which specifies the maximum contaminant levels which, in the judgment of the Administrator, are requisite to protect the public welfare" [42 U.S.C. § 300f(2)]. The NSDWR "may apply to any contaminant in drinking water which may adversely affect the odor or appearance of such water and consequently may cause a substantial number of persons served by the PWSs providing such water to discontinue its use, or which may otherwise adversely affect the public welfare" (Id). NSDWRs are not federally enforceable but offer additional guidance based on odor, aesthetics, and appearance to water systems and states. NSDWRs may vary according to geography and other circumstances. To date, NSDWRs have been established for several contaminants, including copper, fluoride, pH, and total dissolved solids. These regulations are in 40 C.F.R. Part 143.

Consumer Information

A major objective of the SDWA is to increase communication between PWSs and their customers. Consequently, Congress required an annual "Consumer Confidence Report" for PWSs. EPA regulations require each CWS to mail to each customer, at least once annually, a report on the level of contaminants in the drinking water purveyed by that system. These reports also indicate the source of the water supplied to the consumer and notify customers that a source water assessment is available.

VARIANCES AND EXEMPTIONS

General Variance

A state that has primacy over the SDWA may issue a variance if it determines that a system cannot comply with a MCL, despite application of the best available technology (BAT). The EPA determines the BAT and treatment method for each NPDWR after examination for efficacy under field conditions, rather than solely under laboratory conditions, and after considering cost. (40 C.F.R. § 141.2). A state may not issue a variance where an unreasonable risk to health exists or where alternative sources of water are reasonably available to the system. Under Section 1415, EPA must propose and promulgate its BAT finding at the same time it proposes and promulgates a MCL for each contaminant (42 U.S.C. § 300g-4). BATs may vary among systems, depending upon the number of persons served by the system or for other physical conditions related to engineering feasibility and costs of complying with MCLs.

The 1996 amendments allow the EPA to review and object to any variance granted by a state [42 U.S.C. § 300g-4(e)(10)]. If the state does not resolve these objections, the EPA may overturn the variance when it violates SDWA requirements. Consumers served by a PWS that has been granted a variance may petition EPA to begin the objection and review process.

A variance will be granted for a maximum of 5 years with the possibility of a 3-year extension. At the time a variance is granted, it will contain a schedule of steps necessary to achieve ultimate compliance with the particular NPDWR applicable in the variance. The variance may also contain additional control measures for protecting public health during the period that the variance is in effect. The EPA's final rule, issued in August 1998, states that 5 years is a reasonable time frame for a PWS to come into compliance; however, the state has the flexibility to set a feasible schedule if it determines that more than 5 years are required [63 Fed. Reg. 43841 (Aug. 14, 1998)].

Small System Variance

Congress responded to concerns that NPDWR compliance costs unfairly burden small PWSs. The 1996 Amendments added a special variance applicable only to small systems. See 42 U.S.C. § 300g-4(e). A small system variance may be available to systems that serve fewer than 3,300 persons (or up to 10,000 with special EPA approval). The variance should be of special interest to small community systems as well as the schools, factories, and other institutions that qualify as noncommunity water systems under the Act. The small system variance is available only where EPA has identified a less expensive version of the best available technology, called "variance technology," and the water system cannot afford to comply with the regular NPDWR. All variances must continue to provide adequate protection of human health. The proposed maximum period for a small system variance is 3 years with the possibility of a 2-year extension to complete improvements, obtain an alternate water source, or obtain federal or state financial assistance.

Exemptions

Under Section 1416(a), a state may exempt a PWS from any MCL or treatment technique requirement if it finds that

1. due to compelling factors (which may include economic factors), the system is unable to comply;
2. the system was in operation on the effective date of the MCL or treatment technique, or, for a newer system, that no reasonable alternative source of drinking water is available to that system;
3. the exemption will not result in an unreasonable risk to health; and
4. restructuring and management changes cannot reasonably be made that will result in compliance or otherwise improve the quality of the water (42 U.S.C. § 300g-5).

Under section 1418(b), a state is to prescribe a compliance schedule and a schedule for implementing any required interim control measures at the same time it grants an exemption [42 U.S.C. § 300g-7(b)].

In a major change in the exemption provisions, the 1996 Amendments deleted provisions which limited an exemption to 12 months, subject to a 3-year extension [42 U.S.C. § 300g-5(b)(2)(A)]. The new provisions require that the schedule for an exemption include compliance with each contaminant level and treatment technique for which the exemption was granted, as soon as practicable, but not later than 3 years after the otherwise applicable compliance date. The only exception to this time period is for small systems that serve less than 3300 persons, under certain specified conditions, for which extensions may be renewed for one or more additional 2-year periods, but not to exceed a total of 6 years [42 U.S.C. § 300g-5(b)(2)(C)].

The amendments now require that the state also consider whether the PWS is a "disadvantaged community" and whether management or restructuring changes can be made that will result in compliance or, if compliance cannot be achieved, would improve the quality of the drinking water [42 U.S.C. § 300g-5(b)(4)]. Measures to develop an alternative source of water supply must also be considered.

The 1996 Amendments also gave states more flexibility to adopt alternative protective strategies. For example, a state exercising primary enforcement responsibility for a PWS may, case-by-case and after notice and opportunity for public comment, establish watershed management programs as an alternative to filtration for systems that have uninhabited, undeveloped watersheds. See 42 U.S.C. § 300g-1(b)(7)(C)(v).

UNDERGROUND INJECTION CONTROL (UIC) UNDER THE SDWA

Scope of the UIC Program

SDWA established the UIC program to protect existing and future underground sources of drinking water from contamination caused by the subsurface disposal of waste fluids into wells. See 42 U.S.C. §§ 300h-300h-5. Improper operation of an injection well that allows movement of contaminants into an underground source of drinking water can lead to substantial civil penalties. The SDWA allows states to administer their own UIC programs if the state regulations and statutes meet the EPA's minimum requirements specified in 40 C.F.R. Parts 144–146. See http://www.epa.gov/safewater/states.html.

The overriding standard applicable to all underground injection activities is that

> No owner or operator shall construct, operate, maintain, convert, plug, abandon, or conduct any other injection activity in a manner that allows the movement of fluid containing any contaminant into underground sources of drinking water, if the presence of that contaminant may cause a violation of any primary drinking water regulation under 40 C.F.R. Part 142 or may otherwise adversely affect the health of persons . . . [40 C.F.R. § 144.12(a)].

Underground injection is defined as well injection, or the subsurface emplacement of fluids through a bored, drilled or driven well, or through a dug well where the depth of the dug well is greater than the largest surface dimension" (40 C.F.R. § 144.3). Fluid is broadly defined as "any material or substance which flows or moves whether in a semisolid, liquid, sludge, gas, or any other former state" (Id).

EPA has defined five classes of underground injection systems:

Class I: Wells injecting hazardous or nonhazardous waste below the lower most underground source of drinking water

Class II: Wells injecting fluids associated with oil and gas production

Class III: Wells injecting fluids for mineral extraction

Class IV: Wells injecting hazardous waste into or above an underground source of drinking water

Class V: All injection wells not covered by Classes I–IV (40 C.F.R. § 144.6).

All Class IV wells are banned by SDWA (40 C.F.R. § 144.13). Class V wells are "authorized by rule," and no individual permit is required. There are currently few regulatory requirements for Class V wells other than reporting under 40 C.F.R. § 144.26. Class V wells are the systems most commonly used by industry and small commercial operations. Common Class V wells include air conditioning return flow wells, cesspools, and cooling water return flow wells. See EPA's Class V websites at http://www.epa.gov.sefewater/uic/classv.html and http://www.epa.gov/safewater/uic/c5fin-fs.html. The EPA has announced that it is discontinuing its permission to operate Class V wells for motor vehicle waste disposal and large capacity cesspools. [64 Fed.Reg. 68545 (Dec. 7, 1999)].

Certain Class I, II, and III wells are not required to obtain individual permits (40 C.F.R. § 144.21). These wells may be authorized by rule if the operator injects within 1 year of a new UIC rule or performs an inventory under 40 C.F.R. § 144.26 within 1 year. All other Class I, II, and III wells require an UIC permit. An application for a UIC permit for a new injection well must be submitted by a "reasonable time before construction is expected to begin" [40 C.F.R. § 144.31(c)(2)]. If a facility or activity is owned by one person but is operated by another person, it is the operator's duty to obtain an UIC permit [40 C.F.R. § 144.31(b)]. Applicants for a UIC permit must use the application form provided by the EPA [40 C.F.R. § 144.31(e)]. The EPA may issue a permit for an area, rather than for each well individually, if the wells are within the same well field, facility site, reservoir, project, or similar unit in the same state; the wells are operated by a single owner or operator; and if the wells are used to inject something other than hazardous waste [40 C.F.R. § 144.33(a)].

If cause exists, the Administrator may modify or revoke and reissue a UIC permit. The Administrator may terminate a UIC permit during its term, or deny a permit renewal application if there is noncompliance by the permittee, failure to disclose relevant facts, or the permitted activity endangers human health or the environment (40 CFR § 144.40). A detailed description of the UIC program is available at http://www.epa.gov/safewater/uic.html.

OTHER SDWA PROVISIONS

The SDWA gives the EPA Administrator the power to classify an aquifer as a "sole source aquifer" (SSA) if the aquifer is the sole source of drinking water for a community. The SSA designation gives the EPA greater ability to scrutinize federal projects in the designated area to ensure that the aquifer is not contaminated [42 U.S.C. § 300h-3(e)]. The SSA regulations are located at 40 C.F.R. Part 149. The SDWA also requires that states with primacy to implement a Source Water Assessment Program to protect source waters for PWSs better from contamination (42 U.S.C. § 300j-13). SDWA also provides federal funding under the Drinking Water State Revolving Loan Fund to states for drinking water infrastructure projects (42 U.S.C. § 300j-12).

REPRESENTING GEOPOLITICS OF (HYDRO) BORDERS IN SOUTH ASIA

Eva Saroch
Panjab University
Chandigarh, India

INTRODUCTION

In the tradition of political geography, the concept of boundary/border has been of major importance where researchers have understood it mainly as an empirical manifestation of political processes and particularly of the sovereignty of the state. But borders not only represent a 'fixed line' in space or time, rather, they need to be understood as being produced and reproduced in the *socio-spatial consciousness* of society (a broader form of consciousness that reflects the ideological and hegemonic structures). Therefore, it is argued here that boundaries, apart from being located on terra-firma as a physical line, also exist metaphorically, symbolically in many ways as a manifestation of socio-spatial consciousness and as 'plays of power' that generate and exert various codes, rules and procedures of 'distinction' in the process of Othering such as us/them, sacred/profane, inclusive/exclusive, to impose specific understanding through the construction of knowledge in sociocultural practices and discourses in politics, administration, economics, or the organization of ethnic relations on various scales.

In the context of traditional geopolitics of water, 'mastering space' by deploying strategies of spatial domination and control and acquiring and guarding access to freshwater resources has always been a highly contested geopolitical issue both among and within sovereign states. A critical geopolitical approach, focusing the intricate but intimate interplay between space and its natural endowments such as water, and the socio-spatial consciousness of its various stakeholders, seems to suggest that rivers, for example, are not simply 'located' physically on ground as water flows or as static lines on maps but are situated/implicated in the very process of 'Othering' or the construction of symbolic/cultural boundaries between 'us' and 'them' (see Campbell, 1992, in Ref. 1, p. 3). Attention is thus drawn to how growing disagreements and rivalries over who gets, when, how and how much transforms seemingly innocent water flows into highly resilient hydro-borders. A critical geopolitical perspective motivates us to look for the sites where hydroborders are produced and reproduced, both in the form of various discourses (administrative, political, economic, cultural, and religious) and practices on various—spatial scales local, provincial, and national. At yet another analytical level, it is worth exploring how the 'criticality' of water resources is inscribed on the mental maps of various stakeholders (at local, national, and regional levels) as symbols of socio-cultural–religious identification or differentiation, identity formation, and power-political pursuit of primacy and security.

Even though the states and societies of South Asia are hydrographically united—they share the Indus River Basin (India and Pakistan), the Ganges–Brahmaputra–Meghna Basin (India and Bangladesh), and the Ganges–Mahakali Basin (India and Nepal), which the brief profile of the South Asian waterways suggests—geopolitically they stand divided. Hydro-borders in the form of mental borders or barriers continue to appear and reappear in different guises within an existing asymmetry of wealth, knowledge, and information, and as part of conflict and struggle among various actors for spatial control or mastering space (2, p. 115).

Thus, it is argued here that in the context of traditional, state-centric geopolitics of water resources, which seems to persist in post-colonial, post-partition South Asia, the 'hydroborders' in South Asia continue to be constructed, reinforced, and legitimized through competing notions of domestic stability/instability, security/insecurity, and legitimacy/illegitimacy. Constructed through 'nationalist' metaphors, state-sponsored security narratives and even politically motivated religious speeches, these mental borders, deceptively hydrographic in argument as well as in appearance, remain integral to the politics of place-making and group differentiation in the region. Drawing upon insights from the ongoing tensions/conflicts between India–Pakistan, India–Bangladesh, and India–Nepal (as well as within these countries) over the so-called 'sharing' of water resources, this article critically examines the interplay between the boundary-defying/unifying nature of waterways and the bounding/excluding logic of geopolitical discourses, imaginations, and representations.

A PREFACE TO SOUTH ASIAN WATERWAYS

Ecologically speaking, a river knows no boundaries. Flowing through farms, cities, and nations, rivers join rather than divide places. Any river that flows through two or more nations is supported by an ecosystem that cuts across political boundaries and joins the basin states. In similar perspective, South Asian waterways are the epitomes of sociocultural synergies, binding the South Asian landscape into one composite whole. The ancient 'Sapt Sindu Valley' and the 'Gangetic Basin,' together known as the Indo–Gangetic Basin, encompass South Asian waterways. The River Indus and the River Ganga are the principal rivers of two separate systems, but their separation is overridden by the unity of the Indo–Gangetic Plain, which spreads between the Himalayas and the Deccan. The Great Plains consist of two river basins, those of the 'River Indus' and the 'Ganga–Brahmaputra,' and the network of these rivers constitutes the 'Himalayan river system,' which has not only maintained the geographical contiguity on the subcontinent but has also been a fulcrum of different cultural streams. Having sustained inhabitants, the aquatic communities, and the ecosystem over centuries, these vast river systems have been the unifying–binding force for the South Asian geo-economic and geo-cultural landscape.

PARTITION, OTHERNESS, AND HYDRO-BORDERS

A critical geopolitical approach to the study of partition suggests that the partition of 'British India' was the convergence of two different phenomena—ethno-politics and geopolitics. According to Denis Retaille, ethnopolitics takes identity not territory as its starting point (3, p. 34), whereas geopolitics is a question of rivalries between powers for land and for those who live there or rivalries for territory (4, p. 122). Each complements the other in producing the other's 'excess' or excessive geopolitics. Excessive geopolitics "What", as aptly put forth by Chaturvedi, "does" is transform ideological–ethnopolitical conflicts relating to the boundaries of identity groups into geopolitical rivalries over 'our' territory versus 'their' territory. Consequently, the cold-blooded logic of 'territory for the sake of territory,' or Lebensraum, subsumes the more humane logics of common habitat or shared spaces" (5, p. 150). What sustains excessive geopolitics is the 'reflexive Otherness.' The image of the 'Other' is significant in producing borders that are both physical and symbolic. The permanent presence of 'Other' in discourse over water conflicts in South Asia has produced a manifold character of hydro-borders that are manifest in various foreign policy pronouncements, in defining national identity, and in so-called development projects. Even the language of dispute or the dispute over language suggests the deadly hold of 'nationalist language' not only in conceptualizing or thematizing the problem but also strategizing the resolution of the dispute.

Sir Cyril Radcliffe, a British lawyer who was given just six weeks to draw boundaries in Punjab in the west and Bengal in the east, was aware that the network of canals, River Indus, and its five tributaries were a lifeline for united Punjab and also the continued integration of the irrigation system, at least on a functional basis, was fundamental for the basin as a whole. Such a joint venture run by both countries would not only safeguard the interests of both peoples but also form a basis of cooperation which might prove fruitful in the years to come (as cited in Ref. 6, p. 164). But Radcliffe's hope of joint management of the basin for the optimal benefit of the people and ecology was rebuffed by both Jinnah and Nehru. According to Jinnah, "he would rather have Pakistan deserts than fertile fields watered by courtesy of Hindus." Nehru curtly informed that "what India did with the Indian rivers was India's affair" (6). This is a classic example that shows how a common past is repudiated as a time of oppression in which 'we' were simply the victims of oppressive 'others.' It also shows how partition has always been a disciplining event that shuts out other possibilities of resolving the conundrum whose one form is partitioning country, homelands, or the network of rivers, the arteries of the basin.

Hence, the boundary line in Punjab was drawn between Lahore and Amritsar, cutting across the well-integrated canal system that draws its water from the Indus and its five tributaries, Jehlum, Chenab, Ravi, Sutluj, and Beas. The enforced geography of partition was such that the headwaters of the rivers of the Indus Basin remained in India, thereby giving India the status of upper riparian. Pakistan felt that its livelihood was threatened by the prospect of unilateral Indian control over the tributaries that fed water into the Pakistani portion of the basin. Thus, Pakistan apprehended that a 'hostile' India might, if it so desired, using tunnels, divert water within Kashmir from the Western to the Eastern rivers, affecting a transfer before the water even reached Pakistan or the fringes of 'Azad Kashmir' (which India chooses to call Pakistan-occupied Kashmir) (7, p. 234). Whereas India certainly had its own ambitions for the 'profitable development' of the basin, Pakistani media and the politicians launched a large-scale national campaign over a canal water dispute. Pakistan even used the Indus water dispute as a political tool in the battle over Kashmir being debated at the United Nations. Former Foreign Secretary of India, J.N. Dixit, while addressing a plenary session in a seminar, is reported to have said that, "it was well accepted in our strategic studies circles, that much of the passion on Kashmir was generated because India controls the headwaters of the Indus" (8, p. 161).

A greater insight into the deliberations of the pre-Indus Waters Treaty period reveals that the Treaty signed between India and Pakistan in 1960 was dictated and driven by the logic of 'Othering' that jettisoned and abandoned the more humane logic and vision of joint development and administration of the integrated Indus Basin for the optimal benefit of the people of the two countries. The Treaty led to the fissuring/partitioning of the Indus and its five tributaries (the three eastern rivers went to India and the three western rivers to Pakistan) and of the 'homelands' that dwelled in the canal colonies, but the Treaty also carried, within itself, seeds of bypassed, unresolved, old, and unanticipated new water conflicts in the basin.

Even after partition became an accomplished reality, dialogues to overcome the bitter divides created in the wake of partition became prey to the partitioned times. Nothing can be more illustrative in this context than the water disputes at provincial and local levels. There are intrastate water disputes, for example, between Punjab and Sindh (Pakistan), and Punjab, Haryana, and Rajasthan (India), among others. Within India, in the wake of the partition, the issue that agitated the Sikhs even more than the territorial dispute was the unjust and illegal allocation of Punjab's river waters and hydroelectric power generated from them to non-riparian neighbor states. More recently, Mr. Praksah Singh Badal, former Chief Minister of Punjab in India, reportedly said that every drop of water that flows through Punjab belongs to Punjab. In Pakistan, the water conflicts between Punjab and Sindh have gained momentum. According to Sindh, the upper riparian province has been progressively increasing its illegal share of the waters of the Indus River since 1889 (9). Apart from this, in 1960, the military regime in Pakistan surrendered, under the Indus Waters Treaty, the three eastern rivers to India along with Sindh's acknowledged share without prior consent or compensation to Sindh, leading to water scarcity in the province.

It is possible to argue that what lies at the very core of the matter is the entrenched notion of 'us' versus 'them', as well as a nagging sense of insecurity on the part of Islamabad that a 'permanently hostile' India, which also happens to be the upper riparian state, might use water resources as a politico-strategic weapon to paralyze Pakistan's economy completely. Such imaginations and suspicions continue to mar India–Pakistani relations, and they also keep alive the bitter memories of the bloody historical circumstances, in which the two 'Midnight Children' were born. Needless to say, the persistence of such hydro-borders makes any solutions of relatively fewer complex issues such as the Tulbul Navigation Project/Wular Barrage virtually impossible.

Similarly, the Ganges water dispute between India and Pakistan (and after 1971 between India and Bangladesh) also had its genesis in partition. The Farakka dispute dates back to 1951 when India decided to construct a barrage across the Ganges at Farakka to divert water to Bhagirathi to maintain its navigability, which was being hampered due to siltation. However, a deeper analysis suggests that Farakka is not only a technical problem involving the issue of water sharing but, as put forth by Begum Khurshida, a 'techno-political tangle' (10, p. 196). Technical debates have intermingled with political rhetoric, narratives, and nationalist myths; Farakka is not only a symbol of Indian domination (10, p. 202) but also projects an idiosyncratic 'upper riparian psyche' that intimidates lower riparian Bangladesh and jeopardizes its water security. The entire history of the dispute and the tortuous course of negotiations over Farakka suggests that what was being negotiated was not the flowing waters, but the strategic resource for nationalist politics between India and Bangladesh.

The Mahakali Treaty of 1996, signed between India and Nepal (concerning the integrated development of the Mahakali river), is yet another example where the ethics of water sharing could not bypass the deeply entrenched issues of sovereignty and (in)security or for that matter ideological contestations. In Nepal, the treaty is considered another sellout of water resources. The treaty is said to be 'the blatant manifestation of domination of Indian expansionism, on one hand, and total surrender to the Indian big brother on the other.' Thus, so far, the dominant trend among the two nation-states has been to perceive water issues both as a major problem area and as a valuable resource to enhance their respective 'national' power and defense (8, p. 167). In the process, the water issues have been (mis)used to sustain conventional geopolitical considerations.

It can also be argued that behind these self-locked positions are the deeply seated hydro-borders, created through various kind of geopolitical perceptions, metaphors/rhetorics/narratives by various protagonists both within and among the sovereign states involved at various levels in the dispute over water issues. As a consequence, water has become a crucial item of resource politics, nationalism, provincialism, and sub-regionalism (10, p. 196). All such linkages have shaped and are central to the elite politics of water and the so-called 'sustainable development' of South Asian waterways.

MAPPING OF RIVERS IN THE 'CARTOGRAPHIC ANXIETY' OF NATION

South Asian states continue to suffer from, what Sankaran Krishna (11, p. 82) calls, 'cartographic anxiety' surrounding the questions of national identity and survival. As meaning is invested in all aspects of cartography, so defined cartography becomes nothing less than the 'social and political production of nationality' itself. And these cartographic representations not only become alive during the election campaign, in the everyday life along the 'border' (see 12), but interestingly enough, different imaginations/mapping of the river that produce hydro-borders are invoked in the construction/representation of 'imagined landscape' or 'national identity' or securing 'territorial unity.'

Pakistan, argues Ian Talbot, has been a state searching for its national identity, and due to persistent failure to find such an identity, ethnic and tribal identities remain strong. Even five decades after its creation, the question remains whether Pakistan is a land for the Muslims or a nation of Muslims moving towards its destiny as a nation? (as cited in Ref. 12, p. 153). In an attempt to define 'national identity,' sometimes 'pasts' are invoked and 'histories are constructed' (12). For instance, in a major restatement (rather 'rewriting of history of the Indian subcontinent') Pakistani historian Aitzaz Ahsan, argues in his work *The Indus Saga and the Making of Pakistan,* that the Indus region (Pakistan) has a primordial existence outside India and centrifugal forces of its own (13). The essential purpose of this work is, in the words of its author, "to discover and define 'Indus person,' the Pakistani citizen." According to Ahsan, history states that Pakistan is said to have existed "for almost five and half thousand of the last six thousand years" and emphasizes that the "Indus has seldom been part of India."

Subsequently, his work contends that the Indian subcontinent has always been at least two different worlds. The divide between India and Indus is civilizational and cultural. There has existed a 'primordial divide' between the two: 'a palpable divide between two lands, two peoples and two civilisations: Indus and India. In fact the twain has seldom, if ever, truly met. Arguing that these differences are deep rooted, primordial, and many, he observes that

> The sub-continent is made up of two civilisations, Indus and Indic or Gangetic and that Indus has been one large, independent, politico-economic zone for the past countless centuries. The truly 'Indic region' comprising the Gangetic plain and peninsular India, on the one hand, and the Indus basin, consisting of Indus river and its tributaries (i.e., Pakistan) on the other. Further, more than the giant mountain range that separate the Indus region from the Central Asia, that discernible hump between Indus and India along a line roughly connecting Gurdaspur, in Eastern Punjab, to Kaithawar on the Arabian sea, has been the critical dividing line of history and culture. It approximates the division between India and Pakistan, thus giving to that border the sanction and strength of history (13, p. 289).

This kind of rewriting of history is an attempt to evade the conspicuous hydrographic oneness/unity of the Indus–Gangetic basin. By ingeniously selecting the facts that serve his 'partitioning and Othering' analyses and fitting his mapping of national identity based on the re-presentation and apt distortion of the 'Indus Basin' hydrographically, historically, culturally, and civilizationally, he is able to suitably construct a 'Indus Person' or Pakistani identity. Further, in reconstructing a narrative of a distinct cultural heritage, Ahsan has traced the civilizational roots of a nation-state that came into being only in 1947, into the distant past (14, p. 19). According to David Ludden, such an attempt which constructs beleaguered historical narratives around partition and sought to inscribe the past with a new meaning, is a feature of the politics of the cultural anxieties that have surfaced lately across contemporary South Asia (14).

In the traditional sense, river has been used as a boundary to define the territorial limits of a state, but to engage in rituals to purify 'frontier rivers' is not only to revive, the sacredness of the river but also to deploy new meaning(s) to the process of territorialization. The two-day Sindhu Darshan festival (the brainchild of Home Minister L.K. Advani), in Ladakh (on the Indian side of Kashmir), where the river Sindhu or Sindh flows before entering Pakistan territory, was at one level a welcome gesture toward integrating far-flung parts of the country into the mainland, whereas, on the other hand, a symbolic attempt to revive the link between 'Sindhu and Hindu', or a ceremony affirming the sacredness of the River Indus. What has followed 'Sindhu Darshan' is the so-called 'Brahmaputra Darshan,' a similar kind of festival in the northeast part of India, 50 km from the IndoChina border (15).

It is important to note that in imagination about India's national identity, there has always been a conceptual space for Hindu nationalism. Further, Hindu nationalism has two simultaneous impulses: a commitment to the territorial integrity of India as well as a political commitment to Hinduism. And in the geopolitical imagination of Hindu nationalists, 'national unity' and 'identity' are based on territory and religion (16, p. 235). Hence, it is argued that such festivals/practices, that are held at the banks of frontier rivers, are an attempt to engage in the process of sacralization and re-territorialization of the 'frontiers' of the nation-state and also to promote and consolidate the notion of 'Akhand Bharat' (undivided, greater India). These examples also reveal how different geopolitical imaginations and representations of the river have provided meaning(s) and a rationale to different cartographic anxieties, a facet of a larger post-colonial 'anxiety syndrome' or as Samaddar says, 'insecurity syndrome' (17, p. 32), surrounding the question of territorial unity and national identity. Needless to say, through representation of a river in a certain way, the state generates a representation of self and in the process the boundary-defying river also becomes a boundary-producing entity.

CONCLUSION

The ethics of sharing water resources posits that water, as a common natural heritage—especially transboundary watercourses, including aquifers—must be managed in an ecologically sustainable manner. But this ethical imperative is undermined as and when domestic geo-political rivalries, conflicting national ideologies, and geopolitical discourses conspire together to produce hydro-borders that are deeply entrenched and frequently (mis)used by the states as instruments or media of social distinction, domination, or control (18, p. 65). In their quest for domestic stability, political legitimacy, regime survival, and identity building, in both religious-communal and secular-national terms, South Asian states continue to articulate and defend a 'national vision,' that has little space to accommodate the concerns of other state or non-state actors. The process of Otherization that continues to make its place, that is, production and re-production of hydroborders in the bilateral or multilateral dialogue between India/Pakistan/or India/Nepal/Bangladesh over the water disputes does not reflect a dialogue of accommodation/agreement or cooperation but a dialogue of disagreement, separation, and partition itself. This also suggests that a new kind of resource geopolitics, in which different power structures are sustained through the discourse and practices, is in the making in South Asia. As long as the logic of Othering, as manifested in the form of hydroborders, continues to make its place in the South Asian geopolitics of water, the prospects for an ecologically sustainable, gender-sensitive, culturally appropriate, and socially just development and management of South Asian waterways is difficult to achieve. The prospects for peace in South Asian region also require that the construction and reconstruction of hydroborders be undermined new, normative and humane geopolitics of sharing and sustaining a common habitat in place of state-centric, power-political geopolitics of mastering space and resources.

WATER TRANSFERS

David L. Feldman
University of Tennessee
Knoxville, Tennessee

Water transfers are the diversion, reallocation, or appropriation of surface or groundwater from one watershed, drainage basin, or aquifer to another. All transfers entail water exchange between catchments. They may also move water from one *political jurisdiction* to another, exacerbating their impacts and complicating efforts to resolve stakeholder conflicts that they generate. In addition, transfers may be endeavored through various *means* including pipelines, tunnels, aqueducts, pumping facilities, or even seaborne tankers—an idea contemplated under proposals to transfer water from the Great Lakes to the Middle East.

MOTIVES AND MAJOR ISSUES

Water transfers are nearly as old as civilization. The first recorded large-scale transfers occurred in the ancient Near East. About 4000 years ago, the Sumerians discovered how to divert the Euphrates River (in what is present-day Iraq) to irrigate crops and reduce reliance on the vagaries of seasonal rainfall. Other nearby societies followed suit and built administrative infrastructures to support transfers, leading to speculation that the need to maintain such infrastructures contributed to the growth of political authoritarianism (1,2).

One motive for transfers is to provide sufficient water to satisfy agricultural, industrial, or other needs to regions perceived to have inadequate water supplies. A secondary reason is to promote regional development. This was a major motive for building diversion projects in the southwest United States in the nineteenth century, for example. For the exporting region, the benefits of transfers include economic compensation and better relations with neighbors. However, exporting regions are not always willing partners in transfers, in part because they may have unintended environmental consequences or may be undertaken without adequate consultation (3). Regardless of motive, *five* major issues tend to be associated with transfers:

- *Adequacy of Return Flow.* Most water transfers involve some return flow to the basin of origin. Issues raised by this return flow include how much and when water will be returned. If the return flow is relatively prompt and abundant, harm to ecological resources from low river levels, changes in hydrology, and/or losses to the local economy due to foregone benefits are likely to be less than if return flows are small in volume and/or late.
- *Loss of Water Rights.* Transfers impose impacts on those who have access to water through legal guarantee. These may be comparable from place-to-place, but remedies available under common law differ among regions. In states that have prior appropriation systems, there has tended to be less recourse to deterring transfers thought to be harmful than in states that have riparian rights systems—although water rights issues arise in *both* systems.
- *Adverse Ecological Impacts.* In general, water transfers generate two distinct forms of ecological impact: to in-stream flow (the volume, flow, and quality of water naturally found in rivers and streams prior to the building of impoundments or diversion projects) and biota transfer (the consignment, usually unintended, of exotic fish or other aquatic species from one basin to another, that adversely affect native species' welfare).
- *Water Agency Objectives.* Agencies that manage natural or cultural resources are affected by water transfer proposals in several ways. Often, transfer decisions are undertaken by an agency to meet obligations to promote regional development through water delivery (e.g., the Bureau of Reclamation). Conversely, an agency charged with protecting natural/cultural areas (e.g., National Park Service) may be reluctant to permit transfers.
- *Adverse Social Impacts.* Although difficult to measure, transfers generate significant, often adverse social impacts comparable to those engendered by other resource allocation decisions involving unequal power and authority, representation, and resource access. Specific impacts include changes in lifestyle, reductions in regional income, fewer opportunities for economic development, and abridgment of recreational amenities.

ADEQUATE RETURN FLOW

Water transfers, especially if large, can have profound effects on the quality of water in the basin from whence water is taken, *and* on the quality of water in the receiving basin. Here, we consider the first of these. Many water transfers involve what amount to temporary shifts of water between basins. Used, often untreated water is rerouted back to the basin of origin. Such return flows are often negotiated in agreements to contract transfers and, in riparian rights systems, may be *required* to ensure that natural stream flow is unimpeded (in general, this is one reason why riparian rights systems discourage transfers).

When transfers are permitted in riparian rights systems, return flows are supposed to occur in the vicinity of the same riparian landholding from which water was originally diverted, and its quality is supposed to be *unimpaired*. Historically, such return flows are rarely monitored in many states, do not occur with regularity, are usually easier to ensure when the transfer is between two adjoining watersheds *in* the same state, and are difficult to measure precisely when they occur. Moreover, if they do not occur during periods of low flow, when most needed, the ecological resources of the exporting basin may be harmed.

WATER LAW AND WATER TRANSFERS

All water law systems predicate certain principles regarding the judicious transfer of water from one basin to another. At the outset, two characteristics of American water law, significant for water transfers, must be noted. First, far more attention has been paid to regulating *surface*, as opposed to *groundwater,* transfers because it is difficult to determine exactly what constitutes a groundwater transfer. Underground aquifers are connected to one another and to surface waters in enigmatic ways often hard to prove in courts of law. Negotiating allocation formulas for surface waters usually entails measuring the amount of water to be apportioned at gauging stations at different seasons of the year and, then, limiting how much water an "upper" state or user can draw, *or* guaranteeing a certain amount of water to the "lower" state or user. For aquifers, however, there is no upper and lower user in the same sense as for surface waters (5).

Second, states may not discriminate in the way they manage out-of-state, as opposed to in-state, transfers. Article 1, Section 9 of the Constitution prohibits states from giving preference, in their regulation of enterprises, to businesses operating within their borders over those based in other states. Originally applied to regulation of ports and vessels traversing interstate waters, the clause has been construed by federal courts to mean that Congress has broad plenary power to regulate interstate commerce, manage and use water for navigation, and regulate nonnavigable streams. It has also been construed to mean that water is a commodity in interstate commerce and states cannot discriminate against one another's ability to engage in such commerce. This is an important consideration in efforts by states to regulate interbasin transfers (see "Conclusions").

Riparian Doctrine and Water Transfers

Under riparian law, the predominant legal system in the eastern United States, a landowner has the right to "reasonable" use of the water flowing past her/his property, subject to the rights of other downstream riparian landowners. Water used but not consumed must be returned to the watercourse unimpaired inquality. In general, diverting water from the drainage area of a watercourse *without* return flow is deemed "unreasonable" and, if a downstream riparian complains, can be expressly forbidden (6,7).

In practice, courts have ruled that "reasonable" diversions are allowable under riparian rights systems and typically define such transfers as those that are socially beneficial and impose no harm. Included under this definition are transfers undertaken for the use and benefit of public supply systems. In practice, definitions of "reasonableness" vary from case-to-case and court-to-court, and riparian doctrine and court precedents are unclear on the conditions for mitigating their adverse impacts. How to ensure adequately timed return flow is also uncertain (8,9). Moreover, a "reasonable use" transfer right can be superseded if a subsequent user can demonstrate a need that is more reasonable (10).

Transfers Under Prior Appropriation Doctrine

Appropriation law, the predominant water rights doctrine in 19 western and southwestern states lying west of the 100th meridian, quantifies and prioritizes water rights according to the "first in time, first in right" principle: the first to put water to a beneficial and reasonable use acquires a right superior to later appropriators. This principle grants use of a specified amount of water for a stated beneficial use each year, subject only to the rights of other appropriators (11,12). Land ownership is not the basis for this right: one can acquire it through purchase or other means. Moreover, water rights exist only when water is appropriated (i.e., diverted and used) for a *beneficial* purpose. Historically, this encouraged transfers.

Traditionally, off-stream uses (e.g., irrigation) were considered beneficial, whereas in-stream uses by fish and wildlife were treated as inherently wasteful (7). Senior appropriators could take their full allotment even if insufficient water remained for junior appropriators' needs. This practice served to bias the concept of "beneficial" to mean off-stream, consumptive uses. More important, appropriated waters could be used virtually anywhere, regardless of the distance from a stream. Most appropriation states now define beneficial use by statute. Preferred uses are explicitly defined, and reforms intended to reduce environmental damage through unregulated transfers, such as prescription of minimum stream flows, have been adopted (13,14).

ECOLOGICAL IMPACTS OF TRANSFERS

Dams, impoundments, pipelines, and other "hydrologic alterations" that enable water transfers may lead to severe changes in in-stream flow volumes, velocity, and quality in both exporting *and* destination watersheds, as well as fragmentation and loss of aquatic and riparian habitat (15,16). An important, but often overlooked impact is *biota transfer*, which can also result in both basins of origin and destination.

The Garrison Diversion Unit (GDU), a large transfer project in the Upper Missouri basin authorized by Congress in 1965, exemplifies these problems. The project has been criticized by Canadians due to concerns that return flows from its irrigation subunits could have negative impacts on fisheries and flood stage levels in the Red River flowing north into Manitoba. Canada claims that Missouri River biota would be transferred into Canadian waters in violation of the 1909 *Boundary Waters Treaty* designed to prevent contamination, diversion, or degradation of the transboundary waters shared by both nations. The project's size and scope have been significantly curtailed since the 1990s, but the biota transfer issue, especially, exemplifies two general problems of water transfers applicable elsewhere: (1) the benefits and costs of transfers may differ across affected political jurisdictions, and (2) uncertainty regarding impacts may be exacerbated by international disagreement. Canadian scientists were much more adamant about the risks of biota transfer than U.S. researchers whose work was sponsored by the Bureau of Reclamation (3).

AGENCY MANAGEMENT IMPACTS

Proposals for transferring water from one basin to another may challenge the responsibilities of an agency charged with protecting environmental quality or cultural amenities (e.g., historically significant sites) located within lands embraced by its mandate. By contrast, the provision of water supply may be viewed as so central to the mandated responsibility of another resource-development agency as to justify transfers and even override other considerations.

An example of how these divergent views may play out is offered by the experience of the National Park Service (NPS) and Bureau of Reclamation (BOR), agencies which have, on occasion, seen their interests conflict over water transfers. Under the National Park Service Act of 1916, NPS is responsible for protecting the natural, unimpaired flow of rivers flowing through its parks and other protected areas. By contrast, since 1902, the BOR has been responsible for developing irrigation and other water development projects in the West.

Generally, the NPS tries to balance its claims to needed in-stream flow against the reasonable desire of states (both eastern and western) to protect appropriative and riparian rights. To achieve this balance, the NPS asserts rights "for quantities determined to be the minimum amounts needed to protect the primary purposes" of a given park (12). According to one Interior Department solicitor, "appropriation for authorized federal purposes cannot be strictly limited by what state water law says is a 'diversion' of water or a 'beneficial use' for which water can be appropriated" (17).

In practice, when agencies cannot agree on conditions for transfers or when the economic and political stakes are high, Congress may intervene as it did in 1947 in requiring the NPS to allow the BOR to construct a water diversion project (the Colorado-Big Thompson Project) through a portion of Rocky Mountain National Park. This project's purpose was transferring water from the uppermost reaches of the Colorado River basin, which rises on the state's western slope, to the Platte River Basin northeast of Denver. The project's water storage capacity exceeds 710,000 acre-feet, and it now irrigates 1,000,000 acres (18). To compensate for potential harm, storage reservoirs were constructed for the project, in part, to ensure adequate in-stream flow to Upper Colorado River users and to permit reliable transfers to the eastern slope.

ADVERSE SOCIAL IMPACTS

All water transfers generate social impacts. In the western United States, where water marketing has gained widespread acceptance as a means of diverting water from low- to high-value uses, these impacts can be considerable. Studies show that water marketing in conjunction with transfer can be unpopular, especially in an importing region. In the San Joaquin Valley of California and the Grand Valley of western Colorado, two potential water-exporting areas, residents it was found, were more likely to oppose water transfers than residents of water-importing areas. Concerns included potential impacts to residents' economic welfare and way of life and whether allocations between exporting and importing regions provide for reciprocal benefits such as protecting future needs and preventing adverse environmental impacts (19). Generally, agricultural interests are more likely than other groups to approve of water transfers and to favor marketing as a tool for enabling such transfers to occur.

Despite such concerns, other studies suggest that water transfers may serve as an effective means of diverting water from low- to higher valued needs and even as a means of *restoring* in-stream flow (20). In parts of the American West, for example, including California, Montana, Nevada, Oregon, Texas, and Washington, special markets negotiated by environmental groups have had some success in reducing volumes of water diverted off-stream for irrigation and maintaining stream flows for fish and other environmental and recreational benefits (20: 14). In at least one instance, governmental entities have actually purchased the rights to in-stream water, establishing, in effect, a "reverse" transfer (21: pp. 5–11).

Potential barriers to this practice include the lack of a physical infrastructure for moving water from place-to-place; ambiguities in water law permitting markets, especially under riparian systems; and 'aligning' the price of water between buyer and seller. An underlying investment assumption in such deals is that, over time, transfer of water for restoring in-stream flow will yield a greater benefit than diversion for off-stream uses (22).

CONCLUSIONS—WATER TRANSFER DISPUTES AND THEIR IMPLICATIONS

Since the 1980s, disputes over water supply and allocation have arisen in many parts of the southeast United States, underscoring the fact that *no* region is immune from conflicts over competing demands for water. Sources of these disputes include population growth, urbanization, and competing demands, especially for agricultural irrigation, power, and public uses, as well as debate over how to balance off-stream and in-stream needs (23). One result of these disputes has been plans, real or contemplated, to transfer water from one basin to another.

One of the most contentious of such plans began in 1983 when the city of Virginia Beach, Virginia, indicated its intent to divert water from the Roanoke River to satisfy its growing needs. This led North Carolina to protest the project's potentially adverse impacts on ecological resources and the local economy of that part of the Roanoke Basin in the latter. After a nearly 15-year battle costing upward of $12 million, the project was approved after court challenges failed to demonstrate convincingly adverse effects from plans to divert approximately 60 MGD. A continuing legacy of this dispute, however, is the precedent which it may have established for *additional* diversions, as well as *how* to measure adverse impacts: as present-day losses or as potential future ones (24,25)?

Recently, conflict between Alabama, Florida, and Georgia over water allocation in the Apalachicola–Chattahoochee–Flint basin led some Atlanta-area officials—contemplating an eventual ceiling on withdrawals from a tri-state water compact—to look elsewhere for new supply. Among options explored, beginning in 1998, was the possibility of diverting water from the Tennessee River in Southeast Tennessee via pipeline. The mere consideration of this alternative partly convinced officials in Tennessee of that state's vulnerability to outside demands and led the legislature to pass an *Interbasin Water Transfer Act* in 2000 to regulate transfers of water from a basin originating in Tennessee to any other basin—in or outside the state (26–28).

These and other disputes over water transfers are instructive for one major reason: they underscore that decisions to undertake, or to deny, transfers, though partly based on perceived needs and environmental concerns, often result from the distribution of power and authority. Worldwide, a significant impediment to different jurisdictions reaching common accord on water allocation, and coming into conflict over transfers, is the perception by protagonists that they lack adequate influence over the outcome of negotiations or the ability to leverage decisions.

Oftentimes, this lack of influence is manifested in a lack of legal or economic tools (e.g., equitable water markets, effective regulatory frameworks, infrastructure to allocate water and manage competing demands) to resolve disputes. Just as inequalities of power and resources have been recognized as inhibiting durable solutions to water conflicts between, for example, Israel and Jordan, and Israel and the Palestinian West Bank (especially when compounded by secrecy and fundamental value differences), they may also inhibit compromise and accord among states within a nation (29–32). Likewise, when countries—like states within a country—find the means to cooperate, it is often the result of developing conjoint, equitable cooperative management schemes that are adequately funded, as in the Mekong River basin states of Thailand, Cambodia, and Vietnam, for example (33). The challenges facing transfer decisions are formidable, but opportunities for working toward common solutions are plentiful.

RESERVED WATER RIGHTS FOR INDIAN AND FEDERAL LANDS

EVE WOODS
Denver, Colorado

Most rights to the use of water are created under state law. In general, states east of the Missouri River follow riparian law and the nineteen contiguous western states follow the prior appropriation doctrine or a hybrid of the two. The federal government has a strong policy of deference to state water law. However, some federal lands and tribal lands have a unique type of water right that occurs under federal law. These "reserved water rights" attach to federal lands that the Government kept or set aside for particular purposes and to Indian reservation lands that are held for the benefit of a federally recognized American Indian tribe.[1]

Historically, the United States set aside land from the public domain for federal purposes such as parks and national forest without taking the actions necessary to establish a water right under state law. It also negotiated treaties with American Indian Tribes that failed to address the question of a water supply for the lands set aside for the tribe. The doctrine of reserved water rights is based on the contract law theory that the federal government intended to reserve adequate water for itself when it set aside land for federal purposes, even though it did not say so expressly in the document setting aside the land (1). Likewise, when an Indian tribe reserved some of its land for itself while ceding the rest to the United States by treaty, this doctrine recognizes that the tribe must have intended to reserve some waters for itself, to make the land it reserved useable.

The United States Supreme Court first recognized a reserved water right in the 1908 case of "Winters v. United States." The Court held that the Fort Belknap Tribe in Montana and the United States had impliedly reserved water for the Fort Belknap Reservation via their treaty of 1888. The Tribe was awarded 5000 acre feet of water from the Milk River for irrigation use on the Reservation, with a priority date of 1888, which gave the tribal water right priority over the rights of the upstream settlers who had begun farming the area in 1898. Reserved water rights are also called "Winters rights" after the name of that case (2).

From 1908 to 1963, the reserved rights doctrine was applied only to tribal water rights, and rarely at that. In 1963, in *Arizona v. California*, the reserved rights doctrine was extended to provide water rights for nontribal federal lands as well.

Reserved water rights share some characteristics with both riparian water rights and prior appropriation water rights. Reserved rights are riparian in the sense that they extend to the waters adjacent to or beneath the lands that they serve (3). They are riparian because they exist independent of whether the water has been diverted or applied to beneficial use. The full quantity of the reserved right develops in lieu of use and cannot be lost by nonuse. However, unlike riparian rights, a reserved right has a priority date. It is administered within the prior appropriation system—"first in time is first in right"—and so has the power to call out junior users in times of water shortage.

QUANTITY OF THE RIGHT

The quantity of a reserved water right is "that amount necessary to fulfill the purposes of the reservation" (4). It encompasses both the current and the future needs for water on the reserved lands (5).

This amorphous quantification standard has been difficult to implement. For federal lands set aside under an Act of Congress, the Congressional purpose stated or implied in that Act is the "purpose of the reservation" used for measuring the water right (6). The court uses expert testimony to determine the amount of water necessary to preserve wildlife or habitat, or to meet whatever purpose applies. If the land was set aside for more than one purpose, there can be only one reserved water right, and it will only be enough water to meet that primary purpose of the reservation (7).

Until recently, quantification of tribal reserved water rights was usually based on the PIA standard, i.e., enough water to grow crops on the "practicably irrigable acreage" of the Indian reservation, which was because many treaties stated that the purpose of the reservation was to develop a viable agricultural economy, intending that the tribal members would assimilate to the lifestyle of the nonIndian farmers who were then settling the West. To determine the number of practicably irrigable acres, courts look to economic and engineering experts to determine for how many acres the economic benefits of growing crops

---

[1] A list of federally-recognized tribes is published annually by the Department of the Interior in the Federal Register.

will at least equal the costs of transporting and applying the water to the land (8).

More recently, an Arizona court rejected the PIA standard in favor of a "homeland" standard for quantifying tribal reserved rights (9). The purpose of the reservation in that case was not agriculture, but was to provide a permanent homeland for the tribe. The court held that determining the minimal amount of water necessary to accomplish the homeland purpose—both now and in the future—would require analysis of six diverse factors concerning the tribe's cultural practices and the potential for economic development on the reservation. That new test has not yet been applied by any court.

The quantities of reserved rights vary greatly. They range from one thousand acre feet to hundreds of thousands of acre feet. Many tribal and federal reserved rights have yet to be quantified. The eventual use of those reserved rights will have a potentially enormous effect on the amount of water available to junior users on those streams.

McCARREN AMENDMENT

Although they are created under federal law, reserved water rights can be adjudicated by state courts (43 U.S.C. § 666). In the McCarran Act, the United States Congress waived federal sovereign immunity from suit to allow state courts to join federal claims into a comprehensive adjudication of a river system or other source. This 1952 Act prompted many western states to revise their statutes to allow for general stream adjudications, thereby forcing the quantification of reserved rights claims. Such adjudications are complex, requiring inter alia, a field analysis of each water claim in the basin to determine the quantity and priority date of each right.

PRIORITY DATE

The priority date of a reserved right is the date of the federal act or tribal treaty reserving the land, which is usually a relatively early right that will have priority over all water users who settled the area after that date. Under certain circumstances, a tribe may have a "time immemorial" priority date for its reserved right. This water right is, by definition, the earliest right on the stream (10).

The Pueblos of New Mexico also have time immemorial water rights. However, Pueblo water rights are not reserved rights. The quantity of a Pueblo water right is limited to past beneficial use and cannot be expanded to meet current or future Pueblo needs (11). Like reserved rights, Pueblo rights cannot be lost for nonuse.

WETLANDS POLICY IN THE UNITED STATES: FROM DRAINAGE TO RESTORATION

Andrea K. Gerlak
Columbia University
New York, New York

Historically, swamps have been regarded as wastelands, evoking reactions of "disgust at their sight and smell, fear of malaria and yellow fever, and unease about rich resources running to waste within them." George Washington's leadership in the Great Dismal Swamp Company characterized early notions of swamps. The Company, designed to drain Virginia's swamp for timber production, promoted the notion that swamps were useless lands (1). The Swamp Land Acts of the 1850s are a further illustration as the federal government encouraged states to "reclaim" nearly 6.5 million acres of wetlands.

By the beginning of the twentieth century, perceptions began to change. Sportsmen and hunters called attention to declining number of waterfowl and initial federal efforts regarding wetlands focused almost exclusively on waterfowl habitat. In 1903, President Theodore Roosevelt established the first National Wildlife Refuge by executive order to protect endangered species on Pelican Island, Florida. With the Migratory Bird Hunting Stamp Act of 1934, Congress established a special fund to finance wetland acquisitions for duck habitat.

Despite such efforts, however, water resources continued to be managed largely for economic development purposes. The U.S. Army Corps of Engineers (Corps) became a key instrument in "modernization" during America's era of industrialization (2), and exerted broad discretion by undertaking improvements in the navigability of the nation's waterways under the 1880 Rivers and Harbors Act and the 1899 Refuse Act. Many federal programs provided incentives for wetland conversion, including subsidies for agriculture, grazing and forestry, reservoir construction, and flood relief and insurance.

By the 1960s, environmental values emerged to challenge the old paradigm. Public alarm over declines in many animal species, including the symbolic bald eagle, led to endangered species legislation in the 1960s and 1970s. The term “wetland” replaced “swamp.” The Army Corps inched toward reform as well. In response to an emerging concern for water pollution, the Corps began to revise its permit regulations to take into account “public interest review,” beyond pure economic impacts. Based on *Zabel* v. *Tabb* [430 F.2d 199 (5th Cir. 1970), cert. denied, 401 U.S. 910 (1971)] in 1971, the first federal court case over wetlands, the Corps was granted “ecological authority” to weigh noneconomic factors in reviewing and denying permit applications under its original 1899 authority. Real change occurred from passage of the Federal Water Pollution Control Act of 1972. Known as the Clean Water Act (CWA), this legislation marked the beginning of broad-based wetlands protection in the United States. Wetlands came to be valued as biologically diverse ecosystems providing great public benefits such as improved water quality and protection from floods. This marked the beginning of federal efforts at wetlands protection. During the next 30 years, wetlands management would become highly politicized (3).

WETLANDS, LEGISLATION, AND LITIGATION

By the Federal Water Pollution Control Act amendments of 1972, Congress established a comprehensive program of regulations and permits to control water pollution. Section 404 of the CWA marked the first federal policy designed to preserve wetlands. Section 404(b)(1) states that “the guiding principle should be that degradation or destruction of special sites may represent an irreversible loss of valuable aquatic resources.” In less than two pages, Congress established a shared authority between the Army Corps and the newly created U.S. Environmental Protection Agency (EPA). As a political compromise, the Corps was designated as the lead agency to administer the permit system for discharging dredged and fill materials into navigable waters. The Corps’ preliminary permit decisions would then be reviewed by the EPA that had authority to veto the Corps’ decision. This compromise, although appearing innocuous, would complicate and burden Section 404 implementation.

A historic tradition in water resource management, the Corps embodied the older distributive/allocative model of policy-making, referred to as the “pork barrel.” Such an approach allowed a high degree of local and state agenda-setting autonomy. The newly created EPA, meanwhile, embraced the new, centralized regulatory model, referred to as “command and control,” and focused primarily on water quality. Given the distinct organizational culture of the agencies (4) implementation of Section 404 immediately was characterized by conflict between the EPA and Corps. Generally, the Corps preferred a limited approach, whereas the EPA pushed for expansive authority to regulate all wetlands in the United States.

The federal judiciary would play a powerful role as environmental groups challenged the Corps’ implementation and regulatory practices. By *Natural Resources Defense Council* v. *Calloway* (392 F. Supp. 685) in 1975, the U.S. Supreme Court pushed the Corps towards broader wetlands protection and forced the Corps to revise its regulations to include significant intrastate waters, in addition to interstate waterbodies. This case sparked debate in Congress and by the 1977 amendments to the CWA, Congress refined and expanded its definition of wetlands demonstrating a clear congressional commitment to wetlands protection. In response to industry concerns, however, the amendments allowed exemptions for ongoing normal ranching, farming, and silviculture.

President Carter attempted to create a more unified wetland policy by issuing Executive Order 11990 (42 Fed. Reg. 26 (1977). In calling on all federal agencies to minimize wetland loss on land managed by the federal government, this action represents the highest administrative action ever taken to protect wetlands. Two year later, Carter’s Attorney General Benjamin Civiletti gave greater weight to the EPA in wetlands implementation [43 Op. Attorney General 15 (1979)]. In attempting to resolve interagency disputes, he determined that the EPA enjoyed ultimate authority to decide the scope of wetlands regulation because that agency carried the responsibility for implementing the other sections of the 1972 CWA.

The courts pushed wetlands protection even further with *U.S.* v. *Riverside Bayview Homes* (474 U.S. 121) in 1985. Here, the U.S. Supreme Court issued a landmark decision in wetlands policy. By defining the waters covered broadly, the Court ruled that the Corps and EPA could regulate wetlands even when no surface water or other apparent hydrologic connection exists between the wetlands and an adjacent waterbody.

THE POLITICS OF WETLAND MANAGEMENT

At about the same time that it enacted the CWA, Congress passed legislation that brought still more federal agencies and departments into the wetlands policy arena. A 1970 statute, The Water Bank Act, created a federal program that paid farmers to preserve wetlands habitat for waterfowl. Administered by the Department of Agriculture’s Soil Conservation Service (now the Natural Resources and Conservation Service), this program has grown significantly during the past 30 years. In 1973, still another dimension was added when Congress passed the Endangered Species Act (ESA). Administered by the U.S. Fish and Wildlife Service (FWS), this highly controversial statute added another federal player to the list of agencies implementing the wetlands protection policy. Consultation with the FWS became the norm because so many wetlands are home to endangered and threatened species. In some situations, the FWS has been given the authority to manage sensitive wetland areas. For example, in 1973, more than 107,000 acres of the Great Dismal Swamp was deeded to the Department of the Interior for the creation of the Great Dismal Swamp National Wildlife Refuge. How far we have come from the days of George Washington’s Great Dismal Swamp Company. Thus, during the last 30 years, the FWS has become an integral component of national wetlands policy.

By the end of the "environmental decade" of the 1970s, at least four federal agencies had major responsibilities for protecting wetlands. A number of other federal agencies, including the Forest Service, the Bureau of Reclamation, and the Bureau of Land Management, had ancillary responsibilities. Table 1 provides a list of the primary federal agencies involved in wetlands protection today.

Other legislation added several more bureaucratic participants to an already crowded landscape. For example, the Farm Service Agency in the Department of Agriculture came to administer and enforce the Swampbuster provision contained in the 1985 Farm Bill. This disincentive program denies federal farm program benefits to producers who plant an agricultural commodity on converted wetlands. Officials of the Corps believe that Swampbuster has significantly reduced agriculture-related Section 404 permit applications (6). Environmentalists, however, have been critical of the program and the Corps' inadequate enforcement of it (7). Nonetheless, beginning in the 1980s, falling agricultural prices coupled with this shift in federal wetland policies helped reduce agriculture-related wetland loss. According to the U.S. Department of Agriculture analysis, wetland conversions on agricultural lands nationwide slowed to less than 30,000 acres per year between 1987 and 1991, down from 51,000 acres per year between 1982 and 1987 (8, p. 234). However, the building boom of the 1980s increased urban wetlands conversion to 89,000 acres per year, or 57% of the total gross conversion (9, p. 21).

Table 1. Primary Federal Agencies Involved in Wetland Protection[a]

Federal Agency	Role in Wetland Protection
Department of Defense, Army Corps of Engineers	Administers wetland permitting and enforcement under Section 404 of the Clean Water Act
Environmental Protection Agency	Performs oversight over Corps' permitting process and enforcement
Department of the Interior, Fish and Wildlife Service	Reviews Section 404 permit applications, makes recommendations to the Corps, and promotes voluntary restoration programs
Department of Agriculture, Farm Service Agency	Manages voluntary programs to help protect and restore wetlands associated with farmland
Department of Agriculture, Natural Resources Conservation Service	Delineates wetlands under farm bill legislation and provides technical and financial assistance to landowners to restore and enhance wetlands
Department of Commerce, National Oceanic and Atmospheric Administration	Initiates wetland restoration activities associated with marine ecosystems

[a] Reference 5.

In the modern era, implementation of Section 404 has been characterized by heightened polarization of competing interests and politicization of science. The polarization of interests can be traced to the wetlands manual debate of the late 1980s and early 1990s. In 1987, agencies moved to adopt a single manual to delineate wetlands during the permit process. Economic interests, led by the Farm Bureau and the National Wetlands Coalition (NWC), vehemently opposed such efforts. Mobilized under the NWC, this coalition of agriculture, oil, mining, utilities, and real estate developers, strove to "work with Congress and the Administration for legislative reform of regulatory improvements to the federal wetlands permitting program" (10). By drafting legislation and lobbying members of Congress, NWC seeks to protect private property rights and streamline the regulatory process to offer greater regulatory flexibility.

The White House responded with a proposal that restricted the Corps' and EPA's jurisdiction by narrowing the definition of a wetland. Environmental critics charged that the Bush Administration's 1991 manual would write off some 20 to 40 million acres of wetlands (11, p. 5). Field tests of the manual indicated that 30–80% of land delineated as wetlands in the 1989 manual were excluded by the 1991 manual (12). The debate over a politically acceptable definition of wetlands was never resolved. Implementing agencies returned to the 1987 wetlands manual for the wetlands delineation process. Congress eventually moved the wetland delineation issue out of the political arena and into the scientific one. In 1992, Congress authorized a study of wetlands by the National Research Council. Released in 1995, the National Research Council's report, titled "Wetlands: Characteristics and Boundaries," contained a scientifically grounded wetland definition and more than 80 recommendations for improving federal wetlands regulation (13). The report still awaits serious attention and implementation.

Most recently, the debate has focused on the 2001 Supreme Court decision, *Solid Waste Agency of Northern Cook County v. U.S. Army Corps of Engineers* [121 S.Cf. 675]. In this case, a county solid waste agency sought permission to develop a disposal site on 17 acres of land that contained isolated, seasonal ponds used by migratory birds. By a 5–4 decision, the Court denied CWA protection to isolated, nonnavigable ponds and wetlands contained within a single state under the Migratory Bird Rule. In doing so, the Court "reversed elements of more than 15 years of federal jurisdiction when it ruled that the federal government overstepped its authority in regulating certain isolated wetlands" (14, p. 2). Regional offices of the Corps and EPA were then instructed to withhold clean water protection from those types of isolated waters and to seek guidance from headquarters in determining whether to protect other small intrastate streams and waterways that enjoy federal protection (15). Both environmental and industry representatives agree that there is a need for congressional guidance following this ruling. Of course, both sides have radically different notions of what that response should entail.

THE MODERN DEBATE: WETLANDS CONSERVATION AND RESTORATION

Today, the wetlands debate has been framed by a “no-net-loss” goal. Adopted from the National Wetlands Policy Forum, a task force convened by the Conservation Foundation at the request of the EPA and headed by New Jersey Governor Thomas H. Kean in 1988, “no-net-loss” means conservation of wetlands whenever possible and that acres converted should be offset through restoration and creation, thereby, maintaining or increasing the wetland resource base (16). Every president since George H. Bush has adopted this approach, and in doing so, the debate has been framed around acreage. As such, it is the numbers that matter. Wetland values and functions become less important. Recently, the National Academy of Science’s (NAS) Committee on Mitigating Wetlands Loss reported that it is “not convinced that the goal of no net loss for permitted wetlands is being met for wetland functions” (17, p. 3). According to the NAS, insufficient data exists to determine if the goal was even being met.

What has been determined is that wetland conversion rates have dropped during from 458,000 acres per year during the 1950s–1970s to 58,500 acres per year in the 1980s–1990s. This amounts to an 80% reduction in average annual loss from the prior decade (18, p. 9). Figure 1 displays wetlands loss from the 1950s to the 1990s. Conservation programs have helped stem wetland loss nationally. Recent reauthorization of the North American Wetlands Conservation Act where the federal government matches donations for state wildlife agencies, conservationists, landowners, and sportsmen demonstrates this. So too does reauthorization of the Wetlands Reserve Program, which provides financial incentives to farmers to restore and protect wetlands through long-term easements. Congress has elected the conservation approach as opposed to amending the Section 404 permit process. Employing incentive programs like these, as opposed to regulation, are understandably more popular with the public than the Section 404 permit process.

By focusing on wetlands acreage framed by the “no-net-loss” goal, restoration strategies have emerged as the preferred policy solution, attempting to reconcile economic growth and wetland protection. Restoration efforts are becoming increasingly popular as a strategy to mitigate wetland losses and counter past development. Restoration of the Florida Everglades, a joint federal–state effort at an estimated cost of $8 billion over the next two decades, represents the largest ecological restoration project ever attempted. Despite restorative successes of coastal areas (19), however, some scientists are increasingly concerned that hard to create wetlands like bogs and fens are being replaced with common, easy to create wetland types such as cattail marshes (20). Moreover, the National Research Council reports that restored wetlands often cannot re-create natural levels of biodiversity and sustainability (21). In the coming years, the debate over wetlands protection is likely to focus as much on the *quality* of wetlands as it does now on the *quantity* of acres restored.

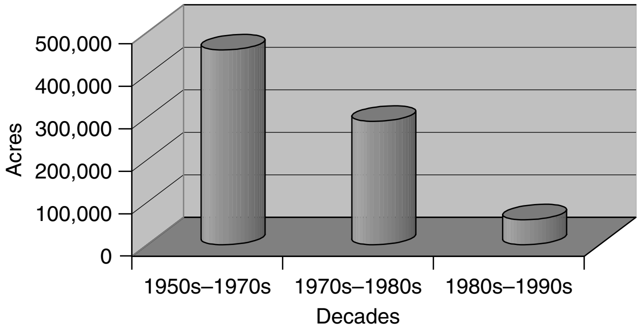

Figure 1. Wetlands loss figures for the mid-1950s to mid-1970s, mid-1970s to mid-1980s, and 1986–1997 (18).

CONCLUSION

In summary, by the 1960s and 1970s, environmental values challenged wetland drainage and destruction practices. Passage of the Clean Water Act marked the first significant federal efforts at wetland protection. Wetland management during the past 30 years has been characterized by litigation, an expansion of federal agency involvement, polarization of interest, and a politicization of science. We have not yet achieved the “no-net-loss” goal, but conservation programs and restoration efforts have helped to stem wetland loss nationally. Will they be enough to protect the wetlands that remain in the United States? Only time will tell.

WATER HISTORY, ART, AND CULTURE

CURIOUS USES OF AGRICULTURAL WATER IN THE WORLD

Eric P. Mollard
Institut de Recherche pour le Développement
France

The agricultural use of regularly flooded zones along large eastern rivers, from the Nile to the Yangtze, goes back to the births of cities and almost to the birth of agriculture. Elsewhere, wetland farming has been heterogeneous. Initially, marshes, flood plains, and coastal areas were sparsely reclaimed, whereas nearby identical wetlands were forsaken and are still unchanged today. At a later time, public intervention based on resource and technology resulting from the Industrial Revolution undertook a lot of total draining. The territorial gain for modern agriculture was accompanied by a dramatic loss of specific advantages such as incomparable aquatic and land biodiversity which can also serve agriculture.

Wetlands show two contradictory characteristics: they discourage and they attract. They are inhospitable because of the fear of marsh fevers, wizards, and legendary animals. More prosaically, great land fertility and moisture are beneficial at the cost of hard labor, not in the direction of general draining, but in that of the work for horticulture. The promise of such lands that have high productivity and are healthier when water is under control, could overcome the fears, real or imaginary, of the wilderness.

The physical duality of high productivity and unhealthiness was translated over time by a social duality, especially between natives and foreigners. Natives supplemented their livelihood by fishing and collecting reeds in a common resource land. The cases of fever were undoubtedly used to keep young people or free riders from defying the elders' authority and to discourage foreigners from seeking free lands. Due to a spooky atmosphere on foggy days, the local populations ended up believing in evil spells launched by their ancestors. Where the foreigners succeeded in settling, one often noted a dramatic social reversal. Indeed, through intense labor and the great fertility of the marsh soils, the last ones to settle became the first. The Aztecs in old Mexico epitomized such history. In the twelfth century A.D., a tribe, originating from the arid north and vassals of the kingdoms occupying the high plateau, could settle only on the immense lake that occupied most of the Valley of Mexico and had a few small islands full of snakes. Tenaciously, the Aztec people created a lake-based agriculture, the chinampas, that enabled them to build one of the largest cities in the world and to subjugate the neighboring kingdoms later.

The relation between wetlands, foreigners, a power that can become an empire, old legends, and current speeches from many stakeholders confers an integral social history on this environment. However, it would be erroneous to believe that the curious uses of water result today only in some anecdotes and relics. Two examples suffice to show how this history is not finished. The mulberry tree dikes on the Pearl River in China are a contemporary and extremely long-lived peculiar use of water. The second example is even more dynamic. The delta of the Chao Phraya River, which used to be a rice bowl in Thailand, is becoming a second Holland; it has horticulture for export, thanks to the technique of raised gardens.

The peculiar uses of water in agriculture prove to be invaluable elements in understanding the relation between water and societies, as well as in designing alternatives to commonplace agriculture instead of the common thought of large polder and irrigation schemes. In this article, we distinguish two types of uses: "raised" style and "hollow" style. The first refer to peasant reclamation, on an individual basis but as a large extension, whereas the second deal with some types of irrigation. The most curious feature of the story is that a local peculiarity is not so peculiar on a planetary level. Inventive men have found similar solutions on every continent.

THE AGRICULTURE OF HOLLOWS

The agriculture of hollows is not a simple adaptation to marshes and lowlands. It embraces the entire range of intensification from floating gardens to cultivated ponds.

Floating Agriculture

Nowadays, vegetables are still grown on natural, floating vegetation rafts or rafts man-made of reed bundles. They are used sometimes as seedbeds before firm ground transplanting. Floating gardens are located on some large lakes in Asia, Latin America, and Africa. Those of Lake Inlé were rediscovered when the border opened in Myamar, whereas those of Lake Dahl, in Kashmir, are less known. Several Chinese lakes, such as Lake Tien close to Kunming in Yunnan, would have witnessed this type of water farming. On Lake Titicaca in the Andes, the rafts of reed are platforms with fishing holes, as in an ice barrier, several thatched houses, some animals, and a small garden. It is not exactly a floating garden because agricultural activities take place on firm ground. On Lake Chad, the natural floating islands are used by fishermen who must continually move under penalty of sinking. In Yap, in Micronesia, the taro is sometimes cultivated on floating gardens cut in the marsh.

Former Chinese authors distinguished two types of rafts: wooden platforms and rafts made of reeds. Both were used for growing rice on the marshy edges of rivers, where a dike would have been difficult to build. Nowadays, the wooden rafts have disappeared, and the floating gardens

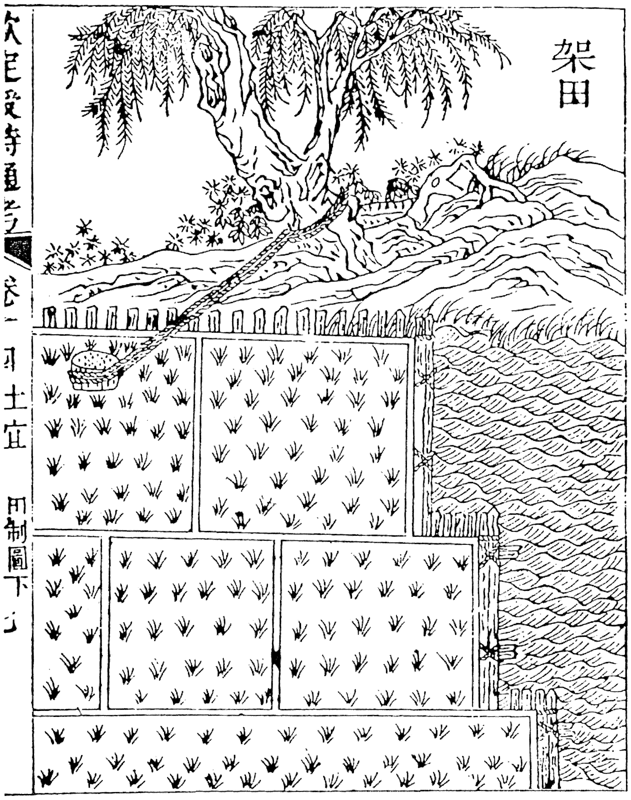

Figure 1. Floating fields.

on reeds are used for more lucrative market gardening (see Fig. 1).

Floating rice growing is a type of flood farming. When the water depth does not exceed 1 meter, one speaks of deep water rice growing with stand bearing and fast lengthening varieties; some of them survive short immersion. Beyond 1 meter, rice varieties have floating stems that lengthen in more than 5 meters of water and lie down when the water recedes. Such farming still exits in the extensive basins along the unprotected rivers in Asia (Chao Phraya, Ganges, Irrawaddy, and Mekong) and in Africa (the inland delta of Niger in Mali). If the water lasts, the harvest takes place in boats. The light work required during the season enabled a family to cultivate up to 20 ha. The great surplus fed the clergy, the warriors, and the rulers of the Angkor Empire in Kampuchea.

The Qochas

In the Quechua language, qocha means lake and generally, any artificial or natural basin. The qochas form connected sets of basins. The stretches of land that separate them are dedicated to animal breeding. Qochas are found in a few areas of the Bolivian and Peruvian altiplano at an altitude of 3850 meters, in particular in the department of Puno. Qochas have three basic forms: round, oblong, and rectangular (see Figs. 2 and 3). Most frequent are round ones that measure between 30 and 200 meters in diameter and have an average surface of 6,000 m^2. The rectangular ones are 150 m by 30 m. Whatever the form, the base is horizontal and the depth varies from 1 to 6 meters (on average, 2 m). Its diameter is crossed by a deep furrow through which water arrives and leaves; the base is surrounded by one or two circular furrows. Perpendicular furrows join the soft sloped edges. The qocha is used as a cultivated field or water tank. Its size is generally expressed in *masas*, the surface plowed by a team of two men and one woman in 1 day. Each family has six or seven *masas*. The crops are mainly potato, qaniwa, and kinuwa, rotating with oats, barley, corn, or a grazed fallow of variable duration.

The Diked Fields

Bordo and caja, dike and basin field, respectively, are words indiscriminately used for many techniques of counterfields or diked fields in Mexico. In tune with farmers, it is preferable to use a neutral terminology because, behind the appearance of a similar technique, the functions and practices vary according to site: flooded banks of a lake or river, rivers of a torrent, or mountain valley. Among the agricultural effects of the use of the technique are irrigation, protection against flooding, fertilization, control of weeds and pests, and water storage.

The Mexican midwest is a string of basins partitioned by volcanic cones of all sizes; many basins do not have natural discharge systems. Before the reclamation of many lakes, flooding was inescapable, and not very deep lakes retracted in dry season. Individual or organized diked fields were both used. Earth embankments measured between 60 centimeters and 2 meters high. They enclosed a surface ranging from several to more than 50 ha. A master diked field was filled by tapping a river or a source. In rainy years, the secondary diked fields were filled,

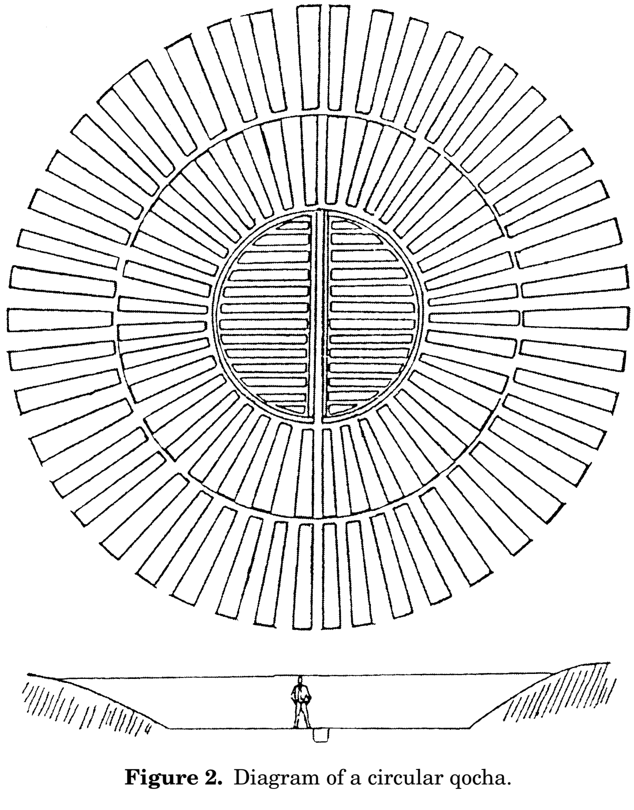

Figure 2. Diagram of a circular qocha.

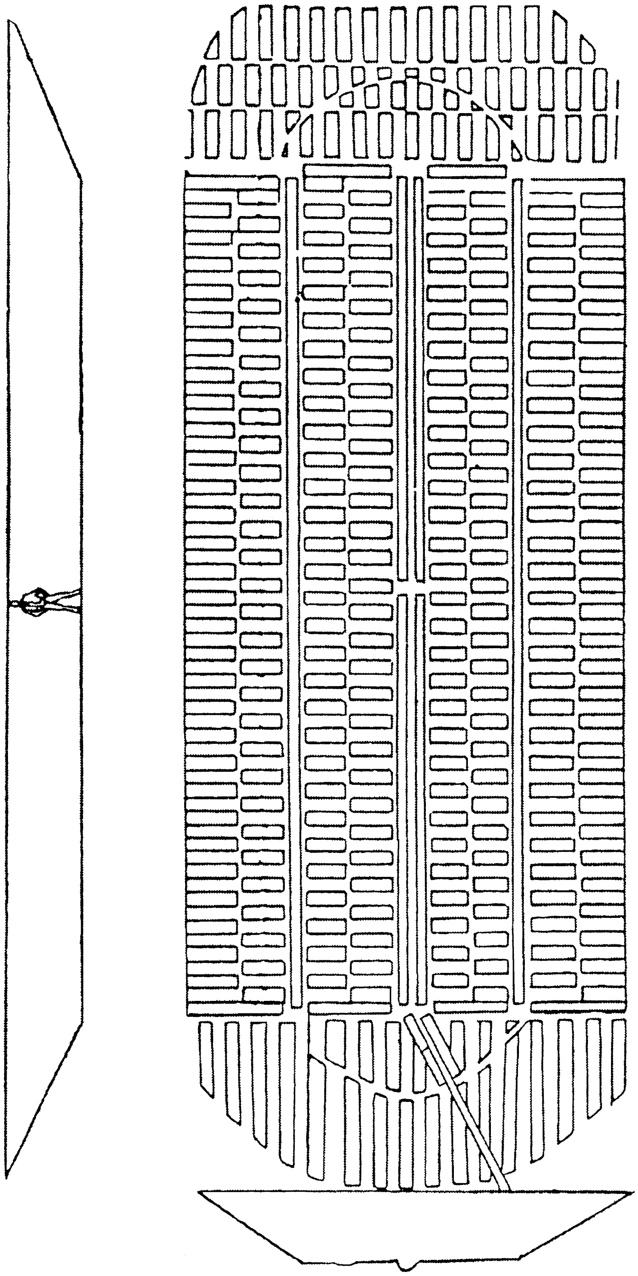

Figure 3. Diagram of a rectangular qocha.

too, to irrigate tens of hectares of wheat and sugar cane inside and outside the diked fields. In dry years, the fields downstream of the only master diked field were sown in chickpea, which received only one irrigation. Owing to the damp soil, the diked fields were farmed themselves with the same chickpea. The dry years provided a considerable surplus of quality fodder which made it possible to feed the cattle of the haciendas and also large pigsties. This region of Mexico is still the greatest industrial pig-breeding area in spite of the disappearance of most bordos during the twentieth century.

The haciendas built the systems of diked fields. After the agrarian reform, many of them were shared with many peasants who were unable to maintain such extensive systems. However, it is possible nowadays to find some diked fields used for lentil and chickpea farming.

Cultivated Ponds: Dombes and Pearl River

Dombes constitutes a undulating basin northeast of Lyons, France. The singularity of the area rests on 1 year of the crop, the assec (or dry pond), which alternates with two years of ponding, the évolage (the root eve comes from the Latin aqua). Agrifishing activity is closely connected with rights on water and land. These rights are contradictory to the French law that does not allow a land to be flooded by a dam built by a neighbor. Only a combination of circumstances and powerful events have perennialized this agriculture.

Dombes is a relatively wet area where clay soils are difficult to work and prevent agriculture from developing. As an independent principality until 1762, it was used as refuge against invaders. The proximity of Lyons, a gastronomical center requiring fresh fish of high quality, and the political independence of the close Dombes, which made it possible to maintain a special law there, are the causes of this agriculture. Indeed, each pond is a particular case combining technical adjustments and contractual agreements between landowners, the owners of the water and dam, and the sharecroppers growing assec, as well as the stakeholders upstream and downstream who can benefit or be affected by runoff, flooding, or water scarcity.

The technique of mulberry tree dikes associated with a fishing pond draws its peculiarity from the narrow association of farming and fishing. These joint activities are more productive than as separate activities. If integrated agriculture is well represented in China and in Vietnam, it seems that the delta of the Pearl River has world exclusivity in the association of the mulberry tree and fishing ponds. In the northern deltas, the frosts damage the mulberry trees and, in the south, heat and extensive flooding limit fish farming. Other situations in the world share this context, but they lack population and markets, which govern integrated agriculture, and the skills required in silkworm farming that the mulberry leaves supplied.

THE AGRICULTURE OF RAISED STYLE

The Gardens of the War

In the 1970s, the remote valleys in the center of New Guinea revealed a Stone Age society. The agriculture of the Dani tribes there is curious. Tuber crops are grown on raised fields built in marshes with spatula-ended sticks and worked by hand. A few-year fallow is characteristic of semi-intensive agriculture. Furthermore, they are "gardens of war" insofar as watchers prevent the raids of enemy tribes that seek to steal the working women. The Dani supplement their production with tubers produced in slash and burn farming. In such a society, where production is not for marketing, unlimited labor is first a social activity, as well as war.

Chinampas and Hortillonnages

Hortillonnages are raised beds from 0.80–1.50 m high. They are separated by ditches and right-angle channels;

both are full of water all year. The drainage makes the roots of the plants safe and gives them the possibility of benefiting from the soil fertility and permanent irrigation. The variety of raised fields in the world provides many local adaptations. The term "Chinese beds" must be reserved for raised beds constructed each season in paddy fields. As for the denominations of raised beds, drained fields, ridged agriculture, poldered fields, campos elevados, camellones, and chinampas, they apply to simple banked-up beds, more or less permanent traditional beds, furrow irrigation, and the various market gardening types. The French language has the specific term of hortillonnages. An unverified anecdote credits Julius Caesar with the use of the term hortilani (perhaps for garden) when he crossed the Somme river near Amiens. Dani from New Guinea show that this type of wetland use is accessible by technology from the Stone Age and that it can be old.

Classification must distinguish seasonal and permanent uses. Seasonal cropping is related to the drying up of channels, flooding, or winter. Permanent cropping is possible in tropical countries; irrigation is ensured, and flooding is controlled. In this case, one distinguishes individual flood control by poldered raised beds on the Thai pattern or by a collective dike on the lakes as was the case at the time of the Aztecs in Mexico. The first pattern includes two alternatives: on the one hand, those crafted for vegetable farming on lower beds (80 cm) that have bent surfaces and, on the other hand, orchard beds $1\frac{1}{2}$ meters high and flat surfaces. For vegetables, construction is by hand to avoid compacted soil, whereas the second option is mechanized. In Thailand, one also finds raised beds for coconut groves where water freely circulates from tides and flooding. In Mexico, Mayas built channeled market gardens where the ditches are dug on the edges of marshes; they are lengthened by traditional embanked raised beds.

In Europe, raised gardens are nowadays located under the cathedrals at the centers of cities, such as in Amiens and Bourges. Some are found in the marshes near Saint-Omer to produce cauliflower. The Atlantic marshes have preserved their raised meadows, but horticulture appeared only between the two wars; the fields were used mainly by cows, which are taken there in small boats. In Latin America, Mexico City nowadays preserves the chinampas in the district of Xochimilco wedged into the urban fabric. In Asia, they do not seem to be more than three centuries old, even in China. In Sumatra and Thailand they are promising a extension for export horticulture. In Burma and Vietnam, their development is still limited. In Java, at the beginning of the century, the surjan technique was developed, which associates rice growing in channels and a mixed crop on raised beds.

Finally, the many archaeological ruins gathered under the term camellon all over the American continent, which are vast undulations, do not necessarily proceed from raised bed or chinampa patterns. They would be closer to the semi-intensive agriculture practiced nowadays in Africa and in the valley bottoms of Rwanda, designed for producing sweet potatoes. Intensive, permanent horticulture requires a market and, as long as no close cities have been identified, camellon ruins bear witness to a more seasonal, low-input horticulture.

WATER BETWEEN ARABS AND ISRAELIS: RESEARCHING TWICE-PROMISED RESOURCES

Clive D. Lipchin
Ann Arbor, Michigan

INTRODUCTION

On November 29, 1947, the General Assembly of the United Nations passed Resolution 181 in favor of partitioning Palestine into a Jewish state and an Arab state. The Zionist movement, which had been preparing itself for statehood accepted the plan, but the Palestine Arabs rejected it. On May 14, 1948, the state of Israel was proclaimed. The borders of the newly proclaimed state of Israel were a strategic nightmare representing two fighting serpents, one the new Jewish state, the other the West Bank under the autonomy of Jordan and the Gaza Strip under Egypt (1). The problems with the borders were many: lack of military strategic depth in the center of the country, an arid south, and a fractured north. No less problematic were access to water resources.

The majority of Israel's water resources are transboundary and are thus, in a sense, shared with her neighbors. The most contentious are the underground aquifers of the West Bank shared between Israel and the Palestinians and the tributaries to the Jordan River that originate in the occupied Golan Heights, which belonged to Syria prior to the 1967 Six-Day War. Since 1948, Israel has embarked on an ambitious development program for the country. The drive behind this program was the Zionist ethos of developing the land to create an attachment between the Jew and the soil. Massive agricultural and water projects ensued in the mid-1950s and 1960s in realizing the Zionist dream. The most significant was the National Water Carrier completed in 1964. The National Water Carrier is a complex system of pipes, pumps, and canals that transfers water from the Sea of Galilee in the north to the arid Negev Desert in the south for irrigation. The repercussions of this interbasin transfer have been the decline of the flow of the Jordan River that flows south from the Sea of Galilee to the Dead Sea. Today, the Jordan River is a trickle of its former self, and the Dead Sea is at its lowest level ever.

Since the mid-1980s, agricultural expansion has declined in Israel and has been surpassed by rapid industrial and urban development. Although agriculture is still the primary consumer of water in the country, the growing industrial and urban sectors require more and more water. In 1948, the Jewish population was approximately 500,000; today, it is approximately 5 million. At least 30% of Israel's water budget now comes from the aquifer systems that underlie the West Bank. These aquifers are recharged on the eastern slopes of the West Bank within autonomous Palestinian regions but flow westward to the Mediterranean across the 1967 "Green Line" into Israel. Both Palestinians and Israelis claim sole sovereignty over these resources due to this hydrologic reality.

Water has featured prominently in Israel's continuous peace negotiations with her Arab neighbors. Two significant opportunities have occurred in equitably managing these transboundary waters. The first was the shuttle diplomacy of U.S. special ambassador Eric Johnston who was sent to the region by the Eisenhower administration in 1953 and 1954. The second were the Oslo Interim Accords signed between Israel and the Palestinians in 1993 and the Israel–Jordan Peace Treaty of 1994.

THE FIRST PROMISE

During the early 1950s and mid-1960s, Israel embarked on two major public works projects to harness water resources for agricultural development. Both of these projects, the draining of the Hula Swamps north of the Sea of Galilee and the creation of the National Water Carrier on the northwestern shore of the Sea of Galilee, entailed diversion of waters from the Jordan River watershed without any formal agreement between the other riparians of the time, Syria and Jordan. Syria's objections to the projects were focused on the confiscation of Arab-owned land in the region of the swamps and Israel's activities in the demilitarized zones set up after the 1948 War of Independence (2). The rattling of sabers over the Jordan at this time prompted the Eisenhower administration to send special ambassador Eric Johnston to try to resolve the water dispute.

Eric Johnston came to the region with a proposal for a joint water development project to provide hydroelectricity and an irrigation network for the benefit of all the states in the region and, in addition, to create fertile land capable of supporting up to 900,000 Palestinian refugees on the West Bank of the Jordan (1). The plan was based on the Tennessee Valley Authority (TVA), which provides hydroelectric power to seven states in the Tennessee Valley. The TVA is the largest public utility in the United States.

Johnston visited the region in 1953 and 1954. The final agreement concerned allocation of the waters of the Jordan River. The final allocations were 45% to Israel and 55% to the Arabs (1). The Johnston Accords, as the agreement became known, was the first serious attempt at cooperation between Israel and her neighbors. It also vindicated third-party mediation (this time, on behalf of the United States) to bring the parties together. The role of external mediators in the Arab–Israeli conflict is now a requisite condition expressed by all parties. Nonetheless, the Arab leaders refused to sign the agreement because, as a matter of principle, they were opposed to the formal recognition of Israel (1). But both Jordan and Israel informed the Americans that they would treat the agreement as if it had been signed, and it served as the basis for Israel's diversion of water via the National Water Carrier and Jordan's diversion of the Yarmouk River via the East Ghor canal (2).

Israel's relationship with Syria, however, increased in belligerency. After completion of the National Water Carrier in 1964, Syria sought to deprive Israel of the headwaters of the Jordan by diverting the waters around Israel and began construction of a canal in 1965 for this purpose. According to Sherman (3), Syria had little to gain from the canal either economically or strategically, and Israel responded to the canal's construction as a personal affront to her national aspirations. In a series of military reprisals, Israel destroyed the bulldozers being used to dig the canal and, in effect, caused the Syrians to abandon the project. It is widely believed that these skirmishes contributed to the atmosphere of confrontation that finally led to the Six-Day War in 1967.

In the interim period between the Johnston Accords of 1954 and the signing of the Oslo Declaration of Principles in 1993, Israel and her neighbors undertook an independent approach to water development. Increasing populations and growing demands for more freshwater in the region coupled with a lack of a joint vision for shared management have created a serious deficit in the water budget of all the countries. The urgency of solving the water allocation problem, something that all the parties agree to, is now seen by many as the elusive catalyst for an overall final peace agreement.

THE SECOND PROMISE

At the conclusion of the Six-Day War in 1967, the hydrostrategic map of the region changed in favor of Israel. By the occupation of the West Bank and Gaza, Israel gained access to the mountain and coastal aquifers and to the headwaters of the Jordan in the Golan Heights. Since 1967, Israel's rapid economic growth has deepened her reliance on the aquifer systems of the West Bank. As the quality of life among Israel's citizens has risen, the gap between Israeli and Palestinian water consumption has grown. Before the peace process began, average annual Palestinian domestic consumption was less than 35 cubic meters, whereas in Israel, per capita consumption was about 100 cubic meters (2).

The Oslo process that began in the mid-1990s was considered the means to redress this balance as well as to lead to an overall peace settlement between Israel and the Palestinians. The principal protocol for implementing an interim accord between Israel and the Palestinians on water allocation is Article 40, together with its appendices, signed in Washington by the two parties in 1995 (4). This agreement is commonly known as Oslo Two.

The agreement created a Joint Water Committee (JWC) to deal with all water- and sewage-related issues during the interim period and led to the creation of the Palestinian Water Authority, which gradually took over control of some of the wells that were initially operated and maintained by the Israeli water company, Mekorot. The most significant aspect of Article 40 is Israel's recognition of Palestinian water rights that are to be determined in the Permanent Status Agreement. This agreement was to be completed within five years of the Oslo process.

The Oslo process and open negotiation between Israel and the Palestinians have suffered an irrevocable setback due to the current violence. Many consider the Oslo process now dead. Criticism among the Palestinians for the failure of Oslo is a lack of visible movement on the ground. Israeli settlements in the Occupied Territories continue to expand, the transfer of water resources to the Palestinian Authority by Israel has been delayed, and the freedom to transfer water and expand water and sewage networks among Palestinian urban centers has been curtailed. Part of this problem is the continued effort in Israeli political and military spheres to link water to security concerns. Nonetheless, even at the height of the recent violence, some channels remain open between Israeli and Palestinian scientists for cooperative water management. It remains to be seen if this cooperation can include the political and military sphere. Whether or not the Oslo process is dead, autonomous Palestinian institutions do exist to manage water resources for the majority of its citizens. Coordinated action, however, still remains a necessity for an equitable solution between Israel and the future Palestinian state.

The multilateral activities between Israel and her neighbors that began in Madrid in 1991 paved the way for the Israel–Jordan Treaty of Peace signed in 1994. Out of all of Israel's neighbors, Jordan has always been the most open to negotiations with the Jewish state. Tacit agreements between the two parties on strategic and water issues existed prior to the signing of the peace treaty. Having a formal peace treaty in place, both parties looked forward to peaceful cooperation and exchange in economics, culture, and security.

The Israel–Jordan peace treaty legally spells out mutually recognized water allocations for the Yarmouk and Jordan Rivers, as well as groundwater in the Arava/Araba valley, and calls for joint efforts to prevent water pollution (5). The treaty also acknowledges the water deficit facing both countries and calls for joint efforts to alleviate water shortages through cooperative efforts on both a regional and international scale (5). In the treaty, Israel agrees to provide storage services of 20 million cubic meters of water to Jordan during the winter in the Sea of Galilee and to work with Jordan to find an additional 50 million cubic meters (2). In return, Israel can continue to use wells in the Arava/Araba valley for agricultural purposes despite the fact that, according to the treaty, these wells now lie on the Jordanian side of the border. The region of the Arava/Araba valley is one of the few regions where open cooperation between Israel and an Arab state continues despite the current violence. Israeli agricultural expertise is being used to develop agricultural projects on the Jordanian side of the valley, and cooperation on combating and preventing oil spills in the Gulf of Aqaba continues between the two cities on the gulf, Eilat in Israel and Aqaba in Jordan.

RENEGOTIATING PROMISES MADE

Israel and her neighbors are inching toward a system of integrated watershed management. Today, agreements exist among three riparians of the Jordan River watershed: Israel, the Palestinian Authority, and Jordan. A fourth riparian has so far been excluded from the process. Movement on the Israeli–Syrian track is stalled in the starting gates. Syria insists on the precondition that Israel withdraw from all of the Golan Heights before any negotiations can begin. Israel rejects any form of preconditions as a basis for negotiation. The hydrostrategic importance of the Golan Heights as the headwaters of the Jordan are considered vital to Israel's water needs. For Syria, the issue of the Golan is not water, but pride in regaining the Golan and its position of influence in the Arab world; most of its water comes from the Tigris–Euphrates.

Accommodation with Syria will most likely require a "land for peace" deal. At the moment, the parties are far from agreement on what such a deal will constitute, but whatever deal is finally agreed on will affect the current agreements between Israel and the Palestinian Authority and Jordan. Both of these agreements discuss water allocations independently of Syria, the fourth riparian. Therefore, the allocation systems currently in place will have to be renegotiated once all the riparians are included ultimately which may seem impossible in today's climate, but it cannot be ignored.

Opportunities for agreement now exist to augment any allocation agreement that may be signed. Desalination is soon to become a reality in the region. Israel, as the dominant riparian, has a lot to gain politically and economically in cooperating with her neighbors in setting up and managing such plants. Trading in desalinated water may be one path toward economic cooperation among the riparians to improve the quality of life for all citizens. Desalination may also help to relieve the pressure on the existing freshwater in the region. Demand management policies also need to be considered, such as a move from agricultural hegemony over water, especially in Israel, toward domestic and industrial uses.

It is likely that the need and the recognition of a sustainable water supply in the region will push the parties together in negotiating an equitable water allocation and management system. This system can then provide the foundation for political agreement by the parties, an agreement that so far has proven to be an elusive promise.

THE MYTH OF BAD CHOLESTEROL: WHY WATER IS A BETTER CHOLESTEROL-LOWERING MEDICATION

F. Batmanghelidj
Global Health Solutions
Falls Church, Virginia

We in the medical profession, totally oblivious to the vital roles of cholesterol in the body, have been duped into thinking that this substance causes arterial disease of the heart and brain. The pharmaceutical industry has capitalized on the slogan of "bad cholesterol" and produced toxic chemicals that minimally lower the level of cholesterol in the body in the process, cause liver damage to thousands of people, some of whom die as a result of using these medications.

It is surprising that none of the frequently quoted and media-popularized doctors has reflected on the fact that cholesterol levels are measured in blood taken from the veins, yet nowhere in medical literature is there a single case of cholesterol having caused obstruction of the veins. Venous blood moves far move slowly than arterial blood and thus would be more inclined to have cholesterol deposits if the assumption of "bad cholesterol" were accurate. This mistake by us in the medical community and its exploitation by the pharmaceutical industry has caused unnecessary mass hysteria and a multibillion-dollar annual drain of financial resources by those who can least afford it in these times of serious economic crisis.

In truth, the so-called bad cholesterol is actually far more beneficial than is appreciated. The reason for its rise in the body is complications caused by chronic unintentional dehydration and insufficient urine production. Dehydration produces concentrated, acidic blood that becomes even more dehydrated during its passage through the lungs before reaching the heart—because of evaporation of water in the lungs during breathing. The membranes of the blood vessels of the heart and main arteries going up to the brain become vulnerable to the shearing pressure produced by the concentrated, acidic blood.

These membranes begin to lose water to the concentrated blood and thus lose resistance and structural integrity. The shearing force of thick, toxic blood tends to produce abrasions and minute tears in the lining of the arteries. Sections of these membranes could easily peel off and become emboli reaching the brain, kidneys, and other organs if some protective measure were not in place. To prevent the damaged blood vessel walls from getting peeled off by blood working its way under the torn lip of the membrane, low-density (so-called bad) cholesterol immediately coats and covers up the abrasions and tears and protects the underlying tissue like a waterproof bandage until the tissue heals. The advantage of "greasy" cholesterol is that blood components could roll over the patch without sticking to it and produce thrombosis in these vital arteries.

Thus, the vital, lifesaving role of low-density cholesterol proves that this substance is of utmost importance. It saves the lives of those who do not adequately hydrate their bodies by enabling their blood to flow easily through the blood vessels without causing damage.

Cholesterol has infinite vital roles. If the physiology of the body places a greater demand on some aspects of cholesterol functions, the liver manufactures more of it. Not knowing any of these functions and interfering with its actions is foolish—yet it is the present state of medicine, as far as cholesterol is concerned. Here are some other of these actions.

Cholesterol is an element from which many of our hormones are made. The body also makes vitamin D from cholesterol, which is deposited in skin that is exposed to sunlight. Cholesterol is used in the insulating membranes that cover our nerve systems. Cholesterol is used in dehydrated cells to bond the cell membrane structure together. There is no such thing as bad cholesterol. If all the primary ingredients are available for its normal functions, the human body does not engage in making things that are bad for its survival. Until now, we did not know that water is a vital nutrient that the body needs at all times—and in sufficient quantity.

By a convoluted process, the rise in the cholesterol concentration of blood is also an indicator of developing osteoporosis. Briefly, water manufactures hydroelectric energy for many of the energy-dependent physiological functions of the body; neurotransmission is on top of the list. In dehydration and low hydroelectric energy output, ATP energy trapped in calcium bonds becomes an alternative source of energy supply. Each atom of calcium that bonds to another calcium traps one unit of ATP energy.

Thus, the bones of the body, the repositories of much stored energy, begin to "decalcify" to contribute to the emergency energy needs of the body. As an integrated biochemical process in the body and to offset the catastrophic outcome of severely decalcified and softened bones, the manufacture of more vitamin D to increase the rate of bone formation becomes a dominant drive. To achieve this, the body has no alternative but to manufacture more cholesterol to be converted to vitamin D by sunlight on exposed skin. This process was used at the turn of last century to cure rickets in children, and it should be used for adults suffering from osteoporosis. They also need to be better hydrated for their bones to become firm and better calcified.

Water itself—not caffeine-containing beverages that further dehydrate—is a better cholesterol-lowering medication than any chemical on the market. It is absolutely safe, unlike the dangerous medications so often used. Please share this information with those you care for.

For more information about my medical breakthrough on the topic of chronic unintentional dehydration and the diseases it causes, read as many of the following titles as you can. They are the products of more than 24 years of focused research on the topic of deep dehydration inside the cells of the body: *Your Body's Many Cries for Wate*r; *ABC of Asthma, Allergies and Lupus; Water for Health, for Healing, for Life; How to Deal with Back Pain and Rheumatoid Joint Pain; Water Cures: Drugs Kill*; and my 2004 book, *Obesity, Cancer, and Depression: The Deadly Diseases of Dehydration*. EARLY CLOCKS

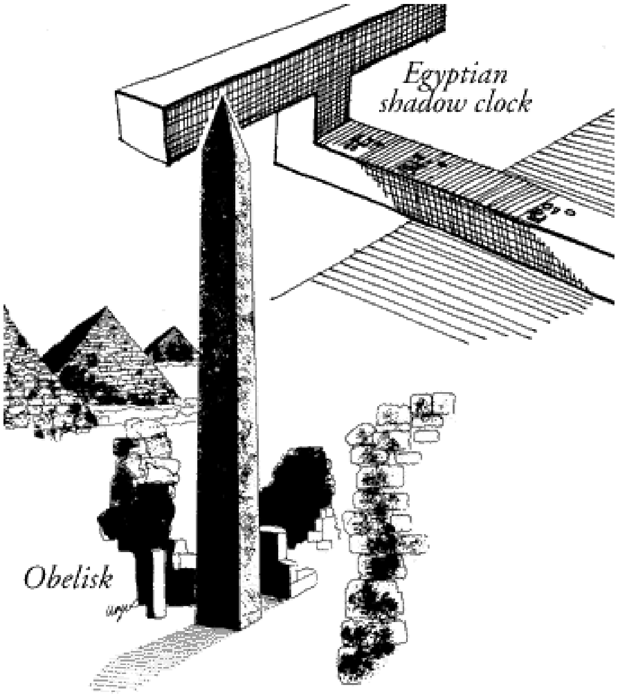
Physics Laboratory, National
Institute of Standards and
Technology

Not until somewhat recently (that is, in terms of human history) did people find a need for knowing the time of day. As best we know, 5000 to 6000 years ago great civilizations in the Middle East and North Africa began to make clocks to augment their calendars. With their attendant



---

bureaucracies, formal religions, and other burgeoning societal activities, these cultures apparently found a need to organize their time more efficiently.

SUN CLOCKS

The Sumerian culture was lost without passing on its knowledge, but the Egyptians were apparently the next to formally divide their day into parts something like our hours. Obelisks (slender, tapering, four-sided monuments) were built as early as 3500 BCE. Their moving shadows formed a kind of sundial, enabling people to partition the day into morning and afternoon. Obelisks also showed the year's longest and shortest days when the shadow at noon was the shortest or longest of the year. Later, additional markers around the base of the monument would indicate further subdivisions of time.

Another Egyptian shadow clock or sundial, possibly the first portable timepiece, came into use around 1500 BCE. This device divided a sunlit day into 10 parts plus two "twilight hours" in the morning and evening. When the long stem with 5 variably spaced marks was oriented east and west in the morning, an elevated crossbar on the east end cast a moving shadow over the marks. At noon, the device was turned in the opposite direction to measure the afternoon "hours."

The *merkhet*, the oldest known astronomical tool, was an Egyptian development of around 600 BCE. A pair of merkhets was used to establish a north-south line (or meridian) by aligning them with the Pole Star. They could then be used to mark off nighttime hours by determining when certain other stars crossed the meridian.

In the quest for better year-round accuracy, sundials evolved from flat horizontal or vertical plates to more elaborate forms. One version was the hemispherical dial, a bowl-shaped depression cut into a block of stone, carrying a central vertical gnomon (pointer) and scribed with sets of hour lines for different seasons. The hemicycle, said to have been invented about 300 BCE, removed the useless half of the hemisphere to give an appearance of a half-bowl cut into the edge of a squared block. By 30 BCE, Vitruvius could describe 13 different sundial styles in use in Greece, Asia Minor, and Italy.

ELEMENTS OF A CLOCK

Before we continue describing the evolution of ways to mark the passage of time, perhaps we should broadly define what constitutes a clock. All clocks must have two basic components:

- *A regular, constant or repetitive process or action to mark off equal increments of time.* Early examples of such processes included the movement of the sun across the sky, candles marked in increments, oil lamps with marked reservoirs, sand glasses (hourglasses), and in the Orient, knotted cords and small stone or metal mazes filled with incense that would burn at a certain pace. Modern clocks use a balance wheel, pendulum, vibrating crystal, or electromagnetic waves associated with the internal workings of atoms as their regulators.
- *A means of keeping track of the increments of time and displaying the result.* Our ways of keeping track of the passage of time include the position of clock hands and digital time displays.

The history of timekeeping is the story of the search for ever more consistent actions or processes to regulate the rate of a clock.

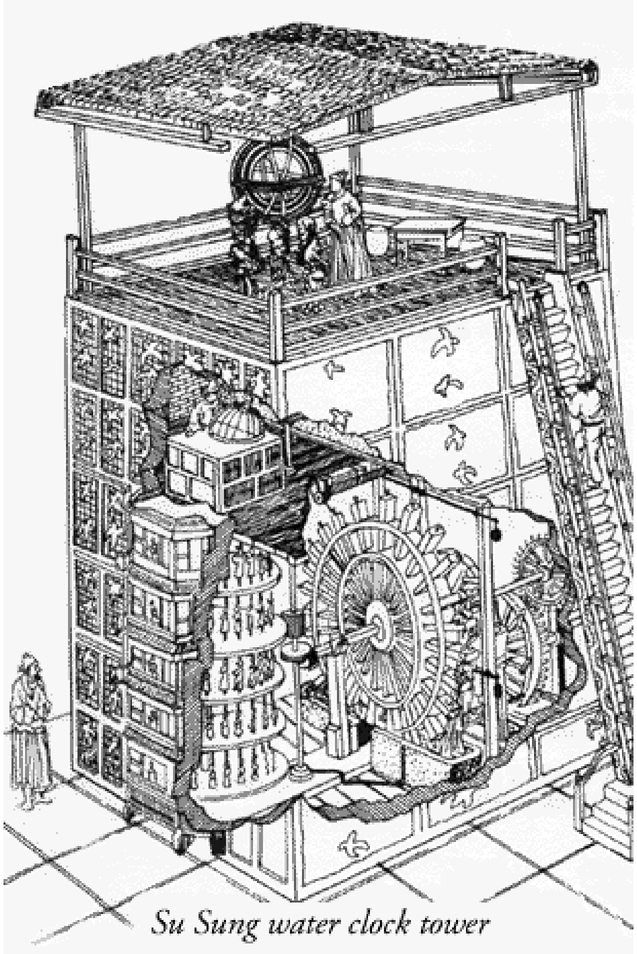
WATER CLOCKS

Water clocks were among the earliest timekeepers that didn't depend on the observation of celestial bodies. One of the oldest was found in the tomb of the Egyptian pharaoh Amenhotep I, buried around 1500 BCE. Later named *clepsydras* ("water thieves") by the Greeks, who began using them about 325 BCE, these were stone vessels with sloping sides that allowed water to drip at a nearly constant rate from a small hole near the bottom. Other clepsydras were cylindrical or bowl-shaped containers designed to slowly fill with water coming in at a constant rate. Markings on the inside surfaces measured the passage of "hours" as the water level reached them. These clocks were used to determine hours at night, but may have been used in daylight as well. Another version consisted of a metal bowl with a hole in the bottom; when placed in a container of water the bowl would fill and sink in a certain time. These were still in use in North Africa in the 20th century.

More elaborate and impressive mechanized water clocks were developed between 100 BCE and 500 CE by Greek and Roman horologists and astronomers. The added complexity was aimed at making the flow more constant by regulating the pressure, and at providing fancier displays of the passage of time. Some water clocks rang bells and gongs; others opened doors and windows to show little figures of people, or moved pointers, dials, and astrological models of the universe.

A Macedonian astronomer, Andronikos, supervised the construction of his *Horologion*, known today as the Tower of the Winds, in the Athens marketplace in the first half

Early water clock



Su Sung water clock tower

of the first century BCE. This octagonal structure showed scholars and shoppers both sundials and mechanical hour indicators. It featured a 24 hour mechanized clepsydra and indicators for the eight winds from which the tower got its name, and it displayed the seasons of the year and astrological dates and periods. The Romans also developed mechanized clepsydras, though their complexity accomplished little improvement over simpler methods for determining the passage of time.

In the Far East, mechanized astronomical/astrological clock making developed from 200 to 1300 CE. Third-century Chinese clepsydras drove various mechanisms that illustrated astronomical phenomena. One of the most elaborate clock towers was built by Su Sung and his associates in 1088 CE. Su Sung's mechanism incorporated a water-driven escapement invented about 725 CE. The Su Sung clock tower, over 30 feet tall, possessed a bronze power-driven armillary sphere for observations, an automatically rotating celestial globe, and five front panels with doors that permitted the viewing of changing manikins which rang bells or gongs, and held tablets indicating the hour or other special times of the day.

Since the rate of flow of water is very difficult to control accurately, a clock based on that flow could never achieve excellent accuracy. People were naturally led to other approaches.

WATER CLOCKS

The science or art of measuring time is known as "horology," and, for the greater part of human history, time was calculated through the use of water clocks.

Ever since the dawn of humanity, we have enjoyed a relationship with water. It was this relationship with water that gave birth to the concept of measuring time.

It is believed that the first human-made timekeeping device was the water clock invented in Egypt around 1400 B.C. This was a very rudimentary timekeeping device based on the flow of water out of or into a bowl-type container. This filling or emptying of a measurable vessel with water provided a basis for telling time. The energy source that powered the first water clocks, and all others that followed, was the fluid properties of water responding to the influence of gravity.

The name given to early water clocks in Greece was "klepsydra" (pronounced KLEP-suh-druh). This name meant "thief of water" and was derived from two Greek words meaning "thief" and "water." These Greek root words can be traced to such present-day words as "kleptomaniac," for one who steals, and water words such as hydrant and hydrology.

The klepsydra migrated from Egypt to Greece, and then later into Rome. The Romans Latinized the Greek *klepsydra* to *clepsydra*, or the *horologium ex aqua*. In early history, there was probably one clepsydra for each village or town. Each clepsydra was set up in a central location and was watched over by responsible representatives, who took turns keeping watch over the device. This "watching" of the clepsydra was necessary to protect the time device and to have an attentive person standing by to fill the water basin constantly.

Some locations used a horn to sound the passage of a certain amount of time; others used a drum or the human voice. In this fashion, everyone within earshot had an idea of the time of day. This ancient system of sounding the passage of time remains in use today. Today, we find the sounding of bells at designated times in centrally located bell towers throughout the world, as well as the blowing of a horn. In some places, there are bell-keepers who ring the tower bell or bells manually at designated times. In other locations, the ringing of bells or blowing of a horn is mechanized and occurs on an automated basis.

In early England and later New England in the United States, there were so-called "walking clocks." A "walking clock" was a person who would use a loud voice to announce the time while walking the streets.

In Muslim countries, where Islam is widely practiced, prayer is timed at five different intervals during the day. In some Islamic areas, there are towers where a human occupant will loudly voice prayers to Allah at the five designated times. While praying aloud to Allah, the prayer-giver always faces in the direction of Mecca.

It is due to this keeping "watch" over the flow of water in early clocks and the watching of time in bell towers and by town criers that we have the etymology for the modern timepiece known today as the "watch."

THE FIRST CLOCK WAS A WATER CLOCK

Without doubt, the very first so-called "water clock" was humanity observing how water was connected to the timing of natural and cosmic events. The timing of moon tides, the timed event of spring floods when the earth turns on its axis and causes snow and icemelt in the mountains, and the calendar of humans watching celestial events to anticipate spring rains or monsoons are three examples.

To survive, humans require a steady source of freshwater. Therefore, the earliest humans naturally learned to observe, understand, and live within the water cycle of their respective regions. Each water cycle was connected to the sourcing of drinking water, the seasonal growth of various wild plant foods, and the migratory patterns of fish and animals. In this fashion, early humans became aware of a natural water rhythm that was connected to the timing cycle of rainfall, which in turn determined the seasons of life. Because of this intimate relationship of the cycle of water to the cycle of life, humans became aware of a water clock that was inherent in the scheme of nature.

For these reasons, early humans evolved in regions where freshwater was readily available constantly. This is why modern archaeologists find evidence of early civilizations evolving along river basins such as the Tigris–Euphrates Valley and along the Nile River. Besides using the river water for consumption and bathing, the wildlife within and around the rivers provided a steady and plentiful source of food. The rivers also provided a convenient way for evolving humans to travel.

As humans gained knowledge of their regional water cycles, they eventually figured out a methodology for raising livestock and growing crops. In other words, early humans became aware of the "big" water clock of nature, a water clock that had a timing sequence that coincided with certain celestial events. Consequently, we see the construction of structures, such as Stonehenge in England and New Grange in Ireland. These stone structures allowed early humans to forecast, or time, future events in nature based on the water cycle.

The flooding of the Nile River, for example, from the end of June into late October, was responsible for depositing rich sediment in Egypt's fertile Nile Valley. After the flooding subsided, various crops were planted from late October into late February. These crops were harvested from late February until the end of June, when the cycle would begin again.

The ancient Egyptian calendar was known as a "nilometer" because it was based on a vertical scale that recorded the annual flood levels of the Nile River. In essence, this was a "water clock" of huge dimension. Eventually, the Egyptians fine-tuned their nilometer water clock by breaking it down into twelve months of thirty days each; five days were added at the end. For the early Egyptians, this water calendar worked well with the seasonal flows of the Nile, which is why it became known as the "Nile year." The Nile year calendar, used by the Egyptians more than 6200 years ago, predated the invention of writing.

The use of the number "12" in creating the number of months is often related to the Egyptians observation of the moon cycle. There are about 12 moon cycles in a year. The division of the year into 12 months may also have provided a basis for the Egyptians and Babylonians to divide the day and night into 12 hour segments.

Originally, the Egyptians and Babylonians divided sunrise to sunset into 12 parts they called "hours," and sunset to sunrise into 12 parts. The lengths of hours for the day and night are not always the same through the year, so water clocks had to be adjusted every night and morning. Eventually they figured out that it was easier to keep time when they created the concept of the 24-hour day. The 24-hour day encompassed the passage of both day and night hours and therefore required little adjustment of water clocks.

Egyptian water clocks were among the earliest timekeeping devices that did not depend on the observation of celestial bodies. One of the oldest was found in the tomb of the Egyptian pharaoh, Amenhotep I, buried around 1500 B.C.E.

As explained by the National Institute of Standards and Technology Physics Laboratory, early water clocks were named clepsydras ("water thieves") by the Greeks. The Greeks began using clepsydras about 325 B.C.E. Clepsydras were stone vessels with sloping sides that allowed water to drip at a nearly constant rate from a small hole near the bottom. The drip-drip sound of water dropping from a water clock was an ancient precursor to the ticktock sound emitted by certain mechanical clocks invented in later times. Water clocks were replaced by the invention of mechanical clocks about 700 years ago.

Other clepsydras were cylindrical or bowl-shaped containers designed to fill slowly with water flowing in at a constant rate. Markings on the inside surfaces measured the passage of "hours" as the water level reached them. These clocks were especially used to determine the passing hours at night but may have been used in daylight as well.

Another version is known as the "sinking bowl" (see Fig. 1). This consisted of a metal or clay bowl with a hole in the bottom center. The larger the bowl, the longer it would take to fill with water and sink below the surface. When placed in a water container or calm body of water, the bowl would slowly fill and then sink after a certain amount of time. As soon as one bowl sank, the next bowl would be set on top of the water. Counting the number of bowls that sank during the daytime, or nighttime, created a crude basis for telling time. This method was often used to keep track of the "dark hours" through the night. The amount of time a bowl took to sink was sometimes measured during daylight so it could be calibrated with a sundial. This method helped ancient humans to compare the passage of time between daylight hours and dark hours, which allowed for knowledge of the coming change of seasons. As daylight hours grew shorter and nighttime hours longer, the earth naturally began to cool.

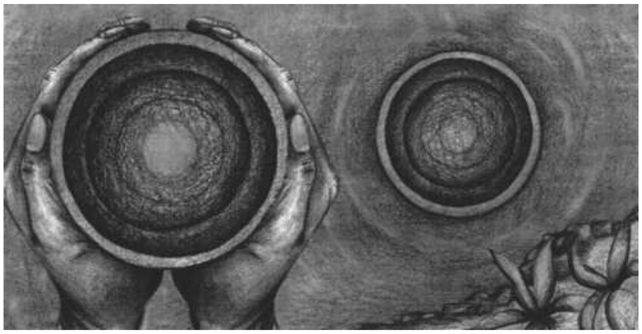

Figure 1. Sinking bowl water clock circa 1400 B.C. to present day. Drawing by: Sarah Adams.

The sinking bowl water clock was so low tech and functional that it remained in use for thousands of years in the Middle East, as well as in parts of North Africa into the twentieth century. The sinking bowl water clock remains in use in some parts of the world today.

More elaborate and impressive mechanized water clocks were developed between 100 B.C.E. and 500 C.E. by Greek and Roman horologists and astronomers. The added complexity was aimed at making the flow more constant by regulating the pressure and at providing fancier displays of the passage of time. Some water clocks rang bells and gongs; others opened doors and windows to show little figures of people, or moved pointers, dials, and astrological models of the universe.

The Greeks as well as the Romans used the water clock as a mechanism for regulating speaking time in courts. In Greece, the clepsydra was used to limit the time for pleading one's case in Athenian courts. Based on water clocks surviving from that time, the water would flow only for about 6 minutes. There are records of legal representatives asking for the flow of the water clock to be stopped so that certain laws or evidence may be presented to the court. On a more humorous level, there are stories where comments about how the orator should quench his thirst by drinking water from the water clock and thereby abbreviate his speaking time.

On a similar note, Romans also used the clepsydra to limit speaking time in Roman legal courts. This limitation of time on legal arguments by Roman orators was instituted by the command of Pompey and was alluded to by Cicero when he stated, "latrare ad clepsydram." When the clepsydra's water ran out, an orator's time ran out, and he was cut off from speaking further. Compared to the 6-minute klepsydras used by Greek courts, Roman courts used a 20-minute clepsydra.

During legal arguments, opposing parties were supposed to enjoy equal amounts of water. However, there are surviving records indicating that lawyers would sometimes request additional amounts of time by asking for a certain quantity of "clepsydrae." If a lawyer spoke too long, the opposing lawyers would argue that his water should be taken away by the court.

Martial, the Latin poet of Rome (c. 40–c. 102), once penned these words about a tiresome speaker who constantly moistened his throat by drinking from a glass of water:

> Seven water-clocks allowance you asked for in loud tones, Caecilianus, and the judge unwillingly granted them. But you speak much and long, and with backtilted head, swill tepid water out of glass flasks. That you may once for all sate your oratory and your thirst, we beg you, Caecilianus, now drink out of the water clock.

This legal limitation of time for presenting legal arguments remains in use in certain governing bodies throughout the world today. Depending on the governing rules of the land, an elected official or legal representative is allowed to hold the floor for only a designated amount of time.

It is also from the Roman legal system that we derived our modern-day A.M. and P.M. designations, representing before midday (*ante meridiem*, A.M.), and after midday (*post meridiem*, P.M.). This A.M. and P.M. split of the day was of legal import to the Romans because lawyers were required to appear in courts before noon.

On another note, the private ownership of a water clock in a home was considered a great status symbol during Roman times. Also, a person who gave the appearance of wasting time in life was referred to as "one who wastes water." Thus, we find an intimate connection between water and life, as perceived in the minds of ancient Greeks and Romans.

In Greece, a Macedonian astronomer, named Andronikos, supervised the construction of a complex Horologion. This mechanical device, known today as the Tower of the Winds, was located in the Athens marketplace during the first half of the first century B.C.E. This octagonal structure showed scholars and shoppers both sundials and mechanical hour indicators. It featured a 24-hour mechanized clepsydra and indicators for the eight winds from which the tower got its name, and it displayed the seasons of the year and astrological dates and periods.

The Romans also developed mechanized clepsydras (water clocks), though their complexity accomplished little improvement over simpler methods for determining the passage of time.

The Greeks divided the year into 12 parts they called "months." They then divided each month into 30 parts they called "days." The Greek year had a total of 360 days, which was equal to 12 times 30. The earth circles the Sun in 1 year, so the Greeks developed the mathematical concept of dividing the circle into 360°.

The division of the hour into 60 minutes and each minute into 60 seconds, probably finds its source in the ancient Sumerian sexagesimal system. This Sumerian system is based on the number 60 and was developed approximately 4000 years ago.

In the Far East, mechanized astronomical/astrological clock making developed from 200–1300 C.E. Third-century Chinese clepsydras drove various mechanisms that illustrated astronomical phenomena. One of the most elaborate clock towers was built by Su Sung and his associates in 1088 C.E. Su Sung's mechanism incorporated a water-driven escapement invented about 725 C.E. The Su Sung clock tower, over 30 feet tall, possessed a bronze, waterpower-driven armillary sphere for observations, an automatically rotating celestial globe, and five front panels with doors that permitted viewing changing manikins which rang bells or gongs and held tablets indicating the hour or other special times of the day. This and other mechanical efforts to use water for keeping time had their limitations. These limitations are inherent in the nature of water.

Water is a sensitive entity that is subject to linear and nonlinear influences. These influences include but are not limited to gravity; temperature; atmospheric pressure (weight of air above at any given moment); wind; alignment of the Moon and other planets; viscosity; sunspots (cause of ionic excitement in atmospheric water and related creation of aurora borealis and aurora australis); speed of the earth's rotation; the "Heisenberg principle" based on quantum mechanics and how that which is observed responds to being observed; sound (travels four times faster through water than through air); light; projection of intention, thought, and emotion as expressed in Masaru Emoto's pioneering water research; chemical and electrical composition of contact materials; suspended solids; the rate of molecular activity within water; the presence of vortical influences; and the spectrum of various wave influences.

Due to water's sensitivity and all of the variables that influence its character at any given second, the rate of flow of water is very difficult to control accurately. Therefore, a clock based on water flow has certain limitations and challenges for achieving high accuracy.

However, throughout time, there have been claims of water clocks that rivaled the accuracy of mechanical clocks. Once such example is an hour-glass type water clock, which had to be inverted as soon as the water from the upper glass chamber emptied into the lower glass chamber. One account of another accurate type of clepsydra, which was invented by a man named, Amontons, was published in the pamphlet, *Remarques & Experiences Physiques fur la Construction d'une nouvelle Clepsydre*, &c. Jombert, Paris, 1695.

Today, no matter what philosophical perspective a person may have about time, the basic fact is that the mechanics of keeping accurate time is a concept created for use as a linear tool.

Regardless of the variety and accuracy of human-made time devices, humankind remains subject to the vicissitudes and rhythm of flowing water, as well as its inherent cycle expressed in nature.

Understanding the rhythm and cycles of water is vital to the survival of life as well as civilization, so we cannot substitute mechanical devices for the water clock presented to us by our natural environment.

Our near future interaction with the earth's water cycle may well determine how much time our species has to survive. In other words, the available water in the earth's clepsydra is rapidly approaching empty at this time, so it behooves us to do more than just talk about altering the way we interact with water.

OUR EVOLVING WATER CONSCIOUSNESS

William E. Marks
Water Consciousness, Inc.
Martha's Vineyard,
Massachusetts

Since the dawn of our species, being conscious of water has been vital to our survival, health, and social behavior.

Hundreds of thousands of years before the written word, humans thought and communicated about water. Besides being essential for survival, water remains a mysterious fluid that science continues to research and study.

Prior to the invention of writing, communication about water found expression in human sign language and the spoken word. In early human writings, such as the Egyptian hieroglyphic system, the symbol for water is a ripple pattern that looks like this (𓈖). This early hieroglyphic symbol resembles almost exactly a purported water symbol carved into bone by a Neanderthal during the Paleolithic period.

Another ancient water symbol is the Chinese character "shui" (水). This character is of such antiquity that it predates Chinese recorded history and is of unknown origin. In *The Book of Changes* (I Ching), which is more than 3000 years old, there is the water trigram "Kan" (☵), whose symbol is obviously an evolution out of the more ancient water character of "shui."

The Chinese character for "water," it was recently discovered, exists as a natural water form. In Masaru Emoto's book, *Messages from Water*, he shows a photograph of crystallized water on page 12 that contains what appears to be a Chinese character. This photo is accompanied by the following text:

> "When water freezes, it becomes crystallized. At the moment right before it returns to its water form (with a rise in temperature, between −5 °C and 0 °C) it creates a crystal shape that is identical to the Chinese character for water. Did people in ancient times know this and make the Chinese character for "water" based on this information?"

Simply stated, the *Chinese Book of Changes* helps mankind deal with the idea of change. Or, as reported in the *Analects* (a book of conversations of Confucius, one of the authors of the I Ching), Confucius states, while standing by a river, "Everything flows on and on like this river, without pause, day and night."

THE TALE OF GILGAMESH

On another note, we find the incredible story of water expressed in the epic poem of Gilgamesh, a poem written in Sumer, an ancient civilization located in the lower Euphrates River Valley. Sumer is where writing is believed to have been invented. These first writings were written by Sumerians on clay tablets in the cuneiform script. Cuneiform script is composed of wedge-shaped characters imprinted into wet clay before it is heated (fired) for permanence.

The Sumerians believed that in the beginning only a vast swirling sea existed and that all things came from this sea. Because of this, it is no surprise to learn the Sumerian word mar meant "sea" as well as "womb." Archaeological evidence indicates that Sumer was the home of some of the earliest humans. The fact that humans lived continuously in Sumer since prehistoric times supports the theory of the way the region's ancient oral history found expression in the first writings of the Sumerians.

As can be expected, interpretations of the ancient texts found in Sumer vary. However, one thing stands without question—"water" served as the source of creation. The god Ea-Enki, the principal divinity of the liquid element—especially freshwater, is expressed as the Creator. Ea-Enki is presented as coming from the sea at the dawn of time and is said to be of supreme intelligence, skillful, ingenious, and the One who knows all things.

The name "Ea," which means "House of the Water," makes up the first two letters of "earth." Ea's domain was the Apsu—all the waters that surrounded the planet and kept it afloat, as well as the springs, rivers, and lakes. The freshwaters of the earth were considered the source of happiness, knowledge, and wisdom.

When writing was invented in Sumer, oral stories of old were rendered in clay. From these first writings came the Gilgamesh poem. However, the discovery of the Gilgamesh poem created concern in the minds of some religious leaders.

In 1872, members of the Society of Biblical Archaeology in London were surprised by the implications drawn by archaeologist, George Smith. Smith had recently deciphered the Gilgamesh poem. A poem that predated the Bible by thousands of years expressed a story about the "great flood," and included information about building a ship to save people and animals.

The discovery and translation of the Gilgamesh poem gave humanity a glimpse into water-related information and rituals passed down by oral history long before the invention of writing. Support for this can be found in the John Gardner and John Maier translation of Gilgamesh, where we are informed that the Gilgamesh "Creation Epic" was recited in Babylon each year during the "New Year's Festival," long before the creation of writing.

METAMORPHOSIS

From Gods to a Unifying Water Philosophy

More than 2500 years ago, in the Greek territory of Ionia, lived a man named Thales. Today, in philosophical circles, Thales is often described as "the world's first philosopher" and, according to Aristotle, "the founder of Ionian natural philosophy." For it is in Ionia where we find history's first naturalists recorded.

Thales, born in the rural Ionian town of Miletus, is renowned for his transformation of many of humankind's belief systems. The profound philosophical concept that Thales delivered to humankind was simply this—water is the first cause of all things seen and unseen.

Before Thales advanced his water philosophy, human thought was captured by the belief in polytheism. Under the concept of polytheism, people believed that all natural and imagined phenomena were created by a plethora of gods.

Besides contributing his water philosophy to Greek thought, Thales introduced other unique concepts to Greek thought. In fact, Thales' contributions were so profound and respected that during his time he was canonized as the wisest member of the Seven Sages of Greece.

Most of what we know about Thales flows from the writings of Plato, Aristotle, Plutarch, and other Greek philosophers. Thales was an original thinker who possessed a keen understanding of the myths and oral histories from hundreds of thousands of years in the past. At the same time, he was a scientist, astronomer, mathematician, teacher, author, politician, and a "seer" who could forecast future events.

For instance, Thales forecast a solar eclipse in the year 585 B.C. Modern scientists have checked on this event and confirm that a solar eclipse did take place on May 28, 585 B.C. and that it was visible in Ionia. How Thales was able to predict this event remains a mystery. According to information available about Thales' time in history, no mathematical formula existed for predicting an eclipse, and his feat is all the more impressive because Thales had to take into consideration the geographical latitude of Ionia.

Thales was born into a world filled with the so-called ancient mythologies and gods that were recorded in the first writings of humankind. By closely observing water and the natural world around him, Thales was able to synthesize his new philosophy into a form of natural science. This natural science helped to define the creation of life and humanity's connection to life and all creation through the entity of water.

Desiring to grasp the "first cause" of all things, Thales searched for a unifying hypothesis for the creation and sustenance of things both visible and invisible. This led him to the startling revelation that all things come from water, that the earth floats on water, that water is the constituent of all things, and that water is the cause of earthquakes. According to Plutarch's Miscellanies, Vol. III,

> Thales the Milesian doth affirm that water is the principle whence all things in the universe spring.... He pronounced, that all things had their original from water, and into water all things are resolved. His first reason was, that whatsoever was the prolific seed in all animals was a principle, and that is moist; so it is probable that all things receive their original from humidity. His second reason was, that all plants are nourished and fructified by that thing which is moist, of which being deprived they wither away. Thirdly, that the fire of which the sun and stars are made is nourished by water exhalations,—yea, and the world itself.

Today, we know that continental plates float and crash into each other and that there are chemical and other changes in groundwater prior to an earthquake. We also know from NASA planetary scientists that water was present in our part of the Universe before the creation of our solar system.

As far as Thales' theory "... that the fire of which the sun and stars are made is nourished by water exhalations,—yea, and the world itself," modern science has corroborated this fact. Recently, scientists discovered a direct relationship between the intensity and frequency of sunspot activity and weather patterns on the earth. Scientists also learned that sunspots contain water. As reported by Reuters on May 26, 1995,

> In research being released today in the journal *Science*, the experts report finding water not in the gaseous heart of the sun itself, but on somewhat cooler sunspots.
>
> "It's really sort of interesting," said Peter Bernath, a chemist who was part of the research team from the National Optical Astronomy Observatories in Tucson, Arizona, and Canada's University of Waterloo. "One is surprised that water can exist on the sun because it is so hot."
>
> Hydrogen and oxygen molecules both exist on the Sun, which is about 10,200 °F. They apparently combine to form water in sunspots, which are about 5200 °F. Because of the heat, the water molecules form vapor or steam, instead of pools or puddles.

Further scientific support of Thales' water theory was revealed by research data provided by a specially designed satellite called the Submillimeter-Wave Astronomy Satellite (SWAS). This satellite was launched in December 1998 to detect radio waves emitted by water molecules in space.

In an interview with the author of this article, Gary Melnick of the Harvard–Smithsonian Astrophysical Observatory in Cambridge provided several insights as to how modern science is providing support for Thales' water philosophy. Melnick is the leading scientist for the SWAS project. "We're seeing water everywhere in the universe. Every region we've looked at so far contains water," Melnick said.

Melnick explained that water found in interstellar space is crucial to the formation of stars. According to Melnick, when a big gas cloud begins to coalesce (form into a mass) under its own gravity, the gases begin to heat up. However, as the gases heat up, they begin to expand naturally. If water was not present to mitigate the heat generated by the condensing gas mixture, it would be difficult for the star to form. "It is because of this phenomenon," said Melnick, "that we see water helping to give birth to stars." Melnick also explained that one of the strangest discoveries of the SWAS project was finding a giant, water producing gas cloud in the heart of the Orion nebula. Based on SWAS data, Orion forms enough water every 24 minutes to fill all of the earth's oceans.

It is from our evolving scientific information, such as that expressed above, that we find corroboration of Thales' statements from more than 2500 years ago. However, along with our evolving water science and philosophies, there is also the wide practice of using water for ceremonial purposes. The use of water for the baptismal ceremony is very ancient and touches on the spiritual dimension of water.

Baptism by water

One of the most ancient and still widely used water rituals is that of baptism. From the second century forward, the value of the baptismal act was widely recognized and practiced in Christianity. Even though there are many meanings and beliefs relative to baptism, as practiced by Catholics, Protestants, and many others, water is always respected for its power to cleanse the body and regenerate the spirit.

For instance, the relationship of Moses to water harks back to his earliest beginnings. Besides his sprinkling of the covenant upon the people, we learn that the name Moses means "the water drawer." Also, not to be overlooked is Moses' origin from the Nile River. Exodus 2:1–10 tells us that as a baby, Moses was discovered floating in a basket by the Pharaoh's daughter. The word "tebah," used in the Old Testament for the basket carrying Moses, is also the same word used to describe Noah's Ark.

Besides Moses, there are other historic personages whose origins spring from water. The god Akki, "the water carrier," rescued Sargon, the founder of Babylon, from water. Karna, the icon of an early Indian epic, was found floating in the Ganges. And, just as there are many renowned people whose origins are linked with water, others find their way through various forms of water baptism.

The early "mystery" religions (Eleusinian, Orphic, Mithraic, Egyptian, Syrian) required baptism and other water rituals to wash away evil in preparation for the rites of communion with the god whose mastery of death assured immortality. These baptisms sometimes symbolized dying of the old life and rising again to the new. A similar idea underlies the baptism by immersion that is part of the initiation of proselytes to Judaism.

Today, many ancient water rituals can be found in almost all the world's religions.

Leonardo da Vinci (1452–1519)

About 500 years ago, Leonardo da Vinci was recording his thoughts about vortical energy as a result of his experiments with water. The subjects of water, hydrology, and hydraulics played a major part in Leonardo's lifetime studies. This fact was established when it was discovered that the largest number of Leonardo's notes were devoted to the subject of water than to any other subject.

The existence of water vortices intrigued Leonardo and prompted him to speculate about the existence and behavior of vortices in the air and in the cosmos. The power and meaning of vortices in water also led Leonardo to study closely the behavior of water under different conditions. In one of his experiments, Leonardo created elongated boxes with glass sidewalls so he could observe the motion of flowing water beneath the surface.

Based on his water experiments, Leonardo invented a double-gated dam. This dam used the pressure of water to make a watertight seal when the two gates met in the center with a projecting bias toward the high water side. This same principle is in evidence today at the Panama Canal and other places around the world.

Besides engineering and scientific inquiries into water, Leonardo's fascination with water dynamics and vortices is apparent in his art. The flowing motions of water vortices are expressed in his brush strokes and are obvious in his paintings, especially when depicting the hair of his subjects. Examples of this can be seen in his paintings "Leda, with the Swan;" the "Mona Lisa," and his "Self-Portrait" (see Fig. 1).

In the Mona Lisa, the hair emerges from the top of her head and flows downward like a fountain of water flowing from a spring, the breast area of her garment appears like a plunging waterfall, the flowing cloth over her left shoulder demonstrates the twisting vortex of water, and the dress sleeves on her arms appear as cascading ripples of darkness and reflected light, much like that of water overflowing from the base of a waterfall.

In Leonardo's "Self-Portrait," again we have the flow of hair springing from the head area. However, in this painting, the wavy flow of his head hair merges in dramatic fashion with his beard.

The existence of bubbles in water was also of interest to Leonardo; he noted from close observations that bubbles rise through water in a spiral motion. His written notes, as expressed in Leonardo's Codex Leicester Folio 23V (now owned by Bill Gates), depict how Leonardo documented that the "... motions of waters always move in a circle from surface to bottom."

Leonardo spent many years in his makeshift laboratory and in the field observing the movements of water and air. To see the fluid dynamics of water at work, Leonardo did experiments using glass so he could watch the motion of flowing water under various scenarios. During his field research, he maintained detailed notes and drawings about his experiences and observations. At times, Leonardo's mind would seemingly take off into other dimensions as his observations triggered ideas. Often, he would jot down or sketch these thoughts along the margins of his papers.

One such series of notes in the upper right hand corner of one of his papers was the outline for his proposed treatise on water. This treatise was divided into fifteen books, each book dealing with a different aspect of water. The classification of these books, as recorded by Leonardo, is as follows:

1. Of Water in Itself
2. Of The Sea
3. Of the Veins
4. Of Rivers

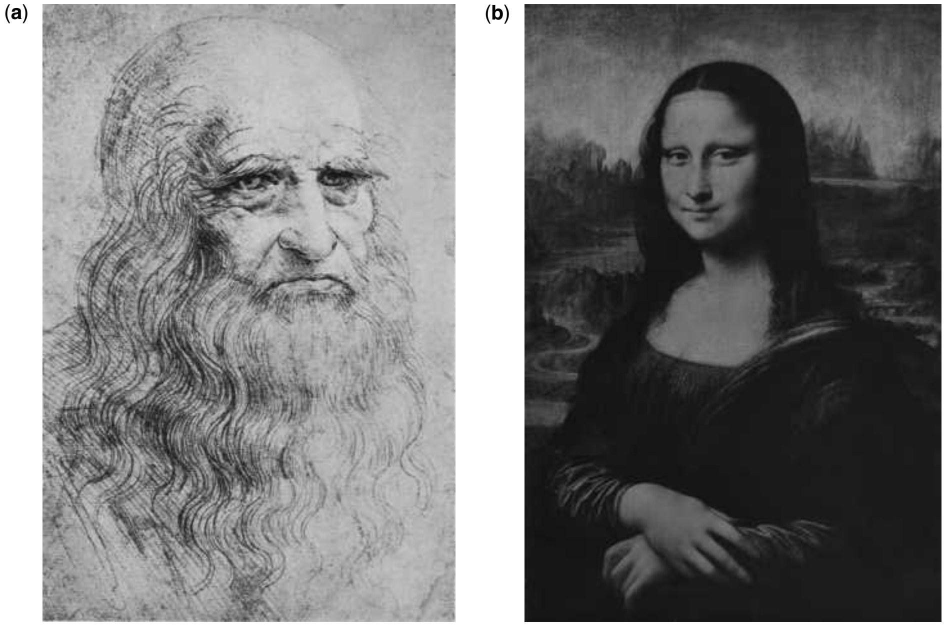

Figure 1. (**a**) Leonardo's "Self-Portrait," demonstrates water-like flow of hair springing from his head and merging in unifying waves with his beard. (**b**) Portrait of the Mona Lisa—depicts flow dynamics of water as her hair flows from her head, then cascades like a waterfall over her breasts down onto her arms, then continues flowing over her arms. Since da Vinci was careful in creating his compositions, it is important to note the mountains and "headwaters" in the background behind Mona Lisa's head, and the curving river meanders in the valleys behind both her shoulders that flow from left to right—in the same direction as the focus of Mona Lisa's eyes.

5. Of the Nature of Bottoms
6. Of Objects
7. Of Various Kinds of Gravel
8. Of the Surface of Water
9. Of Things Moving in It
10. Of River Repairs
11. Of Conduits
12. Of Canals
13. Of Machines Turned by Water
14. Of Raising Water
15. Of Things Worn Away by Water

Given the fullness of the life which Leonardo lived, he never found the time to complete the above books on water. His writings, especially those found in the Codex Leicester, contain many references and brief notes to be included in these books. An example of this can be found in Leonardo's notes dealing with precipitation:

> Write how clouds are formed and how they dissolve, and what it is that causes vapour to rise from the water of the earth into the air, and the cause of mists and of the air becoming thickened, and why it appears more blue or less blue at one time than another. Write in the same way of the regions of the air and the cause of snow and hail, and how water contracts and becomes hard in the form of ice, and of the new shapes that the snow forms in the air . . .

Another of Leonardo's field observations dealt with the physical expression of the vortex principle on a grand scale. His written observations about a water spout he saw along the seashore were recorded on a page entitled "Of wind twists and eddies involving water." In Leonardo's words,

> It often happens that, when one wind meets another at an obtuse angle, these two winds circle around together and twine themselves into the shape of a huge column, and becoming thus condensed, the air acquires weight. I once saw such winds, raging around together, produce a hollow in the sand of the seashore as deep as the height of a man, removing from it stones of considerable size, and carrying sand and seaweed though the air for the space of a mile and dropping them in the water, whirling them around and transforming them into a dense column, which formed dark thick clouds as its upper extremity. . . .

In spite of Leonardo's research and interest into various water phenomena, he was never able to provide a viable theory about the hydrologic cycle. The prevailing thinking in Leonardo's time was that the weight of the oceans waters forced water into the center of the earth. From the center of the earth, the water then flowed underground to where it eventually surfaced on land to appear in lakes, ponds, rivers, and swamps.

DISCOVERING WATER

Hydrologic Cycle

An important turning point in the correct human grasp of the hydrologic cycle came in 1580 with the publication of Bernard Palissy's book, *Discours admirables*. Palissy, a potter by trade, was a keen observer of nature and the workings of water. In *Discours admirables*, Palissy presented a concept of the hydrologic cycle that is accurate according to today's definition. Palissy's book also provided other new hydrologic concepts such as the origin of springs and rivers, how wells are recharged from nearby rivers, the hydrodynamics of artesian wells, the use of forestation for controlling erosion, and plans for constructing fountains for domestic water supply.

It was not until the late 1600s, however, that Edmund Halley, of Halley's Comet fame, actually proved that Palissy's theory was correct. Using his sense of observation and mathematical skills, Halley roughly figured the quantity of water draining from all the rivers of North Africa and Europe into the Mediterranean. From this, Halley determined that the combined flow was about equal to the water falling as rain or snow on the region's drainage area.

$H_2 + O$ = Water

In the late 1700s, Henry Cavendish, a chemist and physicist, experimented with sending electricity through water inside a sealed glass tube. To his surprise, the water disappeared. Many experiments later, Cavendish determined that water is made of two gases. Setting a match to different combinations of these two gases, Cavendish discovered that when he combined two parts of the "inflamable air" with one part of the "vital air," there was an explosion that left a residue of water drops inside the wall of the container. Because of these experiments, humans became aware of how the molecular structure of known matter could be split apart and recombined. Ironically, this experiment opened the door leading to the creation of the atom bomb.

Building upon the work of Cavendish, Antoine Lavoisier renamed "inflammable air" hydrogen—"the water producer"—and "vital air" as oxygen.

However, it was not until 1805 that Louis Joseph Gay-Lussac and Alexander von Humboldt proved that water was made up of two parts hydrogen and one part oxygen. This breakthrough proved that water is neither elemental (in the ancient use of the term), nor an element of chemistry, but a true compound unto itself. This new designation of water set it apart from air and earth (which are mixtures), and fire, which is a chemical process.

FIRST THERMOMETER

Before the invention of the thermometer, there was no way for people to qualify or quantify changes in temperature. The only way people could relate to changes in temperature was to comment how hot or cold something was. Comments like, "It's really a hot day today," or, "Brrrrr, the water is so cold, it gives me chills," were the only means of measuring temperature before the invention of the thermometer.

Galileo, along with others before his time, made the common sense observation that substances expanded when exposed to heat and contracted when chilled. In 1603, Galileo invented what is considered the world's first "thermometer" (Greek—"heat measure"). He did this by placing a heated glass tube upside down in a bowl of room-temperature water. As the hot air in the glass tube contracted, it pulled a column of water up into the tube. Through observation, Galileo made notes about how changes in room temperature caused the column of water in the tube to go up and down. This was one of the very first scientific instruments using glass, other than Leonardo da Vinci's earlier glass-sided boxes that were used for studying the vortical energy of flowing water.

In the mid-1600s, Ferdinand II, Grand Duke of Tuscany, discovered that placing water inside a round bulb with a narrow tube attached that was open at the top, provided a more sensitive way for observing temperature change. This allowed more accurate observations of water's response to temperature under different conditions, changes that, compared with Galileo's first thermometer, were more accurate because there was less influence from atmospheric air pressure.

Eventually, mercury replaced water or alcohol as the liquid of choice in thermometers. Mercury proved more stable because it does not freeze or evaporate. However, it was not until 1714, more than 100 years following Galileo's first thermometer, that Gabriel Daniel Fahrenheit invented a sealed mercury thermometer in combination with a graduated scale. History remains unclear how Fahrenheit selected the scale with which we are now familiar, a scale where water freezes at 32 °F, and boils at 212 °F. As is obvious, the study of water's response to temperature change determined the points on the thermometer. Determining the point on the scale where water turned to ice was considered a notable temperature event, as was the boiling point where water changed into a gas.

In 1742, 28 years after Fahrenheit's creation of a scaled thermometer, Anders Celsius of Sweden, fixed the freezing point of water at 0° and the boiling point at 100°. At first, this was recognized as the centigrade scale because of the 100-degree range where water remained in liquid form. However, in 1948 the centigrade scale became officially recognized by scientists as the "Celsius scale." This was to pay homage to the inventor and to be consistent with the naming of the Fahrenheit scale after its inventor.

The invention of the thermometer opened a whole new era of scientific and medical observation and inquiry. For instance, it was determined that the average human body temperature is 98.6 °F. A degree or two above or below this reading indicated of potential health problems.

Of course, the invention of the thermometer also gave humanity something more to talk about in its everyday life. Instead of just saying, "It's a really a hot day today," we can now say, "My goodness, it's over 90° today!"

SEAWATER BLOOD

About 100 years ago, the French scientist Rene' Quinton established the chemical similarities between seawater and blood plasma. This revelation created considerable media attention and opened the minds of many people to the possible origins of humankind and other life forms.

Today, science and medicine inform us that about 90% of blood plasma is water. This seawater-like blood water distributes necessary nutrients and oxygen to every cell in the human body through a network of approximately 60,000 miles of arteries and veins.

Because water is a universal solvent, seawater contains all elements known to humankind. However, scientists have determined that seawater contains only 11 elements in concentrations greater than 1/100%. Not surprisingly, these 11 elements are present in the human body at the same concentrations found in seawater.

OUR EVOLVING WATER CONSCIOUSNESS

In 1530, Nicolas Copernicus published his pivotal work, *De Revolutionibus*. This work theorized that the earth rotated on its axis every 24 hours and traveled around the Sun every 12 months, certainly, a startling theory for its time.

Today, there is an evolving water theory that may be as startling as Copernicus' discovery. This theory states that water is a conscious entity that responds to human thought and thereby creates our living reality. By doing so, water manifests the world within and around us in direct response to our thoughts and emotions. Think positive and loving thoughts—water responds by creating a healthy environment within and without. Think negative and destructive thoughts—water responds by creating a negative and destructive environment.

In her book, *The Entangled Universe*, Mae Wan Ho, Ph.D., establishes the recent discovery that we humans, as well as "... all living organisms are liquid crystalline." Because of our liquid crystalline makeup, we and other life forms are sensitive to various forms of energy, including the energy waves from sound, thoughts, and emotions. In this same book, Mae Wan Ho also writes:

> The visible body just happens to be where wave function of the organism is most dense. Invisible quantum waves are spreading out from each of us and permeating into all other organisms. At the same time, each of us has the waves of every other organism entangled within our own makeup.... We are participants in the creation drama that is constantly unfolding. We are constantly co-creating and re-creating ourselves and other organisms in the universe, shaping our common futures, making dreams come true, and realizing our potentials and ideals.

In other words, we as liquid crystalline beings, are the creators of our living reality, the same reality that responds to our thoughts and emotions and, in return, influences our very own existence.

Crystals in Water

The fact that "all living organisms are liquid crystalline" and all living organisms contain water is consistent with the fact that water naturally contains crystals. The presence of crystals in water becomes obvious when water is frozen. Snowflakes are another form of frozen water crystals. And, just as no two human faces are exactly alike, the same is true for snowflakes and other forms of frozen water crystals.

In the book, *Messages from Water*, Masaru Emoto provides scientific proof from his research results and photographs, as to how the crystalline structures of various waters respond to environmental factors, pictures, thoughts, words, music, and other influences. Emoto's research shows how water is a sensitive, lifelike entity, that is responsive to a spectrum of human and other energies. For example, Emoto would take a sample of distilled water and freeze it to obtain a baseline of what the frozen crystals looked like. Emoto would then expose samples of the same distilled water to different influences, such as certain thoughts, music, and written words. He would then freeze the water from the samples to see what changes, if any, occurred to the water's crystals. For instance, the projection of loving and caring thoughts into a water sample resulted in fully formed hexagonal crystals, whereas the projection of negative and violent thoughts into a sample of the same water produced incomplete or malformed crystals.

A FUTURE BASED ON WATER

Due to present water shortages and dire forecasts, the subject of water will soon permeate the minds of all levels of people around the world. The building of dams, such as the Three Gorges project in China, the large-scale desalination of seawater in the Middle East, the overpumping of the world's groundwater aquifers, the proposed transoceanic transport of Canadian water via huge floating water bags, and the competition amongst the world's most powerful transnationals to control sources of water are examples of the way humans are attempting to manipulate and distribute water. Simply stated, whoever controls water has political and financial power, as well as power over which life forms live or die.

However, beyond the physical management of water for profit and/or power, there are hints of other dimensions of water that may soon lead humanity to higher levels of consciousness. The fact that water responds to human thoughts and emotions is opening new possibilities to human evolution. In the near future, we may find that the projection of positive and loving human energies into water will deliver us into a healthier world filled with abundant food. If so, such a conscious progression in our evolution will give humanity the opportunity to help restore life to a planet that has been most supportive of our earlier stages of evolution.

This evolution of our water intelligence also includes our gaining a better understanding of the DNA molecule. For we are now discovering that the configuration of DNA is based on hydrogen bonding—the same as water. DNA is the basis for passing along genetic codes, and the H-bond of DNA is intimately connected with surrounding water clusters, so we may find a new basis for understanding genetic intelligence.

Perhaps, in the final analysis, the evolutionary progression of humanity will read as follows: Stone Age; Bronze Age; Iron Age; Industrial Age; Space Age; Computer Age, and then finally, Age of Water.

Whether or not humanity survives the Age of Water, in my opinion, will be determined by humanity's ability to work consciously with the living values and energies existing within water.

EFFECTIVE WATER EDUCATION STRATEGIES IN A NONTRADITIONAL SETTING

Sharon L. Lien
The Groundwater Foundation
Lincoln, Nebraska

INTRODUCTION

The Groundwater Foundation (TGF) is a nonprofit organization whose mission is educating people to care about and for groundwater and encouraging groundwater stewardship in all citizens. TGF's belief, which has come out of 20 years of experience, is that once citizens understand the importance of groundwater, they act to protect it.

Because of this, TGF puts particular emphasis on education and programming for the general public, especially youth. However, these educational programs have not been in the formal classroom setting, but in nontraditional settings, such as a festival environment, in competitions, or in the field.

This article discusses three specific examples of effective water education in nontraditional settings—Children's Groundwater Festival, Groundwater University, and Awesome Aquifers for Science Olympiad—and the impact these efforts have had on educating youth on groundwater protection and conservation.

Children's Groundwater Festival

From its inception in 1989, the Children's Groundwater Festival has been a success. Formulated around the concept of making learning fun, the Festival is staged in a fair-like atmosphere that is stimulating and exciting for participants, very unlike traditional classroom education. Whether witnessing the water cycle or building a well in a cup, students learn about every aspect of water and the environment in a fun way that helps them retain concepts and change their behaviors.

The Festival was designed as an annual 1-day event for fourth- and fifth-grade students of Nebraska. It is a dynamic, energetic day filled with hands-on education. Students from all over the state travel to Grand Island to learn about groundwater and related resources through interactive presentations given by groundwater and natural resources professionals who represent government agencies, environmental organizations, higher education, private business, and interested citizens. At the Festival, students have access to many water-related, experiential activities. There is nowhere else that children can have access to more environmental experts in such a fun and energizing atmosphere. This is a field trip like no other!

What makes the festival concept so effective is the unique and innovative methods used to teach the students about water. They learn what an aquifer is by making one with ice cream, discover how water is delivered to their home by becoming a human water distribution system, and gain an appreciation of the value of water by operating a working model of a treatment plant. Students don't just listen; they experiment, create, participate, react and learn, empowering them to make a difference.

The Children's Groundwater Festival has become an international model of hands-on environmental education. Over the years, water educational festivals have sprung up across the United States and around the world. To meet the demand for specialized training for festival organizers, TGF has published several books and provides workshops on organizing a water festival.

Groundwater University

Groundwater University (GU) was created in 1994 to provide intensive, experience-based groundwater education for youth and to encourage them to pursue science and water-related studies or careers. This program, directed toward junior and senior high school students, provides 3 days of hands-on activities, field trips, and presentations from top water professionals. GU offers participants the opportunity to study groundwater in a summer camp setting. Student activities include

- constructing mini groundwater models
- hiking the Platte River and digging down to the water table
- Participating in field trips to monitor wells, streams, and lakes to collect and test water samples
- investigating the relationship between microorganisms and water quality under a microscope
- building leadership and group skills through individual and team projects on topics of interest

As part of this program, students have the opportunity to share information about many groundwater issues that are unique to their communities. Because GU faculty includes professional hydrologists, chemists, irrigation experts, well drillers, and geologists from government agencies, private water testing laboratories, universities and colleges, and municipal water systems, students gain insight into water and science careers.

All activities at GU are hands-on and require participation. Some activities are done by teams, others are individual. Students take a posttest, and results are compared with those on their pretests to measure the change in knowledge.

Several GU graduates have continued their groundwater-related activities. Through GU, TGF educates students about groundwater helps them understand the connection between safe water supplies and public health, and ignites in them an interest in pursuing science and water-related studies and careers.

Awesome Aquifers for Science Olympiad

Science Olympiad (SO) is an international program devoted to improving the quality of science education, increasing student interest in science, and providing recognition for outstanding achievement in science education by both students and teachers. Student teams in participating middle and high schools all across the United States learn about different scientific topics; build models for some events; and compete at the local, state, and national levels in dozens of different SO events. The program emphasizes science learning, participation, interaction, building team spirit, and having fun. More than 2 million students are involved annually in SO.

Because an event on groundwater did not exist in the SO program, TGF created Awesome Aquifers. This event is designed to increase student understanding of groundwater concepts. Prior to the tournament, students conduct groundwater research and design and build a groundwater flow model according to SO rules that are standardized among participating schools. Students are required to demonstrate certain concepts, but there are almost no restrictions on how they build their models, so the event encourages student creativity.

During competition, students use their models to demonstrate an understanding of the hydrologic cycle, the physical makeup of an aquifer, and changes in the groundwater system. Students can earn bonus points for demonstrating possible contamination remediation techniques, such as using an intervening well to intercept a contaminant plume, chemical or physical treatment, or pump and aeration treatment.

Awesome Aquifers provides an opportunity to teach some of the nation's brightest young scientists about a resource that is critical to human and environmental health at a time when earth science programs are being reduced in many schools. Other objectives for the event are to give students a chance to learn about groundwater-related careers from working scientists who serve as judges or mentors for the event, and to educate two other groups who often know little about groundwater: science teachers, who generally serve as Science Olympiad coaches, and parents, who are often quite involved with student teams.

IMPACT ON EDUCATING YOUTH

In 1994 and again in 2002, TGF invested the time and resources to determine the effectiveness of the Children's Groundwater Festival and Groundwater University in impacting students' knowledge and behaviors positively toward groundwater. Results from this third-party behavior impact study indicated:

- The formats of these programs are especially well geared to the desired learning styles and approaches of students, and students have few suggestions for ways to improve either the Festival or Groundwater University. Students who have participated in these programs are likely to remember them for years, and up to 6 years later are able to relate what they learned during the event.
- The Festival did have a definable impact on students both in terms of gain in knowledge and change in behavior. After students attended the Festival, they exhibited an increase in knowledge as demonstrated through pretest and posttest scores. They also demonstrated a willingness to change their

behaviors, and in some cases actually adopted water conservation and protective actions.

- For Groundwater University students, learning goes far beyond groundwater education; it encompasses the "whole child." Students stated that they attended to learn about groundwater, but equally important for them was the opportunity to learn socialization skills, which they considered just as valuable. Almost all students noted that they appreciated learning about the cultural differences among themselves and their peers from other areas of the country. Many stated that they appreciated opportunities simply to interact with "experts" in the field (noted speakers, college professors, groundwater professionals, etc.) who had been invited to lead parts of the program.
- Students see the connections between groundwater and their own academic and professional interests. Though much of the information presented at Groundwater University is science-related, students can quickly perceive the connection of groundwater to other areas of interest and study, including writing, art, education, etc. Most importantly, the study determined that Groundwater University translates into behavioral change for most of the students (1).

Evaluations conducted by TGF have shown that Awesome Aquifers is also an effective activity to educate students on groundwater concepts. Based on information provided by students who have participated in the event,

- 97 percent of the students who participated liked the event.
- 89 percent indicated that they would participate again.
- 87 percent indicated that the event influenced them to conserve or protect groundwater.

Additionally, students overwhelmingly stated that they learned about the importance of groundwater, the complexity of an aquifer, and that groundwater is an important water source. Comments from students about what they learned included

- "This event helped me learn about the connection between pollution and the environment."
- "I learned that it is very hard to remove pollutants from an aquifer."
- "I learned more about the water cycle and how pollution affects it."
- "What an aquifer is, how it works, and what can we do to help."
- "A lot more about groundwater and the wonderful resource it is!"
- "I learned more than I thought possible and loved every bit of it."
- "We learned a plethora of information about conservation and protection."
- "Human activities affect the groundwater system hugely."
- "I learned how complex the underground water system is."
- "How waste can affect the water."
- "I learned a lot about the groundwater system and had an experience in actually seeing how a real aquifer works."
- "All about wells and the art of well construction. It also taught me how to protect and conserve groundwater."
- "We learned about groundwater and land water systems, and their relationships."

Real changes usually emerge from educational strategies that give the student a sense of involvement and ownership. Hands-on activities are a reliable approach for this as is student-directed learning(2). Thinking out of the box, or in this case out of the classroom, can allow water educators to explore less traditional educational strategies. By building creative and diverse programs that engage and empower youth and measuring the results of these efforts, the goal of protecting our groundwater supplies now and for future generations can be achieved.

EVOLUTION

David Haley
Picacadilly
Ulverston, Cumbria, United Kingdom

> "Those stars are the fleshed forebears
> Of these dark hills, bowed like labourers,
> And of my blood." (1)

In the cosmic sense of evolution, water may be viewed as part of the design of a supernatural "creator," or a quirk of fate—that a certain condition occurred for a combination of atoms (H_2O) to coincide in a particular atmosphere and remain for a sustained period of time within the atmosphere of a planet. And as Theodore Schwenk writes in his analysis of flow forms, *Sensitive Chaos*: "It is not possible to speak of the beginning or end of a circulatory system; everything is inwardly connected and reciprocally related. Water is essentially the element of circulatory systems" (2). He continues: "The great rhythms of the tides are a response to forces that work in the interplay of earth and cosmos. . .and for which, through its great impressionability, the element of water is a receptive 'sense organ'" (3). Governed by the Sun and Moon, this earth-bound phenomenon is claimed by creation myths and scientific conjecture and is the source of inspiration for poets and artists.

> Fallen from heaven, lies across
> The lap of his mother, broken by world.
>
> But water will go on
> Issuing from heaven
>
> In dumbness uttering spirit brightness
> Through its broken mouth.
>
> Scattered in a million pieces and buried
> Its dry tombs will split, at a sign in the sky,
>
> At a rendering of veils.
> It will rise, in a time after times,
>
> After swallowing death and the pit
> It will return stainless
>
> For the delivery of this world.
> So the river is a god
>
> Knee-deep among reeds, watching men,
> Or hung by the heels down the door of a dam
>
> It is a god, and inviolable.
> Immortal. And will wash itself of all deaths (4).

Some cultures and communities believe in forms of divine creation with regard to evolution, but the understanding of much Western science continues to be based on a synthesis of Darwin's natural variation and selection ideas and Mendel's model of genetic inheritance. Central to this theory, known as the Neo-Darwinian synthesis, is the idea that natural selection is based on the transfer of genes through reproduction.

New knowledge of genetics and other evolutionary factors continue to fuel scientific debate, providing different interpretations with regard to the timescales and population patterns of evolutionary change and development. However, what seems to be emerging is that "... it may in general be inappropriate to use a theory of any kind as an ultimate framework for life as a whole" (5).

Lakoff and Johnson explore these concepts in their book, *Philosophy in the Flesh*: "In evolutionary theory, survival is keyed to the ability to fit ecological niches. Fitting a niche and hence surviving can occur for many reasons: coloration that hides one from predators, a large number of offspring, the availability of food ..." (6), and to these we may add the availability of freshwater and the ability to adapt to climate change. They then examine Western culture's understanding of evolution: "There is a common folk theory of evolution, that evolution is a competitive struggle to survive and reproduce. The folk theory has normative implications: Competitive struggle to survive and reproduce is natural. Moreover, it is good, because it got us where we are" (7).

In *The Web of Life: A New Synthesis of Matter and Mind*, Fritjof Capra uses Maturana and Varela's theory of autopoiesis and Lovelock and Margulis' Gaia theory to explore the unfolding of life differently from Darwinian theories. Capra sees evolution as a process of biological and environmental co-evolution—"an ongoing dance that proceeds through a subtle interplay of competition and cooperation, creation, and mutual adaptation" (8). Other developmental strategies are noted in the recombination of DNA among bacteria; Lynn Margulis' theory of "symbiogenesis" recognizes the vital importance of cooperation in evolutionary processes.

Another pattern of development to consider is known as convergence, when different organisms meet similar challenges by evolving in similar ways (e.g., the development of eyes in diverse species). Convergence has also come into play during periods of intense growth and innovation following planetary catastrophes. "Thus the disastrous depletion of hydrogen in the earth's atmosphere over two billion years ago led to one of the greatest evolutionary innovations, the use of water in photosynthesis" (9). However, this led to a catastrophic accumulation of oxygen, which in turn led to the evolution of oxygen-breathing bacteria and that recombined with the hydrogen that was escaping the atmosphere to form water, "...thus keeping the planet moist and preventing its oceans from escaping" (10). Other interactive living processes, like fermentation, also contribute to the balancing of the earth's systems, known as Gaia: "Gaia is just symbiosis as seen from space: all organisms are touching because all are bathed in the same air and the same flowing water" (11).

"The Russian mineralogist Vladimir Vernadsky (1863–1945) recognized life as a great geologic force. Anticipating Hypersea, he called living matter "animated water." Animated water is an excellent description of life" (12).

What is certain is that there is no life without water. Animals evolved from aquatic microorganisms about 700 million years ago and plants followed around 200 million years later. Then, between 400 and 450 million years ago, plants followed by animals started to leave water, to live on land. This major habitat transition called for major evolutionary innovations to cope with the absence of water. These included respiratory systems adapted to oxygen, skin that could cope with increased radiation from the Sun, and muscular and skeletal development to deal with increased gravity. To this day, however, all animals maintain their origins in the form of the

> ... womb that simulates the wetness, buoyancy and salinity of the ancient maritime environment. Moreover, the salt concentrations in the mammal blood and other bodily fluids are remarkably similar to those of the oceans. We came out of the ocean more than 400 million years ago, but we never completely left the seawater behind. We still find it in our blood, sweat and tears (13).

Capra brings the evolutionary story up to the present day:

> Far away from their African homeland, the early humans had to endure extremely harsh climatic conditions that had a strong impact on their further evolution. The entire evolutionary history of the human species, from the emergence of *Homo habilis* to the agricultural revolution almost two million years later, coincided with the famous ice ages (14).

CLIMATE CHANGE

It would seem that extreme and sudden changes in climatic conditions have given rise to great evolutionary innovations and further developments occur over relatively long periods of adaptation to prevailing conditions. However, as the dinosaurs found, not all species or groups of species survive such changes, and these concerns are among the important issues facing the Intergovernmental Panel on Climate Change (IPCC).

In recent history, an Irish scientist, John Tyndall (1820–1893), discovered the importance of water vapor in maintaining the earth's life-sustaining atmosphere.

> Tyndall's experiments also showed that molecules of water vapour, carbon dioxide and ozone are the best absorbers of heat radiation and that even in small quantities these gases absorb much more strongly than the atmosphere itself, a phenomenon of great meteorological importance. He concluded that among the constituents of the atmosphere, water vapour is the strongest absorber of radiant heat and is therefore the most important gas controlling the Earth's surface air temperature. He said that without water vapour the Earth's surface would be "held fast in the iron grip of frost." He later speculated how changes in water vapor and carbon dioxide could be related to climate change (15).

From the nineteenth century, Tyndall's grasp of the potential climatic problems facing the twentyfirst century are now the source of much speculation. In the publication Climate Change 2001: Synthesis Report, Summary for Policymakers, the IPCC was clear about certain consequences:

> Changes in sea level, snow cover, ice extent, and precipitation are consistent with a warming climate near the Earth's surface. Examples of these include a more active hydrological cycle with more heavy precipitation events and shifts in precipitation, widespread retreat of non-polar glaciers, increases in sea level and ocean-heat content, and decreases in snow cover and sea-ice extent and thickness. For instance, it is very likely that the twentieth century warming has contributed significantly to the observed sea-level rise, through thermal expansion of seawater and widespread loss of land ice (16).

A CONFLUENCE OF IDEAS

Uncertainty about how to model predictions of the future effects of global warming and climate change are still contentious issues among the world's top scientists. Different methods of selecting and presenting information produce different scenarios that favor opposing political, social, and commercial lobbying groups. Professor Peter Sammonds of University College London believes that "(t)here is a serious problem that the starting point for discussion on the environment has tended to not be considered scientific knowledge but alarmist interpretations of future climate set in a highly moralistic framework" (17). He ascribes most of the effects of climate change to naturally occurring phenomena, challenging the validity of available data and its misinterpretation. Sammonds criticizes the insurance industry for "(t)his talking up of the threat of global warming..." to meet their own ends and asserts that "... nothing should be done which would curtail global economic growth through misplaced strategies to curb carbon dioxide emission. Otherwise, we would be damaging our very ability to adapt to environmental changes."

However, the IPCC's 2001 Summary concludes,

> Significant progress has been made in ... many aspects of the knowledge required to understand climate change and the human response to it. However, there remain important areas where further work is required, in particular:
>
> - The detection and attribution of climate change
> - The understanding and prediction of regional changes in climate and climate extremes
> - The quantification of climate change impacts at the global, regional, and local levels
> - The analysis of adaptation and mitigation activities
> - The integration of all aspects of the climate change issue into strategies for sustainable development
> - Comprehensive and integrated investigations to support the judgement as to what constitutes dangerous anthropogenic interference with the climate system (18).

Writing from an explicitly "green" perspective, in her book, *Water Wars*, Vandana Shiva expresses her views on the relationship between water and climate change:

> Water is life, but too much or too little of it can become a threat to life. The stories of Noah and Vishnu Purana are tales of mythic floods that whipped out life on the planet. While floods and droughts have always occurred, they have become more intense and more frequent. These climatic extremes are linked to climate change, which is in turn linked to pollution of the atmosphere by fossil fuels ... The impact of climate crisis on all forms of life is mediated through water in the form of floods, cyclones, heat waves, and droughts (19).

This echoes the Renaissance concern for apocalyptic visions, and Leonardo da Vinci's (1452–1519) late drawings of the Deluge (Fig. 1) seem to express this Dantesque preoccupation—water becomes a frightening phenomenon in violent climatic conditions. But Leonardo's aesthetic was to envision these apparently catastrophic events as the spectacularly exciting stuff of life. This description illustrates his imagination and love of the dramatic, as much as his lifetime study of water that could equally find a lyrical likeness between a vortex in water and the curls of a young girl's hair:

> And the ruins of a mountain fall into the depth of a valley, creating a shore for the swollen waters of its river, which having already burst its banks, will rush onwards with monstrous waves, the greatest of which will strike and destroy the walls of the cities and farmhouses in the valley. And the ruins of the high buildings in these cities will throw up immense dust that rises like smoke or wreathed clouds against the falling rain. But the engorged waters will cascade around the pool that contains them, striking in eddying whirlpools

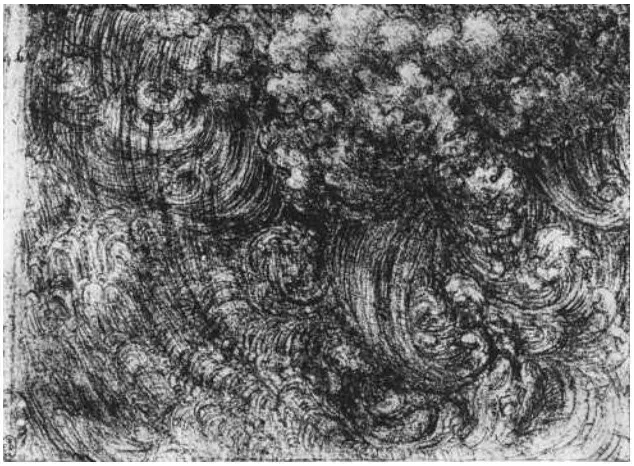

Figure 1. Leonardo da Vinci Deluge drawing No. 46 (146)—12383 Windsor collection.

> against different obstacles, throwing up muddy foam as they leap into the air before falling back and then again being dashed into the air. And the whirling waves that flow from the site of percussion are impelled across other eddies going in opposite direction, and afterward their recoil will be tossed up into the air, without dashing off from the surface. And at the outlet where the water flows from the pool, the spent waves will be seen spreading out toward the outlet, and afterward, falling or pouring through the air, and gaining weight and impetus movement, [this water] will hit the water below, pierce through it in a furious rush to reach bottom, and then being thrown back, the [water] returns to the surface of the lake, carrying with it the air that was submerged within it, and it, remains at the outlet, its foam mingled with logs of wood and other things lighter than water . . .The crests of the waves of the sea tumble down to their bases, whirling and falling with friction above the bubbles on their side (20).

Our evolutionary destiny and those of many other species depend on our ability to maintain adequate supplies of freshwater and adapt to the accelerating effects of climate change: “We must always bear in mind that the water we are using today is borrowed from future generations, who will require it for their survival” (21). Despite pollution, species depletion, and the uncertainties of the effects of global warming, the oceans still hold the greatest diversity of life on the planet and the potential for the continuum of evolution. As E. C. Pielou notes: “Living things depend on water, but water does not depend on living things. It has a life of its own” (22).

HISTORY OF POND FISHERIES IN POLAND

Janusz Guziur
University of Warmia and
Mazury in Olsztyn
Olsztyn, Poland

The origins of carp breeding in Europe and Poland are sunk in the obscurity of bygone times. In Europe, the first historic record of the carp as a cure for ailments is in the writings of St. Hildegard (1098–1170), the prioress of a Benedictine convent. Some time later, carp breeding in ponds was mentioned by the monk, Albertus Magnus (1230–1310), in the archives of the Kladbrubkski monastery in Bohemia (1115), and in an investiture act by King Przemyslaw Otakar II granted in 1227 in Moravia.

Several hypotheses have been suggested concerning the introduction of carp breeding in Poland. It is believed that two routes were taken to bring the carp from its native Black Sea watershed to Poland, but whichever way it traveled, the fish was brought to Poland by the clergy (bishoprics). The oldest monastic order that first engaged in farming and fish breeding was the Order of the Cistercians, which was brought to Poland in twelfth century from the province of Brabant (on the border of Belgium and France).

The domestic mirror carp is known to have been bred in Poland since the mid-thirteenth century. This breed is not found in the wild in Europe or Asia, unlike the wild river carp (sazan), which has local forms that live free, for example, in the Danube. Because of its inferior body exterior and growth rate, wild sazan differs distinctly from domesticated mirror carp and fine-scale carp.

In the 1960s and 1970s, attempts were made to 'refresh' the blood of farm carp by breeding Danube sazan in fish ponds or crossing it with breeding carp (1–3).

According to Balon (3), mirror carp, also known as royal carp (*rex cyprinorium*—Johnston 1650) originated from mutants of the Danube sazan, which Roman legionnaires brought to Rome, where it made its home and from where it was later taken to monasteries around west Europe (Fig. 1). The monasteries propagated the breeding of the cultured (domestic) carp, also in Poland; this was encouraged by frequent and lengthy religious fasts (up to 180 days a year) (3,4).

The first known written document mentioning carp in Poland, dating back to the year 1466, was penned by the famous chronicler of the Battle of Grunwald, Jan Długosz (1415–1480). Długosz (5) describes three carp in the coat of arms of the Silesian nobles Korbczok (*tres pisces, qui carpiones vocantur*), which was later confirmed by Paprocki's Armorial (1584), or two trouts (*duo pisces, qui trutae appelantur*) in the coat of arms of the family Musznik de Dombrova. The carp also appears in the accounting books of the Order of Teutonic Knights (Deutscherdrensritter) of 1399 (6). This evidence proves that the carp was widespread in Poland as early as the thirteenth and fourteenth centuries.

Based on books by several authors (4,6–12), four periods of carp breeding development in Poland can be distinguished:

First Period from the Mid-Thirteenth to the Mid-Seventeenth Centuries (To the End of the Swedish Wars)

This was the time of dynamic development and flourishing of pond fish farming (Fig. 2). The first printed books on fish farming came out. The first pond fish farming textbook in Europe was written by Jan Dubrawski (*Dubravius*) from Ołomuniec (13), who also described fish farms in Polish lands (Cieszyn Silesia). Soon to follow was the first Polish textbook on fish ponds by Olbrycht Strumieński (14) "O sprawie, sypaniu, wymierzaniu i rybieniu stawów," and then a book by Stroynowski (15), reprinted in 1863. In 1568, the Polish historian Marcin Kromer included some information on carp farming in his description of the Polish state (4).

Figure 1. Fishing in a monastery pond (3).

Pond fish farming in Poland, and especially in Upper Silesia, the Polish cradle of pond management, was considered the most modern and strongest in Europe, on a par with fish breeding in Bohemia and Moravia, in terms of modern technologies of constructing fish ponds and management methods (including restocking) as well as the volume of production. Restocking, which involved moving growing fish to other ponds, prepared and filled with water in advance, developed in Poland in the second half of the sixteenth century and became strongest in the following centers: Oświęcim-Zatorze, estates of the archbishops of Gniezno and Krakow, and in the valley of the Barycz river (Milicz). Noteworthy is the fact that the first information about restocking can be found earlier in the works of Strumieński (14) and partly Dubravius (13). In the early eighteenth century, when pond fish breeding in Europe was in decline, this method was forsaken and remained forgotten until the end of the nineteenth century (4,10,16).

The most extensive information on fish management in the fifteenth–seventeenth centuries is available from the region of Silesia, especially Opawa-Cieszyn, Pszczyna, and Racibórz Silesia, described by the Czech historians of carp breeding, including Dubravius (13) and Hurt (17). The area of Silesia had favorable climatic (warm summers), soil (clays with enclaves of loess), and especially water conditions (the sources of the large Polish rivers, the Oder,

Figure 2. Pond fisherman from Milicz region, seventeenth century (9).

Vistula, Olza, and Soła). Politically, Silesia was loosely tied to the Czech Kingdom, which allowed the region to enjoy great economic independence. The total estimated area of fish ponds in upper Silesia in the fifteenth–sixteenth centuries was about 25–30 thousand ha, which contained all categories of ponds used presently (12). Those ponds were used for breeding other fish species apart from the carp: the so-called black fish, including all fish that have a dark skin and scale color (crucian carp, burbot, tench, mud loach, wels) and white fish (common bream, roach, perch, ide, chub, ruffe, bleak, sunbleak) as well as other less valuable species (9). Both groups of fish equaled 15–20% of the total amount of carp, pike, and walleye fished from ponds. From the sixteenth century on, brown trout were farmed in the mountainous parts of Silesia (Cieszyn, Opawa). The fish was carried by highlanders (traveling on foot) over the mountains and then transported to the court in Vienna.

In those days in Poland, as in neighboring countries (Bohemia, Moravia, Hungary, and Bavaria), some nobles and dukes commissioned construction of huge fish ponds built as 'monuments to glory,' such as the ponds *Stary* (700 ha) and *Grabownica* (500 ha) near Wrocław and Milicz, *Kaliski* (625 ha) near Opole, *Bieruński* (500 ha) near Katowice, and *Sigmund August's* (480 ha) near Knyszyn (Białystok). The latter, also called *'Czechowizna*,' was built in 1560 by Czechs brought to Poland by Queen Bona (12,18). Many ponds and whole fish farms have survived and are still in use, for example, **Gołysz, Ochaby**, and **Landek** near Cieszyn; **Zator, Grojec, Osiek**, and **Czernichów** near Kraków; **Łyszkowice** near Łowicz; **Knyszyn** near Białystok; and **Przygodzice** and **Milicz** in the Barycz river valley, together with several smaller ponds in the valleys of the upper Oder and Vistula rivers. The high status that fish and fish pond farming attained then is confirmed by the emblems of many Polish towns that bear images of carp, pike, trout, and other fish.

Second Period from the Mid-Seventeenth Century to the 1860s

This was the time when fish pond breeding declined in all of Europe. Carp breeding became unprofitable and was nearly discontinued. In Poland, more than half of the existing ponds were liquidated (dried) and used for more profitable production of cereals, predominantly wheat (9,17). It was then, however, that Revised Krzysztof Kluk published his excellent work on farming (19), which remained popular until the mid-nineteenth century. The third volume of this book was devoted to fish and fish ponds (9,20,21).

Third Period from 1868 to 1939

This was another period of dynamic development, especially in modern methods of fish pond management. The impulse for this renewed development came from the area of Cieszyn Silesia, a fish pond 'reservoir,' located in the upper Vistula river watershed. It was initiated by the precursor of modern carp breeding methods, Tomas Dubisz (*Dubisch*). Tomasz Dubisz (1813–1888), a Slovak who was born near the Danube and lived in Vienna, was an illiterate fish breeder brought to Ruda Rożaniecka (1868) by Baron Wattman. Later, he worked as a master fisherman in Landek located on the land estates belonging to Cieszyn Manors (property of Archduke Albrecht Habsburg), which today forms Poland's largest experimental fish farm of the Polish Academy of Sciences in Gołysz, Cieszyn Silesia. The year 1869 marked an important event in carp pond breeding, when Tomasz Dubish, master fisherman at a complex of ponds in Iłownica (PAN Gołysz) introduced a new (or actually forgotten) carp breeding method of restocking. That is the system of moving 1-year-old fingerlings to a succession of ponds, prepared earlier and filled with water, reducing the density of stocking at the same time (10,12,22). The creation and implementation of this system made it possible to select the breeding material, shorten the breeding cycle from 4–5 to 2–3 years, and achieve dynamic growth in annual profit (Dubisz himself attained an increase in profit from 3000 to 40,000 zlotys per pond). Soon this system of fish farming was adopted all over Europe (16,18,21) and, with small modifications, is practically used until the present (11,23).

The breakthrough in carp breeding achieved by Tomasz Dubish was continued by his pupils and successors, including Adolf Gash (1839–1915) from Czechowice, a creator of a new breed of Polish carp (known then as the Galician carp) characterized by a strong back; Michał Naimski (1842–1915); Paweł Morcinek (1961–1938) from Skoczów, a known fish breeder active in Silesia and Moravia and also the first biographer of Tomasz Dubisz; Andrzej Gostkowski (1839–1889) from Wadowice; and later the fish breeder Oskar Rudziński (1850–1919) from Osiek near Oświęcim, together with his son, Edward Rudziński (1892–1980), the senior of Polish carp selection breeders in the years between the First and Second World Wars.

Owing to the system developed by Dubisz and the introduction of the new Polish carp breed, the productivity of ponds immediately rose by more than 30% (18). All these achievements by Polish fish farmers and breeders at the turn of the nineteenth and twentieth centuries guaranteed Polish fish farming a leading position in Europe.

The 20 Years Between World Wars I and II

This was the time of a dynamic increase in the area of ponds in Poland. In 1919, the Parliament of the Polish Republic passed an act on leasing unused farmland properties, and a year later (1920), on their liquidation and lease and management free of charge. The two legal acts made it possible to diminish the area of fallow lands from 4.6 million ha (1918) to 0.37 million ha (1923). The total area of fish ponds increased from 37.6 thousand ha in 1923 to 88.8 thousand ha in 1938 (Table 1), mainly in the Lakelands; fewer ponds were in the regions of Pemarania, Wilno, Wołyń, and Podlasie. New fish ponds appeared on numerous water and unused land areas (9,10).

In the years prior to the outbreak of World War I, Poland produced more than 13,000 tons of fish (Table 2) and held first position as a European fish producer in the volume of output (30% of the European fish production) and the amount of fish produced per capita (0.37 kg). The average yield of Polish fish ponds was 163 kg/ha, with

Table 1. Fish Culture in Poland (1923–1938)[a]

Pond production, tons	6,000	9,000	13,000
[%]	100	150	217

[a] References 4 and 10.

strong regional variations. The highest yields were still produced by fish breeders of Silesia and the areas near Kraków (to 800 kg/ha) and in Masovia (300–500 kg/ha), the lowest output was recorded in the provinces of Wilno, Polesie, and in Pomerania (to 123 kg/ha).

The first Polish Committee of Carp Selection was established in those years, headed by Prof. Franciszek Staff (1889–1966) and Edward Rudziński. After World War II, the Committee was presided over by Prof. Kaziemierz Stegman (1911–1978) of the SGGW in Warszawa.

Higher yields were obtained from fish ponds by widespread use of lupine to nourish fish (76% of the pond area) and mechanical and agronomic cultivation of the pond bottom, including fertilization. Pond operation was also aided by high unemployment and inexpensive labor in the countryside. There were also more than 50 centers of trout breeding (mountain and upland trout) of the area of 56 ha.

The FAO publications (Sarig 1966, cited by Ref. 11) indicate that carp from Poland and Germany were transported to Yugoslavia and further to Israel and the countries of the Far East, Indonesia (Java), North America, and Australia.

Postwar Period

After World War II and the subsequent change in the borders of the Polish state, the area of ponds in Poland diminished by more than 22 thousand ha and totaled 66,525 ha in 1945. Although about 9000 ha of fertile and well-managed ponds were taken over in the new lands in the west at the expense of 31.4 thousand ha of less fertile ponds in the former eastern territories of Poland (Table 3), the fish pond output attained at that time was comparable to that of the year 1938.

At present, the largest areas of carp ponds are in south and central Poland (three-quarters of the total area). In north Poland, in the territories of natural lakes (total area of 320 thousand ha) or in the mountainous regions, there are few ponds. The largest area of carp ponds is in the provinces of Silesia (Katowice)—11.4 thousand ha; Lower Silesia (Wrocław)—9.3 thousand ha; Masovia (Warsaw)—6.8 thousand ha; Pokarpackie (Rzeszów)—6.1

[b] European part.

thousand ha; Wielkopolskie (Poznań)—5.8 thousand ha; and Lubelskie (Lublin)—5.7 thousand ha. In some parts of Poland, the total area of fish ponds reaches 6% of the geographical area of the locality (Pszczyna, Skoczów, Oświęcim) or up to 10% (Milicz near Wrocław). The total registered area of carp and trout ponds in Poland is 71 thousand ha (72% of which is the area used). This figure does not include several thousand home ponds built in the last 10 years by private individual farmers.

In the postwar years, inland fisheries in Poland, including pond fish farming, has been reorganized several times. As a result, until 1990 more than three-fourths of the pond area was managed by the State Fish Farms. The remaining area was exploited by fishermen's cooperatives, the Polish Angling Association, and, to a much smaller extent, by farmers and individual private fish farmers [about 16 thousand ha of ponds (23)].

Large and medium size trout farms are now located mainly in north Poland, in the area rich in clean, cold water. Fewer trout ponds are found in south Poland (the Karpaty and Beskidy mountains), predominantly smaller and older pounds (some dating back to prewar times), for example, łopuszna on the Dunajec River. The dynamic growth of this branch of the economy began in the 1960s and 1970s.

Currently there are more than 180 trout pounds in Poland, including very large fish farms whose output is 200–1,000 tons annually and produce mainly rainbow trout, for instance, Mylof (1150 t), Zabrodzie and Tarnowo (400–700 t). The output of trout in Poland was 10–12 thousand tons in the years 2000–2002 and of carp, more than 20,000 tons (Table 4).

Apart from carp farms, since the year 2001, the Polish Angling Association has been managing 16 trout breeding farms (producing mainly salmon fingerlings). These farms are located in the mountainous regions and in the lowlands. They produce fingerlings of salmonids, mainly salmon, and some species of river fish (idus, asp, vimba bream, barbel., chub, beaked carp undermouth, burbot).

The political and social transformation in Poland led to the liquidation of the State Fish Farms. A number of fish farms, some well functioning (both financially and technologically), have been divided into smaller units, not always organizationally efficient. Some of them, subject to restructuring, were taken over by the Agricultural Property Agency of the State Treasury (APA) as one-man companies of the State Treasury until their complete privatization. A considerable number of inland water reservoirs (lakes) has been leased and carp and trout ponds have been sold to private fish farmers and producers.

WATER: THE KEY TO NATURAL HEALTH AND HEALING

F. Batmanghelidj
Global Health Solutions
Falls Church, Virginia

It is true that the micromechanical side of medicine has advanced at dizzying rates, but our scientific understanding of the way the human body works is still in the Dark Ages. The inventive, resourceful, but commerce-motivated employees in science have managed to walk a tightrope between true science and illogical nonsense-science of medicine, to the point that the human body is now viewed as a badly designed product of nature in constant need of their interpretation and meddlesome interferences.

They have sold this false bill of goods to the gullible public to the point that a vast percentage of America's GNP is allocated to cope with their thought in our society. This trend started at the turn of the last century, when scientists were flexing their muscles to gain acceptance for their understanding of the human body. Some of these scientists did produce miracles—but a few did unimaginable damage.

Walter Bradford Cannon, for instance, a prominent physician of his time, did untold harm to the progress of medicine. Cannon asserted that thirst in the human body reveals itself by the presence of a dry mouth, brushing aside the earlier view that thirst is more of a general sensation that needs to be studied and defined. The simplistic but false dogma of "dry mouth portending thirst" gained a foothold in medical science and has been with us ever since.

This seemingly insignificant assertion changed the course of scientific inquiry into the way the human body works. It pushed science in the direction of the chemical composition of the body and how these solid components of the body interact with one another. It gave way to the dominance of "solutes" and application of the science of particle chemistry to the physiological functions of the body—an integrated and complex water-dependent multisystem system. Even now, the hydrolytic role of water in chemical reactions is not given any consideration when evaluating the outcome of chemical actions in the body.

This direction of totally erroneous thought has thrown medical science into ignorance about the complex, water-dependent natural design of the human body. Solute chemists took over and made a mess of medical science. Nowhere is this mistake more apparent than in AIDS research, when every ill that befalls a person with this diagnosis is blamed on a minute particle called a retrovirus—in complete disregard of the obvious.

To survive through the millennia, the human body has overcome deadly viruses such as polio, smallpox, measles, flu, and more, and has developed the ability to mount a very effective immune response within 9 days. In other words, if a virus has not been able to kill the person in the first 9 days of its attack, it will itself be killed, and the immune system will be all the wiser for the encounter. Surely if the body, generation after generation, has survived fast viruses, getting over slow viruses must be a cinch. With this logic installed within the human body, how could we blame a devastating "disease process" on a retrovirus?

Surely the presence of the retrovirus in people with AIDS has other, less commercial explanations that are being ignored for the obvious reason that a natural solution would emerge. If you read my book *Your Body's Many Cries for Water*, you will discover that the AIDS virus is a byproduct of a larger metabolic disturbance that has a drastic disruption of the amino acid pool composition of the body at the foundation of the problem. Naturally, from this direction of thought will emerge a noncommercial natural treatment protocol that will emancipate society from the burden of costly AIDS research.

THE ILLOGICAL FOUNDATIONS OF MEDICAL SCIENCE IN THE TWENTIETH CENTURY

In all, four errors in scientific assumptions have made a mess of our view of the human body—in itself an efficient, self-repairing, self-replicating design:

1. A dry mouth is the only signal indicating the body's need for water.
2. Water has no direct initiative in chemical reactions of the body and is only a subservient and passive element in the actions of the solid matter that it dissolves and circulates in the body.
3. The human body is efficient in regulating its water intake throughout the life span from childhood to old age.
4. Any fluid can satisfy the long-term water needs of the body.

WHY ARE THESE ASSUMPTIONS FALSE?

Dry mouth is not a reliable indicator of thirst because the body produces ample saliva even though there may be established and symptom-producing intracellular drought in different regions of the body. To facilitate the act of chewing and swallowing food, producing saliva, even in a dehydrated state, is an overriding primary function in the body. The salivary glands produce about 2 liters of saliva a day to supply the upper parts of the intestinal tract with water and some digestive enzymes, especially when the body is dehydrated. Oversalivation begins when the body is short of sodium, a contributing component of dehydration.

To think that water has no direct and dominant role in the chemical and physiological functions of the body reflects an earlier basic ignorance in molecular chemistry that has been applied to human physiology. It is now almost impossible to expunge this error from the way medical science is evolving. This thoughtless assumption is one of the main reasons we have a "sick-care system," not a healthcare system based on preventing disease.

Water itself must break down first before any chemical reaction can take place. It is the hydrolytic property of water that drives all chemical reactions. A chunk of meat has no energy value unless water acts on it and performs its hydrolytic act of breaking it down to small, energized particles that can then, and only then, be assimilated within the metabolic systems of the body.

Advising people to rely on the sharpness of their thirst sensation to hydrate their bodies optimally is yet another mistake of modern medical education. As we grow older, we gradually lose our thirst perception, to the point that the elderly can become obviously dehydrated yet not have the urge to reach for a glass of water sitting right next to them.

- Does this mean that the body can function efficiently in a comparatively drier state?
- Does this mean that fully hydrated plumlike cells can become prunelike without impacting most of the physiological events of the body that depend on their efficiency of function?

The answer to both questions is an emphatic no. In their earliest prunelike state, even minimally dehydrated cells begin to produce symptoms. Modern medicine has classified these manifestations as "diseases of unknown etiology." The dis-eases of dehydration have led to the creation of various fields of specialty medicine. Larger and larger hospitals and nursing homes have been formed to serve the medical profession and maintain a firm grip on a society that still does not know that water is a disease-preventing medication. It is essential for survival, and it is the master key to vibrant well-being of the human body.

The fourth mistake is the view that anything fluid can supply the long-term water needs of the body—hence the emergence of the soft drink industry, wines and beers included. Suffice it to say that both caffeine and alcohol are addictive and have cumulative adverse chemical effects on the body. Alcohol, even in small doses, negatively affects brain function by shutting down an important water-delivery system to the brain cells. In larger quantities, this effect becomes pronounced to the point of causing hangover headaches, indicators of brain thirst.

Caffeine is a chemical much like morphine and cocaine that some plants manufacture to protect themselves against animals that would feast on their nourishing leaves, seeds, and exotic poppies, the instruments of their survival as species on Mother Earth. Caffeine is a dehydrating substance. It also suppresses the brain tissue enzymes that are vital to the retentive powers of the nervous system. When the plant made caffeine in its process of development, it did so to make its feasting foes stupid enough to become easier prey to their own predators. The plant had no idea that humans would become its protectors and harvest its caffeine in greater and greater quantities. For the plant, caffeine is a chemical weapon.

If a child or a teenager is allowed to drink caffeinated sodas in place of water, attention deficit disorder and low scholastic results should be the early expected outcome. And all we need do is visit a few old age homes to see the state of the mind of people parked there by a society that does not understand the important difference between simple, tasteless natural water and taste-enhanced caffeine-laced water. The introduction of artificial sweeteners has been an added burden on our society. You can get a clear understanding of this problem by referring to my book, *Your Body's Many Cries for Water*.

About 100 years of fast-track travel on the train of these medical misconceptions has produced the commerce-driven quagmire of a sick-care system now known to be based on ignorance, if not fraud. The drug industry's hijacking of medical education has been so successful that even the shocking recent revelation that prescription medications—taken correctly and according to a physician's instructions—make over 2 million people sicker and kill more than 106,000 a year does not raise any eyebrows in official quarters. It is also known that another 98,000 die from mistaken prescriptions. These are only the *reported* cases; God knows how many die silently. These figures together—204,000 a year—put the use of prescription medications as the third most frequent cause of death in America, only after heart disease and cancer. Doctors are now fully aware that the chemicals they prescribe have been manufactured as palliatives.

WHY WATER IS A BETTER MEDICATION THAN ALL THE DRUGS ON THE MARKET

Water is a better medication than whatever is manufactured by the drug industry for any of the presently recognized painful degenerative diseases. These diseases are the products of an inefficient, water-deprived, prunelike state of cells that cannot keep up with the demands placed on them. Each year, more than 700,000 people die of heart disease, 500,000 die of cancer, and arterial disease of the brain kills over 160,000. All of these deaths might have been prevented if water was given a primary position in the daily diet.

THE NATURAL ELOQUENCE OF PAIN: IT SIGNIFIES THIRST

It took me many years of clinical and scientific research to uncover the significance of the pain mechanism as a primary indicator of water shortage in the body.

The human body is a satellite of water-dependent units of life—about a hundred trillion of them housed together in one capsule on their journey of life. The cells of the body, each endowed with the same genetic secrets of life, have accepted a division of labor for an orderly conduct of business in their collective land-based shelter—"the body." It has an intricate water-dependent design—a mobile chemical refinery—that has established a foothold on "dry land." The medical pundits have misunderstood the various ways the body deals with its inner cleansing processes. Nonetheless, they use commerce-suited treatment protocols for different pain sensations, without the slightest understanding why the body, at times, manifests diverse localized or general pains.

It is now clear that there is a direct link between overproduction of histamine, as the neurotransmitter that regulates the water balance of the body, and the induced pain-producing inflammatory effect of histamine that is its mechanism of directing increased circulation to a drought-stricken area. If the blood is concentrated because of water shortage, the pain threshold of the brain is automatically lowered and pain is felt until the drought-stricken area receives water. Many systems and mechanisms are engaged in this process, all of them regulated by the water level of the body.

The trigger mechanism is the balance between the acidity and the alkalinity inside cells. The interior of the cells of the body must be alkaline—a pH of about 7.4. Water and the element sodium from salt flow in and out of the cells and wash out the acid that is produced as a result of the metabolism of working cells. In dehydration, the rate of acid clearance is diminished, and the interiors of the cells in that area become more and more acidic. At a certain level of acidity—a level that obviously eats into and hurts the gene pool—an acid-sensitive substance in the nerve tissue called kininogen is converted to kinin. Kinin itself is a pain-producing substance. Thus, the nerve endings in the area report the local chemical environmental change to the brain.

The brain translates this information into a form of pain for the conscious mind and takes away the ability to use the area so that extra acid production is stopped until water comes and washes the excess acid away. This process causes a localized inflammatory reaction. The circulation opens up, and more blood is brought to cleanse the area and activate the repair processes to "undo" the damage. This damage is often in the joints of the hands and the legs; it could also be in the spinal column, in the heart muscle (causing angina), or in the intestinal tract (causing colitis).

There are about 10 frequently produced pains that should denote dehydration in the area in question: heartburn, joint pain, back pain, migraine headaches, angina, colitis pain, fibromyalgia, false appendicitis pain, peptic ulcer pains, and the eye pains of glaucoma. It is said that 110 million Americans suffer one or more of these pains at one time or another. The cost of pain management for these people is estimated at more than $100 billion a year.

RESOURCE MANAGEMENT: NOT DISEASE

Water is the universal solvent. It is also the solvent of what you might have been told is disease. When the body is short of water, the ingredients that it dissolves and carries around are also missing. Like any well-organized industrial complex, the body has a resource allocation program—a strict rationing plan. Water and the substances it distributes become subject to preplanned priority distribution protocols. Vital cells in vital organs are served first, even at the expense of the less critical parts of the body.

Water conservation, the emergency water-distribution and resource-management programs of the body, have been called allergies, asthma, hypertension, diabetes, and the autoimmune group of diseases.

Allergies

The body deals with foreign agents by producing antibodies that attach to the offending agents and chemically neutralize them, be they pollen, bacteria, or viruses. Histamine has the dual role of being the water- and resource-management regulator, as well as the immune system monitor and activator.

The design of the immune system is such that in dehydration and overactivity of histamine as the resource manager, the activity of the immune system is inhibited at—of all places—the very center of activity, the bone marrow. There are twice as many inhibitor cells responsive to histamine in the bone marrow as there are killer cells within the immune system. Thus, in dehydration and the added presence of histamine, the immune system becomes less and less active and leaves the body vulnerable to pollen, infections, and development of cancer cells. The relationship of allergies and the broader implications of the diminished immune system activity initiated by unintentional dehydration should be taken very seriously. Allergic reactions of the body in childhood translate to a variety of health problems in later years.

Asthma

Air that is exhaled in breathing carries with it lots of water—the winter steam in front of your face. In 24 hours, we lose about a liter of water through breathing. In its capacity as the body's primary water-management regulator, histamine brings about bronchial constrictions to restrict the free flow of air from the lungs, along with the water that would otherwise go with it. The restrictive breathing in asthma will totally disappear if the body becomes fully hydrated.

Seventeen million people in America, mostly children, suffer from asthma—never realizing that water is their lifesaving medication and is freely available in their own kitchens. I predict that in the near future, it will be revealed that the drug industry knew about the relationship of histamine and dehydration, but concealed this from doctors and the public to profit from innocent children who live in constant fear of suffocation and frequently die from asthma.

Hypertension

Sixty million people in America alone suffer from hypertension—yet these people are actually experiencing internal drought. The extra pressure is needed to filter water from an already concentrated blood and inject it through clusters of holes—as wide as only one water molecule—in the membranes of the cells in vital organs. This is how organs such as the brain, the liver, the lungs, the endocrine glands, the heart, and more, receive some water when the body is dehydrated. When the blood becomes concentrated, it tends to pull water osmotically out of the cells of the body. The process of injecting water into vital organs is a compensation mechanism. If adequate water and some minerals needed by the cell interior are taken daily to the point of making the blood more dilute, blood pressure levels will drop back to normal. For more information about hypertension, read *Your Body's Many Cries for Water*—and take a look at another book, *Water Cures: Drugs Kill*, to see how easily others have gotten over hypertension by adjusting their daily water intake.

Type II Diabetes

When food enters the stomach and intestines and is processed, insulin is produced to help feed the cells of the body. It facilitates the entry of circulating sugar and amino acids into the cell through its cell membrane receptor channels. Sugar and amino acids also pull the water that is osmotically attached to them into the cell through these channels. In a dehydrated body, this would be counterproductive for the needs of the brain. The brain is 85% water and does not need insulin to pick up its food components from blood circulation. To avoid the catastrophic outcome of delivering the vital needs of the brain to less vital organs, the process that regulates blood flow to the pancreas, when the body is suffering from internal drought, also inhibits insulin release from the pancreatic cells that produce it. The extra sugar in blood circulation also osmotically compensates for the salt that is missing in dehydration. Increased water intake and supplementation of minerals, with salt on top of the list, will correct the physiological imbalance in this condition, and the diabetes will clear up.

For more information about chronic unintentional dehydration and the diseases it causes, read as many of the following titles as you can. They are the products of more than 24 years of focused research on the topic of deep dehydration inside the cells of the body: *Your Body's Many Cries for Water; ABC of Asthma, Allergies and Lupus; Water for Health, for Healing, for Life; How to Deal with Back Pain and Rheumatoid Joint Pain; Water Cures: Drugs Kill*; and my 2004 book, *Obesity, Cancer, and Depression: The Deadly Diseases of Dehydration*. These books will leave no doubt in your mind that your body is truly a marvel of creation, designed to give your soul a perfect habitat for you to achieve the anxiety-free greatness you are capable of. When your brain is not preoccupied with the aches and pains of your body, you will have the freedom to soar through the limitless horizon of ideas and ideals—how the curative power of water came into light.

For more information on dehydration, visit www.watercure.com and www.nafhim.org.

WATER IN HISTORY

Geoff Petts
University of Birmingham
Birmingham, United Kingdom

The story of water in history is about human ambition to achieve food security, economic growth, and political power. It is both a social and a technological history. The history of civilization is about social organization and coordination, and for six millennia, successful water resource management was the basis of civilizations. Early cultures were built on the food surpluses produced by managing the floodwaters of large rivers for irrigation. In humid areas dominated by rain-fed agriculture, water was influential in other ways by enabling trade along inland waterways. Water also powered mills that fueled industrial and economic growth. But the successful use of riparian and floodplain sites was frequently interrupted by tragedies caused by flood and drought. The notorious Huang He was popularly known as 'China's Sorrow' because of its devastating floods and dramatic changes in its course, but it is also prone to severe droughts. In recent history, major floods in 1855 and 1938 took millions of lives and in destroying crops, brought widespread famine and disease. In the great drought of 1877–79, 13 million people died of starvation. Similarly, early Sumerian and Babylonian civilizations had to survive flood disasters. The Biblical famine described in Genesis (47: 13–21) may relate to a period of persistent drought when the Nile flood failed. In more recent times, the great Mississippi flood of 1927 was a disaster for millions of people, and it also changed the course of the American nation.

Throughout our history, the popular pioneering vision has seen the human conquest of nature as the route to greater wealth and security (1). In all long-settled regions of the world, modernization involved large-scale water projects to reclaim 'wastelands,' 'conserve' water, 'control' floods, and 'harvest' energy. But water is also fundamental to sustaining the earth's ecosystems upon which human societies depend. Two key events in history supported the establishment of the first civilizations: the advent of farming and the control of water. From that point on, humans gradually and then with increasing power, exerted control on the ecosystems in which they lived. During the past 6000 years, but especially since the Industrial Revolution, the human desire to control waters and to reclaim wetlands has led to widespread ecological degradation (2,3). From the mid-1960s and more widely during the past two decades, the role of water in history has changed to become a symbol for a new social philosophy (4), that focuses on *sustainable* environmental management, the protection of biodiversity, the restoration of river corridors and lakes, and the protection of the seas and oceans. The history of this relationship between humans and water is summarized in Table 1. This highlights four phases in the human conquest of water: (1) overcoming the threat of drought, (2) generating power, (3) protecting public health, and (4) protecting (and restoring) water environments.

WATER IN THE ANCIENT WORLD

The foundation of the earliest civilizations involved the efficient and equitable distribution of water through advancement of both technology and management systems. Goubert (5) considered our preoccupation with water one of the subdivisions of the religion of progress. In Judeo-Christian literature, water is a symbol of salvation demanding human vigilance and the imposition of order (6). However, the first revolution in water technology was possible only following the introduction of an indispensable new tool, script. This was necessary for organizing people, water, and soil in quantities that were too vast to be handled efficiently by the unrecorded memorizing of oral arrangements and instructions (7, p. 51). Thus, the Sumerian civilization depended for its survival on effective control and also on effective administration of the waters of the lower Tigris-Euphrates (7). Early, highly structured 'hydraulic civilizations' (8) developed throughout the Old World, in northern India, Southeast Asia, China, and MesoAmerica. These civilizations were founded on centralized state authorities. Water yielded

6000	4000 B.C.	

privileges for a nobility that generated considerable revenues from irrigated agriculture, mills, fisheries, and navigation. However, political power and social stability depended on advances in water management technology to secure food surpluses and water supplies for urban centers.

In these early civilizations, advances in water management were inspired by the desire to conquer drought and flood. Diversion weirs, storage reservoirs, and irrigation systems were developed along valley bottoms. In China, the Great Yu undertook complex drainage and flood control works on the Huang He about 4200 years ago (9). In mountain valleys, terracing was developed to conserve water, and soil conservation was an important by-product. However, two inventions had a particularly dramatic impact on the relationship between human civilizations and water. First, the invention of the arch by the Sumerians around 6000 years ago (10) overcame obstacles to transport and water conveyance. The bridge has been described as a symbol of the human conquest of nature, and the river crossing is prominent in social, economic, and military history (10). Worldwide, folklore indicates that bridges had an important place in the lives of early communities and a strong ritualistic character. River gods were made angry by the building of bridges that deprived them of their regular toll of drowning people and animals, and sacrifices were deliberately made during construction to appease the angry spirits (10). Second, the invention of the water wheel around 2300 years ago (11) made conservation and management of limited or fluctuating water supplies possible.

The Egyptian Nile spawned a great civilization some 5000 years ago which depended entirely on the river and its annual flood (11). The oldest agricultural sites in Egypt date from around 7200–6000 years ago. By the end of this period, the ancient Egyptian hydraulic civilization had evolved into strong state, kingship, and political capitals with temples, palaces, and royal cemeteries. Levees, cross dikes, dams, and canals were built to capture flood waters for cultivating a single winter crop. This farming method has been traditionally credited to King Menes, the founder of the 1st Dynasty in 5100 y B.P. However, a 200-year dry period between about 4200 and 4000 years ago had an adverse effect on the economic base of many early civilizations from Greece to Mesopotamia that entered a Dark Age dominated by social disorder, crop failures, famine, and political collapse. This pattern of economic prosperity and political stability during years of a reliable flood and periods of dry years of political impotence, famine, and civil war is repeated in the ancient history of these hydraulic civilizations.

Early basin agriculture was no more than an advanced stage of subsistence agriculture. The invention of lift irrigation about 3500 years ago sustained perennial irrigation. New technology (the shadouf or pale and bucket lever) and deep wells allowed the development of a second growing season during the summer months. This led to a new era of wealth. But this technology was effective only for small plots. Large-scale irrigation became possible only in Ptolemaic times, from about 2300 years ago, when the Archimedes screw pump and the water wheel were introduced. They could raise water to higher elevations and at a faster rate than the shadouf. Ptolemaic engineers were supported by a strong administration to supervise irrigation, land surveying, and dike, weir, and canal maintenance. Their efforts doubled the area of cultivable land and reclaimed some 325,000 acres of fertile land for agriculture by lowering the lake level in the Fayum basin. However, this was also the first era of major human impact upon river corridor ecosystems. Conversion of the floodplain to intensive agriculture destroyed the virgin pasture, wooded thickets, and pools.

ROME TO THE MIDDLE AGES

The Romans were the greatest engineers in ancient history. They built large water-powered mills and complex water-supply systems with long aqueducts. By about 2100 years ago, Rome had a large and complicated water distribution system capable of supplying an estimated 680,000–900,000 m^3 of water per day. The Roman Empire was in no sense a hydraulic civilization, but the monumental masonry aqueducts that led water to their cities endure as symbols of the power and glory of the empire.

The Romans channelized rivers to aid navigation, and important towns, such as York in the United Kingdom, became established at the head of navigable waterways (12). However, the most important legacy of the Roman Empire was the water mill, which Marx saw as a key force in the making of feudal civilizations. In England alone, 5000 water mills were listed in the Doomsday Survey of 1086 (13). Water power remained the chief provider of mechanical power for corn milling, textile manufacture and iron works until the nineteenth century.

However, another revolution in water engineering technology followed the change from feudal to early capitalist systems of land management. By the fifteenth century, the core areas of European market capitalism, upper Italy and Flanders, witnessed early innovation in the mechanical control of water flows and river regulation (6). From the late sixteenth century, the pace and scale of water engineering accelerated, underwritten legislatively and financially by the new centralized states and a capitalist land market. A primary driver was to reclaim marshlands and floodplains to increase the area for productive agriculture and the area that could contribute taxes, and to contribute to national pride in conquering nature (14). Thus, new engineering techniques were advanced to achieve more efficient land drainage. The Dutch developed dredging technology and designs for floodgates, retaining walls, and groins. In Italy, the problem of *La bonifica* (land reclamation in its broadest sense) stimulated advances in the systematic control of rivers. The 'fens' of England were drained between 1630 and 1653 by the Dutch engineer Cornelius Vermuyden using techniques previously employed in Holland and Italy. Once again, the management of the drainage required the transfer of administration from localized, decentralized, self-governing bodies to a more centralized authority, in this case, Parliament. But now there had evolved a new driver of progress, a scientific approach to water management. By the end of the seventeenth century the 'art' of water management had been replaced by a scientific methodology (15), not least as a result of the work of Castelli (1577–1643), the founder of modern hydraulics.

Prestigious projects were conceived. The Canal d'Entreroches, built between 1638 and 1664 and originally designed to link Lake Neuenberg and Lake Geneva, crossed the great European water divide between the catchments of the Rhine and Rhone rivers (16). This caught the public imagination and received funding from the Dutch and the citizens of Bern and Geneva. The scheme failed, but one section was completed and remained open for 180 years, transporting wine and salt. Other notable schemes include, in France, Vauban's great military works for Louis XIV in the Canal du Midi (6). Thus began an era of belief in the domination of nature by science, freeing societies from scarcity, want, and natural disasters. This belief grew into the nineteenth century when Europeans exhibited an extraordinary faith in the power of science to control, manipulate, and enhance the natural world. Scientific innovation and technical skill drove dramatic expansion of European commercial and industrial power. Heffernan (17) considers Roudaire's *la mer interieure*, a proposal to create a vast sea deep within the Saharan desert, a classical illustration of European imperial ambition.

The Postindustrial Revolution Era

In the Industrial Revolution, water assumed an ever-widening role for power, navigation, water supply, and waste disposal. Urban and economic growth brought wetland drainage, canalization of natural channels for boat traffic, and embanking and dredging of rivers for flood control. Freshwater springs dried up as groundwater abstraction increased to supply rapidly growing populations. Overcrowding resulted from the desire to house as many workers as possible in a small space near the industrial workplace. Contaminated ditches and streams became open sewers and breeding grounds for disease. Small streams and brooks were often lost, buried beneath expanding urban developments. Large lowland rivers stagnated, and important fisheries died. In London, chronic conditions had been reached on streams and rivers by the late eighteenth century, but even the tidal river was severely polluted by the 1840s (18). However, it was not until the link between water and health was established at the end of the nineteenth century that a revolution in water and wastewater management occurred (5,19).

Water and Health

Great epidemics of cholera and typhoid in nineteenth century Europe led to the establishment of Public Health Committees composed of public-spirited people and led to systematic sampling of water for laboratory analysis. From the 1830s, the notion of public health placed the issue of water supply in a wider context, including housing, cleanliness of towns, poverty, domestic habits, and disease. Cholera arrived in Britain in 1831 and in London, the most severe outbreak, in 1848–9, claimed 14,137 lives. Popular belief, known as the 'miasmic orthodoxy,' was that illness was spread by an infected atmosphere. The first connection between water and health was made by a London doctor, John Snow, who in 1849, suggested that water polluted by sewage might be the vehicle by which cholera was transmitted. In 1854, he traced the cause of a cholera epidemic in Soho to a single source, a polluted well. However, until the Pasteurian revolution (1880–1890), 'clean' water was synonymous with running water and 'dirty' water with stagnant water. Running waters were seen as self-purifying, capable of diluting wastes and destroying organic pollutants by oxidation. Public health management focused on draining ditches and marshes where mosquitoes bred, separating clean water supplies from sewage, and providing running water via complex systems of pipes and pumps to supply city dwellers. Paradoxically, public health problems were made worse by attempts to exploit the 'self-cleaning' capacity of running water by creating complex sewage collection and conveyance systems. The introduction of the water closet into common use in the 1840s (and the dramatic growth of London's population) coincided with a severe cholera outbreak in 1849 and appears to have promoted epidemics because the sewer systems to which they were connected could not support the volume of liquid waste. In London, the River Thames was so bad in the summer of 1858 that it became known as the 'Year of the Great Stink.'

Pasteur focused attention on the role of microbes in water pollution and established a new scientifically based definition of 'pure' water. In 1883, the German bacteriologist, Robert Koch, isolated the cholera bacillus and confirmed that cholera is usually spread by water contaminated by the feces of an infected person. Clean, running water became an indispensable element of the urban landscape; domestic space was restructured, the toilet became a separate room, personal hygiene became a private and solitary activity, and fountains gained utilitarian as well as aesthetic and religious significance.

The Technological Revolution in Water Storage and Power Generation

The twentieth century realized the control of water, both through the advancement of large-dam building technology (2) and of basinwide management programs. America's New Deal and the electrification of the Soviet Union were both as much social and ideological as they were symbols of national pride. Developments accelerated at the end of the nineteenth century following new advances in earth-moving and concrete technology. New schemes such as the Vyrnwy Dam in the River Severn Basin, United Kingdom, represented a new phase in both dam building (the dam was more than 40 m high and impounded a reservoir of 59.7 million m^3 (the largest in Europe at the time), the beginning of large-scale interbasin transfers across 100 km, and raised issues of multipurpose river regulation for water-supply, navigation, and fisheries (15).

Hydroelectric power was first demonstrated in 1882. The invention of electricity had a dramatic impact because it can be readily and exactly applied to a wide variety of functions and also because it can be easily delivered to a precise and remote point where it is wanted. The earliest operating combined water turbine and electricity generator was built in Northumberland, United Kingdom in 1879–82, and the first commercial hydroelectric power station was operated at Salmon Leap Falls on the River Bush in Northern Ireland in 1883 (20). However, the control of Niagara Falls between 1890 and 1910 inspired the utopian imagination through the capacity to control nature. The giant turbines allowed generating electricity on a new scale, and the scheme also demonstrated the potential for long-distance power transmission, on lines to New York (21).

During the 1930s in the United States, the wholesale transformation of river basins in the Appalachian valleys of the Tennessee Valley scheme and the construction of massive dams and reservoirs in the Colorado basin (22) opened the megaproject era. The 221-m high Hoover Dam and its 37,000-million m^3 reservoir, Lake Mead, dwarfed earlier schemes (2). In the Soviet Union, Lenin's vision of communism as socialism plus electrification of the whole country evolved in the great HEP schemes along the Volga, Dnieper and Don, and later along the Siberian River. All regions of the world experienced further acceleration in the rate of dam construction after 1950 to secure water supplies and generate hydroelectric power.

Harvey (23, p. 13) sees the twentieth century as one characterized by a new 'lust to dominate nature' and a fierce and uncompromising patriotism fed by reckless personal ambition. He suggests that the mammoth river regulation and HEP schemes built in Africa in the immediate postcolonial era, such as Kariba (1959) and Cabora Bassa (1974) on the Zambezi (1959) and Akosombo on the Volta (1965), are examples. By 1990, there were more than 40,000 large dams over 15 m high, and 400 megaprojects had been constructed or were planned. These megaprojects have dams over 150 m high, a dam volume of over 25 million m^3, a reservoir volume exceeding 25 billion m^3, and an installed capacity of more than 1000 megawatts (24). Irrigated agriculture produced 40% of the world's food but consumed some 2500 km^3 of water. By the mid-1970s, the great multipurpose dam, once a symbol of social advancement and technological prowess, was being attacked as environmentally and socially destructive (25). By 1984, there was a wealth of scientific research to demonstrate the ecological damage caused by dams and river regulation (2).

The most recent chapter in the history of the Nile valley (11) began in the nineteenth century when the desire to modernize Egypt focused on expanding the cultivation of cotton, a summer crop, to generate foreign exchange. Later rice and sugar cane, both large water users, became desirable commodities. The construction of dams sluices and canals began in 1861. The Aswan Dam was first completed in 1902 and then enlarged in 1912 and 1993. Finally, it created a storage reservoir of 5.2 billion cubic meters and supports an irrigated area five times that under early basin agriculture and a cropping intensity of nearly 170%. But this phase of development was not without its environmental consequences. The raising of soil moisture levels created favorable habitat for plant and animal parasites and caused waterlogged soils and salinization. Pesticide use exceeded 16,000 metric tons in the mid-1980s when the fertilizer application was nearly 150 kg per 1.038 acre. A high count of undesirable algae developed in the regulated flows causing odor and taste problems. Thirty of the 47 commercial fish species disappeared, and the sardine catch in the eastern Mediterranean was decimated. This stage in the regulation of the Nile changed the face of Egypt (11).

In 1990, Barbara Cummings published a book entitled *Dam the Rivers, Damn the People*, that focused attention on the wide environmental and social impacts of large hydroelectric schemes in Amazonia (26). In 1996, McCully in *Silenced Rivers. The Ecology and Politics of Large Dams*, wrote of 'pharaonic works' that mortgage an entire society to benefit the elite and to enhance national prestige, but which bring little long-term benefit to society at large (27). Yet megaprojects continued to be built, and new projects, such as the Three Gorges in China and Alqueva in Portugal, continue to fuel the sustainable development debate.

In the developed economies, problems of river regulation were subordinate to those of pollution. A typical industrial river in Europe, the Rhine (28), shows the growing severity of fecal and organic pollution until 1972. Since then, improved sewage and wastewater treatment have decreased the input of labile organics to rivers. However, following the impacts of fecal and organic pollution, other major water quality problems appeared (29). Three common problems have been accelerated eutrophication (30), resulting in nutrient input rates much higher those of natural environments; acidification (31) caused by 'acid rain' from long-range cross-frontier transport of air pollutants, especially sulphur dioxide; and salinization of rivers, lakes and soils in dry land areas (32). Pesticides, organic micropollutants, and metals have caused additional problems that often have slow, long-term effects where problems are magnified through food chains to impact higher animals severely, especially the top predators (33).

The change in the industrial base during the second half of the twentieth century led, finally, to the death of the waterfront. Shipping that had provided the transport system for the Industrial Revolution was replaced by road, rail and air transport, and a technological revolution caused the virtual disappearance of labor-intensive heavy industry. In the United Kingdom, the catastrophic decline of the powerful shipbuilding industry of the great deepwater cities, London, Liverpool, Newcastle, and Glasgow of the Thames, Mersey, Tyne, and Clyde, respectively, led to mass unemployment and decay of the urban fabric. The social response to urban living was one where people became increasingly alienated from, and disinterested in, the local natural environment. Nature and wildness became associated with remote areas, to be visited when desired, for recreation and leisure. Yet water has retained its value for societies, for supply and power production and also for its important amenity value. In aesthetic terms, water is strongly prospect oriented; the riverbank and lakeshore provide the classic compromise offering the advantage of good visibility and security at the same time. Indeed, the introduction of a reservoir or canal into an artificial landscape can greatly enhance landscape quality, and the waterfront has become an attractive and valuable asset for business and residential developments.

The New Age of Environmental Responsibility

The last 50 years of our history—since the quantitative revolution in science of the 1960s—has witnessed scientific advances that have demonstrated the full nature of human impacts on waters. Early classic works include *Man's Role in Changing the Face of the Earth* edited by William Thomas in 1956 and *Water, Earth and Man* edited by Richard Chorley in 1969 (34,35). However, from a political perspective, the dramatic impact of Rachel Carson's book, *Silent Spring* (36), aroused public concern about contamination of water and air and the threat to wildlife and human health and provided the catalyst for change in policy and practice.

By the last decade of the twentieth century, a new approach to water management emerged (4) that has five facets. The first focuses on wastewater treatment and pollution control. The second is concerned with allocating water to protect aquatic ecosystems from the impacts of abstraction and river flow regulation. The third is concerned with the 'nature-like' channel designs and environmentally sensitive civil engineering works. Fourth, there is increasing concern for establishing protected areas and habitat refuges isolated from human interference, including fishing and hunting as well as habitat disturbance. However, the fifth is particularly important: collaborative decision-making involving informed stakeholders and public participation, supported by public educational strategies promoting community ownership of waters and their associated ecosystems.

Advancements in the scientific understanding of large waterbodies (37) and complex water transfer schemes (38) have provided the context for these advances. New scientifically based tools for water management have evolved (39,40). However, legislation and public participation are key elements of the new approach. Legislation for managing commercial and recreational fisheries has a long history (41). In the late twentieth century, some governments passed legislation limiting the uses of waterbodies for a wide range of reasons, including nature conservation (42). At the Earth Summit of 1992, *The Rio Declaration* and *Agenda 21: Programme for Action for Sustainable Development* (43) placed biodiversity, ecosystems, and popular participation at the head of the 'development' agenda. We now need to close the debate about unsustainable exploitation or scientifically based stewardship.

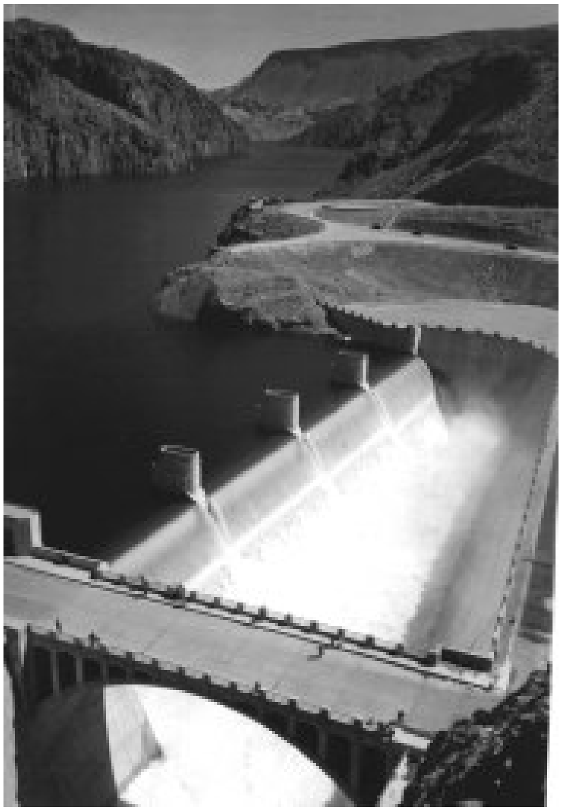
HOOVER DAM HISTORY

Bureau of Reclamation—U.S.
Department of the Interior

SPILLWAYS

The following article was put together by George, a former guide at Hoover Dam.

Many people who take the tour here at Hoover Dam want to know when they will get to see the water go over the top of the dam. Well, the water has never gone over the top of the dam and probably never will. We don't want the water to go over the top of the dam for a couple of reasons. First, the power house is located at the foot of the dam. The power house contains 17 large generators, each producing enough electricity to service about 100,000 people. All that water would be bad for the electrical generators (water and electricity don't play well together). Second, there are about 18,200 vehicles a day going across the top of the dam, and we don't want those vehicles to get swept away. The road across the top of the dam is a federal highway, and it is the shortest way to get from Las Vegas to points east.



Water will probably never go over the top of the dam due to the spillways. The spillways work just like the overflow hole in your bathtub or sink at home (if you don't remember seeing that hole, go look for it right now). If the water ever gets up that high, it will go in the hole and down the drain, not over the top and onto the bathroom

---

floor (unless, you have children and they plugged up the hole). The spillways are located 27 feet below the top of the dam, one on each side of the dam. Any water getting up that high will go into the spillways then into tunnels 50 feet in diameter, and 600 feet long which are inclined at a steep angle and connect to two of the original diversion tunnels. Each spillway can handle 200,000 cubic feet per second (cfs) of water. The flow at Niagara Falls is about 200,000 cfs, so there is the potential for two Niagara Falls here.

Each spillway has four steel drum gates, each 100 feet long and 16 feet high. These gates can't stop the water going into the spillway, but they do allow an additional 16 feet of water to be stored in the reservoir. Each gate weighs approximately 5,000,000 pounds. Automatic control with optional manual operation is provided for raising and lowering the gates. When in raised position a gate may be held continuously in that position by the pressure of water against its bottom, until the water surface of the reservoir rises above a fixed point, when by action of a float the gate is automatically lowered. As the flood peak decreases, the gate can be operated manually so as to gradually empty the flood control portion of the reservoir without creation of flood conditions down stream. The spillways have been used twice. The first time, in 1941, was a test of the system. The second time, in 1983, was for a flood.

The Arizona spillway was placed in operation for the first time on August 6, 1941, soon after the reservoir level had reached a maximum elevation of 1220.44. The drum gates were raised for several hours on August 14, 1941, and a hurried inspection revealed that the tunnel lining was intact, and the inclined portion showed little or no signs of erosion at that time. Operations were then continued without interruption until the reservoir level had been lowered to elevation 1205.60 on December 1, 1942. The average discharge flow through the Arizona spillway during this period was approximately 13,500 cfs with a maximum flow of 38,000 cfs on October 28, 1941, when one of the drum gates dropped without warning.

That much water falling 600 feet down a very steep tunnel caused erosion of the tunnel lining. The eroded area was approximately 115 feet long and 30 feet wide, with a maximum depth of approximately 45 feet. The original volume of the cavity was 1069.6 cubic yards. Repair work was started almost immediately, but because it was believed that ordinary concrete was not suitable it was decided to utilize the Prepack and Intrusion process of concrete repair developed by the Dur-ite Company of Chicago, IL. After repair, the tunnel was polished smooth to help prevent future erosion.

During 1983, record flows into Lake Mead were recorded. The record surface elevation was recorded on July 24, with more than two feet of water spilling over the raised spillway gates of Nevada and Arizona. The record flows through the spillway tunnels again caused erosion in the concrete base, which had to be repaired. High water was responsible for wide spread damage throughout the project.

HYDROPSYCHOLOGY

Bellie Sivakumar
University of California
Davis, California

INTRODUCTION

Population growth and environmental degradation have become primary reasons for water scarcity on Earth. Added to this, inadequate water planning and management activities have resulted in numerous water conflicts around the world, whether in developed, developing, or underdeveloped areas. Although efforts to address these problems continue on one hand, one cannot help but also witness the role of regional, social, political, economic, and even religious and linguistic factors, among others, as an increasingly troubling menace in these conflicts.

This gathering threat is further evident from the major shift in human perception and expression of the water scarcity problem. If recent reports are any indication, we are faced with a situation where any or a combination of these factors can take precedence over "humanity" and, thus, we are left with no choice but to express our unhappiness/dissatisfaction about the consequences in the "most blunt and even antagonizing" way [e.g., "What a Lovely Water War!" (1); "Water shortages foster terrorism" (2)] rather than in a "diplomatic" manner.

Under these circumstances, what we, as water scientists, planners, and managers, can and must do to alleviate the violent and dangerous consequences, in addition to what we are already doing in terms of "water science" per se, is and will be under serious public scrutiny. Asking ourselves two relevant questions (and possibly others) would help address this:

1. How do our water planning and management activities affect human behavior?
2. How does human behavior, in turn, influence our water planning and management activities?

It is clear that answering these questions is not a simple and straightforward task, particularly in light of our traditional "rule" of conducting water research, i.e., quantity and quality (although not without "exceptions" involving also social, political, economic, and other factors). It is rather more complicated, warranting inclusion of yet another important dimension, the "human side."

In view of the significance of this "human dimension," Sivakumar (3) argues that studying the transactions between humans and water-related activities (e.g., planning and management) should be an essential part of water research, and also proposes the term "hydropsychology" for this field of research. Citing an ongoing interstate water conflict in south India (the Cauvery River water dispute) as an example, Sivakumar (3) discusses the contribution of "human behavior" to this conflict, in terms of the two questions raised above. He opines that the "linguistic" factor combined with politics, rather than social and economic factors, plays the key role in this conflict, which is only worsening with the passage of time. His question, particularly directed at water researchers and managers in these two states, is how do they balance their "science and management" on one hand against their "emotional and psychological interests" on the other. Specifically discussing their responsibilities and obligations in accurately reporting the ground realities on water data and disseminating research findings, Sivakumar (3) points out an important moral dilemma they (we) face: to be (more) faithful to science or to region, community, language, etc.?

With the increasing disorder, violence, and even hatred among various human sections around the world because of social, political, economic, and other factors, it should not be difficult to foresee a gloomy world order because of the continued worsening of the water situation as well. In fact, many observers even believe that (fresh)water *will* be the source of violent conflict among communities and nation-states in the not-too-distant future [e.g., (4,5)]. As a combination of "water scarcity" and "human behavior" can have profound consequences, the traditional "water quantity and quality" research must be supplemented and complemented with the new "hydropsychology" research. The purpose of this article is to present possible ways to make progress in hydropsychology research, which, in turn, could shed some light on studying the water crisis and the associated conflicts as a whole.

PROGRESS IN HYDROPSYCHOLOGY

The field of hydropsychology is new and, therefore, research is yet to take shape. In what follows, some ideas are presented to begin research in this field.

Problem Acknowledgment

Like in any other study, the first step in studying the role of human behavior in water conflicts is the recognition that it indeed exists and the acknowledgment that it is significant. It is often possible (and even considered wise) to "overlook" this role, because studying human behavior involves some "sensitive" aspects, such as social and economic inequality, political ideological differences, and cultural, racial, religious, and linguistic differences. Any effort toward making progress in hydropsychology, therefore, requires an open and gracious admission on our part of the need to study these sensitive issues and our willingness to do so.

Problem Identification

On acknowledging the problem, the second step is to investigate the "actual" relevance of human behaviors in water conflicts and vice-versa, which is extremely important, because some of the so-called "water" conflicts may not necessarily be related to water in itself, but water may be used merely as a "scapegoat" for advancing other interests. These interests may involve one or more of the sensitive aspects mentioned above. For example, Sivakumar (3) opines that linguistic interests and political compulsions in Karnataka and Tamil Nadu play more important roles than water itself in the Cauvery River dispute, either as sources of the dispute or as obstacles to find an amicable solution. Many "water" conflicts around the world exist that have "other" facets to them than just water, e.g., the Indus River water dispute between India and Pakistan (political and religious compulsions, national pride).

Although it is clear that accurate assessment of the "correlation" between human behaviors and water conflicts is important to move forward in hydropsychology research, this task is tremendously difficult, or at least can be tricky, at times. The only way to address this issue is by identifying all the relevant parties that, we feel, may have a role to play in the conflict, in the water sector, and/or in the human behavior sector. Depending on the conflict of interest, this may involve bringing the public (e.g., community leaders) and politicians together with researchers in various disciplines, such as water science, environmental science, political science, social science, psychology, theology, etc.

Problem Solving

With the above identification of the relevant parties, the next step is to conduct extensive individual and group consultations and discussions. Of particular importance among these parties are the water researchers and managers, politicians, and community leaders. Water researchers and managers play crucial roles in water planning and management, such as assessment of water availability, storage, and distribution; the existence of any conflict of interest to us may also motivate, and even define, our specific research agenda, as highlighted by Sivakumar (3), who cites his own (regional) interests in discussing the Cauvery River water dispute. Politicians make important policy decisions in regard to water and, therefore, have the authority to approve or reject our proposals for not only water storage and distribution but also water research itself; Sivakumar (3) extensively discusses the role of local and national politics, politicians, and political compulsions in the Cauvery water dispute. Community leaders (e.g., social, cultural, religious), by their own status and privilege, have a crucial responsibility and also the means to advise and guide the people (their followers) in ways that would negate conflicts and violence; in other words, they have a responsibility to keep a "check" on the people.

Although there is no question that these aspects have been studied in water science, in one way or another, such studies have been limited only to "quantity and quality" aspects. For example, farmer participation [e.g., (6)] and socio-economic analysis (7) have been increasingly studied. A host of scientific techniques have also been employed in these studies, such as Delphi Technique, Expert System, and Decision Support System. What has not been studied, however, is the specific role of human "behavioral or psychological" aspect in water science, which, unfortunately, seems to be a more important factor in the existing water conflicts around the world, and may become even more crucial in the future ones.

As studying the human behavioral aspect transcends our traditional water science expertise, developing ideas and techniques would indeed be challenging. It is obvious that we would benefit from, and even require, concepts and tools used in behavioral science. What efforts we will make to combine the knowledge gained in water science and in behavioral science and how (much) we will succeed in supplementing and complementing the ideas and concepts remains to be seen. In this regard, it is encouraging to note that recent advances made in the study of complex systems (e.g., nonlinear dynamics and chaos) and others have proven to be useful in water science [e.g., (8)] as well as in psychology (9). The existing techniques for studying other aspects in water science, such as farmer participation and socio-economic analysis, should also help us lay out a solid groundwork in this challenging task.

Research Dissemination

The outcomes of the hydropsychology research must be disseminated not just to researchers in water and other scientific fields but also to common people. Particular emphasis must be given to dissemination through media outlets, so that it would be easily accessible by all sections of the society. Also, the communication must be simple and effective for even the layman to understand, just like he also understands "What a Lovely Water War!" and "Water shortages foster terrorism." In other words, we, as water researchers and managers, must communicate with all sections of the society (particularly with the common people) with a clear message that we understand and care about their plight and that we are willing to work with everyone to solve their water crisis and the conflicts, which, of course, is easier said than done. Not only is this task extremely challenging, it may also result in "backlashes" and "negative effects." Although we must expect these, we must also keep in mind that these negative effects are often short-term ones. We must be willing, therefore, to continue to move forward with our efforts, only for the long-term benefits of "humanity as a whole" rather than the short-term benefits of "special interest groups."

CLOSING REMARKS

Recent trends in population growth and environmental degradation have brought us to a realization that fresh water *will* be the source of violent conflicts around the world in the near future. Although lack of water is certainly part of this problem, existing water conflicts around the world reveal that other facets also exist (e.g., socio-politico-economic and even regional, religious, and linguistic factors), which are reflections of human behavior.

This article is a follow-up of a recent "hydropsychology" proposal (3) that advocated studying the transactions between humans and water-related activities to improve our water resources planning and management. Some preliminary ideas to begin research in this field were presented, which range from acknowledging the problem in the first place to its identification and solution and, finally, to dissemination of outcomes.

We, as water researchers and managers, as members of the society, and as the more fortunate members of the scientific community dealing with the most precious ingredient for our life only next to air, have a moral responsibility and obligation to find amicable solutions to existing water conflicts as well as to avoid potential future ones. It is my hope that we will start making efforts on hydropsychology research sooner rather than later, and we will strive toward planning and managing water for humanity and peace on Earth.

JACOB'S WELL

ARTHUR M. HOLST
Philadelphia Water Department
Philadelphia, Pennsylvania

Jacob's well was dug two miles southeast of the ancient city of Schechem, an area that is currently recognized as the city of Nablus in Israel. The generally accepted history of this well begins with Jacob, the original owner of the well and one of the Hebrew patriarchs. It is said that Jacob purchased the plot of land for grazing purposes "for a hundred pieces of money" (Gen. 33:18–19; Josh. 24:32; John 4:5–6). Jacob and his twelve sons were said to have dug the well together in the center of the property he purchased.

Jacob's well is famous for its religious connection to Jacob, and also to Jesus as well. It is believed that at this well, Jesus asked a Samaritan woman to retrieve water for him. Although its religious significance made it famous, there are other reasons that make this water source important. Limited rainfall and water supply plague the area. The story in the Bible (John 4:1–42) about Jesus and the Samaritan woman at Jacob's well, at a purely literal level, reveals the importance of fresh water sources to the people of this arid land.

> *"Jesus answered, 'Everyone who drinks this water will be thirsty again, but whoever drinks the water I give him will never thirst. Indeed, the water I give him will become a spring of water welling up to eternal life.*
>
> *The woman said to him, 'Sir, give me this water so that I won't get thirsty and have to keep coming here to draw water." (John 4:13–15)*

The Samaritan woman takes his offer literally as an end to her need for water, instead, Jesus attempted to draw a parallel to thing that she could relate to, her survival by means of water, his offer of salvation by drinking the "living water." Her response shows how important a water source, such as Jacob's well, was to their continued existence.

The well alone is an example how the people of this region and their livestock have sustained themselves since ancient times. The effort that was put into building a well of this magnitude illustrates the importance of this water source.

Water rights in this area have been contested for centuries. It was one of the conflicts between Samaritans and Jews in ancient times and part of the current conflict between the Israelis and the Arabs. The struggle is over a limited amount of land that is suitable for sustaining life in this area. It has become a more serious issue due to population growth over the years as a result of higher birth rates and immigration.

Jacob's well is approximately 100 feet deep and 9 feet in diameter, though it is very likely that when it was first dug, it exceeded this depth. Water gathers in the well from an underground spring. It has been called "living water" because the water comes from a moving, fresh stream. A well of these dimensions would have required a great deal of work and a large sum of money in ancient times. Today, Jacob's well is still being used; it has become a tourist attraction and religious shrine. A large, unfinished church has been erected over it. The land that surrounds the well is currently owned and tended by the Greek Orthodox Church.

JAUBERT DE PASSA: THE FIRST WORLD HISTORY OF IRRIGATION IN 1846

Eric P. Mollard
Institut de Recherche pour le
Développement
France

The first world history of irrigation appeared in 1846, and it has remained the only one to the present. The four volumes of the "Recherches sur les arrosages chez les peuples anciens" (Research on Watering among Ancients) describe hydraulic enterprizes from the most modest to the most monumental, and provide the political and social history of people who mobilized and organized themselves for this purpose. François Jaubert de Passa (1785–1856) was 61 years old when he wrote The First World History of Irrigation. This Catalan landowner, trained in law and after a political career, defended the conviction of a lifetime and intended to demonstrate it by systematically writing of irrigation from antiquity to the beginning of the nineteenth century. The lessons he drew from the comparisons in various cultural and political contexts are always topical, so much so that they match contemporary international issues. How is it possible that this early work, which had the potential for becoming an important foundation for organizing irrigation, has been all but ignored for one century and a half?

THE AUTHOR, HIS TIME, HIS CONVICTIONS

The book was published at a time when France experienced an institutional shift. The first half of the nineteenth century was under a political economy, and the second was marked by the reinforcement of technocracies and state intervention.

After the Napoleonic epic and the Congress of Vienna in 1815, France resumed military operations: the Spanish expedition, naval intervention in Greece, and the seizure of Algiers. The Geography Society of Paris has existed since 1822, the date when Champollion deciphered hieroglyphics. The military interventions continued (Rio de la Plata in 1838), and commercial establishments were set up in the Ivory Coast and Madagascar. Detailed accounts of travelers animated the discussions of many scientific societies under the reign of Louis-Philippe (1830–1848). In line with Montesquieu[1] and Toqueville,[2] political systems and their advantages for economic activity were discussed.[3]

In 1845, the Great Famine in Ireland began and lasted until 1867. Agronomists theorized around Liebig's discoveries in biology and, after the physiocrats, they strove to diffuse the intensive Norfolk rotation. At the end of the first half-century, the Research is directly influenced by the agronomy of notable landowners and the political economy. Jaubert de Passa gave an account of his observations in silkworm, mulberry tree, and oak cork farming, as well as in watering in the department of Pyrénées-Orientales. As a lawyer, he wrote the rules of the Têt users association, a river which crossed Perpignan and irrigated the plantations of Rousillon. Using the Research, he wanted to convince the politicians of the

[2] *De la démocratie en Amérique* was published in 1840.

[3] The Revue d'Économie Politique was created in 1833; the review Economie Politique Chrétienne of Villeneuve-Bargemont dates from 1834; the Société d'Économie Politique was created between Augustin Thierry et Michelet's books; the Annales de la Société d'Économie Politique were published in 1846.

productivity of irrigated agriculture:[4] "How much there are not, even in France, enlightened spirits persuaded that irrigation cannot have, in the fields of Gaul, results other than to multiply the meadows and to increase the desirable production of meat." He also tried to convince people of the role of institutions in guaranteeing freedom and authority. In addition to his own writings,[5] he gathered two sources, ancient authors' and travelers' descriptions. As a comparative history of civilizations covering the Old World, except sub-Saharan Africa, this treatise incorporated the sagacity of a field man sensitive to water government and social practices. In other words, Jaubert de Passa built an irrigation history on the basis of users' behavior, the real contracts that they have, and the local relationships that mediate the interaction between a regime and productive needs.

In 1851, the reign of Napoleon III began. Interventionism, which was legitimated by Auguste Comte's positivism,[6] resulted in great reclamation operations: the Suez Canal, development of the Gascogne Moors, and damming of the Rhone river. Upon the advent of state bodies of engineers, the debates gave up the ground of the political economy and the Research losts their interest at a time that emphasized technology. One of the possible reasons for the oblivion of the social component in irrigation was that local arrangements do not make the fame of the ruler sufficiently obvious, nor does homage to "progress." It is amusing to read, one decade in advance, an explanation of the exclusivity given to monumental technology. The next choices of Napoleon III echo with those of a pharaoh: "in his turn Menes raized dams and dug canals; moreover, he rectified the Nile riverbed and created artificial lakes to multiply jobs, to fertilize new soils, and to give royalty a character of beneficial greatness,"[7] as well as an Egyptian vice-pasha at the time: "The dam (at the apex of the delta) is not a modern idea ... Mehemet-Ali wanted to resume the project, to attach his name to a colossal work worthy of his genius."[8]

The interest in great irrigation under the aegis of the state was concretized one-half century later in Algeria and by general resident Lyautey in Morocco. It is possible that the Research influenced the French law of 1865 on user associations, which granted them legal status. Conversely, it is not certain whether small peasant irrigation was ever encouraged by the ruler as he had wished.

IRRIGATION AND GOVERNANCE IN THE "RESEARCH"

The Research is composed of six geographical parts (Table 1), which detail, region by region, the history of irrigation. Jaubert de Passa's objective is not theoretical, and only the final chapter advances some principles for an institutional framework to support the installation and durability of irrigation in France. However, one can highlight five great ideas through the combinations of situations and lessons that he draws through writing.

Irrigation and Civilization

Jaubert de Passa underlined the colossal aspect of antique hydraulic works, which are not unrelated to the Pyramids, the Hanging Gardens of Babylon, and the Great Wall of China: the construction of the Imperial canal spread out over five hundred years, "we will have an overall length of 440 leagues, the longest navigable canal in the world."[9] In a more pharaonic way, "... in the area that the Ionians were the first to indicate by the name Delta (Herodotus) ... with periodic floods on a flat ground without defense, it was required there to raize hillocks to build the villages and insulated dwellings. These hillocks required immense embankments because the delta had large cities, temples of extraordinary extension ...."[10]

Would Karl Wittfogel, one century later, have written "Oriental Despotism" (2) in the same manner if he had read Jaubert de Passa? Through the study of great hydraulic civilizations of the past, Wittfogel highlighted the need for a strong bureaucracy in creating and managing hydraulic projects, a bureaucracy that gave structure to the state apparatus and eventually to the whole society. The material and ideological bases of "Oriental Despotism" would reside in great irrigation. The two authors thus agreed on the institutional and political nature that underlies the construction of collective works.[11] On the other hand, Jaubert de Passa granted more credit to governance than to institutional structures. He showed that despotism or democracy can be either a brake on or a lever for irrigation.

Table 1. Composition of the Book

1st part	Assyrian Empire	Assyria, Babylon, Armenia ...
2nd part	Hindustan and Ganges valley	Hindustan, India, Thibet, Sindh, Nepal, Assam, Burma, Siam, Java ...
3rd part	China	Waterings, hydraulic works, agriculture, Japan, Siberia
4th part	Syria, Arabia, Egypt	Damascus, Antioch, Phonicia, Arabia, Yemen, Ethiopia ...
5th part	East	Cyprus, Ancient Greece, Thessalia, Asia Minor
6th part	Ancient Sicily, Italy, Roman Africa	Property among Romans, Republic, Empire, Tuscany, Algeria, the Sahara, Morocco
Chapter IV of the 6th part	About laws and water regime in relation to agriculture	Classification of water, concession, administration, competence, and jurisdiction

[11] "In a hydraulic society, civil servants have privileged rents, which benefit owners in occidental society."

The Factors in the Origin of Hydraulic Works

A large hydraulic enterprize supposes the capacity to mobilize and organize an enormous labor force in a more or less coercive way. Wittfogel translates gigantism into social terms: “the delegates of power behave like tax masters of the national surplus and prestigious consumers.” Unlike administrative terror and tax and legal submission in Wittfogel’s book, Jaubert de Passa proposes a contract or, at least, sharing between leaders and people of social norms where religion would play an essential role, just like the confidence delegated to an administration that would animate a paternalist design of its role. Jaubert de Passa stated that tyranny within despotism is not durable.

The Research specified the factors in the origin of the canals, which do not necessarily have irrigation as their first goal. “From now on it was less a question of opening new canals than to improve, extend and especially to apply the discharge canals to the needs for agriculture.”[12] The canals frequently have contradictory functions which require arbitration by the authority. The multifunctional character of the hydraulic technique applies besides to other sectors, in particular, the use of water in agriculture. Also, watering is used not only to irrigate, strictly speaking, to bring water to profit from additional production, but also to fertilize or improve the quality of production.[13] This plurality of functions, which results in distinguishing places and times, makes any attempt at generalization a delicate matter. Finally, irrigation is also related to land colonization and the possibilities of selling agricultural goods: “the multiplication of the canals accentuated the role of the Nile in transport.”[14] Other factors took part in creating hydraulic works: trade, army, cities, tax department, and strengthening power,[15] and the ruler’s fame. Water marketing is seldom practiced: “the public sale of derived water, in the only area of Ispahan, produced for the Shah, at the time of Chardin,[16] [. . .] 180,000 francs.”[17] The comparison of tax pressures established by Jaubert de Passa displays the great disparity which prevailed between the countries and the times. Like ancient Greece, where the tax was at the sixteenth under Solon,[18] imperial China also had the wisdom to limit pressure: “At no time, the emperor could be unaware of the public sufferings . . . China is thus the region in Asia where land is the least taxed.”[19] In fact, the surpluses released by irrigated agriculture could lead to strong tax pressures. But it was not only the tax department which was to be taken into account, but all measures that encourage or discourage the farmer: “Not only the rates, but arbitrary taxes, in the East, harm agriculture.”[20] Moreover, throughout his work, the author gave more emphasis to social practices and abuses than to formal government structures.

The Sharing of Social Standards

Social cement, which ensured the thousand-year-old sustainability of irrigated agriculture, rests on the standards shared by the various classes in a society: users, an attentive administration, and a fair ruler, whose richness comes from the farming community. Social submission and terror cannot function for long because farmers can unite in great masses and revolt against the establishment. Such revolts resulted in the overthrow of several Chinese dynasties by exasperated peasants. Civil disobedience, infrastructure destruction, revolts, abandonment of irrigated farming,[21] even emigration, as in the Nile delta under the Turks, are realities a government, tyrannical though it can be, authorizes only in the event of a major crisis. Consequently, the author suggested that communities placed their prerogatives and their confidence in the hands of the government to repair the infrastructure quickly, to protect rights, and to arbitrate conflicts. As the territory was extended by military invasion or land colonization, the more the state incorporated these prerogatives, the more it was able to mobilize labor and resources for increasingly monumental works. The surplus released by irrigated agriculture reinforced the class not depending on the land and the capacity to undertake increasingly colossal work, often at the request of the peasants themselves.

The contract was not always explicit because it was embedded in a total social fabric. In India, a religious reference is at the origin of irrigation: “There are even poor men who beg for several years to have a tarpa dug later in an uncultivated soil or on the edge of a commercial road. Bringing water in a deprived place is a commendable action in the eyes of Brahma;”[22] “In Egypt, in ancient times, the magistrates appointed for water supervision were taken from the caste of priests; their judgements were all the more respected because they were provided in front of the gates of the sanctuaries.”[23] In an identical way, the civil water court in Valencia, Spain, always sits at the entrance to the cathedral.

Religion played a political role of countervailing power and a barrier to despotism: “As agents of this legislation, the priests always opposed a salutary brake on the sovereign authority and popularity; their

[13] “Irrigation was mainly aimed at increasing the acreage and the return of meadows. In the rich grassland of Thessalia a horse breed adapted to warfare was reared” V57. “The Sibi district is crippled with rocky hills . . . Man draws an admirable benefit from restricted resource of nature: with the streams and on poor and sandy soils, he created rich soils whose fertility seems inexhaustible” VI252.

[14] IV292.

[15] For instance, “The Persian king blocked a small valley, thereby holding the water and making a vast reservoir . . . Suddenly deprived of irrigation, lowland farmers saw their millet and sesame crop perishing [. . .] Tired of so many pains, users came to implore at the palace gate, and they got, against high fees, that the water gates . . . would be opened successively for the watering of the five small valleys” I191.

[23] VI351.

intervention imposed on the ruler circumspect functioning in conformity with the laws, at the same time as they gave to the people lessons of morals and more moderate feelings."[24] Jaubert de Passa added, "From absolute possession of the land to the control of the agricultural classes and the humiliation of the privileged caste, the distance is short and easy to cross: the priests understood it, and soon, advized or intimidated by them, Joseph returned to the owners of the lands which they had sold to the king, with the charge for them to pay annually to the royal treasure the fifth of all the products."[25] Not only is the purpose of one good administrative organization to intervene advizedly, but it must also share the social standard and be subject to control. The administration must justify its presence to the taxpayer. Tax and operational involvement of an administration are invariant and, for lack of countervailing power, it can easily justify itself in the eyes of the only ruler by an opinion which favors the monumental enterprize. This double function of the administration was particularly clear in Egypt: "Notifications transmitted by the inspector of the nilometer were going regularly to warn the governors of the provinces: the farmers and the officers of the king modeled themselves on these notifications, the ones, as Strabon says, to warn with the distribution of water and to do the necessary work on canals and dikes; others, to establish the tax, because they adjust it to the extent of the height of water."[26]

Conversely, the pragmatism that the management of water requires resulted sometimes in sacrificing the best principles. The Chinese administration thus chose the confusion of powers: "This apparent confusion in the performance of two quite distinct duties (delegate of water and judge) has as a result, in an empire where centralization and control are thorough until the last detail, to prevent conflicts between rival authorities and to facilitate the operations."[27]

The Decline of Civilizations

Nothing is ever gained, and the factors in the origin of great civilizations can be called into question. The ecological factors and the natural disasters were exploited little by Jaubert de Passa, who overlooked land salinization in Mesopotamia and the recurring silting up of tanks and canals.[28] Should we, therefore, assume that societies, at any given time, cannot mobilize themselves to rehabilitate drains, clean canals, and create new tanks?

His analysis of the decline of Egyptian irrigation under the Turkish empire led to detail governance resulting from the regime set up by the Divan.[29] First of all, he criticized the Ptolemaic kings: "Under Arcadius (395 A.D.), the tyranny of the tax department was extreme, but it respected watering, even by attacking ownership . . . One of the laws stated that those who were accused of having opened a dam along the Nile were to be condemned to be burned at the stake . . . Under Zenon in the year 474, the annual tribute of Egypt was suddenly raized from 50 pounds to 500 pounds of gold . . . Under Phocas, the Egyptians were excluded from all public employment. Lastly, under Heraclius (year 641), the religious fights caused a civil turmoil which put an end to the domination of Greek emperors."[30] At the time of Arab domination, which was often favorable to the diffusion of irrigation, he showed that it resulted in weakening the pillars of traditional Egyptian religion. But it was especially the Turkish regime which caused the abandonment of a good part of the delta by farmers.[31]

The first problem occurred from new task sharing imposed by the Turkish government: "To reduce the burden on the treasury, the Divan maintained the old habits, and it declared the population responsible for maintenance, in spite of confiscation, which deprives them, mainly, of the benefit resulting from this work."[32] The negligence and incompetence of the high administration are added: "Since the drudgery was maintained, work from now on was exposed to the inexperience and arbitrariness of the governors: they forgot, rather generally, to carry out certain repairs in due course . . . Often materials are missed, the time is short, and the unhappy fellah, curved under the whip, drives in posts, piles up corn canes."[33] The submission became physical and there remained nothing but terror to try, with dubious success, to preserve irrigated agriculture. The abuses and the privileges of big men resulted in appropriating water. Corruption increased in all levels of the administration. That will provide Bonaparte's words: "Better than Mamelucks, or let's retire."

Law and Institutions

Good legislation and freedom of undertakings are two principles on which, Jaubert de Passa claimed, irrigated agriculture needed to be developed in France. Watering must "be freed from the obstacles of the tax department, protected by the law and encouraged by the ruler."[34] He established a parallel between landed property and water rights. Private though it is, property requires an authority that is respected on the one hand; in addition, it is subject to the public interest which demands various constraints, in particular the right of easement (or land crossing). In a period when feudal survival had maintained local rights in many countries, Jaubert de Passa believed that water must belong in the public domain. In the East, such a principle is rooted in religion and is confirmed by legislation: "the laws of Zarathushtra, Manu and the

followers of Buddha admit as private water only that which runs in an artificial bed."[35] In Italy, nationalization which appeared at the end of the Middle Ages authorized the reclamation of the Po Valley. In France, the phenomenon occurred later, but nationalization is essential not only due to the advantages for economic activity, but also because it trimmed feudal power down and reinforced the alliance between landowners and the crown. The state was able then to concede a right to a legal or physical entity for the benefit of the public interest. The administration must then supervise the use of this right and the application of the clauses of the concession.

JAUBERT DE PASSA BEFORE TECHNOCRACY

The "Research on Watering among Ancients" gives the primary role to local practices and governance. The Orient, where institutions favored irrigation, was at the time a source of inspiration, and this arrangement resulted in a model to be followed, even a legacy. After one and a half centuries of technical progress that came primarily from the Occident, the direction of moral debt was reversed. All the countries did not undergo colonial imposition, but all developed a qualified administration set on progress and technologies: it was gravity irrigation; it is now pressure irrigation. Jaubert de Passa had not envisaged this drift which marginalized social arrangements, nor that which, under cover of authority, led the French administration to create and manage directly the hydraulic equipment, exceeding the initial mandate of control, standardization, and sanction.

Jaubert de Passa attached less interest to the technique than to the social forms to which it owes its existence, its choice and its mode of management. In no case is the absence of irrigation ascribable to a defect in technological knowledge, and he rejects the exclusively ecological or technological explanations: "It is thus not the nature of the soil nor the defect of intelligence which deprived Sicily of the benefit of irrigation."[36] Jaubert de Passa supplemented the advantages of modern technology with a social analysis; that was the case during the debates caused by the construction of the Mehemet-Ali dam in Egypt: "Increasing the volume of water for irrigation is not only to add to the production of the land, but also to facilitate work and to assist the poor fellah; it is also to free the modest field workman from a fight, always disastrous, against the large usurpers of water; it is finally to bring back law and order in the villages, and to remove from the agents of power a means of oppression and a ceaseless cause of venality."[37]

Private initiative needs authority. It guarantees rights and secures against conflicts. However, Jaubert de Passa avoided setting up universal principles because he knew the price of flexibility when public and private interest change. His field experience led him to highlight the bad years, which can be catastrophic in irrigated agriculture: among Egyptians as among the Chinese, taxation was adjusted in bad years. Moreover, Egyptian irrigation functioned without concessions, and the great Roman landowners did their business without turning to the state for help. His demonstration applies to the French case where small holdings dominate. "Even under a successively despotic, feudal, monarchical and constitutional government one can make broad concessions with agriculture." [38] Egyptian and Chinese despotism conditioned the extraordinary epic of irrigation, whereas Turkish despotism undermined it. The Athenian and Roman democracies did not show great effectiveness in this field. It is the agreement between the type of farmers, the institutional context, and the sociocultural practices at which any reform must aim. From the remarkable diversity of situations, which is born from reading the Research, a last lesson arises: the importance of the details of arrangements for each one mirror obvious social participation. The latter cannot fit with bureaucratic monolithism, which does not lend itself either to the necessary flexibility for irrigated agriculture. This is the meaning we have to give to the paradigm of governance, which applies both in the time of Jaubert de Passa and the present.

BENJAMIN FRANKLIN: FROM KITE TO LIGHTNING ROD

William E. Marks
Water Consciousness, Inc.
Martha's Vineyard,
Massachusetts

Benjamin Franklin (1706–1790) is an unusual rags to riches story. At age 17, he left his home in Boston, after a falling out with his family, and found his way to Philadelphia. Arriving penniless, but rich in reading knowledge and from working as a writer and newspaper printer with his brother in Boston, he began his rise in life. He entered a common-law marriage in 1730 with Deborah Read, a Pennsylvania woman with whom he was long acquainted. They had one son who was lost to smallpox as a boy, but raised a daughter, Sally, along with Franklin's illegitimate son, William. The mother of William, with whom Franklin had an affair, has been lost to history.

Franklin was a founding father of the United States, the first Grandmaster of the Freemasons in North America, a family man, business man, a printer, inventor, author, publisher, scientist, musician, diplomat, and politician. Obviously, Franklin was many things to many people.

Franklin's relationship with water may be outlined as follows:

1. His kite flying stunt to experiment with understanding how storm clouds filled with water generated electricity. Lightning is a phenomenon that still perplexes science.
2. His invention of the lightning rod.
3. His invention of the Armonica water music instrument.
4. His study of the Gulf Stream and his epiphany for having it printed on a navigation chart.
5. His study of weather patterns.
6. His invention of swimming flippers.

FROM ELECTRICITY-PRODUCING WATER IN THE SKY TO LIGHTNING RODS

One stormy day in June of 1752, Benjamin Franklin took a walk into a field to go kite flying with his 21-year-old son, William. The field rested along the banks of the Schuylkill. Trusting in his fathers scientific know-how, William probably had no idea that he was participating in a potentially life-threatening experiment. At the time, little did William realize that Franklin had so much excitement and interest in studying storms that he could have been dubbed "the world's first official storm chaser."

As the story goes, Franklin attached a piece of metal wire to the fuselage of his homemade kite to help attract electrical charges flying among the overhead clouds. The hemp string played out through Franklin's fingers, and the kite twisted and turned in the turbulent winds as it soared higher and higher. After a considerable length of the string had played out, Franklin tied a key to the taut string. Then, with a dampened silk ribbon tied to the knuckles of his free hand, Franklin and William waited to see what would happen.

Whether it was a collection of static electricity gathered along the moist hemp string or a "gentle" lightning strike, we may never know. Regardless, Ben Franklin reported that when he placed his hand with the insulating silk ribbon near the key, he received a jolt of electricity as sparks leaped from the key. Franklin's grounded body acted as a grounding path for the electrical current built up in the electric field of the storm clouds overhead. In addition to proving that thunderclouds generate electricity, Franklin also extrapolated his negative/positive electrical research from his laboratory and theorized that the lower part of the thunderclouds was mostly negatively charged.

"The rest," as is often said, "is history." Franklin and his son, William, survived this experiment, But others who have tried to duplicate this experiment have paid dearly with their lives or their bodies were crippled.

Long before his famous kite-flying experiment, Franklin believed that lightning and static electricity shared similarities. While living in Boston in 1746, Franklin set up a laboratory to conduct his "electrical amusements." At the time, there were other scientists in Boston conducting electrical experiments. It was in 1746, during his first year of conducting electrical experiments, that Franklin suffered a not-too-amusing jolt of electricity. In a letter to a friend he expressed the shocking experience as, "...a universal blow throughout my whole body from head to foot, which seemed within as well as without; after which the first thing I took notice of was a violent quick shaking of my body..." As a result of this electrical shock, Franklin experienced numbness in his arms and the back of his neck for a few days.

As Franklin continued to conduct his electrical experiments, he wrote down his efforts and shared them in letters to Peter Collinson in London. Collinson was a friend and scientist who shared an interest in Franklin's experiments. In 1749, Franklin sent a letter to Collinson describing the concept of an electrical battery that could hold a charge for a brief period of time. In the same letter, Franklin expressed doubts as to how such an invention could be of service to humankind.

During Franklin's experiments, he observed that when glass was rubbed, it became "filled" with an electrical charge, making it "positively charged." He also observed that when other objects, such as amber, were rubbed, electricity flowed out from them, and therefore they became "negatively charged." This designation by Franklin of "positive" and "negative" electrical charges established a new base language for understanding electricity that remains with us to this day. Prior to Franklin's time the words "vitreous" and "resinous" were used to express the charges of electricity.

In his experiments, Franklin observed that when certain objects were "filled" with static electricity, they would discharge a "spark" of electricity when placed near a pointed metal needle. Franklin was not the first to speculate about a relationship between lightning and the harmless sparks created by static electricity. William

Wall, a British scholar, had suggested such a relationship in 1708.

However, Franklin was the first to propose an experiment using a lightning rod on top of a building to capture the "fire" from the clouds. The first lightning rod described by Franklin was an iron rod 8 to 10 feet long that came to a sharpened point at its uppermost tip. Figures 1–4 show a variety of lightning rods throughout the years.

Two years prior to his kite experiment, Franklin conducted experiments where he used a large sharp iron needle to draw electricity away from a charged metal sphere. Through his observations, Franklin extrapolated the results to his invention of the lightning rod to protect the tops of buildings.

In 1750 he wrote two letters to his friend, Collinson. In these letters, Franklin postulated:

> May not the knowledge of this power of points be of use to mankind, in preserving houses, churches, ships, etc., from the stroke of lightning, by directing us to fix, on the highest parts of those edifices, upright rods of iron made sharp as a needle…Would not these pointed rods probably draw the electrical fire silently out of a cloud before it came nigh enough to strike, and thereby secure us from that most sudden and terrible mischief!

Figure 1. Ventilator/Lightning Rod from Gay Head Lighthouse wick 1900, Martha's Vineyard, Massachusetts (photograph courtesy of William Waterway).

Figure 2. A weathervane and lightning rod combination. Location: Trinity Methodist Church, Oak Bluffs, Massachusetts (photograph courtesy of William Waterway).

> …On top of some high tower or steeple, place a kind of sentry box big enough to contain a man and an electrical stand. From the middle of the stand, let an iron rod rise…upright 20 or 30 feet, pointed very sharp at the end. If the electrical stand be kept clean and dry, a man standing on it when such clouds are passing low might be electrified and afford sparks, the rod drawing fire to him from the cloud. If any danger to the man be apprehended (though there would be none) let him stand on the floor of his box, and now and then bring near to the rod the loop of a wire that has one end fastened to the leads; he holding it by a wax candle [i.e., insulating him from it]. So the sparks, if the rod is electrified, will strike from the rod to the wire and not affect him.

Even though Franklin's lightning rod proposal was first published in England in 1750 by *The Gentleman's Magazine* and then by the Royal Society of London in 1751, there was little interest in England in acting on Franklin's invention.

However, in 1752, Franklin's letters were translated into French. Soon after, the lightning rod concept was quickly embraced by King Louis XV and his two leading natural scientists, Comte de Buffon and Thomas-Francois D'Alibard.

On May 10, 1752 in the country village of Marly located near Paris, the French built a sentry box according to Franklin's published recommendations. The sentry box was equipped with a 40-foot lightning rod. A

Figure 3. A cross with lightning rod attached. Location: Town of Oak Bluffs on Martha's Vineyard, Massachusetts (photograph courtesy of William Waterway).

retired soldier, Thomas Francois D'Alibard, was somehow influenced to volunteer for the experiment. As fate would deliver, a storm passed over the sentry box in midafternoon. Much to the soldier's surprise, he and others witnessed the sparks leaping between the lightning rod and the insulated wire. Soon, the same experiment was conducted and verified in other areas of France.

When the French lightning rod experiment worked according to Franklin's theory, the King of France sent a message to Franklin expressing his compliments. However, due to the slow transit of mail in those days, Franklin did not receive the French King's message until August of 1752, two months after he had already proven his theory by successfully using the dangerous kite and key rig.

In June of 1752, Franklin was in Philadelphia watching the progress of a steeple being built on top of the Christ Church. Franklin was going to use this steeple for his first lightning rod experiment.

Figure 4. Four lightning rods on top of old Whaling Church, Edgartown, Massachusetts (photograph courtesy of William Waterway).

From his research and other "electrical amusements," Franklin speculated that the placement of pointed iron "rods" on top of buildings would prevent lightning from causing fires. He figured fires could be prevented because the pointed rod would capture the lightning's "fire sparks." On this note, Franklin was half right. It did not take Franklin long to figure out that lightning rods need to be "grounded." He accomplished this by using an insulated metal wire or cable to draw the charge from the lightning rod and to guide the electric charge harmlessly down into the ground away from the structure.

In 1753, Franklin published his lightning rod research in his Poor Richard's Almanac. He also provided a detailed description of his lightning rod invention. This helped to stimulate the installation of lightning rods throughout the American colonies.

The largest lightning rod installed in Franklin's lifetime was in 1788 at Maryland's State House. This rod was installed according to Franklin's specifications and has effectively protected the State House for more than 208 years.

Before Franklin's invention, lightning destroyed or damaged many buildings. Evidence of how rampant lightning damage was in the early 1700s can be found in various records. For instance, during a period of 33 years, in Germany alone, approximately 400 towers were damaged by lightning, and 120 bell ringers were killed. On a similar note, in France between 1753 to 1786, 386 church towers were struck, and 103 bell ringers were killed.

The installation of lightning rods in France and other countries immediately began to reduce the number of buildings struck by lightning and also reduced the deaths of bell ringers and other people in buildings with tall steeples. As the use of lightning rods slowly began to reduce the number of fires and deaths, the governments and the public began to appreciate the practical applications of Franklin's research into electricity and weather, especially, when one considers the antiquated fire fighting apparatus available in the 1700s. In Franklin's time, entire towns were known to burn down in fires ignited by lightning strikes.

Buildings, such as those with tall steeples (churches, tall mansions, and commercial buildings) were all susceptible to lightning strikes. Once outfitted with lightning rods, these tall structures were less likely to be struck by lightning. The tangible results of Franklin's invention in saving homes and buildings soon made him an international celebrity and a respected scientific genius.

However, when it came to installing lightning rods on churches or on public buildings where the church held influence, there was considerable resistance from many Catholic and Protestant church leaders. Relatively speaking, it was as though history was repeating itself; these same institutions also condemned the scientific theories of Copernicus and Galileo.

Both of these faiths taught and preached that being struck by lightning was a "sign" of God's punishment. When Franklin's experiments indicated that being struck by lightning was the unfortunate result of a random act in nature, he was immediately attacked by various church leaders.

Prior to Franklin's lightning rod, there was the age-old belief that the ringing of "consecrated" bells in a tower would help repel violent storms and lightning strikes. Therefore, as a thunder-and-lightning storm approached a town, the local bell ringer would do his religious duty to save the community. Little did he know that grabbing hold of the ringing rope and ringing the bells to ward off the evil storm was playing roulette with lightning. During thunderstorms, it was the accepted practice to ring the bells as violently as possible. This was done on the theory that the sound waves from the consecrated bells would break up the lightning in the overhead clouds. It is for this reason we find the words "Fulgaro Frango" inscribed on many medieval bells. "Fulgaro Frango" means "I break up the lightning flashes."

As people awakened to the relationship of lightning and the death of bell ringers, there soon became a struggle between the religious belief of ringing bells to ward off evil and the reality of being struck by lightning. Eventually, in 1786, 34 years after Franklin's lightning rod was first successfully tested in France, the Parliament of Paris signed an edict. The passing of this edict was "to make the custom of ringing church bells during storms illegal on account of the many deaths it caused to those pulling the ropes."

Due to this 1786 edict in France, we find one of the first examples of the forthcoming separation between church and state. A separation that was more or less prompted by Franklin's founding of the "scientific method," a method of inquiry into the nature of our world that caused some people to question the teachings of religion. This also helped to form the basis of fear from a religious perspective.

A well-documented attack against Franklin's lightning rod came in 1755 from a church leader in Massachusetts. The Reverend Thomas Prince, pastor of the Old South Church, published a sermon on the subject of lightning rods. In that sermon, he expressed the opinion that the recent big earthquake in Massachusetts was related to the installation of "iron points invented by the sagacious Mr. Franklin." His sermon also mentioned that when it came to installing lightning rods—"in Boston, are more erected than anywhere else in New England, and Boston seems to be more dreadfully shaken. Oh! there is no getting out of the mighty hand of God."

Due to the strong influence of religion in England, the first lightning rod installation on a church spire did not take place until 1762—10 years after the French began their installations. In the interim, London's Saint Bride's church was damaged by lightning several times.

In Austria's mountains of Carinthia, the Catholic church of Rosenberg was struck so frequently by lightning that peasants attending services were killed on several occasions. As a result, many of the peasants stopped attending services during stormy weather. The church steeple suffered lightning damage so severe, that it was completely rebuilt three times. When a lightning rod was installed in 1778, all lightning damage ceased.

In Italy, the tower of St. Mark's in Venice suffered lightning strike after strike. Records from 1417 onward show that the wooden spire was struck by lightning and consumed by fire on several occasions and suffered severe damage from many other lightning strikes. Due to the influence of the church, St. Mark's spire went unprotected. This is in spite of the fact that Beccaria, the respected Italian physicist, had introduced Franklin's invention to his country many years earlier. Even after St. Mark's spire was hit by lightning in 1761 and 1762, the church refused to install the "heretical rod." In time, as overwhelming evidence of the rod's effectiveness grew in neighboring countries, the church acquiesced, and a lightning rod was finally installed in 1766. Afterward, St. Mark's tower was never again damaged by lightning.

However, lessons such as this came too late to save the Church of St. Nazaire in Brescia, where the Republic of Venice had stored 100 tons of gunpowder. In those times, church vaults were often used for this purpose because they were dry. In 1767, a lightning strike hit the church spire and traveled down to the stored gunpowder. Over 3,000 people lost their lives, and a large portion of the city was destroyed.

Because of this common use of churches for storing gunpowder, there are similar stories well into the 1800s.

For example, in 1856, on the island of Rhodes, a lightning strike exploded the munition vaults and killed more than 4000 people.

Franklin's invention of the lightning rod proved to people the connection of lightning to storm clouds and thunder. This was the first proof that lightning was an electrical force generated in nature by the action of water molecules in the clouds. The mystery of how lightning is created by the motion of water molecules in storms was something that intrigued Franklin. However, he could only theorize as to the distribution of negative and positive charges in the clouds.

Franklin believed that his creation of the lightning rod was his greatest and most useful invention for the benefit of humankind. In spite of Franklin's apparent habit of keeping records and sharing information about his experiments through letters, it is of historic note that he never documented his kite experiment or wrote letters about the event. The only witness to the kite experiment was his son, William. And, the only written account of the kite and key experiment was by another person some 15 years after the event took place.

Franklin's lightning rod design was of an iron rod honed to a sharp point on its skyward tip. This design probably was developed as an extension of his laboratory experiments where he used an oversized needle with a sharpened point.

England was one of the last countries to begin installing lightning rods. The first lightning rod installation in England took place in 1760. The location was the Eddystone Lighthouse, an old wooden structure that had a history of damage by lightning. This lighthouse was vital to marine navigation safety and the commercial shipping interests of England.

As fate would deliver, nature further helped spur the use of Franklin's pointed lightning rod in England. In 1764, a bolt of lightning struck England's Saint Bride's steeple, already struck many times in the past. Saint Bride's church, a historic building in England, has a spire that stabs skyward prominently. The steeple's damage from lightning in 1764 prompted the Royal Society to recommend the use of Franklin's pointed lightning rods to protect the rest of the country's buildings.

As Franklin's pointed lightning rods were installed throughout Europe and America, King George III decided on a different approach. He decided to protect his palace with blunt-knobbed lightning rods, which he believed were superior to Franklin's. At the time, this also represented a political statement because King George viewed Franklin as a rebel. The use of blunt-knobbed lightning rods therefore represented a symbol of loyalty.

Regardless of King George III's, motivation to use blunt-tipped lightning rods in 1752, varying opinions and arguments have existed since that time, as to which lightning rod design is superior.

The controversy over which lightning rod was most effective was recently put to rest. In experiments conducted by the American Geophysical Union during the past decade, it was determined that the blunt lightning rod is more effective. Even though Franklin's design did not win this competition, he still deserves credit for bringing the lightning rod invention to the service of humankind. Besides the pointed and blunt versions of the lightning rod, there are many variations on the theme. Lightning rods have almost evolved into a folk art form, and many have considerable value to collectors.

On a closing note, as in the case of his inventions of the glass Armonica, bifocals, and the Franklin wood stove, Franklin never made money from his inventions, including the lightning rod. To quote Franklin, "As we enjoy great Advantages from the Inventions of others we should be glad of an Opportunity to serve others by any Invention of ours, and this we should do freely and generously."

This philosophy of Franklin's, about serving humanity, was also reflected in the words he wrote in 1790, the year of his death. From the tone of these words, it is evident that Franklin approached his earthly departure with philosophical humor:

> "I believe in one God, Creator of the universe....That the most acceptable service we render Him is doing good to His other children....As to Jesus...I have...some doubts as to his divinity; though it is a question I do not dogmatize upon, having never studied it, and think it needless to busy myself with it now, when I expect soon an opportunity of knowing the truth with less trouble."

WATER AND THE HISTORY OF MAN

Ann Azadpour-Keeley
National Risk Management
Research Laboratory, ORD,

Jack W. Keeley
Environmental Engineer
Ada, Oklahoma

> And Isaac digged again the wells of water, which they had digged in the days of Abraham his father; for the Philistines had stopped them after the death of Abraham: and he called their names after the names by which his father had called them. (Genesis 26:18)

Before the earth was created, hydrogen, the oldest and most abundant material in the universe, and oxygen, created in the womb of stars, combined to form H_2O. Since the beginning of life on this planet and probably other planets scattered throughout infinite space, water has played a critical role in all facets of human existence, including the creation of life itself. We are made of water, and water produces the food we eat, from fish to fowl to fiber. It is the only substance on the earth that exists naturally in three phases, liquid, solid, and gas. As it serves us today in industry, agriculture, medicine, transportation, and the production of energy, it has served humans and all of the earth's creatures since the beginning of time.

In the days of Abraham, following family feuds and other conflicts, the victor often stopped wells by filling them with earth and stones. It was the equivalent of burning the village. Wells of water were so important that their owners gave them names, and communities which took root in the area assumed the names of the wells. In John 4:6, Jesus meets a woman from Samaria at Jacob's well and later reveals that He is the Messiah. The Christian Bible is replete with references to the importance of water to the fabric of life. It speaks of irrigation, of aqueducts, its creation, its purification, and even of it being turned into wine.

The Koran, the sacred book of the Moslems, was revealed to Mohammed by the angel Gabriel between A.D. 610 and 632. It mentions *water* 95 times in reference to such issues as springs pouring from rocks, hygiene, irrigation, pollution, prayer, thirst, and law. It even suggests that humans were made from water.

Hammurabi, the father of law, discussed the legal ramifications of water management in his Codes which were scripted 1700 years B.C. The Greeks constructed a 4200 foot tunnel or aqueduct to bring water to the city of Athens 2500 years ago, and the early Romans built 10 aqueducts which brought 220 million gallons of water to the city daily from mountain springs. The Aqua Claudia still stands in part around Rome, and the Pont du Gard in southern France was designed 20 centuries ago by the engineer Marcus Agrippa. The greatest water purveyor of all was the Zaghouan aqueduct in North Africa which crossed 130 miles of desert to deliver water to ancient Carthage. Even as the wheel was invented about 2000 B.C., the water clock (Clepsydra), fashioned by Plato, was first used to record time about 400 B.C., and the water mill came to be in the first century B.C.

Early civilizations took root near sources of abundant water: the Tigris–Euphrates Valley of Mesopotamia, the Nile Valley in Egypt, the Indus Valley in India, and the Hwang Ho Valley in China. These were the cradles of civilization which prospered, in great measure, because of the availability of water and the construction of extensive irrigation systems which made the land productive. In some cases, however, when the water systems failed, the civilization collapsed. It is believed, for example, that the Sumerian civilization of Mesopotamia failed because of poor irrigation practices which caused increased salinity in the soil and the eventual collapse of agriculture.

To an extent, the problems of managing a water system are mirrored today as major cities are forced to obtain water from greater and greater distances from the city. Often the search for available water as well as water rights litigation spans decades. The fall of groundwater levels increases pumping costs until irrigation is no longer cost-effective, and the effects of pollution increase both the cost of palatable water as well as the threat to human health.

Water has played an important as well as diverse role in many aspects of human history. It was the focus of religious rites, science, art, music, mythology, transportation, power, healing and architecture, to mention only the obvious. For example, the immersion into or the sprinkling of water have been forms of baptism long before the birth of Christianity. Ea or Enki had the distinction of being both the god of water and wisdom in several ancient religious peoples, including the Hittites and Babylonians and was often considered the creator of humanity. And, of course, the early scientists and philosophers such as Empedocles and Aristotle believed that everything was composed of only the four elements, earth, air, fire, and water. We all remember the story of the Greek mathematician Archimedes who formulated his fluid displacement law after stepping into a public bath and observed the overflowing water. He was so excited that he ran home naked crying Eureka! Eureka! He later used this water displacement knowledge to demonstrate that the king's goldsmith had adulterated a gold crown with less expensive silver.

For centuries, people around the world have bathed in mineral water to relax their souls and cure ailments. There are a number of religious shrines where the sick have been cured by holy water. One example is spring water near the site where Bernadette, a French saint, had a vision of the Virgin Mary in 1858. In music, we find Handel's Water Music (1717). Claude Monet produced a series of water-lily murals between 1900 and 1909, and in architecture Frank Lloyd Wright created the stunning Falling Water structure near Pittsburgh in 1936.

Even as water has given birth to all of the creatures of the earth and served them so well in many ways, so has it emulated the Apocalyptic horsemen of pestilence and death. Its overabundance has caused floods since the days of Noah, and its absence has resulted in drought and starvation for countless millions. Water from hurricanes and typhoons causes death and property damage of herculean proportions each year in all corners of the globe. Waterborne diseases (diarrhea is the leading cause of death in the world) cause 80% of the illness in Third World countries, and malaria from mosquitoes born in stagnant water affects 400 million people worldwide and results in 5 million deaths. The Industrial Revolution made sewers of streams and rivers.

The history of human association with water has been a union as blessed as it has been complicated, and on many occasions as wicked as Pandora's box. Perhaps it can best been capsulated in the words of John Dyer:

> And see the rivers how they run through woods and meads, in shade and sun, sometimes swift, sometimes slow, wave succeeding wave, they go a various journey to the deep like human life to endless sleep!

WATER, BACTERIA, LIFE ON MARS, AND MICROBIAL DIVERSITY

David B. Vance
ARCADIS
Midland, Texas

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

Microbial life is extremely diverse with regard to ambient conditions, metabolic pathways, and geographic dispersion at depth in soils and sedimentary formations on Earth. Original bacterial life on Earth started in anaerobic conditions, without free oxygen in the atmosphere. Water chemistry in the primitive oceans would have been devoid of significant dissolved oxygen. The primitive atmosphere was chiefly carbon monoxide (CO), hydrogen sulfide (H_2S), nitrogen (N_2), hydrogen (H_2), and water. Some of the more volatile trace elements such as chromium, manganese, and sodium may also have been present (1). Since that time, almost every niche on Earth has been colonized by some type of microbial life. Given the robust nature of microbial life on Earth, it is possible that microbial life existed on other planets having similar elements and compounds. As the very early history of Mars may have been somewhat similar to that of Earth, Mars may have had the conditions for microbial life. In the oceans, the gases in the primitive atmosphere were present as dissolved constituents. In addition, given the reducing conditions, soluble forms of reduced metals were also present, with ferrous iron likely being a dominant species.

INTRODUCTION

From 3.5 to 1.5 billion years ago, the atmosphere of Earth was anoxic (primarily consisting of nitrogen and methane) and the dominant life forms were methanogenic, sulfate-reducing and iron-reducing anaerobic microbes. Near the end off this period, around 2 billion years ago, bacteria that could use nitrate to convert ferrous iron to ferric literally began to precipitate the soluble ferrous iron out of the ocean, forming the great Precambrian banded iron deposits and the later Paleozoic reworked redbeds.

Slowly starting about 3 billion years ago microbes that used the sun's light as an energy source became the dominant life form on the planet. These photosynthetic species began to become active and excrete oxygen as a waste product of their metabolism. Between 1.5 and 1.0 billion years ago, the "first" great environmental disaster occurred when photosynthetic life became abundant enough to elevate atmospheric oxygen to near current levels.

The type of bacteria that are indicated to have existed on Mars appear to be similar to those on Earth termed archaebacteria. These are bacteria with an ancient history, first appearing on Earth 3.5 billion years ago under the atmospheric conditions described above. Recent advances in genetic analysis indicate that these bacteria are a third form of life different from regular bacteria (Eubacteria) and all multicellular life (Eukaryotes). These archaebacteria survive through exotic metabolic processes that rely on a wide variety of chemical reactions to provide energy.

The archaebacteria fall into four major classes:

- Acidophiles that are able to grow in the pH range of 0.0 to 5.0.
- Thermophiles that can grow in a temperature range of +30 °C to +250 °C.
- Halophiles that survive in 10% to 27% sodium chloride solutions.
- Methanogens that are the best known archaebacteria and form methane in sediments and the intestinal tracts of animals.

MARTIAN ARCHAEACTERIA?

Also, modern (relatively speaking) Eubacteria are capable of adaptation to extreme environments, including:

- Alkalophiles that can grow in the pH range of 8.5 to 11.5.
- Barotolerant bacteria can exist under hydrostatic pressures up to 1100 atmospheres.
- Other chemoautotrophic bacteria such as denitrifiers, nitrate reducers, ferric iron reducers, sulfate reducers, hydrogen formers, sulfide oxidizers, and ferrous iron oxidizers.

The biochemical diversity is astounding. Just a few specifics are as follows:

- Bacteria have been found in aquifers at depths of 1.5 miles.
- They have been found in oil production formations at depths of almost 4 miles.
- Within the last year, bacteria have been found that survive using only surrounding rock and that generate hydrogen gas in the process; these are near 1 mile deep in basalt.
- Sulfate reduction is extremely common place in groundwater. Well water with the odor of hydrogen sulfide (rotten eggs) is a manifestation of bacteria-driven sulfate reduction.

Additional aquifer conditions under which it is common to find sulfate-reducing bacterial species are as follows:

- Eh conditions less than −200 mV.
- The presence of greater than 20 millimolar sulfate from geologic origins.

In the western United States, many aquifers are anaerobic and contain sulfate. Anthranilic acid, benzyl alcohol, and P-cresol have all been demonstrated to be biodegraded in the presence of sulfate-reducing bacteria. Research is currently under way evaluating the use of sulfate reducers for the degradation of chlorinated solvents and PCBs.

Two other dominant and effective anaerobic processes are denitrification and methanogenesis. In general, most aromatic hydrocarbons can be degraded anaerobically under methanogenic or denitrifying conditions.

Some thought should always be put into the exploitation of these alternative bacterial systems. The exact stoichiometrics should always be worked out with a complete assessment of all byproducts. For example, it is important to evaluate the overall electron flux in nitrate reduction systems:

For each mole of nitrate consumed, one mole of KOH or NaOH is generated, which in turn can lower aquifer pH and form limestone or other precipitates, that plug the infiltration or treatment zones. An acid must be added concurrent with the nitrate source in the appropriate amount.

Bacteria that produce hydrogen can sequentially dehalogenate chlorinated hydrocarbons to innocuous ethane or ethene gas.

Of course, all various metabolic systems are not equal with regard to energy yielded to the organism for each reaction that takes place.

On a scale of 1 to 10, with 10 having the highest energy yield:

— Aerobic oxygen based metabolism is 10.
— Nitrate reduction is 9.
— Iron reduction is 5
— Sulfate reduction is 4.
— Methanogenesis is 2.

Thus, the source of the dominance of aerobic life was precipitated by events 1 billion years ago (as described above). Given surface conditions, it is the most cost-effective metabolic system available. However, all other metabolic options still take precedent under the appropriate conditions. It has proven particularly difficult to drive hydrocarbon contaminated aquifers into oxic conditions mainly because of the poor transport properties of oxygen in water (the reason hemoglobin exists in our blood cells is to address that issue within our bodies). The power of many of the other metabolic systems is that they are driven by chemical species that are highly soluble in water (sulfate and nitrate, for example). The less-efficient energy yield is compensated by the dramatically improved transport properties.

In addition, these alternative metabolic systems are showing to have some capacity to degrade xenobiotic hydrocarbons that prove to be recalcitrant to aerobic attack.

The power of bioremediation lies in harnessing the vitality of bacterial life in the subsurface. The ubiquitous nature of bacterial life is constantly being revised upward. Archaebacteria exist under the extremes of physical/chemical conditions. Bacteria are found at such depths that it is almost certain they were laid down with the surrounding sediments and have been able to survive since. The potential presence of microbial life on Mars is an even more extreme example of the concept. *In situ* bioremediation is a process that appears to be viable almost under any subsurface conditions.

The history of Mars exploration has focused in a large part on the potential for past or current life on the planet. The first close-up picture of Mars was obtained in 1965. Since that time, a variety of satellites have traveled by Mars and a few spacecraft have landed on the surface of Mars. In 1976, the National Aeronautics and Space Adminstration's (NASA) Viking Mission to Mars had two spacecraft, *Viking 1* and *Viking 2*. Each craft consisted of an orbiter and a lander. NASA's Mars Global Surveyor began to orbit Mars in 1997 for the purpose of high-resolution imaging of the surface of Mars, studies of the topography and gravity, and the role of water and dust on the surface and in the atmosphere. This project also evaluated the weather and climate of Mars, the composition of the surface and atmosphere, and the existence and evolution of the Martian magnetic field (2). The Mars Pathfinder with the Sojourner Rover toured the surface of Mars in 1997. In 2001, the NASA Mars Surveyor 2001 lander was renamed the 2001 Mars Odyssey; the mission was to gather data to help determine whether the environment on Mars was ever conducive to life, to characterize the climate and geology of Mars, and to study potential radiation hazards on Mars.

The most recent information about Mars has come from NASA's two Rover Opportunity and Rover Spirit landing crafts, which inspected Mars during 2004. These remote studies indicate that the elements on Mars are the same elements found on Earth. On Earth, life started in water, and there is ample evidence of large amounts of water on Mars in the past (3).

Based on the similarities with Earth, the geologic conditions on Mars are still tantalizing scientists to examine the shallow Martian soil for any sign of past or current microbial life forms.

CANALS IN THE MEKONG DELTA: A HISTORICAL OVERVIEW FROM 200 C.E. TO THE PRESENT

DAVID BIGGS
University of Washington
Seattle, Washington

The Mekong Delta is one of the most productive agricultural regions in the world. It supports more than 20 million people living in a dense network of canals and creeks that today irrigate more than 2 million hectares of rice paddy. This landscape of dense settlement and intensive irrigated agriculture is relatively recent, although the earliest canal projects date to "Fu Nan" or Oc Eo culture circa 200 C.E. Today's water regime is not so much a single water system as it is a landscape built of multiple layers of canals in various stages of development and degradation. Some waterways continue to serve as primary transportation and irrigation works: others lie abandoned, their traces sometimes only visible through analysis of aerial photography or historical reports. This overview describes these historical layers of canalization and the context for some of the major projects in each period.

GEOLOGIC OVERVIEW

The Mekong Delta of today comprises roughly 6 million hectares (5 million in Vietnam and 1 million in Cambodia) of alluvial plains. It is bordered by the Gulf of Thailand in the west and the South China Sea in the east. The main channel of the Mekong River is believed to have formed sometime between 2 and 50 million years ago in the late Tertiary period. The older, higher terraces of its delta may have formed as early as 1 million years ago. Corings of sediment in the lower delta alluvium show alternating bands affected by freshwater and saltwater, suggesting that as recently as 6000 years ago, mean sea level may have reached a post-Ice Age high water point before declining to recent historical levels.

The slope of the delta is so flat that tidal surges affect water flow in canals and creeks up to 100 kilometers upstream. Two separate tidal regimes along the western and eastern coasts cause complicated periodic variations in water currents, depending on the proximity to both coasts. When opposing water currents meet, either at an intersection of waterways or along the path of a canal, they deposit sediment into bars that often block boat traffic. Vietnamese settlers, and probably earlier inhabitants, formed markets at these halfway points, convenient places for exchange. Choices for early modern settlements here were largely responses to water conditions and associated soil deposits.

From a soils perspective, the delta can be divided into subregions connected to geologic and ecological processes: a freshwater alluvial zone, the Dông Tháp floodplain, the Long Xuyên Quadrangle, the eastern coastal zone, and the Cà Mau Peninsula (Fig. 1). The Mekong River deposits fresh sediment along the banks of the channel, creating alluvial banks that rise 2–3 meters above mean sea level. This freshwater alluvium area fosters the development of the richest natural paddy in the delta, allowing two and three rice crops per year. The combination of high banks and good drainage allows farmers to irrigate easily and also to raise fruit trees without fear of flooding. Ancient alluvium is characterized by higher soils associated with a postulated high seas episode that occurred roughly 6000 years before the present. In the present era, this higher land forms a natural barrier to the Dông Tháp floodplain, a depressed area characterized by high soil acidity and annual floods. The other large flood zone is the Long Xuyên Quadrangle south of the main river channel. The Quadrangle is remarkable for granite and limestone

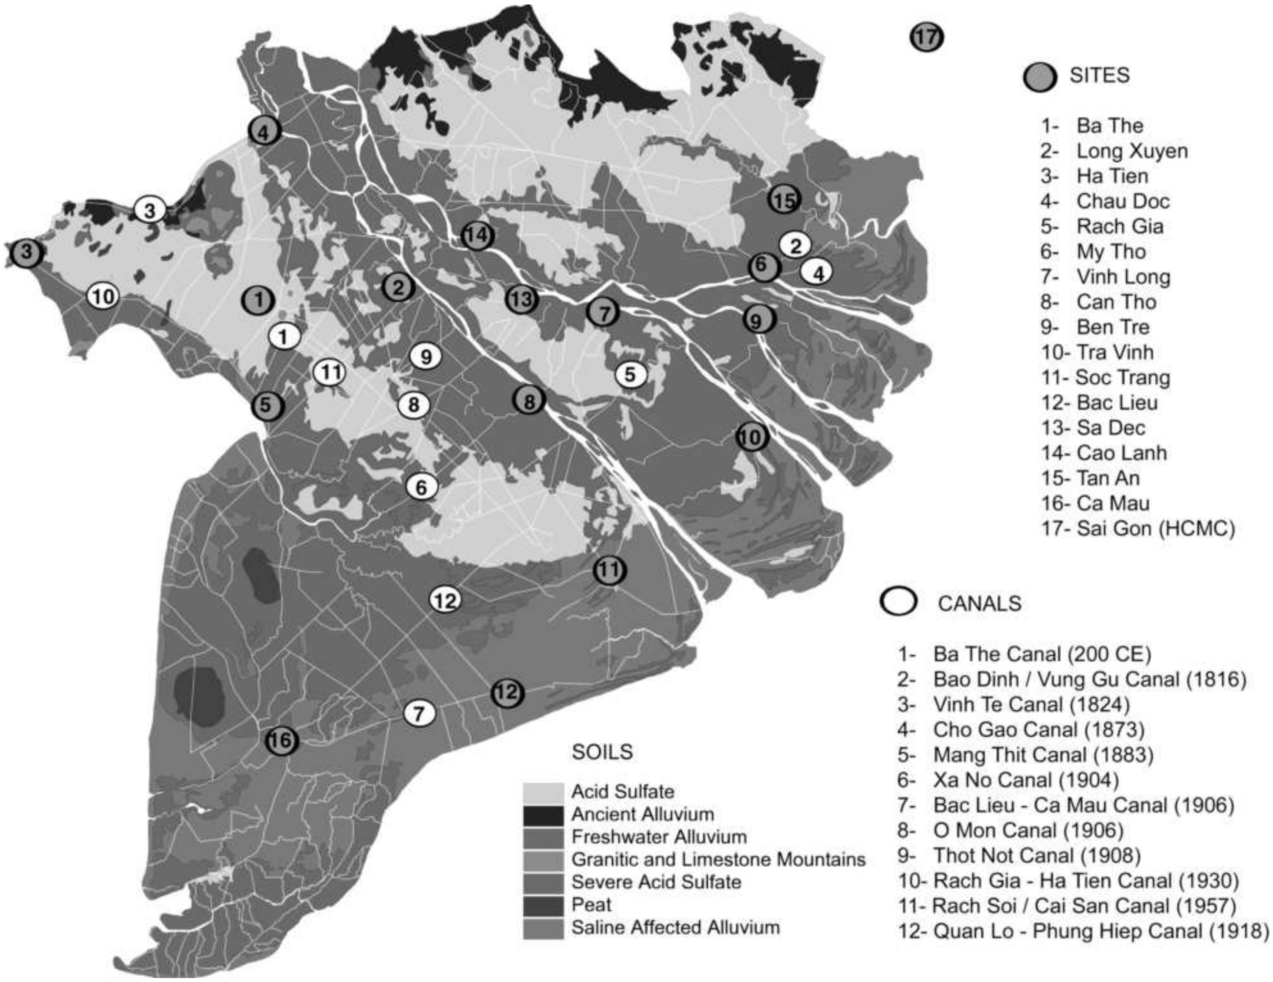

Figure 1. Mekong Delta divided into subregions.

mountains that rise up dramatically from the plains some 200–700 meters to form islands on the land. At the base of Ba Thê mountain in this Quadrangle lie some of the most substantial sites for what George Coedès described as the "Fu Nan Kingdom": the first example of an Indianized kingdom in Indochina.

Both of these two depressed floodplains, whose average altitudes are less than 1 meter above mean sea level, form two flood sinks that form virtual, inland seas each September as the Mekong River reaches its annual flood stage in the wet season monsoon. The annual flooding of the Mekong from August to October is important for far-reaching effects on almost all activity in the region. The Tonle Sap (Great Lake) in Cambodia grows to three times its dry season size in June, July, and August. As the lake reaches its limit, water flow reverses in the Tonle Sap River, flows downstream, and recombines with the mainstream rivers at Phnom Penh. The river then floods the Long Xuyên Quadrangle and the Dông Tháp Plain.

ANCIENT SETTLEMENT

The earliest traces of organized human settlement in the Mekong Delta date to the "Fu Nan" period (100 B.C.E.–550 C.E.). The types of evidence found in these settlements can be grouped roughly into wooden piers and structures, jewelry and statuary, and vestiges of infrastructure—brick foundations, brick towers, and canal traces. The largest brick foundations lie at the Ba Thê site in the Long Xuyên Quadrangle. Using aerial photography in 1931, an amateur archeologist, Pierre Paris, discovered traces of canals crossing the western delta, from Rạch Gía on the coast to Angkor Borei about 100 km to the northwest. What had previously been noted through ground surveys as straight creeks were actually the remaining traces of human-constructed waterways. Louis Malleret, a former director of the Ecole Francaise de l'Extrême-Orient, led digs in the 1940s and 1950s at canal sites discovered through aerial and ground surveys. Malleret's work and that of successive Vietnamese and international researchers has proven through comparison of pottery shards and other means that these canals dated to roughly 200–400 C.E. Styles in the pottery indicate containers for oils and other goods that resemble similar containers from eastern India in that time. The ancient canals also extended deep into the Cambodian portion of the Mekong Delta, connecting the gulf coast ports with inland river ports at Tak Ev and Angkor Borei.

In the ancient world, the Mekong Delta was an important halfway point for sailing ships travelling with the monsoons between India and China. As a possible warehousing center developed along these ancient canals, the Oc Eo site allowed ships from both destinations a useful trade interchange and provided them with important naval stores and valuable supplies brought downriver from the forest interior: rhinoceros horn, elephants, feathers, aromatic woods, and wild spices. Chinese records from both trade missions and accounts of Fu Nan monks visiting China note major settlements along the main course of the Mekong River below Phnom Penh, including the sites at Oc Eo/Ba Thê, Angkor Borei, and a site in Dông Tháp Muòi. Inscriptions described Indian merchant colonies at Southeast Asian ports, including those in the Mekong Delta. The situation of Indian merchants here enriched local rulers, allowing them to raise funds and craftsmen to build ships of their own.

Environmental factors may have played a role in the decline of pottery and evidence of population in the lower delta. Soil cores at the Oc Eo site reveal high concentrations of Rhizophera pollen spores in deeper layers, suggesting that saltwater mangrove trees populated a floodplain that is entirely freshwater today. Every year, the sea coast may have receded further from the Oc Eo site, and the canals may have slowly filled with sediment from the rivers, turning them into shallow creeks and ponds. This would in turn change the wetlands ecology to one favorable for freshwater tree species. This freshwater plant community would have also attracted mosquitoes that carry endemic malaria and parasites, thus putting dense populations at greater risk of disease outbreaks.

VIETNAMESE SETTLEMENT

There is no further evidence of major canal projects or dense settlement in the Mekong Delta for more than 1000 years after the decline of "Fu Nan." From the ninth to fourteenth centuries, the upstream kingdom of Angkor controlled the entire region and conducted its major trade routes by highways that stretched westward into present-day Thailand and to the west coast of the Isthmus of Kra. Archeological evidence near present-day coastal towns of Trà Vinh and Sóc Trang suggest that river ports here conducted small-scale local trade with Southeast Asian and Chinese merchant ships. One possible explanation for the lag in development of the Mekong Delta after Fu Nan could be that the very same waterways and flat landscape that facilitated easy transportation also allowed easy attack by enemy fleets. Steles at Angkor Thom (Siem Reap) depict naval battles with ships from Champa that attacked the Khmer capital by way of the Mekong River. The numerous islands in the Gulf of Thailand also provided easy harbor for all manner of pirates—Malay, Siamese, Chinese, European. Until Vietnamese settlers began migrating southward to the delta in the seventeenth century, island-like Khmer trading ports and administrative outposts of the Khmer kingdom characterized the area. Populations of Khmer villagers lived in some of the richest, naturally irrigated alluvial regions in areas that are today still ethnically Khmer: Sóc Trang, Trà Vinh, Trà Nóc, and Sa Déc.

One of the most important factors in Vietnamese settlement and early modern canalization was the increasing importance of rice as a trade commodity. Until the seventeenth century, rice was rarely traded by ship and in cities as were gold, spices, ivory, and aromatic woods. It was a local subsistence commodity and generally in greater abundance than the human labor necessary to cultivate it. In the seventeenth century, increasing population pressures in the Red River Delta brought on widespread famines and social unrest; to the present day, this population density in the north and the "southward progression" have played important roles in spurring development of waterways and infrastructure in the Mekong Delta. The upset of the ruling Minh Dynasty in 1644 also led to a mass exodus of Minh loyalists to Vietnam and other kingdoms that granted them asylum. In 1679, 3000 Fukien troops arrived in the Vietnamese kingdom. The Vietnamese ruler, anxious not to have them so close to his capital, sent them to the south where they formed the commercial towns of Biên Hòa, Sài Gòn, and Mỹ Tho. In 1681, another Chinese emigré, Mặc Cúu, immigrated to Cambodia and succeeded in winning a concession from the Khmer king to develop a trading port at Hà Tiên. From 1690 to 1780, Hà Tiên became a virtual city-state, trading most of the forest products of Cambodia by a Chinese-controlled shipping network centered at this Gulf Coast port. The more powerful kingdom of Siam now controlled the Isthmus of Kra, so Hà Tiên became an important trading port much in the same way as Oc Eo before it.

The Vietnamese kingdom established military and administrative posts in the Mekong Delta in the eighteenth century. In 1732, military campaigns led to the establishment of camps at Mesar (Mỹ Tho), Kampong Reussey (Bên Trè), Koh Gong (Gò Cong) and Peam Ba-rach (Long Xuyên). The court sent troops and new migrants to establish military plantations [dôn diên] in the new territories. These military plantations functioned as both garrisons and farming communities. At the same time, the Chinese developed mercantile posts and arranged the marketing of rice. The Tây Son civil war (1789–1802) and repeated Siamese invasions at Hà Tiên (1705, 1717, and 1771) led to the eventual abandonment of Hà Tiên and the establishment of Vietnamese control of the delta in 1802. For 60 years, the Court enticed settlers to establish garrisons and villages. In 1818, still worried about the threat of Siamese invasion, King Gia Long ordered his military governor in the delta, Thoại Ngọc Hâu, to assemble an army of conscript laborers to dig a canal 67 kilometers from a new river citadel at Châu Dôc to Hà Tiên. More than 50,000 laborers worked for 5 years and through several Khmer-led rebellions to complete the waterway. This strategic project was intended to allow greater Vietnamese control of the Gulf Coast and direct water routes to river garrisons. Two other major projects in this period connected the increasingly dense Sài Gòn watershed with the intermediate Vàm Co watershed and the Mekong river. The Bạo Dình Canal in 1816 allowed more direct access to the Khmer territory east of Mỹ Tho and solidified trading routes and administrative communication in the eastern delta. The Thoại Hà (Long Xuyên–Rach Giá) Canal was also completed in 1816. The rapidity of this project (3 months) and its location in the heart of the former "Fu Nan" kingdom suggests that this waterway may have dated to a much earlier period and only been "cleaned" in 1816. Historical records in the nineteenth century do not specify this difference, and they often alternately describe canals as rivers.

Midcentury violence led to the abandonment of coastal outposts for periods of years, and the neglect of these new waterways led to their being choked off with silt. The natural processes of sediment accretion and growth of aquatic plants played an important role in canal projects, especially in the costs of their upkeep. The interplay of tidal pulses and opposing river currents led to formation of transverse sediment bars across the channel of a canal. In a matter of months, if not continually cleaned by hand, these bars would reduce the navigable channel to a depth of half a meter, even at high tide in the dry season. Besides this hydraulic challenge, the water hyacinth or luc bình could quickly reproduce and choke off an entire waterway with a thick, floating mat of roots on the water's surface. Thus, without the continuous application of human labor in large numbers, most artificial waterways could not remain navigable for long. With each social uprising, canals quickly deteriorated so that after a few years, the costs of redredging would approach the original cost of construction. Another theme of canal degradation that also continued through the colonial and postcolonial eras was its role in aiding rebel groups.

With the French colonial conquest beginning in 1858 and lasting until 1867, rebel groups could only survive in the deep swamps far away from deeper rivers and streams. Battles at the Plain of Reeds in 1873 proved that control of waterways was vital for the French colonial regime. For two decades, the French colony's ruling admirals focused their efforts on linking strategic areas with the colonial metropole at Sài Gòn. In 1875, Admiral Duperré organized a permanent committee to improve naval communications between Sài Gòn and the Mekong Delta. This commission surveyed existing and proposed routes until 1879. During this time, the colonial government mobilized armies of corvée [conscript] laborers into government service. These first canals included Trà On (1876), Chò Gạo (1877), Set Say (1878), Phụ Tục (1878), Mirador (1879), and Saintard (1879). Of these, the Chò Gao Canal was one of the most vital. Via several large waterways, it linked Sài Gòn with Mỹ Tho, the largest river port at the time. A gunboat or cannonière could now make the trip to the delta in just 8 hours.

The same problems of sediment accretion and controlling vegetation continued to dog French engineers as it had their Vietnamese predecessors. In just a few years, Chò Gạo was silted again, preventing passage of the larger boats and forcing them to make the much longer journey to the river port by entering the river from the sea. In 1883, the government paid the Eiffel company to construct steel railway bridges across the intermediate Vàm Co River to connect Sài Gòn with Mỹ Tho by train. As the colonial government grew stronger in the 1880s and the French succeeded in using mechanical dredges at Suez, the regime introduced mechanical dredges. The shallow and high-clay sediments here, however, forced the government to rely on labor crews until new dredges were built in the 1890s.

The period of colonial dredging contracts with a mechanical dredging firm lasted from 1894–1945. During the peak of colonial expansion from 1894–1930, the colonial regime dredged some of the major "transverse" waterways connecting the lower branch of the Mekong or Hậu Giang with the Gulf of Thailand. This lower part of the delta was the least inhabited, making it the easiest space for French colons to build plantations several thousand hectares in size. Major canals such as Xà No (1904), Lai Hiêu (1906), Thôt Nôt (1908), Ô

Môn (1906), Vinh Tê (redredged,1914), Quạn Lô–Phụng Hiêp (1918), Ba Thê (redredged,1923), and Tri Tôn (1928) were developed. They also, dredged important waterways into Dông Tháp (1890–1904), from Bac Liêu to Cà Mau (1906), and from Rạch Giá to Hà Tiên (1930). This massive effort in mechanical dredging was accompanied by the immigration of laborers from the north; the population increased from 500,000 to almost 4 million in 1930.

Some areas, especially the fields near Cân Tho, flourished, but many of the waterways proved to be both economic and ecological disasters. The Lai Hiêu Canal brought on higher flooding, and its embankments cut off existing water circulation that led both to the spread of cholera in 1908 and the failure of many preexisting fields. A series of typhoons from 1904–1908 caused abnormally high flooding in the Plain of Reeds and the abandonment of plantations and fields after several years of lost crops. Canals also led to drying of soils in floodplains that were high in sulfate content. This drying of soils produced acid sulfate that then leached into the waterways and in turn quickly reduced crop productivity. With the onset of the world depression in 1931 and the collapse in rice markets, the masses of migrant laborers employed as tenant farmers on the plantations began to protest. Hydraulic engineers also began to debate the future of projects in the area. One camp argued that it was necessary first to improve existing yields and to let some of the failed projects lie fallow. Another camp argued for more sophisticated mechanical approaches to drainage and irrigation, suggesting the redevelopment of casier or grids of irrigation canals where farmers could be resettled. Except for small settlement projects near Ba Thê, the colonial government did not develop any other large projects before it was ousted from power in 1945 and subsequently entered into a 9-year war with the Viêt Minh.

During the Second Indochina War (1945–1954), the Government of South Vietnam attempted to develop several of these casier styled resettlement projects in a fashion similar to those proposed by the French before them. Of these, the single permanent project was the Cái San Project, a series of "transverse" canals in the lower delta and a smaller network of intersecting canals numbered from 1 to 17 and letters A to H. From 1955–1962, the Government resettled approximately 50,000 settlers, mostly Catholic, from their original villages in North Vietnam to 3-hectare tracts at Cái Săn. During the 1960s, American military and private contractors further built up the area with a highway paralleling the Rạch Sọi Canal (Highway 80) and an airport at the southern end of the area (today Rạch Giá Airport). For the most part, both wars prevented steady extension of waterways due to continued guerilla attacks. Like preceding antistate rebels, preventing easy circulation of government troops on the waterways and (increasingly) roads was vital to survival. Most of the familiar scenes of combat during the "American War" were encounters in the swampy interiors of swamps where previous canals had either deteriorated or been abandoned because of their low agricultural utility.

Since the conclusion of the war in 1975, and especially with the market orientation stimulated by Dôi Mói Reform in 1986, the Government today has begun a series of new projects. Like projects enacted in the 1950s, many of these contemporary development projects were continuations of earlier plans developed in the 1960s and early 1970s. For example, in 1996, the Government began work on the Mỹ Thuận Bridge, a project first surveyed by the Nippon Koei Corporation in 1963. This bridge, completed in 2001, became the longest span bridge in Southeast Asia and for the first time, allowed continuous highway transport across the upper branch of the Mekong River. A second span is due to be completed near C`ân Tho in 2005. Now at peace, government leaders have refocused their attention on Dông Tháp and former guerilla strongholds for future agricultural development. The Vietnamese delta population now is well over 17 million persons, however, so decisions to build canals and flood dikes are becoming increasingly difficult. Flood control in one area often results in diversion of the floodwaters to another zone or province downstream, thus giving rise to interprovincial disputes over access to clean water. A related issue is the construction of dams on the upper and middle Mekong Basin. The Mekong Committee is an international advisory body made up of representatives of the six riparian countries. With the reunification of the region and all member states into both the Mekong Committee and ASEAN, downstream countries have begun to lobby against diversionary projects upstream.

Another future concern in the Mekong Delta is the impact of global warming. As sea level rises just a few feet, thousands of hectares along the coast would be permanently inundated with salt water. The Mekong Delta is one of the flattest deltas in the world, so fluctuations in both river levels and sea levels could require the construction of unprecedented sea dikes to protect areas of coastal rice paddy.

The apparent "system" of canals and water projects in the Mekong Delta reflects nearly 2000 years of experimentation. Some of those trials lasted into the present, and some others are barely visible now. The economic or environmental health of this system is largely dependent on regional social factors and the intensity of human activity here. Currently, the challenge for engineers and planners in this region is to reconcile these factors to distribute "clean" water equitably in a more predictable fashion.

CONFLICT AND WATER USE IN THE MIDDLE EAST

Clive D. Lipchin
Ann Arbor, Michigan

INTRODUCTION

Freshwater is unevenly and patchily distributed across the surface of the earth, some regions have either ample supply or unlimited access, and other regions suffer from unpredictable rainfall patterns and long periods of drought. As human populations grow and their activities continue to alter environmental patterns, the demand for freshwater will increase as the availability and quality of freshwater decreases. These conditions make water-related conflicts more likely between nation states that are forced to share a common water resource under the strain of locally increasing populations and increasing regional demands for water. In the semiarid and arid regions of the globe, especially the Middle East, conflict over water seems a more and more likely prospect (Table 1).

Where water is scarce, competition for limited supplies can lead nations to seek access to water as a matter of national security. As recently as the mid-1980s, U.S. government intelligence services estimated that there were at least 10 places in the world where war could break out over dwindling shared water resources; the majority of these locations are in the Middle East. Jordan, Israel, Cyprus, Malta, and the countries of the Arabian Peninsula are sliding into the perilous zone where all available fresh surface and groundwater supplies will be fully used. In Israel, the Palestinian Authority, and Jordan, a water deficit already exists, and all available water resources are overexploited.

The conflicts in the Middle East are probably unique in the world and are many faceted and complex. As the birthplace of modern Western civilization and three of the world's largest religions, conflicts, whether political, racial, or religious, have been a part of the system since civilization first began between the twin rivers of the Tigris–Euphrates. The ongoing conflicts taking place on today's political stage can be traced back to Biblical times and beyond. In the face of such an historic record of conflict, solving disputes over shared water resources automatically involves cultural, economic, and political factors.

Table 1. Percapita Water Availability in 1990 and 2025[a]

Country	1990	2025, Cubic Meters Per Person Per Year
Kuwait	75	57
Saudia Arabia	306	113
United Arab Emirates	308	176
Jordan	327	121
Yemen	445	152
Israel	461	264
Qatar	1171	684
Oman	1266	410

The emergence of modern independent states since the decline of colonialism in the region has strengthened nationalistic ideals and exacerbated common property issues that transcend their borders. Given the importance of the region as the world's main supplier of fossil fuels, the international community has been quick to realize the delicate power balance in the region and how precarious and volatile it can be. In the current global political environment, it is in the world's best interest to foster cooperation among the states in equitably managing their shared waters.

Across the globe, many rivers, lakes, and groundwater aquifers transcend arbitrary political borders. This geographical fact has led to the geopolitical reality of disputes over shared waters; the situation in the Middle East (especially the Nile, Jordan, and Tigris–Euphrates) is just one such example. Other regions where water disputes have or are likely to develop are the Indus, Ganges, and Brahmaputra in southern Asia; and the Colorado, Rio Grande, and Parana in the Americas.

Water is a fundamental resource vital for survival, and it also provides a source of economic and political strength. Under these conditions, ensuring access to water provides a justification for going to war, and therefore water supply systems can become a goal of military conquest (2). Gleik (3) outlined the following characteristics that make water likely to be a source of strategic rivalry:

1. the degree of scarcity,
2. the extent to which the water supply is shared by more than one region or state,
3. the relative powers of the basin states, and
4. the ease of access to alternative freshwater sources.

The Middle East and its many ideological, religious, and geographical disputes fits within this framework.

SETTING

The current water crisis plaguing the region can be traced back to the arbitrary political division of the region into competing states by the withdrawal of the post-World War I colonial powers (4). The subsequent map of the region disregarded the issue of water in forming possible natural political boundaries. Except for Lebanon, none of the states that the colonial powers created was provided with independent water resources, and no mechanisms were established for coordinating the use of internationally shared water resources (4). The Tigris–Euphrates Basin was sectioned irregularly and placed in the domains of three competing states (Turkey, Syria, and Iraq); the Jordan River was divided up among four states (Israel, Jordan, the Palestinian Authority, and Syria) (4). The Nile River Basin is shared by no less than nine states, and the balance of power is heavily skewed toward the two

Table 2. International River Basins in the Middle East[a]

River Basin	Total Area of Basin, Square Kilometers	Countries in Basin	Area, Square Kilometers	Percentage of Total Area
Tigris	378,850	Iran	220,000	58
		Iraq	110,000	29
		Turkey	48,000	13
		Syria	850	<1
Euphrates	444,000	Iraq	177,000	40
		Turkey	125,000	28

economically and militarily powerful downstream states, Egypt and the Sudan (Table 2).

An example to illustrate the tensions inherent in water resources development in the region is the conflict that took place between Israel and Syria. In the 1950s, Syria tried to prevent Israel from building its National Water Carrier, an extensive canal and piping system to provide water to the extremely arid areas of southern Israel. When Syria attempted to divert the headwaters of the Jordan in the mid-1960s, Israel used force, including air strikes against the diversion facilities, to prevent their construction and operation (5). These military actions, it is thought, contributed to the outbreak of the 1967 Six-Day War.

Having more mouths to feed, the allocation of freshwater becomes a pressing problem. More mouths means more food, and so, more water needs to be allocated to agricultural production. This issue is especially true for Turkey, Syria, and Iraq, which have all embarked independently on ambitious irrigation projects on the Tigris–Euphrates river system to increase their agricultural capacity (6). Water allocation, for the riparian states along the Jordan River, has become a balancing act between agriculture and domestic use as more of the population becomes urbanized. The allocation of water can lead immediately to issues of conflict as upstream states control the flow of a river course and inadvertently disadvantage those downstream that depend on the same flow.

The Tigris–Euphrates headwaters originate in Turkey but empty into the sea at the Persian Gulf in Iraq, flowing through Syria on the way to the sea. Egypt is entirely dependent on the Nile River for practically all of its water requirements but is at the mercy of the upstream states (especially Ethiopia) that contain the headwaters of the Nile, the Blue and White Nile, within their borders. Israel, Jordan, and the Palestinian Authority are in an even worse position. They possess few internal renewable water resources and all depend on one river system, the Jordan and associated aquifers, which has its headwaters originating outside of their territories in Lebanon and Syria.

Wolf (7) has provided a framework for analyzing transboundary waters and the potential for conflict. Within this framework, the problem, background, attempts at conflict management, and the potential for a positive outcome where conflict can be averted is provided. Wolf's framework is applied here in analyzing the three primary water systems in the Middle East: the Tigris–Euphrates, the Jordan, and the Nile.

THE TIGRIS–EUPHRATES RIVER BASIN

The Problem

In 1975, unilateral water developments came close to provoking warfare among the riparians of the Tigris–Euphrates (Turkey, Syria, and Iraq). Since the 1960s, population pressures drove the three states to pursue water development projects independently, primarily for agricultural expansion. Specifically, these were projects in southern Anatolia in Turkey, the Keban Dam (1965–1973), and in Syria, the Tabqa Dam (1968–1973) (7).

Background

From source to sea, the Euphrates is the longest river in the whole region of West Asia (8). It traverses a distance of 2,700 kilometers, of which some 40% is in the modern state of Turkey, 25% in Syria, and 35% in Iraq. Its twin, the Tigris, has a total length of 1,900 kilometers, of which about 20% lies in Turkey, 78% in Iraq, and only 2% along the pointed northeastern corner of Syria, known as the "Duck's Beak" (4).

Probably the most ambitious development project carried out in the region is Turkey's South East Anatolia Project known by the Turkish acronym GAP (for Guneydogu Anadolu Projesi, in Turkish). The project aims to develop the regions bordering Syria and Iraq that encompass the headwaters of the Tigris and Euphrates. The area is sparsely inhabited by a population of around 6 million; the majority consists of ethnic Kurds, who claim the region as part of their national homeland. By transforming this semiarid region into the country's breadbasket, Turkey hopes to encourage and promote the development of agriculture and industry and also to offset the Kurdish majority by attracting Turks into the area and so diluting Kurdish nationalistic claims (6).

The Turkish government has promoted the GAP project for its great eventual benefits for all, but recently, more than 250,000 people were displaced from their homes, which were to be inundated by dams. A conflict broke out between the Turkish government and the Kurdish Workers Party (PKK), which has repeatedly opposed GAP and regarded it as a Turkish theft of Kurdish waters (4).

The GAP plan calls for constructing 80 dams, 66 hydroelectric power stations that have a total capacity of 7700 megawatts, and 68 irrigation projects covering up to 2 million hectares. Among the principal dams are the Keban, the Karakaya, and the Ataturk, which is the linchpin of the entire GAP complex (4).

Despite its great agricultural potential, Iraq has, in the last decade, become a net importer of grain to feed its population of 26 million. Iraq's main irrigated lands are the regions of lower Mesopotamia. However, waterlogging and salinization plague this region and therefore an imperative need has developed for a coordinated scheme of rehabilitation and sustainable water management, especially to provide regional drainage.

In 1953, Iraq began work on a regional canal to provide comprehensive drainage. This canal has been dubbed "The Third River" because it flows midway between the Tigris and Euphrates. During the Gulf War, bombing caused great damage to Iraq's hydraulic works, but it managed to complete the project in December 1992.

The project was designed to drain 1.5 million hectares of land, allowing Iraq to increase its domestic food output significantly and thus help achieve its aims of economic independence. However, like Turkey's GAP project, Iraq's third river has displaced the indigenous Marsh Arabs, and the UN has criticized the canal as an environmental crime that threatens to destroy an entire ecosystem (6). An ulterior motive for draining the region has been the possible exposure of oil deposits that it is thought underlie the marshes and are considered as extensive as those in Kuwait.

More than Turkey and Iraq, Syria depends nearly entirely on the flow of the Euphrates for the development of its economy. Apart from the Euphrates, Syria has access to a few underground aquifers from which, through the sinking of thousands of wells, has already caused overdrawing and salinization of the groundwater. In 1974, Syria began its greatest engineering feat, the damming of the Euphrates and the creation of Lake Assad. The dam, built with Soviet engineering and financial aid, was supposed to irrigate some 400,000 hectares, generate electricity, and make the region prosperous (4). In this project, as for the projects described, 70,000 indigenous Bedouin were displaced. In addition, the project has turned out to be a disappointment; the imported Soviet water generators proved faulty, and the land originally designated for irrigation proved unsuitable because the soil contains large amounts of gypsum (4).

Attempts at Conflict Management

According to Shultz (8), the real problems that the three states currently face are management, apportionment, and development planning, which have led to disagreements among them. This joint dependency on the river waters clearly indicates that the national security of the three states are linked. Turkey, Syria, and Iraq may, therefore, be considered to form a hydropolitical security complex. A hydrosecurity complex is defined as those states that are geographically part owners and technically users of the rivers and, as a consequence, consider the rivers a major security issue (8).

Disputes over the Tigris–Euphrates waters consist of conflicts between upstream and downstream neighbors, but also between the state and ethnoreligious groups (Kurds, Marsh Arabs, and Bedouins). Both Syria and Iraq depend on Turkey for the continual flow of the Euphrates. The intensification in using the Euphrates for Turkey's GAP project has caused sporadic decreases in flow in both Syria and Iraq. Such a decrease in flow is especially important for Syria, as, unlike Iraq, it cannot rely on the flow of the Tigris. The issues of an amicable apportionment of the river's flow could probably be easily met because there is enough water for all three states (8). Surprisingly enough, however, no tripartite agreement has yet been signed by the three riparians on flow regulation, dams, and sustainable water management.

The issue in contention then is how to weigh historical rights against proportionate contributions to flow, taking into consideration the real needs of each country. These are the availability of energy, the need for hydroelectricity, the feasibility of developing economic alternatives to irrigation farming, the efficiency of water use, and the size of each country's population. In 1980, a Joint Economic Committee was established between Turkey and Iraq, which included meetings related to water resources. Syria began participating in 1983, but meetings have been sporadic at best (7).

Outcome

Turkish and Syrian leaders had agreed to resolve the issues of water allocation by the end of 1993, but no agreement has yet been negotiated. Thus far, it seems that the levels of mistrust among the countries makes any serious settlement unlikely in the near future.

THE JORDAN RIVER WATERSHED

The Problem

Ever since the mid-1950s, the issue facing the riparians of the Jordan River watershed has been one of recognizing rights and equitably apportioning surface and groundwaters. An agreement came close to being signed by the riparians in the early 1950s, which was based on the Johnson accords, named after U.S. special envoy Eric Johnson. Although Israel agreed to sign the accords, the Arab states officially rejected the agreement but have unofficially used the accords as a basis for ongoing negotiation. Since 1991, beginning with the Arab–Israeli peace accords, especially those between Israel and Jordan and between Israel and the Palestinian Authority, progress has been made on rights, use, and apportionment. The Oslo accords and the Israel–Jordan Peace Treaty of 1994 both included means for joint water resource management. Today, the ongoing Palestinian–Israeli violence has made the agreements signed at Oslo exceedingly difficult to implement.

Background

The Jordan Basin is an elongated valley in the central Middle East. Draining some 18,300 square kilometers, it extends from Mount Hermon in the north to the Dead Sea in the south and lies within the pre-June 1967 boundaries of Israel, Jordan, Lebanon, and Syria. Its waters, which originate in rainfall and in rivers and streams of Lebanon, Syria, and the Golan Heights, drain the lands to the east and to the west of the Jordan Valley. Precipitation in the basin ranges from more than 1000 mm/y in the north to less than 50 mm/y in the south but averages less than 200 mm/y on both sides of the Jordan River (9). Much of the basin is arid or semiarid and requires irrigation for agricultural development.

Critical to the region's water supply is access to the water resources of the Jordan and also to the underground aquifers of the region. Such access is especially crucial for Israel because 60% of its total potential water supplies are in the region's two largest aquifers, the coastal plain aquifer and the mountain aquifer (6).

As early as the mid-1970s, Israel has been overabstracting water from the coastal aquifer, causing saltwater intrusion. The Gaza Strip also depends on this aquifer, from which it is estimated that 65 MCM/y (million cubic meters per year) is available. Rapid population growth, however, has severely taxed the system and caused lowering of the water table and severe intrusion of seawater into wells. Consequently, most of the local drinking water in Gaza exceeds the salinity level of 500 ppm, considered the upper threshold for safe drinking water; in some areas, the salinity level has reached 1500 ppm and made drinking water next to intolerable (4).

The mountain aquifer or Yarkon–Taninim aquifer extends beyond the Green Line (Israel's pre-1967 borders) into the mountainous regions of the West Bank. The aquifer extends about 150 kilometers from north to south. The aquifer's sustainable yield of fresh water is estimated at about 300 MCM/y. It is tapped by more than 300 wells, whose total annual pumpage averages 375 MCM. Like the coastal aquifer, the mountain aquifer is suffering from overpumping and a decline in water quality.

Since the 1950s, Israel and Jordan have pursued unilateral plans for developing the Jordan River Basin. Israel drained the Huleh swamps to create arable land and constructed the National Water Carrier that pumps water from the Sea of Galilee to the central and southern regions of the country. Jordan created the King Abdullah canal on the eastern shores of the Jordan for irrigation and drinking purposes. Both of these projects have, in effect, dried up the natural flow of the Jordan to its terminus at the Dead Sea.

Attempts at Conflict Management

Although never signed, the Johnson Plan of 1955 offered a regional approach to the management of the Jordan, although groundwater was not considered. Today, groundwater is a key point in negotiations between Israelis and Palestinians because groundwater development will be integral to creating a Palestinian State.

Outcome

Since the Madrid talks of October 30, 1991, Israel and the Arab states agreed on the need for multilateral negotiations on water resources. This multilateral track runs in parallel with the bilateral negotiations on a political settlement between Israel and the Palestinian Authority (now stalled) and Israel and Syria (also stalled). The multilateral track on water serves as a venue for discussing problems of water supply and demand, and joint institutions have been created between Israelis and Palestinians and between Israel and Jordan on water issues. The idea of multilateral working groups is to create opportunity for progress on the bilateral track (7). In other words, agreement on water issues can become a catalyst for bilateral political agreements. The current Working Group on Water Resources has thus been more about fact-finding and sharing information than on the more contentious issues of water rights and allocations (7). It can be said, however, that Israel and Jordan have, to a large degree, agreed on these issues by signing the Israel–Jordan Peace Treaty in 1994. Nonetheless, a true accounting of rights and allocations in the region will need to include the Palestinian Authority as a fellow riparian to the Jordan, as well as Syria and Lebanon, that contain the river's headwaters.

THE NILE RIVER BASIN

The Problem

Management of the Nile waters is a case of historical rights (essentially claimed by Egypt) to the river and the political and economical power of the riparians. Egypt, as the power broker of the region, wields the greatest influence over the Nile, even though all of the Nile's water flow originates outside of Egypt. To date, only Egypt and the Sudan have negotiated on means for managing the Nile. However, nine sovereign states share the waters of the Nile. The core question is thus where best to control the river for the benefit of all riparians—upstream or down (7).

Background

The Nile is one of the great natural wonders of the world: It is the longest river and flows 6,825 km south to north across 35° latitude. The Nile's catchment basin covers approximately one-tenth of the African continent, an area of 3,007,000 square kilometers. Because of its size and variety of climates and topographies, the Nile Basin constitutes one of the most complex of all major river basins. Throughout the northern reaches of the Nile, human civilizations have depended on the river for their very survival; without the river, Egyptian civilization would not exist.

The Nile has two major tributaries, the White Nile and the Blue Nile. These two principal headwaters are very different from each other; they arise in contrasting climatic and physiographical areas and are characterized by disparate hydrologic regimes. The White Nile flows out of the tropical rainbelt of Central Africa and has relatively little interseasonal variation. The seasonal rainfall fluctuations in the Blue Nile headwater region of Ethiopia are much more marked than those prevailing at the source of the White Nile. In sum, approximately 86% of the Nile's flow originates in Ethiopia: The Blue

Nile contributes 73% and the Atbara 13%. The other 14% is contributed by the White Nile (10). The total volume of water available in any given year is subject to substantial hydrologic variability.

The Nile River Basin, along with all the water it carries, traverses the territories of nine separate nations: Burundi, Egypt, Ethiopia, Kenya, Rwanda, the Sudan, Tanzania, Uganda, and Zaire. Although these countries share one of the greatest rivers in the world, many inequities over this common resource exist and are especially difficult to redress. The Nile presents a classic riparian problem: A river does not recognize boundaries between states—it flows continuously. The ways in which it is diverted, collected, used, and returned to the stream determine the quality and quantity of water that each successive downstream nation will receive.

The Nile region is unique in economics and development. The pattern of water demand and use in the Nile Basin contrasts sharply with the pattern of supply: The upper valley states, in particular Ethiopia, are best placed geographically, but the lower valley states, especially Egypt, have a vital resource interest and can exercise decisive military and economic power. The paradox is that the countries that contribute the most water use the least, but the countries that use the most are those that have political and economic influence.

Egypt and the Sudan account for more than 90% of the water drawn from the Nile. However, there are seven other basin states, and their demand for water will inevitably grow. The upper riparian states, Tanzania, Uganda, Rwanda, Kenya, Burundi, and Zaire, use 0.05 km^3/yr collectively; Ethiopia uses only 0.6 km^3/yr. This is ironic because combined, these states contribute 72 km^3 of water per year, or about 86% of the Nile's flow (10).

Attempts at Conflict Management

Optimal development of the basin's water resources depends on agreement and cooperation among individual countries that share several common difficulties. Among them are population growth, insufficient agricultural production, and evaporative losses (10). These all directly impact the available water supply for all basin countries. An integrated approach to resolving these issues is most logical given that all countries have a stake in the outcome. In addition, these dilemmas transcend international boundaries, so any action taken by one nation will almost assuredly impact other nations in the region.

In 1929, the Nile Waters Agreement between Egypt and the Sudan was signed. This agreement guaranteed allocations to Sudan, but the entire seasonal flow of the river was reserved for Egypt (7). The agreement was heavily weighted in Egypt's favor by assurances that no works would be developed on the river that would threaten Egypt's interests. Intermittent negotiations occurred between Egypt and the Sudan on the building of the Aswan High Dam in Egypt in the late 1950s. No agreement on joint management of the dam was reached, in 1959, Sudan unilaterally built the Sennar Dam and by so doing, repudiated the 1929 agreement (7). However, when the military regime gained power in the Sudan in 1958, a Nile Waters Treaty was signed in 1959 called the Agreement for the Full Utilization of the Nile Waters.

The upstream states' reaction to the treaty was that the downstream states had simply divided the recognized average flow of the Nile between themselves and left nothing for any other countries (10).

Outcome

Egypt and the Sudan have agreed that any claims to Nile waters by the other riparians will be met with one unified Egyptian–Sudanese position. No other state riparian to the Nile has ever exercised a legal claim to the waters allocated in the 1959 Treaty (7). Ethiopia, which has an estimated 75–85% of the river's annual flow, has not been a major player in Nile hydropolitics. So far, it has pursued unilateral projects to meet its growing need for irrigation. Recently, however, a new Nile Initiative created dialogue among all the riparians on joint planning for the basin, and a new treaty, inclusive of all the riparians, may be in the offing.

CLOSING

Wars over water have not occurred. The last 50 years have seen only 37 acute disputes that involved violence. During the same period, 157 treaties have been negotiated and signed (7). But the growing lack of clean freshwater coupled with the rise in demand has led to intense political instability, and acute violence has occasionally resulted (7). Many of the world's water conflicts are also in the developing world, where political instability is coupled with socioeconomic ills such as poverty. Within the Middle East, the legacy of colonialism, mistrust between riparians, disparities in economic, infrastructural, and social capacity, and political orientation further complicate an integrated and regional approach to water resources development.

Middle Eastern water development has followed a pattern of unilateral development first due to perceived claims of sovereignty or to avoid political intricacies. At some point, a regional power may implement a project that will impact other riparians, such as the Aswan High Dam on the Nile and the GAP project in Turkey. The absence of relations or institutions for resolving these developments can be a flashpoint for violence. General legal principles for transboundary water management are, however, currently being defined and improved on, such as the Convention on the Non-Navigational Uses of International Watercourse ratified by the UN Assembly in 1997 (7). These principles are beginning to provide a framework to which countries can turn in formulating cooperative water regimes.

As described before, although the issues are highly contentious and complex, all-out war over water has not occurred in the Middle East. Positive outcomes to conflict resolution have occurred in some cases, for example, the Israel–Jordan peace treaty. In other conflicts, the countries are moving slowly toward resolution, as in the case of the Nile riparians.

BENJAMIN FRANKLIN'S ARMONICA: A WATER MUSIC INSTRUMENT

William E. Marks
Water Consciousness, Inc.
Martha's Vineyard,
Massachusetts

The art of creating music from water-filled glass receptacles is probably as ancient as glassmaking. Some music scholars date the phenomenon of water music back to 2500 B.C. Because this time predates recorded history, all we have as documentation are references in early folklore and tales.

In the ancient days of Pythagoras, a variety of music was composed by musicians using water-filled bowls that held different levels of water. This use of creating water music according to a mathematical scale, resonated with Pythagorean philosophy, which believed in transmigration of the soul and a related belief in a numerical scale.

In Persia, where some methods of their glassblowing techniques remain a mystery to this day, we find accounts, as early as the fourteenth century, of water music being played from glasses. Largely because glass music was often played by amateur performers who created their own folk music, glass music has a history that is obscure and mysterious.

For instance, in Europe, the earliest reference to musical glasses dates back to 1492. Shortly thereafter, we find the visionary Nostradamus (1503–1566) using a water-filled bowl to see into the affairs of humankind across the span of time. This method of using a water bowl for divining the future is known as "scrying."

As expressed in the book, *The Holy Order of Water*, Nostradamus would sit alone at night on a "tripod stool of brass" and look deeply into a large bowl of water. Using a special branch that was wetted with water on both ends, he would rub one end of the wet branch in a circular motion around the rim of the water-filled bowl. This would produce tones, or ethereal voices, that according to Nostradamus, gave him information and insight about the future.

It is curious to note that there is little if any elaboration on the source of the water used by Nostradamus to see into other dimensions, a fact that may have been a hidden secret—just as it was hidden in writings concerning the creation of the "Philosopher's Stone," which is often referred to in ancient lore. Certainly, with what modern science is revealing at this time, we know that the quality and source of waters used for healing and for other "higher" purposes has to be of unique quality and handled with care.

When Galileo (1564–1642) was writing about pendulums, he wrote the following about water music being played with wine glasses filled with water:

> If one bows the bass string on a viola rather smartly and brings near it a goblet of fine, thin glass having the same tone [tuono] as that of the string, this goblet will vibrate and audibly resound. That the undulations of the medium are widely dispersed about the sounding body is evinced by the fact that a glass of water may be made to emit a tone merely by the friction of the fingertip upon the rim of the glass; for in this water is produced a series of regular waves. The same phenomenon is observed to better advantage by fixing the base of the goblet upon the bottom of a rather large vessel of water filled nearly to the edge of the goblet; for if, as before, we sound the glass by friction of the finger, we shall see ripples spreading with the utmost regularity and with high speed to large distances about the glass. I have often remarked, in thus sounding a rather large glass nearly full of water, that at first the waves are spaced with great uniformity, and when, as sometimes happens, the tone of the glass jumps an octave higher I have noted that at this moment each of the aforesaid waves divides into two; a phenomenon which shows clearly that the ratio involved in the octave [forma dell' ottava] is two (1,2).

For whatever reason, this ancient connection of the soul to water glass music plays itself again and again in various countries throughout history, including the life and times of Benjamin Franklin. Water is the source of life, and life depends on an ongoing healthy source of water, so the connection of creation and the soul to water cannot be taken for granted. As expressed above by Galileo, the water in glasses near the vibrating glass of water will vibrate as well. It takes only a small leap of imagination to grasp the concept that the cellular water within the bodies of people near a musician playing water glasses will also vibrate.

Throughout the seventeenth century, amateur performances are documented that featured sets of wine glasses arranged on a table, played with moistened fingers and tuned by the addition of small amounts of water. This "glass music" became popular throughout Europe and was played in churches and parlor circles (known as 'Gay Wine Music' in 1667 London). The unique qualities of this water glass music captured the imagination of many composers and was well entrenched in Europe during the height of Romanticism in the 1700s.

During 1743, Handel's Water Music was played on an 'Angelic Organ' (a set of tuned wine glasses) by the Irish musician Richard Pockridge. Franklin may have been exposed to this rendition of Handel's Water Music on water glasses because he attended many music concerts while in Europe. In 1759, Franklin wrote the following in his diary after watching Handel's last concert, "... the sublime old Handel was led to the organ and conducted the Messiah for the last time eight days before his death."

Also of musical record, we have the composer Gluck, who in 1746 impressed audiences throughout Europe with his "Verrillon." In doing so, Gluck used a set of wine glasses to produce his water music ('verres' is the French word for 'glass').

In 1757, the Pennsylvania assembly directed Franklin "to go home to England" and negotiate a fairer system of taxation for the colonies. That same year, while living in London he heard E. H. Delaval of the Royal Society play music on water-filled glasses. Afterward, Franklin wrote about the Delaval water music concert he attended:

> He collected a number of glasses of different sizes, fixed them near each other on a table, and tuned them by putting into them water, more or less as each note required. The tones were brought out by passing his fingers round their brims. He was unfortunately burnt here, with his instrument, in a fire which consumed the house he lived in (1759). Mr. E. (Edmund Hussey) Delaval, a most ingenious member of our Royal Society, made one in imitation of it, with a better choice and form of glasses, which was the first I saw or heard (3, p. 297).

Upon hearing the water glasses played, Franklin was moved to refer to it as, "That charming science." Having inherited an interest in music from his father, Franklin already had a strong foundation in the history, theory, and artistry of playing and composing music. Wanting to hear more harmonies with his melody, he set about inventing a way to mimic the sound of water glass music.

> Being charmed by the sweetness of its tones and the music he produced from it, I wished to see the glasses disposed in a more convenient form, and brought together in a narrower compass, so as to admit a greater number of tunes and all within reach of hand to a person sitting before the instrument (3, p. 298).

Enlisting the assistance of a London glassblower named Charles James, Franklin had 37 glass bowls (hemispheres) blown and ground to different sizes and thicknesses to produce 37 distinct tones. Each of these was then painted to help identify the note it produced. In the center of each glass bowl was a hole into which Franklin inserted a piece of cork. He then lined up the bowls chromatically, from lowest tone to highest, on a horizontal spindle (iron rod) according to size. The largest glass bowl was mounted to the left and then each subsequent bowl installed to the right was progressively smaller. The larger the bowl, the lower the tone, and the smaller the bowl, the higher the tone.

The iron spindle was attached to an apparatus similar to a spinning wheel, which was then turned by a foot treadle, a configuration common in those days on foot-operated sewing machines.

As the foot treadle turned the wheel, the spindle rotated the glass bowls. This allowed Franklin to sit at the Armonica, use his feet to turn the bowls, and by wetting his fingers from a bowl of water, produce music that rivaled that of the musical glasses containing water.

To make it easier to identify the notes of the bowls, Franklin painted the bowls using a combination of the seven colors of the rainbow along with the color white. Franklin's "Armonica" included two of the three octaves of the musical scale, giving musicians a greater creative range for their compositions (See Fig. 1).

The vibrations produced from the spinning glasses in the Armonica produced sounds with different frequencies when touched with moistened fingers. Therefore, a variety of musical tones could be created. The handmade glass used in Franklin's time was mostly soda-lime glass (containing sodium) or lead glass (containing lead).

When playing the Armonica, a moistened finger held to the rim of the glass as it rotates, produces a pure and constant tone. The pitch was altered by changing the pressure of the finger touching the rim of the glass, by adding more water to one's fingers, or by decreasing the size of the glass being touched. Therefore, Franklin's use of glasses of varying sizes arranged on the Armonica allowed a musician to create a range of melodies on the instrument. Because Franklin's Armonica instrument included two to three octaves of the musical scale, it permitted a composer greater personal freedom in creating musical arrangements.

When and how Franklin decided to coin the word "Armonica" for his musical invention is not known. What we do know is that on July 13, 1762, Franklin sent a letter to Padre Giambastista Beccaria of Italy, describing the attributes of this new musical invention:

> The advantages of this instrument are that its tones are incomparable sweet beyond those of any other; that they can be swelled and softened at pleasure by stronger or weaker pressures on the fingers, and continued at any length, and that the instrument, being once well tuned, never again wants tuning (3, p. 298).

Figure 1. 1920s painting of Franklin playing the Armonica. "Of all my inventions, the glass armonica has given me the greatest personal satisfaction"—Benjamin Franklin. (Photograph courtesy William Waterway).

In the same letter, Franklin writes, "In honour of your musical language, I have borrowed from it the name of this instrument, calling it the Armonica."

Considering this letter, it appears appropriate that Franklin chose "Armonica" as the name his musical instrument invention because "armonica" is the Italian word for "harmony."

Shortly after its introduction in England and Europe, the Armonica became widely accepted as a new musical instrument. As greater numbers of musicians began playing the Armonica, it soon became a fad. To meet the demand, Armonica factories were built. One of them reportedly employed more than 100 workers. It is estimated that more than 6000 Armonicas were manufactured during a period of about 40 years.

It is of historic note that many of the musicians who played the Armonica were women, which was unusual for that time. The French queen Marie Antoinette took lessons from a famed European Armonica player named Marianne Davies.

Always the charming statesman, Franklin would often take his Armonica to social gatherings, where he would set about entertaining the social elite. In short order, famous composers such as Schmittbauer, Richard Straus, J. A. Schultz, Mozart, Haydn, Galuppi, Martini, Beethoven, Donizetti, J. G. Naumann, Jommelli, J. F. Reichardt, Saint-Saens, and Leopold Rollig began composing music to fit Franklin's Armonica. In 1787, Rollig wrote, "...the sensation the harmonica [Armonica] produced after its first appearance and the unanimous applause of all who heard it, make the instrument...the most satisfying and most beautiful mankind has ever possessed."

Rollig's statement seems to echo what Franklin wrote 24 years earlier on December 11, 1763,

> I play some of the softest Tunes on my armonica, with which Entertainment our people here are quite charmed and conceive the Scottish Tunes to be the finest in the World. And indeed, there is so much simple Beauty in many of them, that in my Opinion they will never die, but in all ages find a Number of Admirers.

To say the least, Franklin was already renowned in England and Europe for his invention of the lightning rod. With the invention of the Armonica, Franklin's overseas popularity made him one of America's first international superstars.

Even though Franklin invented the Armonica, it is historical fact that Germany's society of musicians and fine glassmakers embraced this instrument more than musicians in any other nation. Most of the periods' literature on the Glass Armonica was available only in the German language. The only method book for playing the Armonica was authored by J. C. Müller in 1788 and published in Leipzig, Germany.

ARMONICA AS A HEALING WATER INSTRUMENT

Today, as we have evolved to understand the relationship of music to water for healing, it was something that Franklin seemed to understand in his day as well. We have the following account of Franklin using his Armonica for healing Princess Izabella Czartoryska of Poland from "melancholia."

As expressed in her own writings of 1772,

> I was ill, in a state of melancholia, and writing my testament and farewell letters. Wishing to distract me, my husband explained to me who Franklin was and to what he owed his fame...Franklin had a noble face with an expression of engaging kindness. Surprised by my immobility, he took my hands and gazed at me saying: pauvre jeune femme ["poor young lady"]. He then opened an armonica, sat down and played long. The music made a strong impression on me and tears began flowing from my eyes. Then Franklin sat by my side and looking with compassion said, "Madam, you are cured." Indeed that moment was a reaction to my melancholia. Franklin offered to teach me how to play the armonica—I accepted without hesitation, hence he gave me twelve lessons (4).

Another documented case of the Armonica used for healing involves Franz Mesmer (1734–1815). Mesmer was a Viennese psychiatrist who is known for his theory on "animal magnetism." Today, many people believe that Mesmer invented hypnosis. This misconception is due to the use of his name in the word "mesmerize." However, Mesmer did not invent or use hypnosis. One of Mesmer's water healing methods was to use a wooden tub filled with magnetized water. Besides using tubs with treated water, Mesmer also used the Armonica in his treatments.

The following is an account given by a Dr. Le Roux sometime between 1778 and 1779. Dr. Le Roux had taken an army surgeon to Mesmer's clinic for treatment of gout:

> After several turns around the room, Mr. Mesmer unbuttoned the patient's shirt and, moving back somewhat, placed his finger against the part affected. My friend felt a tickling pain. Mr. Mesmer then moved his finger perpendicularly across his abdomen and chest, and the pain followed the finger exactly. He then asked the patient to extend his index finger and pointed his own finger toward it at a distance of three or four steps, whereupon my friend felt an electric tingling at the tip of his finger, which penetrated the whole finger toward the palm. Mr. Mesmer then seated him near the harmonica [Armonica]; he had hardly begun to play when my friend was affected emotionally, trembled, lost his breath, changed color, and felt pulled toward the floor (5).

Being ahead of his time, Mesmer was using a water treatment method that is now becoming quite popular in Europe. Water, light, and sound are now used to stimulate healing while a patient is submerged in a tub of mineral water.

Mesmer, Mozart, and Franklin were Freemasons and were thus connected in their appreciation and use of the Armonica for helping humankind.

As noted in history, all three were highly regarded when it came to playing the Armonica. In 1773, Leopold Mozart met Marianne Davies in Vienna and started playing the Armonica shortly afterward. In a letter to his wife, Mozart wrote,

> Do you know that Herr von Mesmer plays Miss Davies' armonica unusually well? He is the only person in Vienna who has learned it, and he possesses a much finer instrument than Miss Davies does. Wolfgang too has played upon it. How I should love to have one!

Mesmer believed so much in the power of the Armonica that his dying request was to have a priest play the Armonica for him.

Besides the use of the Armonica for healing in the time of Benjamin Franklin, the harp was also used for healing. The ethereal connection of healing harp and Armonica music can be found in the adage, "If the harp is the instrument of the Angels, the Armonica is the voice of the Angels."

The use of the harp and Armonica for healing is based on the vibrational tones generated by these instruments. In theory, these tones cause the intracellular and intercellular water of the human body to be energized in a way that is conducive to healing. Testimony to this can be found in one of today's musical healing societies known as "Healing Harps (www.healingharps.org).

On another note, just as Franklin's lightning rod invention quickly found its way from America to all of Europe, in reverse fashion, his Armonica quickly found its way from Europe to all of America.

Needless to say, when Franklin returned home to America, he set up a room specifically for music and entertaining. This became known as the Franklins' "Blue Room." Even though this room was complemented with an assortment of musical instruments, the Armonica was always Franklin's favorite. In testimony to Franklin's appreciation for his musical invention, he leaves us the following quote, "Of all my inventions, the glass Armonica has given me the greatest personal satisfaction."

Ben Franklin collected no money from his glass Armonica invention. He refused to patent any of his inventions, saying: "As we enjoy great Advantages from the Inventions of others we should be glad of an Opportunity to serve others by any Invention of ours, and this we should do freely and generously."

THE DEATH AND RESURRECTION OF THE ARMONICA

After about 40 years as a popular musical instrument, the Armonica suddenly began to fall into disfavor during the early 1900s. There are various theories as to why this occurred. Some theorists say people were fearful of contracting lead poisoning from the bowls which were made of lead crystal. Others say that the Armonica was responsible for causing nervous disorders and possibly insanity and that the toning of the Armonica opens doorways to ethereal realms that caused maladies and possibly death. In Germany, where the Armonica was most popular, there was the unfortunate coincidence of a young child dying while an Armonica was being played in a performance hall. Rumors became so rampant that the Armonica became banned in some towns.

As controversy raged throughout Europe over the theorized negative health impacts of the Armonica, Franklin ignored these rumors and continued playing the Armonica his entire life without suffering any illness. However, the Armonica's popularity never really returned to what it was during the height of its popularity.

From a more practical perspective, it was believed that the growing popularity and versatility of the piano may have contributed to the Armonica's downfall. In about 1720, Christofori finished his real pianoforte. Christofori constructed a case superior to those used for harpsichords, which allowed the piano to withstand the increased strain of heavier strings. Christofori also added other improvements to the piano, which allowed the performer to produce a delicate pianissimo as well as a strong fortissimo, not possible on either the clavichord or harpsichord. These improvements in the piano also produced tones of music which could fill a concert hall and were easily heard by the entire audience.

Regardless of what caused the demise of the Armonica, there is now a renewed interest in its use. In the 1980s, American glassmaker, Gerhard Finkenbeiner of Waltham, Massachusetts, researched and resurrected Franklin's Armonica from obscurity. His glassmaking company, G. Finkenbeiner, Inc., makes a quality Quartz Glass Harmonica (Armonica) that contains no lead. According to Finkenbeiner, the use of pure crystal glass also gives a superior sound to the reinvented Armonica.

Finkenbeiner's version of the Armonica is finding interest and popularity as a musical instrument. It has been used at the Metropolitan Opera; in radio commercials, and in various movie tracks.

Today, a handful of musicians play the Armonica. Noted musician, William Wilde Zeitler, has composed several new musical compositions for the Armonica, which are available as CDs.

Another musician, Cecilia Brauer, is world renowned for her Armonica performances. Ms. Brauer gives lecture/demonstration programs called "Ben Franklin and the Armonica" at museums, historical sites, libraries, and social institutions such as the Carnegie Museum; the Franklin Institute, and the National Portrait Gallery in Washington, DC. Besides composing original music for several CDs, Ms. Brauer is also known for playing the Armonica at the Metropolitan Opera House, for the sound track of the movie "Interview with the Vampire," and for several PBS specials.

On an ethereal note, Gerhard Finkenbeiner, the glassmaker from Massachusetts responsible for resurrecting interest in the Armonica, disappeared under strange circumstances in the late 1990s. The mystery of his sudden disappearance has yet to be solved. However, company employees have rallied to keep the company as an ongoing enterprise. In 2003, the employees of G. Finkenbeiner, Inc., issued the following statement:

> The Quartz Glass Harmonica, Gerhard's invention and musical triumph, will also be continued faithfully by G. Finkenbeiner Inc., as Gerhard would have wanted it that way. This unique musical apparatus and its wonderfully ethereal tones will continue to delight listeners around the world.
>
> If you have any questions or comments, we would love to hear from you. Your satisfaction is our priority! Your continued support has been an invaluable asset during these somber times, and we thank you sincerely for your patronage.

THE ARMONICA'S FUTURE

To have a grasp of the Armonica's future, the author of this article contacted two the world's most prominent players, William Wilde Zeitler and Cecilia Brauer. Their responses speak for themselves:

William Wilde Zeitler (info@glassarmonica.com)

> In spite of the publicity the Armonica has received of late on the History Channel, NPR, etc., I think its future is quite precarious. At present I'm the ONLY full-time composer/performer for the instrument; I know of one other full-time player, and maybe a half-dozen part time players. That definitely puts it on "the endangered musical instrument list.

Cecilia Brauer (brauerarmonica@webtv.net)

> It is very difficult to predict the Armonica's future. So far as I know, the only manufacturer of the Armonica in the U.S. was Gerhard Finkenbeiner in Waltham, Massachusetts. He "disappeared" in a private airplane flight almost five years ago. And, unless his descendants decide to keep the Armonica segment of his company, G. Finkenbeiner Inc., as a going concern, I do not know what the prognosis is. I would hate to see it disappear again as it is such a beautiful, unique sounding instrument and also such an important part of Franklin's history. Franklin felt that of all the things he accomplished, the Armonica gave him his greatest personal joy.
>
> There is a man, Sacha Reckert in Germany, who makes them, but they are somewhat different than Gerhard's. Perhaps the people at Finkenbeiner's might be able to help. The contact is DHession@finkenbeiner.com.

Based on the opinions of William Wilde Zeitler and Cecilia Brauer, it certainly does sound as though the future of the Armonica is somewhat dubious. However, this is one of the few glass water instruments in the world, and due to its history in the cultures of Europe and America, the Armonica will hopefully continue to provide enjoyment for many future generations.

WATER TRANSPORTATION OCCUPATIONS

Bureau of Labor Statistics, U.S.
Department of Labor

SIGNIFICANT POINTS

- Many jobs in water transportation occupations require a merchant mariner's document or a license from the U.S. Coast Guard.
- Merchant mariners on oceangoing ships are hired for periods ranging from a single voyage to several continuous voyages and may be away from home continuously for months.
- Jobs aboard oceangoing vessels have high pay, but competition for them remains keen, and merchant mariners might have to wait months between work opportunities.

NATURE OF THE WORK

The movement of huge amounts of cargo, as well as passengers, between nations and within our Nation depends on workers in water transportation occupations, also known on commercial ships as merchant mariners. They operate and maintain deep-sea merchant ships,

---

tugboats, towboats, ferries, dredges, excursion vessels, and other waterborne craft on the oceans, the Great Lakes, rivers, canals, and other waterways, as well as in harbors. (Workers who operate watercraft used in commercial fishing are described in the section on **fishers and fishing vessel operators** elsewhere in the *Handbook*.)

Captains, mates, and pilots of water vessels command or supervise the operations of ships and water vessels, both within domestic waterways and on the deep sea. *Captains* or *masters* are in overall command of the operation of a vessel, and they supervise the work of all other officers and crew. They determine the course and speed of the vessel, maneuver to avoid hazards, and continuously monitor the vessel's position with charts and navigational aides. Captains either direct or oversee crew members who steer the vessel, determine its location, operate engines, communicate with other vessels, perform maintenance, handle lines, or operate equipment on the vessel. Captains and their department heads ensure that proper procedures and safety practices are followed, check to make sure that machinery and equipment are in good working order, and oversee the loading and discharging of cargo or passengers. They also maintain logs and other records tracking the ships' movements, efforts at controlling pollution, and cargo and passengers carried.

Deck officers or *mates* direct the routine operation of the vessel for the captain during the shifts when they are on watch. All mates stand watch for specified periods, usually 4 hours on and 8 hours off. However, on smaller vessels, there may be only one mate (called a *pilot* on some inland towing vessels), who alternates watches with the captain. The mate would assume command of the ship if the captain became incapacitated. When more than one mate is necessary aboard a ship, they typically are designated chief mate or first mate, second mate, third mate, etc. Mates also supervise and coordinate activities of the crew aboard the ship. They inspect the cargo holds during loading to ensure that the load is stowed according to specifications and regulations. Mates supervise crew members engaged in maintenance and the primary upkeep of the vessel.

Pilots guide ships in and out of harbors, through straits, and on rivers and other confined waterways where a familiarity with local water depths, winds, tides, currents, and hazards such as reefs and shoals are of prime importance. Pilots on river and canal vessels usually are regular crew members, like mates. Harbor pilots are generally independent contractors who accompany vessels while they enter or leave port. Harbor pilots may pilot many ships in a single day. *Motorboat operators* operate small, motor-driven boats that carry six of fewer passengers on fishing charters. They also take depth soundings in turning basins and serve as liaisons between ships, between ship and shore, between harbors and beaches, or on area patrol.

Ship engineers operate, maintain, and repair propulsion engines, boilers, generators, pumps, and other machinery. Merchant marine vessels usually have four engineering officers: A chief engineer and a first, second, and third assistant engineer. Assistant engineers stand periodic watches, overseeing the safe operation of engines and machinery.

Marine oilers and more experienced *qualified members of the engine department*, or QMEDs, maintain the vessel in proper running order in the engine spaces below decks, under the direction of the ship's engineering officers. These workers lubricate gears, shafts, bearings, and other moving parts of engines and motors; read pressure and temperature gauges; record data; and sometimes assist with repairs and adjust machinery.

Sailors operate the vessel and its deck equipment under the direction of the ship's officers and keep the nonengineering areas in good condition. They stand watch, looking out for other vessels and obstructions in the ship's path, as well as for navigational aids such as buoys and lighthouses. They also steer the ship, measure water depth in shallow water, and maintain and operate deck equipment such as lifeboats, anchors, and cargo-handling gear. On vessels handling liquid cargo, mariners designated as *pumpmen* hook up hoses, operate pumps, and clean tanks; on tugboats or tow vessels, they tie barges together into tow units, inspect them periodically, and disconnect them when the destination is reached. When docking or departing, they handle lines. They also perform routine maintenance chores, such as repairing lines, chipping rust, and painting and cleaning decks or other areas. Experienced sailors are designated *able seamen* on oceangoing vessels, but may be called simply *deckhands* on inland waters; larger vessels usually have a *boatswain*, or head seaman.

A typical deep-sea merchant ship has a captain, three deck officers or mates, a chief engineer and three assistant engineers, a radio operator, plus six or more unlicensed seamen, such as able seamen, oilers, QMEDs, and cooks or food handlers. The size and service of the ship determine the number of crewmembers for a particular voyage. Small vessels operating in harbors, on rivers, or along the coast may have a crew comprising only a captain and one deckhand. The cooking responsibilities usually fall under the deckhands' duties.

On larger coastal ships, the crew may include a captain, a mate or pilot, an engineer, and seven or eight seamen. Some ships may have special unlicensed positions for entry level apprentice trainees. Unlicensed positions on a large ship may include a full-time cook, an electrician, and machinery mechanics. On cruise ships, *bedroom stewards* keep passengers' quarters clean and comfortable.

WORKING CONDITIONS

Merchant mariners spend extended periods at sea. Most deep-sea mariners are hired for one or more voyages that last for several months; there is no job security after that. The length of time between voyages varies depending on job availability and personal preference.

The rate of unionization for these workers is about 24 percent, much higher than the average for all occupations. Consequently, merchant marine officers and seamen, both veterans and beginners, are hired for voyages through union hiring halls or directly by shipping companies. Hiring halls rank the candidates by the length of time the person has been out of work and fill open slots accordingly. Hiring halls typically are found in major seaports.

At sea, these workers usually stand watch for 4 hours and are off for 8 hours, 7 days a week. Those employed on Great Lakes ships work 60 days and have 30 days off, but do not work in the winter when the lakes are frozen. Workers on rivers, on canals, and in harbors are more likely to have year-round work. Some work 8- or 12-hour shifts and go home every day. Others work steadily for a week or a month and then have an extended period off. When working, they usually are on duty for 6 or 12 hours and off for 6 or 12 hours. Those on smaller vessels are normally assigned to one vessel and have steady employment.

People in water transportation occupations work in all weather conditions. Although merchant mariners try to avoid severe storms while at sea, working in damp and cold conditions often is inevitable. While it is uncommon nowadays for vessels to suffer disasters such as fire, explosion, or a sinking, workers face the possibility that they may have to abandon their craft on short notice if it collides with other vessels or runs aground. They also risk injury or death from falling overboard and hazards associated with working with machinery, heavy loads, and dangerous cargo. However, modern safety management procedures, advanced emergency communications, and effective international rescue systems place modern mariners in a much safer position.

Most newer vessels are air conditioned, soundproofed from noisy machinery, and equipped with comfortable living quarters. For some mariners, these amenities have helped ease the sometimes difficult circumstances of long periods away from home. Also, modern communications, especially email, link modern mariners to their families. Nevertheless, some mariners dislike the long periods away from home and the confinement aboard ship and consequently leave the occupation.

EMPLOYMENT

Water transportation workers held about 68,000 jobs in 2002. The total number that worked at some point in the year was perhaps twice as large because many merchant marine officers and seamen worked only part of the year. The following tabulation shows employment in the occupations that make up this group:

Sailors and marine oilers	27,000
Captains, mates, and pilots of water vessels	25,000
Ship engineers	8,200
Motorboat operators	4,100
All other water transportation workers	3,600

About 30 percent of all workers were employed in water transportation services. About one half worked in inland water transportation—primarily the Mississippi River system—while the other half were employed in water transportation on the deep seas, along the coasts, and on the Great Lakes. About another 28 percent worked in establishments related to port and harbor operations, marine cargo handling, or navigational services to shipping. The Federal government employed approximately 5 percent of all water transportation workers, most of whom worked on supply ships and are Civilian Mariners of the Department Navy's Military Sealift Command.

TRAINING, OTHER QUALIFICATIONS, AND ADVANCEMENT

Entry, training, and educational requirements for most water transportation occupations are established and regulated by the U.S. Coast Guard, an agency of the U.S. Department of Homeland Security. All officers and operators of commercially operated vessels must be licensed by the Coast Guard, which offers various kinds of licenses, depending on the position and type of vessel.

There are two ways to qualify for a deck or engineering officer's license: applicants either must accumulate sea time and meet regulatory requirements or must graduate from the U.S. Merchant Marine Academy or one of the six State maritime academies. In both cases, applicants must pass a written examination. Federal regulations also require that an applicant pass a physical examination, a drug screening, and a National Driver Register Check before being considered. Persons without formal training can be licensed if they pass the written exam and possess sea service appropriate to the license for which they are applying. However, it is difficult to pass the examination without substantial formal schooling or independent study. Also, because seamen may work 6 or fewer months a year, it can take 5 to 8 years to accumulate the necessary experience. The academies offer a 4-year academic program leading to a bachelor-of-science degree, a license (issued only by the Coast Guard) as a third mate (deck officer) or third assistant engineer (engineering officer), and, if the person is qualified, a commission as ensign in the U.S. Naval Reserve, Merchant Marine Reserve, or Coast Guard Reserve. With experience and additional training, third officers may qualify for higher rank.

Sailors and unlicensed engineers working on U.S. flagged deep-sea and Great Lakes vessels must hold a Coast Guard-issued document. In addition, they must hold certification when working aboard liquid-carrying vessels. Able seamen also must hold government-issued certification. For employment in the merchant marine as an unlicensed seaman, a merchant mariner's document issued by the Coast Guard is needed. Most of the jobs must be filled by U.S. citizens; however, a small percentage of applicants for merchant mariner documents do not need to be U.S. citizens, but must at least be aliens legally admitted into the United States and holding a green card. A medical certificate of excellent health attesting to vision, color perception, and general physical condition is required for higher level deckhands and unlicensed engineers. While no experience or formal schooling is required, training at a union-operated school is the best source. Beginners are classified as ordinary seamen and may be assigned to any of the three unlicensed departments: Deck, engine, or steward. With experience at sea and perhaps union-sponsored training, an ordinary seaman can pass the able-seaman exam and move up with 3 years of service.

No special training or experience is needed to become a seaman or deckhand on vessels operating in harbors or on rivers or other waterways. Newly hired workers generally are given a short introductory course and then learn skills on the job. After sufficient experience, they are eligible to take a Coast Guard exam to qualify as a mate, pilot, or captain. Substantial knowledge gained through experience, courses taught at approved schools, and independent study is needed to pass the exam.

Harbor pilot training usually consists of an extended apprenticeship with a towing company or a pilots' association. Entrants may be able seamen or licensed officers.

JOB OUTLOOK

Keen competition is expected to continue for jobs in water transportation occupations. Overall, employment in these occupations is projected to **grow more slowly than the average** for all occupations through the year 2012. Opportunities will vary by sector, and some of the best opportunities will be in scenic transportation and sightseeing and deep sea, coastal, and Great Lakes transportation.

Employment in deep-sea shipping for American mariners is expected to stabilize after several years of decline. New international regulations have raised shipping standards with respect to safety, training, and working conditions. Consequently, competition from ships that sail under foreign *flags of convenience* should lessen as insurance rates rise for ships that do not meet the new standards. Insuring ships under industrialized countries' flags, including that of the United States, should become less expensive, increasing the amount of international cargo carried by U.S. ships. A fleet of deep-sea U.S.-flagged ships is considered to be vital to the Nation's defense, so some receive Federal support through a maritime security subsidy and other provisions in laws that limit certain Federal cargoes to ships that fly the U.S. flag. Possible future developments include "fast ships"—oceangoing cargo vessels that use jet propulsion—which would decrease ocean-crossing times significantly. If such plans are successful, the industry will benefit in terms of increased business and employment.

Vessels on rivers and canals and on the Great Lakes carry mostly bulk products, such as coal, iron ore, petroleum, sand and gravel, grain, and chemicals. Although shipments of these products are expected to grow through the year 2012, current imports of steel are dampening employment on the Lakes, but actually leading to greater chances for overall employment for transport up the Mississippi River system. Employment in water transportation services is likely to rise, and efforts are underway at the Federal level that could lead to significantly greater use of ferries to handle commuter traffic around major metropolitan areas.

Employment growth also is expected in passenger cruise ships within U.S. waters. Vessels that operate between U.S. ports are required by law to be U.S.-flagged vessels. The building and staffing of several new cruise ships that will travel around the Hawaiian Islands will create new opportunities for employment at sea in the cruise line industry, which is composed mostly of foreign-flagged ships.

Openings within the traditional water transportation sector for mariners, although expanding only slightly, should be quite numerous because of the sizable need to replace those leaving the occupation Some experienced merchant mariners may continue to go without work for varying periods. However, this situation appears to be changing, with demand for licensed and unlicensed personnel rising. Maritime academy graduates who have not found licensed shipboard jobs in the U.S. merchant marine find jobs in related industries. Because they are commissioned as ensigns in the Naval or Coast Guard Reserve, some are selected for active duty in those branches of the Service. Some find jobs as seamen on U.S.-flagged or foreign-flagged vessels, tugboats, and other watercraft or enter civilian jobs with the U.S. Navy or Coast Guard. Some take land-based jobs with shipping companies, marine insurance companies, manufacturers of boilers or related machinery, or other related jobs.

EARNINGS

Earnings vary widely with the particular water transportation position and the worker's experience, ranging from the minimum wage for some beginning seamen or mate positions to more than $37.37 an hour for some experienced ship engineers. Median hourly earnings of water transportation occupations in 2002 were as follows:

Ship engineers	$24.61
Captains, mates, and pilots of water vessels	23.97
All other water transportation workers	14.67
Sailors and marine oilers	13.64
Motorboat operators	12.71

Annual pay for captains of larger vessels, such as container ships, oil tankers, or passenger ships, may exceed $100,000, but only after many years of experience. Similarly, captains of tugboats often earn more than the median reported here, with earnings dependent on the port and the nature of the cargo.

RELATED OCCUPATIONS

Workers in other occupations who make their living on the seas and coastal waters include **fishers and fishing vessel operators** and some **members of branches of the Armed Forces**.

SOURCES OF ADDITIONAL INFORMATION

Information on a program called "Careers Afloat", which includes a substantial listing of training and employment descriptive information and contacts in the U.S., may be obtained through:

A CONCISE GLIMPSE OF WATER IN THE HISTORY OF PHOTOGRAPHY

Basia Irland
University of New Mexico
Albuquerque, New Mexico

> "#125. When you photograph water you strip it of its form: of its restless, liquid reality."
> "#126. When you photograph water you give it an image that in essential ways bears no likeness to water."
> "#127. When you photograph water you speak in graphic terms about something that has no graphic aspect."
> Rebecca Horn, *Dictionary of Water* (1)

Water is universal and indispensable to life. Therefore, it has always been a central metaphor, both sprightly and exacting, for artists. In this brief article, we examine how a few photographers have looked to water for inspiration and also used it as the very substance of their work. There have, of course, been hundreds of photographers who have tested water as their subject matter or used it in their work in various ways at some stage of their career; some of the more notable and interesting are presented here. A few examples have been chosen, beginning with the earliest photographers of the nineteenth century.

Not just images of water caught on photographic paper, but the intricate process of developing and fixing these images depended on water. We tend to take the process for granted today as we have moved into an era of digital images, but it took many fumbling experiments before it was possible to capture the world "out there" and put it onto an object we could hold in our hands and gaze upon for generations (or at least as long as the chemical process would allow). The English scientist, Sir John Herschel (born 1792 and buried in 1871 next to Sir Isaac Newton at Westminster Abbey), explained in his letters to William Henry Fox Talbot (1800–1877), one of the earliest photographic artists, about the important role that clean water played in rinsing images. Although Herschel is best remembered for his discovery of hyposulfate as a fixative, he also discovered that one could fix photographs with plain water. After several unsuccessful attempts, it was found that the water must be as pure as possible and the rinsing process has to be repeated three times. Melting snow worked, as did distilled water. Salt traces in well water and the many forms of pollution finding their way into England's water supply would ruin a print. In March of 1839, Herschel communicated to his scientific colleagues at the Royal Society about the chemical compounds used in his new discoveries to aid ways of developing a print and how the photograph needed to be immersed two or three times in clean spring water and dried between blotting papers.

Most of Talbot's photographs of water were incidental fluid flowing under the more important human-made constructions of bridges (*Lattice Iron Bridge*, 1841; *The Hungerford Suspension Bridge*, 1845; and *The Suspension Bridge at Rouen*, 1843), or doubling the impact of architecture (*Lacock Abbey, Reflected in the Avon*, 1840–41). But in 1844, he took a series, *Sun Pictures of Scotland*, that leave the city and focus on the water itself with such titles as, *A Mountain Rivulet which flows at the foot of Doune Castle, Scenery of Loch Katrine*, and *A Waterfall*.

Colonel Stuart Wortley (1832–1890) presents an almost operatic view of the sea, complete with reflected moonlight, dark suspended cumulus clouds, and titles borrowed from poems such as "How calm, how beautiful comes on / The stilly hour when storms are gone" (1869) and "All the air was white with moonlight / All the water black with shadow" (1869). Wortley, along with Gustave Le Gray, was among the first photographers to capture a sense of stopped movement in an enlarged image. *A Wave Rolling In* (1861) shows a small, single breaking wave caught on film along with two tiny black figures in a rowboat off in the distance.

Gustave Le Gray (born in France, 1820), spent a 5-year period from 1855–1860 primarily involved in photographing sailing ships and ports, but mostly ocean waves. With a taste for the dramatic similar to Wortley's, Le Gray's seascapes (albumen prints from wet collodion on glass negatives) show dark, brooding bodies of water barely lit from the sun's dim rays hidden behind black ominous clouds. Most of these ocean views were taken on the Normandy coast and often included breaking surf in the lower right-hand corner. Le Gray was experimenting with ways to capture the movement of water and the atmospheric effects of light and cloud by using two overlaid negatives. Often, he would use the same seascape negative in combination with a different sky negative. *Grande vague—Sete* (1856/59) predates Wortley's wave photograph by 2 years. It shows a somber jetty jutting halfway across the print with a not so large wave breaking against shadowed rocks in the foreground. On October 27, 1999 this particular print broke the record for the sale of a single photograph at Sotheby's London auction, selling for $760,150. Le Gray spent the last 20 years of his life primarily photographing antiquities in Cairo, Egypt and died in 1882.

Anna Atkins (1799–1871), one of the earliest photographers, incorporated Herschel's cyanotype method, which was inexpensive and easily worked, to produce camera-less photograms using flowing pieces of sea algae. The first part of her series of these photograms was produced in 1843. *Photographs of British Algae; Cyanotype Impressions*, a handmade portfolio of images, was the first use of photography for scientific illustrations. Photograms, which use neither camera nor negative, are produced when objects, placed on a photosensitive surface and exposed to light briefly to create a shadow, are then developed. "Dispensing with lens, aperture, depth of field, and perspective, the photogram assumes the guise of a real trace, a visual footprint on the scale of the original, a memory of the essential contour devoid of redundant information" (2).

The ocean-blue tint of the cyanotype lent itself to the aquatic pictures of algae. Used until recently in the form of the architectural blueprint, cyanotypes involve only two chemical compounds, ferric ammonium citrate and potassium ferricyanide, which are applied to paper using a sponge or brush. After the paper is dried in the dark, an object such as Atkin's algae is placed on the paper and exposed to the sun. Rinsing the exposed cyanotype in water makes the print permanent and brings out the blue color. Halstead Place, where Atkins worked, was known for the quality of its well water.

Atkins was already an accomplished scientific illustrator, especially of seashells. In the handwritten cyanotype introduction to Part I of her book, Atkins explains that the need to make accurate drawings of such intricate algae led her to use the photographic process developed by Sir John Herschel to explore her studies of botany and make them available to a wider audience through publication. Atkins made numerous trips to the ocean to collect specimens of algae, or her friends would provide her with examples. Seaweed would be washed in water and pressed between blotting paper to dry within a few days. The silhouettes of algae hover on her photographic paper as if still in the sea. *Bangia fusco-purpurea* is as delicate as winter breath. *Polysiphonia violacea* is a soft, dendritic wisp. *Himanthalia lorea* begins with two bulbs and spreads out across the paper as if painted with a brush, exiting the confines of the page. In addition to her 10-year period of work with algae (Fig. 1), Atkins made prints of feathers (peacock, parrot, emu, partridge), grasses, lace, flowering plants, and an extensive study of ferns.

Two contemporary British photographers who have also created photographic images without using a camera are Susan Durges (born 1955) and Adam Fuss (1961). A baby of only a few weeks old floats in a liquid universe outside the mother's womb. A snake slithers silently through turquoise fluid leaving a trail of chain-link ripples. Perfectly formed concentric circles radiate outward from a still center. Adam Fuss fills a shallow glass tray with several inches of water over photosensitive paper and then places the baby or snake directly into this warm bath. As Eugenia Parry writes in her essay for the book, *Adam Fuss*, "He wasn't guided by Talbot or Atkins. He'd barely heard of them. But he shared their desires: To let what is mute speak; to capture and keep an object's mysterious self-inscription" (3).

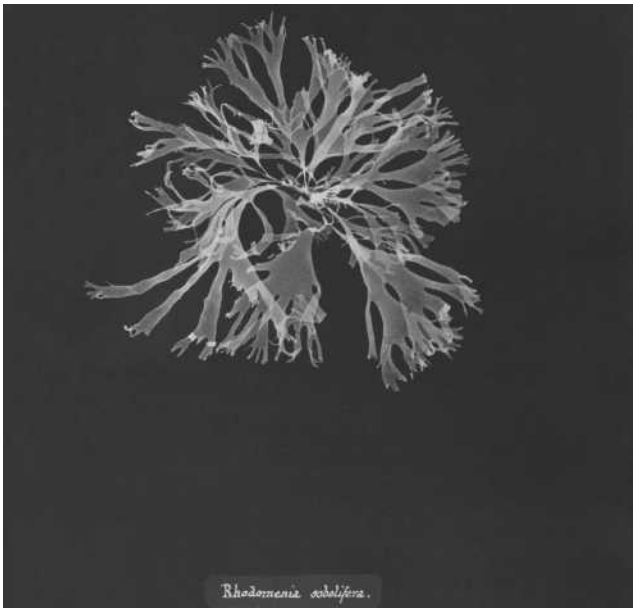

Figure 1. Artist: Anna Atkins. Title: Rhodomenia Sobolifera. Cyanotype negative, bound into a copy of Volume 1 of British Algae, 1850. 26.4 × 20.4 cm. Courtesy: Hans P. Kraus, Jr., Inc., New York.

Whereas most photographers have created photograms within the confines of the studio, Susan Derges (resides in Devon, England) in her *River Taw* series (1997–99), submerges photographic paper directly into a river at night. Enormous sheets of photosensitive paper (66″ × 24″) resting in an aluminum slide are placed just beneath the water surface and exposed to a bright, diffuse flash that captures images of water patterns sometimes overlaid with tree shadows. These are then processed in the darkroom. "Ambient light in the sky adds a colour cast to the Cibachrome (colour positive) images, which ranges from deep blue at full moon to dark green at new moon," writes Martin Kemp in an essay about the artist, in *Susan Derges Liquid Form 1985–99* (2).

Her *Waterfall* series (1997–98, 7′ × 3 1/2′) was created by holding the light-sensitive paper at the top of a water-mill chute using the same nighttime exposures. To create the *Shoreline* series, 1997–99, Derges put the photographic paper on the shoreline at night, waiting for the exact moment a wave would break and exposing it to a microsecond of flash. The ambient light from the moon or a nearby town affected the color of the print, often turning it magenta or dusky pink. Small bits of sand deposited by the wave created vortices and spiral forms.

Another British photographer who eschews preconceived notions of making a photograph is Steven Pippin (born 1960, Surrey, England). In 1993, Pippin began his performance/project, *The Continued Saga of an Amateur Photographer*, which took place in the bathroom on a British train. Ingrid Schaffner, in her essay, "Dirty Hole: Steven Pippin's Obscure Routes," describes how he "…goes about his business converting the toilet into a camera, taking a picture, and developing it. All the while the train rattles and hurls over the tracks" (4). The semicircular prints fit neatly into the commode bowl.

A toilet is not the only object Pippin converted into a camera. He also used washing machines in 1997 for *Laundromat-Locomotion.* In this project, he trip-wired the washers to take photographs and then developed them within the same machine. The wash and spin cycles ripped, scratched, and cracked the emulsion, creating prints that appear Victorian in age.

Across the ocean in the United States and back in the 1930s, we find Dr. Harold Edgerton, Center for Advanced Visual Studies, Massachusetts Institute of Technology, explaining in his book entitled *flash! Seeing the Unseen by Ultra High-Speed Photography* (1939), the process for taking photos that are now part of our iconic language of modernist images (5). These include a bullet passing through an apple, a child popping a balloon, and a drop of milk forming a crown-shape. In one photograph, using the stroboscope, a device that uses a flash to illuminate a moving object intermittently, what appears to be ice or translucent plastic is actually tap water coming out of a faucet caught in Edgerton's camera at 1/50,000 of a second. He also stopped the fluid action of water used to cut pulp and showed the figure eight emitting from a lawn sprinkler. He recorded spiral patterns revolving around a ship's propeller. These studies of motion are reminiscent of Leonardo da Vinci's investigative drawings in pen, ink, and red chalk done in the early 1500s. In *Studies of the Formation of Water in Motion* and *Studies of Water Formation* we see the same vortical shapes that Edgerton caught with his stop-action method 500 years later. The text written on da Vinci's 1510 *Studies of an Old Man and of Swirling Water* reads: "…thus the water forms eddying whirlpools, one part of which is due to the impetus of the principal current and the other to the incidental motion and return flow."

Theodor Schwenk was obsessed with these same vortices formed by fluids and in *Sensitive Chaos*, 1965, he compared liquid spiral forms with other natural phenomenon in his photographs of the bark of a cypress tree, descending hail clouds, unfurling fern leaves, and a drawing of horns of the African kudu antelope.

A few examples of Schwenk's descriptions in his index to the photographs of various vortices are "25. Trains of vortices also arise if a solid object is drawn in a straight line through stationary liquid. 26. The vortices push into the surrounding liquid like the ball part of a joint into its socket. A suitable length of exposure reveals a delicate structure. 33. A suitable length of exposure has revealed something of the structure of vortices. A meandering stream winds its way between the separate vortices. 41. A photograph of a vortex taken under water reveals the spiraling surface between the water and the air which is being sucked in" (6).

In *River Sutra*, Gita Metha describes how every river should have its own minstrel—someone to sing the praises of that body of flowing water (7). Perhaps every river, stream, brook and creek should also have its own photographer. Even though Roni Horn (8) describes water as too elusive an element to hold within the confines of a photograph's rectilinear frame, that certainly has not stopped artists throughout history from trying to capture something of the nature of a particular river. The 1875-mile length of the Rio Grande/Rio Bravo flows from its source in the San Juan Mountains of Southern Colorado, through New Mexico, and provides the border between Texas and Mexico. Photographer Laura Gilpin's (9) documentation in the 1940s of this muddy liquid ribbon (published in 1949 as *The Rio Grande, River of Destiny*) began in 1945 at the end of a war that left a scarcity of photographic materials and difficulties in traveling by car. She also experienced 2 years of drought in her three expeditions along the river. The book's simple chapter headings, "The Source," "Midstream," and "The Border," lead the viewer along a journey witnessing the flow of the river and also the surrounding towns and people living along the banks.

Photographer Jim Bones, in *Rio Grande, Mountains to the Sea*, however, focuses only on the plants and moving water within the riparian zone. "I fell in love with the Rio Grande because of a dream that repeatedly told me if I wanted to know the secrets of my own being, I must go first to the mountains and then to the sea. For the past twenty years, as I walked, rode, and floated throughout the Rio Grande's home country, I discovered that rivers cut to the very heart of things, of rock and life and even dreams" (10). Bones understands that the "end" of a river, as it empties into the sea, is also a beginning because it is here that the hydrologic cycle of evaporation, cloud formation, and rain continue the process of creating rivers all over again.

One of the chapters in Hans Silvester's book, H_2O *The Beauty and Mystery of Water* (11) is dedicated to "The Water Cycle, Disrupted" and mirrors back to the viewer the devastation humans can cause to bodies of water. It is a wake-up call to change our ways. A few of the disturbing images include five children playing in untreated sewage from Mexico City in the Tula River; a dead egret with a fly on its head floating in the polluted Coto Donana, Spain; and an irrigation canal, Bouches-du-Rhone, France, near Marseille's waste discharge where the trash, particularly plastic bags, is piled so high and wide that it is difficult to see the water.

The photographs of the River Thames for Roni Horn's book, *Another Water*, were taken in the Central London area in January and May of 1999 (8). Filling the page, with no reference points or shoreline, the water images could have been taken anywhere. Running continuously along the bottom of each page are 832 comments about the Thames or water in general. "#193. When you go down to the river you're killing two birds with one stone: you stand there and you go places." "#142. Water is sexy. I want to swim in it—to move, song-like, through it. I want to swim in it—push, kick, thrash, slide myself through it. I want to swim in it. I want to be held by it."

In among the references to water are brief descriptions of those who have chosen to take their life by drowning. "#465. An old man was found in the river last Christmas Eve. He was wearing so many layers of clothing (including two wool coats and a jacket) police couldn't lift him out of the water. (They towed it to the pier.)." "#586. A young Parisian woman came to London recently to drown herself in the river. It's curious how the Thames attracts people from far away. I've never heard of any other river doing this. I mean people don't travel from Canada to kill themselves in the Hudson—or even from Ohio." "#446. A young man was found in the river yesterday with a pair of Walkman headphones wrapped around his neck." And every so often there will be a whole white page with an autopsy or police report of someone who was found in the Thames, including details about their lives, whether they wore dentures and exactly where and how their body was located.

Another Water was followed the next year in 2001 by a second book, *Dictionary of Water,* using similar photographs of the Thames taken during the same months. In fact, Horn did not even take the photographs. Dusseldorf artist Nic Tenwiggenhorn made these images assisted by Uwe Schmidt and Helena Blaker. There is no mention within either of Horn's books about the Thames of the photographs being changed by computer, but on a web site providing information about *Dictionary of Water*, it states that this is a collection of digitally manipulated photographic images.

Industrial photographer Wim Cox (born Netherlands, 1938, moved to Germany, 1961) created likenesses of water to those similar by Horn, but they are accompanied by a very different tone of writing done by his brother, filmmaker Paul Cox (born 1940, Netherlands, resides, Melbourne, Australia) (12). The brief text is a poem—a kind of love poem—to water. It begins, "I am. I am water." And so, throughout history, water has pulled photographers to its side, embraced them, and helped in creating memorable images.

WATER AS A HUMAN RIGHT

Laurel Phoenix
Green Bay, Wisconsin

"The human right to drinking water is fundamental to life and health. Sufficient and safe drinking water is a precondition for the realization of human rights... the human right to water entitles everyone to sufficient; affordable; physically accessible; safe and acceptable water for personal and domestic uses" (1).

The human right to physical and economic access to water has recently been declared by nongovernmental institutions and civil society groups worldwide. The movement to establish this right has been driven by two related issues. First, global populations are currently experiencing a water crisis predicted to become much worse. Second, the growing global trend of water privatization has created additional concerns regarding access to potable water.

GLOBAL WATER CRISIS

The United Nations, Earth Policy Institute, Pacific Institute, and other organizations have been following concurrent global trends of rising population and decreasing access to potable water. Currently, there are over 1 billion people lacking access to safe water and by 2010 this number will grow to 2.5 billion (2). Associated with this problem is lack of sanitation. There are currently 2.4 billion people lacking sanitation facilities. As this sanitation problem is exacerbated by growing populations, even more water becomes too polluted to safely drink.

PRIVATIZATION

Privatization of water supplies in developing countries has been met with ambivalence. Rather than increasing the number of people served with potable water, the higher water bills attendant with privatization have made poorer citizens lose access. In several instances, the very poor cannot afford to pay the higher rates without forfeiting some other necessity, like heating or food (3). Privatized facilities in many cases have shut off the water to those who cannot pay, forcing them to use polluted supplies, resulting in sickness or death. For example, Nkobongo, South Africa privatized their water system and rates were increased. As water was shut off to those who could not pay, people turned to polluted lakes and streams, creating a spectacular cholera epidemic killing almost 300 people and sickening over 250,000 over the course of 300 miles and several years (4). This scenario was repeated in many townships, causing the government to spend enormous amounts of money to deal with the health crisis. Moreover, when utilities are privatized in developing countries, there is little oversight regarding how often or to what degree rates are raised. Consequently, water shut-offs or the use of prepaid water meter cards can externalize the problems of poverty in one region to a wider area, while private water companies are insulated from the public health crisis that ensues.

Opponents of privatization demand that the minimum amount of water needed for basic needs ought to be provided for free, and then fees for water used per household can be charged for water used in addition to this subsistence requirement. This minimum amount varies from 20 liters per person per day for drinking and cooking to 40 liters per person per day to include water for hygiene. Opponents also contend that once a profit motive is introduced into provision of water, companies may demonstrate more concern for their profit margin than for the quality of the water, either through delaying needed maintenance, reducing quality control, or hiking prices even further and cutting off more citizens from a potable supply.

DECLARATIONS OF WATER AS A HUMAN RIGHT

In response to the global water crisis and privatization concerns, numerous groups have issued statements delineating the right to water. The National Forum on Water Privatization meeting in Ghana declared in May of 2001 that "water is a fundamental human right, essential to human life to which every person, rich or poor, man or woman, child or adult is entitled." The Blue Planet Project created a Treaty Initiative to Share and Protect the Global Water Commons, where they stated: "The global fresh water supply is a shared legacy, a public trust and a fundamental human right and, therefore, a collective responsibility" (5). By "collective" they mean every nation. The public trust theme is repeated in the 3rd World Water Forum: "Water, as a public trust and an inalienable human right, must be controlled by the peoples and communities that rely on it for their lives and livelihoods" (6).

IS THIS A NEW HUMAN RIGHT?

Human rights are not established in a vacuum. Citizens agitate for rights only when clear injustices or inequities occur. New rights are incorporated into law when those currently holding those rights agree to share those rights with the disenfranchised. Now that so many people do not have access to clean water globally, the call for human rights to water focuses world governments' attention on the distribution and access to water worldwide.

Human rights to critical natural resources spring from ancient laws regarding use of the commons. The Roman Emperor Justinian declared in 533–534 B.C.E. that running water, seas, air, and wildlife were things that could not be owned but could be used under regulation to ensure vital common resources were not exploited (7). Perhaps because of its ubiquity, governments never thought to declare a right to something so obvious. Even so, a right to water naturally comes before other rights for equality, freedom, and so on, because there would be no need to establish these other rights if you could not live to enjoy them. Scanlon et al. (8) surveyed documents written by international organizations such as the UN Charter or the Universal Declaration of Human Rights that support a "right to life" or "right to higher standards of living," noting they implied a right to water but did not state it. The Geneva Conventions and Protocols declare a right to drinking water only. Two human rights treaties, the Convention on the Elimination of All Forms of Discrimination against Women (CEDAW) and the Convention on the Rights of the Child, both specifically mention a right to water. For women, they declare a right to a water supply, and clean drinking water is mandated for children. Although mention of rights to water can be found in international law documents, they are not clearly defined, and recognized nation-states still need to incorporate them into national law.

RELATED ISSUES

Other issues interrelated with human rights to water are international influences [e.g., globalization and intergovernmental organizations (IGOs)] and governmental obligations to protect marginalized populations and manage water wisely.

Globalization

Globalization has hastened and consolidated the ability of multinational water corporations to search the world for new contracts. Globalization has also injected a new level of haste in developing countries wanting to industrialize, but first needing adequate water infrastructure to attract foreign investment. Countries wanting improved infrastructure but not having the means to pay for it often will enter into agreements for privatization that are not in their citizens' best interests. Mechanisms for institutionalizing globalization, such as the General Agreement on Tariffs and Trade (GATT), North American Free Trade Agreement (NAFTA), and many bilateral investment treaties (BITs), all assist in establishing free trade, deregulation at the state level, and the promotion of privatization. The negative effects on countries and their citizens with regard to democratic control over their water supplies or their ability to disagree with corporate objectives are analyzed in detail in *Thirst for Control* (9) and *Blue Gold: The Fight to Stop the Corporate Theft of the World's Water* (10).

IGOs

Related to globalization is the influence that IGOs and related multilateral financial institutions such as the World Bank and International Monetary Fund (IMF) have. Loans to developing countries are often preconditioned on the privatization of the country's water and/or sewer facilities (11). At the same time, guarantees regarding percentage of profit or length of contract are given to corporations. Consequently, countries can be assuming risks while corporations receive security from risk. The terms of these agreements can put citizens at risk and increase the likelihood that the poorest in cities will lose access to potable water.

Governmental Obligations

The human right to water is related to the public trust, a doctrine that recognizes the government as trustee for its citizens regarding common resources. Essentially, the government will hold ownership over common properties like water bodies, wildlife, and air; this then gives government the ability to regulate use or access to these common resources so that current and future populations will be able to benefit from them. This doctrine also presumes that a government will give equal access and treatment to all of its citizens, rich or poor, and uphold their right to access. Consequently, the human right to water is dependent on a government that takes its public trust doctrine seriously to declare a human right to safe water, and then to follow through with laws and policy that ensures each person will be able to physically and economically access that water.

Water for the Poor

The rural poor comprise 80% of the world population without access to safe water. The other 20% are the poor in city slums and squatter settlements on the city periphery. Rural people must walk hours to access dirty and open water sources contaminated by animal and human waste. The poor in the city either walk to an open stream or pay water vendors 6 to 12 times the cost of piped water (12). Money spent on expensive water will be money unavailable for food or housing or education.

Women's and Children's Rights

Declaring a human right to water benefits most women and children around the world, because it is commonly their job to search out and carry water back to their homes (13). Rural African women spend 26% of their day getting water from open sources such as rivers, muddy holes, or small lakes. Walking to distant water not only exposes women and children to rape, other physical attacks, schistosomiasis, or more mosquito bites but also takes time away from growing food, earning income, and consistent attendance at school. Children exposed to unsafe water become vulnerable to disease and death. Chemically polluted water endangers children more than adults because children consume more liters of water per kilogram of body weight. A study in Karachi, India concluded that people without water and sanitation spent six times more on medical bills than people linked to those services (14). Health is also compromised if there is not enough water to grow or cook a variety of food. As unsafe water translates into poor health, little money for other necessities, and little time to become educated, it predisposes the poor to a life of weak constitutions and unskilled, part-time labor. They remain unable to move up out of poverty.

Indigenous People

These people have often not enjoyed the same civil rights as other citizens of their country, so it is common for their waters to be diverted for use elsewhere (e.g., a large dam project) or to be polluted from mineral mining or drilling for oil. Civil governments rarely come to their aid and sometimes are the instigators of the water theft or pollution.

Intergenerational Water Resources

Because governments are assumed to be entities existing far beyond any human lifespan, the public trust implies that a government manage its natural resources for current as well as future citizens. In countries with growing populations, this requires a government to plan for future increased demand while managing current resources, which necessitates sustainable use of current resources as well as conservation measures to "produce" more water for future demand. Future generations are a marginalized population because their needs are barely acknowledged in current decision-making and highly discounted in cost/benefit calculations.

Irrigation and Water Management

Agriculture uses over 75% of the available fresh water in the world; therefore increases in efficiency would free up more water available for domestic use. Irrigation that "wastes" water has different driving forces in poor and rich countries. Irrigation in low or no technology countries tends to be the simplest forms, such as flooding the fields, diverting water into irrigation channels for too long, or using unlined irrigation ditches. These farmers generally cannot afford to install high-tech, pinpointed delivery systems, so much water is lost to evaporation or percolation.

In wealthier countries, subsidies for particular crops (e.g., cotton and rice) encourage the growth of water-intensive crops rather than other crops that the region's rainfall can support. If the farms rely primarily on groundwater, choosing a more water-intensive crop essentially exports additional water out of the area. This combination of agricultural subsidies and outdated water laws result in no monetary or legal incentives to conserve water.

CONCLUSION

The global water crisis and growing privatization have increased calls for human rights to water. Organizations interested in the establishment of this right argue that individual governments must protect their citizens from the negative effects of global forces, and that in securing and working toward full establishment of this right, they will fulfill their public trust obligations to their disenfranchised citizens. Creating "new" water by increasing global irrigation efficiency will require either increased expenditures on the part of developing countries, or a transfer of technology and financial assistance to them from the developed countries.

ANCIENT WATER AND SOIL CONSERVATION ECOSYSTEMS OF SRI LANKA

Lucius O. Mendis
Colombo, Sri Lanka

INTRODUCTION

Sri Lanka, an island of approximately 65,000 sq km, in the Indian ocean, lying between 6° and 8° North latitude, at the southern tip of the Indian subcontinent, experiences two monsoons, the northeast between October and March and the southwest between April and September, with occasional intermonsoon rains. Northeast monsoon rainfall is spread over much of the island, but the southwest monsoon is largely intercepted by a south-central hill massif, and a dry southwest wind blows over the north and east. On account of topography and rainfall, 103 rivers rising in the central highlands flow in a radial pattern to the sea (Fig. 1). Perennial rivers are called *ganga*, and nonperennial rivers and streams are called *oya, ara, dola*, or *ela* in Sinhala, and *aru* in Tamil. (Sinhalese constitute 74% of the population, Tamils about 12%.) A wet zone and dry zone are defined today; the criterion is 75 inches of annual rainfall. Humid-tropical conditions exist, ideal for year-round cultivation of rice, a water-intensive crop.

ANCIENT DEVELOPMENT

There were three political regions, Rajarata (King's country), Ruhunurata, and Mayarata in ancient Sri Lanka whose written history goes back to the mid-first millennium B.C. Actual writing began early in the Christian era on ola (palm) leaf manuscripts, many still preserved in temples and archives. The Mahavamsa, or great chronicle, and Culavamsa, little chronicle, translated by modern scholars, conform with contemporaneous rock inscriptions.

A famous king, Parakrama Bahu I, said *"Let not a drop of rain water flow to the sea without being made useful to man!"* (Mahavamsa, quoted in Reference 1). Human intervention in nature's hydrologic cycle is seen in the plains of ancient Rajarata and Ruhunurata in the form of river diversion systems and small, medium,

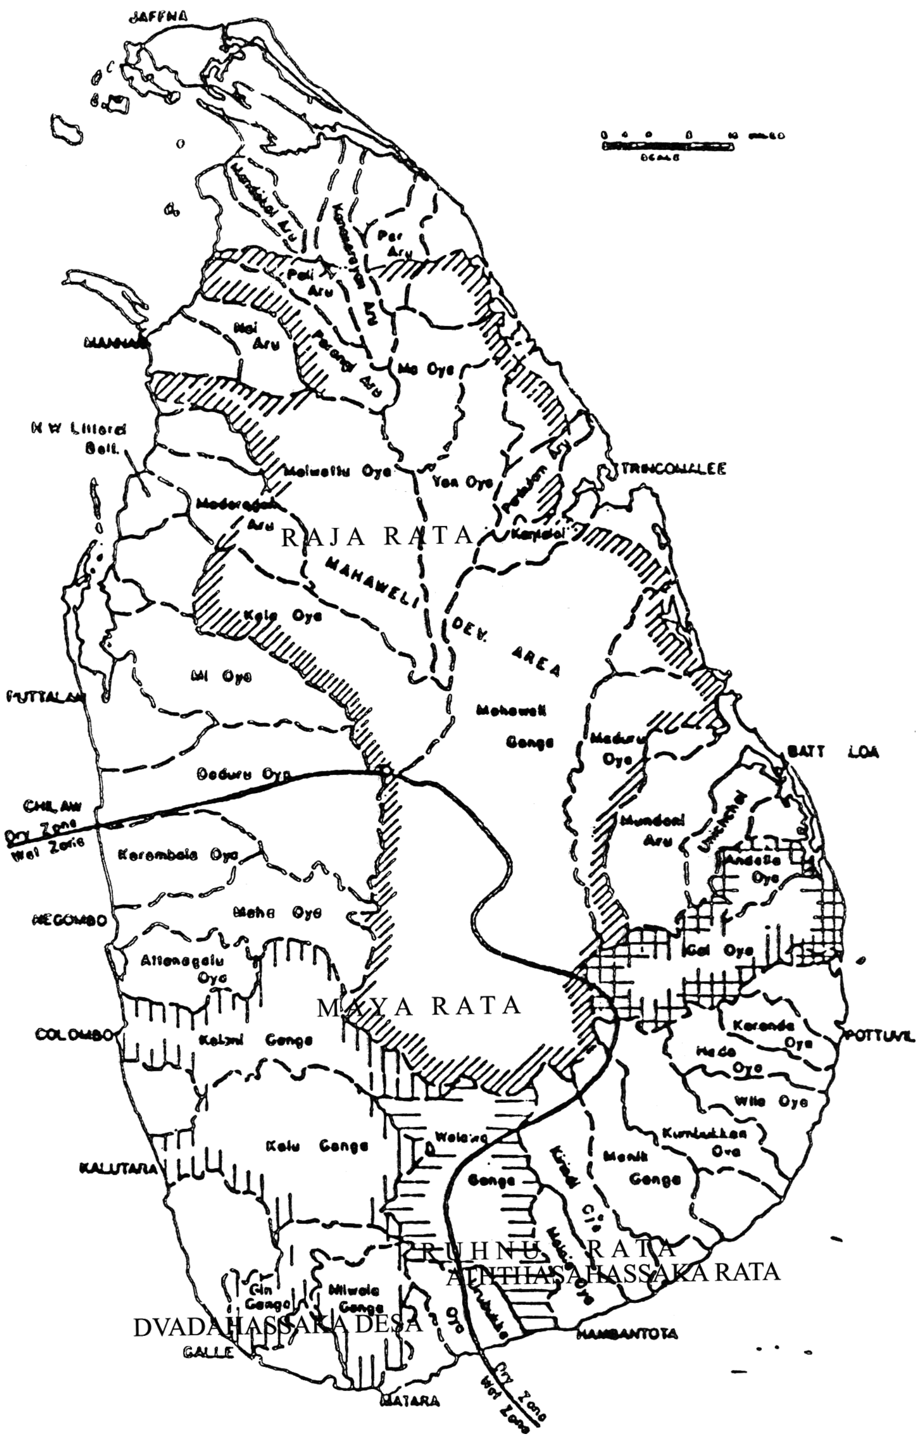

Figure 1. Rivers of Sri Lanka.

and large reservoirs. In wet zone uplands, much later, terraced rice fields saw reuse of irrigation water under gravity, benefiting from forest cover induced fertility. In colonial times, destruction of forests for planting coffee, and later tea, led to adverse impacts (2). Ancient diversion systems include stone anicuts (derived from the Tamil language) or weirs, called *amuna* in Sinhala and *tekkam* in Tamil, channels diverting streams for both irrigated agriculture, and storage in reservoirs. Large reservoirs with massive earth dams were built after the invention of the sluice with its *bisokotuwa* or access tower, forerunner of the valve tower (3, p. 379). Small tanks (Portuguese *tanque*) were synonymous with villages. Small earth dams without sluices, locally known as *vetiyas,* are incorrectly described on topographical survey sheets as *abandoned small tanks*. New metric-scale topo sheets have omitted many of these vetiyas, which checked surface runoff in nonperennial streams for storage in the earth itself, a water harvesting technique understood in India today (4) but not in Sri Lanka. Conservation of fauna began when

Table 1. Contrasting Perspectives on Ancient and Modern Projects

	Hydraulic Engineering Perspective—Hard Technology Design of Modern Projects	Ecosystems Perspective—Soft Technology Design seen in Ancient Projects
1. Water	Inanimate, active	animate, passive
2. Small tank	Inefficient, early stage in evolution and development of irrigation systems, to be submerged by a large reservoir built later	microwater and soil conservation ecosystem in downstream development area below a large reservoir; name of tank often identical to name of village
3. Large reservoir	Efficient irrigation system in combination with downstream channel distribution irrigation system without any small tanks in its command area	Main item in a macrowater and soil conservation ecosystem with microwater and soil conservation ecosystems in its command area
4. Diversion structure, dam or weir, and diversion channel	Built to augment a large reservoir—last stage in development of ancient irrigation systems in Sri Lanka (5,6)	Earliest stage in irrigated agriculture and evolution and development of ancient water and soil conservation ecosystems in Sri Lanka (7)
5. Vetiya, breached small earth embankment or bund, found in dry zone jungles	Embankment or bund of abandoned small tank	Deflection structure—microwater and soil conservation ecosystem; maintains water table
6. Downstream development area in modern projects	Cleared of all vegetation to lay out channel irrigation systems	Should be designed as a series of microwater and soil conservation ecosystems, including forest areas, as in ancient systems
7. Forest areas	Limited to catchment areas in modern projects	Not only in catchment areas in ancient projects, but interspersed with fields in downstream development areas for better nutrient flow

King Devanampiya Tissa, on a hunting trip about 223 B.C., was converted to Buddhism. Arahant Mahinda, son of Emperor Asoka of India, preached a sermon at Mihintale, a mount near the capital city Anuradhapura: *"The birds of the air and the beasts of the jungle have as much right to life as thou, O great King!"* (4). Hence, the ancient systems involved conservation of water and *interactions* of water, soil, flora, and fauna, with *functions* including irrigation, drainage, flood control, and domestic water supply. They should be called *water and soil conservation ecosystems*, as described in Table 1. Three aspects merit study:

—their evolution and development beginning in about the mid-first millennium B.C.;

—their stability and sustainability for about 17 centuries until about the thirteenth century A.D.; and

—their apparently irreversible decline after the Parakrama Bahu I (1153–1186) era.

These are being addressed in a multidisciplinary project, *Science and Civilisation in Sri Lanka,* started recently following Joseph Needham's *Science and Civilisation in China* (8).

ANCIENT RAJARATA

Anuradhapura in Rajarata was the capital city of Sri Lanka from about the fourth century B.C. to about the tenth century. Polonnaruwa, further east, became an alternative capital in about the eighth century on account of invasions from southern India and remained the capital until the thirteenth century, after which drift to the southwest began (9). Water and soil conservation ecosystems in Rajarata were highly developed in the Anuradhapura period (5,10–13). Only restoration was necessary in modern times, until the advent of new projects, Gal oya (1947–1949) and the aid funded Mahaweli (1978–1986). However, the Sri Lanka National Atlas does not have a chapter on the ancient systems.

In western Rajarata, Anuradhapura city tanks were built in stages: Basawakkulama (fourth century B.C.), Nuwara weva (reservoir) (first century), Tissa weva (third century) and Nachchaduwa weva (fifth century). The $54\frac{1}{2}$-mile-long channel, Kalaweva Jayaganga (River of Victory), starts from the right bank sluice of the great twin reservoirs Kalaweva–Balaluweva built by King Dhatusena (459–477), feeding Tissa weva directly, with a branch channel to Nachchaduwa. Brohier (10) documented the *Interrelation of Large Reservoirs and Channels* in western and eastern Rajarata. Nicholas and Paranavitana (12) further expanded this (Fig. 2).

The drought-resisting capability of this interconnected system augmented *cascades of small tanks* whose names were synonymous with village names [Fig. 3 (14)] [Fig. 4 (15)].

In eastern Rajarata, ancient ecosystems were developed through more than 11 centuries from the first century to the twelfth century (5,13,16,17). The Elahera stone diversion anicut and the first 24 miles of the Elahera canal were built by King Vasabha (65–109); King Mahasena (276–303) built Minneriya weva at the tail end of this canal and started the extension of the

Elahera–Minneriya canal beyond Minneriya weva. King Agga Bodhi I (575–608) completed this extension, and King Agga Bodhi II (608–618) built Gantala weva, the modern Kantalai reservoir, at the tail end of this canal, and an extension to the sea near Trincomalee. Finally, King Parakrama Bahu I (1153–1186) improved the whole system and constructed three large reservoirs, called Seas of Parakrama: Parakrama Samudra, restored in modern times; Parakrama Talaka still unidentified; and Parakrama Sagara, created by raising the Elahera anicut and strengthening the earthen canal embankment between Elahera and Konduruweva. This formed a series of reservoirs because there is a fall of about 60 feet in this reach (5,15) (Fig. 5). Parakrama Sagara was also called *Koththabadhdhanijjara*, translated as *the weir furnished with a reservoir* and also as *the reservoir whose flood escape was walled up* (18,19).

ANCIENT RUHUNURATA

In ancient Ruhunurata, remains of thousands of ancient irrigation works are found in the southeastern area, once described as Aththasahasaka rata, the region of 8000 villages, and the southwestern area called Dvadahassaka desa, the region of 12,000 villages (Fig. 1). But they have not been studied and understood as those in ancient Rajarata, and modern development has impacted the ancient projects adversely.

JAFFNA PENINSULA

The climate and topography of the northern Jaffna peninsula are quite distinctive. Rainfall is comparatively sparse, and underlying limestone makes groundwater the

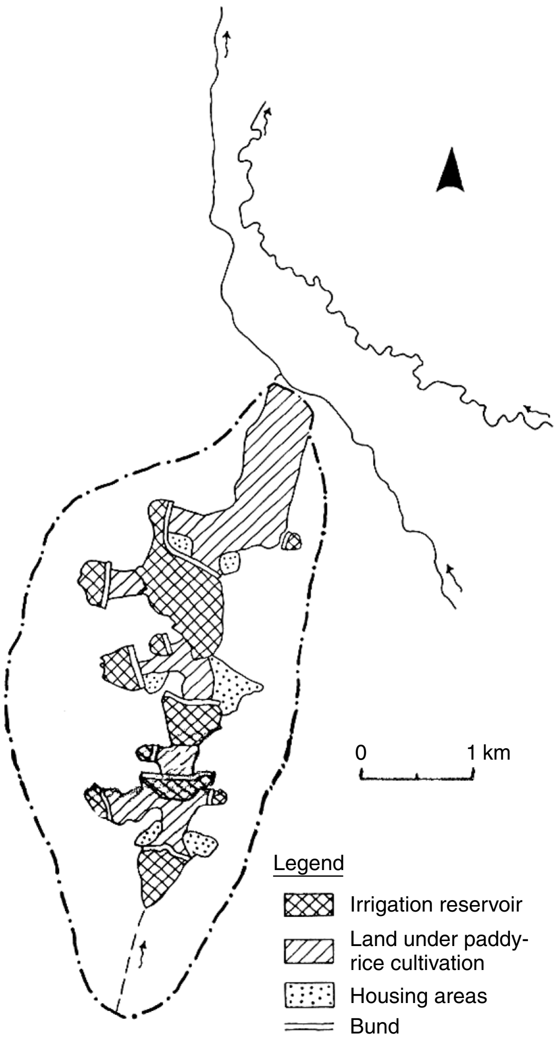

Figure 3. General layout of the cascade of four villages located in a local catchment.

principal source of water, extracted from dug wells, using the well sweep from ancient times (20).

MODERN DEVELOPMENT

Irrigation engineers today use a hydraulic engineering approach to design new projects, almost diametrically opposite to an ecosystems approach. In the hydraulic engineering or hard technology perspective, water is treated as inanimate and active, in the ecosystems or soft technology perspective, water is animate and passive. Consequences are shown in Table 1.

A four-stage hypothesis for the evolution and development of ancient irrigation systems follows the hydraulic engineering perspective (6,21):

—rainwater tanks from which water was bailed
—small storage reservoirs, called village tanks
—large storage reservoirs that submerged a number of small tanks
—augmentation of large reservoirs by diverting a river

Here, the evolution and development of storage reservoirs, in terms of storage capacity is followed by river diversion as a later development. But river diversion irrigation systems or water management in space existed before storage reservoirs or water management in time (which depended on the invention of the sluice) in all ancient civilizations.

Therefore, an alternative seven-stage hypothesis was proposed (7):

1. Rain-fed agriculture
2. Temporary or seasonal river diversion and inundation irrigation on river banks
3. Permanent river diversion and development of canal irrigation systems
4. Development of weirs and spillways on contour channels
5. Invention of the sorowwa (sluice) with its bisokotuwa (access tower)
6. Construction of small, medium, and large storage reservoirs
7. Damming a perennial river using a sluice for temporary river diversion, or the twin-tank technique, as in Kalaweva–Balaluweva in the fifth century

Meanwhile, a map entitled the Water Resources Development Plan (1959) showed proposed new large reservoirs, submerging ancient small village tanks, following the third stage of the four-stage hypothesis. Of ancient water and soil conservation ecosystems, only very large reservoirs and channels were shown.

In the southern area, location of the gigantic new Uda Walawe and Lunuganvehera reservoirs, follows the third stage in the four-stage hypothesis. Both Uda Walawe (1965–67) (Fig. 6) and Lunuganvehera (1978–1986) were built without considering alternative upstream sites. Environmental problems have made both these new projects unstable and unsustainable, contributing to insurrections against the government in 1971 and 1987–1989 that were suppressed with much loss of life and damage to property (22–25).

A similar possibility exists if Moragahakande, selected from the Water Resources Development Plan, 1959, for cost feasibility studies, is built (Fig. 5), compounded by the ethnic discord between separatist Tamils and the government. This large new reservoir will also destroy any possibility of restoring the potentially stable and sustainable ancient Parakrama Sagara.

A RIVER FOR JAFFNA—THE ARUMUGAM PLAN

A proposal called A River for Jaffna, prepared 50 years ago and partly implemented, will avoid all potential problems of Moragahakande. It involves enhancing both the quality and quantity of Jaffna groundwater by infinite dilution over the years by floodwater from the mainland Iranamadu reservoir (Fig. 7).

BEN FRANKLIN'S GULF STREAM WEATHER AND SWIM FINS

William E. Marks
Water Consciousness, Inc.
Martha's Vineyard,
Massachusetts

THE DISCOVERY OF THE GULF STREAM

In 1950, renowned nature writer Rachel Carson's book, *The Sea Around Us*, was published by Oxford University Press (1). In this book, Carson discusses at length, Benjamin Franklin's chart of the Gulf Stream (Fig. 1). A copy of Ben Franklin's chart is reproduced in Carson's book as an endpaper. In her writings, Carson credits the accuracy of Franklin's chart that was first created in 1769 and uses it and other information to help explain the flow of ocean currents.

In all fairness to the historic record, Franklin did not discover the Gulf Stream. The pre-Columbian Florida Seminole Indians, who traveled local waters, probably were aware of the Gulf Stream's current and its influence on their local sea travel and fisheries. As well, in 1492, Christopher Columbus pioneered Gulf Stream observations while sailing the equatorial current near the West Indies. While taking soundings, Columbus observed that the warmer surface waters were moving faster and in a different direction than the colder deeper waters (2).

In addition to the above, and thanks to research of Midshipman Pamela Phillips of the U.S. Naval Academy and Richard Gasparovic of the Applied Physics laboratory of John Hopkins University, we have the following time line:

1513: Ponce de Leon describes the Florida Current.
1519: Existence of the Gulf Stream is widely known to sailors.
1575: Andre Thevet associates the Gulf Stream with the rivers of the Gulf of Mexico.
1590: John White becomes the first person to mention the counter-currents on the coastward side of the Gulf Stream.
1606: Lescabot describes the meeting of the Labrador and Gulf Stream currents.
1660: Varenius classifies the Gulf Stream as a "perpetual special" motion of the sea and describes it as a giant stream.
1665: Kircher publishes showing the Gulf Stream.
1685: Happelius publishes second chart showing the Gulf Stream.
1769: Benjamin Franklin and Timothy Folger design and publish their chart of the Gulf Stream with notes on how to avoid it.

As expressed above, the first actual record of the Gulf Stream was on April 22, 1513, as related in the Chronicle of Ponce de Leon's Expedition, which eventually led to the so-called discovery of Florida. This 1513 document states:

> A current such that, although they had great wind, they could not proceed forward, but backward and it seemed that they were proceeding well; and at the end it was known that in such wise current was more powerful than the wind (3).

Further maritime observations of the Gulf Stream were recorded on an ongoing basis after its initial discovery. However, these observations remained the "secret" of the ship's captains and pilots. This fact was noted in an article by Franklin Bache, published by the American Philosophical Society in 1936 (4):

> Apparently the Spaniards soon learned that this northerly flowing current was not merely a local current but one of wide extent; for six years later [after 1513] when Antonio de Alaminos set out for Spain from Vera Cruz, he sailed northward with the Gulf Stream for a number of days before turning east toward Europe. This same Aliminos was pilot of Ponce de Leon's expedition of 1513, when the Gulf stream was first noted. It is, therefore, quite proper to credit the discovery of the Gulf Stream to Alaminos (Marmer H. A. *The Gulf Stream and its Problems*).
>
> For two and half centuries following its discovery the growth of knowledge regarding the Gulf Stream was slow. The story is told in detail by Kohl and more briefly by Pillsbury. During this period, to be sure, the mariner and more especially the whaler, became acquainted with the Gulf Stream throughout the greater part of its course. Much of this information, however, was kept as a professional secret,... (Marmer, 1929).

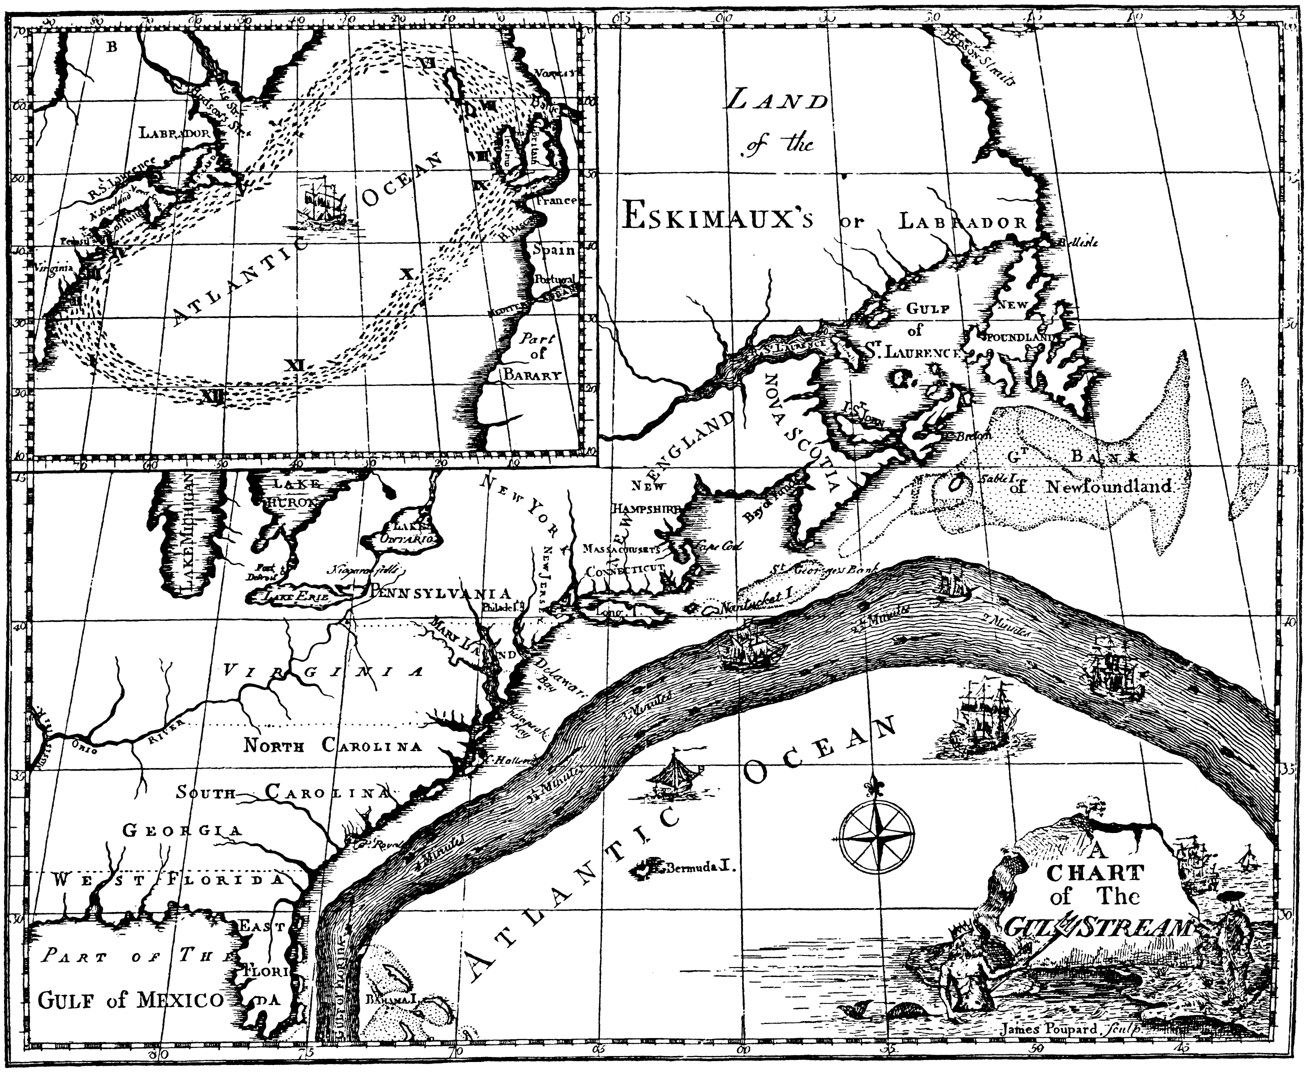

Figure 1. A chart of the Gulf Stream.

In 1513, after Ponce de Leon landed in Florida in the area known today as St. Augustine, he attempted to return to Puerto Rico after failing to locate the Fountain of Youth. However, as documented above, the current was so strong that his ships floated northward, even though they were sailing with a fair wind that should have taken them southward.

Six years later, Anton de Alaminos, found himself guiding Cortes's treasure ships from Mexico. With his prior knowledge as a pilot for Ponce de Leon, Alaminos used the northerly current of the Gulf Stream to his advantage.

Even though the discovery of the Gulf Stream by Alaminos was lost to history, there was another sailor who documented the current in 1735. Captain Walter Haxton, was a shipowner who also had a financial interest in understanding and using the currents of the ocean to his advantage. Besides being a captain, Haxton also owned several tobacco farms in the Maryland area and often shipped his produce to buyers in London.

In 1735, Haxton created the first detailed chart of the Chesapeake Bay area, which included bottom soundings, prevailing winds, and water current velocities and direction. As an addendum to this chart, Haxton plotted the latitude and longitude of the Gulf Stream (Northeast Current), as well as its direction and velocity.

Some 64 years before Franklin's chart in 1769, Haxton penned the following:

> It is generally known by those who trade to the northern parts of America that the current which comes out of the Gulph of Florida runs constantly along the coast of Carolina and Virginia and considerably further to the Northward, varying its course as it is obstructed by shores. Now if said current always runs nearly in the same part or space of the ocean (as from a great number of Tryals and observations which I have made in 23 voyages to Maryland, I have reason to think it does), the knowledge of its Limits Course and Strength may be very useful to those who have occasion to sail in it.

For some reason, Haxton's chart and related information about the Gulf Stream never received wide distribution or application. It was due to such oversight, as well as centuries of secrecy by various captains over the existence of the Gulf Stream, that the stage was set for the Franklin–Folger chart to make a splash in the annals of oceanic history. So much so, that most people today still harbor the belief that Benjamin Franklin discovered the Gulf Stream.

THE FRANKLIN/FOLGER GULF STREAM CHART

When Franklin had his and Folger's version of the Gulf Stream printed on a navigational chart in 1769, there was no such chart available. Franklin could only create the chart after receiving the benefit of Timothy Folger's drawings and advice. At the time, Folger was an active Nantucket whaling captain. Folger is credited for depicting the width and breadth of the Gulf Stream's current by drawing it on an Atlantic Ocean chart. Folger's chart included notes on how the Gulf Stream's current influenced the speed of ships crossing the Atlantic between America and Europe. Folger's drawing of the shape and speed of the Gulf Stream's current were extremely accurate for his time and in general, hold true to this day. Folger drew the Gulf Stream on a chart in answer to Franklin's inquiry about the forces of nature that may be impacting the speed of ships crossing the Atlantic Ocean. On another note, Folger was Franklin's cousin, twice removed (Nantucket Historical Society).

Today, it is generally recognized that the Franklin–Folger chart represents an accurate summary of the average width, length, and direction of the Gulf Stream, as well as the average speed of its current.

The name "Gulph Stream" was first suggested in 1762 by Benjamin Franklin because of the stream's sourcing from the Gulf of Mexico. Prior to 1762 it was generally known as the "Northeast Current."

The initial concept of creating Franklin's famous chart of the Gulf Stream was prompted in 1768 when Franklin was in London serving as Deputy Postmaster General for North America (Van Doren, 1938). While in London, Franklin received complaints from America as to how westbound mail packets [English ships] took up to two weeks longer than American merchant ships (5) *Am. Philos. Soc.* lxxvi (5). (1936). At about the same time, the English postal authorities had written to Franklin asking similar questions. These inquiries from Americans and the English about the speed of ships crossing the Atlantic prompted Franklin to do some research.

While researching the answers to these complaints in 1768, Franklin made inquiries of Timothy Folger, who happened to be in London at the time. Folger informed Franklin that based on experience, Nantucket whalers had developed a working knowledge of the Gulf Stream between Europe and America. This knowledge came from the whalers following the migration patterns of whales, which were consistently found north or south beyond the edges of the Gulf Stream, but never inside the Gulf Stream. Whaling captains from Nantucket and Martha's Vineyard knew that whales could be found feeding along the Gulf Streams plankton-rich boundaries. They also had learned that sailing back to New England whaling ports could be achieved in less time by staying north of the Gulf Stream and thereby avoiding its current.

Over time, Nantucket whalers learned to use the current of the Gulf Stream to their advantage when sailing in a northerly direction to England, but avoiding it when sailing in a southerly direction back to America. Folger told Franklin that American captains often told British captains about avoiding the current, but their hubris caused them to ignore the Americans advice. "They were too wise to be counselled by simple American fishermen," Folger told Franklin.

A letter from Franklin dated October 29, 1768, tells of Folger's role in the creation of the Gulf Stream chart:

> Discoursing with Captain Folger a very intelligent Mariner of the Island of Nantucket in New England concerning the long passages made by some Ships bound from England to New York I received from him the following information. Vizt
> That the Island in which he lives is Inhabited Chiefly by people concerned in the Whale Fishery, in which they employ near 150 Sail Vessels, that the whales are found generally near the Edges of the Gulph Stream, a strong current so called which comes out of the Gulph of Florida, passing Northeasterly along the Coast of America, and the turning off most Easterly running at the rate of 4, 3 1/2, 3 and 2 1/2 Miles an Hour; that the Whaling Business leading these people to Cruise along the Edges of the Stream in quest of Whales,. . ."

When the chart was created in 1769, Franklin wrote the following notes based in large part on the advice he received from Nantucket's Timothy Folger:

> By observing these directions and keeping between the stream and the shoals [that lie to the south of Nantucket and St. George's Banks], the passage from the Banks of Newfoundland to New York, Delaware, or Virginia, may be considerably shortened; for so you will have the advantage of the eddy current, which moves contrary to the Gulph Stream. Whereas if to avoid the shoals you keep too far to the southward, and get into that stream, you will be retarded by it at the rate of 60 or 70 miles a day.
> The Nantucket whale-men being extremely well acquainted with the Gulph Stream, its course, strength and extent, by their constant practice of whaling on the edges of it, from their island quite down to the Bahamas, this draft of that stream was obtained from one of them, Capt. Folger, and caused to be engraved on the old chart in London, for the benefit of navigators
> . . . Note, the Nantucket captains who are acquainted with this stream, make their voyages from England to Boston in as short a time generally as others take in going from Boston to England, viz. from 20 to 30 days.
> A stranger may know when he is in the Gulph Stream, by the warmth of the water, which is much greater than that of the water on each side of it. If then he is bound to the westward, he should cross the stream to get out of it as soon as possible (6).

Besides the above two sources referring to Timothy Folger's role in creating the Gulf Stream chart, we also have the following quote from Franklin's *Maritime Observations*. These observations were written at sea in August, 1785, and expressed in his letter to David Le Roy:

> I then observed it was a pity no notice was taken of this current upon the charts, and requested him [Timothy Folger]

> to mark it out for me, which he readily complied with, adding directions for avoiding it in sailing from Europe to North America. I procured it to be engraved by order from the general post-office, on the old chart of the Atlantic, at Mount and Page's, Tower Hill; and copies were sent down to Falmouth for the [English] captains of the packets [ships], who slighted it however; but is since printed in France, of which edition I annex a copy.

It is in Franklin's *Maritime Observations* that we find mention of his two charts of the Gulf Stream. Both of which he published—the first chart in England in 1769, and the second in France circa 1778. It was also during this 1785 voyage that Franklin expressed his theory about how the Trade Winds create the Gulf Stream. Franklin's theory was that the winds created the Gulf Stream current by the friction of the moving air on the surface of the water. This theory, in general has remained correct to this day. As expressed in Franklin's words:

> This Stream is probably generated by the great accumulation of water on the eastern coast of America between the tropics, by the Trade Winds which constantly blow there. It is known that a large piece of water ten miles broad and generally only three feet deep, has by a strong wind had its waters driven to one side and sustained so as to become six feet deep, while the windward side is laid dry.
>
> . . . The power of the wind to raise water above its common level in the sea is known to us in America, by the high tides occasioned in all our seaports when a strong northeaster blows against the Gulf Stream.

After having the chart of the Gulf Stream printed, Franklin made copies available to British captains. However, Franklin noted that the British captains refused to believe in information about the Gulf Stream proffered by Nantucket whalers. On similar note, the Franklin–Folger chart, and its related information about the Gulf Stream were also rejected by English captains. For this reason, as well as the revolt of the colonies against England in the early 1770 s, Franklin's 1769 chart of the Gulf Stream became extremely rare.

It is believed by some historians that Franklin and other Americans in England may have suppressed the distribution of this 1769 chart. The reason that Franklin suppressed his 1769 chart of the Gulf Stream may have been to prevent the English Navy from using it to its advantage against the colonies. This has merit because it was in 1786 and after the Revolutionary War, that Franklin again published Folger's sketch of the Gulf Stream as part of an article in the *Proceedings of the American Philosophical Society of Philadelphia* (7).

When Franklin was returning to America from London in March 1775, he took temperature measurements of the Gulf Stream four times each day. During this voyage he discovered that the Gulf Stream was warmer than surrounding waters and that it had a color different from the colder waters on either side. These observations were consistent with those of Nantucket whalers.

In 1776, when Franklin was sent by the colonies as envoy to Paris to negotiate a treaty, he again took temperature measurements of the Gulf Stream and kept a record of his observations. These observations rekindled Franklin's interest in understanding the Gulf Stream. Upon arrival in France, he had the original Folger chart of the Gulf Stream copied and printed by Le Rouge. Soon after, the Le Rouge chart was made available to French captains sailing to America with arms and supplies. Even though the Le Rouge version of the Gulf Stream chart is undated, the copy in the Bibliotheque National has the following note inscribed on its underside, "communique' par M. de Franklin en 1778."

In 1785, at age 79, and five years before his death, Franklin made his last transatlantic voyage when he sailed home from France on the London packet. Continuing with his research in to the Gulf Stream, Franklin directed his grandnephew, Jonathan Williams, Jr., when and how to take temperature readings of the Gulf Stream. It was during this final voyage that Franklin wrote *Maritime Observations*. This paper was published in 1786 and includes the best known versions of the making of the Franklin–Folger chart of the Gulf Stream, as well as its related genesis.

The original Franklin–Folger chart of 1769 was lost to history for close to 200 years and was assumed forever lost. During that time, the only surviving record of the original 1769 chart was expressed in the writings of Franklin and others. Concern for finding a copy of the 1769 chart surfaced from time to time. For example, on April 24, 1936, The American Philosophical Society printed an article entitled, "WHERE IS FRANKLIN'S FIRST CHART OF THE GULF STREAM?." The article was authored by Franklin Bache, and was an international plea for people to search for a copy of the chart. It was not until 52 years later that this plea was answered. And, most appropriately, by a scientist who had interest in studying ocean currents.

In 1978, Dr. Philip L. Richardson of Woods Hole Oceanographic Institute found the original 1769 Franklin–Folger chart while doing research in France. As expressed by Richardson (8) *Science* (1980). **207**; 8.

> In September 1978, I found two prints of the Franklin–Folger chart in the Bibliotheque Nationale in Paris (Fig. 1) (7). It occurred to me that a copy of the chart might have been saved by the French because Franklin was envoy to France from 1776 to 1785 and both Franklin and his ideas were highly regarded by the French.
>
> Richardson would later publish his in-depth Gulf Stream research in *The Geographical Magazine*, London, LII (8), pgs. 575–58, in an article entitled "Progress on the Gulf Stream (9)."

When the author of this article contacted Dr. Richardson by email at Woods Hole Oceanographic Institute, he answered:

> I discovered the 1769 chart while I was working on Gulf Stream Rings, which are eddies that pinch off from Gulf Stream meanders. We were tracking them, measuring their paths in the ocean and their decay. I was spending a year in Paris analyzing some data and writing papers.
>
> I was thrilled by my discovery and spent a lot of time in further research of the Gulf Stream and Ben Franklin, and other early charts of the Gulf Stream. Based on that, I published the 1980 paper in Science vol 207, 643–645 and one in the book

Oceanography: *The Past*, (1980). Springer Verlag, New York. I also worked on derelict ship trajectories in the Stream, and compared them to drifting buoy trajectories and with Walter, Haxton's 1735 description of the Stream (10) (1982, *J. Mar. Res. Supp.,* **40**: 597–603).

Today, Dr. Philip L. Richardson has the status of Scientist Emeritus at Woods Hole Oceanographic Institute, where he continues to pursue his passion of oceanographic research.

FRANKLIN AND WEATHER

"Some are weatherwise, some are otherwise," wrote Franklin under his pen name of "Poor Richard" in 1735.

It was also in Poor Richard's Almanac that Franklin dared to be so weatherwise that he published some of the first recorded weather forecasts. Poor Richard's Almanac was first published in 1732 under Franklin's nom de plume of Richard Saunders.

Franklin recorded some of his first theories on weather phenomena while in Philadelphia in 1743. On the evening of October 21, he had plans to observe a lunar eclipse which was scheduled to occur at 8:30 P.M. As Franklin waited with anticipation to watch the eclipse, his plans were suddenly interrupted when a fast moving violent storm blocked his view of the moon.

As the following weeks passed, Franklin read in various newspapers that the violent storm tracked northeasterly, causing considerable damage from Virginia all the way to Boston. However, much to Franklin's surprise, the newspapers from Boston reported accounts of the lunar eclipse, and that the storm arrived in Boston long after the eclipse had come and gone.

This series of events intrigued Franklin; he became curious why Boston, which was located hundreds of miles northeast of Philadelphia, would experience the delayed arrival of the storm. Another factor that intrigued Franklin was that the winds and the direction of the storm seemed contrary. After much inquiry and observation of other storms, Franklin told his friend Jared Eliot that his research had led him to the "very singular opinion that, though the course of the wind is from the northeast to the southwest, yet the course of the storm is from the southwest to the northeast." This observation by Franklins established him as the first to observe that storm winds can rotate counterclockwise, even though the entire storm is traveling in a clockwise direction.

In his attempt to decipher how such weather patterns could occur, Franklin theorized that heated air rising skyward in the south created a vacuum effect (low pressure), which in turn attracted winds from the north (high pressure). This theory of low and high pressure systems was the first known explanation of how storms moved in the Northern Hemisphere.

Today, weather forecasters recognize and respect the accuracy of Franklin's theory as it contributes to our understanding of the hydrologic cycle and forecasting the movement of hurricanes. "With this began the science of weather prediction," said the renowned scholar, William Morris Davis, 150 years later. Perhaps this distinction qualifies Franklin as America's first meteorological scientist.

Franklin's penchant for weather phenomena surfaced again in 1755 when he had the occasion to see a dust devil, or whirlwind funnel, bouncing across the landscape, while he was on horseback in Maryland. Franklin was so excited that he chased the dust devil and rode beside it for a considerable time before it disappeared in the forest. He wrote of this experience at length, on August 25, to his longtime friend and correspondent, Peter Collinson.

This lifelong interest in weather surfaced again 6 years before his death when he published *Meteorological Imaginations and Conjectures*. In this publication, Franklin explores such weather phenomena as heat radiation, insulating clouds, the shifting direction of winds, and creation of fog. In his own fashion, Franklin correctly defines circulation patterns of the hydrologic cycle. As well, he is correct in his attempt to deduce the rare manifestation of hail and ice during the summer months. He correctly figures out that warm moist air reaches high into the atmosphere where it cools and freezes into ice. This heavy ice then falls to earth before it is melted by the summer sun.

Also, toward the twilight of his life, Franklin again made some brilliant deductions. Before he died in 1790, he researched the effects that volcanic eruptions had on weather patterns and cloud electrification. In doing so, he correctly hypothesized that the severe winter of 1783–84 was exacerbated by the summer 1783 volcanic eruption in Iceland. Franklin theorized that dust from volcanic eruptions was instrumental in reducing the amount of solar energy reaching the earth's surface.

SWIM FINS

Since boyhood, Franklin enjoyed the experience of swimming and had a reputation for his strength and agility at plying the waters. His innate ingenuity expressed itself early when, still a boy, Franklin invented swimming fins, which he secured to his hands to help him swim faster and with less fatigue. According to Franklin, he developed the swim fins as a way to reduce what he referred to as "a laborious and fatiguing operation."

No matter where he traveled, Franklin always found time to enjoy his favorite exercise of swimming. When in Boston, he swam in the Atlantic Ocean and the Charles River. And when in England, he swam the Thames River. Benjamin Franklin "was considered to be an expert swimmer and while in England attracted attention by swimming the two to three miles from Chelsea to Blackfriars" (Franklin Bache, 1936).

On his first trip to London in 1724, Franklin was known for entertaining observers with his "ornamental" maneuvers while splashing around in the Thames. Franklin enjoyed swimming so much that he once considered taking a full-time job as a swimming instructor while in England.

Out of respect for Franklin's lifelong interest in swimming, he was inducted posthumously into the International Swimming Hall of Fame.

On a closing note, it should be recognized that even though Benjamin Franklin was affectionately referred to and often addressed as Dr. Franklin, Benjamin Franklin never received a Ph.D. from any academic institution. However, this in no way detracts from the historic contributions Franklin made to the worlds of science, politics, music, invention, social studies, publishing, printing, meteorology, navigation, optometry, swimming, oceanography, and God knows what else.

In Franklin, we find a human being who had an unsatiable curiosity about the world and a strong belief that he could make a difference through his contributions.

WATER SYMBOLISM

D.L. Marrin
Hanalei, Hawaii

Since the beginning of recorded history, water has held a special place in the spiritual and physical lives of people who represent a wide range of cultures and civilizations. Though rituals, languages, and beliefs among ancient cultures differed greatly, water was routinely used to symbolize a myriad of places and events in both the observable and unobservable realms.

MESOPOTAMIA

The first generally recognized written history comes from the Sumerians, who inhabited the Mesopotamian region more than 5000 years ago. In the Sumerian pantheon, various gods personified heaven, earth, air, and water. *Enki*, the primary water god, represented wisdom and evolved from a great underworld ocean that also gave rise to heaven (1). The underworld was sometimes referred to as a river and apparently existed beneath the surface of the earth as a freshwater (not saline) body of water. Enki (later known as *Ea* by the Babylonians) ruled over this watery underworld and symbolized the primordial waters, which were associated with the "chaos" that existed before creation. Myths from around the world recognize that creation was preceded by an original state of chaos, which defined a state of formlessness and was often identified as a watery abyss or primordial sea (2). Such a sea apparently reflected the fact that ancient people recognized creation as the emergence of form from formlessness.

EGYPT

The Egyptians, similar to the Sumerians and Babylonians, believed that the heavens and the earth (including all the inhabitants of the earth) were created from the primordial or celestial waters. *Ra*, the great Egyptian sun god, was intimately involved in creating the manifested world as his Sun disk appeared above the waters to signal the beginning of time (3). Ra made his symbolic journey over the water in a boat because the Sun was made of fire and, therefore, could not have risen out of the waters of chaos on its own. According to the Egyptian pantheon, everything is created from the waters of chaos by a being that, similar to God in the Bible's Book of Genesis, appears above or within the primordial waters. The primordial waters or seas often symbolized the formless chaos and undifferentiated matter of the underworld waters that comprised the cosmos before its division into the realms of heaven and earth. Hence, heaven, earth, and all life emerged from "the waters."

CHINA

The Chinese culture was one of only a few that did not associate the primordial chaos with water in the form of a sea. Instead, the ancient Chinese apparently portrayed chaos as a misty vapor that embodied the cosmic energy governing space, time, and matter (4). The formless misty vapor, from which the duality of *yin* and *yang* were born, gave rise to all earthly life forms. Some historians believe that the ancient Chinese people divided even the spirit world into a Ministry of Waters, whereby seawater is overseen by four dragon-kings representing the cardinal directions and freshwater is ruled by four dragon-kings representing each of the major rivers of China.

OCEANIA

The ancient Maori culture of New Zealand referred to water as *wai*, which also means remembrance or the recollection of something that has been. In the Maori culture, water symbolizes the memory of all that has ever been and will be (5). Like so many ancient and indigenous cultures, the Maori consider that water's memory serves as the spark of life and is intimately associated with the process of creation. How water is able to retain or access memory is not a component of ancient or indigenous myths; however, the almost universal insight that such memory is constrained neither by space nor time is one that has stirred considerable controversy in the modern world.

GREECE

Born from the primordial chaos (water) was the Greek goddess *Gaia*, who represents the manifested world and the first pantheistic being to inhabit our planet after it was formed. Gaia (as the earth mother) and Uranus (as the sky) gave birth to *Oceanus*, who is generally considered the Greek personification of water. The god known as Oceanus is, of course, at the root of our English word "ocean," where most of the water on the earth is contained. The ancient Greeks believed that water was everywhere and also constituted everything, such that all things manifest in this world represented different transformations of water.

In addition to their pantheistic characters, the ancient Greeks were one of the first cultures to begin incorporating their intuitive or mythical views of water into a more philosophical and, from a modern perspective, comprehensible format. Though such early philosophies often echoed the message of ancient myths, they began to explain water's relationship to other aspects of the physical world. Losing little of its mystique as a symbol of the primordial chaos, water was associated with geometries, numbers, vibrations, and physical structures.

ELEMENTS AND ENERGIES

A sixth century B.C. philosopher, named Thales, hypothesized that water is the primary substance of all being, out of which everything is created and to which everything returns (6). He was perhaps the first to recognize water's unusual physical properties and its apparent universality, both as a solvent and as a so-called creational medium. During the fifth century B.C., a Hermetic philosopher, named Empedocles, expanded on Thales' notion by proposing that all matter in the universe is composed of differing combinations of four original substances and two moving forces. Empedocles referred to these four substances as the *elements* of fire, air, water, and earth, and he identified love and strife as the *moving forces*. The moving forces energized the combining or dissociating of elements, such that matter could not be created without love nor uncreated (destroyed) without its opposite moving force of strife.

In addition to the four elements, there is a fifth substance that, according to Greek philosopher Plato, was essential to creating the universe (7). This mysterious fifth substance was referred to as *aether*, a word coined by the Greeks to identify the substance filling all space beyond the earth. Similar to the four elements, aether is an integral component of most ancient beliefs, where it is generally associated with a life energy or vital force. The ancient Hindus also recognized the four elements and aether, or *akasha*, as fundamental components of the natural world.

THE PLATONIC SOLIDS

The four elements and aether were symbolized by three-dimensional geometries known as Platonic solids (see Fig. 1). These angular solids were believed to connect the etheric and worldly realms to the primordial waters of chaos (usually represented by a sphere). The solid that most often symbolizes water is the icosahedron, which represents the creative principle connecting the etheric and worldly realms. The reciprocal geometric relationship between the icosahedron (representing water) and the dodecahedron (representing aether) symbolized the intimate relationship between the two. Because matter or the material world (represented by a cube) was supposedly manifested from the aether via the water, it follows that the icosahedron and dodecahedron are mathematically related to the cube according to the golden ratio (as ϕ and $1/\phi$, respectively). The golden ratio ($\phi = 1.618\ldots$) was believed by some ancient cultures to represent the mathematical code underlying the creation of the manifested world.

BIBLICAL PERSPECTIVES

Water is frequently referenced in the Bible in a variety of contexts designed to communicate very different kinds of messages. Biblical scholars believe that the significance of water was heightened in a desert region (i.e., the Holy Land) where water was scarce and drought was a constant threat to life. Beyond water's more practical

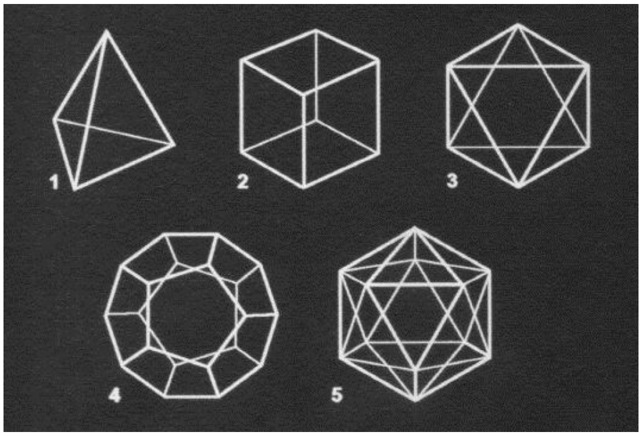

Figure 1. The five regular Platonic solids include (1) the tetrahedron symbolizing fire, (2) the cube symbolizing the earth, (3) the octahedron symbolizing air, (4) the dodecahedron symbolizing aether, and (5) the icosahedron symbolizing water.

considerations, the Bible portrays the spiritual aspects of water under several commonly recognized labels (8).

- *Cosmic water* describes a primordial force that only God can govern. The cosmic sea symbolizes the undifferentiated realm from which God created heaven and the earth.
- *Living water* symbolizes a source of life and a gift from God. Living water was considered distinct from ordinary water and symbolized both wisdom and knowledge.
- *Ceremonial water* symbolizes both the cleansing process and the passage between life and death. Ceremonial water is portrayed as an agent for removing or dissolving impurities.

If the biblical account of creation is consistent with that of other ancient accounts, heaven and earth are manifested from the symbolic, rather than literal, waters of which God is one. In this context, cosmic water is analogous to the waters of chaos rather than to literal water present in interstellar space (i.e., the modern scientific reference to cosmic water). Living water appears to be a designation for a special type of literal water, such that there is a recognizable difference between living and ordinary water. Living water is very rare, satisfies one's thirst, and also imparts life to the world. Most of the water used for religious ceremonies is ordinary water (sometimes symbolizing living water) that is blessed by an appropriate person.

ART AND NATURE

If one studies water in its natural state, it is difficult not to notice the variety of *flow forms* (e.g., whirlpools, eddies, ripples) that constantly appear and disappear. Many ancient cultures placed considerable import on these motions and believed that they held great powers for both creation and destruction. Renaissance artist Leonardo da Vinci is best known for his paintings and sculptures, but he was also a great student of water and its flow forms. He apparently believed that the vortical motion of fluids (particularly water) was a key to understanding and using the power of the universe. Two of the twentieth century's most renowned students of water flow forms were the European naturalists Theodor Schwenk and Viktor Schauberger, who expanded on ancient understandings and symbolisms of water.

According to Schauberger, water is the earth's blood and the essence of the *first substance*, whose boundaries and banks are the capillaries that guide it and in which it circulates (9). His view of water is similar to ancient perceptions inasmuch as water serves as the primordial substance of the universe and the fundamental component of both an organism's circulatory system and the planet's hydrologic cycle. Schwenk hypothesized that water's relationship to time was inherent in its rhythmical movement, which spanned cycles that ranged from seconds to years (10). He referred to different wave patterns and flow forms within a body of water as possessing distinct frequencies, overtones, and resonances—not unlike a musical instrument. Others have referred to this rhythm as "water's song," which often symbolizes the sound-shapes or music contained within the ripples and waves of water bodies.

POSTMODERN METAPHORS

The term "living water" is used today as a label or symbol for various aqueous concoctions in which ordinary water is treated with a combination of electrolytes, crystals, metals, colloids, and polymers, or exposed to various fields. The objective is to produce an optimal fluid that supports biological processes and, hence, retards both aging and disease. The exact mechanisms underlying a wide range of health claims have yet to be elucidated, but the modern practice of *water structuring* is based on the ancient understanding that water is able to retain or access a type of information that is colloquially referred to as "memory."

Perhaps the most recent water-related metaphor is that of *virtual water*, which was originally used to describe and, in some instances, quantify the influence of policy decisions on water resources in arid regions (11). Virtual water is a term used primarily in international trade for estimating the amount of water that is implicitly exchanged in goods and services (e.g., a ton of wheat requires 1000 tons of water) and the net gain for nations that import such goods and services. Although no actual water is traded during such transactions, the virtual water metaphor illustrates the extent to which real water is currently perceived as an economic commodity and is routinely transported across both geographic and political boundaries.

GORDON AND FRANKLIN RIVERS AND THE TASMANIAN WILDERNESS WORLD HERITAGE AREA

ARTHUR M. HOLST
Philadelphia Water Department
Philadelphia, Pennsylvania

The Tasmanian Wilderness World Heritage Area (TWWHA) is one of the largest temperate wildernesses in the world. Covering more than 8500 square miles, or more than 20% of the island of Tasmania, it contains three state reserves, four national parks, four conservation areas, two protected archaeological sites, and three forest reserves. Mountain ranges, rivers, Australia's deepest caves, waterfalls, and many endangered species are also present, as well as three lakes: Lake Gordon, Lake Peddler, and Lake St. Clair. The TWWHA was adjudged worthy of environmental protection in 1982 by the World Heritage Committee.

There are many reasons that the Tasmanian Wilderness was chosen as a World Heritage Area. It contains the largest peatlands in the Southern Hemisphere. It has great geological significance; it contains rocks from all but one geological period, and its oldest rocks are from the Precambrian period, more than a billion years ago. Also, sandstones and siltstones contain fossils of early marine life, fossilized when Tasmania was still underwater (Fig. 1). Much of the Wilderness' mountain landscape is the result of three glacial periods that occurred during the Pleistocene Epoch.

One of TWWHA's attractions is the Cradle Mountain–Lake St. Clair National Park. Lake St. Clair, the source of the Derwent River, is Australia's deepest lake and is enclosed by mountains. The Park contains myrtle, pine, and beech trees. Another attraction is the Central Plateau and Walls of Jerusalem National Park. This plateau was formed by glaciers during the last Ice Age; the area's lakes and tarns were created when the Ice Age's glaciers melted.

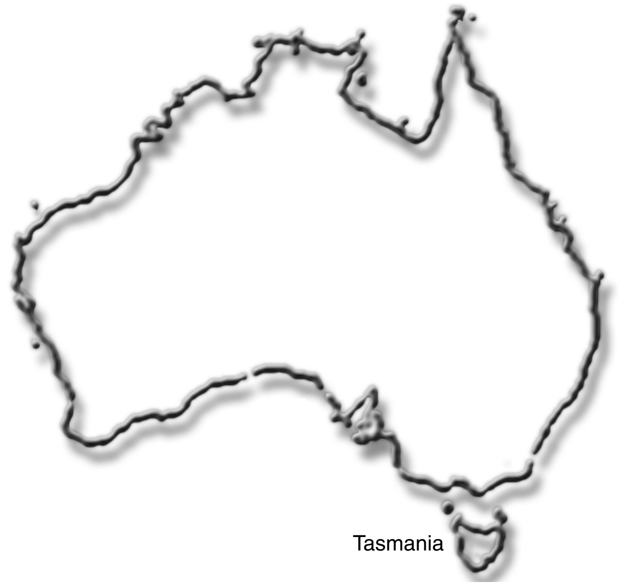

Figure 1. The island of Tasmania.

Many people visit the Tasmanian Wilderness World Heritage Area for its various activities. One of the most popular is known as bushwalking. This is basically hiking. There are advanced bushwalkers, and there are amateur bushwalkers, who take walks ranging from 15 minutes to an entire day. Advanced bushwalkers make longer and more arduous journeys over paths known as tracks. Tasmania's best-known track is called the Overland Track. About 80 km long, this track takes bushwalkers from 5–10 days to traverse. It features an alpine backdrop and passes the highest peak in Tasmania, Mount Ossa. This track is not exceptionally difficult; it is rated T1 by the Walking Track Management Strategy, the lowest rating, based on track hardening and track facilities.

Another favorite track of experienced bushwalkers is Frenchman's Cap. This track leads to the peak of the white quartzite Frenchman's Cap, the most prominent mountain in Franklin–Gordon Wild Rivers National Park. This track is considerably more difficult than the Overland Track; it has been assigned a T2 rating by the Walking Track Management Strategy. It usually takes bushwalkers 4 or 5 days to traverse this track.

A third popular track is the South Coast Track. It also has a T2 rating. This track has magnificent coastline views and spectacular beaches. It is located in Southwest National Park, and the main reason it is T2 is that the track is rather remote and far from any possible assistance. It is more than 80 km long and takes from 6–10 days to complete. It is often combined with the Port Davey Track to form a T3-grade track that takes from 10–16 days.

Another popular TWWHA activity is camping. Huts are provided along many common paths for general use, although tents are often used when the huts are full or where huts are unavailable.

The second most popular recreational activity in the TWWHA, after walking, is fishing. Local lakes, of which there are many, are often stocked with trout. These lakes, as well as rivers, are also sometimes used for boating, rafting, and kayaking. Some people opt to climb the peak of Frenchman's Cap. And the long, deep caves can be explored by experienced spelunkers. Marakoopa Cave is open to the general public.

Franklin–Gordon Rivers Wild Park (FGRWP), instated as a national park on May 13, 1981, is located in the southwest corner of Tasmania, between Southwest National Park, Cradle Mountain–Lake St. Clair National Park, and Walls of Jerusalem National Park. Not only the Franklin and Gordon Rivers, but also Jane River and Denison River are in FGRWP.

The Tasmanian World Wilderness Heritage Area is run by the Convention for the Protection of the World's Cultural and Natural Heritage, or World Heritage Convention. It was formed by UNESCO, the United Nations Educational, Scientific, and Cultural Organization, and it is the most extensive environmental convention in the world today. The area of the TWWHA is also world-renowned for its animal population. An unusually large number of species are endemic to Tasmania due to its remoteness from the rest of the world. Among these are the duck-billed platypus, the orange-bellied parrot, and the Tasmanian devil.

Along with all of these natural factors, the TWWHA possesses cultural significance as well. Thousands of years ago, Tasmania was detached from mainland Australia by Bass Strait, and the local Aborigines remained unaffected by outside influences until "discovered" by Abel Tasman in 1642. Many cave paintings have been found in Southwest Tasmania, including probably the southernmost cave paintings in the world.

The TWWHA's pristine quality is threatened by many factors. A major one is the soil erosion caused by bushwalkers hiking through the area. Many regulations are in place to attempt to lessen its impact on the environment. Another factor is cave degradation. Tasmania's many caves can be damaged easily by excessive visitors, so guides are available in many instances. Also, nonnative species have been introduced to the area, and they can have negative effects on local ecology. Fire can also devastate the environment; much of the TWWHA is designated fuel stove use only; the illegal use of campfires carries heavy fines.

There are many World Heritage Areas, but few can compare to the TWWHA in natural and cultural significance. It is one of only 13 World Heritage properties to satisfy all natural criteria. To this day, only one other World Heritage site has fulfilled as many criteria as the TWWHA.

THE MISTAKE OF WAITING TO GET THIRSTY

F. Batmanghelidj
Global Health Solutions
Falls Church, Virginia

At the start of the twenty-first century, medicine is still muddled about the way the human body deals with a water shortage in its complex water-dependent inner environment. It is not yet clear even to physiologists of long standing in the field how local or general water shortages in the body manifest themselves. The following example is particularly dangerous: A respected scientist made an announcement that was quickly and widely publicized—unacceptable to me because its adoption will undoubtedly hurt people. As a means of airing the reasons why we need to prevent thirst rather that wait to get thirsty, I am responding here.

Heinz Valtin, M.D., an emeritus professor at Dartmouth Medical School, has ventured the opinion that there is no scientific merit in drinking eight 8-ounce glasses of water a day and not waiting to get thirsty before correcting dehydration. This view—published in the *American Journal of Physiology*, August 2002, and reiterated in the 2003 report of the Food and Nutrition Panel of the National Academy of Sciences—is the very foundation of all that is wrong with modern medicine, which is costing this nation $1.7 trillion a year (a figure rising at the rate of 12% annually). Dr. Valtin's view is as absurd as waiting for the final stages of a killer infection before giving a patient the appropriate antibiotics. His views are based on the erroneous inherited assumption that a dry mouth is an accurate sign of dehydration.

Dr. Valtin does not seem to be aware of an important paradigmatic shift in medicine. In the past, it was wrongly assumed that solutes in the body regulate all functions and the solvent has no direct role in any physiological functions. In medical schools, it is taught that water is only a solvent, a packing material and a means of transport and has no metabolic function of its own. I have come across this limited view at another Ivy League medical school from another eminent professor of physiology who, like Dr. Valtin, researched and taught the water-regulatory mechanisms of the kidney to medical students and doctors. Only when I asked him what "hydrolysis" is did the penny drop: He admitted that water is a nutrient and does indeed possess a dominant metabolic role in all physiological functions of the body.

Dr. Valtin's emphasis on the water-regulatory role of the kidneys limits his knowledge to the body's mechanisms of water deficit management. He seems to base his views of thirst management on the vital roles of vasopressin, the antidiuretic hormone, and the renin-angiotensin system, the elements that are engaged in the drought-management programs of the body when the body has already become dehydrated. He defines *dehydration* as a state of the body when it loses 5% of its water content. Yet he believes that we should wait until, at some such level of water loss, the urge to drink will correct the water deficit in the body. This view might have seemed plausible 25 years ago. Today, it exposes the tragic limitations of knowledge of human physiology available at a prestigious medical school in America.

Dr. Valtin does not take into consideration the fact that water is a nutrient. Its vital hydrolytic role would be lost to all the physiological functions affected by its shortage in its osmotically "free state." Another oversight is the fact that it is the interior of the cells of the body that would become drastically dehydrated. In dehydration, 66% of the water loss is from the interior of the cells, 26% of the loss is from extracellular fluid volume, and only 8% is borne by the blood tissue in the vascular system, which constricts within its network of capillaries and maintains the integrity of the circulation system.

Philippa M. Wiggin has shown that the mechanism that controls or brings about the effective function of cation pumps uses the energy-transforming property of water, the solvent: "The source of energy for cation transport or ATP synthesis lies in increases in chemical potentials with increasing hydration of small cations and polyphosphate anions in the highly structured interfacial aqueous phase of the two phosphorylated intermediates" (1). Waiting to get thirsty, when body fluids become concentrated, we lose the energy-generating properties of water in the dehydrated cells of the body. This is a major reason why we should prevent dehydration, rather than wait to correct it. This new understanding of the role of water in cation exchange is enough justification to let the body engage in prudent surplus water management rather than forcing it into drought and deficit water management, which is what Dr. Valtin is recommending.

In his research on "conformational change in biological macromolecules," Ephraim Katchalski-Katzir of the Weizmann Institute of Science has shown that the "proteins and enzymes of the body function more efficiently in solutions of lower viscosity"(2). Thus water loss from the interior of the cells would adversely affect their efficiency of function. This finding alone negates Dr. Valtin's view that we should let dehydration get established before drinking water. It is desirable that all cells of the body function efficiently within their physiological roles, so it would be more prudent to hydrate the body optimally rather than wait for the drought-management programs of the body to induce thirst. Furthermore, it is much easier for the body to deal with a slight surplus of water than to suffer from its shortfall and have to ration and allocate water to vital organs at the expense of less vital body functions. The circulation of concentrated blood in the vascular system is truly an invitation to catastrophe.

The tragedy of waiting to get thirsty hits home when it is realized that the sharpness of thirst perception is gradually lost as we get older. Phillips and associates have shown that even after 24 hours of water deprivation, the elderly still do not recognize that they are thirsty: "The important finding is that despite their obvious physiologic need, the elderly subjects were not markedly thirsty"(3). Bruce and associates have shown that, between the ages of 20 and 70, the ratio of water inside the cells to the amount of water outside the cells changes drastically—from 1.1 to 0.8.(4) Undoubtedly, this marked change in the intracellular water balance would not take place if the osmotic push and pull of life could favor water diffusion through the cell membranes everywhere in the body at the rate of 10^{-3} centimeters per second. Only by relying on the reverse osmotic process of expanding the extracellular water content of the body to filter and inject "load-free" water into vital cells by the actions of vasopressin and the renin-angiotensin-aldosterone systems—when the body physiology is constantly forced to rely on its drought-management programs—could such a drastic change in the water balance of the body result.

Two other scientific discoveries are disregarded when Dr. Valtin recommends that people should wait until they get thirsty before they drink water. One, the initiation of the thirst mechanisms is not triggered by vasopressin and the renin-angiotensin systems—these systems are involved only in water conservation and forced hydration of the cells. Thirst is initiated when the Na^+-K^+-ATPase pump is inadequately hydrated. It is water that generates voltage gradient by adequately hydrating the pump proteins in the neurotransmission systems of the body(1). This is the reason that brain tissue is 85% water(5) and cannot endure the level of "thirst-inducing" dehydration that is considered safe in the article published by Dr. Valtin.

Two, the missing piece of the scientific puzzle in the water-regulatory mechanisms of the body—which has been exposed since 1987, and Dr. Valtin and his colleagues need to know about it—is the coupled activity of the neurotransmitter histamine to the efficiency of the cation exchange, its role in initiating the drought-management programs, and its role in catabolic processes when the body is becoming more and more dehydrated(5). Based on the primary water-regulatory functions of histamine and the active role of water in all physiological and metabolic functions of the body—as the hydrolytic initiator of all solute functions—the symptoms of thirst are those produced by excess histamine activity and its subordinate mechanisms, which get engaged in the drought-management programs of the body. They include asthma, allergies, and the major pains of the body, such as heartburn, colitis pain, rheumatoid joint pain, back pain, migraine headaches, fibromyalgic pains, and even anginal pain(5,6). And because vasopressin and the renin-angiotensin-aldosterone activity in the body are subordinate to the activation of histamine, their role in raising blood pressure is a part of the drought-management programs of the body(6). The forced delivery of water into vital cells demands a greater injection pressure to counteract the direction of osmotic pull of water from inside the cells of the body, when it is dehydrated.

From the new perspective of my clinical and scientific research into the molecular physiology of dehydration and the peer-reviewed introduction of a paradigmatic shift in medical science recognizing histamine as a neurotransmitter in charge of the water regulation of the body, I can safely say that the 60 million Americans with hypertension, the 110 million with chronic pain, the

15 million with diabetes, the 17 million with asthma, the 50 million with allergies, and more, all did exactly as Dr. Valtin recommends. They all waited to get thirsty. Had they realized that water is a natural antihistamine(5,7,8) and a more effective diuretic, these people could have been saved the agony of their health problems.

For more information about the medical breakthrough on chronic unintentional dehydration and the diseases it causes, read as many of the following titles as you can. They are the products of more than 24 years of focused research on the topic of deep dehydration inside the cells of the body: *Your Body's Many Cries for Water; ABC of Asthma, Allergies and Lupus; Water for Health, for Healing, for Life; How to Deal with Back Pain and Rheumatoid Joint Pain; Water Cures: Drugs Kill*; and my 2004 book, *Obesity, Cancer, and Depression: The Deadly Diseases of Dehydration.* For more information on dehydration, visit www.watercure.com and www.nafhim.org.

WATER AND WELL-BEING

David Haley
Picacadilly
Ulverston, Cumbria, United Kingdom

> "Connected in water
> Where the seas touch the sky
> Tears bring forth oceans." (1)

If well-being is defined as "... the maximisation of the pleasure available to us" (2) and is related to health, safety, welfare, comfort, security, happiness, goodness, and contentment, then water must play an important part in maintaining this desirable state. For without water, none of these qualities of life can be achieved. Water connects all life and water connects all aspects of well-being, including social, economic, environmental, health, and aesthetic well-being, as a basic human right.

Article 25, Universal Declaration of Human Rights (1948) states: "Everyone has the right to a standard of living adequate for the health and well-being of himself and his family" (3). Kofi Annan, United Nations Secretary-General confirmed that "(a)ccess to safe water is a fundamental human need and therefore, a basic human right.

Contaminated water jeopardizes both the physical and social health of all people. It is an affront to human dignity" (4). But Dr. Gro Harlem Brundtland, Director-General World Health Organisation recognized that the right to water and well-being is not available to all: "Yes we have entered the new millennium with one of our most fundamental conditions of human development unmet: universal access to water. Of the world's 6 billion people, at least 1.1 billion lack access to safe drinking water. The lives of these people who are among the poorest on our planet are often devastated by this deprivation, which impedes the enjoyment of health and other human rights such as the right to food and adequate housing" (5).

NEEDS FOR WELL-BEING

Apart from the supply of safe drinking water and irrigation for food production, water is also essential to food preparation and personal hygiene. Environmental hygiene through adequate sanitation, safe housing, and water-based cultural practices are just as important to psychological well-being as they are to physical health. And water for the survival of ecosystems is critical to supporting biodiversity and also to maintaining aesthetic beauty. This, again is confirmed by the World Health Organisation: "Human livelihoods are intimately connected to natural life on the planet, and that, in turn, depends on water for survival. Natural ecosystems are often found in water or are heavily dependent on it. Without water, soil would parch, forests would wither, and species would die out" (6).

However, uncertainty—fear of the unknown—undermines well-being, particularly when it is related to an essential life-sustaining resource. As seen through history to the present day, uncertain access to adequate, safe water, provokes hostility and even war between communities competing for this vital element of survival. Likewise, the threat of flood has great physical and psychological impacts, threatening people's ability to house themselves and attachment to place.

CULTURAL DIVERSITY

> "By means of water we give life to everything." (7)—Koran 21:30

Every culture has a particular and very important relationship with water. In Jewish, Christian, and Muslim religions, water plays a fundamental role in creation, sacred dwelling, blessings, affirmation of faith, and divine retribution. Vandana Shiva points out that "... the root of the Urdu word *abadi*, or human settlement, is *ab*, or water, reflecting the foundation of human settlements and civilization along water sources" (8).

From China, the Taoist yin/yang symbol depicts the dynamic balance and unity between opposite forces, representing our potential well-being with water and symbolizing the flow of life—water is by its very nature a dynamic element. However, too much or too little brings disaster, so our ability to adapt to change and the flow of water is a measure of our well-being. The ancient Chinese art of "geomancy," Feng Shui, translates into English as wind and water and pays particular attention to achieving well-being through the relationship with water. This important cultural concern influences the harmonious use of water within the home, office, restaurant, and other places of business because the water is believed to draw in money. Inappropriate use or placement of water could bring misfortune. Likewise, the beneficial design and positioning of buildings in relation to water is taken very seriously—supposedly, the tender for the construction of the Headquarters of the Hong Kong and Shanghi Bank was won by the architect, Sir Norman Foster, because his design incorporated Feng Shui principles of the building's relationship to the sea.

An old Chinese saying, "he who controls water, governs the empire," (9) refers to the emperor's ability to govern a contented population by controlling floods, rivers, and canals; a factor still understood, if contentiously applied in modern China, as plans for vast dam developments threaten the well-being of communities and ecosystems in return for hydroelectric power and cash crop irrigation. Like many societies, now, water is becoming valued as a commercial commodity, a finite resource that may be controlled and sold for private, industrial, agricultural, or leisure use. Reverence for water as a heavenly gift, spiritual source, or common resource seems to be diminishing.

In her book *Water Wars*, Vandana Shiva strongly maintains that "(w)ater is a common because it is the ecological basis of all life and because its sustainability and equitable allocation depend on cooperation among community members" (10). And she asserts that "(c)ommunity control avoids ecological breakdown and prevents social conflict. Over the centuries, indigenous water management systems have relied on ancient knowledge and evolved into complex systems that ensure the equitable distribution of water" (11). Water was, and still is recognized as a prime factor in well-being. This condition is beautifully expressed in the ancient Rig Veda hymn, *Water of Life:*

> Waters, you are the ones that bring us the life force.
> Help us to find nourishment,
> So that we may look upon great joy.
> Let us share in the most delicious sap that you have,
> As if you are loving mothers,
> Let us go straight to the house of the one,
> For whom you waters give us life and give us birth.
> For our well-being, let the goddesses be an aid to us,
> The waters be for us to drink.
> Let them cause well-being and health to flow over us.
> Mistresses of all the things that are chosen,
> Rulers over all peoples,
> The waters are the ones I beg for a cure.
> Waters—yield your cure as an armour for my body,
> So that I may see the sun for a long time.
> Waters—carry away all of this that has gone bad in me.
> Either that I have done in malicious deceit,
> Or whatever lie I have sworn to,
> I here sort the waters today.
> We have joined with their sap,
> Oh Agni, full of moisture,
> Come and flood me with splendour! (12)

THE FLOW OF LIFE—WATER AND WELL-BEING

Let us consider water and well-being as a flowing life system. "Water in one form or another circulates around us, all the time and everywhere" (13). Blockages, floods, and droughts may be thought of as disruptions to this flow. Evolution may be considered a process of morphing forms through structural diversity within an aquatic planetary system, rather than a linear progression. And climate change is one form of that evolutionary process. We may then see water as a dynamic major determinant in the structure, pattern, and process of evolution, life, and well-being. "The waters on the surface of the earth flow together wherever they can, as for example in the ocean, where all rivers come together" (14).

In his book, *Sensitive Chaos*: *The Creation of Flowing Forms in Water and Air*, Theodore Schwenk develops this idea:

> It is in the nature of water that it possesses those characteristics fundamental to all organisms for the maintenance of life; yet all is purely functional and without fixed form. These living qualities are nevertheless so clearly present and so evidently at work that the picture of the human organism is conjured up before us in three-fold nature—metabolic, nerve-sense and rhythmic organisations—revealing in harmony the basic characteristics of all living organisms.

And this notion is reinforced by architect philosopher, Christopher Alexander: "We came from the water; our bodies are largely water; and water plays a fundamental role in our psychology. We need constant access to water, all around us; and we cannot have it without reverence for water in all its forms." (15) Alexander continues: "Jung and the Jungian analysts take great bodies of water as representing the dreamer's unconscious. We even speculate, in light of the psychoanalytic evidence, that going into the water may bring a person closer to the unconscious processes in his life" (16).

And finally, marine biologist Commodore Jacques Cousteau expresses his love for water and the profound sense of well-being it can evokes:

> My body floated weightlessly through space, the water took possession of my skin, the clear outlines of marine creatures had something almost provocative, and economy of movement acquired moral significance. Gravity—I saw it in a flash—was

the original sin, committed by the first living beings who left the sea. Redemption could come only when we returned to the ocean as already the sea mammals have done. (17)

FREE FLOWING WATER: A SOURCE OF WISDOM

MAGGIE LEE
Santa Fe, New Mexico

“Indeed it is because life is wisdom and water wisdom’s element, that there can be such a thing as the water of life” (1).

In early August, while visiting gardens in the Boulder area of the Rocky Mountains, I discovered El Dorado Canyon, 10 minutes south. A brochure on the area relates...the tilted layers carry groundwater from the Rockies, down and eastward to a depth of 8,000′, before it is pushed to the surface as an artesian spring. Nearby, this tenacious spring feeds a 20 × 80′ pool. Swimming in this cool, turquoise, silky water, I moved with noticeable ease and buoyancy...refreshed in beneficent living water.

This article’s title and beginning sentence, so eloquently expressed by Theodor Schwenk, continues with his experience of living water. “Water constantly pouring out of a spring in the middle of a flower-filled mountain meadow, sparkling in the pure cold air, with light reflected from the shimmering snowy peaks around.” Generous, effervescent, living water.

Clearly, the beauty in the looking and the beauty in the seen, connected.

Sensing a similar mystery, David Abrams writes (when our perceptive practices reveal)...“a reciprocal phenomenon organized as much by the surrounding worlds as by (the perceiver)” (2).

Recently I discovered a passage by Rudolf Steiner saying that springs are the eyes of the earth.

In his extraordinary, rich, and comprehensive lectures and writings of the early 1960s and into the 1970s, Theodor Schwenk (1910–1986) proposed a new ‘water consciousness,’ a transformative way of thinking about this universal element. He described and illustrated fluid circulation, movement, and rhythms of the earth’s water cycle and resulting organic forms. His experiments demonstrated the rhythmical, metamorphic potential hidden within fluid processes. Included here are a few of his insights and discoveries.

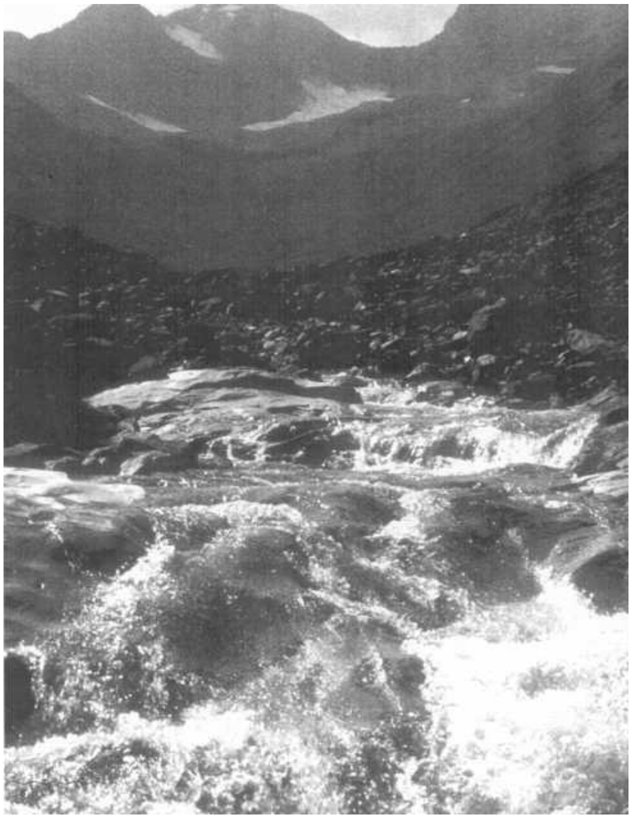

Figure 1. Waterscapes p. 8 edited by Herbert Dreiseitl, Dieter Grau, and Karl H.C. Luduig, 2001, Birkhauser, Switzerland.

In *Water, The Element of Life*, Schwenk develops a picture.

> Water as mediator between the centric (earthly) and the universal forces, setting them in balance and interweaving them with its very substance, reveals the activity of the heavens on earth. It is the port of entry through which cosmic-peripheral forces pass into the earth realm, directing the shaping, 'formative forces', organizing and patterning organic forms (Fig. 1).
>
> Renouncing any form of its own, it becomes the creative matrix for form in everything else.
>
> Contemplating this vast living organism, Earth, one's attention is drawn again and again to the layer-structure of its great enveloping mantles and to the rhythms that play in and through them.
>
> A glance at the surface configuration of the earth reminds us that 71% of it is covered by water. This watery surface in its immense extension provides a plane of contact with the atmosphere. . .where it works as the great regulator in matters of climate, meteorological processes and their rhythms.

Water's ability to regulate the climate is due to its thermal properties, in its tremendous capacity for storing warmth. . .evident too, in the origin of ocean currents and biological processes.

> Water's ability to absorb gases allows life on continents to come together with deep seas and thus these seas become great regulators of the respiratory processes of earth. In autumn, the plant world withers away and no longer inhales carbon dioxide and in the breaking down processes of plant substance, in the disintegrating foliage, much carbon dioxide is released into the air and is absorbed by the seas. When, however, in spring, the plant world grows anew and forms the substance for its foliage out of the carbon dioxide in the air, the waters of the earth once again release some of the necessary carbon dioxide. By absorbing carbon dioxide, it increases its ability to dissolve solid substance.
>
> Almost every property of water shows itself, in its relationship to warmth, as maximally suited to support the life of earth and its inhabitants. In this vein, water is unequaled, as L.J. Henderson has shown; the temperature anomaly, as a result of which water reaches its greatest density at +4 °C and grows lighter again at the freezing point, is the reason solid ice does not sink, rather floats, thus keeping earth from becoming a totally lifeless block of ice (3).

"Water is an element that brings a state of balance everywhere. Rhythm is its life element and the more it can be active rhythmically, the more it remains alive in its innermost nature" (4).

Linking similarities between water and thinking, Schwenk offers,

> The capacity of water in the realm of substances to dissolve and bind together, reappears in thinking as a spiritual activity.
>
> Like water, thought can create forms, can unite and relate the forms to one another as ideas. We speak of a capacity to think fluently when someone is skillfully able to carry out creation of form in thought, harmoniously coordinating the stream of thoughts and progressing from one idea to another.
>
> In thinking there prevails the etheric life of the water forces; through water flows the wisdom of the universe. Is it not this wisdom itself which has created the element of water, a tool for its own activity.
>
> Everything in Nature forms one indivisible fabric woven of living interchange. An all encompassing world of life comes into being from the interplay of cosmic-peripheral forces, meteorological forces, forces of the elements, the earth and all its living organisms (5).

Viktor Schauberger was a pioneering Austrian forester and brilliant inventor (1885–1958). His inventions were linked to water supply, natural river regulation, agriculture, propulsion and energy generation. They were all based on his observations of an underlying principle governing all natural processes, implosion.

> Implosion is an inward, curving (centripetal) suctional motion which follows a spiraling, whirling path as a vortex. Modern technology is primarily based on explosion, that is the outward moving, centrifugal motion of heating, burning, pushing or exploding. Inefficient, most of the energy is lost during an explosive process through frictional resistance, which produces useless waste heat. A characteristic feature of the life-generating vortex, is that the outside moves slowly, while the inside moves rapidly. As water is imploded in a vortex, suspended particles, which are denser than water, are sucked into the center of flow, so the frictional resistance is reduced and the speed of flow increased (6).

In 1961, Theodor Schwenk joined with George Adams, a mathematician, who for decades, with the assistance of Olive Whicher, had been researching projective geometry connected with organic forms, to found the Institute of Flow Sciences in the Black Forest in southern Germany. Just then his classic book on water, *Sensitive Chaos*, was published. Describing his experiences in seas worldwide, Jacques Cousteau wrote in the Preface,... "all around us there arose from the living sea a hymn to the 'sensitive chaos.' These memories have now taken for me a new meaning suggested by the book of Theodor Schwenk" (Fig. 2).

John Wilkes, a sculptor, had also joined the staff and was responsible for technical production of geometric models. In l970, Wilkes, now at Emerson College in Sussex, England, began developing the Flowform Method and founded the Flow Design Research Group, currently based at the Virbela Rhythm Research Institute at Emerson College.

Concerned with enhancing water's quality, he posed his initial question, "can we create a form for water that will enable it to manifest its potential for metamorphosis and order?"

> This was inspired by observing controlled experiments revealing paths of vortices in contrast to the complexity of water movements in outer nature. Streaming water generates asymmetrical forms, but studying the results of living processes, it became clear that these forms tend strongly toward symmetry. Such forms have to do with thrust processes. Wilkes created simple symmetrical channels with mirrored meandering walls and changing proportions. He was looking at symmetry in this moment as of a higher order, with the idea of lifting water towards the living. The fortuitous event

Figure 2. Tentacles of the sea curl inland, eroding the Dutch coastline along the Waddenzee. In this view from 14,000′, a very low tide has revealed pale plains of mud and sand, giving the tidelands the look of a river delta. The darker veins are channels cut deep by the land-stealing sea; when the tide is high, they serve fisherman as navigation lanes (5).

> of proportion variation led to pulsing process in one particular place. This opened up for him a wide spectrum of investigation which led to the Flowform Method.
>
> Water's capacity to support life is actually related to its ability to move within itself...to generate membranes (surfaces) within its own volume. These form sensitive 'organs' through which water mediates between individual organisms and its total surroundings, carrying information. Movement, especially vortical movement, sensitizes water to this task (Fig. 3).
>
> The Flowform is a vessel, generally ovoid in shape, with a narrow entrance and exit, which create a resistance, inducing an oscillating figure of eight (lemniscate) movement. Flowing into alternate sides, whorls or vortices form, folding the water upon itself, oxygenating, enlivening the inner mobility of its many surfaces, the basis of its vitality, its freshness. Oxygenation fosters biological processes necessary to effect purification. The frequency of the rhythm varies with the size of Flowform, while the character of movement depends on the shape (7).

Special restorative value derives from water features designed in water's own terms...shaped surfaces caressed intimately by flowing, pulsing water.

Since 1973, in England and in collaboration with associates worldwide, well over 1000 Flowform installations have spanned more than 30 countries.

Also at that time, Arne Klingborg, director of the Rudolf Steiner Seminariet in Jarna, Sweden, invited Wilkes to test the beautifying and ecological possibilities of Flowforms in a lagoon purification system. Three Flowform cascades are operating through seven ponds with progressive wetland ecosystems from an algae pool to reed bed. Wilkes tells us, "not only is the coliform bacterial concentration in the treated water significantly below official levels permissible for public swimming, but the entire site serves as a community park and bird sanctuary" (Fig. 4).

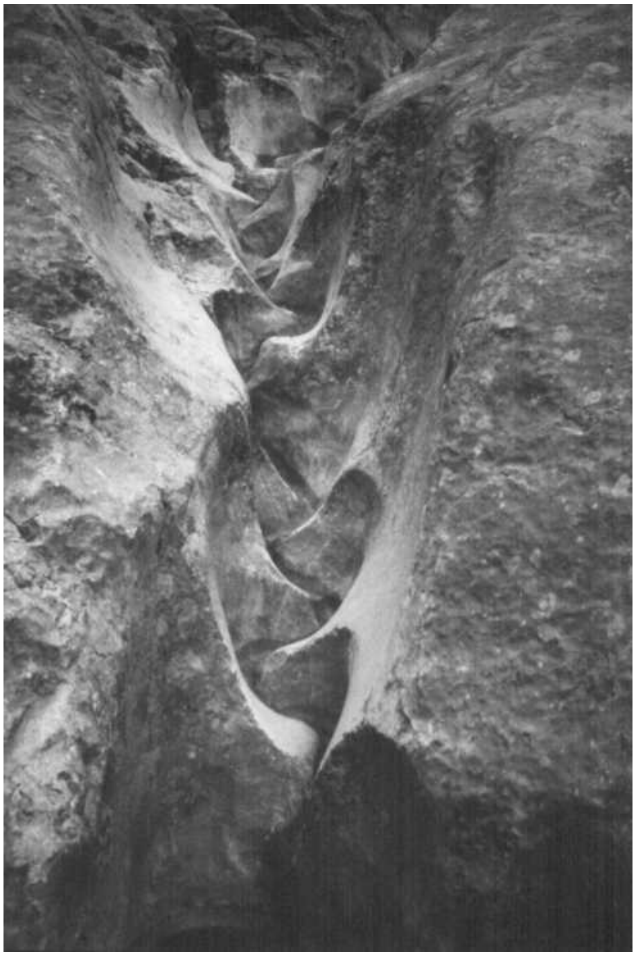

Figure 3. Such meander channels can be found below glaciers where streams have caused erosion over thousands of years. Photo supplied by John Wilkes.

Other applications of Flowforms include water purification, desalinated water treatment, stored-water treatment, swimming pools; air-conditioning and humidity; agricultural research centers, farms, homes, public gardens, parks and offices; aquaculture systems such as fish ladders for seasonally migrating species; pharmaceutics; and therapeutic and medicinal application.

In 1997, Flowforms America was founded. Its CEO, Sven Schunemann, worked with John Wilkes for a short period before this. Sven relates..."When water's movement is optimized for circularity, the liquid itself is able to be more effective as a natural element. Naturally flowing water is better aerated as more surface area is exposed."

John Wilkes added,

Figure 4. Malmö Flowform installed by a mountain stream at Sundet, Mösvatn, Norway. Water from the stream higher up is directed through the vessels which generate an ordered rhythmic swinging movement, like a living pulse, in contrast to the multitude of rhythmic movements in the streambed. If mounted below a hydroelectric turbine at a much larger scale, cast in situ, these more life-related rhythms, would improve the vital qualities of the water for irrigation, in a shorter distance! (11).

> It is necessary for Flowform creators to learn, in working with water's circular movements, to find the very special proportions which will finally generate pulsing processes.
> "Naturally flowing water is also more bioavailable...by allowing the nutrients it carries to be accessed more easily by plants. A plant, in turn, plays its part by taking nutrients out of such circulating water; thus fulfilling two roles, that of cleansing the water and of feeding itself" (8).

Wolfram Schwenk, a hydrobiologist and leading member of the Institute of Flow Sciences, writes about water and the creative process.

> If a creative artist wants to bring about cosmic and organic Flowforms in water, this cannot be done in the same way as a sculpture would be created. They can be evoked by handling water as an instrument. The creative process then takes place in the water itself. The artist learns how water twists and turns as it flows, eddies, trickles and spurts, surges, rests and reflects; enhancing and emphasizing by creative design, the theme develops as a joint work of art. Inspired, others may discover and experience special features of water. I know of no better, more attractive and sustainable ecological study course than this (9).

From his website, Herbert Dreiseitl informs, when referring to technology and infrastructure, of the lack of respect for the intrinsic aesthetics of water. He is actively participating in solving this dilemma.

During some months of 1978, he came to study the Flowform process with John Wilkes. In 1980, he established Atelier Dreiseitl in Uberlingen on Lake Constance in southern Germany. In his recently published book, *Waterscapes* (10), he writes, "to do justice to water, we have to go into the waterworld ourselves and experiment with it and learn to think in an integrated and interdisciplinary manner, about its flow and flexibility."

With regard to integrated planning, he states,

> water always creates a relationship between the detail and the whole. Each individual drop contributes to the balance of the earth's climate. Water projects become valuable when they help this process and can show that the place is being addressed and how it is connected with the world around it (10).

Further, he brings attention " to the special inner flexibility necessary to work with water successfully. The designs improve gradually and start to carry the signature of the water itself" (10).

Over the years, Atelier Dreiseitl has had opportunity through the scope of its commissions, which range from open-space planning in parks, water playgrounds, town squares to housing developments and urban hydrology, of linking water art to other complex themes, such as rainwater and surface water management, restoration and creation of waterbodies, incorporating Flowforms, storage and circulation cisterns, light and sound technologies, inlaid waterworks, and air-conditioning systems. Herbert relates, "demonstrating sustainable environmental technologies succeeds when everyone involved in the planning process, really does use interdisciplinary practices" (10) (Fig. 5).

Again, from his beautifully presented website, "water resources can only become sustainable when social values grant water the necessary priority. Water deserves everyones awareness" (10).

John Wilkes' new book, *Flowforms*, *The Rhythmic Power of Water*, is now available through Steiner Books (11).

Through our inventive, progressive and collaborative efforts, demonstrated and practiced with care, in our art and technology, may we allow water to be vigorous and free to the depths of its innermost nature.

> Choose to be changed. Oh be infused with the rapture of a fire that shows not what's changing in it as it burns for the

Sidebars

1. Why does water rise to such great heights in mountain springs or artesian wells?
   Artesian springs come bubbling up vertically out of the ground. The source of the water comes welling up in pulses from the center of a column. . .this movement is similar to a telescopic extension.
   We can observe that in every stream, the water at the edges flow more slowly than in the middle, where the water is colder. . .faster layers flow past slower layers. . .building layer upon layer and creating extensive inner surfaces. These layers have different temperatures and densities. The inside layer is most dense, coolest and has the highest electrical potential, resulting in increased centripetal, spiraling motion. The outside layers warm up and expand in that warming up.
   Within a closed channel, i.e., underground, the outer layers exert pressure on the inside layers. . .tension builds from the temperature difference of the layers, disturbing the equilibrium inviting water to move! Just as a plum seed is shot forward from its fruit if you squeeze it. . .the denser body shoots forward as relief from pressure. Water always seeks the path of least resistance (adapted from Reference 13).
2. The vortex with its different speeds, is closely akin to the great movements of the planetary system. A given planet circles round the Sun as though in a vortex, in as much as it moves faster when near the Sun and slowly when further away. The vortex in its law of movement is thus a miniature image of the solar system and its planets.
   Also, if a very small floating object with a fixed pointer is allowed to circle in a vortex, the pointer always points in the direction in which it was originally placed, that is, it always remains parallel to itself!. . .it is always directed to the same point at infinity. This illustrates how a vortex is oriented, as though by invisible threads, with respect to the entire firmament of fixed stars (5, pp. 44–45).
3. Water as an information carrier.
   Various researchers such as Professor Benveniste, Dr. W. Ludwig (Treven and Talkenhammer, ed., Umweltmedizin Move-Verlag-Idstein, 1991), and Professor David Schweitzer have provided clear proof that water acts as a liquid tape recorder and is able to receive, store, and transmit electromagnetic vibrations. Because water molecules have positive and negative poles, they behave like little magnets. They attach themselves to their neighboring molecules and form clusters of several hundred molecules. These clusters are very sensitive structures and are impressionable by vibrational influences. This is what give water the ability to store information.
   This is closely linked to homeopathy, where a substance is diluted so many times, that eventually there is no molecule of the original substance left. . .yet it still has an effect. Homeopathy works because of the cluster ability to store vibrational imprints.
   Every substance and element has its own individual vibrational pattern, a bit like an energy blueprint. If you carry out the homeopathic process of diluting and succussing, the vibrational pattern of the remedy material becomes locked into the cluster structure of the carrier water. When you take this homeopathically prepared remedy, the cluster structure is transferred into the body and you react to the vibrational pattern of the original substance from which the remedy was prepared (14).

THE MEDICINAL PROPERTIES OF THE WATERS OF SARATOGA SPRINGS

A. Trent Millet
Newark, Vermont

My personal experience with American waters led me to investigate the widespread use of water for medical purposes in Europe, the United States, and other countries using Western medical systems similar or identical to our own.

It is important to note initially, however, that a number of Europe's great medical universities were established on or around waters that for centuries have been known to have medicinal properties. The European health systems and insurance companies have a long-standing practice of sending their clientele to spa for three weeks a year, both prescriptively as a treatment and as a preventive medium. The most commonly stated reason, throughout countries such as France, Poland, Germany, Czechoslovakia, the former USSR, and Hungary, is an expected ten to fifteen year increase in vital life expectancy: "vital" meaning not only the possible increase of number of years alive, but also, most importantly, the number of years individuals continue to be active and contributing members of society.

Czechoslovakia, Hungary, and Germany as of the late 1950s and early 1960s all had over 300 state-run spas. The former USSR had over 3500 (1). At that time in Europe alone, over 3,700,000 people per year were attending spas.

Ninety percent of patients sent to Bad Neuenahr are directed there by their own doctors (Ref. 1, p. 506) 50% of patients there suffering from diabetes. Health insurance companies, physicians representing those companies, social security agencies, unions, and corporations and municipal governments refer 50% of those sent to Bad Hall (Ref. 1, p. 507). "Thus, the state insurance fund of Hungary declared that its computed outlay for therapy and compensation in the rheumatoid group of diseases diminished 23% percent by the use of spa therapy" (Ref. 1, p. 507).

Of 2 million people sent to German spas by insurance companies, 25% suffered from rheumatism, 21% from diseases of the heart and blood vessels, 21% from respiratory diseases, 12% from digestive track disorders, and 8% from conditions causing exhaustion (Ref. 1, p. 507). Similar statistics continue in present-day Europe (A. Trent Miller, personal observation).

I began investigating the reported healing properties and medical use of American waters in 1998. A large number of American waters were used medicinally up until the 1960s. I concentrated my research around the Saratoga, New York area due to the well cataloged medicinal and historic use of Saratoga's many waters.

The anecdotal evidence, personal interviews, and personal experience lie outside the scope of this work. We are concerned here with patient statistics, prescriptive use, and the qualitative medical properties of Saratoga's spa waters.

People have been coming to use the waters for health since the 1700s. The 300-year use of Saratoga's waters for healing reached its pinnacle with the building of Sartoga's Roosevelt Spa by President Franklin D. Roosevelt in the 1930s. The famous Lincoln and Washington Baths had already been operating for almost half a century with 107,299 treatments given by the two combined baths in 1927 (2). By 1930, Lincoln Bath had the ability to give 4500 treatments a day.

Roosevelt Spa and the surrounding Saratoga State Park contained bathhouses, a drinking hall, inhalation rooms, and a bottling plant. Saratoga had always been known for its multitude of drinking halls, several bottling plants, and large number of bathhouses. Due to the fact that Roosevelt Spa was under the direction of three eminent doctors, Simon Baruch, MD, Walter S. McClellan, MD, and Oskar Baudisch, Ph.D., who directed the Research Lab, a great deal of the medical evidence, studies, and resulting statistics exist today. Hence my focus on Roosevelt Spa. By the 1930s only 18 of Saratoga's original 145 waters remained available for medicinal and public use. (About 127 springs were shut down because of the exhaustive pumping of carbon dioxide for use in the increasingly popular soda fountains, lowering the water level of the entire area.) The spa waters were commonly used in conjunction with other treatments, such as electrotherapy, ultraviolet and interred therapy, massage, and standard allopathic medicines. Because of this, statistics pertaining to the results of water treatments alone are difficult to find. Of the comprehensive number of waters, we will be looking at the treatment rationale of several. Table 1 defines the specific, subtle, and very individual ingredients contained in 17 of the 70 plus waters once available (3).

In consideration of this, the following is an example of how doctors used the waters prescriptively. "The choice of springs should be guided by the nature of the local manifestations, and the preponderance of constitutional plethora or anemia. For the uncomplicated dyscrasia, notably alkaline waters, with comparatively slight saline admixture—such as the Kissengen and Vichy—may answer well. With abdominal torpidity, a greater proportion of chloride of sodium is indicated, and then the Patterson, Hathorn, Congress or Excelsior may be recommended; or, if plethoric engorgement, is still more conspicuous, the powerfully saline Carlsbad, Champion or Geyser. In atonic cases, with well marked debility, often resulting from repeated attacks, or too prolonged depressing treatment, the saline-chalybeates may prove most beneficial."

Of the springs mentioned above, only Hathorn, Congress, and Geyser still flow. The spring called "Old Red," which is an iron water, has been used for all kinds of eruptive skin diseases and inflammation of the eyes. Dr. Oskar Baudisch, an authority on magnetochemistry, worked on the iron molecule. "In the course of his research he investigated the iron contained in Saratoga mineral water. He demonstrated that the iron contained in the water in spite of the relatively small amount in solution exceeded much larger amounts in therapeutic value as a remedy for anemia. This effect he showed to be due to the fact that the peculiar internal structure of the specific iron molecule contained in the water was similar to that of the iron molecule contained in the hemoglobin of blood. For this reason the iron in the water can be readily assimilated in the body and is, therefore, more readily available to the body than are other forms of iron" (Ref. 2, p. 37).

In the case of Old Red mentioned above, the water also contains two human cell salts (2). It is explained by Dr. Grace Swagger in a video interview contained in "Spa City, The History of Saratoga Spas," that the iron and cell salts were originally dissolved from the flesh of dinosaurs, animals, and plants. Kenneth Cohen, in his book *Honoring the Medicine* (4), backs this up with a statement that "the

same water that flowed through the bodies of the dinosaurs has been recycled for millions of years to flow through our own bodies today."

Hathorn Spring, a saline–alkaline carbon dioxide charged water (which has a taste similar to the commercial product Alka Seltzer) has been used for stomach and digestive problems for over a century. Hathorn water was listed as one of the four most important medicinal waters bottled in Saratoga. Apparently, the very specific type of minerals and their very refined particle size and frequency allow absorption into the system regardless of the patient's age. Hence, having the proper mineralization to interact with vitamins allows continued enzyme production throughout a person's life. The common belief that people approaching a half century or more cease to make digestive enzymes is not the case when ingesting this type of water.

One of the waters considered the most important is the carbon dioxide water. The CO_2 water of the Lincoln group of wells at Saratoga is considered to have the highest content of carbon dioxide in the world. Its most common use is in the treatment of heart-related ailments. "The natural CO_2 is considered to have special merit in the treatment of the cardiac patient because of its unique ability to cause vasodilatation of the cutaneous blood vessels without any increase in the work of the heart, such as would occur in a warm bath causing an equal vasodilatation. On the contrary, the CO_2 bath reduces the work of the heart. Though administered at a neutral temperature, the CO_2 bath gives the sensation of warmth because of the layer of insulating gas bubbles next to the skin. It has been found that the carbonic acid dissolved in a natural CO_2 bath diffuses through the skin at a rate of about 30 mL per minute. The hyperemia is due to released histamine and acetylcholine. As a result, the pressure in the afferent capillary loop is increased about four times; the venous capillary pressure increases; the deep venous plexuses of the skin are emptied; and the increased vascularity of the skin drains the splanchnic pool. The diastolic pressure and the heart rate are lowered. In addition, the hydrostatic pressure exerted by the bath improves the venous return flow through compression of the lymph channels and veins (5).

Although Saratoga utilized the CO_2 waters for heart ailments, it was largely in conjunction with other medical treatments. There are no records detailing patient results from just the CO_2 water treatments alone. However, Tables 2–7 show the use of the water by disease classification and the patient results, illustrating the effectiveness in diseases other than the heart.

Table 3 shows the distribution of all the patients in this group on the basis of the usual classification of rheumatic diseases. The largest group was diagnosed as osteoarthritis in its various forms and included 438 of the patients treated. Rheumatoid arthritis was second on the list with a total of 331 patients, nearly all of whom were classified as chronic. The remainder of the patients represented smaller groups as indicated in the table. From the study of this table it is clear that the two large groups of patients with osteoarthritis and rheumatoid arthritis accounted for a large majority of the patients.

The results of treatment recorded by the hospital physicians on discharge have been tabulated for each of the groups of rheumatic disease in Table 4. They show that 262 patients or 26.3% were slightly improved, 568 patients or 57.2% were moderately improved, and 86 patients or 8.7% were markedly improved. This gives a total improvement of 92.2%. Only 77 patients or 7.8% were unimproved or were transferred for other treatment. No deaths occurred in the series.

It is obvious immediately that any statistical analysis dealing with the number of patients treated in groups 3 to 8 would have little value. Because of the larger number of

[a] Total percent of improvement is 93.1%.

patients with osteoarthritis and with rheumatoid arthritis, a more detailed study was made.

In another series of observations, McClellan and Comstock found that radon added to the bath was also absorbed through the skin, both from baths of plain water and, to a greater degree, from baths in the naturally carbonated mineral water. Both carbon dioxide and radon are important substances in many spas about the world. The demonstration that they are actually absorbed from the water of the bath supports the conclusion that the absorbed carbon dioxide or radon plays a role in the physiologic changes observed.

Table 5 presents the results of treatment for patients with osteoarthritis analyzed in relation to the total amount of treatment received. The total amount of treatment was gauged by the number of mineral water baths, because for practically all patients it represented the major feature of the program. Even with 10 baths or less, some patients showed improvement, but the proportion of those who were not improved was much higher than in the other groups. When the patients received 11–21 baths, there was some increase in the percentage of patients who obtained benefit. When the baths were continued longer, over 21 in number, there was considerable increase in those who showed moderate improvement. When the treatment program extended beyond what is usually considered two average courses of treatment, little additional benefit was evident.

It is interesting to note that the variation of improvement was essentially in keeping with the figures, noted in the larger groups of patients. With the variety of conditions in the remaining 20% of the patients, it was impossible to apply this detailed analysis because of the relatively small numbers.

Moving southwest 45 miles west of Albany is Sharon Springs, New York. Although now open only a few weeks per year, at one time the sulfur magnesium and calcium waters were waters utilized in over 82,000 treatments a year during the 12-week season. After WWII and up to the present day, many of the victims of the German concentration camps, predominantly Hasidic Jews, and currently the Russian victims of similar camps use the water of Sharon Springs for recovery and rejuvenation. Most are paid for by the medical services of their countries of origin. The sulfur water is particularly beneficial for rheumatoid and osteoarthritis, skin problems, and general revitalization of the body.

It is common to find calcium and magnesium waters in close proximity to the sulfur springs. The calcium–magnesium balance is one of the most important balances in the body, along with the sodium chloride and acid alkalinity (pH, also adjustable with the use of water). The type of magnesium and calcium found in the water is ideally suited to the human body. Several qualified sources (6) have stated that the use of natural calcium and magnesium water maintains that ratio at ideal levels.

In closing, although this entry is certainly not a complete and comprehensive discussion of all the medicinal uses and statistics, it is an example of water's inherent natural medicinal qualities.

A HISTORY OF HAWAIIAN FRESHWATER RESOURCES

M. Eric Benbow
Mollie D. McIntosh
Michigan State University
East Lansing, Michigan

Albert J. Burky
University of Dayton
Dayton, Ohio

INTRODUCTION

The present economy of the Hawaiian Islands is primarily dependent on tourism. Visitors spend millions of dollars at hotels, in shopping malls and shops, at restaurants, and travel to and from islands. This money provides the economic foundation for many local Hawaiian families, and it serves to drive the state's economy. However, the economy has not always been based on tourism, but rather on the agricultural strength of sugar cane from the late nineteenth century through most of the twentieth century. Historically, the rise of agriculture was based on freshwater, the resource that drives tourism and expanding commercial development today. However, the surface waters and aquifers are limited, and a balanced concern exists for the effects of continued freshwater withdrawal from these sources. In particular, the streams of Hawaii are home to many endemic organisms (found only in Hawaii) that are threatened by continued surface water withdrawal. Many of the aquifers are being overpumped, increasing the salinity of groundwater resources and sometimes influencing surface flows.

For this topic, we provide a brief historical description of the geological origin and predominate climate patterns of the Hawaiian Islands, an introduction to endemism and the freshwater ecosystems, early Hawaiian cultural use and contemporary freshwater management, the expansion of sugar cane as a catalyst for freshwater exploitation, the cultural consequences of sugar cane expansion, and existing political struggles. We conclude with a short discussion about the future of Hawaiian freshwater resources, one of delicate balance and immediate concern.

GEOLOGICAL ORIGIN

The Hawaiian Islands have grown from a permanent "hot spot" located at an unknown depth beneath the Pacific Ocean seafloor. As it has been difficult to determine detailed information on this hot spot, the geological formation of Hawaii remains partly theory (1). The hot spot is a huge lake of melted rock under tremendous pressure in the Earth's mantle where molten rock erupts, accumulates on the ocean floor, and finally emerges from the ocean surface after millions of years (2). The hot spot is believed to remain stationary, but the outer crustal plate has been shifting (1). The shifting plates, timing of eruptions, and sea level changes have resulted in a chain of submerged and remnant volcanic islands to the northwest (Emperor Seamount Chain) of Midway Atoll, and the existing main Hawaiian Islands to the southeast (2).

The largest Hawaiian Islands are the most recently formed. The two oldest are Kauai and Niihau, with Oahu and the islands of Maui Nui (Maui, Molokai, Lanai, and Kahoolawe) sequentially younger moving southeast, and the appropriately named Big Island (or Hawaii) that is volcanically active (Fig. 1) (3,4). A new island about 1000 m (called Loihi) below the ocean surface is developing off the southern coast of the Big Island (5). As one travels from the northwest to the southeast, the existing islands become younger, larger, taller, and less eroded.

CLIMATE PATTERNS

Remotely located in the Pacific Ocean, the climate and precipitation patterns of Hawaii are dependent on predominant wind patterns and ocean currents. The Trade Winds (Prevailing Westerly Winds) blow across the Hawaiian Islands in a northeasterly to southwesterly direction, with stronger intensity occurring during the drier summer months (Fig. 1) (6). As these winds move across the ocean collecting water vapor, they move up, around, and sometimes over the mountains. As the air moves to higher altitudes, it cools, clouds form, and it rains, causing a rain shadow effect responsible for perennially wet northeastern shores (windward) opposite dry southwestern shores (leeward) (6). High rainfall, lush tropical rainforest vegetation, rushing streams, and abundant cascades and waterfalls characterize the windward sides, whereas the leeward sides have little rainfall and desert lands of dry-tolerant shrubs and cacti. The spatial distribution of precipitation combined with steep elevational gradients and ocean currents create climate patterns conducive for biome and ecosystem variety in a relatively small geographical area, ecosystems where many organisms evolved and are found nowhere else on Earth.

HAWAIIAN ECOSYSTEMS AND ENDEMISM

The variety of ecosystems and biomes in Hawaii area a result of five general characteristics: (a) geographic

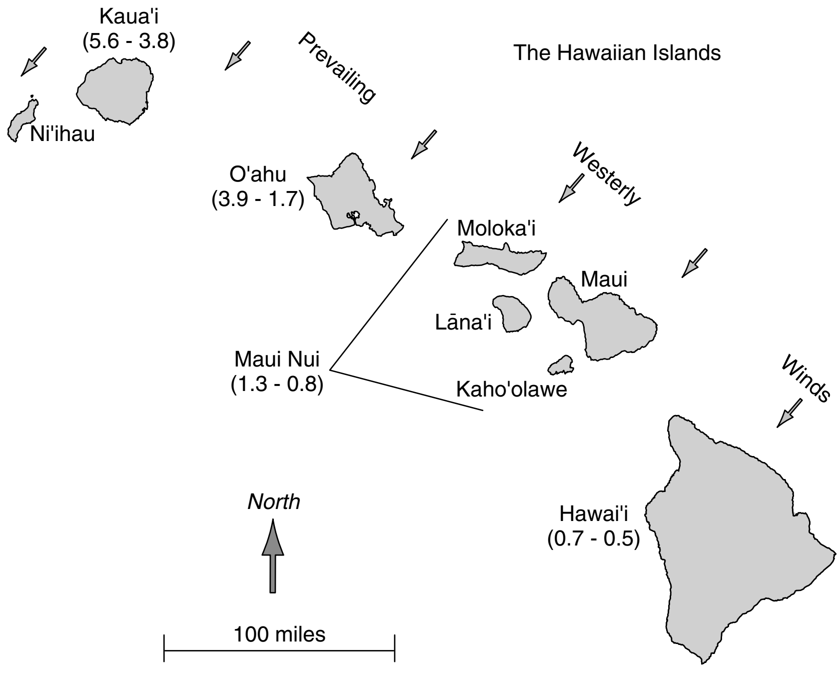

Figure 1. A map of the main Hawaiian Islands. Approximate island (or island group) ages are given in parentheses below the island name. Island ages are in millions of years and were estimated from two sources (3,4). Maui, Moloka'i, Lana'i, and Kaho'olawe were once a single island called Maui Nui until about 0.4–0.3 million years ago.

isolation, (b) small relative size and area, (c) recent age, (d) unique evolution, and (e) climate patterns (7). The Hawaiian Islands are some of the most isolated land masses in the world, which kept original immigrant species dispersal minimal (8). Relatively few species became established, but those that did underwent rapid speciation in the absence of many variables typical of mainland ecosystems (7). For example, some birds and many insects are flightless in response to evolving in predator absence (8). Many species never evolved effective defenses against predators or aggressive alien competitors, making the endemic flora and fauna easy prey, or out competed by introduced species that evolved with aggressive predators and competitors. Hawaii has approximately 10,000–15,000 endemic and indigenous species with over 30% of the total threatened or endangered species in the United States (4,7). In light of this, appropriate conservation, preservation, and management are needed to protect these rare habitats and endemic communities. The freshwater communities are threatened by continued and expanding riparian (land adjacent to a stream or river) habitat destruction, surface water removal, and introduced and invasive species.

HAWAIIAN STREAM ANIMAL COMMUNITIES

Hawaiian streams respond to unpredictable rainfall events that determine flow volume changes over short- and long-term time periods. The geology is commonly porous and precipitation quickly saturates riparian soils, creating rapid and high-volume surface runoff. Flash floods are common throughout the year. The local name for a flood is “freshet”, indicative of the historical description, and contemporary observations of scoured and rearranged stream channels moved by tremendous hydrodynamic forces. It is thought that many Hawaiian stream organisms have evolved specialized life cycles (e.g., amphidromy, see below) to accommodate these unpredictable and frequently extreme events (9–11).

AMPHIDROMY

The native Hawaiian fish, shrimp, prawn, and snail species have a diadromous life cycle, meaning they migrate between freshwater and seawater (1). These native species are amphidromous, a subcategory of diadromy (Fig. 2) (12,13). Adults reproduce in streams, eggs hatch, and embryos (now called larvae) drift to the ocean for growth and development into postlarvae (from 10–30 mm body length) over several months (14–16), and then migrate back into the streams. In amphidromy, the purpose of migration is not for immediate breeding as in diadromy (e.g., salmon); instead, postlarvae, not adults, migrate into freshwater to feed, grow, and remain for the rest of their existence through multiple reproductive events (12,17,18).

There are four endemic and one indigenous amphidromous fish species in Hawaiian streams (Table 1) (16,19,20). The pelvic fins of the gobies are fused and form a ventral sucker used to cling to rocks and climb waterfalls as postlarvae and early juveniles (16,21). One fish species has been reported to climb single waterfalls >100 m high and combined waterfalls totaling a height of 300 m (19). The native shrimp, snails, and prawns (Table 1) also have the ability to climb waterfalls (20). Postlarval migration has been found to be directly related to stream discharge (22,23).

OTHER ENDEMIC STREAM ANIMALS

The native stream organisms have closely related marine relatives, and it is evident that the freshwater species

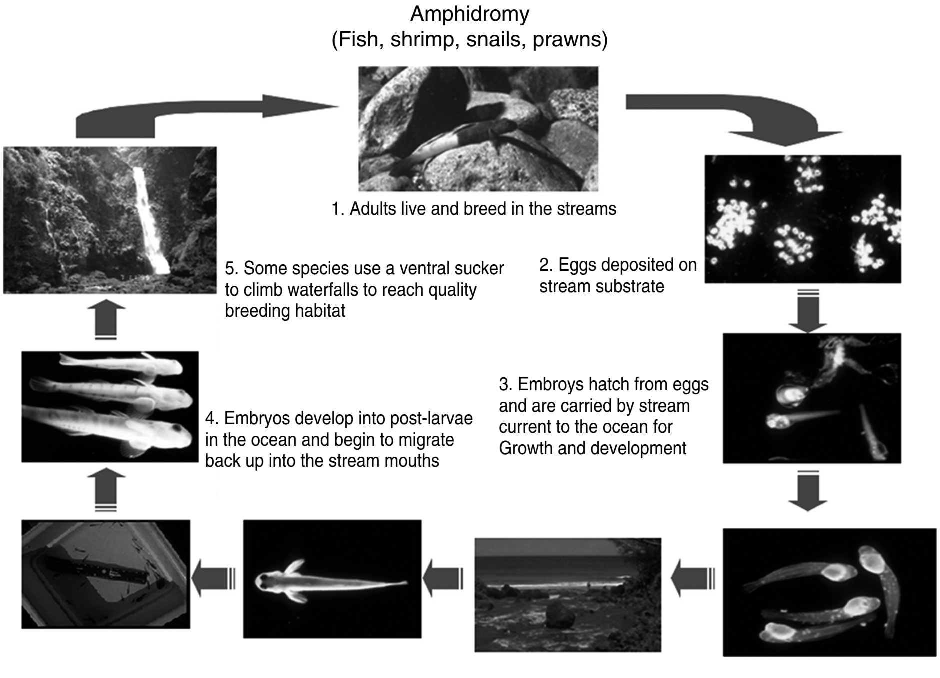

Figure 2. A schematic depicting the amphidromous life cycle of the native fish, snails, shrimp, and prawns found in Hawaiian streams. The life cycle requires postlarval development in the ocean and a migration back into the streams that is not immediately for breeding.

Table 1. The Freshwater Animals of Hawaiian Streams Including the Common Name, Scientific Name, Hawaiian Name, and Geographic Range

Taxa Type	Common Name	Scientific Name	Hawaiian Name	Range
Fish	general term for freshwater fishes		‘o’opu	
	freshwater amphidromous gobies	*Lentipes concolor*	‘o’opu ’alamo’o ‘o’opu hi’u kole ‘o’opu hi‘u’ula ‘o’opu nu’ukole	endemic
		Sicyopterus stimpsoni	‘o’opu nopili	endemic
		Awaous guamensis	‘o’opu nakea	indigenous
		Stenogobius hawaiiensis	‘o’opu naniha	endemic
	freshwater amphidromous eleotrid	*Eleotris sandwicensis*	‘o’opu ’akupa	endemic
	euryhaline-Hawaiian flag-tail fish	*Kuhlia sandvicensis*	aholehole	endemic
	euryhaline-striped or gray mullet	*Mugil cephalus*	‘ama’ama	worldwide
Snails	freshwater amphidromous snail	*Neritina granosa*	hihiwai wi	endemic
	estuarine amphidromous snail	*Neritina vespertina*	hapawai hapakai	endemic
	brackish/marine neritid snail	*Theodoxus cariosus*	pipiwai	endemic
	lymnaeid snails	*Erinna newcombi*	*	endemic
Sponge	freshwater sponge	*Heteromyenia baileyi*	*	indigenous
Crustaceans	general term for freshwater shrimp		’opae	
	freshwater, mountain srhimp	*Atyoida bisulcata*	’opaekala’ole ’opae kuahiwi ’opae kolo	endemic
	freshwater prawn	*Macrobrachium grandimanus*	’opae ’oeha’a	endemic
	anchialine pond shrimp	*Halocaridina rubra*	’opae ’ula	endemic
Insects	adult dragonfly	*Anas* spp.	pinao	endemic
	adult damselfly	*Megalagrion* spp.	pinao ’ula	endemic
	immature dragonfly or damselfly	*Megalagrion & Anax* spp.	lohelohe	endemic
	immature dragonfly or damselfly	*Megalagrion & Anax* spp.	lohaloha	endemic

	immature dragonfly or damselfly	*Megalagrion & Anax* spp.	’olopelope	endemic
	many other endemic insects	various species	*	endemic

*Indicates that a Hawaiian name is not available.

evolved from marine habitats (Table 1) (10,16,24,25). Some examples of this can be found in stream insect communities consisting of midges, *Telmatogeton* (Chironomidae); beach flies, *Procanace* (Canacidae); and shore flies, *Scatella* (Ephydridae), which are thought to have radiated into streams from ancestral intertidal habitats (26–28). The Hawaiian *Telmatogeton* complex is unique with all five endemic species restricted to freshwater, the only representatives of an exclusively marine intertidal subfamily worldwide (26–29).

Another important insect group is the endemic damselflies of the *Megalagrion* complex. This genus has shown rapid speciation in concert with specific freshwater and terrestrial habitats (30–32). Contrary to many other aquatic insects of Hawaii, the endemic damselflies are thought to have evolved from one freshwater ancestor to Hawaii (31,32). As a result of recent extinctions, numerous research initiatives have been carried out to understand the evolution, biology, and conservation of this unique group of insects (31,32). Other freshwater organisms are reported in Table 1.

SURFACE WATER REMOVAL

The streams of Hawaii are habitat to relatively recently evolved communities with close marine ancestors (e.g., fish, snails, shrimp, and some insects) and/or isolated populations that have undergone rapid speciation (e.g., the damselflies). For millennia, these systems connected the mountains to the ocean along what is called in Hawaiian the mauka—makai continuum. The physical connection was the flowing streams supporting the biological connections of the amphidromous species. However, many streams were heavily diverted in the late 1800s for irrigating an expanding sugar cane industry. Stream flow removal and riparian degradation has had the following effects: (a) destroying and eliminating breeding habitat for all stream animals, (b) preventing amphidromous egg and larval drift to the ocean, (c) obstructing postlarval recruitment back into the streams, and (d) facilitating invasive species establishment (9,22,33–35). Water is a critical and limited resource, not only to humans but also to the native stream organisms. Balancing these will take compromise and scientifically based freshwater resource management.

FRESHWATER RESOURCE USE AND MANAGEMENT

Historic Management

The ahupua’a system was the first freshwater management system in Hawaii. Developed by the ali’i (chiefs) of the first Hawaiians 1500–1600 years ago, it maintained adequate freshwater resources for the entire population of each island. The ahupua'a was what now is considered a watershed and extended from the headwater springs into the ocean. Along this mauka—makai continuum, the land along the stream was divided into pie-like slices called 'ili kuponos, that were designated to maka'ainana (commoners) and overseen by a chief-appointed konohiki. The commoners did not own the land or water, for they only maintained them for the chiefs. Each konohiki was appointed to a single ahupua'a, and each 'ili kupono was divided into kalo lo'i (taro patches). Stream water was diverted by pani wai (diversions) and carried through small 'auwai (ditches) to the lo'i. The lo'i were connected in a stair-step manner by additional ditches maintained by the responsible commoners. If the ditches were not maintained upstream, all downstream lo'i would be affected. Contrary to contemporary freshwater management, the stream water was always returned to the stream before it entered the ocean, and was never carried out of the watershed. Therefore, the water continually connected the highest mountain reaches to the lowland settlements near the sea, maintaining the mauka—makai continuum.

The early Hawaiians understood the connectivity of the land, freshwater, and sea. The ahupua'a system maintained adequate freshwater resources for human use while balancing ecological function. Hawaiians also understood the power and importance of water to their culture. For example, the Hawaiian word for water, wai, is the root for wealth (waiwai) and law (kanawai) (36). Over the next 60 years, native Hawaiians would find just how important water could be to foreigners, or haoles—those without breathe, or mana (spirit). The sugar cane industry completely changed freshwater resource management: water would be removed from the ahupua'a, along with much of the native Hawaiian culture.

Contemporary Management

The influence of western missionaries and merchants shifted the Hawaiian perception of water from a shared resource to a commodity that provided maximum use and greatest reward to plantation owners (37). After the arrival of Captain James Cook in 1778, freshwater management changed little until the The Great Mahele of 1848, enacted by King Kamehameha III under heavy influence by the decedents of original missionaries, the new owners of the sugar cane industry (and pineapple later). The Great Mahele was the first act to privatize land and water in Hawaii. For nearly 25 years the kings of Hawaii attempted to negotiate reciprocity treaties with the United States In 1876, King Kalakaua finally established a reciprocity treaty assuring duty-free exchange between Hawaii and the United States, giving sugar companies a competitive edge in the world market and giving Pearl Harbor to the United States, which was the same year of the first water licenses, the creation of the first private water company, and the construction of the diversion-ditch systems, which relocated millions of gallons of water from the windward watersheds to leeward sugar cane fields. According to Wilcox (36), one pound of sugar takes approximately 4000 pounds, or 500 gallons, of water.

The growth of sugar cane and pineapple took over and "transformed Hawaii from a traditional, insular, agrarian, and debt-ridden society into a multicultural, cosmopolitan, and prosperous one" (36). During this time, the number of sugar plantations rose from 5 in 1857 to 90 in 1884 (36). From the late 1870s to the mid-1900s, the Hawaiian sugar cane industry continued to grow, in part because of political access to surface and groundwater resources. By the early 1900s, almost every stream on the windward sides of each island was at least partially diverted, and in 1920, the sugar cane industry was diverting >800 mgd and pumping an additional 400 mgd from aquifers (36). Almost 20 years later, the entire city of Boston was only consuming 80 mdg (36). The privately developed surface water of Hawaii was quite different from publicly controlled surface water development of the western United States, which put control of water into the hands of western businessmen, those who would eventually contribute to the overthrow of the last Hawaiian Monarchy. (Several books are available that describe the sequence of events that led to the overthrow (38–40).)

With the developing agricultural industry, the population and ethnic diversity expanded as well. A larger labor force was needed to construct the ditches and diversions and work the agricultural fields. For cheap labor, the agricultural companies looked to Japan, China, and other Asian nations. This immigration resulted in several ethnic populations living and working on plantation property, creating mixed nonHawaiian communities that are the roots of the ethnic diversity found in Hawaii today. As the population and successful industries increased, the popularity of the islands grew in the mid-1900s, whereas the sugar cane industry met fierce competition from other nations, and has resulted in the slow demise of the former economic strength. With the buildup and maintained military presence of Pearl Harber from World War II, the economic focus of Hawaii saw a change from agriculture to military establishment to tourism that is now the economic base of the state. Along the southwestern coast of each island, numerous hotels, shopping malls, golf courses, and restaurants have been developed because most people prefer to vacation on the sunny, dry side of the island. However, similar to the sugar cane scenario, water is not readily available on the leeward side. Therefore, water remains diverted from streams, or pumped from dwindling freshwater aquifers, in order to accommodate tourists, water the green lawns, and fill hotel swimming pools and spas.

A BRIEF INTRODUCTION TO HAWAIIAN WATER LAW

Water Rights

The expansion of the sugar industry resulted in many water disputes between sugar companies, various landowners, and native Hawaiians. These disputes helped recognize the following water rights: (a) appurtenant, (b) riparian, (c) prescriptive, and (d) surplus (41). Appurtenant rights developed from ancient rights and were officially declared in the earliest Hawaiian water case, Peck vs. Baily (1867). This case determined that if land was entitled by a landowner to cultivate taro, than some stream water was also. Riparian rights permit water use to those who own land next to a stream; however, use must be reasonable and not harmful to other landowners (42). In riparian law, the focus is on maintaining stream integrity while allowing landowner priority uses (e.g., domestic drinking and washing) over nonpriority uses (e.g., irrigation, mining) (41). Both appurtenant and riparian water rights consider water as a common good. Prescriptive and surplus water rights address private ownership of water sources.

Prescriptive water rights are granted if a party has proven using water "belonging" to another party for an extended and continuous period of time (e.g., 20 years) (37). Surplus water is defined as the amount of water in a stream not covered by any prior water right (37). In court, cases of surplus water were heard independently, which precluded the establishment of defined standards for future disputes. For example, in the case of Hawaiian Commercial & Sugar Co. v. Wailuku Sugar Co. (1904), the court ruled that surplus water traveling through an ahupua'a belonged to the private land owner, but in Carter v. Territory (1917), the court concluded that surplus water was to be used reasonably according to riparian principles, thus shared among landowners. The inconsistent rulings and absence of an established in-stream flow standard left the status of surplus waters questionable until the state code in 1987.

Summary of Case Law

From the 1850s to the 1980s, the water rights of Hawaii were evolving according to case law, yet no standard criteria for the allocation, transport, and quantity of freshwater was resolved. There were several political, economical, and social reasons for no established criteria. First, the rise of the sugar cane industry boosted the economy, and with it came political power to the foreign owners. Second, during this period, the Hawaiian Islands shifted from a monarchy to a republic to a U.S. Territory, and finally became a U.S. state, which created an atmosphere of economic and political change that left many native Hawaiians in a state of social and political confusion (36), where they did not resist changes in water law, as it was not in their culture to protest actions of the King. As a result of this, there was difficulty in establishing a cause-effect relationship, and many of the villages most affected were too small to fight the wealthy plantation owners (36,37).

In 1978, the Hawaii State Constitution mandated that a water code and commission be established to manage water resources. And in the late 1980s, a Hawaii State Water Code and the Commission on Water Resource Management was passed by the Hawaii State Legislature (37). The State Water Code became a regulatory mechanism for state agencies and counties and required the Commission to monitor and guide water allocation by establishing minimum in-stream flow standards that were to enhance, protect, and re-establish beneficial in-stream uses. Current trends have been developing during the 1990s that are testing the utility of the Hawaii State Water Code. The first of several cases, and a landmark case for future petitions, was the Waiahole Combined Contested Case Hearing. In this case, the Hawaii Supreme Court ruled for the establishment of minimum in-stream flow standards and than any additional flow secondarily allocated for other uses. In-stream flow standards are currently being investigated. The Waiahole Ditch Case was the first test of the State Water Code, yet many similar cases are being petitioned at the time of this writing. The diminishing sugar industry is opening a new chapter in Hawaiian case law, a chapter that must not only consider economics but also "traditional and customary Hawaiian rights, protection and procreation of fish and wildlife, ecological balance, scenic beauty, public recreation, beneficial in-stream uses, and public interest" (36).

SUMMARY AND SYNTHESIS

The history of Hawaiian water resource issues is complex. The system of surface water management went through a dramatic change with the explosion of agriculture and the associated political power of missionary descendents; however, this explosion was inherently dependent on privately developed surface waters—a feedback proliferation of each other. The surface water development from the late 1800s through the mid-1900s drained watersheds of both water and native Hawaiian culture. The efficient removal of water high in the watersheds left a trickle downstream for native taro farmers. With the construction of massive diversion-ditch systems, native Hawaiians emigrated from the ahupua'a to build ditches and work sugar cane fields. At the same time, thousands of immigrants from China, Japan, and the Philippines melted into the sugar cane plantation farms, changing the demographics of Hawaii. The push by sugar businessmen to get an extended reciprocity treaty secured rights of Pearl Harbor to the United States; it also led to the coup of the Hawaiian Monarchy. At the same time, streams were being impacted by water removal and rapid riparian destruction, negatively affecting the native biological communities of the mauka–makai continuum.

The degradation of stream habitats in Hawaii has become an increasingly important issue to many native Hawaiians, scientists, private organizations, and individuals. Water resources have been, and will continue to be, a highly debated political issue. Water is necessary for agricultural, industrial, and municipal uses throughout Hawaii; however, in order to maintain the unique biodiversity of the streams, a compromise must be made between continued development and conservation. Thus, the future of the Hawaii's freshwater ecosystems and economic security is dependent on wise freshwater management and allocation, which should not be made in a scientific vacuum. Objective and sustainable answers can only be achieved with a solid scientific base, one free from political bias that has been the history of Hawaiian freshwater resources.
