PREFACE

No natural molecule on the planet is more fascinating than water. It has unique properties ranging from the unusual angles formed between its two hydrogen ions and its single oxygen molecule, to the fact that unlike most substances, it expands when it freezes rather than shrinks and reaches a maximum density as a liquid 4°F above its freezing point. These and many other aspects of the special physics and chemistry are described in this volume, including the impact of a wide variety of chemicals occurring in water, osmosis, diffusion, hydration, isotope exchange, along with the fun physics of the mariotte bottle.

Equally fascinating are the many unusual physical and chemical encounters in both the ocean and the atmosphere. Although oceanography and meteorology are frequently considered separate sciences from hydrology, their limited inclusion in the *Water Encyclopedia* was deemed necessary to tell the complete story. Tidal changes, benthic nutrients, the sea floor, el nino, sea level, and ocean/climate relationships make up but a few of the oceans fascinating stories, whereas water spouts, hurricanes, monsoons, droughts, sublimation, and barometric efficiency just touch the tip of what this volume has in store in the area of meteorology.

But water has a wonderful human face as well. We have reached around the world to describe the history of water and its role in the development of civilizations and the many beliefs held about it. As society developed, the distribution of water needed supervision, which lead to a wide variety of water laws we have attempted to categorize and describe in an interesting and meaningful way.

We are equally proud of our open-minded effort to describe the role that water has played in art and culture. We have attempted not be judgmental, with stories of water forms and water intelligence along with some medical theories and, of course, the wonderful descriptions of early water clocks. This volume is a true intellectual cornucopia of water in the life of humankind on a personal level.

We are confident that in the coming years and editions of the *Water Encyclopedia*, this volume will expand with more participation from individuals working in unusual fields relating to water.

Jay Lehr
Jack Keeley

AIR–SEA INTERACTION

S.A. Hsu
Louisiana State University
Baton Rouge, Louisiana

INTRODUCTION

Air–sea interaction is, according to Geer (1), the interchange of energy (e.g., heat and kinetic energy) and mass (e.g., moisture and particles) that takes place across the active surface interface between the top layer of the ocean and the layer of air in contact with it and vice versa. The fluxes of momentum, heat, moisture, gas, and particulate matter at the air–water interface play important roles, for example, in environmental hydraulics and water–environment–health interactions, during low wind speeds before the onset of wave breaking, the exchange of air bubbles is limited. If this situation persists for a long time, algal blooms may develop, ultimately affecting water quality. On the other hand, during typhoon/hurricane conditions, the storm surge may affect the sewerage outflow at a greater depth than normal because of shoaling. In the area on the right-hand side of the storm track (in the Northern Hemisphere), runoff may also be blocked due to the surge, thus increasing the flood potential and saltwater intrusion.

Air–sea interaction encompasses vast scales in both spatial and temporal viewpoints, so only a few basic and applied topics are summarized here, including the parameterization of stability length, determination of friction velocity, wind–wave interaction, and the estimation of shoaling depth during storms. For more detailed laws and mechanisms in air–sea interaction, see Donelan (2) and recently Csanady (3); for air–sea exchange of gases and particles, see Liss (4) and most recently Donelan et al. (5); for the role of air–sea exchange in geochemical cycling, see Buat-Menard (6) and recently Liss (7); for larger scale air–sea interaction by La Niña and its impacts, see Glantz (8); for more physics, chemistry, and dynamics related to air–sea exchange, see Geernaert (9); and for wind–wave interaction, see Janssen (10).

PARAMETERIZATION OF THE STABILITY LENGTH

In the atmospheric boundary layer, the buoyancy length scale, L, also known as the Obukhov (or Monin–Obukhov) length, is a fundamental parameter that characterizes the "stability" of the surface layer (11). L describes the relative importance between the buoyancy effect (or thermal turbulence) and wind shear (or mechanical turbulence). According to Hsu and Blanchard (12), L can be parameterized as follows.

For unstable conditions (i.e., when $T_{\text{sea}} > T_{\text{air}}$),

$$\frac{z}{L} = -\frac{1000(T_{\text{sea}} - T_{\text{air}})(1 + \dfrac{0.07}{B})}{(T_{\text{air}} + 273.2)U_z^2} \tag{1}$$

For stable conditions ($T_{\text{air}} > T_{\text{sea}}$),

$$\frac{z}{L} = \frac{620(T_{\text{air}} - T_{\text{sea}})}{(T_{\text{air}} + 273.2)U_z^2} \tag{2}$$

According to Hsu (13,14),

$$B = 0.146(T_{\text{sea}} - T_{\text{air}})^{0.49} \tag{3}$$

where z is the height normally set to 10 m; T_{air} and T_{sea} stand for the air and sea temperatures, respectively; U_z is the wind speed at height z; and B is the Bowen ratio.

For operational and engineering applications, $z/L \leq -0.4$ is unstable, $|z/L| < 0.4$ is neutral, and $z/L \geq 0.4$ is stable.

PARAMETERIZATION OF THE ROUGHNESS LENGTH

The roughness parameter Z_0 can be computed based on the formula provided in Taylor and Yelland (15) that

$$\frac{Z_0}{H_{\text{s}}} = 1200\left(\frac{H_{\text{s}}}{L_{\text{p}}}\right)^{4.5} \tag{4}$$

and, for deep water waves,

$$L_{\text{p}} = \frac{gT_{\text{p}}^2}{2\pi} \tag{5}$$

where g is gravitational acceleration, H_{s} and L_{p} are the significant wave height and peak wavelength for the combined sea and swell spectrum, and T_{p} is its corresponding wave period. Note that H_{s} is defined as the average of the highest one-third of all wave heights during the 20-minute sampling period.

ESTIMATION OF THE FRICTION VELOCITY

The friction velocity (u_*) can be obtained as follows:

$$u_* = U_{10}C_{\text{d}}^{1/2} \tag{6}$$

where U_{10} is the wind speed at 10 m and C_{d} is the drag coefficient.

According to Amorocho and DeVries (16), the WAMDI Group (17), and Hsu (18), one may classify the air–sea interaction into three broad categories based on wave breaking conditions:

In light winds, $U_{10} < 7.5$ m/s, prior to the onset of wave breakers,

$$C_{\text{d}} = \left(\frac{u_*}{U_{10}}\right)^2 = 1.2875 * 10^{-3} \tag{7}$$

Both thermal and mechanical turbulence are important.

In moderate winds, $7.5 \leq U_{10} \leq 20$ m/s, the range after the onset but before the saturation of wave breakers,

$$C_{\text{d}} = (0.8 + 0.065U_{10}) * 10^{-3} \tag{8}$$

Mechanical turbulence is more important than thermal effects.

In strong winds, $U_{10} > 20$ m/s, after the saturation of wave breakers,

$$C_{\mathrm{d}} = 2.5 * 10^{-3} \tag{9}$$

Mechanical turbulence dominates.

ESTIMATING LATENT HEAT FLUX (OR EVAPORATION)

Using the parameter of the Bowen ratio supplied by Hsu (13,14), as shown in Eq. 3, the latent heat flux (H_{latent}) can be estimated as

$$H_{\mathrm{latent}}(\mathrm{W\,m^{-2}}) = \frac{1}{B}H_{\mathrm{sensible}} = \frac{1}{B}\rho_{\mathrm{a}}C_{\mathrm{p}}C_{\mathrm{T}}(T_{\mathrm{sea}} - T_{\mathrm{air}})U_{10} \tag{10}$$

where H_{sensible} is the sensible heat flux, ρ_{a} (=1.2 kg m^{-3}) is the air density, C_{p} (=1004 J kg^{-1} K^{-1}) is the specific heat at constant pressure for dry air, C_{T} (=$1.1 * 10^{-3}$) is the transfer coefficient for heat, ($T_{\mathrm{sea}} - T_{\mathrm{air}}$) is in K, and U_{10} in m s^{-1}.

A latent heat flux of 1 W m^{-2} is equivalent to an evaporation rate of $3.56 * 10^{-3}$ cm day^{-1}, so Eq. 10 can be used to estimate the evaporation rate.

ESTIMATING MAXIMUM SUSTAINED WIND SPEED DURING A HURRICANE

Under hurricane/typhoon conditions, intense air–sea interaction occurs. Beach erosion, engineering structures, storm surge, and sewerage outflow can all be affected, so this topic should deserve more attention than the deepwater environment. The very first subject related to a tropical cyclone is to estimate its maximum sustained wind speed at the standard height of 10 m (i.e., U_{10}). This is accomplished as follows.

From the cyclostrophic equation (i.e., centrifugal force = pressure gradient) (11),

$$\frac{U_{\mathrm{a}}^2}{\gamma} = \frac{1}{\rho_{\mathrm{a}}}\frac{\partial P}{\partial \gamma} = \frac{1}{\rho_{\mathrm{a}}}\frac{\Delta P}{\Delta \gamma} = \frac{1}{\rho_{\mathrm{a}}}\frac{P_{\mathrm{n}} - P_0}{\gamma - 0} \tag{11}$$

where U_{a} is the maximum sustained wind speed above the surface boundary layer, γ is the radius of the hurricane, $\partial P/\partial\gamma$ is the radial pressure gradient, P_{n} is the pressure outside the hurricane effect (1013 mb, the mean sea level pressure), and P_0 is the hurricane's minimum central pressure. Because $\rho_{\mathrm{a}} = 1.2$ kg m^{-3}, $\Delta P = (1013 - P_0)$ mb, and 1 mb = 100 N m^{-2} = 100 kg m^{-1} s^{-2}, Eq. 11 becomes

$$U_{\mathrm{a}} = \left[\frac{100\ \mathrm{kg\,m^{-1}\,s^{-2}}}{1.2\ \mathrm{kg\,m^{-3}}}\right]^{1/2}\sqrt{\Delta P} = 9\sqrt{\Delta P} \tag{12}$$

According to Powell (19), $U_{10} = 0.7\mathrm{U_a}$; therefore

$$U_{10} = 6.3\sqrt{\Delta P} = 6.3(1013 - P_0)^{1/2} \tag{13}$$

where U_{10} is in m s^{-1} and ΔP in mb.

Equation 13 has been verified by Hsu (18). In 1985, during Hurricane Kate over the Gulf of Mexico, the U.S. National Data Buoy Center (NDBC) buoy #42003, located on the right-hand-side of the storm track near the radius of maximum wind, recorded a minimum sea-level pressure (P_0) of 957.1 mb. Therefore, $\Delta P = (1013 - 957.1) = 55.9$ mb. Substituting this value in Eq. 13, $U_{10} = 47.1$ m s^{-1} which is in excellent agreement with the measured $U_{10} = 47.3$ m s^{-1}.

Another verification is provided in Fig. 1. According to Anthes (20, p. 22 and Fig. 2.8),

$$U_{10\gamma} = U_{10\,\mathrm{max}}\left(\frac{R}{\gamma}\right)^{0.5} \tag{14}$$

where $U_{10\gamma}$ is the sustained wind speed at a distance 10 m away from the storm center and $U_{10\,\mathrm{max}}$ is the maximum sustained wind at 10 m at the radius of maximum wind, R.

According to Hsu et al. (21), for operational applications,

$$\frac{R}{\gamma} = \ln\left(\frac{1013 - P_0}{P_\gamma - P_0}\right) \tag{15}$$

where P_γ is the pressure at a point located at a distance from the storm center and ln is the natural logarithm.

Substituting Eq. 15 in Eq. 14,

$$U_{10\gamma} = U_{10\,\mathrm{max}}\left[\ln\left(\frac{1013 - P_0}{P_\gamma - P_0}\right)\right]^{0.5} \tag{16}$$

During Hurricane Lili in 2002, the NDBC had two buoys, #42001 located near R, and #42003 located due east along 26 °N, approximately 280 km from 42001. The wind speed measurement at both buoys was 10 m. From the NDBC website (www.ndbc.noaa.gov/), at 20Z 2 October 2002 at #42001, $P_0 = 956.1$ mb. Substituting this P_0 in Equation 13, $U_{10\,\mathrm{max}} = 47.5$ m s^{-1}, in excellent agreement with the measured value of 47.2 m s^{-1} (=106 mph). Therefore, Eq. 13 is further verified. At the same time, $P_\gamma = 1011.1$ mb was measured at #42003. Substituting this P_γ in Eq. 16, we obtain $U_{10\gamma} = 8.8$ m s^{-1}. The measured $U_{10\gamma}$ at 42003 was 9.2 m s^{-1}. The difference is only about 4%, so we conclude that Eqs. 13 and 16 can be used for nowcasting using the pressure measurements at P_γ and P_0 which are normally available via the official "Advisory" during a hurricane.

ESTIMATING MAXIMUM SIGNIFICANT WAVE HEIGHT DURING A HURRICANE

According to the USACE (22, p. 3–85, Eq. 3–64),

$$T_{\mathrm{p}} = 12.1\sqrt{\frac{H_{\mathrm{s}}}{g}} \tag{17}$$

$$\therefore\ \frac{H_{\mathrm{s}}}{gT_{\mathrm{p}}^2} = 0.0068 \tag{18}$$

More verification of Eq. 18 is provided in Hsu (23).

According to Hsu et al. (21), based on the evaluation of nine fetch-limited wind–wave interaction formulas, that provided by Donelan et al. (24) ranked best as follows:

$$\frac{gH_{\mathrm{s}}}{U_{10}^2} = 0.00958\left(\frac{gT_{\mathrm{p}}}{U_{10}}\right)^{1.65} \tag{19}$$

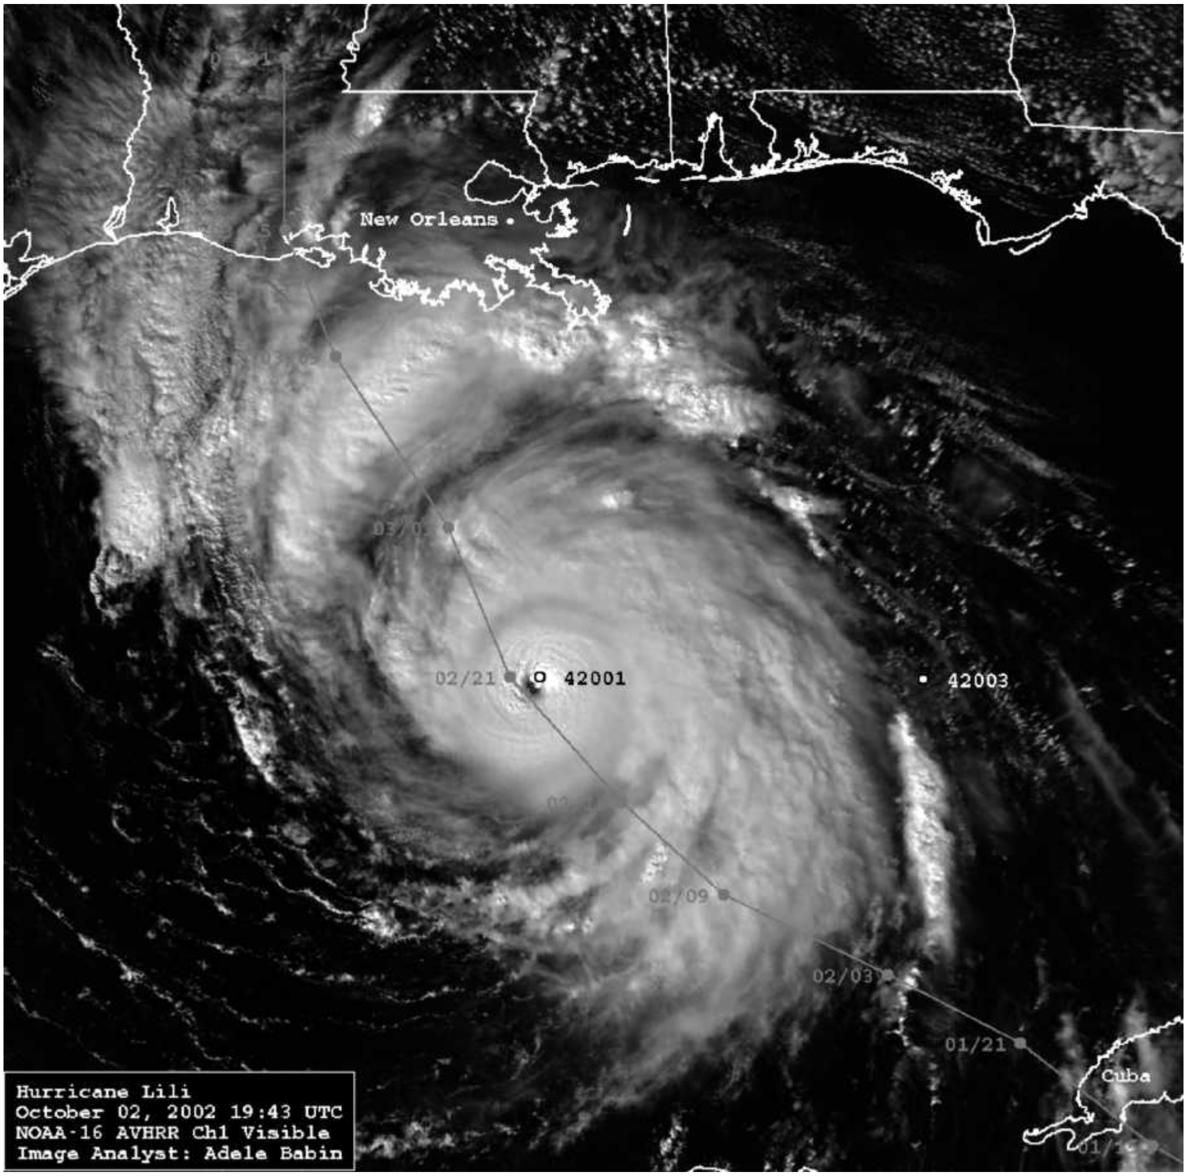

Figure 1. Satellite data (visible channel from NOAA-16) received and processed at the Earth Scan Lab, Louisiana State University, during Hurricane Lili (2002) in the Gulf of Mexico. The solid line represents the storm track. Data from NDBC buoys 42001 and 42003 are employed in this study. Note that the anemometers for both bouys were located at the standard 10 m height.

From Eqs. 18 and 19,

$$H_{\mathrm{s}} = 0.00492\, U_{10}^{2} \tag{20}$$

Substituting Eq. 13 in Eq. 20,

$$H_{\mathrm{s\ max}} = 0.20\, \Delta P \tag{21}$$

where $H_{\mathrm{s\ max}}$ is in meters and ΔP is in mb. Equation 21 is verified in Fig. 1. Buoy 42001, located near the radius of maximum wind, measured $P_0 = 956.1$ mb at 20Z 2 October 2002, so that $\Delta P = (1013 - 956.1) = 56.9$ mb. Substituting this value in Eq. 21, $H_{\mathrm{s\ max}} = 11.38$ m, which is in excellent agreement with that of 11.22 m measured at 21Z 2 October 2002 (within 1 hour after the measured minimal P_0).

ESTIMATING STORM SURGE AND SHOALING DEPTH

To estimate a typhoon/hurricane—generated storm surge (ΔS), and shoaling depth (D_{shoaling}), the following formulas are useful operationally, provided that the storm's minimum (or central) pressure near the sea surface (P_0) is known.

According to Hsu (23), for the storm surge in deep water before shoaling (i.e., when the waves feel the sea floor),

$$S_{\mathrm{I}} = 0.070(1010 - P_0) \tag{22}$$

where S_{I} is the initial peak storm surge before shoaling. For the peak surge at the coast,

$$S_{\mathrm{P}} = 0.070\,(1010 - P_0) * F_{\mathrm{S}} * F_{\mathrm{M}} \tag{23}$$

where F_S is a shoaling factor dependent on shelf topography and width and F_M is a correction factor for storm motion. Both F_S and F_M for certain areas are included in Hsu (23). A verification of Eq. 23 during Hurricane Georges in 1998 is also available in Hsu (23).

The shoaling depth is computed as follows:

From Taylor and Yelland (15), $D_{\text{shoaling}} = 0.2\ L_{\text{p}}$, and from Eq. 5,

$$D_{\text{shoaling}} = 0.2\,\frac{gT_{\text{p}}^2}{2\pi} = \frac{0.2\,H_{\text{s}}}{2\pi\left(\dfrac{H_{\text{s}}}{gT_{\text{p}}^2}\right)}$$

where $H_{\text{s}}/g{T_{\text{p}}}^2$ is called wave steepness, a useful parameter in coastal engineering.

From Hsu et al. (21) and under hurricane conditions from Eq. 18, $H_{\text{s}}/g{T_{\text{p}}}^2 = 0.0068$. Thus, from Eq. 21,

$$D_{\text{shoaling}} = 4.7\,H_{\text{s}} = 4.7 * 0.2(1013 - P_0)$$

$$\therefore \text{shoaling depth (meters)} \approx (1013 - P_0) \qquad (24)$$

CONCLUDING REMARKS

Although all formulas presented in this article are based on the open literature, they may need some verification before being applied to site-specific conditions. For example, Eq. 22 for the storm surge is for an open coast before shoaling. It needs to be adjusted for flooding at the coast due to different storm speeds and local bathymetry, as needed in Eq. 23.

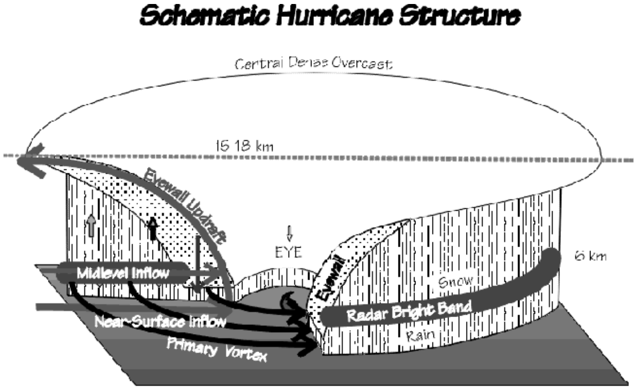
NOAA'S ATLANTIC OCEANOGRAPHIC AND METEOROLOGICAL LABORATORY

National Oceanographic and
Atmospheric Administration
(NOAA)

June 18, 1999—The Atlantic Oceanographic and Meteorological Laboratory (AOML) in Miami, Florida, is one of 12 environmental research laboratories that work on environmental issues for NOAA's Office of Oceanic and Atmospheric Research (OAR). OAR research advances NOAA's ability to predict weather, helps monitor and provides understanding of climate and global change, as well as improve coastal ocean health.

AOML's mission is to conduct a basic and applied research program in oceanography, tropical meteorology, atmospheric and oceanic chemistry, and acoustics. The programs seek to understand the physical characteristics and processes of the ocean and the atmosphere, both individually and as a coupled system.

The principal focus of these investigations is to provide knowledge that may ultimately lead to improved prediction and forecasting of severe storms, better use and management of marine resources, better understanding of the factors affecting both climate and environmental quality, and improved ocean and weather services for the nation.



The inner core of a mature hurricane, showing the clear eye surrounded by the wall cloud, which is in turn surrounded by the overhanging Central Dense Overcast (CDO). The primary circulation is the air orbiting horizontally around an axis of rotation inside the eye. Superimposed upon the primary circulation is a secondary, in-up-out, circulation. The updrafts slope outward so that rain and snow or graupel fall from them.

Originally under the jurisdiction of the Environmental Science Services Administration (ESSA), the forerunner of NOAA, AOML was founded in Miami, Florida, in 1967. Several months after NOAA was established in 1970, groundbreaking began on a new 12-acre federally funded research facility on Virginia Key. AOML dedicated its new location on Feb. 9, 1973. It celebrated its 25th anniversary in 1998.

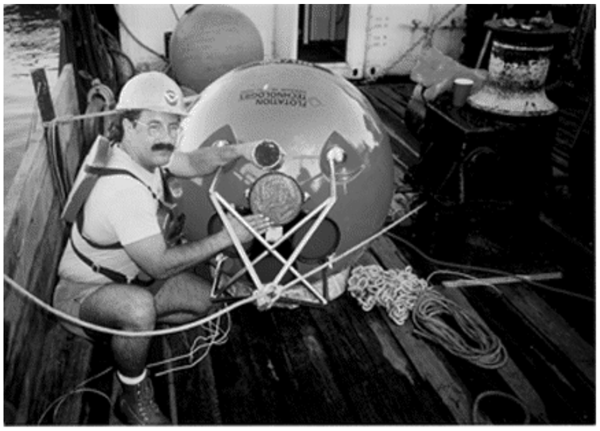
AOML has four main research divisions: Hurricane Research, Ocean Acoustics, Ocean Chemistry, and Physical Oceanography.

To learn more about AOML visit: http://www.aoml.noaa.gov/

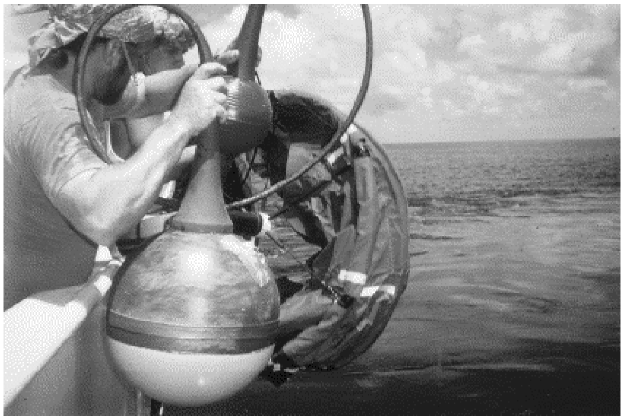
HURRICANE RESEARCH DIVISION

The Hurricane Research Division (HRD) is NOAA's primary component for research on hurricanes. Its highest priority is improving the understanding and prediction of hurricane motion and intensity change. A key aspect of this work is the annual hurricane field program, supported by the NOAA Aircraft Operation's Center research/reconnaissance aircraft. Research teams analyze data from field programs, develop numerical hurricane models, conduct theoretical studies of hurricanes, prepare storm surge atlases, and study the tropical climate.

HRD works with the National Hurricane Center/Tropical Prediction Center in all phases of its research, the National Meteorological Center and the Geophysical Fluid Dynamics Laboratory—another of OAR's research labs—in research related to numerical modeling of hurricanes, and the National Severe Storms Laboratory—yet another OAR lab—in the study of landfalling hurricanes,



An AOML/OAD Oceanographer prepares a 150 kHZ upward looking Acoustic Doppler Current Profiler (ADCP) for deployment 3 miles east of the Port of Miami. The 4 red transducers are covered with a mixture of cayenne pepper and silicone grease to prevent biofouling. The ADCP is used to obtain water column current profiles and provides such information as current speed and direction, information used in this project to determine optimal conditions for disposal of dredge materials.

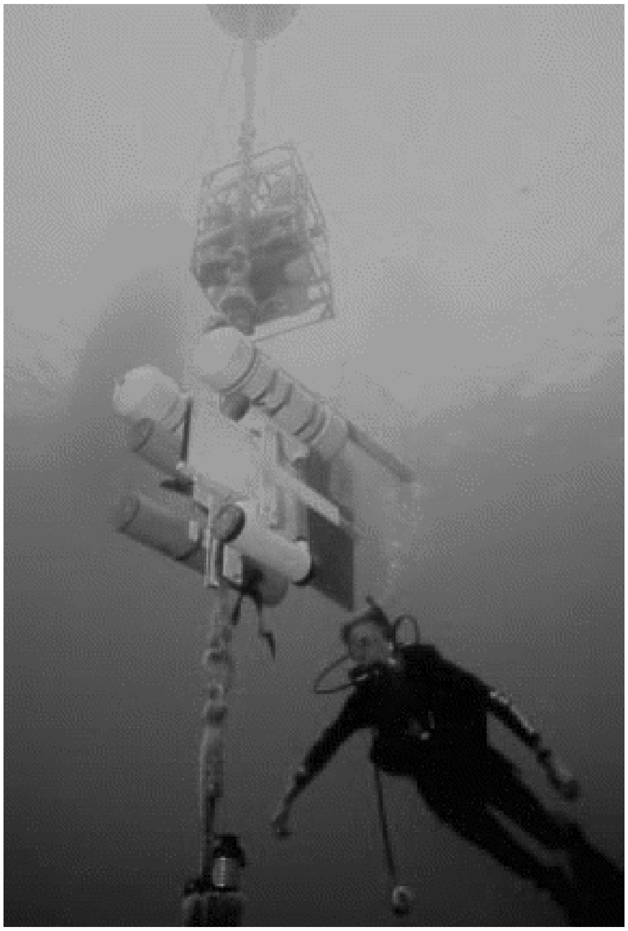


This image depicts the manual deployment of a global surface Lagrangian drifter (buoy). These devices measure sea surface temperature, surface currents, bathymetric pressure and wind. There are currently 756 of these instruments transmitting data back to AOML/PhOD from the oceanic regions all over the globe. The data are used for a variety of projects and programs.

as well as other NOAA groups, federal agencies, and universities in a variety of basic and applied research.

OCEAN ACOUSTICS DIVISION

The Ocean Acoustics Division (OAD) gathers, analyzes and reports coastal ocean data on human-related discharges and their potential environmental impacts. Additionally, OAD has an ongoing research program on the use of acoustics to measure coastal and deep ocean rainfall, an important element in calculating the global energy balance for climate monitoring and prediction. The Division works in cooperation with other federal, state, and local authorities to maximize research knowledge for use in economically and environmentally important projects in the coastal ocean.



AOML/OCD and RSMAS scientists install multi-sensor optical/acoustic moorings off the Florida Keys in support of an ERL funded Pilot Study investigating the biology, physics and chemistry of Gulf Stream topographic and frontal eddies. The moorings provide time series data within an Ocean Surface Current Radar (OSCR) field.

OCEAN CHEMISTRY DIVISION

With a diverse scientific staff of marine, atmospheric, and geological chemists, as well as chemical, biological, and geological oceanographers, the Ocean Chemistry Division (OCD) is able to use multidisciplinary approaches to solve scientific research questions. The Division's work includes projects that are important in assessing the current and future effects of human activities on our coastal to deep ocean and atmospheric environments.

PHYSICAL OCEANOGRAPHY DIVISION

The Physical Oceanography Division (PhOD) provides and interprets oceanographic data and conducts research relevant to decadal climate change and coastal ecosystems. This research includes the dynamics of the ocean, its interaction with the atmosphere, and its role in climate and climate change. Data is collected from scientific expeditions, both in the deep ocean and in coastal regions. Satellite data is processed and incorporated into the analyses. PhOD manages the Global Ocean Observing (GOOS) Center, which manages the global collection, processing, and distribution of drifting buoy data and the information collected from ocean temperature profilers. This information is crucial to understanding and predicting shifts in weather patterns and the relationship of the ocean and the atmosphere as a coupled system.

LABORATORY EXPERIMENTS ON BIVALVE EXCRETION RATES OF NUTRIENTS

Paolo Magni
IMC—International Marine Centre
Torregrande-Oristano, Italy

Shigeru Montani
Hokkaido University
Hakodate, Japan

BACKGROUND

Benthic nutrient regeneration may be referred to as a new availability to the water column of significant amounts of nitrogen, phosphorus, and other nutrients, as a consequence of the metabolism of organic matter by the benthos (1). The processes of benthic nutrient regeneration in coastal marine systems are strongly influenced by the presence of abundant macrofauna (2–5). Correct evaluation of the biogenic flux of nutrients due to the excretory activity of infaunal species is therefore an important background of information to investigate the cycling of biophilic elements (nitrogen, phosphorus, and silicon).

In field studies, major drawbacks include the difficulty to discern between nutrient upward flux due to animal excretion and a number of local effects, such as microbial mineralization (4,6–8) and uptake (9–14), animal bioturbation and irrigation currents (15–19), tidal currents and wind-generated waves (20–22). Laboratory experiments on the animal excretion rates of nutrients under more controlled conditions represent a useful tool for quantifying the actual biogenic contribution by macrofauna to the total upward flux of nutrients from sediments. Nevertheless, these experiments have often restricted their investigations to ammonium (23–28) or, in a few cases, to ammonium and phosphate (29).

CASE STUDY

This study was conducted within a multidisciplinary project on the cycling of nutrients and organic matter in a tidal estuary in the Seto Inland Sea (30–37). Laboratory experiments were carried out on the excretion rates of ammonium, phosphate, and silicate by different size classes of the bivalves, *Ruditapes philippinarum* and *Musculista senhousia*. These species were selected as they were dominant on a sandflat of the estuary under investigation. An extrapolation of these results to a field community is presented in Temporal Scaling of Benthic Nutrient Regeneration in Bivalve-Dominated Tidal Flat. Both studies will be the basis of a third companion paper on the relationship between the temporal scaling of bivalve nutrient excretion and the seasonal change of nutrient concentrations in the porewater (Seasonal Coupling Between Intertidal Macrofauna and Sediment Column Porewater Nutrient Concentrations).

In these experiments, 2.5 L aquaria with and without (control) animals were employed and run on two different occasions for 24 hours. Each experiment consisted of a 10 h day (light) and a 10 h night (dark) treatment in which the changes in nutrient concentrations were measured every 2 h. Between the two (light and dark) treatments, a low tide lasting 2 h (like that approximately on the flat where animals were collected) was created, during which the experimental animals were not removed from sediments to keep the experiment continuous. The experimental setup and procedure are detailed in our associated paper where the bivalve excretion rates of ammonium and phosphate have been presented and discussed (35). We will extend this study to silicate, a nutrient species whose regeneration through animal excretory activity has been less investigated, either *in situ* (38,39) or in the laboratory (5,40). Table 1 includes some characteristics of the experimental animals, as well as the field-relevant (33) amount of algal food (*Thalassiosira* sp.) offered in four spikes during each experiment (35). In all treatments, there was a marked increase in all three nutrient concentrations, in the control (no animals), the increase was much more limited (i.e., silicate) or not observed (i.e., ammonium) (Fig. 1).

Based on the differences in nutrient concentrations between treatments and controls, relevant linear regression lines of five to six measurements were used to calculate the nutrient excretion rates for each size class of *R. philippinarum* and *M. senhousia* (Table 2). This approach may be a more reliable way to quantify the daily bivalve excretion, whereas previous similar experiments have been based on shorter incubations and/or the sole difference between initial and final values of nutrient concentrations (4,7,22,28,29). The data sets were subjected to ANOVA in a two-factor randomized complete block design, using the day/night variable as factor A, the time (hour) variable as factor B, and the size classes of each bivalve species as replicates (35). As found for ammonium in *R. philippinarum*, but not in *M. senhousia*, silicate excretion was significantly higher (57%, $p < 0.001$, $n = 36$) during the day than during the night, suggesting a possible effect of light on the excretory activity of this bivalve species. A comparison of nutrient excretion rates (μmol g^{-1} DW h^{-1}) of bivalve species obtained through *in situ* or laboratory experiments is given in Table 3.

According to the excretion rates of silicate found in our laboratory experiments, this study points to the importance of the excretory activity of these bivalve species to the biogenic regeneration of silicate. This aspect

[b] Mean day (light) excretion significantly higher (ANOVA $p < 0.001$) than night (dark) excretion (based on Reference 35).

has been more controversial than the contribution of bivalves to the regeneration of ammonium and phosphate. The extent of silicate excretion also varies considerably, depending on the bivalve species investigated and the environmental/experimental conditions employed.

In *in situ* experiments, Prins & Small (4) found no significant excretion of silicate by *Mytilus edulis* beds on an intertidal zone of the Westerschelde (The Netherlands). The occurrence of silicate fluxes was attributed to the possible increased rate of dissolution of silicate at higher temperature. Asmus et al. (38) in the eastern Wadden Sea (Germany) and Dame et al. (39) in the Easterschelde and the western Wadden Sea (The Netherlands) found high fluxes of silicate from mussel beds of *M. edulis*. Although, in both studies, the actual excretion rate of silicate by *M. edulis* was not estimated per biomass unit (e.g., μmol g^{-1} DW h^{-1}), Dame et al. (39) suggested that silicate release from mussel beds results from phytoplankton cells breaking down as they are metabolized by the mussels. Dame et al. (39) argued that the longer turnover time for silicate, compared to phosphate and ammonium, implies a lesser role for the mussel beds in recycling this nutrient species in the two estuaries under investigation.

In contrast, Asmus et al. (38) found rapid silicate release in the Sylt-flume study and suggested that the mussels are an accelerator in recycling biogenic silica. Similarly, a study on the nutrient excretion of *R. philippinarum* in core incubation experiments found that silicate regeneration was, on average, 9.2 times faster in the site farmed with clams (5). In mesocosm experiments using large tanks, Doering et al. (40) also found that the level of flux was elevated in the presence of another clam, *Mercenaria mercenaria*, by 86% and 57% for silicate and ammonium, respectively. Our results indicate

well-balanced stoichiometric ratios among the nutrient species excreted by the bivalves (35), which can also be related to the use of the diatom *Thalassiosira* sp. as a food (35). This was aimed to approximate the actual field situation on the tidal flat, where abundant microalgal biomass, including resuspended benthic diatoms, is available to filter-feeders such as in *R. philippinarum* and *M. senhousia* (31,33). The high excretion rates of silicate of these two dominant bivalve species found in our laboratory experiments, together with those of ammonium and phosphate, suggest a major contribution of bivalve nutrient excretion to the upward flux of nutrients from sediments in our relevant study area. This will be the subject of the subsequent paper where we will apply these rates to the actual bivalve standing stock found in the field (Temporal Scaling of Benthic Nutrient Regeneration in Bivalve-Dominated Tidal Flat).

TEMPORAL SCALING OF BENTHIC NUTRIENT REGENERATION IN BIVALVE-DOMINATED TIDAL FLAT

Paolo Magni
IMC—International Marine Centre
Torregrande-Oristano, Italy

Shigeru Montani
Hokkaido University
Hakodate, Japan

Beside light and temperature (1–5), nutrients such as ammonium ($NH_4{}^+$-N), phosphate ($PO_4{}^{3-}$-P), and silicate [$Si(OH)_4$-Si] are a key factor in controlling the growth, abundance, and structure of primary producers in the ocean (6,7). Hence, it is important to investigate the availability, sources, and distribution of these nutrient species, as well as their spatial and temporal scaling. Biological processes strongly influence nutrient regeneration in different marine systems. In the open ocean, an important portion of reduced N-forms (e.g., $NH_4{}^+$-N), for instance, is made available *in situ* from waste products of plankton metabolism (8,9) and supports the so-called "regenerated" primary production (10). In coastal marine ecosystems, benthic nutrient regeneration is a major driving force in cycling biophilic elements (e.g., N, P, and Si) (11–13) and abundant macrofauna, for example, dense assemblages of bivalves, it has been shown, play a major role in these processes (14–16).

BACKGROUND

The contribution of benthic macrofauna to the total upward flux of nutrients has been investigated (mostly for ammonium and, to a lesser extent, for phosphate) in many coastal and estuarine areas using several approaches. They include laboratory and mesocosm experiments (17–19). *In situ* benthic chambers and sediment core incubations (20–22), and open flow/tunnel systems (16,23–26). Measurements of macrofauna-influenced nutrient flux, however, often have temporal limitations as they are based on one or relatively few sampling occasions, and thus seasonal patterns are in most cases not known. In this article, we evaluate the magnitude and temporal scaling of biogenic flux of nutrients from intertidal sediments densely populated by bivalves, based on extrapolating nutrient excretion rates of dominant bivalves to a field community. In particular, we show that the seasonal pattern of nutrient fluxes can be strongly influenced by the animal standing stock and its temporal distribution. This is beside the effect and importance of variation in excretion rate due to animal physiological factors, such as seasonal cycles of gametogenesis, storage and use of body reserves, and water temperature (27,28). The nutrient species considered in this study include ammonium, phosphate, and silicate, for which we quantified in associated laboratory experiments LABORATORY EXPERIMENTS ON BIVALVE EXCRETION RATES OF NUTRIENTS the excretion rates of different size classes of two dominant bivalve species. The relevance of macrofaunal excretion in regenerating the inorganic forms of three major bioelements such as N, P, and Si is discussed.

MACROFAUNAL COMMUNITIES

We present here the macrofaunal composition and distribution at an individual station (Stn B5) of a transect line selected in a sandflat of the Seto Inland Sea of Japan (29). At this station, the porewater nutrient concentrations (ammonium, phosphate, and silicate) in the uppermost 10 cm of sediments were also investigated in parallel from January 1995 to April 1996. They will be the subject of a subsequent associated paper focusing on the relationship between the seasonal pattern of bivalve nutrient excretion, described here, and the seasonal variation of porewater nutrient concentrations SEASONAL COUPLING BETWEEN INTERTIDAL MACROFAUNA AND SEDIMENT COLUMN POREWATER NUTRIENT CONCENTRATIONS. The total density and biomass of macrofauna varied from 7,400 (July 1995) to 22,050 ind.m^{-2} (October 1995), and from 70.9 (July 1995) to 244 g DW m^{-2} (September 7, 1995), respectively (Fig. 1). The bivalves *Ruditapes philippinarum* and *Musculista senhousia* and the polychaetes *Ceratonereis erithraeensis* and *Cirriformia tentaculata* were dominant; they accounted for 60.5% and 94.7% of the total density and biomass, respectively. Remarkably, *R. philippinarum* and *M. senhousia* alone accounted for up to 83.3 ± 6.7% of the total biomass when this exceeded

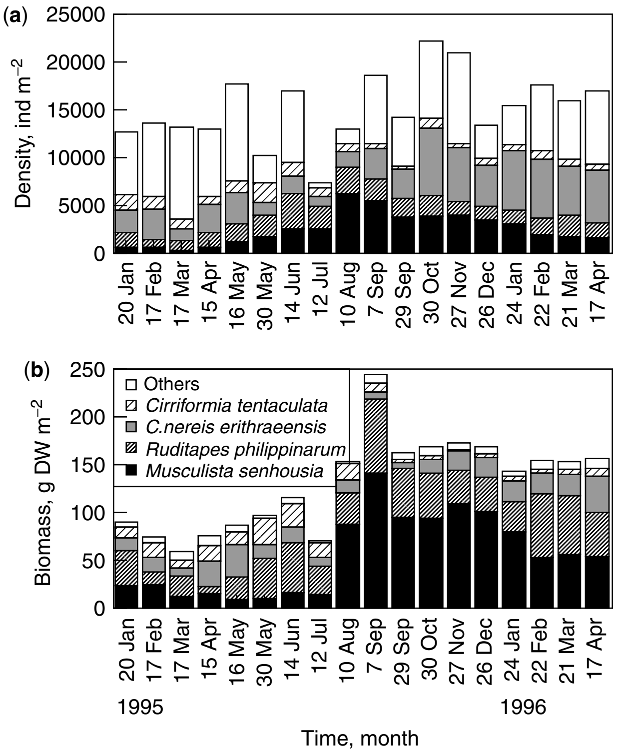

Figure 1. Seasonal variation of density (**a**) and biomass (**b**) of dominant macrozoobenthic species at Stn B5 (29). Note that in May 1995 and September 1995, sampling was carried out fortnightly.

120 g DW m^{-2}, from August 1995 till the end of the investigations. The high values of total macrofaunal and bivalve biomass may be regarded as a typical feature of many estuarine and intertidal areas, which are amongst the most productive systems in the ocean (30). In addition, biomass was markedly lower during the first half of the year (January 1995 to July 1995) than between late summer and winter; yet values progressively increased from early spring (March 1995) to early summer (June 1995). These marked temporal changes of macrofaunal communities reflect the high variability of these ecosystems. To estimate the magnitude and temporal scaling of biogenic nutrient excretion, we used an indirect approach. The mean excretion rates of ammonium, phosphate, and silicate for the two dominant bivalves *R. philippinarum* and *M. senhousia*, which were obtained in laboratory experiments LABORATORY EXPERIMENTS ON BIVALVE EXCRETION RATES OF NUTRIENTS, were applied to the relevant monthly biomass values found in the field. The ammonium and phosphate excretion rates of each bivalve species and their scaling to a field community have been extensively reported in Magni et al. (29). In this article, we applied these excretion rates to the bivalve biomass found at Stn B5 and extended this scaling to silicate, whose size-class dependent excretion rates are presented in LABORATORY EXPERIMENTS ON BIVALVE EXCRETION RATES OF NUTRIENTS. For silicate, we adopted the same temperature-dependent excretion rate factors as those used for ammonium and phosphate (Table 1).

BIVALVE NUTRIENT EXCRETION

The highest excretion rates of nutrients were estimated in September 7, 1995, up to a total of 50.2, 7.5, and 34.1 mmol m^{-2} d^{-1} for ammonium, phosphate, and silicate, respectively (Fig. 2). This corresponded to the period of highest biomass of both *R. philippinarum* and *M. senhousia*, which also accounted for the highest bivalve percentage (91.8%) of the total macrofaunal biomass. The lowest excretion rates occurred in April 1995 for *R. philippinarum* (lowest biomass on the same occasion), in March 1995 for *M. senhousia* (lowest biomass on May 16, 1995), and in February 1995 as the sum of the two bivalve species excretion rates. These latter rates were 4.1, 0.64, and 2.9 mmol m^{-2} d^{-1} for ammonium, phosphate, and silicate, respectively. The upward flux rates of nutrients obtained through this extrapolation of laboratory experiments on bivalve nutrient excretion to a field community are comparable to the highest biogenic releases reported for dense assemblages of bivalves such as oyster reefs (34) and mussel beds (16,35). This study also points to the importance of bivalve excretion to the biogenic regeneration of silicate, as previously suggested by field measurements indicating evidence of increased levels of silicate flux in the

[a] A factor (*f*) of 1 is used for the mean of the excretion rates obtained in laboratory experiments (see LABORATORY EXPERIMENTS ON BIVALVE EXCRETION RATES OF NUTRIENTS and based on Ref. 29).

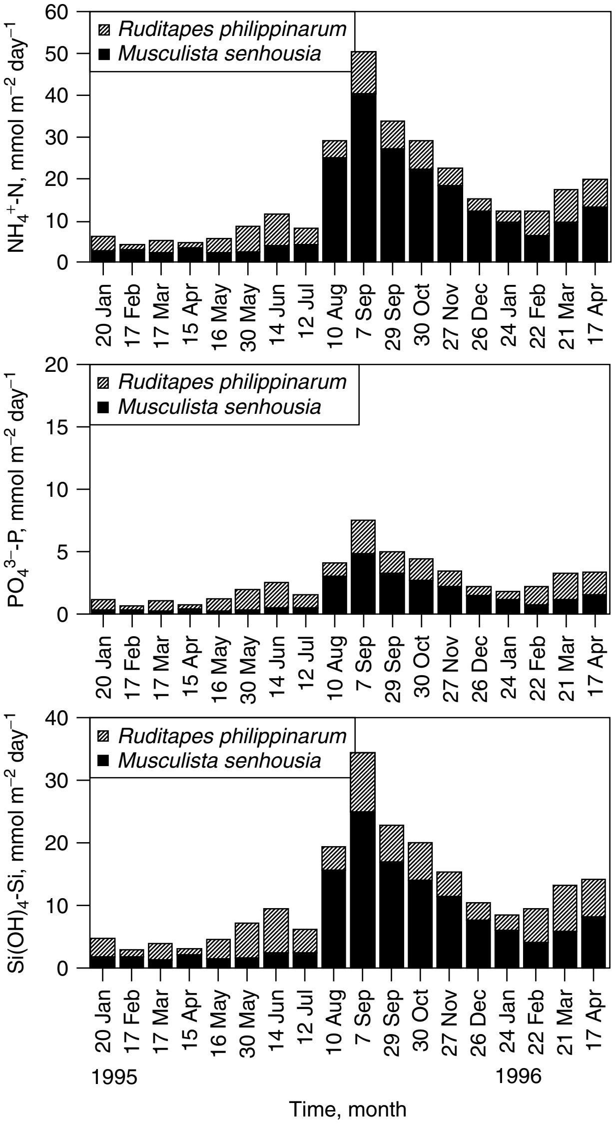

Figure 2. Magnitude and temporal scaling of ammonium (NH_4^+-N), phosphate (PO_4^{3-}-P), and silicate [$Si(OH)_4$-Si] excretion by *Ruditapes philippinarum* and *Musculista senhousia* in a field community.

presence of bivalves (17,24,36). The temporal scaling of bivalve nutrient excretion showed a marked seasonal pattern of large variations of nutrient flux, up to ca. 10-fold (*R. philppinarum*) and 20-fold (*M. senhousia*) between March–April 1995 and September 7, 1995, and a progressive decrease from late summer through winter. This approach may involve some limitations, such as the effect of differences between the bivalve performance in controlled laboratory experiments and that in the field and a relative approximation in adopting different excretion rates at temperatures other than those actually employed in the laboratory experiments (29). However, it indicates the strong influence of animal distribution on the magnitude and temporal scaling of biogenic nutrient regeneration due to bivalve excretion.

The great potential of this biogenic source of nutrients in cycling biophilic elements can also be highlighted by a comparison with the extent of benthic nutrient regeneration through diffusive flux. In particular, nutrient flux measured from nutrient concentrations in the porewater in adjacent intertidal and coastal areas was more than one order of magnitude lower; it varied from 0.2 to 1.5 mmol NH_4^+-N m^{-2} d^{-1} and from 0.01 to 0.05 mmol PO_4^{3-}-P m^{-2} d^{-1}. It can be inferred that a marked increase in biogenic nutrient regeneration is importantly controlled by the animal biomass increase (36) and has a major impact, acting as a positive feedback, on primary producers (41). These results indicate that abundant macrofauna and its excretory products play a primary role in benthic nutrient regeneration, are well balanced in their stoichiometric ratios, and thus act as a major factor to support primary production within the intertidal zone.

BREAKWATERS

Stefano Pagliara
Pietro Chiavaccini
Università di Pisa
Pisa, Italy

Breakwaters are coastal structures used to protect harbor and shore areas by dissipating and reflecting wave energy. They are built to

— reduce wave disturbance in coastal and harbor areas and preserve related activities;
— protect ships and boats from wave forces;
— when located near shore, in the same direction as the coastline, they can stabilize the coastline, modifying cross-shore and long-shore sediment transport.

The choice of the type of structure depends on the availability of materials used, the characteristics of the incident wave, the bottom morphology, the geotechnical parameters of the soil, and the necessity of obtaining a flexible or rigid structure. Breakwaters can be classified as rubble-mound structures, vertical breakwaters, and floating breakwaters.

RUBBLE-MOUND STRUCTURES

The typical cross section of a rubble-mound breakwater is sketched in Fig. 1. It consists of different layers of stones. The center core is made up of quarry run. The external layer (armor) consists of large armor units, that can be either rock or specially designed concrete units (cubes, tetrapods, dolos). The breakwater crest is generally 1–2 m over the still water level (SWL). The crest width should be large enough to allow transport and installation of material during construction and when a repair is made (1).

Because of the relative dimensions of the units of the armor and those of the core, in some cases, it is necessary to build the breakwater as a filter of three or four layers (underlayers), so that the finer material of the core cannot be removed by the waves through the voids of the armor layer. To prevent removal of finer material, the filter must satisfy the following relations:

$$D_{15}(\mathit{upper\ layer}) < 4 \div 5D_{85}(\mathit{lower\ layer}) \tag{1}$$

$$D_{15}(\mathit{upper\ layer}) < 20 \div 25D_{15}(\mathit{lower\ layer}) \tag{2}$$

where D_{15} = nominal size that is exceeded by the 85% of the sample

D_{85} = nominal size that is exceeded by the 15% of the sample

A toe filter is necessary if the breakwater is built on erodible material. The toe filter prevents breaking waves from removing material from the base of the structure. If the breakwater is located in shallow water, the filter toe is exposed to extreme wave action. To avoid, or just limit, wave overtopping, it is possible to use a concrete structure (crown wall) located over the crest (Fig. 1).

When the breakwater is small and not high, it is possible to avoid using a center core. This kind of structure, of single sized stones, is called a "reef breakwater," and it is normally used for small submerged breakwaters (2).

Stability

The rubble-mound breakwater causes the dissipation of wave energy by generating eddies due to the breaking. The voids and the roughness of the structural material, as well as the permeability of the structure, are very important in the dissipation process. The wave energy entering through the structure creates shear stresses that can move the masses causing loss of stability.

Armor Stability. The stability formulas are based on experiments carried out on hydraulic models. One of the most used stability formulas is Hudson's (3) determined for a nonovertopping structure:

$$\frac{H}{\Delta D_{n50}^2} = (K \cot \alpha)^{1/3} \tag{3}$$

where H = characteristic height of the wave (H_s to $H_{1/10}$);

D_{n50} = equivalent cube length of median rock;

α = slope angle;

Δ = $(\rho_s/\rho_w - 1)$ where ρ_s and ρ_w are rock density and water density, respectively;

K = stability coefficient (Tables 1 and 2).

The damage D represents the measure of the modification of the structure's profile under wave action. The damage can be defined by counting the number of rocks moved or by measuring the variation of the armor layer

Table 1. Values of the Stability Coefficient *K* for $H = H_s$[a]

		Damage D 0–5%	
Stone Shape	Placement	Breaking Waves	Nonbreaking Waves
Smooth, rounded	Random	2.1	2.4
Rough, angular	Random	3.5	4.0
Rough, angular	Special	4.8	5.5

[a] Slope $1.5 \le \cot\alpha \le 3.0$.

Table 2. Values of the Stability Coefficient *K* for $H = H_{1/10}$

		Damage D 0–5%			
		Breaking Waves		Non Breaking Waves	
Stone shape	Placement	Trunk	Head	Trunk	Head
Smooth, rounded	Random	1.2	1.1	2.4	1.9
Rough, angular	Random	2.0	1.3[a]–1.9[b]	4.0	2.3[a]–3.2[b]
Rough, angular	Special	5.8	5.3	7.0	6.4
Tetrapods	Random	7.0	3.5[a]–5[b]	8.0	4.0[a]–6.0[b]

[a] $\cot\alpha = 3$.
[b] $\cot\alpha = 1.5$.

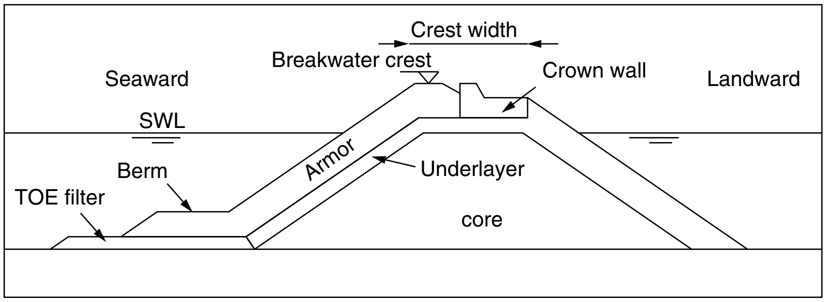

Figure 1. Typical section of a rubble-mound breakwater.

area (eroded area A of the damaged section). For this second case, Broderick (4) introduced a parameter (relative eroded area) defined as

$$S = \frac{A}{D_{n50}^2} \tag{4}$$

where D_{n50} is the nominal diameter, corresponding to 50% of the weight of the sample. The damage can be considered the number of masses of dimension equal to D_{n50} eroded in a strip of section of the same length. Zero damage means that there is nominally no removal of the armor units from the breakwater face.

The K value of Hudson's formula is different for the trunk and the head of the structure. The stones will be less stable on the head than on the trunk. In this case, K must be decreased by about 20%.

Van der Meer (5) derives expressions that include some additional parameters for an incident wave:

$$\frac{H_s}{\Delta D_{n50}} = 6.2 S^{0.2} P^{0.18} N_z^{-0.1} \xi_m^{-0.5} \qquad \text{plunging waves } \xi_m < \xi_{cm} \tag{5}$$

$$\frac{H_s}{\Delta D_{n50}} = 1.0 S^{0.2} P^{-0.13} N_z^{-0.1} (\cot\alpha)^{0.5} \xi_m^P \qquad \text{surging waves } \xi_m > \xi_{cm} \tag{6}$$

$$\xi_m = s_m^{-0.5} \tan\alpha$$

$$\xi_{mc} = [6.2 P^{0.31} (\tan\alpha)^{0.5}]^{1/(P+0.5)}$$

where S = relative eroded area (normally equal to 2);
P = notional permeability;
N_z = number of waves;
s_m = wave steepness $s_m = H_s/L_{\text{om}}$;
L_{om} = deepwater wavelength corresponding to the mean period.

For a homogeneous structure (no core, no filter, and stones of the same size), $P = 0.6$; a rock armor layer with a permeable core gives $P = 0.5$; an armor layer with filter on a permeable core gives $P = 0.4$. For a breakwater with an impermeable core, $P = 0.1$.

For overtopped and low crested structures, Van der Meer suggests multiplying D_{n50} by a reduction factor f_i defined by

$$f_i = \left(1.25 - 4.8\frac{R_c}{H_s}\sqrt{\frac{s_{\text{op}}}{2\pi}}\right) \tag{7}$$

R_c is the freeboard, and $s_{\text{op}} = H_s/L_{\text{op}}$ (L_{op} is the deep water wavelength referred to the peak period). Expression (7) can be used in the range $0 < \left(\frac{R_c}{H_s}\sqrt{\frac{s_{\text{op}}}{2\pi}}\right) < 0.052$.

For submerged breakwaters, the following expression can be used (6):

$$\frac{h_c}{h} = (2.1 + 0.1S)\exp(0.14 N_s^*) \tag{8}$$

where h = water depth;
h_c' = height of the structure from the base;
S = relative eroded area;
$N_s^* = \frac{H_s}{\Delta D_{n50}} s_p^{-1/3}$ = spectral stability number.

Run Up and Overtopping

Run up is a phenomenon in which the incident crest wave runs up along a sloping structure to a level higher then the original wave crest. Together with overtopping, it plays, a very important role in the design of a rubble-mound structure because it depends on the characteristics of the structure (slope roughness, berm length, permeability).

Run up is expressed by $R_{u,x\%}$ that represents the level reached by the wave exceeded in x% of the cases by the incident wave. The run up level is referred to the SWL. For rubble-mound structures, Van der Meer's (6) formula is used:

$$\frac{R_{u,x\%}}{H_s} = a\xi_m, \qquad \xi_m < 1.5 \tag{9}$$

$$\frac{R_{u,x\%}}{H_s} = b\xi_m^c, \qquad \xi_m > 1.5 \tag{10}$$

These formulas are valid for breakwaters that have an impermeable or almost impermeable core ($P < 0.1$). If the breakwaters have a permeable core ($0.1 < P < 0.4$) Equations 9 and 10 become

$$\frac{R_{u,x\%}}{H_s} = d \tag{11}$$

It is usual in breakwater design to consider that $x\% = 2$; this means that $R_{u,2\%}$ is the run up exceeded by 2% of the waves. In this case, the values of the parameters of Equations (9,10), and 11 are $a = 0.96$, $b = 1.17$, $c = 0.46$, and $d = 1.97$.

ξ_m is the breaker parameter for deep water, corresponding to the mean period ($\xi_m = s_m^{-0.5}\tan\alpha$ where the symbols are explained in Equations 5 and 6).

In a low crest elevation, overtopping is allowed. Overtopping is the quantity of water passing over the crest of a structure per unit time, and it has the same dimensions of a discharge $Q(m^3/s)$, often expressed for unit length $q[m^3/(sm)]$.

A knowledge of overtopping is important in defining the necessary protection of the splash area and in assessing the risk to people or installations behind the breakwater. The amount of overtopping varies considerably from wave to wave; the overtopping discharge changes in time and space, and the greatest quantity is due to a small number of the incident waves. Wave overtopping for an impermeable rock armored slope structure with a crown wall can be expressed by the equation of Bradbury and Allsop (7), using the parameters of Aminti and Franco (8):

$$\frac{q}{gH_sT_{\text{om}}} = a\left[\left(\frac{R_c}{H_s}\right)^2\sqrt{\frac{s_{\text{om}}}{2\pi}}\right]^{-b} \tag{12}$$

where S_{om} = deepwater wave steepness, based on mean period;
H_s = significant wave height;
R_c = crest freeboard relative to SWL in m;
T_{om} = deepwater wave mean period;
a, b = parameters as specified in Table 3.

G is the width (seaward) of the armor crest till the crown wall, and α is the slope of the armor layer.

Table 3. Coefficients for Equation 15 from Experimental Results

Armor Units	Cotα	G/H_s	a	b
Rock	2	1.10	17×10^{-8}	2.41
	2	1.85	19×10^{-8}	2.30
	2	2.60	2.3×10^{-8}	2.68
	1.33	1.10	5.0×10^{-8}	3.10
	1.33	1.85	6.8×10^{-8}	2.65
	1.33	2.60	3.1×10^{-8}	2.69
Tetrapods	2	1.10	1.9×10^{-8}	3.08
	2	1.65	1.3×10^{-8}	3.80
	2	2.6	1.1×10^{-8}	2.86
	1.33	1.10	5.6×10^{-8}	2.81
	1.33	1.85	1.7×10^{-8}	3.02
	1.33	2.60	0.92×10^{-8}	2.98

For rock armored permeable slopes, that have a theoretical permeability $P = 0.4$ and a berm in front of a crown wall, we can use the Pedersen and Burcharth formula (9):

$$\frac{qT_{\text{om}}}{L_{\text{om}}^2} = 3.2 \times 10^{-5} \left(\frac{H_s}{R_c}\right)^3 \frac{H_s^2}{A_c B \cot\alpha} \qquad (13)$$

where A_c = level of the berm from SWL;
B = the width of the berm;
R_c = the level of the crest of the crown wall from SWL;
α = slope of armor.

Wave Reflection

Each coastal structure causes a wave reflection. Reflection plays a very important role because of the interaction between reflected and incident waves that can create a very confused sea, increasing the wave steepness. It is a problem especially at the entrance of an harbor because the steepness makes ship and boat maneuver very difficult. Besides, strong reflection increases the erosive force in front of the structure.

Rubble-mound breakwaters, which are permeable, rough, and sloping structures and structure of limited crest level, absorb a significant portion of the wave energy. For these structures, the reflection coefficient is small. For nonovertopped structures, that have a theoretical permeability P, we can use the following equation (10):

$$K_r = 0.071 P^{-0.082} (\cot\alpha)^{-0.62} S_{\text{op}}^{-0.46} \qquad (14)$$

where K_r is the ratio of the reflected wave height and the incident wave height.

Wave Transmission

When energy passes over and through a breakwater, there is a wave transmission. The wave action in the landward side of the structure is smaller than in the seaward side. A wave is transmitted when a considerable amount of water overtops the structure and when the breakwater is very permeable and the wave period is relatively long. We define the coefficient of transmission as the ratio of transmitted to incident characteristic wave height or the ratio of the square of transmitted mean energy to incident mean wave energy:

$$K_t = \frac{H_{\text{st}}}{H_s} = \left(\frac{E_{\text{st}}}{E_s}\right)^{0.5} \qquad (15)$$

For rock armored, low crested, submerged and reef breakwaters, we can use the Van der Meer and d'Angremond formula (11):

$$K_t = \left(0.031 \frac{H_s}{D_{n50}} - 0.24\right) \frac{R_c}{D_{n50}} + b \qquad (16)$$

where $b = -5.42 s_{\text{op}} + 0.0323 \frac{H_s}{D_{n50}} - 0.0017 \left(\frac{B}{D_{n50}}\right)^{1.84} + 0.51$ for a conventional structure,
$b = -2.6 s_{\text{op}} - 0.05 \frac{H_s}{D_{n50}} + 0.85$ for a reef type structure,
H_s = significant wave height;
s_{om} = deepwater wave steepness, based on peak period;
R_c = crest freeboard relative to SWL, negative for submerged breakwaters;
B = width of crest;
D_{n50} = median of nominal diameter of rock for design conditions.

For conventional structures, K_t has a maximum of 0.75 and a minimum of 0.075, and for reef type structures, K_t varies between 0.15 and 0.6.

This formula can be used in the following range:

$$1 < \frac{H_s}{D_{n50}} < 6, \quad 0.01 < s_{\text{op}} < 0.05, \quad -2 < \frac{R_c}{D_{n50}} < 6$$

VERTICAL BREAKWATERS

Vertical breakwaters are rigid and not as flexible as rock armored ones. It is necessary to know very well the wave climate (direction, intensity, frequency, and duration of waves) to obtain a good design. A typical cross section of a vertical breakwater is sketched in Fig. 2a.

Forces on Vertical Structures

Nonbreaking Wave. A nonbreaking wave is perfectly reflected (coefficient of reflection = 1.0) and can be considered static because the period is longer than the natural period of oscillation of the structure. This stationary and static wave is called "clapotis." Assuming perfect reflection, the seaward wave has a height double the incident wave.

If the vertical breakwater is overtopped, a reduction of wave pressure occurs because it is truncated at the crest level. According to Sainflou (12), the pressures are (Fig. 2a)

$$p_1 = p_2 + \rho_w g h_s \left(\frac{H + \delta_0}{h_s + H + \delta_0}\right) \qquad (17)$$

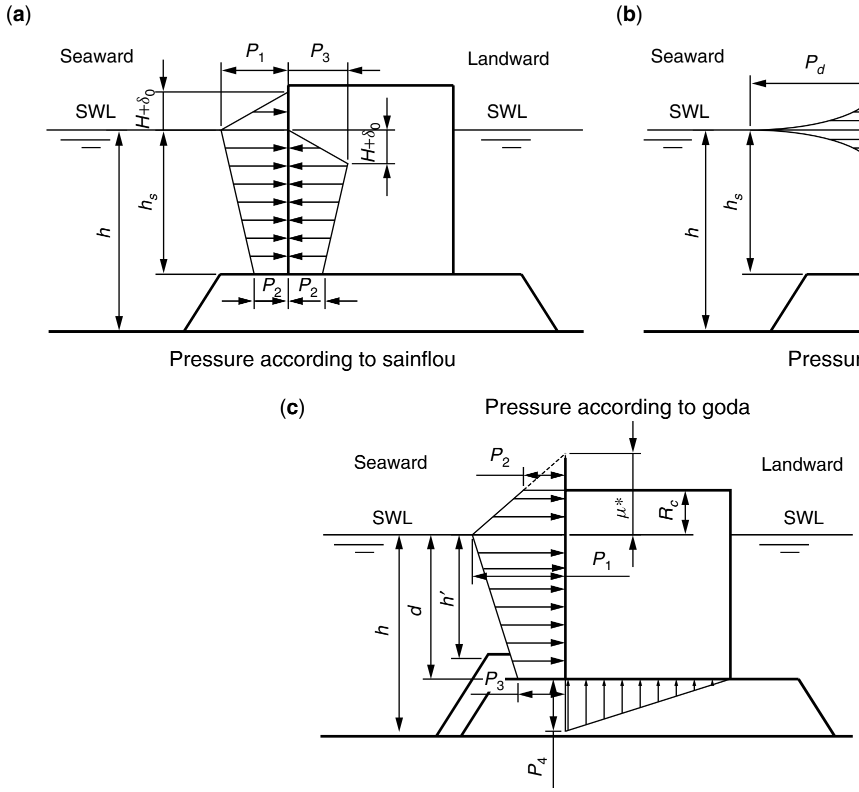

Figure 2. Pressure on vertical breakwaters.

$$p_2 = \frac{\rho_w g H}{\cosh(2\pi h_s/L_0)} \tag{18}$$

$$p_3 = \rho_w g(H - \delta_0) \tag{19}$$

$$\delta_0 = \frac{\pi H^2}{L_0}\coth(2\pi h_s/L_0) \tag{20}$$

where H = wave height;
p_1 = pressure at the still water level (SWL), corresponding to wave crest;
p_2 = pressure at the base of a vertical wall;
p_3 = pressure at the still water level, corresponding to a wave trough;
δ_0 = vertical shift in the wave crest and trough at the wall;
ρ_w = water density;
h_s = water depth at the foot of the structure;
L_0 = wavelength in deep water.

Breaking Waves. The worst condition for a vertical breakwater occurs when the water depth in front of the structure causes the wave to break. In this case, the dynamic component of the pressure must be considered, especially if the breaking is sudden, as happens for plunging waves. The forces generated by breaking are very high and a very short duration. According to Minikin (13), the dynamic pressure (Fig. 2b) is

$$p_d = 100\frac{h_t}{h_s L_0}(h_s + h_t)\rho_w g H \tag{21}$$

where H = wave height;
p_d = dynamic pressure at the still water level, corresponding to the wave crest;
ρ_w = water density;
h_s = water depth at the foot of the structure;
h_t = height of the caisson between the SWL and the berm;
L_0 = wavelength in deep water.

Another expression that can be used to determine the total pressure for breaking waves is (14)

$$p_1 = 0.5(1 + \cos\beta)(\alpha_1 + \alpha_2\cos^2\beta)\gamma H \tag{22}$$

$$p_2 = p_1\frac{\eta^* - h_c}{\eta^*} \tag{23}$$

$$p_3 = \alpha_3 p_1 \tag{24}$$

$$p_4 = 0.5(1 + \cos\beta)\alpha_1\alpha_3\gamma H \tag{25}$$

$$\eta^* = 0.75(1 + \cos\beta)H \tag{26}$$

$$\alpha_1 = 0.6 + 0.5\left(\frac{2kh}{\sinh 2kh}\right)^2 \tag{27}$$

$$\alpha_2 = \min\left\{\frac{h_b - d}{3h_b}\left(\frac{H}{d}\right)^2, \frac{2d}{H}\right\} \tag{28}$$

$$\alpha_3 = 1 - \frac{h}{h}\left(1 - \frac{1}{\cosh kh}\right) \tag{29}$$

$$H = \min(1.8H_s, H_f) \tag{30}$$

$$H_f = 0.18\frac{gT^2}{2\pi}\left(1 - \exp\left\{\frac{3\pi^2 h_b}{gT^2}[1 + 15(\tan\vartheta)]^{4/3}\right\}\right) \quad (31)$$

where h_b = water depth at a distance of $5H_s$ from the vertical breakwater (seaward);
β = angle of incidence of the wave;
ϑ = bottom angle within the horizontal.

The other symbols are explained in Fig. 2c.

Ice Force. Ice exerts a force on both the landward and seaward sides. Ice force acts at the water level, and it can be as high as the crushing strength of the ice (1.5 Mpa) multiplied by the ice thickness. Even if ice is present in both sides of the structure, the worst case (ice acting only on one side) represents the design condition. Ice and waves do not occur simultaneously.

Wave Transmission

Wave transmission for a vertical breakwater is mainly the result of overtopping. Goda (15) has investigated the wave transmission of a vertical wall breakwater placed over a rock berm. He related $K_t = H_t/H_i$ to the relative freeboard $R_c/H(-1 < R_c/H < 1)$ and found this equation:

$$K_t = 0.2\left(\frac{h_v}{h_s}\right)^2 - 0.4\left(\frac{h_v}{h_s}\right) + 0.58 - 0.32\left(\frac{R_c}{H}\right) \quad (32)$$

where h_s = water depth at the foot of the structure;
h_v = height of the wall from the berm;
R_c = freeboard crest;
H = design wave height.

Wave Overtopping

The overtopping of a vertical breakwater can be determined by using Franco's formula (16):

$$\frac{q}{\sqrt{gH_s^3}} = a\exp\left(-b\frac{Rc}{\gamma_g\gamma_{b\sigma}H_s}\right) \quad (33)$$

where q = unit discharge (m^3/s per m);
a, b = coefficient depending on structure shape and on the water behavior at the seaward face; for a vertical plain wall, $a = 0.082$, $b = 3$;
$\gamma_{b\sigma}$ = depends on the direction of wave attack. For long crested waves,

$\gamma_{b\sigma} = \cos(\beta)$ for $0 \leq \beta \leq 37^\circ$,
$\gamma_{b\sigma} = 0.79$ for $37^\circ \leq \beta$.

For short crested waves,

$\gamma_{b\sigma} = 0.83$ for $0 \leq \beta \leq 20^\circ$
$\gamma_{b\sigma} = 0.83\cos(20 - \beta)$ for $20^\circ \leq \beta$.

γ_g = depends on the type of the wall: for a plain wall $\gamma_g = 1$; for a plain wall with round hole perforations, $\gamma_g = 0.792$; for a plain wall with rectangular hole perforations, $\gamma_g = 0.722$; for a plain wall with rectangular hole perforations and open deck, $\gamma_g = 0.577$.

Concrete Caissons

The main component of a vertical breakwater is a cellular concrete caisson, a hollow box that is floated and *in situ*is filled with granular material to be sunk and placed on a berm prepared with sand or rock to form a stable structure (Fig. 3b).

Sometimes, the berm is a partial rubble-mound structure forming a composite breakwater. In some locations, the seaward face of the caisson is protected by sloping armor to avoid the breaking of incident waves in the front of the structure. The types of failure of a vertical caisson are shown in Fig. 3c. Normally, the loss of stability occurs from

- — sliding of the caisson over the base;
- — overturning of the caisson around its landward corner;
- — loss of geotechnical stability of the base.

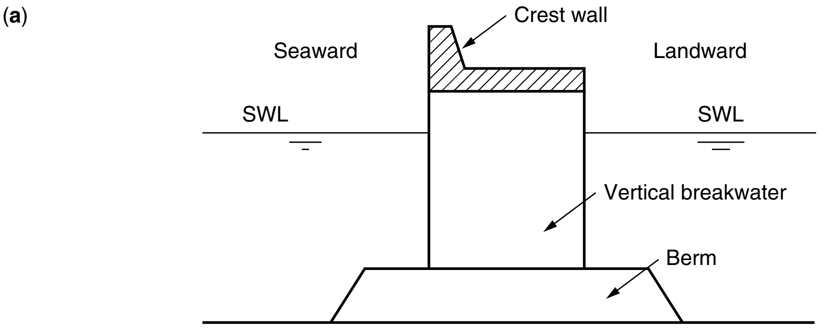
The forces acting are total wave pressure seaward (different for breaking or nonbreaking waves), hydrostatic force landward due to the still water depth, the buoyancy and the uplift force under the caisson, and the weight of the caisson. In some locations, ice force must be considered.

Sliding is verified if the total normal force multiplied by the coefficient of friction between the caisson and the berm is greater then 1.3 times the horizontal sliding force. Overturning is verified if the total stabilizing moment is greater then 1.5 times the overturning total moment. The point of overturning is the landward corner of the caisson. The last verification is to see if the resistance of the base (its critical value) is greater than the pressure due to the resultant of the acting forces. Stress is transmitted from the bottom of the caisson to the soil at an angle of 45°; this is ensured if the berm is large enough with respect to the caisson.

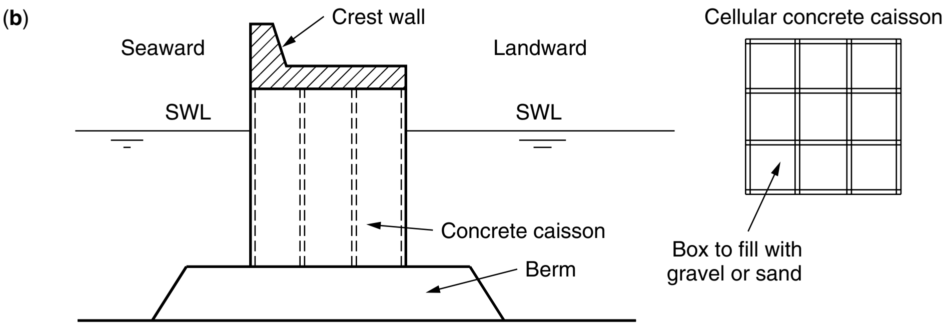
Sheet Piling Breakwater

Sheet piling structures are a particular type of vertical breakwater that consist of a series of piles engaged to form a continuous structure. The material most used is steel, but it possible to use reinforced concrete and timber. The choice depends on economic considerations and the availability of material. A vertical breakwater can be made of a single line of sheet piling, a double wall of sheet piles, or a cellular unit that has its the cavity filled with sand or rock. The head of a sheet piling is generally of rock, concrete slab, or paving. If steel piling is used, protection against corrosion should be provided.

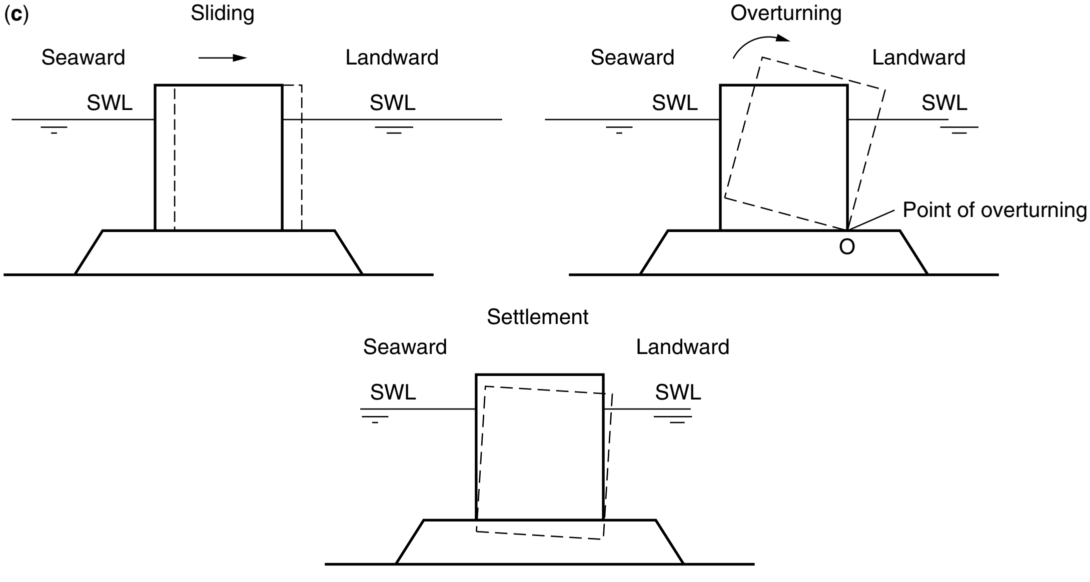
The forces acting on sheet piling are the same as on caissons. Generally the worst conditions happen when the trough of the waves passes. In this case, the saturated backfill soil could cause the wall to fail seaward. The penetration of the sheet pile in to the soil has to develop the necessary resistance to cantilever action. The double wall ensures more resistance; the walls are as far apart as the depth of the water, and can be connected by cross-walls to form boxes. These boxes can be filled with sand or rocks to increase stability. A cellular sheet piling is necessary in deep water to stiffen the structure. Timber sheet pilings



Typical vertical breakwater



Concrete caisson vertical breakwater



Types of failure

Figure 3. Vertical breakwater sections and types of failure.

are used in shallow water locations where wave conditions are moderate.

FLOATING BREAKWATERS

Floating breakwaters consist of composite structures that float on water (17). They can be used where waves are moderate and have a very short period. These structures are low in cost, insensitive to water depth and are easily portable, even if they provide less protection than fixed breakwaters. Generally, they consist of a box, pontoons, tethered floats, and floating docks affixed to piles. The floating breakwater reduces wave energy by reflection, dissipation interference, and conversion of the energy into a mono-oscillatory motion. The dimensions of floating breakwaters (the penetration depth, in particular) depend on the amount of energy that is necessary to dissipate and the mooring force on the anchor of the structure. The more the structure extends to the bottom the greater the reflection and the dissipation, but the mooring force also increases.

THE OCEAN IN CLIMATE

Edward S. Sarachik

(from *The Handbook of Weather, Climate, and Water: Dynamics, Climate, Physical Meteorology, Weather Systems, and Measurements*, Wiley 2003)

INTRODUCTION

Earth's present climate is intrinsically affected by the ocean—the climate without the ocean would be different in many essential ways: Without the evaporation of water from the sea surface, the hydrological cycle would be different; without ocean heat transport and uptake, the temperature distribution of the globe would be different; and without the biota in the ocean, the total amount of carbon in the atmosphere would be many time its current value. Yet, while we may appreciate the role of the ocean in climate, the difficulty and expense of making measurements below the ocean's surface has rendered the vast volume of the ocean a sort of *mare incognita*. Why is the ocean so important in Earth's climate, and which of its properties are of special significance for climate? How have we learned about the ocean and its role in climate, and what more do we need to know?

PROPERTIES OF THE OCEAN AND PROCESSES IN THE OCEAN

The ocean covers 70% of Earth's surface to an average depth of about 4 km. The mass of the ocean is 30 times and its heat capacity 120 times that of the atmosphere, and the ocean contains 80 times the carbon dioxide stored in the atmosphere.

The density of the ocean is controlled both by its temperature and by its salt content. Ocean density increases with salinity and decreases with temperature. Unlike fresh water, which has a maximum density at 4 °C (so that colder water and ice float on 4 °C water and the temperature at the bottom of a nonfrozen lake is 4 °C), water saltier than 26 parts per thousand of water is continuously denser as the temperature is lowered, and the temperature at the bottom of the ocean is closer to 1 °C.

Since heat always diffuses from warm to cool temperatures, why does not the temperature of the deep ocean eventually adjust and become the same as its surface temperature? Cold water constantly sinks at high latitudes (both in the Northern and Southern Hemispheres) and fills the deeper parts of the oceans with cold water so that the water at depth is always cold, even when the surface temperature is very warm. This circulation is called the thermohaline circulation.

About 7% of the ocean surface is covered by sea ice. Growth of sea ice radically changes the nature of the ocean surface: Sea ice reflects solar radiation, thereby preventing it from being absorbed by the surface and blocks the transfer of heat and moisture from the surface of the ocean to the atmosphere.

The average salinity in the global oceans is 34.7 parts per thousand salt to water by weight. As the total amount of salt in the ocean is constant, changes in salinity only occur because of additions and subtractions of fresh water. Salinity decreases as rain falls on the ocean or river water enters the ocean, and it increases as water evaporates from the surface of the ocean. As sea ice grows, it rejects salt into the ocean thereby increasing its salinity. Similarly, as ice melts, it dilutes the surrounding ocean and lowers its salinity. A specific parcel of water can either increase or decrease its salinity by mixing with parcels with different salinities.

HOW THE OCEAN INTERACTS WITH THE ATMOSPHERE TO AFFECT THE CLIMATE

The ocean interacts with the atmosphere at (or very near) the sea surface where the two media meet. Visible light can penetrate into the ocean several tens of meters, but heat, moisture, and momentum, carbon dioxide, and other gases exchange directly at the surface. Sea ice forms at the surface and helps to determine the local exchanges. The basic problem of the ocean in climate is to explain these interchanges and to determine those characteristics of the ocean that affect these exchanges.

The ocean may be considered to interact with the atmosphere in two distinct ways: passively and actively. It interacts passively when the ocean affects the atmosphere but does not change the essential manner in which the atmosphere is operating. An example of a passive interaction is the oceanic response to adding CO_2 to the atmosphere where the ocean simply delays the greenhouse warming of the atmosphere as heat and CO_2 enters the ocean.

Active interaction with the atmosphere produces results that would not otherwise be there—an example is where the warming of the atmosphere reduces the thermohaline circulation and produces a climate reaction that could not have been obtained without the essential interaction of the ocean. In particular, since the northern branch, say, of the thermohaline circulation brings cold water from high latitudes toward the equator, and since the water must be replaced by warm water that is cooled as it moves northward, the net effect of the thermohaline circulation is to transport heat northward and thereby warm the higher latitudes. As the atmosphere warms, the water becomes less dense both by the effect of temperature and by increased rainfall, a necessary concomitant of global warming. Since the atmosphere sees a reduced north–south temperature gradient at the sea surface, it reacts fundamentally differently than if the thermohaline circulation were at full strength.

Our present models of greenhouse warming have the ocean acting in both the active and passive modes—active when warming leads to a slowed thermohaline circulation and passive when heat and CO_2 simply enter the ocean surface and is therefore lost to the atmosphere. Another example of active interaction is El Niño, a phenomenon that would not exist were it not for the active interaction of the atmosphere and the ocean (see the chapter by Trenberth). The ocean also has been inferred (by examining the composition of ancient ice stored in the Greenland and Antarctic ice sheets) to have, and probably actively take part in causing, climatic variability on time scales anywhere from decades to a few thousand years, a type of variability not seen on Earth since it emerged from the last glacial maximum some 18,000 years ago.

MEASURING THE OCEAN

The ocean is remarkably poorly measured. While the global atmosphere is constantly probed and analyzed for the purposes of weather prediction, until recently no such imperative existed for the ocean. Our ability to measure the ocean is severely limited basically by the inability of radiation to penetrate very far into the ocean—this requires direct *in situ* measurements of the interior of the ocean. The world's oceanographic research fleet is small and incapable of monitoring the breadth and depth of the world's ocean, although valuable research measurements are constantly being taken at selected places. As a result of ocean observations, we know the basic pathways of water in the ocean, we have a good idea of the transports by the ocean, we have some idea of the basic mechanisms for much of the major ocean currents, and we have a good idea of how the exchanges at the surface are accomplished. Yet we cannot measure vertical velocity (it is far too small), and so we remain completely ignorant of the processes by which the interior of the ocean affects the surface. Similarly, we are ignorant of the basic processes of mixing and friction in the ocean, both basic to being able to model the ocean for climate purposes.

Major oceanographic programs have been conducted in the last decade (the World Ocean Circulation Experiment, WOCE) and (the Tropical Ocean–Global Atmosphere, TOGA), and while they have taught us much about the ocean circulation and El Niño, respectively, the basic lesson is that, unless we can make continuous long-term measurements beneath the surface of the ocean, it will forever remain unknown territory.

MODELING THE OCEAN

Because the ocean is poorly measured, and because much of what we need to know about the past and predict about the future cannot be directly known, only inferred, models have played a particularly important role in the development of oceanography and, in particular, the role of the ocean in climate.

The basic tool of climate studies is the coupled model, where the various components of the climate system—the atmosphere, ocean, cryosphere, biosphere, and chemosphere—are simultaneously and consistently coupled. The ocean component of such a coupled model exchanges its heat, fresh water, and momentum with the atmosphere at the sea surface. The test of the successful coupling of the atmosphere and ocean is the correct simulation of the time-varying sea surface temperature and surface winds, both of which are relatively easy to measure: Directly by ship or mooring, remotely by satellite, or by a combination of the two.

The development of off-line ocean-only models requires the heat, momentum, and freshwater forcing from the atmosphere to be known. Since precipitation and evaporation, in particular, are so poorly measured over the ocean, it is a continual struggle to know whether errors in the ocean model are due to errors in the model itself or errors in the forcing of the ocean by the atmosphere.

Ocean models themselves are relatively simple in concept: The known equations of water and salt are discretized and time stepped into the future. The discretization process requires a trade-off between fine resolution for accuracy and the need to simulate over long periods of time, which, because of limited computer resources, requires coarser resolution. While the equation of state of seawater relating density to salt, temperature, and pressure cannot be written down simply, it has, over the course of time, become known to high accuracy.

What makes ocean modeling difficult is the specification of those mixing processes that unavoidably cannot be resolved by whatever resolution is chosen. We are beginning to understand that enhanced small-scale mixing occurs near bottom topography and near boundaries: Purposeful release experiments, where a dye is released and then followed in time to see how the dye cloud evolves, has revealed this to us. Larger scale mixing, where parcels are interchanged because of the large-scale circulation (but still unresolved by the ocean models) itself is more problematic, but recent advances in parameterizing these unresolved mixing effects have shown promise.

THE FUTURE OF THE OCEAN IN CLIMATE

It is clear that the ocean is a crucial component of the climate system. Since so much of what is not known about the past and future of the climate system depends on active interactions with the ocean, it is clear that we have to learn more about its essential processes. How to go about learning about the ocean is the difficult question.

Direct measurements are very expensive, and satellites, while giving a global look at the entire ocean, see only its surface. Designs are currently underway for a Global Ocean Observing System (GOOS), but the cost of implementing such a system in toto is prohibitive, even if shared among the wealthier countries of the world.

It is likely that a combination of studies, perhaps conducted for entirely different purposes, will advance the field most rapidly. In particular, the advent of the El Niño–Southern Oscillation (ENSO) prediction, which requires subsurface ocean data as initial conditions, has made almost permanent the Tropical Atmosphere-Ocean (TAO) array in the tropical Pacific, giving an unprecedented and continuous view of a significant part of the tropical ocean. We may extend the reasoning to say that, where predictability is indicated and shows societal or economic value, the measurement systems to produce the initial data will almost certainly be implemented. The promise of predicting climate from seasons to a few years will expand the ocean-observing system considerably. Additional expansions will come from resource monitoring, pollution monitoring, and various types of monitoring for national security purposes. While monitoring for security has traditionally meant the data is classified, once taken, data can eventually reach the research arena—the vast amount of Soviet and U.S. data that was declassified after the end of the cold war has shown this.

Observations can be also combined with models to give "value-added" observations. Data at individual points in the ocean exist without reference to neighboring points unless models are used to dynamically interpolate the data to neighboring points using the equation of motion of a fluid. This so-called four-dimensional data assimilation is in the process of development and shows promise as a powerful way of optimally using the ocean data that can be taken.

Models can also be compared with other models. While this might seem sterile, fine-resolution models can be used to develop parameterizations of large-scale mixing for use in coarse-resolution ocean models that can be run the long times needed to participate in coupled model simulations of climate. Advances in computer power will ultimately allow successive refinements in resolution so that finer scale resolution models can be run directly.

We close by reemphasizing the crucial role that the ocean plays in climate and climate variability and the necessity to know more about the ocean for all aspects of the climate problem.

COASTAL WATERS

Susan-Marie Stedman
Silver Spring, Maryland

Coastal waters are usually defined as those waters in a zone whose landward boundary is the limit of tidal influence and whose seaward boundary is the edge of the continental shelf (or a depth of 200 m if there is no continental shelf). Salinity, temperature, turbidity, and other characteristics of coastal waters vary considerably in this transitional and very dynamic zone.

The effects of waves, wind, and other processes create two distinct layers in coastal waters: an upper surface layer known as the "mixed layer," which varies in thickness from tens to hundreds of meters thick, and a lower "deep layer." The mixed layer is warmer and less saline than the deep layer. The deep layer generally contains more nutrients due to the decomposition of organic matter that has fallen to the ocean bottom. The transition between the two layers, called the pycnocline, is usually very abrupt, occurring over a space of a meter or less (1).

The majority of coastal waters occur in three types of environments: the relatively low energy environments of estuaries and bays, the high-energy environments of waters along rocky shores and beaches, and the deeper waters of the continental shelf. All coastal waters are subject to the effects of tides, waves, and currents, to varying degrees. Coastal waters are also often affected by activities in coastal terrestrial areas, especially in parts of the world where urban and suburban development in coastal areas is intense.

PHYSICAL PROCESSES IN COASTAL WATERS

Waves

Waves in coastal waters are produced by the wind and modified by their interaction with the coastline itself. There are two general types of waves: chop, which are the short steep waves seen on windy days; and swell, which are the long gentle waves that are present even on calm days. Chop is produced by local wind conditions, whereas swell is produced by storms very distant from the coastline. Waves are often described by their period (the time between two successive crests passing the same point), length (the distance from one crest to another), height (the distance from the trough to the crest of the wave), and their speed, which is determined using the equation

$$C(\text{speed}) = \Lambda(\text{length})/T(\text{period})$$

As waves move from the deep ocean to shallow coastal waters their speed is affected by the depth of the water as defined by the equation $c = \sqrt{gH}$, where g is the acceleration due to gravity and H is the water depth. As waves approach the shore, the speed of the wave crests becomes greater than the speed of the wave troughs, creating the characteristic "breakers" that crash onto the shore.

If waves approach a shoreline at an angle they will be refracted: that is, they will bend so that they become more parallel to the shore. Wave refraction affects where wave energy is concentrated; for example, a protrusion of the shoreline will cause waves to bend toward it, concentrating wave energy in that area. Areas of wave convergence are usually subject to intense erosion, whereas areas of wave divergence tend to be depositional; thus the overall effect of waves is to straighten the coastline.

Tides

Tides are created by complex interactions between astronomical forces and the earth's geomorphology. One can begin to understand tides by imagining that the earth is covered with a layer of water with uniform depth. Gravitational and centrifugal forces associated with the moon and, to a lesser extent, the sun produce a bulge in the water at points both closest to the moon and on the opposite side of the earth. As the earth completes one rotation, a hypothetical point on the earth's surface will pass through a bulge twice, generating two high tides (and two low tides), which is known as a semidiurnal tide. Because the moon is rotating around the earth, each high tide theoretically occurs a bit later (approximately 30 min) than 12 h after the previous one. The sun's effect on tides produces the difference in tidal range seen during the lunar cycle. When the earth, moon, and sun are aligned, the tidal bulge is largest and the coast sees the highest high tides and the lowest low tides (both are known as "spring" tides). When the sun and moon are aligned at right angles with respect to each other and the earth, the tidal bulge is decreased, resulting in reduced tides (know as "neap" tides).

The actual dynamics of tides is much more complex than this simple theory alone can explain. Tides are affected not only by astronomical factors but also by the sizes, shapes, and depths of water bodies, by winds, by the earth's rotation, and by changes in barometric pressure. A wide range of tidal cycles and tidal ranges occurs around the world. Although most parts of the world have semidiurnal tides, some have only one high tide and one low tide per day (diurnal tides), and some experience a phenomenon known as "double low water," where two extreme low tides occur between high tides occurring 24 h apart (2). Tidal ranges vary not only with the lunar cycle but geographically, from a few centimeters in the Gulf of Mexico to the famous 12-m tides in the Bay of Fundy. However, at any given location along the coast, the tidal cycle is fairly constant, allowing prediction of tidal periodicity and height based on data from past years. As physical oceanographers become more adept at modeling tidal dynamics, predictions also can be made for areas without such records.

Currents

Both waves and tides, as well as the wind, generate currents in the ocean that circulate water between numerous and sometimes disparate oceanic and coastal environments. Where these currents are close to shore, they strongly influence not only the coastal waters but the shape of the coastline itself. Of most importance, however, is the way currents transport nutrients, sediments, and marine life along the coasts. Currents generally fall into three categories: tidal currents, drift currents, and a phenomenon known as upwelling.

Tidal Currents. Among the strongest forces affecting coastal waters are tides. Tidal currents are strongest where a constriction (such as a narrow tidal inlet) or other topographic feature (a valley in the continental shelf) concentrates the tidal flow. Tidal current velocities range between zero at slack tide (exact high or low tide) to midtide maximums that are generally in the range of 1–5 km/h. Under the Golden Gate Bridge in San Francisco, tidal currents sometimes reach 9 km/h, and at Seymour Narrows, British Columbia, they can reach 24 km/h (3). Tidal currents have long been considered a source of renewable energy and are being used to generate power in Canada, Russia, and France. These projects involve damming a portion of an estuary and using the force of the tide leaving the estuary to turn turbines. More recently, proposals have been made to place undersea "windmills" in areas of strong tidal currents to generate power without incurring the environmental cost of damming an estuary.

Drift Currents. Drift currents are caused by winds moving the surface layer of water. The strength of a drift current depends on wind speed, duration (how long the wind has been blowing), and fetch (how wide the body of water is). The velocity of drift currents rarely exceeds 1–2% of wind speed (1). Drift currents tend to move in the direction the wind is blowing but are also affected by the rotation of the earth, which creates a phenomenon known as the Coriolis effect. The Coriolis effect is best known for describing the direction in which a whirlpool or hurricane will rotate (clockwise in the northern hemisphere, counterclockwise in the southern hemisphere), but it also affects currents the same way. Thus, drift currents in the northern hemisphere will tend to curve to the right (and in the southern hemisphere to the left), giving rise to what is known as "Ekman drift." Finally, when a drift current encounters a coastline, it will tend to parallel the coastline in what is known as "littoral drift."

Upwelling. Upwelling refers to the vertical movement of water that occurs when the surface layer is pushed offshore

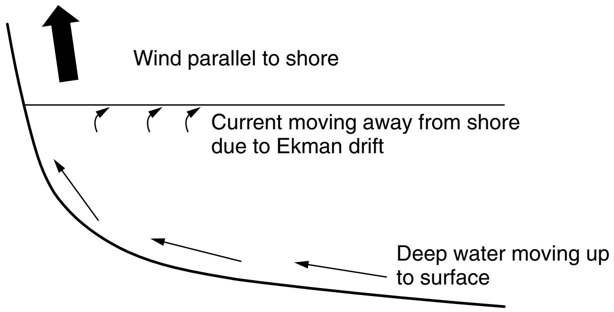

Figure 1. Upwelling along a coast.

by wind and Ekman drift, causing deeper waters to rise up and take its place (Fig. 1). While upwelling can be localized and transitory, prevailing winds create major upwelling areas along the coasts of Oregon in the United States, Peru in South America, northwest Africa, southwest Africa, and the western Indian Ocean. Where winds are steady, the upwelling is likewise fairly constant, for example, the Peruvian upwelling system; but where winds fluctuate (northwest Africa) or are only seasonal (the monsoon winds of the eastern Indian Ocean), upwelling is also periodic or seasonal. Upwelling introduces deep waters rich in nutrients into the coastal ecosystems, creating areas of high productivity and high concentration of marine life (4).

CHEMICAL CHARACTERISTICS OF COASTAL WATERS

Although fresh water is an important component of estuaries, ocean water is the primary component of most coastal waters. The primary dissolved constituents of ocean water (in greatest to lowest concentration) are calcium, magnesium, sodium, potassium, bicarbonate, sulfide, chloride, and bromide. These molecules combine in various ways to create salts, of which sodium chloride (table salt) is the most common. Salt content, or salinity, is measured in parts per thousand (ppt). The average salinity of ocean water is 35 ppt (5), but in coastal waters salinity can be reduced by the addition of fresh water from rivers, overland runoff, and/or groundwater discharge.

Ocean water also contains nutrients in the form of nitrogen and phosphate salts. The concentration of these nutrients is very low in the surface layer of the open ocean, only 0.001–0.08 mg/L N and 0.002–0.003 mg/L P, but can be 10–100 times higher in the deep layer. Oxygen, a very important constituent for biological activity, is dissolved in ocean water at concentrations from about 8 cm^3/L (for cold waters near the poles) to 4.5 cm^3/L (for warm waters at the equator). Other dissolved gases in ocean water include nitrogen, carbon dioxide, and hydrogen sulfide. The pH of ocean water varies between 7.9 and 8.3 (1).

With 44% of the world's population living within 150 km of the coast (6), human activities have a significant influence on the chemistry of coastal waters. Garbage, sewage, effluent from manufacturing plants, runoff from industrial and agricultural areas, as well as many other sources contribute nutrients, sediment, metals, pesticides, hydrocarbons, and other pollutants to coastal waters. Clumps of floating garbage, dead fish, and oiled beaches are some of the most visible effects of humans on coastal waters, but more recent concern has centered on "dead zones," areas where excess nutrients have led to overproduction of plant material, which in turn leads to oxygen depletion in a process known as "eutrophication" (7). Nutrient enrichment of coastal waters is a global problem that continues to grow as more countries increase their use of fossil fuels and inorganic fertilizers, the two principal sources of anthropogenic phosphorus and nitrogen (8).

TYPES OF COASTAL WATERS

Estuaries and Bays

An estuary is "a semi-enclosed coastal body of water which has a free connection with the open sea and within which sea water is measurably diluted with fresh water derived from land drainage" (9). Although the "land drainage" is not specified in Pritchard's classic definition, it is generally assumed that the freshwater source is a river, as is mentioned in many other definitions of an estuary (10). The tidal portion of streams that drain into estuaries is also considered to be part of the estuary. Bays are also semienclosed bodies of water, normally open to the ocean, but they differ from estuaries in not being associated with a river. Estuaries are much more common along the world's coasts than bays, although the term "bay" is often used in the name of an estuary, for example, Chesapeake Bay. Both estuaries and bays provide protected aquatic environments for marine life, but estuaries are more diverse and often more productive due to the range of habitats created by the salinity gradient and input of nutrients from streams. Dyer (11) described four physiographic types of estuaries: coastal plain estuaries (such as the drowned river valleys along the southeast coast of the United States), fjords (such as the submerged glacial valleys of Canada and New Zealand), lagoons (estuaries created by spits or bars), and tectonic estuaries (such as San Francisco Bay).

Rivers bring fresh water into an estuary, and tides bring saline water into the estuary. Where mixing is minimal, a layered water body is created with the less dense fresh water on top and the more dense saline water on the bottom (Fig. 2).

Turbulence in the water causes mixing of the two layers, which increases the thickness of the fresher upper layer as it moves from the landward part of the estuary toward

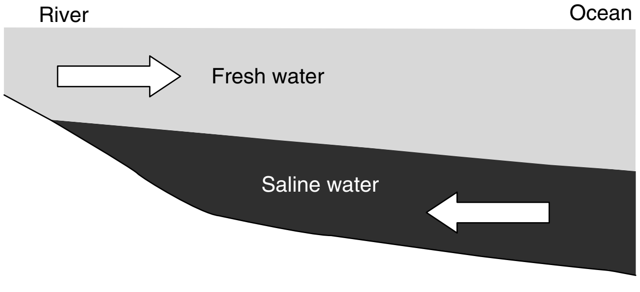

Figure 2. Layers of fresh water and saline water in a stratified estuary.

the ocean (4). The degree of mixing between the layers depends on the amount of freshwater input, the strength of tidal flow, and the effects of wind. Estuaries are often described as being one of three types: salt-wedge, partially mixed, or vertically homogeneous. When an estuary has a large freshwater input relative to tidal flow, the saline water tends to remain at the bottom with minimal mixing and the tip of this “salt wedge” changes location with the seasonal variation of freshwater flow. In partially mixed estuaries, the effects of tides and/or wind create a transition zone between the saline and fresh water layers. The mixing of the layers results in resuspension of sediments and nutrients brought into the estuary by the river and tide. In a vertically homogeneous estuary, there are no longer two water layers, but rather a single mixed body of water with a salinity gradient from low at the river mouth to high at the estuary’s outlet to the ocean. In fjords, a sill at the mouth of the estuary traps saline water behind it, and mixing of fresh and saline water only occurs at the surface in water lying above the sill. The deeper waters behind the sill are replaced only when storm events disrupt this balance.

River discharge and tidal exchange both bring sediment and nutrients into an estuary. Estuaries tend to act as sediment traps due to two changes that occur when river discharge meets seawater. First, when clay particles in fresh water encounter saline water, the particles tend to flocculate (creating what is called a “turbidity maximum”) and ultimately sink to the bottom of the estuary. Second, as rivers discharge fresh water at the surface of the estuary and tides bring saline water into the bottom of the estuary, current velocities decrease, causing sand particles to settle out. Complex hydrodynamics determine how much sediment stays in the estuary and how much is transported through the estuary to the ocean. Ultimately, sediments in estuaries undergo many cycles of transport by tides, currents, and waves before they find a permanent resting place (12).

Nutrients can be brought into estuaries in particular form, as dissolved constituents, or even via the atmosphere. Phosphorus, one important nutrient, has natural sources in soils and rocks. Weathering creates small particles with phosphorus bound to them that are carried into estuaries. Nitrogen, another important nutrient, is also found naturally in soils, but it is much more soluble than phosphorus and so tends to enter an estuary predominantly in dissolved form. Natural sources of nitrogen and phosphorus are generally small when compared to human-related sources such as agriculture (inorganic fertilizers), wastewater, and fossil fuel. Atmospheric deposition of nitrogen derived from fossil fuel combustion or animal waste is thought to be an important source of excess nutrients to estuaries in the United States (8).

Rocky Shores and Beaches

Rocky shores and beaches are high energy environments. Waves and currents keep the water almost constantly in motion and well aerated. The shoreface is a transition zone where waves become influenced by the bottom and change shape, increase in height, and realign to become more parallel to the shoreline. In the surf zone, currents are driven by the interaction of waves with the shoreface and with other waves. In some places the water draining off the shoreface creates very strong seaward-moving currents known as “rip currents.” Offshore from the surf zone, currents are dominated by wind and tide energy but still tend to parallel the coastline.

Plants and animals must have special adaptations to thrive in these environments. Kelp and seaweed have strong attachment systems to keep them in place, and the dominant invertebrates have protective shells. Furthermore, the vigorous movement of water along rocky shores and beaches is essential to the survival of these organisms because they feed by filtering the water or snatching debris as it floats by. Sandy areas are the most dynamic because not only is the water constantly moving, but the substrate itself tends to move as well. Although many beaches seem devoid of plant or animal life, that appearance occurs only because most beach inhabitants are buried in the sand.

Shelf Waters

Seaward of estuaries and the coastline are the waters overlying the continental shelf. Tides continue to influence these waters, creating turbulence that results in a mixed water layer that can extend for tens of kilometers outward from the coast (2). Beyond this mixed layer, coastal waters become stratified into the surface and deep layers described earlier. Areas of high productivity tend to occur at the transition between mixed and stratified waters.

Coastal shelf waters are an important component of ocean circulation. Prevailing winds and the earth’s rotation create a system of major currents that circle the ocean basins and in some cases move water from one basin to another. The strongest currents occur on the western sides of ocean basins, where they carry water toward the poles, and weaker currents occur on the eastern sides of ocean basins, where they carry water toward the equator. These major currents, which transport volumes ranging from 10 to 100 m^3/s (2), serve many important biological functions related to migration, dispersal of juvenile organisms, and transportation of nutrients. One of the best-known oceanic currents is the Gulf Stream, which occurs off the east coast of North America. Coastal waters also contain coastal boundary currents that trend parallel to the coastline, their overall direction determined by the shape of the coastline and the way winds tend to reorient perpendicular to the coast as they approach the coastline. For example, landward of the Gulf Stream in the western north Atlantic Ocean, a coastal boundary current flows south—opposite to the direction of Gulf Stream flow. Coastal boundary currents transport lesser volumes of water than oceanic currents—about 10 m^3/s on the average (2).

IMPORTANCE OF COASTAL WATERS

Coastal waters are extremely important for fisheries. With the exception of a few deep-water migratory species such as tuna, most other commercial and recreational marine fish (and shellfish) feed, reproduce, and are harvested in coastal waters. In the United States, coastal waters support a commercial fishing industry that in 2002 landed 4.3 million metric tons of fish and shellfish valued at $3.1 billion. The commercial fishing industry as a whole contributed $28.4 billion to the U.S. gross national product (GNP) in 2002 (13). Recreational fishing also produces billions of dollars of economic benefits per year (14). Coastal waters are also a very important habitat for marine mammals such as seals, manatees, and sea lions, some of which are listed as threatened or endangered under the U.S. Endangered Species Act.

Coastal waters are also very important to interstate and international commerce. Transport by water is generally the most economical and efficient means to move goods. U.S. ports and waterways transport more than 2 billion tons of domestic and foreign goods each year. The marine transportation industry contributes $742 billion to the U.S. GNP and provides approximately 13 million jobs (15).

Given the importance of coastal waters to fisheries, marine transportation, and numerous other uses that are significant from either an economic or ecological perspective, conflicts over coastal waters are common. Laws and regulations governing environmental protection and management of natural resources in the United States and other countries often require a cost–benefit analysis of proposed activities in coastal waters, or a determination that a proposal is in the best interests of the public. However, uncertainties about quantifying ecological values and predicting the response of coastal systems to change make it difficult to conduct these kinds of evaluations. The future health of coastal waters depends on a better understanding of their processes and their response to human activities.

MARINE COLLOIDS

Peter H. Santschi
Texas A&M University
Galveston, Texas

Aquatic colloids, as nanoparticles and macromolecules in the 1 nm to 1 µm size range (1), differ fundamentally from solutions. In a solution, all the relevant interactions are comparable to the thermal energy, kT. Thus, even if water 'prefers' water, the tendency toward disorder—entropy—is dominant. In contrast, the colloidal state is unstable because of large interfacial energies and because particle–particle interactions are stronger than kT. In aquatic systems, physical techniques such as diffusion, permeation, light scattering, and viscosity can be used to characterize colloidal systems, chemical techniques can help to unravel their compositional complexities, and biological techniques can give insights into degradability, bioavailability, and stability. New insights into colloids in marine systems require application of state-of-the-art techniques and also paradigm shifts.

Most of the organic matter in the ocean is in the dissolved state, and 20–30% of the marine DOC is colloidal and subject to rapid turnover (2). Marine colloidal matter (COM) contains biologically resistant heteropolycondensations, such as humic-type molecules (geopolymers) that act as soaps, and products of carbon fixation and consumption, such as exopolymeric substances (EPS) that self-assemble (3,4) and thus act as glues (5,6, and references therein). Both geopolymers and biopolymers also contain strong metal-binding ligand groups, rendering them as metal-sequestering agents. Therefore, colloids in the ocean can act as vectors of metal removal and of solubilization, depending on the biomolecule, as well as modifiers of metal bioavailability. In addition to questions of metal bioavailability in the delicately balanced marine ecosystem, EPS in the marine colloidal pool are also important in their response to global change, as they provide some of the sinking material, that is, one of the conveyor belts of global carbon cycling. Last but not least, man-made nanoparticles, such as buckeyballs, carbon fibers, and nanotubes, which are potentially toxic to man, will make their way into the environment, and ultimately into the ocean, where they have unknown behavior and fate.

Colloids in seawater can be small and globular or long and fibrillar, as shown in Figure 1. Aquagenic fibrillar gel-forming microbial exudates are classified as “rigid”, other colloids, such as terrestrially derived (pedogenic) nanometer-sized humic acids, are more globular and are called “flexible” polymers (8–11). Both types of colloids are stabilized by metal ions such as Ca^{2+}, which holds individual humic acid molecules together as

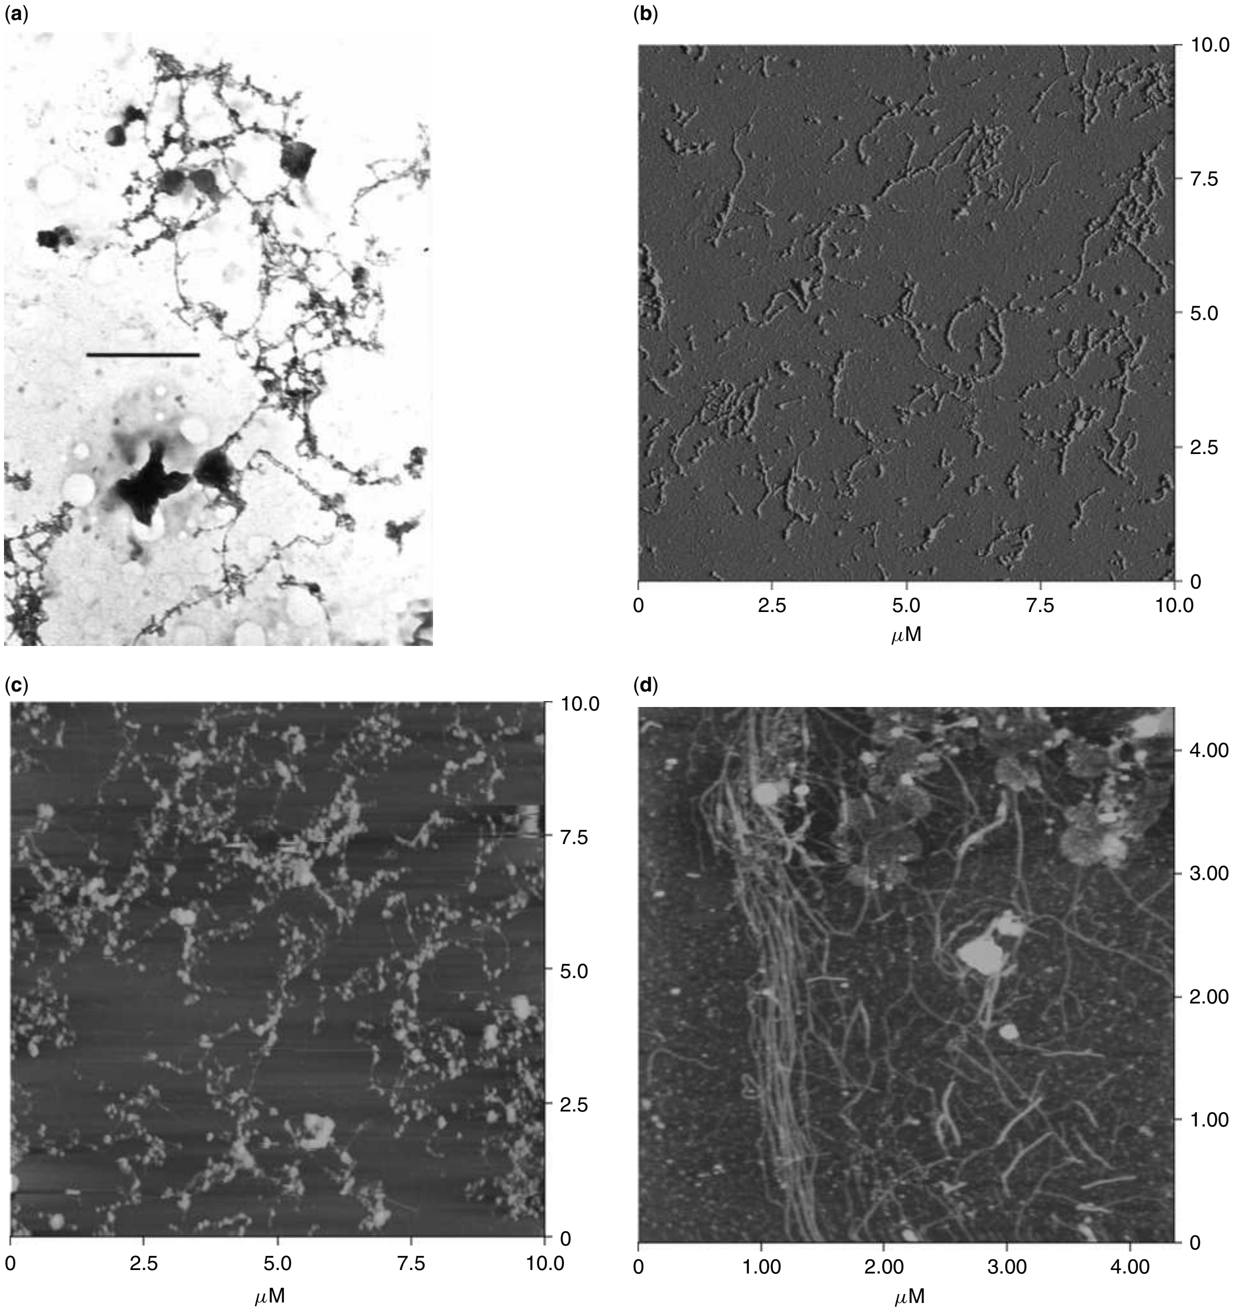

Figure 1. Fibrillar network of colloidal particles and fibrils (7) arranged in a pearl-on-necklace fashion. (**a**). Transmission electron microscopy (TEM) of stained fibrillar network, embedded in a hydrophilic resin, which is part of colloidal organic matter, COM (ultrafilter size range of 2–400 nm), sampled from Middle Atlantic Bight surface waters (courtesy of K. Wilkinson); (**b**). Atomic force microscopy (AFM) of sample from Middle Atlantic Bight surface water COM; Fibrils were also identified by AFM, albeit at lower abundance, in nepheloid layers at 2500 m but not in midwaters; (**c**). AFM of COM from Galveston Bay waters, TX. (**d**). AFM image of COM from surface waters of the Gulf of Mexico, which shows the potential for gel formation of fibrillar macromolecules at the edge of the mica support plate, where the gel-like aggregates likely formed as a consequence of drying.

aggregates (12) and gives rigidity to alpha-helical regions within exopolymeric fibrils (13). These exopolymeric fibrils are up to several 1000 nm in length, but only 1–3 nm wide, and can exist abundantly attached to cell surfaces or as free colloids (7,14–16). The degree of rigidity of fibrillar biopolymers can be studied using atomic force microscopy (AFM) or SANS (small angle neutron scattering). These fibrils can also be characterized by persistence length (defines a kind of stiff-chain-segment length for a linear polymer chain), end-to-end distance, and contour length (11). These measures allow predicting their physicochemical behavior in solution.

Marine colloids are commonly sampled for characterization using cross-flow ultrafiltration (17,18, and references therein) or field-flow fractionation techniques (19). Recent applications of ultrafiltration methods to the sampling of aquatic colloids have advanced our understanding of the abundance, distribution, physical conformation, chemical composition, and environmental behavior of colloids in aquatic systems, including freshwater, seawater, and groundwater. Applications of ultrafiltration to marine systems date back to the 1970s and 1980s, when mostly stirred cell ultrafiltration units with membrane disks were used. Applications of large volume cross-flow ultrafiltration systems to sampling marine colloids started in the early 1990s, and they are now commonly used in marine science (20,21).

In estuarine waters, many metals such as Cu, Ag, Fe, Hg, and Zn, have been found largely in colloidal form (5,18,22,23, and references therein). In marine environments, studies indicated that high molecular weight (HMW) COM has relatively high biological and chemical reactivity and short residence times in the water column (2,24). Therefore, colloids are also important intermediaries in organic carbon cycling in aquatic environments. Recent advances in sampling techniques now enable the isolation of large quantities (e.g., 100s of mg) of environmental colloids from large volumes of natural waters for elemental, isotopic, and molecular characterization (2,7,20,25–27), although there is still a debate about optimal sampling procedures (21,28, and references therein).

Due to their amphiphilic (or amphipathic) nature, aquatic colloids are not only charged, thus providing potentially strong chelating binding sites for trace metals and radionuclides, but also contain hydrophobic moieties for binding more hydrophobic organic trace compounds (5,29,30, and references therein). There are many potential metal binding sites in aquatic biomacromolecules, but most of them are occupied by major seawater cations, and much fewer with the much rarer trace metal ions. Binding sites include carboxyl, hydroxyl, phosphate, sulfate, amino, and sulfhydryl groups; A (or hard) metals prefer O over N and S binding sites, and B (or soft) metals prefer S (or N) over O binding sites (31). One would also expect to find that metal enrichments follow the Irving–Williams series, which has been documented for marine colloids by Guo et al. (32), and for bacterial EPS by Rudd et al. (33). Many of these sites are not exceptionally strong when acting alone, but the particular steric environment of the macromolecule can provide strongly chelating binding sites for trace metals when acting in concert (34,35). In addition, in the "egg-box" chelating environment (13,36), where Ca^{2+} stabilizes the alpha helix of acid polysaccharides (APS) such as alginic acid, Ca^{2+} can be replaced by other cations with similar radii.

EPS are usually rich in APS, and because much more is known about biopolymers such as APS that are studied in food science or biomedical science, where they are used as emulsifiers, stabilizers, coagulants (or anticoagulants) through their amphiphilic properties (37), the concepts and approaches in these scientific disciplines are very useful here. APS include alginates, carrageenans, xanthans, and hyaluronic acids, which contain building blocks that are also found in EPS and transparent exopolymeric particles (TEP) (14,38,39). One may therefore apply knowledge from these scientific disciplines to the biomolecular complexants in the marine colloidal pool, which are not as well studied. The physicochemical properties of EPS molecules are important because they can provide "hideouts" for micronutrients such as trace metals. EPS molecules contain APS and also proteins or lipids, which makes these molecules amphiphilic (1). The amphipilicity is caused by the generally hydrophilic properties of their acid polysaccharidic regions and the more hydrophobic properties of their protein or lipid-rich regions (37). Many of these EPS biopolymers also form gels (3,6) and thus, have properties of hydrocolloids.

Colloidal ligands that have surface-active properties and are found in the filter-passing fraction can be the cause of particle concentration effects on particle–water partition coefficients (K_d, the concentration ratio in particles and in solution) and kinetic constants (k_i) of trace metals or radionuclides, which have been documented in the literature for many years. Colloidal ligands can often be removed by coagulation (40,41) and flocculation (5). Such particle-concentration effects disappear, however, when one corrects for the presence of colloidal ligands (29). Values of the partition coefficients of the A-metal ^{234}Th(IV) to colloids (K_c) are generally similar to K_d values for particles (42), but this is not necessarily the case for B-metals such as Cu (43,44) where generally K_c is larger than K_d.

Aggregation rates of colloidally complexed metals show two distinctive reaction rates; a larger rate constant is consistent with Brownian "colloidal pumping" that occurs at a uniform rate and is faster at higher particle concentrations and a smaller rate constant that is different for different metals (22,45).

^{234}Th, which is generated *in situ* from the radioactive decay of ^{238}U and has a half-life of 24 days, can be used to derive residence times of Th(IV)-binding colloids. Average colloidal residence times (with respect to coagulation) range from fractions of days in estuaries to a few weeks in the surface ocean (2,20). Similar results are obtained in controlled laboratory coagulation experiments using radioactive metals bound to estuarine COM (23,45). These laboratory results also confirmed particle concentration effects on removal rate constants, previously demonstrated for Th(IV) (34,40,41).

Residence times that reflect colloidal organic carbon ages are longer, as much of the carbon is recycled. For example, Santschi et al. (2,7) and Guo et al. (42,46) obtained mostly “modern” (i.e., younger than 1950) apparent radiocarbon ages for high molecular weight colloids $\geq$10 kDa, but mostly older ages, for example, 400 to 4500 years, for low molecular weight COM $\geq$1 kDa in surface waters containing mostly biopolymers (2). In contrast, if the COM $\geq$1 kDa is enriched to 100% polysaccharides through repeated alcohol precipitation, modern radiocarbon ages are obtained for this material (7). In contrast to colloids from the euphotic zone, colloids from benthic nepheloid layers of estuaries and continental shelf or slope areas of the Gulf of Mexico and the Middle Atlantic Bight, which contain mostly geopolymers generated by hydrodynamic and physicochemical fractionation processes near the sediment–water interface during sediment resuspension (46,47), this age distribution is reversed. For example, apparent radiocarbon ages are up to 10 ky for $\geq$10 kDa colloids, and younger for $\geq$1 kDa colloids, indicating fundamental differences between biopolymers and geopolymers.

It thus appears that whenever colloids are generated by microorganisms in surface and bottom waters, their importance in trace metal binding and removal might be disproportionately higher than would be expected from the observed colloidal fractions of trace metals.

TEP-like biopolymers control the scavenging of metals and radionuclides and the coagulation/flocculation of particles in marine systems (5, and references therein) and also the early development of biofilms (15), which is largely due to their surface-active nature. These biopolymers can also initiate or modify precipitation of MnO_2 and FeOOH (48,49), SiO_2 (50), and $CaCO_3$ (51). Moreover, APS rich polymers in the extracellular milieu form flocs (52,53) and also bind extracellular enzymes in their active forms. This enzymatic activity allows trace metal binding (24,34) and modifies the solubility of associated molecules (14).

What do we know about the physicochemical parameters of colloidal organic matter in the ocean, for example, proton reactive sites, their pK_a values, electrophoretic mobilities, and relative hydrophobicities? Santschi et al. (2) reported a total concentration of 1.4 meq/g of proton reactive sites in marine colloids from the Gulf of Mexico, which is intermediate between that of humic and fulvic acids (10–16 meq/g) and polysaccharides (0.3–0.8 meq/g) (1). These proton-reactive sites are often assumed to have pK_a values of 2, 4, 6, 8, and 10 (54). Actual values of $pK_{a1} \leq 3$ have been determined for aquatic colloids (7,34,54–56), which could suggest sulfate or polyphosphate as possible ligands. Values for pK_{a2} are more variable and increase from about 4 to 9 across the salinity gradient in the Firth of Clyde estuary (55,56), suggesting that the nature of colloids changes dramatically across an estuarine salinity gradient. Interestingly, log K values, as well as fractions of metal-specific ligands (C_L) in the colloidal fraction (colloidal C_L/total C_L) of selected metals in coastal waters were significantly related to the pK_{a2} of the colloids; Cu showed a positive relationship for both log K and % colloidal C_L with pK_{a2}, whereas for Pb, a negative relationship was found (55). This is possibly due to the different affinities of these two metals to the two predominant forms of freshwater colloids (19), that is, the smaller organic carbon rich (enriched in Cu) and larger Fe-rich (enriched in Pb) colloids, both of which are also found in coastal waters (23).

In agreement with the pKa values, measured electrophoretic mobilities of aquatic colloids are negative. Electrophoretic mobilities, u_E, determined by dynamic light scattering in a ZetaSizer instrument at pH 8, were measured at about -2.5×10^{-8} m^2 V^{-1} s^{-1}, ranging from about (-2 to -3.4) $\times 10^{-8}$ m^2 V^{-1} s^{-1} (55–57). Their values were weakly related to the colloidal fraction of metal-specific ligands (colloidal C_L/total C_L); Cu and Pb again related in opposite ways.

In accordance with the relative high concentration of moderately strong acidic sites, for example, pK_{a1} values of $\sim$3 (55,56) or below for marine colloids (9), isoelectric points of about 2 to 4 for marine colloids have been determined by Quigley et al. (34) and Alvarado-Quiroz (35), suggesting that the surface charge is dominated by relatively strong acidic groups. Conversely, positively charged ligand groups such as amino groups are considerably rarer.

Marine colloids are negatively charged, suggesting hydrocolloid-like behavior, but that does not preclude coexistence with more hydrophobic sites, as has been said before. EPS and APS have been described as amphiphilic (1,37,58). Furthermore, it is likely that more hydrophobic ligands would be more particle-reactive and thus, have a shorter residence time in water. However, this has not yet been demonstrated in the field. Laboratory studies of bacterial attachment, however, show a clear relationship between attachment probability and relative hydrophobicity of bacterial surfaces (58,59), which are composed of EPS.

There are many things we do not know yet about marine colloids. For example, more than 50% of the organic matter in this pool remains uncharacterized at the molecular level (26,27,60), our knowledge about their tendency toward gel formation is still in its infancy (6), and we still do not have a quantitative assessment of the relative role of biodegradation (61) versus self-assembly (3) or aggregation contributing to the observed size distribution of marine colloids and particles (2,6,24). Even the molecular weight distribution of DOC is not as certain as one would conclude from the application of just one single method. For example, results from the application of state-of-the-art electrospray mass spectrometry techniques (62,63) indicate average molecular weights of DOC, normalized to charge, of less than 1 kDa, possibly due to fragmentation of carboxylic acid-rich compounds during electrospray ionization. On the other hand, much higher average molecular weights of 10^5 to 10^6 Da can be obtained from images of freshwater (9) or marine colloids (7) when using transmission electron microscopy (TEM) of stained specimens consisting of abundant fibrillar macromolecules 100s to 1000s of nm long, when embedded in hydrophilic resins, or AFM techniques of the same specimens mounted by adsorption or centrifugation onto mica surfaces that are flat on the atomic scale (Fig. 1). Thus, scientists interested in the properties of marine colloidal matter still have a long way to go until the role of this abundant material in seawater and self-assembles on the nanoscale (3) become better understood.

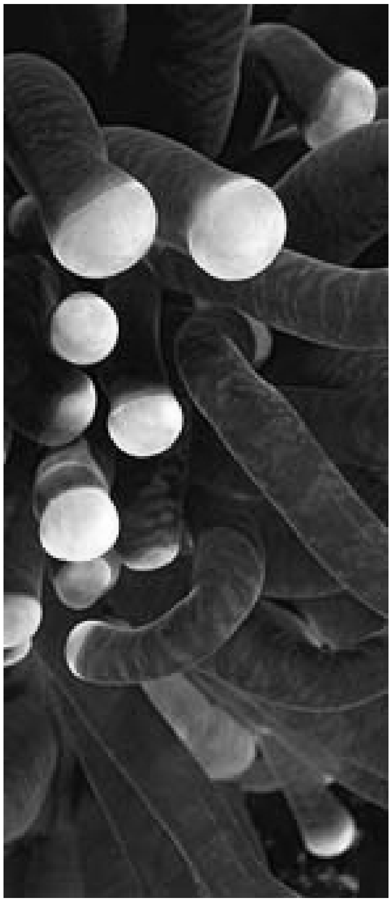
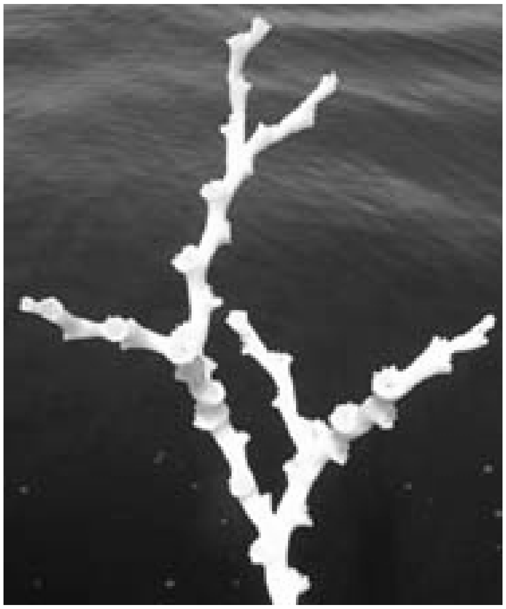
DEEP WATER CORALS

NOAA Coral Reef Information
System (CORIS)



Many people are familiar with the coral reefs that thrive in shallow, well lighted, clear tropical waters where

---



This healthy branch of *Lophelia* coral was sampled from deep ocean reefs off the coast of South Carolina. Unlike tropical species of coral, *Lophelia* possesses no symbiotic algae (zooxanthellae).

myriad colorful hard and soft corals provide habitat “infrastructure” for numerous invertebrates and fishes. The corals provide protection and cover, sources of nutrition, and sites for reproduction. Corals, however, also grow in the deep, cold sea. Although the existence of some of these deep-sea coral thickets has been known for several centuries, initially from pieces of broken corals brought up with fishing gear, scientists know little about their distribution, biology, behavior, and function as essential habitats for fishes and invertebrates.

Some deep-water corals (also called cold-water corals) do not form reefs exactly like those in tropical waters. Often, they form colonial aggregations called patches, mounds, banks, bioherms, massifs, thickets or groves. These aggregations are often still referred to as “reefs.” Deep-water corals also provide crucial habitat and reproductive grounds for commercially important fisheries including sea bass, snapper, porgy, rock shrimp and calico shrimp, thus drawing the commercial fishing industry to these fragile areas.

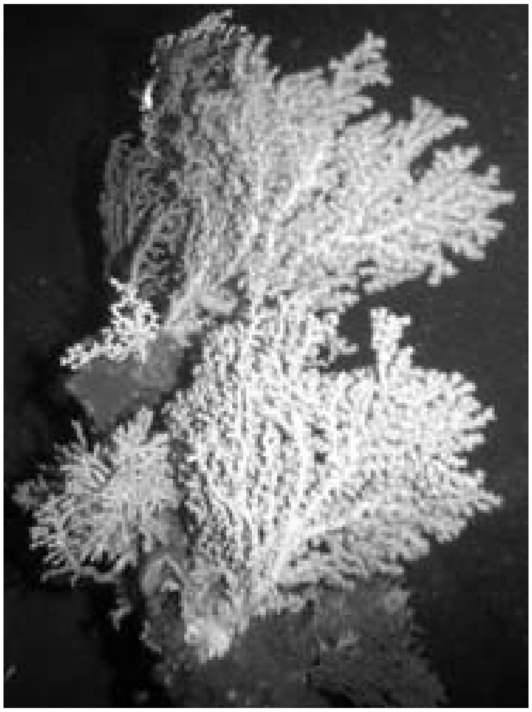
Human activities constitute the most serious threat to these fragile corals. Destructive bottom fishing, as well as oil and gas exploration and exploitation have the potential to destroy large areas of coral habitat in a relatively short time. These activities create coral rubble, which is not a suitable habitat for fishes and invertebrates. In recent years, scientists have begun to study deep-water corals more closely, and some countries with deep-water corals in their territorial waters have begun to implement fishing restrictions in sensitive coral areas.

WHAT ARE DEEP-WATER CORALS?

Far fewer species of corals exist in cold, deep water than in the tropics. Three main groups of corals make up deep-water coral communities: hard (stony) corals of the Order Scleractinia, which form hard, ahermatypic reefs; black and horny corals of the Order Antipatharia; and soft corals of the order Alcyonacea, which includes the gorgonians (sea fans) (1). Deep-water corals are similar in some ways to the more familiar corals of shallow, tropical seas. Like their tropical equivalents, the hard corals develop sizeable reef structures that host rich and varied invertebrate and fish fauna. However, unlike their tropical cousins, which are typically found in waters above 70 m depth and at temperatures between 23° and 29 °C, deep-water corals live at depths just beneath the surface to the abyss (2000 m), where water temperatures may be as cold as 4 °C and utter darkness prevails.

At these depths, corals lack zooxanthellae. These symbiotic algae provide food for many shallow-water corals through photosynthesis. They also assist in the formation of the calcareous skeleton, and give most tropical corals their coloration. By contrast, the polyps of deep-water corals appear to be suspension feeders. They capture and consume organic detritus and plankton that are transported by strong, deep-sea currents. These corals are commonly found along bathymetric highs such as seamounts, ridges, pinnacles and mounds (2).

Deep-water corals range in size from small solitary colonies to huge, massive reef structures, which appear as oases of teeming life surrounded by more barren bathymetry. The gorgonians (sea fans) also range from small individuals to those with tree-like dimensions. The gorgonian, *Paragorgia arborea,* may grow in excess of three meters in length (3). Growth rates of branching deep-water coral species, such as *Lophelia* and *Oculina,* range



This thicket of *Paragorgia* corals was viewed by the deep-sea submersible *Alvin* at 1,043 m depth. *Photo*: Barbara Hecker.

from ~1.0–2.5 cm/yr, whereas branching shallow-water corals, such as *Acropora,* may exceed 10–20 cm/yr. Using coral age-dating methods, scientists have estimated that some living deep-water corals date back at least 10,000 years (4). However, little is known of their basic biology, including how they feed or their methods and timing of reproduction.

GENERAL DISTRIBUTION OF COLD-WATER CORALS

Deep-water corals are found globally, from coastal Antarctica to the Arctic Circle. In northern Atlantic waters, the principal coral species that contribute to reef formation are *Lophelia pertusa, Oculina varicosa, Madrepora oculata, Desmophyllum cristagalli, Enallopsammia rostrata, Solenosmilia variabilis*, and *Goniocorella dumosa*. Four of those genera (*Lophelia, Desmophyllum, Solenosmilia*, and *Goniocorella*) constitute the majority of known deep-water coral banks at depths of 400 to 700 m (5).

Madrepora oculata occurs as deep as 2,020 m and is one of a dozen species that occur globally and in all oceans, including the Subantarctic (6). Colonies of *Enallopsammia* contribute to the framework of deep-water coral banks found at depths of 600 to 800 m in the Straits of Florida (5).

TWO IMPORTANT DEEP-WATER CORALS

Two of the more significant deep-sea coral species are *Lophelia pertusa* and *Oculina varicosa*. These species form extensive deep-water communities that attract commercially important species of fishes, making them susceptible to destructive bottom trawling practices (7). Increased sedimentation places additional stress on corals.

Oil and gas exploration structures and activities, particularly in the North Sea and adjacent areas, also damage *Lophelia* communities. Subsequent oil and gas production activities may also introduce noxious substances into these areas.

LOPHELIA PERTUSA DISTRIBUTION

Lophelia pertusa is the most common aggregate-forming deep-water coral. Typically, it is found at depths between 200 and 1,000 m in the northeast Atlantic, the Mediterranean Sea, along the mid-Atlantic Ridge, the West African and Brazilian coasts, and along the eastern shores of North America (e.g., Nova Scotia, Blake Plateau, Florida Straits, Gulf of Mexico) as well as in parts of the Indian and Pacific Oceans. Like tropical coral reefs, *Lophelia* communities support diverse marine life, such as sponges, polychaete worms, mollusks, crustaceans, brittle stars, starfish, sea urchins, bryozoans, sea spiders, fishes, and many other vertebrate and invertebrate species.

Lophelia has been found most frequently on the northern European continental shelves between 200 and 1000 m, where temperatures range from 4° to 12 °C, but it has also been found at depths greater than 2,000 m. Once a colonial patch is established, it can spread over a broad area by growing on dead and broken pieces of coral (coral rubble). *Lophelia* has a linear extension of the polyps of about 10 mm per year. The reef structure has been estimated to grow about 1 mm per year (8). Scientists have also found *Lophelia* colonies on oil installations in the North Sea (9).

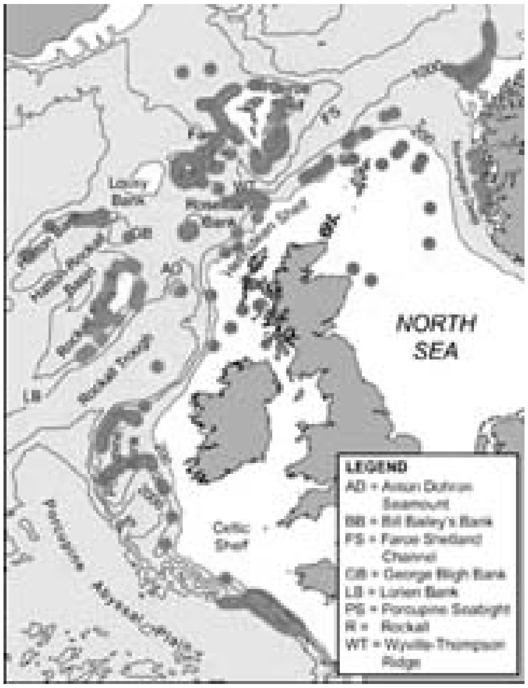
Lophelia pertusa can occur in a variety of structures and forms. DNA-based sequencing tests conducted at the University of Southampton Oceanography Centre, UK, have indicated that different morphological varieties of *Lophelia* all belong to the same species (10).

NOTED LOPHELIA AREAS

The world's largest known deep-water *Lophelia* coral complex is the Røst Reef. It lies in depths between 300 and 400 m west of Røst Island in the Lofoten archipelago, Norway. Discovered during a routine survey in May 2002, the reef is still largely intact. It covers an area approximately 40 km long by 3 km wide.

Relatively close by is the Sula Reef, located on the Sula Ridge, west of Trondheim on the mid-Norwegian Shelf,

Global distribution of *Lophelia pertusa*. Image: Southampton Oceanography Centre, UK.



Reefs of *Lophelia pertusa* have been recorded on raised offshore seabeds in the north Atlantic off Britain and west Ireland. Image: Dr. Brian Bett, Southampton Oceanography Centre, UK.

at 200 to 300 m depth. It is estimated to be 13 km long, 700 m wide, and up to 35 m high (11), an area one-tenth the size of the 100 km^2 Røst Reef.

Discovered and mapped in 2002, Norway's 1,000-year-old and 2-km-long Tisler Reef lies in the Skagerrak—the submarine border between Norway and Sweden at a depth of 74 to 155 m. The Tisler Reef contains the world's only known yellow *Lophelia pertusa* corals. At present, Norway is the only European nation to enact laws protecting its *Lophelia* reefs from trawling, pollution, and oil and gas exploration. However, the European Commission has introduced an interim ban on trawling in the Darwin Mounds area, west of Scotland, in August 2003. A permanent ban on trawling is expected to follow.

Elsewhere in the northeastern Atlantic, *Lophelia* is found around the Faroe Islands, an island group between the Norwegian Sea and the Northeast Atlantic Ocean. At depths from 200 to 500 m, *Lophelia* is chiefly on the Rockall Bank and on the shelf break north and west of Scotland (12).

One of the most researched deep-water coral areas in the United Kingdom are the Darwin Mounds. The mounds were discovered in 1998 by the Atlantic Frontier Environmental Network (AFEN) while conducting large-scale regional surveys of the sea floor north of Scotland. They discovered two areas of hundreds of sand and cold-water coral mounds at depths of about 1,000 m, in the northeast corner of the Rockall Trough, approximately 185 km northwest of the northwest tip of Scotland. Named after the research vessel *Charles Darwin,* the Darwin Mounds have been extensively mapped using low-frequency side-scan sonar. They cover an area of approximately 100 km^2 and consist of two main fields—the Darwin Mounds East, with about 75 mounds, and the Darwin Mounds West, with about 150 mounds. Other mounds are scattered in adjacent areas. Each mound is about 100 m in diameter and 5 m high.

The tops of the mounds are covered with *Lophelia* corals and coral rubble, which attract other marine life. Side-scan sonar images show that the mounds appear to be sand volcanoes, each with a unique feature—a "tail." The tails are up to several hundred m long, all oriented downstream (13). The tails and the mounds are uniquely characterized by large congregations of deep-sea organisms called xenophyophores (*Syringammina fragilissima*), which are giant unicellular organisms that can grow up to 25 cm in diameter (14). Scientists are uncertain why these interesting organisms congregate in these areas. In addition, the *Lophelia* of the Darwin Mounds are growing on sand rather than hard substrate, an unusual condition unique to this area. Usually, coral larvae almost always settle and grow on hard substrates, such as dead coral skeletons or rock.

Lophelia corals exist in Irish waters as well (15). The Porcupine Seabight, the southern end of the Rockall Bank, and the shelf to the northwest of Donegal all exhibit large, mound-like *Lophelia* structures. One of them, the Theresa Mound, is particularly noted for its *Lophelia pertusa* and *Madrepora oculata* colonies. *Lophelia* reefs are also found along the U.S. East Coast at depths of 500 to 850 m along the base of the Florida-Hatteras slope. South of Cape Lookout, NC, rising from the flat sea bed of the Blake Plateau, is a band of ridges capped with thickets of *Lophelia*. These are the northernmost East Coast *Lophelia pertusa* growths. The coral mounds and ridges here rise as much as 150 m from the plateau plain. These *Lophelia* communities lie in unprotected areas of potential oil and gas exploration and cable-laying operations, rendering them vulnerable to future threats (16).

Finally, *Lophelia* is known to exist around the Bay of Biscay, the Canary Islands, Portugal, Madeira, the Azores, and the western basin of the Mediterranean Sea (13).

OCULINA VARICOSA DISTRIBUTION

Oculina varicosa is a branching ivory coral that forms giant but slow-growing, bushy thickets on pinnacles up to 30 m in height. The Oculina Banks, so named because they consist mostly of *Oculina varicosa*, exist in 50 to 100 m of water along the continental shelf edge about 26 to 50 km off of Florida's central east coast.

Discovered in 1975 by scientists from the Harbor Branch Oceanographic Institution conducting surveys of the continental shelf, *Oculina* thickets grow on a series of pinnacles and ridges extending from Fort Pierce to Daytona, Florida (7,17–19).

Like the *Lophelia* thickets, the Oculina Banks host a wide array of macroinvertebrates and fishes. They also are significant spawning grounds for commercially important species of food fishes including gag, scamp, red grouper, speckled hind, black sea bass, red porgy, rock shrimp, and the calico scallop (20).

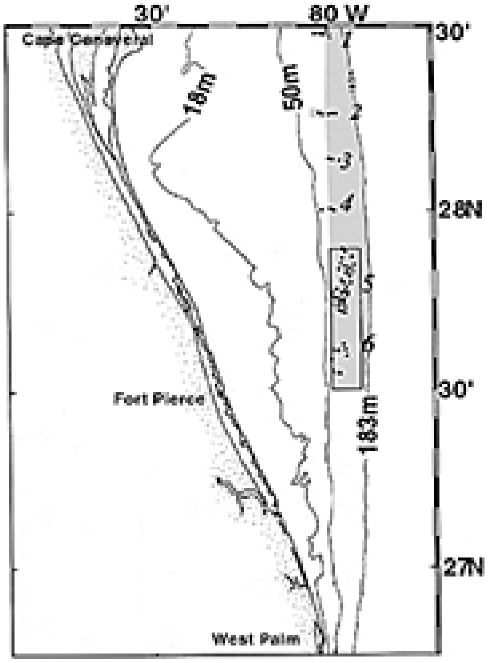


Chart of the Deep-water Oculina Coral Banks Marine Protected Area (MPA). The shaded area is the entire Oculina Habitat Area of Particular Concern (HAPC); the Experimental Oculina Research Reserve (EORR) is the smaller inset box. Recent dive sites from 2001 to 2003 include: 1) Cape Canaveral, 2) Cocoa Beach, 3) Eau Gallie, 4) Malabar, 5) Sebastian, and 6) Chapmans Lumps/Jeff's Reef. (Courtesy of: Dr. John K. Reed, Harbor Branch Oceanographic Institution).

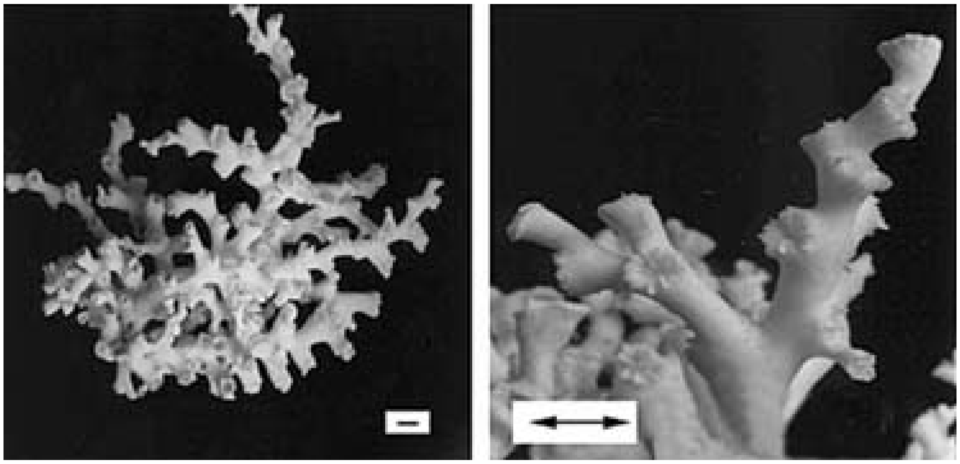
THREATS TO LOPHELIA AND OCULINA CORALS

Both *Lophelia* and *Oculina* corals face uncertain futures. Until recently, *Lophelia* habitats remained undisturbed by human activity. However, as traditional fish stocks are depleted from northern European waters, bottom trawling has moved into deeper waters, where the gear has affected the coral beds. The towed nets break up the reef structure, kill the coral polyps and expose the reef to sediment by altering the hydrodynamic and sedimentary processes around the reef (21). The fishes and invertebrates that depend on the coral structure lose their habitat and move out of the area. Damage may range from a decrease in the size of the coral habitat with a corresponding decrease in the abundance and biodiversity of the associated invertebrate and fish species, to the complete destruction of the coral habitat. The trawls also may resuspend sediments that, in turn, may smother corals growing downstream of the current. In addition, oil and gas exploration and extraction operations have begun to move into these deep-water areas, further threatening the resident corals.

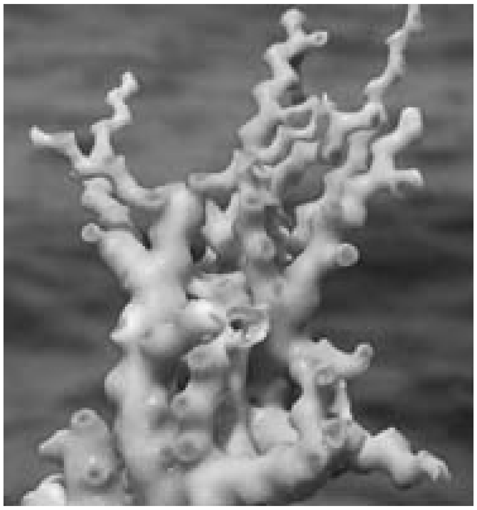
Scientists estimate that within the Norwegian Exclusive Economic Zone, 30 to 50 percent of the total coral area of the Norwegian shelf has been damaged or destroyed by trawling (8). Scientists from the International Council for the Exploration of the Sea, the main provider of scientific advice to the European Commission on fisheries and environmental issues in the northeast Atlantic, have recommended that to protect the remaining deep-water coral groves, all of Europe's deep corals must be accurately mapped and then closed to fishing trawlers (22).

In 1999, the first complete mapping of the Sula Reef was carried out by the Norwegian Hydrographic Society, which used the latest available multibeam echosounder equipment to record both depth and backscatter data. The mapping was the product of joint cooperation between the Geological Survey of Norway and the Institute of Marine Research. That same year, the Norwegian Ministry of Fisheries issued regulations for the protection of the *Lophelia* reefs. An area of 1,000 km^2 at Sula, including the large reef, is now closed to bottom trawling. In 2000, an additional area, about 600 km^2 was closed. The Røst Reef, an area of about 300 km^2, was closed to bottom trawling in 2002.

Florida's Oculina Banks, once teeming with commercially important fish, now appear to be severely depleted of fish stocks (23). Much of the *Oculina* coral has been reduced to rubble, probably the result of a combination of destructive bottom trawling and natural causes like bioerosion and episodic die-offs. Regardless of the cause, the Oculina Banks now support a drastically reduced fishery because most of the significant spawning grounds have been destroyed (7,19).



Two images of the deep sea coral *Lophelia pertusa*. The image on the left shows the complex growth structure of a small colony. On the right is a closeup of individual polyps. *Photo*: Ref. 7.



This beautiful species of *Lophelia* coral was collected off the coast of South Carolina.

Efforts to protect the Oculina Banks began in 1980, when scientists from Harbor Branch Oceanographic Institution initiated a call to implement protective measures for the area. Since then, progressively stricter legal protections have been implemented to facilitate a recovery. In 1984, a 315 km^2 portion of deep-water Oculina reef system was designated as a Habitat Area of Particular Concern by the South Atlantic Fishery Management Council (7,19), a designation that categorized it as an area of special ecological significance worthy of stricter regulatory and enforcement activity.

In 1994, after the area showed no significant recovery, part of the Oculina Banks was completely closed to bottom fishing in an area called the Experimental *Oculina* Research Reserve. In 1996, the South Atlantic Fisheries Management Council implemented additional protections in the reserve by prohibiting fishing vessels from dropping anchors, grapples, or attached chains there. In 1998, the council also designated the reserve as an Essential Fish Habitat. In 2000, the deep-water Oculina Marine Protected Area was extended to 1029 km^2 (7,19,24).

The Oculina Banks remain a hot spot for research and efforts to rehabilitate the coral (23). Scientists recently deployed concrete “reef balls” in the area in an attempt to attract fish and provide substrate for coral attachment, settlement and growth. They are cautiously optimistic about their initial restorative efforts in the reserve (23).

MARINE DEBRIS ABATEMENT

JAVIER VELEZ-AROCHO
U.S. Environmental Protection Agency
Washington, District of Columbia

TRASH IN OUR OCEANS—YOU CAN BE PART OF THE SOLUTION

Marine debris, often called litter, has become a problem along shorelines, coastal waters, estuaries, and oceans throughout the world. It is defined as any man-made, solid material that enters our waterways directly (e.g., by dumping) or indirectly (e.g., washed out to sea via rivers, streams, storm drains, etc.). Objects ranging from detergent bottles, hazardous medical wastes, and discarded fishing line all qualify as marine debris. In addition to being unsightly, it poses a serious threat to everything with which it comes into contact. Marine debris can be life-threatening to marine organisms and humans and can wreak havoc on coastal communities and the fishing industry.

Sources of Marine Debris

There are two different sources from which debris pollutes our oceans. The first is from the land and includes users of

---

the beach, storm water-runoff, landfills, solid waste, rivers, and streams, floating structures, ill maintained garbage bins and dumps and litterbugs. Marine debris also comes from combined sewer overflows, and storm drains. Typical debris from these sources includes medical waste, street litter and sewage. Land-based sources cause 80% of the marine debris found on our beaches and waters.

The second source of marine debris is from ocean sources, and this type of debris includes galley waste and other trash from ships, recreational boaters and fishermen and offshore oil and gas exploration and production facilities.

Adding to this problem is the population influx along our nation's shores. More people means more paved area and wastes generated in coastal areas. These factors; combined with the growing demand for manufactured and packaged goods, have led to an increase in non-biodegradable solid wastes in our waterways.

The Beaches Environmental Assessment and Coastal Health Act (BEACH) of 2000

The BEACH Act was enacted on October 10, 2000, and it is designed to reduce the risk of disease to users of the Nation's coastal recreation waters. The act authorizes the EPA to award program development and implementation grants to eligible states, territories, tribes, and local governments to support microbiological testing and monitoring of coastal recreational waters, including the Great Lakes, that are adjacent to beaches or similar points of access used by the public. BEACH Act grants provide support for developing and implementing programs to notify the public of the potential for exposure to disease-causing microorganisms in coastal recreation waters. The act also authorizes EPA to provide technical assistance to States and local governments for the assessment and monitoring of floatable materials. In partially fulfilling that obligation, EPA has compiled the most current information to date on assessing and monitoring floatable materials in the document Assessing and Monitoring Floatable Debris.

The International Coastal Cleanup

The Ocean Conservancy, formerly known as the Center for Marine Conservation, established and maintains the annual International Coastal Cleanup (ICC) with support from EPA and other stakeholders. The first cleanup was in 1986 in Texas, and the campaign currently involves all of the states and territories of the United States and more than 100 countries around the world. The ICC is the largest volunteer environmental data-gathering effort and associated cleanup of coastal and underwater areas in the world. It takes place every year on the third Saturday in September. In 2001, over 140,000 people across the U.S. participated in the ICCC. They removed about 3.6 million pounds of debris from more than 7,700 miles of coasts, shorelines, and underwater sites.

National Marine Debris Monitoring Program

EPA along with other federal agencies helped to design the National Marine Debris Monitoring Program (NMDMP), and EPA is supporting The Ocean Conservancy's implementation of the study. NMDMP is designed to gather scientifically valid marine debris data following a rigorous statistical protocol. The NMDMP is designed to identify trends in the amounts of marine debris affecting the U.S. coastline and to determine the main sources of the debris. This scientific study is conducted every 28 days by teams of volunteers at randomly selected study sites along the U.S. coastline. The NMDMP requires, at a maximum, that 180 monitoring sites located along the coast of contiguous U.S. States and Alaska, Hawaii, Puerto Rico, and the U.S. Virgin Islands be fully operational. The program began in 1996 with the establishment of 40 monitoring sites ranging from the Texas/Mexico border to Port Everglades, Florida and included Puerto Rico and the U.S. Virgin Islands. To date 163 study sites have been designated and 128 sites are collecting data. The program will run for a 5-year period once all of the study sites have been established. For more information please visit: http://www.oceanconservancy.org/dynamic/learn/issues/debris/debris.htm.

Other Floatable Debris-Related Legislation

In response to a growing concern over floatable debris, governments have taken actions nationally, as well as internationally, to reduce discharges at their source. For example, intentional at-sea dumping of garbage generated on land became subject to international control in 1972 through the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter,

commonly called the London Convention. Similarly, at-sea disposal of garbage generated during the routine operation of ships (e.g., garbage not deliberately carried to sea for the purpose of disposal) was addressed through a 1978 Protocol to the 1973 International Convention for the Prevention of Pollution by Ships (commonly called the MARPOL Convention).

In the Shore Protection Act of 1989 provides for controls on operations relating to the vessel transport of certain solid wastes (municipal or commercial waste) so that those wastes are not deposited in coastal waters. This act has provisions that reduce wastes being deposited in coastal waters during the transfer of waste from the waste source to the transport vessel to the waste receiving station.

As amended by the Water Quality Act of 1987, the Clean Water Act requires EPA to establish regulations that treat storm water and combined sewer overflows (CSOs) as point source discharges that must be regulated under the National Pollutant Discharge Elimination System (NPDES). The permits will prohibit non-storm water discharges into storm sewers while leading to improved control techniques and best management practices.

Debris Hazardous for Marine Animals

Each year millions of seabirds, sea turtles, fish, and marine mammals become entangled in marine debris or ingest plastics which they have mistaken for food. As many as 30,000 northern fur seals per year get caught in abandoned fishing nets and either drown or suffocate. Whales mistake plastic bags for squid, and birds may mistake plastic pellets for fish eggs. At other times, animals accidentally eat the plastic while feeding on natural food. According to recent estimates, 267 marine species have been reported entangled in or having ingested marine debris (Marine Mammal Commission, 1998). The plastic constricts the animals' movements, or kills the marine animals through starvation, exhaustion, or infection from deep wounds caused by tightening material. The animals may starve to death, because the plastic clogs their intestines preventing them from obtaining vital nutrients. Toxic substances present in plastics can cause death or reproductive failure in the fish, shellfish, and wildlife that use the habitat.

Polluted Waters Make Trouble for Humans, Too

Humans can also be directly affected by marine debris. Swimmers and divers can become entangled in abandoned netting and fishing lines like marine organisms. Beach users can be injured by stepping on broken glass, cans, needles or other litter. Appearance of debris, such as plastic, can also result in economic consequences. Floating debris, either as a floating slick or as dispersed items, is visually unappealing and can result in lost tourism revenues. New Jersey now spends $1,500,000 annually to clean up its beaches, and $40,000 to remove debris from the New York/New Jersey Harbor (YOTO Discussion Papers, 1998).

Fishing Industries and Communities Hit Hard by Marine Debris

Marine debris also acts as a navigational hazard to fishing and recreational boats by entangling propellers and clogging cooling water intake valves. Repairing boats damaged by marine debris are both time consuming and expensive. Fixing a small dent in a large, slow-moving vessel can take up to 2 days, costing the shipping company $30,000–40,000 per day in lost carrying fees, as well as up to $100,000 for the repair itself (Peter Wallace, personal contact). According to Japanese estimates, the Japanese fishing industry spent $4.1 billion (U.S.) on boat repairs in 1992 (YOTO Discussion Papers, 1998). Lost lobster traps cost New England fishing communities $250 million in

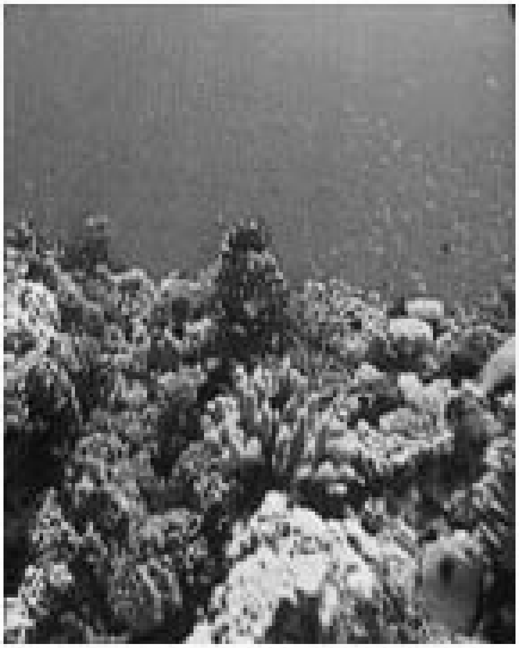
1978. These traps continue to catch lobsters and other marine organisms that are never harvested and sold; the communities' economies are therefore adversely affected.

Beach Raking

Mechanical beach raking, which is accomplished with a tractor and is used to remove debris from the shoreline, can help to remove floatable material from beaches and marine shorelines. However, it can also be harmful to aquatic vegetation, nesting birds, sea turtles, and other types of aquatic life. A study in Maine compared a raked beach and an adjacent natural beach to determine the effects of beach raking on vegetation. Beach raking not only prevents the natural re-vegetation process, but it reduces the integrity of the sand root mat just below the surface that is important in slowing beach erosion. Other problems include disturbance of vegetation if raking is conducted too, close to a dune. By removing seaweed, beach erosion can also be caused. Sand compaction is reduced when seaweed is removed, resulting in suspension of the sand in the water during high tides and contributing to loss of sand and erosion of the beach. Beach cleaning machines are harmful to nest birds and can destroy potential nesting sites, crush plover nests and chicks, and remove the plovers' natural wrack-line feeding habitat. To reduce the effects on nesting birds, beach raking should not be done during the nesting season.

Unseen Consequences

Once debris reaches coastal and ocean bottom, especially in areas with little current, it may continue to cause environmental problems. When plastic film and other debris settle on the bottom, it can suffocate immobile plants and animals, producing areas essentially devoid of life. In areas with some currents, such as coral reefs, debris can wrap around living coral, smothering the animals and breaking up their coraline structures.



Trash Indicator of Bigger Problems

The typical floatable debris from Combined Sewer Overflows includes street litter, sewage (e.g., condoms, tampons, applicators), and medical items (e.g., syringes), resin pellets, and other material that might have washed into the storm drains or from land runoff. These materials or objects can make it unsafe to walk on the beaches, and pathogens or algae's blooms can make it unsafe to swim. Pollutants, such as toxic substances, can make it unsafe to eat the fish caught from the waters. Swimming in or ingesting waters which are contaminated with pathogens can result in human health problems such as, sore throat, gastroenteritis, meningitis or even encephalitis. Pathogens can also contaminate shellfish beds.

What Needs to Be Done

Reducing marine debris means reducing the amount of waste generated on land and disposing of it properly. Recycling can significantly reduce the amounts of litter reaching marine and coastal waters. Volunteer coastal cleanups and public education efforts can also help reduce the amount of debris reaching our waterways.

What You Can Do

- Dispose of trash properly. This will help reduce the amount of trash that is washed into our waterways from storm drains.
- Reduce, reuse and recycle. Visit the EPA's solid waste web site for more information.
- Cut the rings of plastic six-pack holders. This lowers the risk of entanglement to marine animals if the holders do make it out to sea.
- Participate in local beach, river or stream clean ups.
- Practice good housekeeping.
- Look for alternative materials or avoid excessive packaging when deciding on purchases.
- Educate others about marine debris.
- Get involved in your local area.

What the EPA and Other Partners Are Doing

- Providing resources to educate the public on the impact of marine debris and guidance for how to eliminate it.
- Providing resources and technical support for the development of studies to address the impact of marine debris.
- Providing guidance for the implementation of regulations addressing marine debris.
- Organizing and sponsoring cleanup efforts, like the U.S. and International Coastal Cleanups.

Whether directly or indirectly, many of our land-based activities ultimately impact and adversely affect the oceans. At the heart of the problem lie the great quantities of trash generated in our daily lives. Reusing and recycling efforts have helped, but a great deal more can be done. You can be part of the solution.

LARVAE AND SMALL SPECIES OF POLYCHAETES IN MARINE TOXICOLOGICAL TESTING

Jian-Wen Qiu
Ming Hung Wong
Hong Kong Baptist University
Kowloon Tong, Kowloon, Hong Kong

The ultimate goal of ecotoxicological testing is to provide data to predict potential impacts of pollutants on the ecosystem. To fulfill this goal, the tests should meet several criteria: the species should be ecologically relevant and sensitive to pollutants; the species should be readily available through field collection or laboratory culture; and the tests should yield reasonably rapid results at low cost. Although rarely consumed as seafood, polychaetes are a diverse group in marine ecosystems, typically consisting 35% to 75% of the total number of species in soft bottom coastal areas (1). They serve as prey for demersal fish and are important in the transfer of organic material and nutrients between the sediment and the overlying water. The use of polychaetes as bioassay organisms began in the 1960s, stimulated by the awareness that many pollutants were threatening the ecosystems and the surge in studies of polychaete life history. Reish and Gerlinger (2) is the most updated comprehensive review on the use of polychaetes in bioassays. Among the 8000 described species worldwide, only 49 polychaete species have been used in bioassays, of which all inhabit shallow waters. Most tests have been conducted with small species (*Neanthes arenaceodentata, Capitella capitata, Dinophilus gyrociliatus, Ophryotrocha labronica*, and *O. diadema*), which can be obtained from laboratory culture. Large polychaetes, i.e., *Nereis virens* and *Neanthes diversicolor*, have also been used. These species are usually obtained from field populations and have been used mostly in pollutant accumulation studies.

Polychaetes have been employed in acute, chronic, and life-cycle tests to determine the toxicity of metals, contaminated sediment, sediment pore water, municipal effluents, petroleum hydrocarbons, pesticides, and other synthetic organic chemicals. Although several species, such as *Capitella capitata, Dinophilus gyrociliatus, Ophryotrocha labronica*, and *O. diadema*, have been used in all test types, many other species have been used only in acute or chronic tests. The acute tests can be conducted with larvae, juveniles, and adults. During the test, the worms are usually not fed. When juveniles and adults are used, the acute test is usually run for 96 h. The test can be static, static renewal, or flow-through. In larval tests, however, the tests are usually static, with shorter exposure periods (24 or 48 h). Survivorship is usually the endpoint of acute tests. Chronic tests are usually conducted using juveniles or adults. The test protocol is the same as in acute test except the exposure duration is 10 to 28 days, during which the polychaetes are fed. The bioassay usually adopts a static renewal design. In addition to survival, sublethal effects such as cessation of feeding, defecation, or reduced growth are the endpoints. The life-cycle tests have been employed infrequently in the past. The test protocol is similar to that of the chronic test. In addition to survival and growth effects, reproductive parameters, such as eggs or juveniles produced, are the endpoints. Only small species have been used in life-cycle tests because their life cycle can be completed in less than one month. In recent years, many published toxicity studies have used small polychaete species in chronic or life-cycle tests. Examples are Bridges and Farrar (3), Anderson et al. (4), Linke-Gamenick et al. (5), McPherson et al. (6), and Nipper and Carr (7). There has also been new development in the use of polychaete larvae (8–10).

Below are several general conclusions regarding the use of polychaetes in bioassays. These conclusions are supported by examples.

1. *Polychaete Larvae are Very Sensitive to Pollutants*. In *Capitella capitata,* bifurcated abnormal larvae occurred at 10 ppb copper (11). In *Arenicola cristata*, abnormal larvae occurred at 0.75 ppb TBTO (12). In *Galeolaria caespitosa*, the 48-h EC50 for larval development ranged from 20 to 28 ppb copper (9).
2. *Polychaete Larvae are More Sensitive than the Adults to Pollutants*. In *Capitella capitata,* the 96-h LC50 for trochophores and adults was 0.22 and 7.5 ppm cadmium, respectively (13). In *Hydroides elegans*, the EC50 for trochophores was 29 ppb copper, whereas mortality of the adults occurred only when copper concentrations reached 500 ppb (10).
3. *Test Sensitivity Varies with Polychaete Species and Toxicant*. Reish and LeMay (14) compared the toxicity of seven metals with five polychaete species. They found that, for the same metal, different polychaete species gave very different results. For cadmium, the 96-h LC50 ranged from 2.6 ppm in *Pectinaria californiensis* to 14.1 ppm in *Neanthes arenaceodentata*. For the same species, sensitivity varies with toxicant. *Ophryotrocha labronica* was the most sensitive to copper, but it was the second most tolerant to chromium, and the most tolerant to mercury.
4. *The Chronic Test may not be More Sensitive than the Acute Test*. Reish and Gerlinger (2) noted that very limited data on the comparison of acute and chronic tests existed. After exposure of *Neanthes arenaceodentata* to 5.1 ppm cadmium for 20 days, no mortality existed, but the growth rate was significantly lower than that of the control. In another study with the same polychaete species, however, the 28-d LC50 values for mercury and copper were not lower than the 4-day values (15).
5. *Life-Cycle Tests may not be more Sensitive than Acute Tests*. At 100 ppb pentachlorophenol, *Dinophilus gyrociliatus* adults survived well, but the total number of eggs plus juveniles was significantly reduced (16). Similarly, at 50 ppb mercury, *Ophryotrocha diadema* survived well, but the number of offspring was reduced; in contrast, the 96-h LC50 for mercury was very close to the concentration that resulted in declined reproductive output (17).

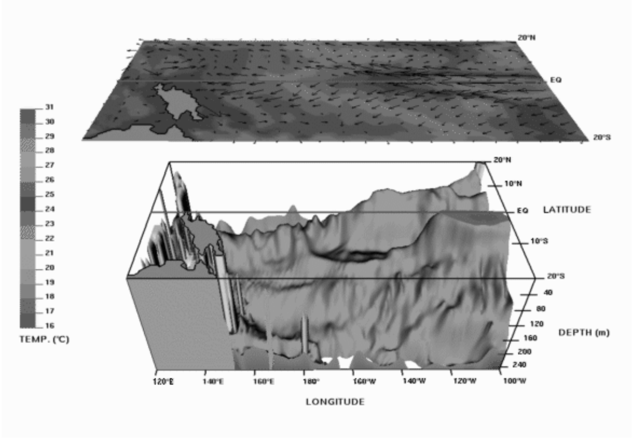
EL NIÑO: THE INTERANNUAL PREDICTION PROBLEM

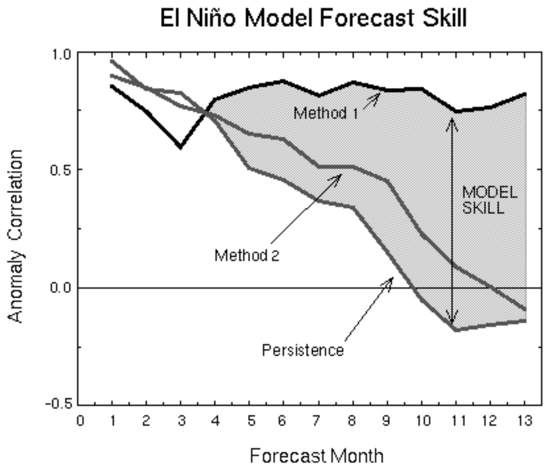
Geophysical Fluid Dynamics
Laboratory—NOAA

Once every few years, the normally cool waters of the eastern tropical Pacific become unusually warm in a phenomenon known as El Niño. During El Niño years, disruptive weather patterns often occur over wide regions of the globe, including North America. For example, flooding rains can strike California, producing coastal erosion, mudslides, and crop damage, while droughts may occur in Australia and other regions. Along the South American coast, the local fishing industry is severely disrupted by the unusually warm ocean waters.

GFDL and Princeton University maintain active collaborative efforts aimed at understanding and predicting El Niño. George Philander of Princeton University is a pioneer in the field of El Niño simulation and theory. His work with GFDL's Ron Pacanowski established the viability of simulating El Niño using coupled ocean-atmosphere models and set the stage for attempts to use such models for El Niño prediction. At GFDL, Kikuro Miyakoda and Tony Rosati have led efforts to build a system to predict both El Niño and its impact on large-scale weather



Modeled ocean temperature and surface current distribution over the tropical Pacific Ocean region obtained from a GFDL coupled ocean-atmosphere model used to predict El Niño/Southern Oscillation (ENSO). Lower (blue surface): three-dimensional depiction of the surface on which the ocean temperature is 20 °C. Undulations of this surface can be used to monitor ocean heat content changes associated with ENSO. During the cold phase of ENSO, this surface is deep in the warmer western tropical Pacific but rises toward the sea surface in the cooler eastern equatorial Pacific, as in the example shown. Upper: corresponding distribution of sea surface temperature and surface ocean currents. Gray regions depict land areas of New Guinea and northern Australia.



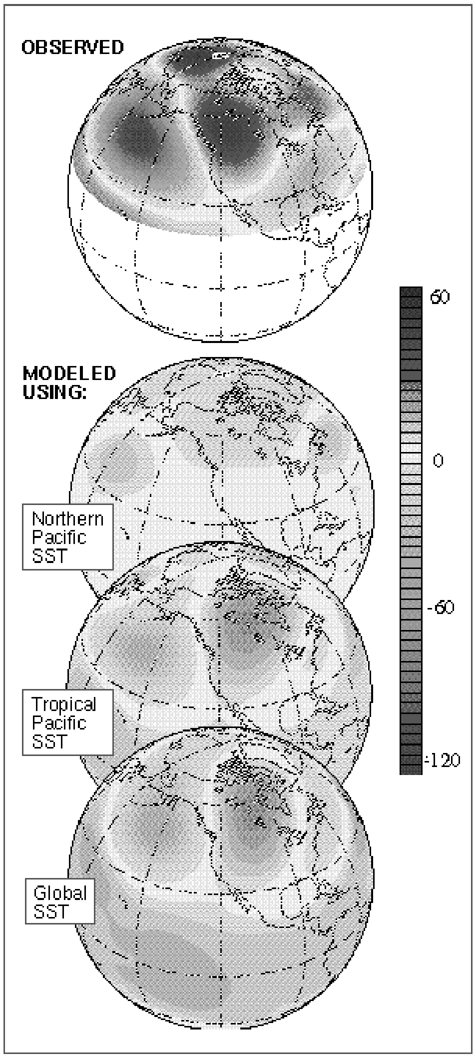
Model skill in the prediction of eastern tropical Pacific sea surface temperature anomalies for different forecast lead times. Higher values indicate greater skill. Based on an ensemble of 14 retrospective forecasts for 1982–1988 using a GFDL coupled ocean-atmosphere model. Forecast Method 1 uses both surface and sub-surface ocean data for initialization, whereas Forecast Method 2 uses only surface data. The results show the crucial importance of subsurface data for the success of the forecasts with this prediction system. [*Source*: Anthony Rosati, et al., Monthly Weather Review, submitted.]

patterns. Miyakoda has long been a leader in efforts to extend the limits of useful weather forecasts. Many of his research group's earlier modeling innovations had been incorporated into operational weather forecasting models at the National Meteorological Center, leading to significant improvements in the 3–5 day forecasts now available to the public.

Using coupled ocean-atmosphere models developed at GFDL and other research centers, scientists now have begun to make physically based predictions of El Niño conditions, with lead times of a year or more. These models have the potential to predict El Niño's effects on weather patterns over North America and other regions far removed from the tropical Pacific. Farmers, energy planners, and water resource managers are examples of those who would benefit from improved extended-range weather and short-term climate predictions.

GFDL'S MODULAR OCEAN MODEL

Detailed predictions of El Niño are made possible by the "Modular Ocean Model," a product of extensive research at GFDL. Through the efforts and foresight of Mike Cox, Keith Dixon, Ron Pacanowski, and Tony Rosati at GFDL, this ocean model is now a shared resource, used by hundreds of researchers worldwide. The model has become the mainstay of the oceanographic modeling community, not just in new operational El Niño predictions at the National Centers for Environmental Prediction, but for global climate change research and other applications as well.



Observed and modeled atmospheric circulation anomalies over the Pacific Ocean and North America during six El Niño winters. The model simulations illustrate how long-range (1 year) predictions of tropical Pacific sea surface temperature may ultimately lead to improved long-range predictions of seasonal weather anomalies, even in regions remote from the tropical Pacific such as the continental United States. Shown are composite 500 mb geopotential height anomalies in meters. The three bottom diagrams are from atmospheric model experiments in which observed sea surface temperatures have been specified for different domains. RENEWABLE ENERGIES FROM THE OCEAN

Purnima Jalihal
National Institute of Ocean
Technology
Chennai, India

INTRODUCTION

Today renewable energies are the focus of attention because of the realization that fossil fuels are on the verge of extinction. Renewables like solar and wind energy have been studied thoroughly, and a lot of standard energy conversion devices have also been designed, tested, and proven. The ocean has a large potential in terms of the energy availability. However, harnessing the ocean energy forms is still in the infancy stage.

The oceans have several untapped features like varying temperature, waves, and tides. The mechanical motions and the thermal variation caused by solar radiation cause the oceans to have entrapped in them tremendous amounts of energy, which can be tapped. The energy tapped from these phenomena occurring in the oceans is renewable and therefore needs exploration. Although several attempts have been made to harness these energies and convert them into electricity, none of the methods are yet commercially viable. However, further studies in these areas and performance evaluation of pilot plants can lead to improvements in the economic and technical prospects of such plants. The three energy sources in the oceans are waves, tides, and thermal variation along the depth. This chapter gives a brief description of each type of energy and gives the Indian case studies for wave energy and ocean thermal energy conversion.

WAVE ENERGY

Waves result when wind blows over the ocean surface and energy gets transferred from the wind to the sea. The amount of energy transferred depends on the wind speed, the distance along which it affects the water, and the amount of time during which the wind blows. When a wave breaks at seashore, one can see the tremendous amount of energy released.

Wave energy is an irregular and oscillating low-frequency energy source that can be converted into usable electric energy. It varies from location to location and from season to season.

Harnessing wave energy involves complicated devices in which the mechanical motion of the pressure waves has to be converted to electrical energy. These devices can be generally categorized as follows:

1. Floating or pitching devices
2. Oscillating water columns (OWC)
3. Surge or focusing devices

The first type consists of mechanical linkages between floating or fixed objects. The oscillating water column type of devices transfer the energy from the waves to pneumatic power by alternate compression and decompression of air in a duct or chamber. This pneumatic power is converted to mechanical power and thereby to electric power through a generator. The surge devices channel large waves into a small area, which forces the height of waves to increase, and when this water passes through hydroelectric turbines on its way back to sea level, electricity is generated.

Wave Energy Plants Around the World

In Japan, research on wave energy began during the late 1970s. Several tests were conducted on OWCs, and the biggest focus has been on what is known as the "Mighty Whale" developed by Japan Marine Science and Technology (JAMSTEC). This OWC is probably the world's largest. However, Japan has been active in the area of the floating OWC and a concept called the Backward Bent Ducted Buoy has been developed. This is a floating conventional OWC but with the opening away from the wave direction. Norway has had research being carried out in wave energy for the past 25 years mainly by the Norwegean University of Science and Technology. They have been working on the Tapered Channel and OWC schemes. Portugal also is an active player in wave energy research. The Archimedes wave swing was invented here, and the concept uses the periodic wave pressure to cause the upper part of a buoy to move while the lower part stays in position. The United Kingdom has conducted research on the largest number of varied type of wave energy devices. The Shoreline OWC on Islay, the LIMPET OWC with Wells turbine, and the large OSPREY OWC are all the U.K.'s contributions to wave energy research. Some large prototypes like OSPREY failed before installation was completed. In Sweden, work has been carried out on a floating buoy with a submerged tube underneath. The tube is open to the sea at both ends, and there are some components for the power take off mechanism in the buoy. However, until now, no single plant has been completely commercialized and made repeatable. One must note that the Indian wave energy plant has been functional for the past 10 years, but it generates very low average powers. Details of this plant follow in a later section. Before we move on to the case study, a few details on the nature of waves will be discussed briefly.

Wave Theory

The average power P (W/m) in a regular sine wave per meter wave front of waves with height H and period T can be expressed as

$$P = \rho g^2 H^2 T / 8\pi$$

where ρ is the density of water and g is the acceleration caused by gravity. However, in practice, waves are far from ideal. In nature, waves are irregular and can be described by statistical models. If the wave conditions are measured, over 20 minutes, for example, the mean wave height H_m and the significant wave height H_s can be calculated. The significant wave height is defined as the average of the highest 33% of the waves. Under such circumstances, the wave power can be stated as:

$$P = 0.55 H^2{}_s T_z \text{ kW/m length of wave crest}$$

where T_z is the zero crossing period (1). It is very clear from the above equations that the energy in waves is dependent directly on the wave height and period, which makes it a variable and intermittent source of energy.

CASE STUDY

The Indian Wave Energy program

Indian wave energy research began in 1983 under the sponsorship of the Government's Department of

Figure 1. Wave energy plant.

Ocean Development. After about 6 years of research in the laboratory, the wave energy group and the Ocean Engineering Center, Indian Institute of Technology, Madras, coordinated a project, which involved the fabrication, and construction of the OWC-based wave energy system, which is shown in Fig. 1.

The structure consists of a heavy concrete caisson. The site selected was 45 m in front of the Vizhinjam Fisheries Harbor breakwater, off the Trivandrum Coast at the southern tip of the Indian Peninsula. The water depth at this location is 10 m, typical for fisheries breakwaters, and the average annual wave power potential is of the order of 15 kW/m. The already existing breakwater gives the approach needed for this structure. Figure 2 shows the sectional view of the caisson.

Stages of Research

Several stages of research were carried out on the power module by IIT, Chennai, and subsequently by the National Institute of Ocean Technology, India.

Stage I (1991–1994). The Constant chord Wells turbine coupled to a 150-kW slip ring-type induction generator was used. The major defect found in the system was the stalling behavior of the turbine at higher flow rate. Hence, efforts were made to carry out further studies on turbine and to reduce the no-load losses in the system. The studies resulted in the development of the stage II turbine.

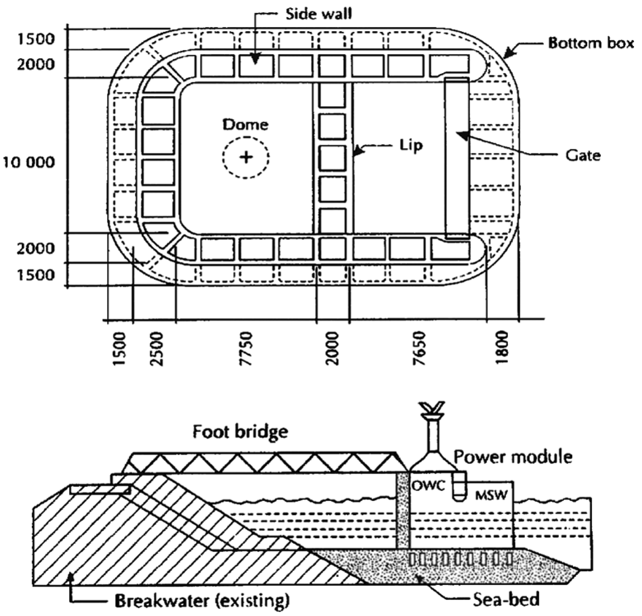

Figure 2. Cross-sectional view and elevation of wave energy device.

Stage II (1994–1997). A varying chord Wells turbine that has characteristics of self-pitch control, which can reduce the stalling effect, was installed in 1995. The data studies made on the system revealed that the efficiency of the turbine has been improved because of the reduced stalling and the selection of proper generator rating.

Stage III (1997–2000). An Impulse turbine with self-governing guide vanes coupled to a 55-kW generator was installed, and the studies revealed that the system was operable for all periods of the year. The problem with the impulse turbine is that the flipping guide vanes deteriorate the efficiency with time because of the corrosion of bearings in the marine environment, and a change in the geometry of vanes can result because of many cycles of operation. Hence, it was decided to change to fixed guide vanes.

Stage IV (2000–Present). A special variable-speed permanent magnet brushless alternator with constant power output is now used along with the impulse turbine with fixed guide vanes. The system can deliver power to charge a battery bank of 300 Ah capacity between 400 rpm and 1000 rpm. The objective of using a battery bank is to deliver a constant power requirement of 7 hp to a desalination system already installed at the site. These studies helped to understand the wave-to-wire conversion process and the pumping of power to the grid. The impulse turbine proved to give the highest efficiency, and this finding has led other wave energy researchers around the world to also consider using impulse turbine in place of wells turbine for wave energy conversion. It was decided to use the average power being generated by the plant to run a reverse osmosis-based desalination plant.

Wave-Powered Desalination System

The wave-powered desalination system consists of the impulse turbine, a special variable-speed alternator, and a battery backup. As the waves are random in nature, the alternator is a device that gives a constant DC voltage with varying input. When the wave heights are low, the turbine speed is low and may not be in the range within which the alternator generates voltage. In this case, the battery discharges and powers up the load. When more power is generated than is required by the load, the batteries are charged. This system was put in place after rigorous computer simulations and laboratory testing. The system is now operational and is now supplying water to the local village community. The system is self-sustaining in that energy from the sea generates freshwater out of seawater.

TIDAL ENERGY

Tides are caused by the gravitational attraction of the moon and the sun acting on the rotation of Earth. The relative motions of these bodies cause the surface of the sea to be raised and lowered periodically, according to several interacting cycles.

The tide moves a huge amount of water twice each day, and if we could harness it, large amounts of energy could be generated. However, converting it into useful electrical power is not easy. Tidal power works in a manner similar to a hydroelectric plant except that the dam is much larger. A huge dam or barrage is built across a river or a bay with a large difference between its low and high tides. When the tide goes in and out, the water flows through tunnels in the dam. The ebb and flow of the tides can turn a turbine. A major drawback of tidal power stations is that they can only generate when the tide is flowing in or out, i.e., only for 10 hours each day. However, some advantages are that there are no wastes like greenhouse gases, and production of electricity is reliable because tides are totally predictable.

Tidal energy potential has been investigated by several countries, notably, France, where a 240-MW demonstration plant was built on the Rance estuary during the 1960s and has now completed 30 years of successful operation. The Russians have built a small 400-kW device near Murmansk, which was later followed by a 17.4-MW experimental device, built by the Canadians at Annapolis on a small inlet off the Bay of Fundy. Small plants have also been installed in China. None of these countries have developed these plants any further. In the United Kingdom, a series of industrial consortia in collaboration with the Government have investigated the prospects for tidal energy on the Severn, Mersey and several smaller estuaries (2).

Every type of renewable energy project has its drawbacks, and tidal power plants have their problems. Obviously these stations would not be effective as the sole supplier of required energy (3). Also, some environmental issues develop with tidal energy. One issue is that the flooding of surrounding land can bring about much destruction. It could mean the relocation of settlement and agriculture plots. It can also change the composition of the habitat and threaten local inhabitants. Vegetation and marine life may not to adapt to the new water levels and may cease to grow or live where they previously existed. The main advantage of tidal energy is that it is nonpolluting. Hence, when designing tidal energy plants, these factors can be built into the design to make it economical.

India is also trying to venture into tidal energy in the Gulf of Khambhat region of Gujarat on the western side of India. Once the Gulf is closed, water levels within the reservoir can be controlled while the tidal fluctuation outside the reservoir continues, and hence, they can be harnessed for the generation of tidal energy.

OCEAN THERMAL ENERGY CONVERSION

The method of harnessing the energy by using the temperature difference between the surface of the ocean and at depths of around 1000 m is called ocean thermal energy conversion (OTEC) and is again a nonpolluting renewable energy source. It is capital intensive, but the unit cost comes down drastically as the rating becomes higher.

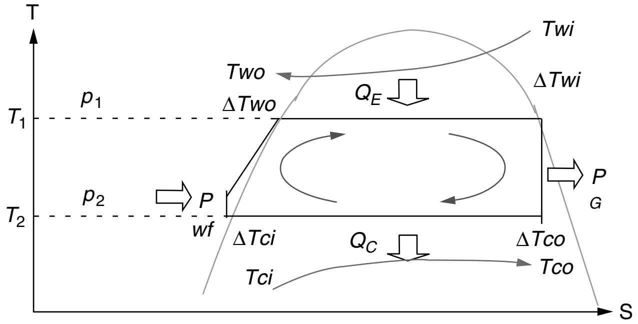

Figure 3. T-S Diagram for the closed Rankine cycle.

OTEC—Principle and Systems

OTEC uses the temperature-difference existing between warm surface seawater of around 27–29 °C and the cold deep-sea water of around 5–7 °C, which is available at a depth of 800 to 1000 m (4). Based on the power cycle, the OTEC system can be classified in to two open cycle and closed cycle systems. In the open cycle system, the warm surface water is flash-evaporated in a chamber maintained under high vacuum and the generated vapor drives a low-pressure turbine connected with the generator. The exhaust steam is condensed with cold seawater taken from the ocean depth. For an open cycle system, a condenser can be a means for freshwater production. The closed cycle system working on Rankine cycle uses a low boiling point liquid like R 134a or ammonia as the working fluid. The T-S diagram for the closed Rankine cycle is shown in Fig. 3.

The fluid is evaporated in a heat exchanger with the warm seawater from the ocean surface. After the vapor is expanded and drives the turbine, it is condensed by cold seawater from the depth of the ocean. This condensate is pumped back to the evaporator and recycled with the working fluid pump. A simplified flow diagram of the OTEC power cycle along with the Rankine cycle is shown below in Fig. 4.

Design Requirements of OTEC Plants

Choice of Working Fluid. The selection of equipment, sizing of piping, working conditions, and so on depend on the working fluid, which should have low-temperature boiling and condensation, high heat transfer coefficient, be environment friendly, safe, nontoxic, and so on. Some working fluids are ammonia, fluro carbon, tetra fluro ethane (HFL-1349), and propane. If safety is the most important issue, HFL-134a is the choice; however, ammonia is less expensive, easily available, and has superior thermodynamic properties. To handle ammonia, certain safety guidelines need to be followed carefully and strictly.

Choice of Material for Heat Exchangers. For an OTEC plant, the heat exchanger material should have corrosion resistance to seawater and compatibility with working

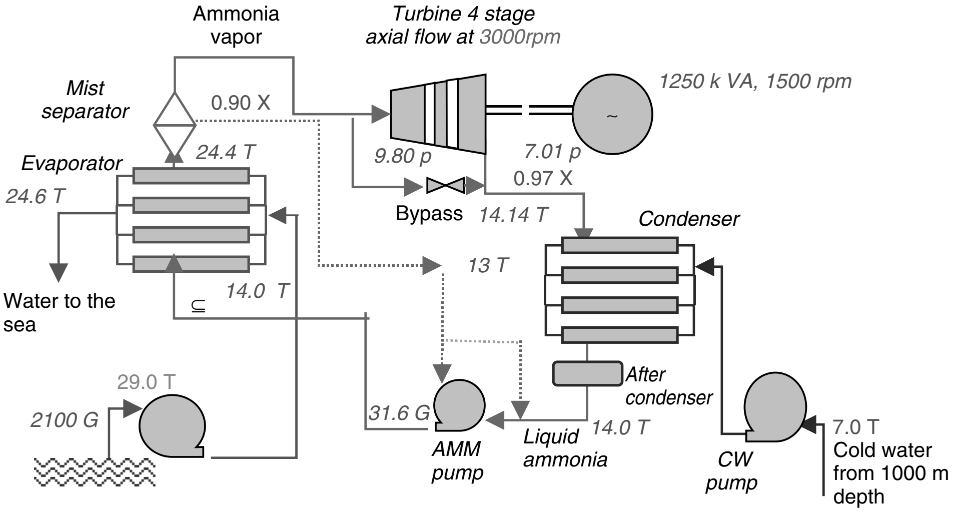

Figure 4. Energy balance diagram for 1-MW OTEC plant.

fluid. Materials that can be considered are aluminum, nickel, stainless steel, and titanium. Combinations like titanium with ammonia and aluminum with propane are workable.

Equipment Selection

Heat Exchangers. Heat exchangers are critical components, and the shell-tube, plate-fin, plate type of exchangers need to be compared. Considering volume required, fouling rates, heat transfer area, pressure drop, maximum working pressure, and other criteria, plate heat exchangers may have an edge over other types.

Turbine. The turbine generator system is another critical component of an OTEC plant, and the net power production depends on the turbine efficiency. Axial flow turbines give better adiabatic efficiency compared with radial flow turbines.

Sea Water Pumps. Seawater pumps for the warm and cold seawater consume about 30–40% of the gross power produced by the plant. The choice of material and characteristics to suit large discharge and low head should be considered for the selection.

Cold Water Pipe Material. The cold water pipe is usually around 1 km long and is subjected to varying hydrostatic pressures, temperatures, and forces caused by current drag and waves. In addition to the conventional steel pipes, other materials that can be considered are concrete, high-density polyethylene (HDPE), glass reinforced plastics (GRP), and so on. HDPE has some additional advantages in that it is buoyant and can float in water, which helps during towing and installation.

Other Criteria to be Considered

Station Keeping Systems. For floating OTEC plants, either the platform should be self-propelled or moored offshore. Design of the mooring depends on various environmental factors and the life expectancy of the plant.

Biofouling Control. In warm seawater, any solid surface begins to acquire a film in the form of a slime layer in a few hours. This process is called fouling, and it affects the heat exchanger performance when it grows within. It also increases drag on the pipes and vessels if not cleared for extended periods of time.

Some means of regular cleaning and addition of antifoulants like chlorine are measures to be taken to reduce the effects.

Power Transmission. For offshore plants, the power generated needs to be transmitted to shore and this requires underwater cables, which should have minimum transmission losses, resistance to water pressure, and such other characteristics. These requirements and more need to be catered to for designing an OTEC plant.

The most complex part of setting up a floating OTEC plant offshore is the deployment of the long cold water pipe and its connection to the barge. A HDPE pipe is buoyant, and it floats easily when towed on the surface. However, the lowering and the upending of the pipe requires several craft and tugs with cranes and other handling equipment. The mooring system should be designed well for operating as well as for storm conditions.

Case Study: The Indian 1-MW OTEC Plant

The National Institute of Ocean Technology is currently in the process of installing a floating barge-mounted OTEC plant off the Southern coast of India of gross rating 1 MW. A 1-km-long pipe made of high-density polyethylene will draw the cold water. The heat exchangers are of plate type and made of titanium. The turbine is a 1-MW ammonia turbine designed and fabricated for the first time. The working fluid is ammonia, and the Rankine cycle is being used. The power plant is housed on a non-self-propelled barge, which needs to be moored in 1000-m water depth. The configuration of the pipe/mooring system is shown in Fig. 5.

The motions of the barge under the environmental forces caused by wind, wave, and current affect the pipe and mooring behavior. Several analyses have been carried

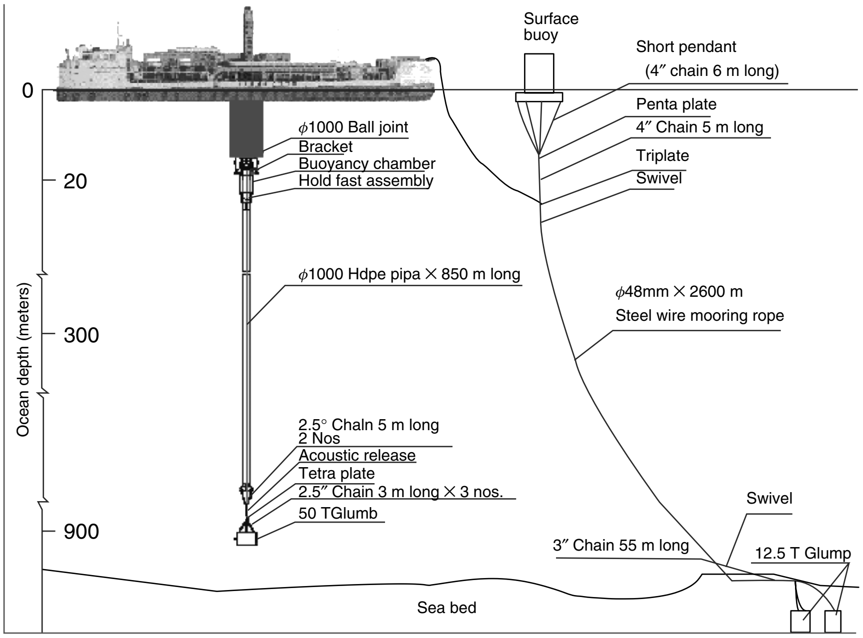

Figure 5. Pipe mooring configuration for 1-MW OTEC plant.

out to study the behavior of the system and arrive at the final design. The barge was specially designed for the OTEC plant, and some special features have been introduced in it, such as:

- A large 14-m-high retractable sump supporting the cold water pumps to meet the pump net positive suction head (NPSH) requirements.
- A quick-release mechanism to disconnect the mooring from the barge.
- A quick-release mechanism to disconnect the cold water pipe.

When commissioned, this will be the first megawatt-rating floating OTEC plant in the world.

CONCLUSIONS

Harnessing ocean energies in the various forms described in this article is challenging and needs several engineering and technological innovations. Most methods are still under study. However, with a focus toward overcoming the engineering complexities, a day will dawn when these renewable sources of energy will be harnessed and will replace the fossil fuels. The oceans are vast storehouses of energy, and man's endeavors and ingenuity will capture these ocean energy forms in such a way as to be environment friendly and convert energy-starved areas in the world to areas self-sufficient in energy.

ESTUARIAN WATERS

Priyanka K. Dissanayake
Moratuwa, Sri Lanka

IMPORTANCE OF ESTUARIES

Estuaries are in many ways the most complicated and variable of aquatic ecosystems. An estuary is a place where salt water from an ocean mixes with freshwater from the land and creates a unique and special environment in which marine species live, feed, and reproduce. Estuaries and intertidal regions are naturally exposed to stressful conditions.

An estuary and its immediate catchments form a complex system of ecological, physical, chemical, and social processes that interact in a highly involved and, at times, unexpected fashion. Estuaries are the end point for the detrimental effects of many upstream catchment activities. Materials carried from the land by rivers vary in quality and quantity, sometimes with strong seasonal patterns of high biological significance. Tidal oscillations cause vigorous reversals of flow. Inherent hydrographic patterns can lead to accumulation of materials and to upstream transport from the point of addition. The estuaries as recipients of wastes from rivers entering them and cities and industries along their shores are obviously more immediately susceptible to pollution damage than any other part of the marine system. Increased loads of nutrients and sediments from activities in the surrounding catchments are the two key threats to marine and estuarine water quality.

Estuaries are often used as disposal sites for unwanted biological or industrial products, usually referred to as waste. If such waste enters the estuarine ecosystem and is potentially harmful to life or has potentially detrimental effects on its health it is usually called a pollutant.

The usual way of controlling negative impacts of pollutant dispersal in estuaries is by monitoring its concentration in the water and making sure that the concentration does not exceed a certain level above which the pollutant is considered harmful. This problem consists of two parts, the *near field* and the *far field*. The near field problem considers technical details of pollutant outfall design and ways to inject the pollutant into the estuary from a point source so that its concentration is reduced as rapidly as possible. This is an engineering task, and therefore, the near field problem is not considered in oceanography. The far field problem studies the distribution of the pollutant through the entire estuary, starting from the disposal site not as a point source but as an extended source of uniform concentration across the estuary depth and width. The far field problem thus assumes that the engineering design of the pollutant outfall achieves reasonably uniform distribution over a sizeable section of the estuary and uses this situation as the starting point for the analysis.

PHYSICOCHEMICAL PROCESSES IN ESTUARIES

If the concentration of a pollutant where it is introduced into the estuary is known, its distribution through the estuary can be predicted from theoretical considerations. To understand how this is done, it is useful to begin with a look at the distribution of salt and freshwater in the estuary. Let us consider salt as a "pollutant" and follow its path through the estuary. Its source is at the estuary mouth, where its concentration is given by the oceanic salinity S_0. The salt enters the estuary with the net water movement of the lower layer. As it moves up the estuary, its concentration decreases through turbulent diffusion; in other words, the salt "pollutant" is diluted with freshwater that comes down from the river. We can normalize the salt "pollutant" distribution along the estuary by making it independent of its original "concentration" S_0 and define the salt–water fraction s as $s = S/S_0$, where S is the local depth averaged salinity at any arbitrary location in the estuary. This normalized salt concentration or saltwater fraction decreases from 1 at the mouth to 0 at the inner end of the estuary.

Similarly, we can consider the freshwater introduced by the river as a "pollutant" and follow its path through the estuary. Its source is at the inner end of the estuary, where its normalized concentration or freshwater fraction f is equal to 1. The freshwater then moves down through the estuary with the net water movement in the upper layer and reaches a concentration of zero at the estuary mouth. The estuary contains only saltwater and freshwater, so the saltwater fraction and the freshwater fraction always add up to 1 locally, which means that $f + s = 1$.

Not all pollutants are introduced into the estuary through the river or from the ocean. There are three classes of marine pollutants. Conservative pollutants are substances that are inert in the marine environment; their concentrations change only as a result of turbulent diffusion. (Salt and freshwater can be considered such substances.) Nonconservative pollutants undergo natural decay; their concentration depends on turbulent diffusion and also on the time elapsed since their introduction into the environment. The concentration of coupled nonconservative pollutants depends on turbulent diffusion and natural decay, both of which act to decrease their concentration, and on the availability of other substances in the environment, which allow the concentration to increase over time.

Conservative Pollutants

A conservative pollutant released at a point between the inner end and the mouth of the estuary spreads by turbulent diffusion in both directions, downstream and upstream. Its diffusive behavior is no different from the diffusive behavior of salt or freshwater. In the upstream direction, it diffuses in the same way as the salt water diffuses upstream; in the downstream direction, it follows the freshwater diffusion. If its concentration at the outlet is c_{out}, its concentration C in the estuary upstream from the release point is thus proportional to the salt fraction; downstream from the release point, it is proportional to the freshwater fraction:

$$\text{Upstream:} \quad C = c_{\mathrm{out}}(S/S_{\mathrm{out}})$$

$$\text{Downstream:} \quad C = c_{\mathrm{out}}(f/f_{\mathrm{out}})$$

Here, S_{out} is the vertically averaged salinity at the outlet location, and f_{out} is the freshwater fraction at the outlet. This shows that it is possible to predict the distribution of a pollutant in the entire estuary if the salinity distribution is known. The equation assumes steady-state conditions, continuous release of the pollutant at the constant concentration c_{out}.

Nonconservative Pollutants

The concentration of nonconservative pollutants decreases even in the absence of diffusion, through either biochemical or geochemical reaction. An example is the concentration of coliform bacteria released from a sewage outlet. The relationship between the concentration C of such a pollutant, the salinity S, and the fresh water fraction f is not as straightforward as for conservative pollutants, but concentration levels are always lower than those derived from the conservative case.

The concentration can be estimated by subdividing the estuary into compartments. If the compartments are chosen so that the ratio r of the freshwater volume V_{f} in the compartment and the volume of freshwater R introduced by the river into the estuary in one tidal cycle is constant ($r = V_f/R = \text{constant}$), it can be shown that the concentration of a nonconservative pollutant can be approximated by an equation for the concentration in each compartment:

$$\text{Upstream:} \quad C_p = C_{\text{out}} \frac{S}{S_{\text{out}}} \left[\frac{r}{1-(1-r)e^{-kT}} \right]^{n+1-p}$$

$$\text{Downstream:} \quad C_p = C_{\text{out}} \frac{f}{f_{\text{out}}} \left[\frac{r}{1-(1-r)e^{-kT}} \right]^{p+1-n}$$

In this equation, compartments are numbered from the inner end of the estuary, n is the compartment containing the outfall, and p is the compartment where the concentration is evaluated. T is the tidal period, and k is the decay constant for the pollutant. The larger k, the faster the decrease of the concentration over time. $k = 0$ represents the case where there is no independent decrease without diffusion, or the case of a conservative pollutant. Figure 1 compares this behavior with that of a conservative pollutant. Note that for $k = 0$, the equation for the concentration reduces to

$$\text{Upstream:} \quad C = c_{\text{uot}}(S/S_{\text{out}})$$

$$\text{Downstream:} \quad C = c_{\text{out}}(f/f_{\text{out}})$$

which is the same equation that was derived for the conservative pollutant.

Coupled Nonconservative Pollutants

Biochemical or geochemical processes reduce the concentration of a nonconservative pollutant, and they often also give rise to an increase in the concentration of another substance, which in turn may produce a third substance as a result of its own decay, and so on. Whether this chain of events constitutes pollution or not depends on the degree of harmfulness of each substance. Ammonium nitrogen, for example, is used as a fertilizer on land. Under natural conditions, it converts to nitrate (Fig. 2), which is also a nutrient.

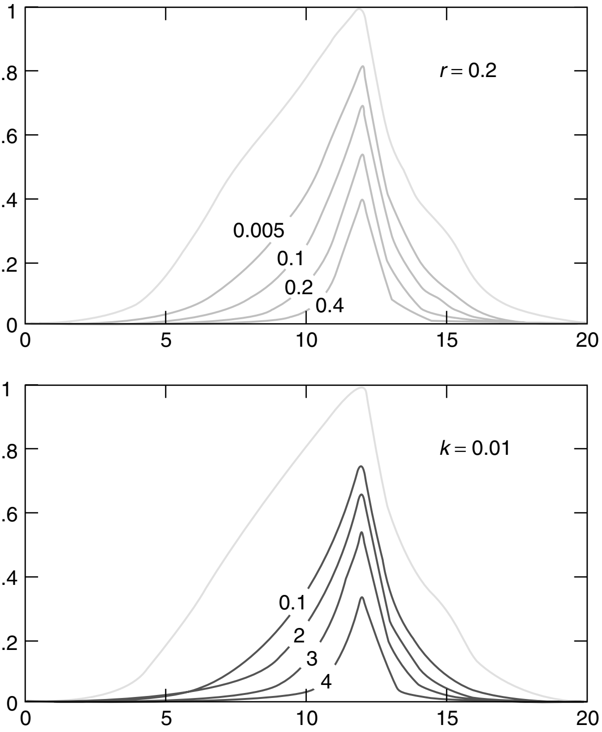

Figure 1. Behavior of conservative and nonconservative pollutants.

The introduction of nutrients into the marine environment does not automatically constitute pollution. But when nitrate and other nutrients are again mineralized in seawater, this process requires oxygen, which is not in unlimited supply in the ocean. Too much nutrient can lead to such a reduction of oxygen levels that the lack of oxygen can become a threat to marine life.

The indicators of nutrients and sediments are influenced by human activities from both diffuse inputs (urbanization and agriculture) and point discharges to the environment. The recommended indicators need to be biologically meaningful, yet readily collected and interpreted in relation to ecological conditions.

ROLE OF NUTRIENTS IN ESTUARIES

Nutrient Status

Six indicators of nutrients are recommended for assessing the status of marine and estuarine waters: dissolved inorganic nitrogen (DIN), total nitrogen (TN), dissolved inorganic phosphorous (DIP), total phosphorous (TP), chlorophyll a (Chl a), and dissolved oxygen (DO). Individual indicators have their own limitations, but when all six are used together, they provide a strong indication of nutrient status.

1. *DIN.* DIN is the combined concentration of nitrate, nitrite, and ammonia. DIN is the bioavailable fraction of the nitrogen in the water column.
2. *TN.* DIN may rapidly disappear as algae assimilate it, and so TN provides a better indication of the nitrogen cycling through the algal community and how much is dissolved in the water. TN is the sum of the concentrations of bioavailable (dissolved) and particulate forms of inorganic and organic nitrogen.

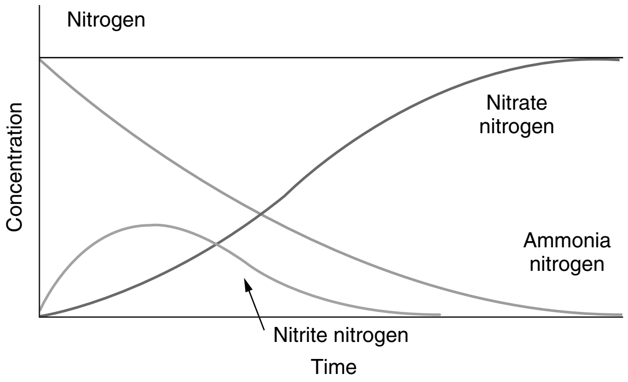

Figure 2. Behavior of a coupled nonconservative pollutant.

3. *DIP*. DIP is typically measured as the concentration of reactive orthophosphates, which is the form of phosphorous most readily bioavailable to aquatic plants.
4. *TP*. Like DIN, algae may rapidly assimilate DIP and so TP provides a better indication of the phosphorous cycling through the algal community and how much is dissolved in the water. TP is the sum of the concentrations of dissolved and particulate forms of inorganic and organic phosphorous.
5. *Chl a*. Chl a is a crude measure of phytoplankton biomass. Apart from light, phytoplankton are primarily limited by nutrient availability; Chl a is often used as an integrated, surrogate measure of nutrient status.
6. *DO*. DO, measured preferably as percent saturation (%), is the net balance of the amount of oxygen produced by photosynthesis, relative to that consumed by respiration and other forms of biological and chemical oxygen demand. Low DO (hypoxia) can arise following blooms of phytoplankton stimulated by nutrient enrichment. As the large mass of plant tissue decays, DO is lowered in the water column, and this can result in fish kills and nutrient inputs from the sediments.

Nutrients That Are Limiting Factors for Estuarine Phytoplankton

A limiting nutrient is a nutrient or trace element that is essential for phytoplankton to grow but is available in quantities smaller than required by the plants or algae to increase in abundance. Therefore, if more of a limiting nutrient is added to an aquatic ecosystem, larger algal populations develop until nutrient limitation or another environmental factor (e.g., light or water temperature) curtails production, although at a higher threshold than previously.

It is often said that nitrogen is the limiting nutrient in marine and coastal waters; however, the general assumption is often incorrect (1). Phosphorous, silica, and iron can also limit production in marine and coastal waters, and different trophic groups within the same ecosystem can be limited by different elements and nutrients (1).

Redfield Ratios. The recommended ratios of nutrients in estuaries are given by Redfield ratios, which are C:N:P = 106:16:1 for algae and Si:N:P = 20:106:16:1 for diatoms (1). Recently, Harris has suggested that a C:N:P ratio of 166:20:1 is probably more representative of the average phytoplankton composition (1). However, a review of the literature by Hecky and Kilham showed that the optimum N:P ratios for 14 freshwater and marine phytoplankton, for which data were available, ranged from 7–87 (1).

If the concentration of Si or N relative to P falls below these ratios (N:P<16:1, Si:P<20:1, these may be limiting nutrients (carbon is never limiting because it is available as a gas (CO_2); carbon in organic matter comes from dissolved CO_2 in water. The nitrogen levels control the rate of primary production. If the system is provided with high levels of nitrogen, algal blooms occur. Systems may be phosphorous limited, however, or become so when nitrogen concentrations are high and N:P>20:1(1). In such cases, excess phosphorous triggers eutrophic conditions. For optimum alagal growth, the N:P ratio should be in the range of 16–20:1(1). Increased reliance on the N:P ratio as a management tool is widely accepted by marine scientists and engineers to control nuisance algal blooms.

Another limitation on using N:P ratios is the considerable uncertainty over what measure of nitrogen and phosphorous should be used in calculating the N:P ratio. The ratio of TN:TP generally overestimates the algal available nitrogen to algal available phosphorous ratio aN:aP because organic phosphorous is more readily available than organic nitrogen and DIN:DRP underestimates aN:aP because DRP includes some organic phosphorous compounds in addition to orthophosphates (1). Therefore, the ratio of DIN:DIP gives a better estimate of the N:P ratio (1).

The recommended levels of total phosphorous in estuaries and coastal ecosystems to avoid algal blooms is 0.01–0.10 mg/*l* and 0.1–1 mg/l nitrogen (a 10:1 ratio of N:P) (1). It is recommended that total phosphorous levels in waterbodies should range within −0.005–0.15 mg/L to prevent eutrophication in estuarine waters; guidelines for protecting aquatic ecosystems recommend that phosphate values should not exceed 0.015 mg/L in estuaries (1).

ANZECC guidelines recommend the following concentration ranges to protect aquatic ecosystems: total N range from 0.01–0.10 mg/L for estuaries and 0.01–0.06 mg/L for coastal waters. The nitrate value should not exceed 0.1 mg/L for estuaries (1).

BUDGETARY MODELS FOR ESTUARIES

In science, models are tools that help us conceptualize, integrate, and generalize knowledge. “Budget models” are simple mass balance calculations of specific variables (such as water, salt, nitrogen, phosphorous, etc.) within defined geographic areas and defined periods.

The fluxes of materials to and from a system may be budgeted by many different procedures, but there are inherent similarities among these procedures. A budget describes the rate of material delivery to the system (‘inputs”), the rate of material removal from the system (“outputs”), and the rate of change of material mass within the system (“storage”). Some materials may undergo internal transformations. Such changes are sometimes referred to as “internal sources and sinks.” Figure 4 depicts the budget for any material.

Without further interpretation, budgets do not provide information on the processes, which account for the summed sources minus sinks (2). Some inferences about the actual processes can be drawn by comparisons among

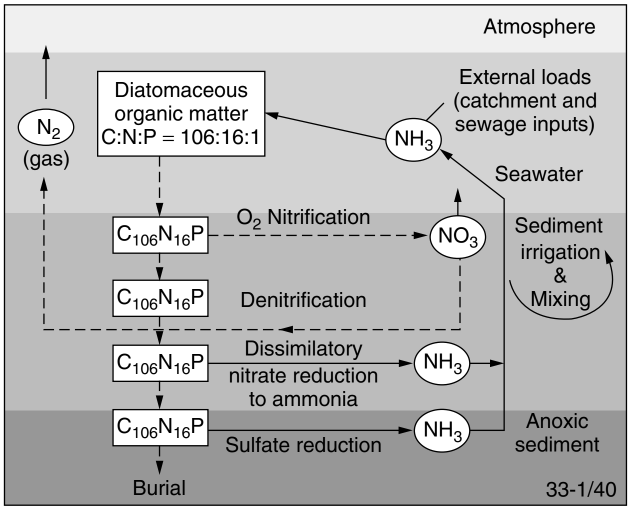

Figure 3. Nitrogen cycle in an estuary.

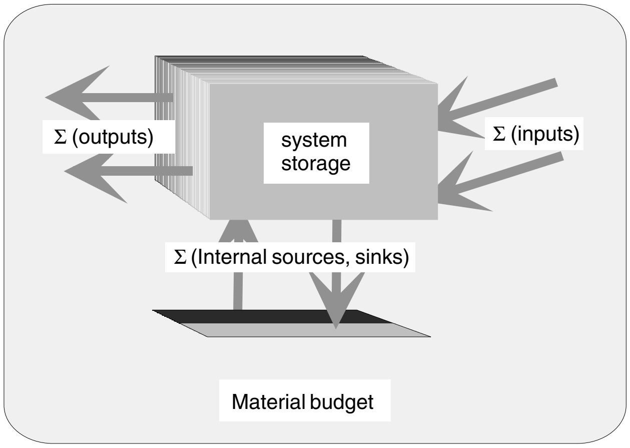

Figure 4. Budget for any material.

budgets for different materials. This approach is referred to as “stoichiometric analysis” of the fluxes.

It is also useful to describe such a budget in terms of this simple equation:

$$\frac{dM}{dt} = \sum \text{inputs} - \sum \text{outputs} + \sum (\text{sources} - \sin \text{ks})$$

where dM/dt represents the change in mass of any particular material in the system with respect to time (2).

In broad summary, water and salt budgets are used to estimate water exchange in coastal systems. Nutrient budgets (as a minimum, dissolved inorganic phosphorus and dissolved inorganic nitrogen) are also developed, and departure of the nutrient budgets from conservative behavior is a measure of net system biogeochemical fluxes.

Stoichiometric Analysis of Fluxes

In chemistry, “stoichiometry” is the study of the combination of elements in chemical reactions. Therefore, we use the term “stoichiometric analysis” to describe this approach to budgetary analysis. It should be kept in mind that the discussion to follow is based on the ΔY’s for C, N, and P, as derived from nutrient budgets. The following is generally computed using the ΔY’s.

- Net ecosystem metabolism, that is, the difference between primary production and respiration
- Net nitrogen fixation minus denitrification
- Net sulfate reduction
- Net $CaCO_3$ precipitation
- Net CO_2 gas flux across the air–sea interface.

NONCONSERVATIVE DISSOLVED INORGANIC P AND N FLUXES IN NEGOMBO ESTUARY, SRI LANKA, USING THE STANDARD LAND–OCEAN INTERACTION IN THE COASTAL ZONE (LOICZ) METHODOLOGY (3)

The Negombo estuary (7°4′–7° 12′ N: 79°47′–79°51′ E) is situated on the west coast of Sri Lanka. The estuary receives water from the Attanagalu Oya (ja-Ela and Dandugam Oya) drainage basin and is a dominant morphological feature of the watershed. The brackish water area is 3239 ha and is considered the estuarine part of the contiguous wetland system of the Muthurajawela Marsh Negombo Estuary. The main freshwater source, Attanagalu Oya, empties at Ja-Ela and Dandugam Oya at the southern tip of the estuary. In addition, the Hamilton canal is the connecting watercourse of the Kelani Estuary and the Negombo Estuary running parallel to the west coast from the north to the south along the Muthurajawela Marsh.

LOICZ, a one-box, one-layer model was used for this study, and the data available are applied on a seasonal basis (dry and wet). The data used are mentioned below and are the averages for dry and wet seasons:

1. river discharge
2. precipitation
3. evaporation
4. average salinity outside the system, within the system, and in the river discharge
5. dissolved inorganic phosphate (DIP) outside the system, within the system, and in the river discharge
6. dissolved inorganic nitrogen (DIN) outside the system, within the system, and in the river discharge

The nonconservative DIN and DIP fluxes are given in (Table 1).

$$[p - r] = -\Delta\text{DIP} \times \left(\frac{C}{P}\right)_{\text{part}}$$

$$[\text{nfix} - \text{denit}] = \Delta N_{\text{obs}} - \Delta N_{\text{exp}}$$

$$(\text{nfix} - \text{denit}) = \Delta N - \Delta P \times (N : P)_{\text{part}}$$

The system is an internal source for DIP and an internal sink for DIN in both the wet and dry seasons. In the dry season, the N:P ratio is less than the Redfield ratio of 16:1; therefore, the estuary is N limiting. In the wet season, the N:P ratio is greater than the Redfield ratio

Table 1. Nonconservative Dissolved Inorganic P and N Fluxes in Negombo Estuary (Sri Lanka) Considering a one–box, one Layer System[a]

Process	Dry Season Rate, ($mmolm^{-2}d^{-1}$)	Wet season Rate, ($mmolm^{-2}d^{-1}$)
Area	32.39 km^2	32.39 km^2
DDIP	+0.052	+0.008

DIN:DIP	13	18
Stoichiometric Analysis		
(nfix-denit)phytoplankton[b]	−0.936	−0.965
(*p-r*) phytoplankton[c]	−5.512	−0.848
(nfix-denit)sea grass[b]	−1.664	−1.077
(*p-r*)sea grass[c]	−28.6	−4.4
nfix-denit)mangrove[b]	−0.676	−0.925
(*p-r*)mangrove[c]	−67.6	−10.4

[a] Reference (3).

[b] $(N:P)_{part}$ assumed to be 16 (plankton), 11(mangrove), and 30 (sea grass).

[c] $(C:P)_{part}$assumed to be 106(plankton), 1300 (mangrove), and 550 (sea grass).

of 16:1 but less than 20:1; therefore, the estuary has optimum nutrient concentrations, which support optimum phytoplankton growth.

The DDIP>0 in both seasons. This system with DDIP>0 is producing DIC via net respiration $(p - r)$ and is heterotrophic. The negative signs of $(p - r)$ calculated for phytoplankton, sea grass, and mangrove support this assumption if phytoplankton, sea grass, and mangrove dominate the input of organic matter from outside the system respectively. The (nfix−denit) is negative for phytoplankton as well as for sea grass and mangroves, indicating that denitrification is the main process taking place. The denitrificate rates are in the range of −0.676 to −1.664 for the dry season and −0.925 to −1.077 in the wet season.

Nitrogen is typically the nutrient that controls primary production in marine coastal ecosystems and, as such, is commonly implicated in the eutrophication of coastal waters. Denitrification is probably the most important nitrogen cycling pathway because it is one of the few natural processes that can counteract eutrophication. Up to 60 to 80% of the external nitrogen load delivered to coastal ecosystems may be lost to coupled sediment nitrification−denitrification. Despite its importance, sediment denitrification has rarely been measured in Sri Lankan coastal ecosystems.

Worldwide denitrification studies in tropical and subtropical estuaries where N_2 fluxes have been directly measured are also rare; most work has been carried out in temperate West European and North American systems. There are distinct biogeochemical differences between tropical/subtropical and temperate estuaries. Differences in tropical/subtropical estuaries most likely to influence denitrification rates include

generally low water column nitrogen concentrations,

different temperature and light regimes,

differences in benthic infauna,

shallower, so benthic processes that interact with denitrification such as benthic productivity are more important, and

episodically driven resulting in differences in the quality, timing, and delivery rates of carbon inputs to the sediments.

WATER QUALITY GOALS

In developing an effective strategy for mitigating the effects of nutrient overenrichment, one must understand the physical and ecological relationships that determine the extent and causes of nutrient overenrichment, along with societal objectives and behavioral responses. Societal objectives determine goals that a management strategy strives to achieve and is the bench mark against which it is evaluated.

The appropriate set of policies for any given estuary depends on the nutrient sources for that estuary. For example, if the main nutrient source is agriculture, a set of policies designed to promote the adoption of best management practices is required. These can be implemented at the local, regional, or national level. Alternatively, if atmospheric deposition is the main source of nutrients, policies that reduce atmospheric emissions of nitrogen are needed. The source of atmospheric nitrogen is often outside the local jurisdiction governing the estuary, so policies to combat this nutrient source must be implemented at the regional or national level.

Establishing Criteria and Standards

A water quality criterion is that concentration, quality, or intensive measure that, if achieved or maintained, allows or makes possible a specific water use. Water quality criteria are often the starting point in deriving standards, but criteria do not have a direct regulatory impact because they relate to the effect of pollution rather than its causes. A water quality standard is the translation of a water quality criterion into a legally enforceable ambient concentration, mass discharge, or effluent limitation expressed as a definite rule, measure, or limit for a particular water quality parameter. A standard may or may not be based on a criterion.

Traditionally, water quality standards have been absolute numbers as a concentration or discharge of a toxic substance that may not be exceeded or an oxygen concentration that must be maintained. However, water quality in a given waterbody can fluctuate as a result of random factors, such as weather and uncertainties in hydrologic processes. Eutrophication impacts include increased primary productivity; increased phytoplankton biomass; reduction in water clarity; increased incidents of low oxygen; changes in trophic structure, trophic interactions, and trophodynamics of phytoplankton, zooplankton, and benthic communities; damage to coral reefs; fish kills; reduced fisheries production; and decreased biotic diversity.

In general, the public must accept the need for improved receiving water quality and prevention measures. If the public does not perceive a problem, it is unlikely that elected officials will pursue this issue or that agency staff will have the resources or authority to implement solutions.

When setting up water quality standards, many other factors must also be considered (4)

- Are damages subject to threshold effects or are they continuous?
- During which season are impacts the greatest?
- Are sudden discharges controlled?
- What are the flushing and mixing conditions in the estuary?
- What timescales are involved?

NOS/NMFS COOPERATIVE RESEARCH ON COASTAL FISHERIES AND HABITATS AT THE BEAUFORT LABORATORY

Jon Hare
NOAA Center for Coastal
Fisheries and Habitat Research

EARLY LIFE HISTORY OF FISHES

Laboratory researchers have studied fish early life history since the early 1900's. Work is conducted on egg, larval and juvenile stages of species ranging from anadromous shad to highly migratory tuna and billfishes. Topics of study include taxonomy, distribution, growth, predation, physical transport, behavior and stock identification.

Research on early life history stages at the Laboratory is supported by a fish rearing facility. A variety of species have been reared ranging from summer flounder, to black sea bass, to spotted sea trout. Fish from this facility are used in ecological, physiological, and behavioral studies.

FISHERIES OCEANOGRAPHY

Laboratory staff have been active in fisheries oceanography since the late-1970's. The goal of this research is to better understand the linkages between biological and physical oceanographic processes and fish population distribution, abundance and dynamics.

Recently, the Laboratory has been involved in the South Atlantic Bight Recruitment Experiment (SABRE), the purpose of which is to understand the effect of environmental variation on young menhaden survival, and ultimately, recruitment to the fishery. Employees have conducted egg and larval investigations on the continental shelf, have studied ingressing larvae at inlets, and have examined juveniles in estuarine nursery habitats. Coupling field observations, behavioral models and physical models has provided insights into the role that physical transport plays in controlling larval supply to inlets.

Current research in fisheries oceanography ranges from the effect of Langmuir circulation on plankton distributions, to the exchange of larval fishes across the Cape Hatteras zoogeographic boundary, to the role of the Charleston Bump as essential spawning and nursery habitat. The scales studied range from meters to hundreds of kilometers and from hours to decades, thereby allowing Laboratory researchers to link processes-oriented work with studies examining annual and decadal variation in fish populations.

HARMFUL ALGAL BLOOMS

Laboratory employees have been studying the "red tide" dinoflagellate, *Gymnodinium breve*, since a bloom in coastal North Carolina waters in 1987 caused both fish kills and shellfish closures. The source of *G. breve* cells is the shelf off the west coast of Florida, where blooms have occurred in 21 of the last 22 years. Local eddy circulation in the northeastern Gulf of Mexico and in the vicinity of the Dry Tortugas affects the retention and coastal distribution of blooms on the western Florida shelf as well as influences the entrainment of cells into the Loop Current-Florida Current-Gulf Stream systems. All blooms off the Florida Keys and in the South Atlantic Bight can be traced to the inoculation of shelf water with Gulf Stream water, as well as the proper physical conditions that support blooms. Monitoring and research of *G. breve* is continuing, as is work with other species that potentially cause harmful algal blooms.

The Laboratory's remote sensing capabilities contribute to the study of harmful algal blooms. The Laboratory serves as the Southeast Node of NOAA's CoastWatch program and researchers at the Laboratory are involved in the development of regional ocean color algorithms for the SeaWIFS satellite.

FLORIDA BAY-EVERGLADES NATIONAL PARK

Laboratory scientists initiated fisheries and habitat research in Florida Bay and adjacent waters in 1983. Past research has examined a variety of topics including larval fish distributions, ecology of juvenile spotted seatrout and gray snapper, evaluation of habitat use by juvenile fishes and invertebrates, nutrient limitation of seagrass growth and responses of both plant and animal communities to the die-off of seagrasses first identified in 1987.

Building on this past work, investigators at the Laboratory are conducting laboratory and field research as part of the Florida Bay Study. The overall goal of this work is to evaluate the relation between environmental and habitat change and the recruitment, growth and survivorship for fishery organisms in Florida Bay. Current research includes: examination of the influence of environment and habitat on larval and juvenile fish growth and survival; development of an individual-based energetic model for larval spotted seatrout; evaluation of the effect of habitat on the distribution of fishes and invertebrates and determination of the origin of elevated mercury levels in upper trophic levels.

SEAGRASS RESTORATION

Research on various aspects of seagrass ecology at the Laboratory has been continuous for 20 years. Areas of investigation have included development and dissemination of planting techniques monitoring protocols, and success criteria, as well as studies to determine the light requirements of seagrasses, functional equivalency of restored beds as compared to natural, undisturbed systems, and landscape scale studies regarding the temporal dynamics of seagrass bed pattern and distribution. Emphasis has been placed on research information transfer to managers, active participation in research projects, and litigation. The research approach has been to sustain a broad-based program covering a variety of ecological processes which allows the scientists to quickly adapt and respond to changing management concerns and issues.

MANAGEMENT AND RESEARCH USES OF GIS

Laboratory employees use Geographic Information Systems for various research and management activities. Menhaden researchers are examining the spatial and environmental aspects of menhaden catch and marine mammal researchers are studying the spatial interaction between fisheries and marine mammals.

As a more in depth example, researchers at the Laboratory are using GIS to map and to understand the distribution of aquatic seagrasses throughout the southeastern United States. Aquatic seagrass beds are important habitat to many fish and shellfish species. Linkage with the NOAA Coastal Assessment Framework associates the aquatic beds with coastal drainage basins. Within North Carolina, the vast majority of seagrass beds are inside the barrier islands of the Pamlico-Albemarle Estuarine Complex. Distribution of seagrass beds is related to annual extremes of salinity but other, more-local factors are also involved. The restricted abundance of seagrass beds along mainland shores reflects salinity stress, water quality, and water use problems from coastal development. These large-scale studies of seagrass are being linked with the smaller scale seagrass dynamics studies conducted by Laboratory employees.

MENHADEN RESEARCH

Scientists at the Beaufort Laboratory have been studying Atlantic menhaden since the 1950's and Gulf menhaden since the 1960's. In 1996, catch of both species totaled 1.8 million pounds and was valued at $94.2 million. Research has included studies of life history, movements, juvenile abundance, and patterns in the fishery. Current efforts include examination of the environmental factors that contribute to recruitment variability and continuation of the monitoring of fishery patterns.

Beginning in the late 1970's, menhaden boasts were asked to complete logbooks of daily purse-seine activities. For each purse-seine set, time, location, catch, and weather conditions are enumerated. Approximately 6,800 forms describing 23,000 purse seine sets are collected annually. Laboratory personnel also collect data on landings, fishing effort, and size and age of catch. These data are used for stock assessments, are helpful to industry personnel and are used by researchers to address various scientific questions. For example, these data are being used to examine the effects of hypoxia on Gulf menhaden distribution. Preliminary analyses indicate that catches during the summer of 1995 were low in hypoxic areas near shore. These data on adult fish distribution allow examination of the effects of hypoxia on higher tropic levels.

REEF FISH RESEARCH

Laboratory employees have studied reef fish off the southeastern United States since the late 1960's and have addressed both applied fishery issues and basic reef fish ecology. The Laboratory's Southeast Region Headboat Survey collects fisheries and biological data to support management activities. Approximately 165 vessels are monitored throughout the southeast, and in 1996, biological samples were collected from 37, 435 fishes of 124 species. These data are also used to examine patterns in the fishery and to study the structure and distribution of reef fish communities.

A variety of studies of reef fish ecology have been conducted by Laboratory employees using SCUBA. A temporal comparison off North Carolina suggests an increase in reef fish diversity and abundance possibly owing to climate change. The impact of removing piscivorous predators from reef areas is also being studied. Employees are continuing to examine changes in fish assemblages on managed and unmanaged reefs at Key Largo and participate in annual dives to assess reef fish populations at the Grays Reef National Marine Sanctuary off Sapelo Island, Georgia. Future research includes working with fisheries and GIS data to map essential reef fish habitat, and studying recruitment of larval fishes to reef habitats.

STOCK ASSESSMENT

Stock assessments are conducted by Laboratory employees for a variety of species in support of fisheries management. Stock assessments involve estimating population size-at-age, data which are collected by laboratory employees. From estimates of population size at age, age-specific fishing mortality for different levels of natural mortality can be calculated. Information on reproduction, such as age-specific maturity and fecundity, are used to calculate spawning potential ratios and to provide an indication of the level of fishing pressure experienced by the stock. The results of these assessments are provided to regional fishery management councils and commissions and include recommendations on how to either build or sustain healthy fish stocks along the Atlantic and Gulf coasts.

Laboratory employees conduct annual stock assessments for Atlantic menhaden and five year assessments for Gulf menhaden. Stock assessments are also completed for various reef fishes; recent assessments include red porgy, black sea bass, red snapper, vermilion snapper and scamp. Staff also conduct or provide advice on stock assessments for other fishery species in the southeast including blue crab, red drum, weakfish and wreckfish.

LINKING STOCK ASSESSMENTS WITH OCEANOGRAPHIC AND ECOLOGICAL PROCESSES

The ability to conduct stock assessment work and process-oriented work has allowed Laboratory researchers to further understand the processes that influence recruitment and stock abundance. For example, Gulf menhaden recruitment has been examined relative to Mississippi River discharge, a relation suggested by work done at the Laboratory during the GOMEX project. As another example, Atlantic menhaden recruitment has been related to the ingress of menhaden larvae into Beaufort Inlet. This time series of wintertime larval ingress at Beaufort Inlet has been used by participants in the SABRE program and data collection will continue.

MARINE MAMMALS

The Laboratory's research on marine mammals focuses on their interactions with fisheries, as well as life history and stock identification. Bottlenose dolphins are the primary species studied. Activities include recovery of stranded animals, live captures for tagging and data collection, photo-identification, and analysis of life-history samples. Results contribute to basic biological knowledge and to effective management and conservation.

As an example of some of the research conducted, dolphin 717 was freeze-branded during a live capture in 1995, and has since been regularly observed in the Beaufort area. Laboratory scientists know that she was a 3.5 year old female at the time of capture. Monitoring continues to determine when she will have her first calf as part of life history and recovery studies.

SEA TURTLES

Laboratory scientists continue an active program of sea turtle research. Surveys conducted since 1988 have underscored the importance of North Carolina's inshore waters, particularly the Pamlico-Albemarle Estuarine Complex, to juvenile loggerhead (*Caretta caretta*), green (*Chelonia mydas*), and Kemp's ridley (*Lepidochelys kempii*) sea turtles. Sea turtles are present in the Complex from April-December and during their emigration in early winter, are vulnerable to capture in pound nets set behind barrier islands. North Carolina pound nets are a passive gear that allow turtles to feed and to surface, to breathe.

Parts of the Pamlico-Albemarle Estuarine Complex were established as a pilot index area for sea turtles in 1995, using catch rates in pound nets as an index of abundance. The feasibility and methodology was established and the fishery was sampled again during fall 1996 and 1997. The goal of this project is to establish an index-abundance-area to monitor, assess, and predict the status of and impacts to sea turtles and their ecosystems. The cooperation of pound net fishermen in the area provides data not only on abundance, but also on movement and demography of these populations. In addition, blood samples are taken for analyses of health status, sex, and genetics.

PHRAGMITES RESEARCH

Researchers at the Laboratory are studying the use of *Phragmites* marsh by fish and shellfish species. Throughout the eastern United States many *Spartina alterniflora* salt marsh systems are being altered through *Phragmites australis* invasion. While information is lacking on the use of *P. australis* marsh by fish and shellfish species, increase in spatial distribution of *Phragmites* has concerned resource managers, who view such a shift as a degradation in habitat quality. Research conducted by Laboratory staff shows no significant differences in fish abundance or biomass between tidal *P. australis* and *S. alterniflora* marsh. Further, species diversity was higher in *P. australis* marsh. Stable isotope data from marsh fauna indicate that *P. australis* is an integral part of the estuarine food web.

MARINE CHEMISTRY

The Laboratory has a long history and continues research in marine chemistry. Although not highlighted here, the work bridges the gap between chemistry and habitat and fisheries issues. Studies include metals in the environment and their transfer through the food chain, the relation between iron and primary production, and otolith microchemistry as an indicator of past environmental exposure.

DISTRIBUTION AND DYNAMICS OF GAS HYDRATES IN THE MARINE ENVIRONMENT

Anne M. Trehu
Marta E. Torres
Oregon State University
Corvallis, Oregon

Gas hydrate is an ice-like substance that forms at low temperature and high pressure when adequate amounts

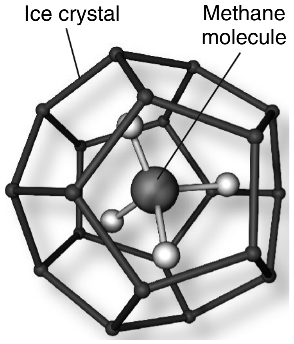

Figure 1. Schematic diagram of a gas hydrate molecule.

of water and low molecular weight gases, such as carbon dioxide, methane, and other hydrocarbons, are present (Fig. 1). In nature, gas hydrates containing primarily methane are widespread in the Arctic and in the shallow sediments on continental margins. Under certain geologic conditions, enough methane hydrate may be present for these deposits to represent a fossil fuel resource for the future. Concentrated deposits of gas hydrate near the seafloor form the substratum for unique assemblages of microbes that are only now being discovered; these microbes constitute the base of a foodweb for clams and other organisms, similar to those found at hydrothermal vent sites. Destabilization of gas hydrate in marine sediment may occur when artificial structures that heat up the surrounding sediments are installed; this may, in turn, result in catastrophic structural collapse. Because methane is a powerful greenhouse gas, sudden destabilization of gas hydrate on a large scale can have an impact on global climate. Indeed, past episodes of climate change linked to gas hydrate destabilization have been documented in the geologic record. For all of these reasons, researchers in many countries are trying to better understand the distribution and dynamics of gas hydrates in the marine environment.

NECESSARY CONDITIONS FOR FORMATION OF GAS HYDRATE IN NATURE

The temperature and pressure conditions required for gas hydrate to be chemically stable are found at the seafloor everywhere the water depth is greater than 300–500 m. (The minimum depth for gas hydrate stability decreases as the water temperature decreases.) As temperature increases beneath the seafloor at a rate that is controlled by the regional geothermal gradient, the effect of increasing temperature will eventually overtake the effect of increasing pressure, and gas hydrate will no longer be stable (Fig. 2). This balance between increasing pressure and temperature results in a gas hydrate stability zone beneath the seafloor that ranges in thickness from a few centimeters to several hundred meters. Based on these criteria, gas hydrate has the potential of forming almost everywhere beneath the continental slope and ocean basins.

Another critical condition that must be met for gas hydrate to form is that the concentration of gas present must exceed that required to stabilize the gas hydrate structure. Not enough methane is present in the sediments throughout most of the ocean basins. Gas hydrate is restricted to regions where organic material, which decomposes to form methane, is unusually abundant or where fluid flow transports gas into the gas hydrate stability zone from greater depth. These conditions are met on many continental margins (Fig. 3).

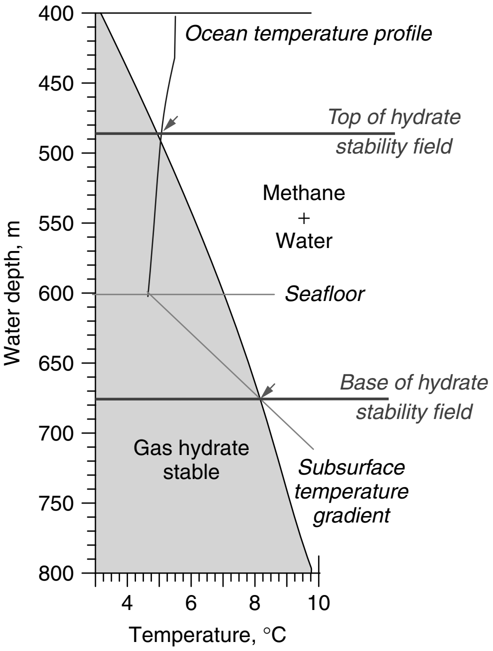

Figure 2. The temperature and pressure conditions under which gas hydrate is stable are constrained thermodynamically as shown by the stability boundary (shown here for pure methane hydrate in seawater). Hydrate is stable at low temperature and high pressure (which increases as water depth increases). This is shown by the light gray field. In this example, which depicts a site located at 600 m depth, the water temperature profile and the subseafloor temperature gradient are typical for the continental margin offshore Oregon. The top of the gas hydrate stability zone here is located within the water column at 485 m. Gas hydrates are stable in the sediments from the seafloor to a depth of 665 m, where the subsurface temperature becomes too high for methane hydrate to be stable.

Other factors affecting gas hydrate stability are the salinity of the pore waters and the composition of the hydrate-forming gases that are present. Moreover, temperature and pressure conditions can change locally as a result of focused fluid flow, tectonic activity, or the introduction of artificial structures. It can change globally as a result of climatic perturbations. The distribution and abundance of gas hydrate in the marine environment are therefore constantly changing. New discoveries are being made every year, increasing the number of verified gas hydrate sites.

ORIGIN OF THE GAS IN GAS HYDRATE

The gas in gas hydrate has two possible origins. Methane can be generated in the upper few hundred meters by microbes (biogenic gas), or it can migrate into the

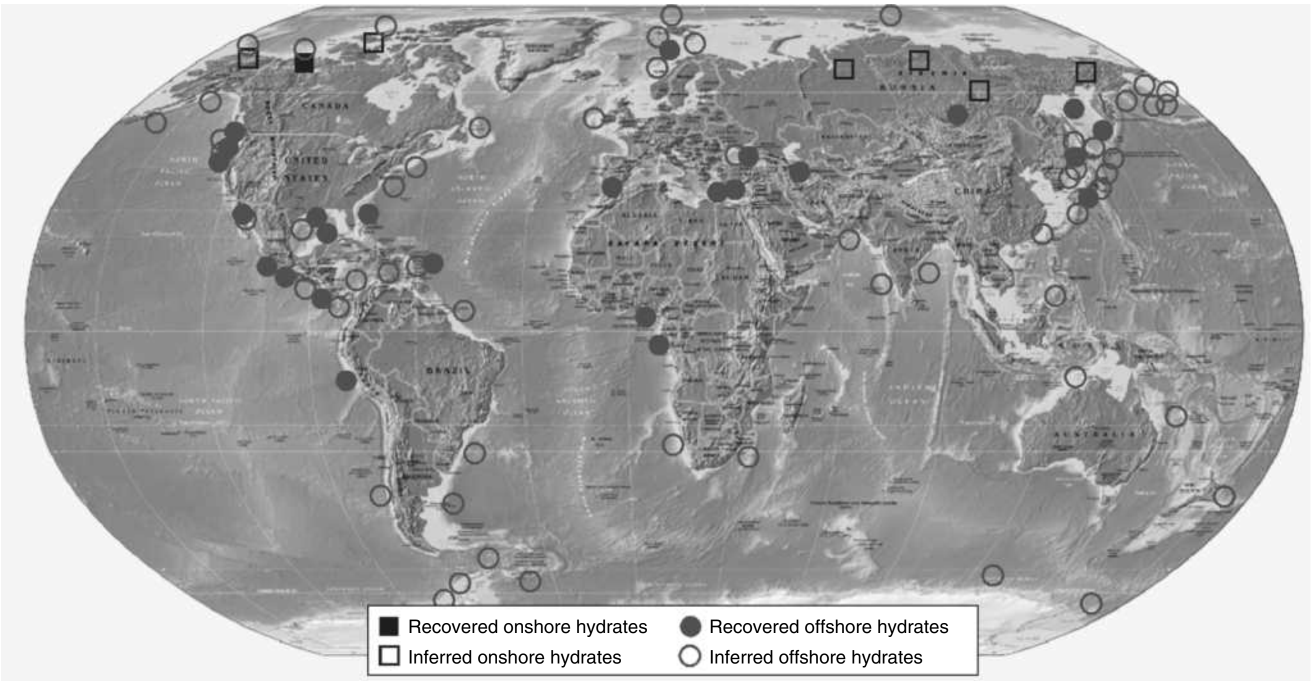

Figure 3. Global map showing locations where gas hydrate has been identified either through sample recovery or remote sensing. Figure courtesy of Alexei Milkov (BP America, Exploration and Production Technology Corp).

gas hydrate stability zone at greater depth. If the gas comes from subseafloor depths greater than about 2 km, it probably contains higher order hydrocarbon gases such as ethane and propane and has a distinctive carbon isotopic signature (thermogenic gas). Both sources of gas contribute to gas hydrate formation in marine sediments. Thermogenic gas is important in focused gas hydrate deposits, whereas biogenic gas dominates in the gas hydrates that are broadly distributed throughout large regions.

REMOTE SENSING FOR SUBMARINE GAS HYDRATES

Because methane hydrate is not stable at atmospheric pressure unless the temperature is below −60 °C, gas hydrate samples are rare. Most of the gas hydrate in a sediment sample is probably lost because the gas hydrate decomposes as the sample is recovered. Only large chunks of gas hydrate survive the trip from the seafloor to the earth's surface. Even these large chunks decompose rapidly after recovery, and the methane that is released by this decomposition can be burned, leading to the dramatic phenomenon of "burning ice" (Fig. 4). Special tools are required to sample and preserve natural gas hydrates for detailed studies.

Figure 4. Burning the methane that is released as a gas hydrate sample decomposes. Hands belong to Robert Collier (College of Oceanic and Atmospheric Science, Oregon State University). Picture taken by one of the authors (M. Torres).

Several geochemical and geophysical techniques are available for indirectly identifying the presence of gas hydrate *in situ*. One of the most widespread techniques is the use of seismic reflection data to detect the subseafloor boundary between sediments containing gas hydrate and sediments that contain free gas (Fig. 5). These data are analogous to an echo sounding of the earth beneath the seafloor. A sharp contrast in the elastic properties of sediments across this boundary results in a distinctive seismic reflection known as the bottom-simulating reflection (BSR). This reflection can be mapped over large areas of the ocean. Similarly, gas hydrates near the seafloor appear as strong reflections at the seafloor, although many other geologic features also produce seafloor "bright spots." Geophysical surveys are therefore a primary tool for determining whether gas hydrate is present in a "frontier" area. In many places, the presence of gas hydrate has been inferred from observations of a BSR in data that were originally

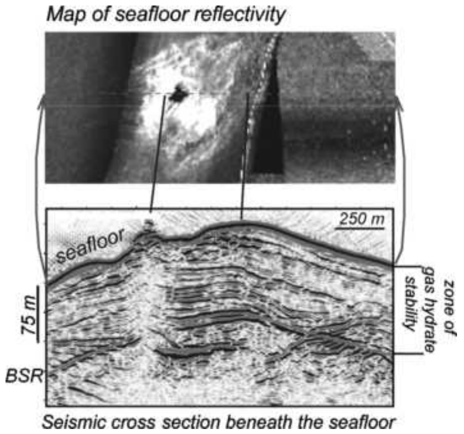

Figure 5. Data showing how the seafloor and subseafloor reflect high frequency sound waves. Such remote sensing strategies are used to survey the seafloor for the presence of gas hydrate. Bright (white) spots in the upper image indicate the presence at the seafloor of gas hydrate and associated carbonate. The presence of the reflection labeled BSR in the subsurface (lower image) indicates that gas hydrate is widespread deep in the sediments, even though massive gas hydrate at the seafloor is restricted to the summit of this structure. The seismic data can also be used to image the subsurface plumbing system that led to development of the hydrate deposit. Seafloor reflectivity data were acquired in 1999 by Chris Goldfinger (College of Oceanic and Atmospheric Science, Oregon State University). Seismic data were acquired by one of the authors (A. Trehu) in collaboration with Nathan Bangs (Institute for Geophysics, University of Texas).

acquired to address other problems in marine geology. These reflective patterns, however, are of limited use for determining how much gas hydrate is present and how it is distributed within the sediments. Researchers are developing new geophysical techniques to better quantify the distribution of gas hydrate from seismic and other remote-sensing techniques.

OBSERVATIONS OF GAS HYDRATE MOUNDS ON THE SEAFLOOR

Mounds of gas hydrates have been directly observed at the seafloor during submersible dives and by using deep-towed cameras and remotely operated vehicles (ROVs). Although many of these gas hydrate occurrences were originally identified on seafloor imaging data, some have been found by serendipity. For example, massive gas hydrate mounds offshore Vancouver Island, Canada, were first discovered when fishermen dragging for ground fish accidentally dredged some up in their nets (Fig. 6). Because gas hydrate is buoyant, their net rose rapidly to the sea surface when the gas hydrate broke free from the seafloor. Someone on board recognized that the bubbling, decomposing “ice” in the net was gas hydrate. Fortunately, no one was smoking!

Although these seafloor gas hydrate deposits may constitute only a small percentage of the total amount of gas hydrate present in marine sediments, they represent the most accessible and best studied deposits and are usually accompanied by complex and as yet poorly understood faunal assemblages. In all cases that have been studied in detail, these deposits contain a mixture of biogenic and thermogenic gas and result from geological structures that focus gas to the seafloor from a deep-seated source. They represent gas hydrate ‘sweet spots” that punctuate widespread diffuse deposits inferred from seismic data.

Vigorous expulsion of gas bubbles into the ocean is often observed above seafloor hydrate mounds, even when the mound lies within the thermodynamic gas hydrate stability field. The gas discharge, which is often episodic, provides evidence for the dynamic processes that lead to the formation of massive hydrate near the seafloor. It is likely that these deposits are ephemeral and that they are subject to destruction when fluid flow patterns change or when the seafloor is perturbed. It is possible that

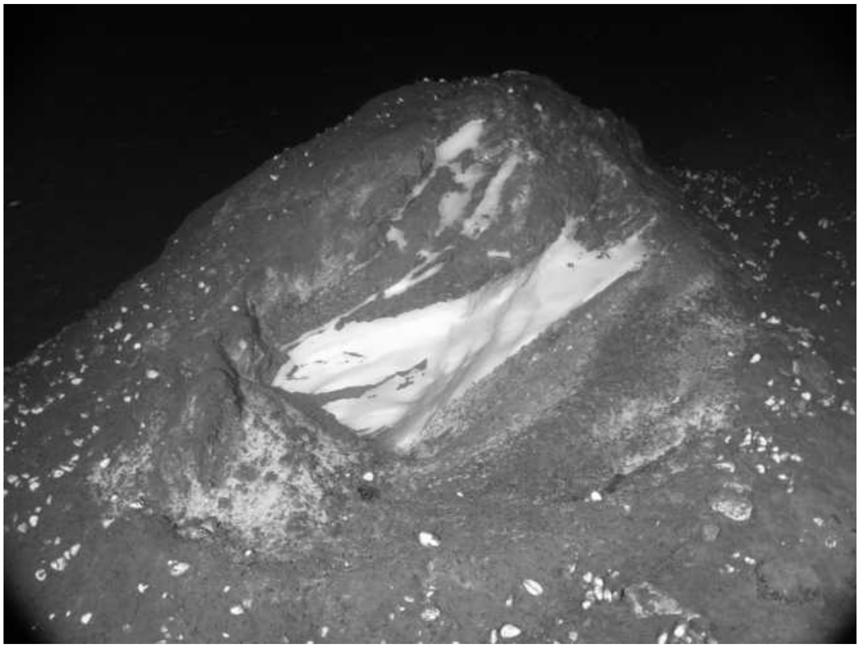

Figure 6. A thinly sedimented mound of gas hydrate exposed on the seafloor. White spots around the hydrate mound are clams, which are often associated with seafloor methane seeps. Photo was taken in August 2002 approximately 50 km offshore Vancouver Island during a survey by ROPOS (Remotely Operated Platform for Ocean Science), a Canadian research vehicle. Courtesy of Ross Chapman (University of Victoria).

large blocks of gas hydrate can spontaneously break away and rise to the sea surface, transporting methane from the seafloor to the atmosphere. Long-term observations of these deposits are needed to evaluate whether they represent a useable resource and whether they are an important factor in transferring methane from the ocean to the atmosphere.

SAMPLING GAS HYDRATES THROUGH DRILLING

More detailed information on the fine-scale distribution of gas hydrate in marine sediments can be obtained by drilling into the subsurface. Logging techniques permit measurement of geophysical and geochemical parameters throughout the entire borehole; coring allows for recovery of subsurface samples. Logging and coring to study gas hydrates is very expensive and has only been undertaken in a handful of places worldwide (Fig. 3). The Ocean Drilling Program (ODP), an international endeavor that enables the research community to sample up to a few kilometers beneath the Earth's surface to address problems of environmental change, earth history, and mantle dynamics, has dedicated several expeditions to study gas hydrates offshore Chile (Leg 141), the eastern United States (Leg 164), Japan (Leg 196), and the Pacific Northwest of the United States (Legs 146 and 204). The Japanese government has recently supported several expeditions to drill gas hydrates in the Nankai Trough offshore Japan. New programs are being planned to sample submarine gas hydrates in the Gulf of Mexico and elsewhere.

These drilling projects provide critical information needed to "ground truth" estimates of gas hydrate abundance and distribution inferred from remote sensing techniques. One conclusion from recent experiments is that the total amount of gas hydrate present in the globe, while still huge, may be less than previously thought. More importantly, these projects have revealed the "patchiness" of gas hydrate distribution beneath the seafloor and provide information on factors, such as sediment grain size, that may be controlling the heterogeneity in their distribution. They also provide unique information of the chemistry of the gases that form the gas hydrate and on the origin of these gases. This information is essential for understanding how gas hydrate deposits develop.

QUANTIFYING THE AMOUNT OF GAS HYDRATE IN BOREHOLES

To estimate the amount of gas hydrate *in situ*, several different types of measurements must be used because different techniques have different sensitivity and spatial resolution. The only way to directly measure the amount of gas in a core is to maintain the *in situ* pressure as it is recovered. This is technically difficult and can only be done for a limited number of samples in each drill hole. Another common technique is to measure the salinity or chloride concentration in the pore waters. Because salts are excluded when gas hydrate forms, the water that is released when it decomposes is fresh. Estimating the amount of hydrate present in the sediments using this technique requires knowledge of the salinity of the *in situ*pore water. This technique is limited by the need to extract pore water from the core, which is time consuming and disrupts the sample for other studies. Yet another technique is to measure the temperature of cores using a scanning infrared camera. Because gas hydrate decomposition is endothermic (takes up heat), locations in the core where gas hydrate is decomposing are up to several degrees colder than the rest of the core. This technique can efficiently and noninvasively sample the entire core but must be calibrated through comparison with other methods. Because core recovery is often incomplete, geophysical logging methods (which measure electrical resistivity, elastic wave velocity, density, and other physical parameters) are needed to sample the entire borehole. Models for interpreting these geophysical parameters obtained through logging must also be calibrated.

CONCLUSION

Gas hydrate is widespread in shallow sediments on the margins of the continents and represents an important, but often overlooked, component of the global carbon cycle. The distribution of gas hydrate is very heterogeneous. While gas hydrate probably represents only ~1–2% of the total volume of continental margin sediments that lie within the gas hydrate stability zone at the present time, concentrated deposits containing 10–30% gas hydrate have been found. These generally result from geologic conditions that lead to focusing of gas from a large volume in the subsurface into the gas hydrate stability zone.

The amount and distribution of gas hydrate in the seafloor, however, are probably not static. Instead, they change with time in response to changes in temperature, pressure, and fluid flow, which are, in turn, driven by tectonics (e.g., earthquakes and underwater mountain building) and global climate change. Rapid release of methane from gas hydrate in response to changes in ocean temperature and depth may affect global climate.

OCEANOGRAPHIC ENVIRONMENT OF GLACIER BAY

Alaska Biological Science
Center—U.S. Geological Survey

Oceanography describes one of the most fundamental physical aspects of a marine ecosystem. Glacier Bay exhibits a highly complex oceanographic regime within a small area. An understanding of many of the resource and research issues in Glacier Bay will not be possible without an understanding of the underlying oceanographic

---

processes causing the large spatial and annual variation found within the Bay.

The Bay is a recently (300 years ago) deglaciated fjord located within Glacier Bay National Park in Southeast Alaska. Glacier Bay is a fjord estuarine system that has multiple sills. These sills are often associated with contractions and are backed by very deep basins with tidewater glaciers and many streams. Glacier Bay experiences a large amount of runoff, high sedimentation, and large tidal variations. Melting occurs year-round, which is thought to fuel the estuarine circulation even through the winter. This runoff, and the presence of the tidewater glaciers makes the bay extremely cold. There are many small- and large-scale mixing and upwelling zones at sills, glacial faces, and streams. The complex topography and strong currents lead to highly variable salinity, temperature, sediment, productivity, light penetration, and current patterns within a small area. This complexity defies simple characterization or modeling based on other areas in Southeast Alaska. While several oceanographic studies have been conducted in Glacier Bay, these studies are contradictory and were of short duration and limited coverage, missing much of the spatial, seasonal and annual variation. In addition, some assumptions based on past studies have been contradicted by recent results. The constantly changing nature of the Bay may contribute to contradictions among past studies and between recent and historical results.

The primary data used in this study (see the Fjord Oceanographic Monitoring Handbook) were oceanographic surveys consisting of samples of 24 central-channel stations from the mouth of the bay to the heads of both the East and West Arm taken between 1992 and 2000. A oceanographic instrument (CTD) capable of recording depth, temperature, salinity, light penetration, amount of sediment, and amount of phytoplankton was used to obtain measurements at one-meter intervals throughout the water column to a depth of 300 m at each station. Surveys were conducted up to seven times a year in such a manner as to encompass the primary annual variation in oceanographic patterns.

Results from the current work indicate several shifts in the dominant paradigm of oceanographic understanding for this area. Primarily, deep-water renewal, and with it increased nutrient availability, is not limited to the winter months but can and probably does occur regularly in the spring/summer/fall at least during spring-tide series. We believe that Glacier Bay is not a traditional silled fjord estuary nor a plain fjord estuary like most estuaries in Southeast Alaska, but a combination of a stratified deep basin estuary and a tidally mixed estuary. This results in a complete blockage of estuarine circulation at the mouth of the bay; instead, mixing occurs by turbulent diffusion rather than buoyancy-driven entrainment as seen in a traditional estuary. In addition, where this turbulent water meets the deep stratified basin, a tidally-mixed front is created. This front is ideal for encouraging high primary productivity by phytoplankton. Mixing phenomena have now been observed to be much more extensive in Glacier Bay than previously thought. This, as with the increased deep-water renewal, almost certainly results in a more nutrient enhanced system. The Bay is now known to exhibit phenomenally high primary productivity, which is sustained throughout the summer in sharp contrast to other interior waters of Southeast Alaska and adjoining shelf and oceanic areas. The limits on this productivity appear to be caused not by grazing by zooplankton or nutrient limitation, but by light penetration. Light penetration in Glacier Bay is significantly reduced by both sedimentation phenomena related to the young nature of the terrestrial environment and to the high levels of the primary productivity itself. In addition to these major changes in understanding, we have identified several new phenomena that will need further study to understand their nature and significance.

As a result of the oceanographic monitoring program and the synthesis effort funded by the NPS there is now an extensive body of oceanographic and weather data integrated into the Glacier Bay information management system and available on CD-ROM. The Oceanographic Analyst Extension, a Geographic Information System (GIS) tool, has been created to allow viewing, analysis, and manipulation of these complex data in 3 and 4 dimensions.

NOS SANCTUARIES PROTECT NATION'S MARITIME HISTORY

NOAA National Ocean Service

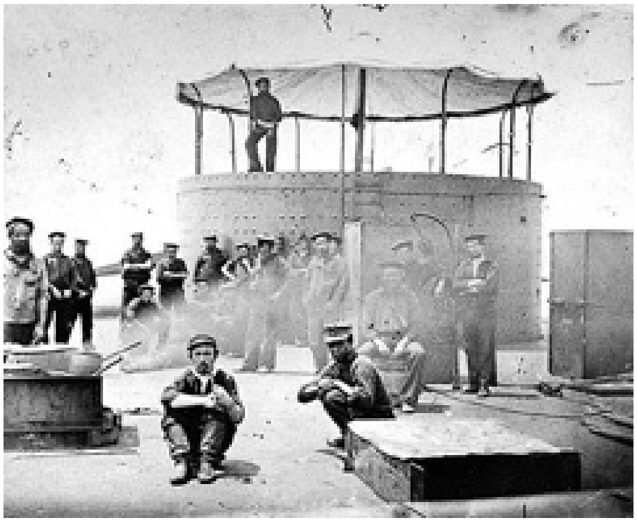
Marine archaeology allows us to unravel the mysteries and riddles of shipwrecks and clarify our history. Each fragile wreck is a time capsule of our past. The remains of sunken vessels and their contents provide a distinctive window into the history of the ships and the lives of its passengers and crew. Using state-of-the-art technology, such as sonar and remotely operated vehicles, marine archaeologists are now able to conduct advanced explorations and create accurate depictions of wreck sites.

The National Ocean Service's National Marine Sanctuary Program plays a pivotal role in the exploration and preservation of the nation's maritime history. By protecting oceanic treasures within a sanctuary, marine archaeologists are able to uncover and preserve invaluable information and artifacts. Shipwrecks discovered in the sanctuaries, such as the *USS Monitor, Portland*, and those in Thunder Bay, are essential to understanding the importance of maritime history.

USS MONITOR

Undiscovered for more than 100 years, the *USS Monitor* was found in 1973 off the coast of North Carolina by scientists from Duke University using sidescan sonar technology. In 1862, this famous Civil War ship's battle with the Confederate ironclad *Virginia* revolutionized the

---



The crew on the deck of the *USS Monitor*. Members of the crew were lost when the *Monitor* sank in 1862. Human remains recently were found when the newly recovered turret was excavated last summer. (Monitor Collection, NOAA)

war at sea, and marked the end of an era of wooden-hulled sailing warships. The *Monitor* was the first of a class of low-freeboard, turreted war ships developed during the Civil War. Its revolving turret revolutionized naval warfare, and other features of the *Monitor* foreshadowed the future of naval technology.

The *Monitor* is more than an era frozen in time. Its dedication in 1975 as the first national marine sanctuary opened the door to advances in maritime archaeology and historic preservation. Since its discovery, numerous research expeditions have been conducted to study and recover the wreck. One of the most recent was in the *summer of 2002*. With the help of a claw-like structure known as the spider, the turret of the *Monitor* was recovered. Human remains also were found during the excavation of the turret in 2002. More than 100 artifacts also have been retrieved from the wreck, including the ship's anchor, condiment bottles, dinnerware, and a portion of leather bookbinding. These artifacts are now part of The Monitor Collection, which is housed in The Mariners' Museum Research Library. More information about the *USS Monitor* is available *from the Monitor National Marine Sanctuary*.

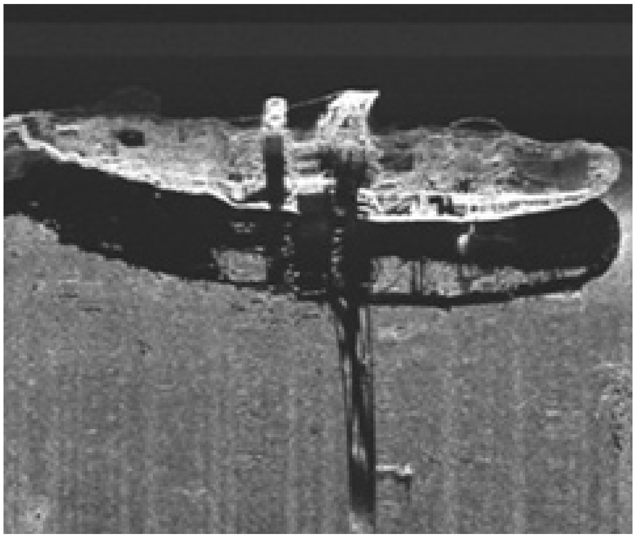
PORTLAND AT STELLWAGEN BANK

The coastal steam ship *Portland*, which rests on the sea floor of the *Stellwagen Bank National Marine Sanctuary*, sank Nov. 27, 1898, during the infamous "Portland Gale of 1898." All 192 passengers and crew were lost. With the help of state-of-the-art technology, the sanctuary obtained three new side-scan sonar images of the wreck. The images clearly show the side-by-side smoke stacks and the diamond-shaped metal walking beam that provided power to the side paddle wheels. The *Portland* has yet to be fully explored, but another mission is scheduled for September 2003. During this missions, scientists will use state-of-the-art technology including side-scan sonar and remote operating vehicles for exploration. View the *side-scan sonar images of the Portland* that were collected last year.

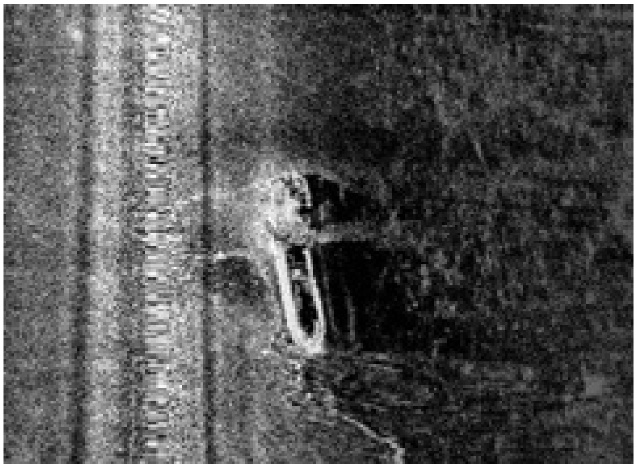
The *Monitor's* turret broke the surface during the summer 2002 expedition—the first time it had done so in 140 years

Stellwagen Bank, first discovered by Captain Henry Stellwagen in 1854, was especially important to navigators when they sailed at night or in poor weather. Mariners could gauge the distance to the sea floor and, when they saw the bank, would know that they were entering the Massachusetts Bay. The wealth of sea life present in the area also allowed for centuries of prosperous fishing fleets and other economic gains.

Stellwagen Bank was designated on Nov. 4, 1992, as the nation's 11th national marine sanctuary. Stretching 842 square miles, more than 1 million people each year visit the sanctuary. Many of them are intent on experiencing an encounter with the well-known Humpback whale.



A sonar image of the *Portland*, taken in 2002



On June 30, 1906, the *New Orleans* was carrying coal when she collided with the *William R. Linn*. Al of the crew boarded the *Linn* safely before the pilothouse of he *New Orleans* blew off and the vessel sank. This sonar image of the wreck was taken in summer 2001

THUNDER BAY

The *Thunder Bay National Marine Sanctuary and Underwater Preserve*, dedicated on Oct. 7, 2000, is the first freshwater and Great Lakes sanctuary. More than 100 19th and 20th century shipwrecks rest in Thunder Bay and the surrounding waters of Lake Huron. For this reason, it has earned the nickname "Shipwreck Alley." Located off the coast of Alpena, Mich., Thunder Bay's collection of shipwrecks represents the diversity of vessels that navigated the Great Lakes, from wooden schooners to steel-hulled steamers.

These preserved vessels still have stories to tell of Great Lakes maritime history and commerce. Some of the wrecks have been broken apart and washed away, and others have recently been found and are waiting to be explored. Many wrecks are yet to be discovered but likely will be found as explorations continue. For more information, read more about *surveying Thunder Bay's Shipwreck Alley* in June 2001.

QUANTIFICATION OF ANOXIA AND HYPOXIA IN WATER BODIES

Gertrud K. Nürnberg
Freshwater Research
Baysville, Ontario, Canada

Hypoxic conditions (dissolved oxygen, DO, concentration below saturation) are widely spread in freshwater and saline environments. Especially in recent years, anthropogenic impacts have led to severe increases in estuarine and coastal anoxia [e.g., Gulf of Mexico (1) and European coast-lines (2)]. Diaz (3) describes 44 marine areas of moderate to severe hypoxia worldwide. Hypoxia and anoxia (lack of oxygen or zero concentration of DO) may even be more established in the freshwater environment, where it can occur naturally in lakes (4) or not (5) and where recent increases in organic and nutrient loading and changes in water flow have increased oxygen depletion in lakes (6), reservoirs (7), and large rivers (8,9).

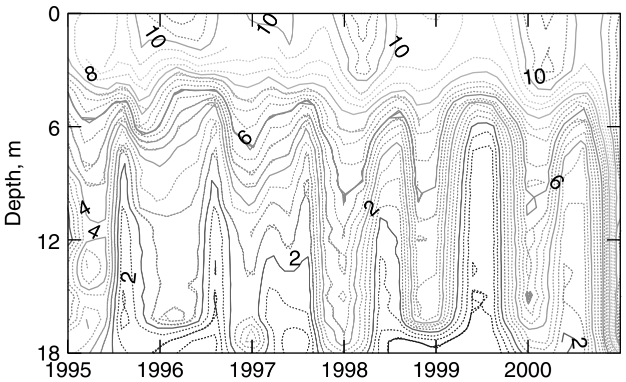


Figure 1. Dissolved oxygen isopleths for small urban Lake Wilcox, Ontario. The beginning of each year is indicated.

OCCURRENCE OF DO DEPLETION

An example isopleth (Fig. 1) for several years of DO data for an urban lake demonstrates DO variability with respect to space and time. The lake experiences severe anoxia in the hypolimnion because the bottom water is stagnant during the summer and fall. Entrainment of hypolimnetic anoxic water may lead to hypoxic conditions in the epilimnion in late summer. Such variation can be quantified by computing anoxic and hypoxic factors.

DEFINITION

The *anoxic* and *hypoxic factor* [AF (4), HF (10)] are calculating methods that quantify the extent and duration of anoxia and hypoxia based on oxygen profiles and morphometric (hypsographic) information. They are based on a series of measured oxygen profiles and morphometric data and can be computed for any water body (lake, reservoir, river, marine area). To render this index comparable across waters like other areal measures, for example, areal nutrient loads and fish yields, AF is corrected for (lake) surface area by simple division. Expressed this way, AF or HF is a ratio that represents the number of days in a year or season that a sediment area equal to the (lake) surface area is anoxic or hypoxic. Hence, its units are d/yr and d/season, summer or winter.

The exact steps in computing the specific factors are described in Fig. 2. The difference between the HF and the AF lies in the different threshold DO concentration used. The AF is based on the oxycline depth or its approximation; the HF is based on a certain threshold that indicates the hypoxic conditions of choice for that particular project, for example, 6.5 mg/L DO. To consider the mixed layer anoxia or hypoxia separately, epilimnetic factors (AF_{epi}, HF_{epi}) can be computed, as defined in Fig. 2.

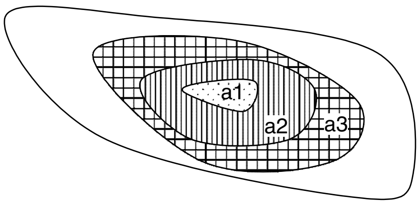

Figure 2. Computation and definition of anoxic and hypoxic factors. The sketch indicates different lake areas that become anoxic sequentially with time, where a_1 becomes anoxic first, then a_2, etc.

Determination of Anoxic or Hypoxic Factor

1. For the anoxic factor, the oxycline is determined at 1 or 2 mg/L dissolved oxygen (DO) concentration from (DO) profiles. The choice of the threshold values depends on the method of DO measurement. For example, 2 mg/L measured by a DO probe may actually coincide with anoxic conditions at the sediment surfaces located at that depth.
   For the hypoxic factor, the depth of the DO concentration threshold in question, for example, 6.5 mg/L, is determined.
2. The periods (total number n), for which the DO levels according to the chosen threshold are at approximately the same depth, are established.
3. The duration of each period of constant DO levels (t_i, in days) is multiplied by the corresponding area (a_i) and divided by the total surface area (A_{oi}) for the period (i). Especially in reservoirs where volumes and therefore areas change, is it important to use the surface area specific for the period. In water bodies without large volume changes, the average surface area A_o can be used instead.
4. These n terms, numbers of periods at different oxyclines, are then added up over the season or year, according to

$$\frac{t_1 \cdot a_1}{A_{o1}} + \frac{t_2 \cdot a_2}{A_{o2}} + \frac{t_3 \cdot a_3}{A_{o3}} + \cdots + \frac{t_n \cdot a_n}{A_{on}} = \sum_{i=1}^{n} \frac{t_i \cdot a_i}{A_{\text{o}i}}$$

   Therefore AF and HF are defined as follows, where a lower DO threshold is used for AF (1 or 2 mg/L) than for HF (e.g., 6.5 mg/L):

$$\text{AF or HF} = \sum_{i=1}^{n} \frac{t_i \cdot a_i}{A_{\text{o}i}}$$

End of Summer Stratification. In stratified lakes, much of the oxygen depletion occurs in the fall when DO profiles may not always be available. The duration of the last period of anoxia or hypoxia can be estimated from the average summer hypolimnetic temperature according to a model that predicts the fall turnover date (or end of summer stratification) from the following equation, based on 92 worldwide lakes, $R^2 = 0.47, p < .0001$ (11):

$$\text{Log(fall turnover date)} = 2.62 - 0.116 \log(T) + 0.042 \log(z) - 0.002 \text{ latitude}$$

where the fall turnover date is the Julian day of the year; T is the average July, August temperature at circa 1 m above the bottom at the deepest location of the lake (C°); and z is mean depth, lake volume/lake surface area (m).

Seasonal Factors. The AF and HF can be determined for the stratification periods separately as winter (e.g., AF_win in d/winter) or summer factor (e.g., AF_sum in d/summer). When there is no winter anoxia, AF_win is zero, and AF_sum is equal to AF in d/yr.

Epilimnetic Factors. In stratified water bodies, it can be interesting to separate hypolimnetic from epilimnetic hypoxia, so that guidelines can be established specifically for the mixed zone. Therefore, epilimnetic factors (AF_epi, HF_epi) can be defined. These factors are determined by subtracting, for each period i, terms corresponding to anoxia or hypoxia in the seasonal stratified area below the thermocline ($a_{\text{thermo } i}$) from those for the whole water column before summation, according to

$$\text{AF}_\text{epi} \text{ or } \text{HF}_\text{epi} = \sum_{i=1}^{n} \left(\frac{t_i \cdot a_i}{A_{\text{o } i}} - \frac{t_i \cdot a_{\text{thermo } i}}{A_{\text{o } i}} \right)$$

Application

Internal Load Calculation. The anoxic factor was originally developed to determine the internal phosphorus load in lakes as the product of anoxic areal release rates (experimentally determined or predicted from sediment phosphorus concentration) and AF according to Eq. 1 (12).

$$\text{Internal load} = \text{Release rate} \times \text{AF}_\text{sum} \qquad (1)$$

where (summer) internal load is in mg TP per lake surface area (m^2) per summer, and release rate represents a summer average in mg TP released per anoxic sediment area per day of the anoxic summer period. If there is phosphorus release under ice in the winter, a release rate representative for the winter and AF_win are substituted in Eq. 1 to estimate the winter internal load.

Lake to Lake Variation. Anoxia can vary extensively between lakes. Even in geographically near areas like the Muskoka—Haliburton region on the Precambrian shield in southern Central Ontario, the AF ranged from 0 to 70 d/yr in relatively pristine lakes that were often small, but deep, whereas at least 50% had an AF > 10 d/yr. Lakes in more fertile regions, such as in the St. Lawrence–Great Lakes region, had consistently high AFs between 40 and 70 d/yr. Such differences in lakes and their AF indicate the need for different management strategies (5).

Quantification of anoxia by the AF has been proven useful in explaining lake to lake variation in anoxia. In particular, dependency of anoxia on nutrient concentration and morphometry was found and multiple regressions of the AF on average lake TP and TN concentrations and a morphometric ratio were highly significant in North American lakes (4) (Table 1, Eqs. A to C). These relationships can be used to model (or predict) the AF

Table 1. Relationships and Models Involving the Anoxic Factor (AF) that Demonstrate Between Lake Variation of Anoxia in North American Stratified Lakes[a]

Equation	Predicted	Regression Equation[b]	N	R^2	Source
A	$\mathrm{AF_{sum}}$	$-35.4\ (5.1) + 44.2\ (4.3)\log(\mathrm{TP_{annual}}) + 0.950\ (0.187)\ z/A^{0.5}$	73	0.65	(4)
B	$\mathrm{AF_{sum}}$	$-36.2\ (5.2) + 50.1\ (4.4)\log(\mathrm{TP_{summer}}) + 0.762\ (0.196)\ z/A^{0.5}$	70	0.67	(13)
C	$\mathrm{AF_{sum}}$	$-173\ (25) + 72.5\ (9.7)\log(\mathrm{TN_{summer}}) + 0.789\ (0.219)\ z/A_o^{0.5}$	61	0.54	unpubl. data
D	$\mathrm{AF_{sum}}$	$-39.9\ (9.7) + 27.0\ (4.0)\log(\text{TP-Load})$	17	0.76	(4)
E	Fish species number	$0.97\ (2.42) - 1.53\ (0.49)\log(\mathrm{AF_{sum}}+1) + 5.38\ (1.02)\log(A_o)$	52	0.51	(14)
F	Fish species number	$4.92\ (1.38) - 6.12\ (1.44)\log(\mathrm{AF_{win}}+1)^b + 0.56\ (0.11)\ z$	32	0.71	(14)
G	Winterkill $\mathrm{AF_{win}}$	$-1 + 10^{(0.091z+0.804)}$	–	–	Based on Eq. F

[a] $\mathrm{AF_{sum}}$, summer AF (d/summer); $\mathrm{AF_{win}}$, winter AF (d/winter); Winterkill-$\mathrm{AF_{win}}$, value of $\mathrm{AF_{win}}$ above which a fish winterkill is likely for a given z; z, mean depth (m); A_o, lake surface area (km^2); $\mathrm{TP_{annual}}$, annual water-column average TP (µg/L); $\mathrm{TP_{summer}}$, epilimnetic summer TP (µg/L); fish species number, also called fish species richness is based on Central Ontario lakes.

[b] All regressions are highly significant at $p < .001$, except as noted by[b], $p < .01$. Standard errors of the regression coefficients are given in parenthesis.

in lakes where DO data are not available or difficult to obtain, as in polymictic lakes. The AF describes the sediment surface that is overlain by anoxic water in stratified lakes, so it can be hypothesized that its predicted value resembles anoxic sediment surfaces in polymictic lakes. Such a modeled variable is useful in determining internal load according to Eq. 1 for shallow lakes, where release rates may be available but not the extent of anoxic sediment areas.

Trophic State Classification. The concept of the anoxic factor was used to establish limits for trophic state classification with respect to anoxia (13). When classified with respect to the trophic state, below 20 d/yr, the AF indicates oligotrophic conditions, 20 to 40 d/yr are usually found in mesotrophic lakes, 40–60 d/yr represents eutrophic conditions, and above 60 d/yr is typical of hypereutrophic conditions (13). A more exact measure of the trophic state would include lake morphometry, measured as $z/A^{0.5}$, because the deeper the lake compared to its area (the larger $z/A^{0.5}$), the larger the AF. Based on the relationship of the AF with the summer average TP and the morphometric ratio of Eq. B in Table 1, a chart was drawn to assist in evaluating a specific lake's trophic state (Fig. 3).

Fish species richness correlated with the AF in Central Ontario lakes after variability due to lake area was taken into account, and winter kill could be predicted by using a seasonal AF that quantifies anoxia under ice, and mean depth (14) (Table 1). In particular, cold water species including *Salmonidaes*, *Coregonidae*, and *Gadidae* were sensitive to summer and winter anoxia, and they occurred only when $\mathrm{AF_{sum}}$ was below 32 d/summer or $\mathrm{AF_{win}}$ was below 4.4 d/winter (Fig. 4).

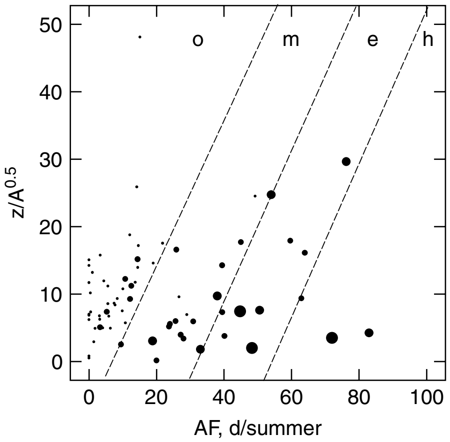

Figure 3. Chart to determine the lake trophic state from the anoxic factor (AF) and the morphometric variable $z/A_o^{0.5}$. Observed values from 70 North American lakes are presented. The symbol size indicates the four trophic states, oligotrophy, mesotrophy, eutrophy, and hypereutrophy (from small to large), and lines indicate the trophic state boundaries based on $\mathrm{TP_{summer}}$ in Equation B, Table 1).

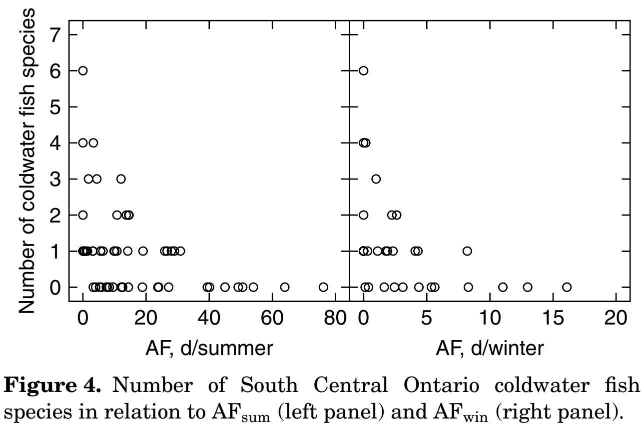

Figure 4. Number of South Central Ontario coldwater fish species in relation to $\mathrm{AF_{sum}}$ (left panel) and $\mathrm{AF_{win}}$ (right panel).

Spatial Within-Lake Variability. In large and morphometrically distinct water bodies, the factors can be estimated separately for different sections. For example, the AF was quite different between the two basins in small (77 ha) Cinder Lake, Ontario, at 12 and 40 d/summer (4). Similarly pronounced were differences for the 100-km long, narrow (maximum 1 km wide) reservoir, Brownlee Reservoir, on the Snake River in Idaho and Oregon (15). The total reservoir had an AF of 68 d/yr on average between 1962 and 2000, ranging from 53 to 90 d/yr. But the AF of the 48-km long, deep lacustrine section was higher, 88 d/yr on average, ranging from 72 to 114 d/yr, because this section is stratified all summer long. The AF for the 52-km long, shallow riverine section was only 10 d/yr in 1999 and 14 d/yr in 2000 because it is often mixed and reaerated from atmospheric oxygen. Epilimnetic factors were smaller than factors for the whole water column, as expected. Severe anoxia in this reservoir is apparent because the long-term average lacustrine AF_{epi} was 10 d/yr, indicating that overall, an area in the lacustrine epilimnion equal to the lacustrine surface area is overlain by water below 2 mg/L DO for 10 days per summer. The average HF_{epi} of 58 d/yr indicates that the Oregon state criterion of 6.5 mg/L DO for the water column was exceeded in the lacustrine epilimnion for an equivalent of circa 2 months, on average.

Annual Variability. Year-to-year variability can be quite large and ranged from 72 to 114 d/yr AF and 102 to 215 d/yr HF in lacustrine Brownlee Reservoir between 1962 and 2000, from 45 to 68 d/yr AF in a small urban lake, Lake Wilcox, between 1987 and 2000, and from 0 to 10, 9 to 30, and 10 to 50 d/yr AF in three small glacial lakes on the Precambrian shield [Nürnberg, unpublished data and (4,5,10)].

Although the average AF can be predicted from TP and morphometry according to the equations in Table 1, TP concentration cannot always explain the variability in the AF between years, as the variation between annual average TP is often small. Instead, physical characteristics, especially hydrology in flow-managed reservoirs have been found to control the residual variance of DO depletion between years.

For example, several annual and seasonal hydrologic variables were significantly ($p < .01$) correlated with AF, HF, AF_{epi}, and HF_{epi} in the Snake River Brownlee Reservoir. In particular, spring (April–May), summer inflow (July–Sept) (Fig. 5), and late fall (Oct–Dec) flushing rate or its inverse, the residence time, were strongly correlated with the factors, so that they were smallest during periods of high inflow or flushing (10). Such a good inverse relationship of the fall outflow with anoxia and hypoxia can be expected because severe DO depletion happens mostly in the summer and fall; high flow rates out of the dam at that time would destabilize stratification in the lacustrine section, leading to decreased hypoxia. On the other hand, a strong inverse correlation for spring inflow with hypoxia can be explained by a delay in the onset of stratification.

Climatic Effects. The factors quantify annual trends, so climatic effects on DO depletion can be investigated. For example, the Pacific Northwest Index (PNI) was significantly correlated with HF and HF_{epi} [Fig. 6 (10)]. The PNI is a normalized index based on three terrestrial climate variables for the western North American continent: the air temperature at San Juan Islands, the total precipitation at Cedar Lake in the Cascade Mountains, and the snowpack depth on Mount Rainier (16).

Establishment of Criteria and Guidelines. The factors are particularly useful in setting DO criteria and guidelines because the quantification of hypoxia is flexibly based on individual threshold values and can be adapted to various DO levels. Typically, a threshold DO concentration is set by governmental agencies under which a water body is considered “impaired” and a plan to attain the guidelines, including the process of determining a TMDL (total maximum total load) (17), is initiated. These thresholds or acceptable levels vary for different water bodies, agencies, and intended usage but can all be accommodated by various definitions of the hypoxic factor.

Additional Applications. Furthermore, AF helped to compare methods to measure denitrification rates in lakes and determine the most appropriate one (18) and reveal the dependency of hypolimnetic anoxia in tropical African reservoirs on stage height and volume (19). The anoxic

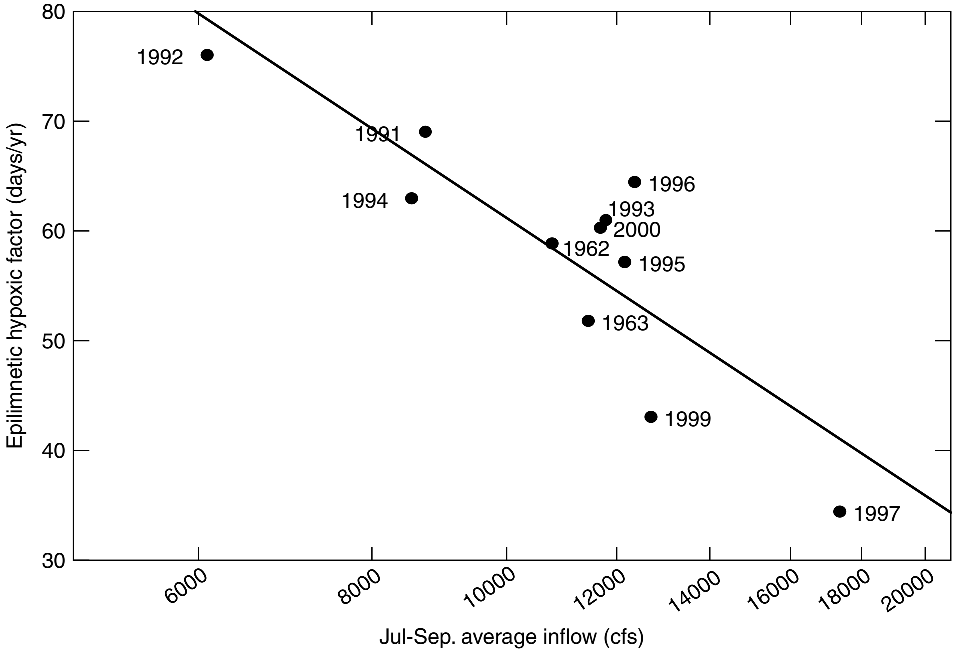

Figure 5. Lacustrine HF_{epi} of the Snake River Brownlee Reservoir, versus average summer inflow (July–Sept, computed from daily average flow values in cubic feet per second) between 1962 and 2000. The regression line is shown for $n = 11$, $p < .001, R^2 = 0.72$.

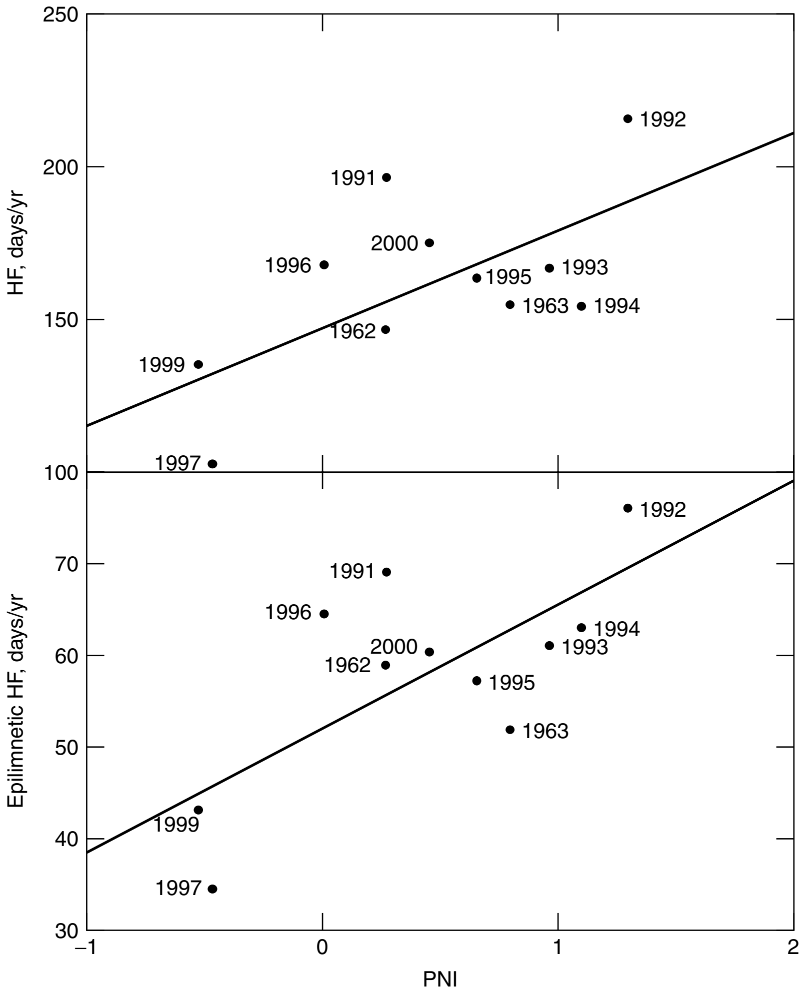

Figure 6. Lacustrine HF (top) and HF_{epi} (bottom) of Brownlee Reservoir versus the Pacific Northwest Climate Index (PNI). Regression lines are shown for $n = 11$, HF: $p < .05$, $R^2 = 0.41$; HF_{epi}: $p < .02, R^2 = 0.49$.

factor and its relationship with TP and morphometry were combined with information on fossil midge (*Chironomidae*) assemblages in paleolimnological studies to establish training sets and hindcast hypolimnetic anoxia for the past (20–22).

CONCLUSIONS

In general it can be concluded that the quantification of anoxia and hypoxia leads to increased knowledge of factors that control oxygen depletion in any freshwater and should be useful in estuarine and marine systems as well.

FLOATING ICE

Aldo Conti
Frascati (RM)
Frascati, Italy

Floating ice, or sea ice, is very important because it regulates the surface exchange of heat, moisture, and salt between the atmosphere and the oceans. It is a high latitude phenomenon and can be found only in the Arctic ocean and in the oceans around Antarctica. Although the local amount of sea ice changes with the season, at any given time sea ice covers, globally, an area larger than the North American continent.

In the Arctic ocean, sea ice covers an average 14 to 16 million square kilometers in late winter and 7 to 9 million square kilometers at the end of summer. Here, the ice cover circulation is characterized by two large-scale motions. A strong transpolar drift current transports sea ice from the Bering Strait over the North Pole down to the east coast of Greenland. Then, much of the Arctic winter is characterized by a persistent high-pressure center over the western Arctic region, which stimulates a clockwise rotation of surface winds and waters, which accumulate a large amount of drifting sea ice that floats around the Beaufort Gyre.

In Antarctica, sea ice covers from 17 to 20 million square kilometers in late winter, but then the seasonal decrease is much larger, with only about 3 to 4 million square kilometers left at the end of summer. Here, sea ice is continually stirred by winds and ocean currents. Ice moves at an average speed of 10 to 20 kilometers per day, and it is divergent northward with divergences of up to 10% per day.

Floating ice can be divided into two categories, namely ice shelf and proper sea ice, which have a completely different origin. Ice shelves are floating masses of ice that originate from the land and are normally attached to the glacier that produced them, which is, in fact, terrestrial ice that has recently seeped onto the surface of the ocean. Icebergs are fragments of these ice shelves. The largest is the Ross Ice Shelf, in Antarctica, that covers an area of about 540,000 square kilometers, about the size of Texas. It contains a third of all the floating ice in the Antarctic oceans and is 90 meters thick at its hinge point and 200 meters at the front.

Sea ice is formed from ocean water that freezes. As the oceans are salty, freezing occurs at −1.8 °C. Sea ice itself is largely fresh, because the ocean salt, by a process called brine rejection, is expelled from the forming and consolidating ice. The resulting highly saline (and hence dense) water has an important influence on the ocean, overturning circulation. Fresh sea ice is formed by the cooling of the ocean as heat is lost into the atmosphere. The uppermost layer of the ocean is supercooled to slightly below the freezing point, at which time tiny ice platelets, known as frazil ice, form. Water movements push the frazil crystals against each other, causing the fragile arms of the crystals to break. Soon, a mixture of damaged crystals and crystal remnants occurs that results in an oily-looking ice soup on the surface of water, called grease ice. The name comes from its dark, oily appearance. In time, grease ice become frozen into a thin, transparent layer of ice. Still dark, like the grease ice, the first transparent stage is called dark nilas. It then grows thicker, thick enough to reflect light, and goes from dark to light. This solid white layer is referred to as light nilas. Water starts freezing at the bottom of the ice, increasing its thickness. When nilas becomes 30 cm thick, it is called first-year ice. In a single winter, first-year ice can grow up to 2.5 meters in thickness.

Sea ice influences the climate system in a number of ways, by altering the heat and chemical exchanges between the atmosphere and oceans. It has a high albedo; that is, sea ice is a strong reflector of solar radiation, and therefore energy. The growth and decay of sea ice are positive feedback processes: freezing and melting processes are self-promoting. When ice melts, for example, more solar energy is absorbed into the ocean surface waters, thereby promoting further melting. Alternately, more energy is reflected as ice growth occurs, restricting the solar radiation that warms the surface of the ocean. Less sea ice during one season may allow surface waters to store enough energy to inhibit sea ice formation in the following season. Sea ice also acts as an insulator, inhibiting exchanges of mass, heat, and momentum across the air-sea interface. The perpetual drift of sea ice extends these influences to regional and global scales. It influences the chemistry and circulation of the world's oceans by redistributing salt and freshwater and stimulating dense water formation, which facilitates overturn of the global ocean.

The seasonal sea ice cycle affects both human activities and biological habitats. For example, shipping vessels have to work quickly during periods of low ice concentration. Sea ice is the natural habitat of many mammals, like polar bears and seals, that hunt, feed, and breed on the ice. Scientists are worried that global warming might reduce ice formation, affecting the very limited food chain these animals depend on.

TECHNOLOGY DEVELOPMENT: HARDWARE DEVELOPMENT—MARINE INSTRUMENTATION LABORATORY (MIL)

Great Lakes Environmental
Research Laboratory (NOAA)

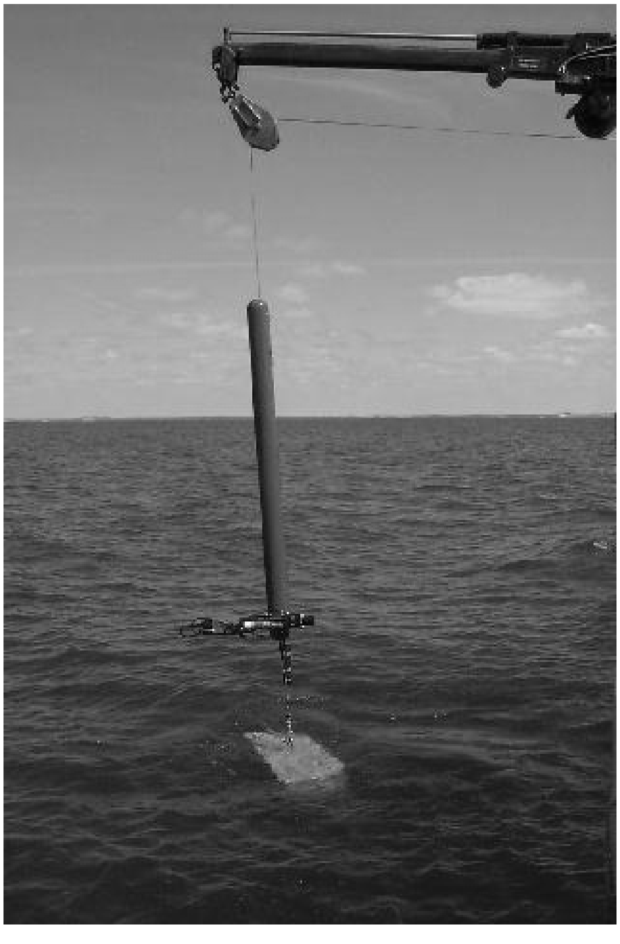
MIL's goal is to provide high quality instrumentation packages for oceanographic, biological, chemical, and water resources data collection. The highly skilled engineers and technicians of the Marine Instrumentation Laboratory (MIL) design electronics, develop schematics, manufacture circuit boards and develop computer software to support major systems design. MIL supports and maintains existing GLERL instrumentation, provides the hardware and software necessary for data acquisition systems, and provide various facility and ancillary support services.

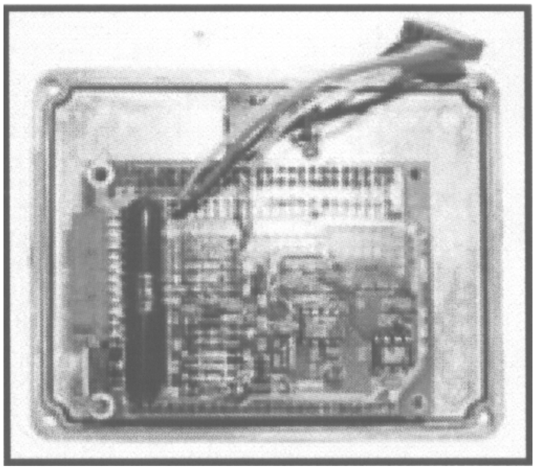
OCEANOGRAPHY

The purpose of this equipment is the measurement of water currents, temperature, water quality parameters, wave conditions and the sampling of water and sediments for subsequent analysis.

Focus on Current Measurements

MIL maintains a strong commitment to maintaining the current state of the art in this area. We currently maintain an inventory consisting of 8 RD ADCP's and several Sontek point current meters. We are currently also investigating the 3DACM current meter produced by Falmouth Scientific. MIL has also developed in house two series of satellite reporting Lagrangian drifters using Loran and GPS position sensing systems. Additionally MIL maintains a large active inventory of Vector Averaging Current Meters (VACM), Marsh-McBirney EM current meters and Neal Brown smart acoustic current meters (SACM). These aging systems are in the sunset phase of their utilization.





Autonomous CTD Profiler

The ACP was programmed to mechanically drive a CTD package up and down a cable through 40 meters of the water column at the rate of once per hour, taking measurements at sub-meter intervals. The ACP uses an electric motor to drive the CTD package up and down a wire rope cable. Rubber end stops attached to the cable determine the limits of travel and can be adjusted to meet the specific requirements of the experiment. The operation of the ACP is controlled by an embedded microprocessor and data is stored onto a compact flash disk. The flexibility of the programmable data logger allows specifying the interval of the cycles as well as the sample rate. The unit can sample and record data from the sensors in intervals as small as 10 cm.

Microcontrollers and Dataloggers

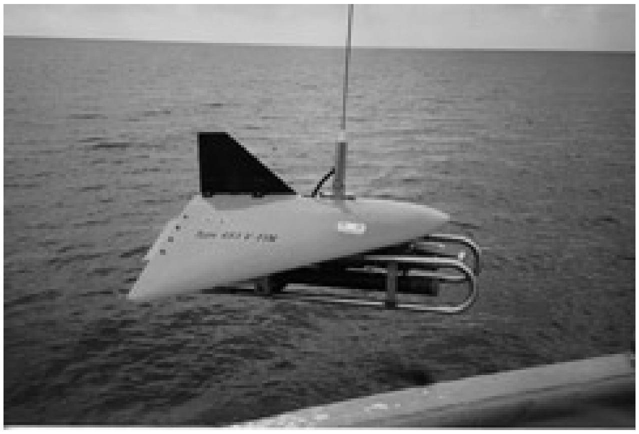
Recent advances in electronics have produced very small and economical computer driven controllers. These powerful tools have made it possible for instrument developers to design powerful measurement platforms with a minimum investment of time and capital. The controller recently developed for the MIL programmable sequential sediment sampler is shown.

Lagrangian Drifters

An important area of work for MIL has been the design and development of drifting current measurement systems. An example of an MIL designed drifter which used the GPS system to report locations to the ARGOS series satellites is shown. This unit is controlled with a Tattletale 2B datalogger. Currently we have 11 of these units in inventory. These units were produced significantly in advance of the availability of similar commercial units.

Sequential Sediment Samplers

MIL has designed in house a programmable 24 bottle suspended sediment sampler. This instrument is currently in it's third version. Early examples utilized an entirely in house designed controller. The current version uses a Tattletale TFX-11 datalogger. Currently there 22 units in active use with 14 committed to the EEGLE project in



FY99. Several of these instruments have been distributed both nationally and internationally.

Plankton Survey System (PSS)

The Plankton Survey System (PSS) was assembled by GLERL's Marine Instrumentation Lab (MIL) in 1997 to measure distribution and abundance of zooplankton, tiny waterborne crustaceans that serve as a food base for various species of larval fish. It measures turbidity, chlorophyll a, photosynthetically active radiation (PAR), conductivity, temperature, and zooplankton distribution. The PSS and its onboard instruments has been successfully used on an ongoing basis to survey physical, chemical and biological conditions before, during and after Lake Michigan sediment resuspension events as part of the 5-year Episodic Events Great Lakes Experiment (EEGLE) program.

METEOROLOGY

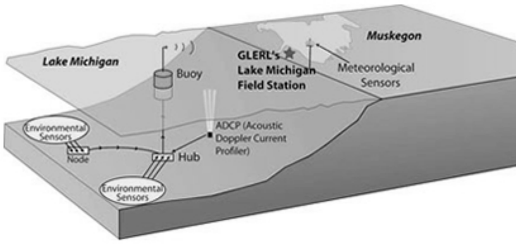
WebCams and Met Stations

GLERL's Marine Instrumentation Laboratory has deployed and is maintaining a real-time network of shore-based meteorological instrument packages in Wisconsin, Michigan, Illinois, and Indiana. Stations in Illinois and Michigan also include web cameras. All meteorological observation stations measure and record wind speed, wind gust, wind direction, and air temperature. In addition, instruments in Chicago measure water levels, and instruments at Muskegon measure dew point, relative humidity, atmospheric pressure, and light level. This data as well as camera images are updated at 5-30 minute intervals and displayed on GLERL's website.

Web Cams:	Met Stations:
Muskegon, MI Alpena, MI Chicago, IL	Alpena, MI Muskegon, MI Saugatuck, MI Michigan City, IN Chicago, IL Kenosha,WI Milwaukee, WI

Lake Michigan Wireless Environmental Observatory

MIL is developing the first environmental observatory using wireless internet technology on the Great Lakes at GLERL's Lake Michigan Field Station in Muskegon, MI. When fully developed, the observatory will provide chemical, physical and biological data to support long-term research on the Great Lakes. These data will be available to the scientific and educational community via



the internet through real-time observations. The goal of this project is to put in place the infrastructure needed to simplify sensor deployment and data acquisition to allow information access by scientific researchers, educators and the public. This is an important contribution to GLERL's leadership in supporting and promoting observation system development among Great Lakes universities and non-governmental organizations.

The environmental observatory consists of an offshore buoy connected to a hub that receives data from various environmental sensors such as an acoustic doppler current profiler. The data are then sent through a wireless link to an onshore receiver connected to the internet.

SEASONAL COUPLING BETWEEN INTERTIDAL MACROFAUNA AND SEDIMENT COLUMN POREWATER NUTRIENT CONCENTRATIONS

Paolo Magni
IMC-International Marine
Centre, Torregrande-Oristano,
Italy

Shigeru Montani
Hokkaido University
Hakodate, Japan

BACKGROUND

It is well established that dense bivalve assemblages play a major role in the processes of benthic nutrient regeneration in coastal marine ecosystems (1–7). In recent years, there is increasing evidence of the close relationship between nutrient concentrations in sediments and macrofauna-influenced upward flux of nutrients that enhances benthic primary productivity. This coupling has been shown, to varying degree, for a variety of benthic communities dominated by both suspension and deposit feeders. The former, including semi-infaunal mussel species, such as *Musculista senhousia* and *Modiolus americanus* (8,9), filter particulate matter from the water column; the latter, such as holothurians (10), consume high amounts of sediment bacteria, microalgae, and dead organic matter (11). Due to the complexity and multiplicity of mechanisms that govern nutrient cycling in coastal ecosystems, these studies highlight the need for integrated investigations on the variability of porewater nutrient concentrations and the composition, biology, and behavior of *in situ* macrofaunal species (12). There is still a noticeable lack of knowledge about the relationship between macrofauna and the temporal distribution and spatial variability of nutrients in sediments. Some works have conducted a seasonal study of porewater chemistry focusing on nitrogen organic compounds, such as dissolved free amino acids (13), and ammonium profiles and production (13–15). These studies have indicated that temperature has a pronounced effect on the porewater ammonium production rate and seasonal variation. In addition to the effect of environmental parameters that exhibit seasonal patterns and mineralization processes in sediments by bacteria, macrofauna also contribute to the total benthic metabolism by feeding, assimilation, and respiration. Recently, we have shown that the excretory activity of macrofauna strongly influences the magnitude and seasonal variability of the biogenic upward flux of nutrients (16; Temporal Scaling of Benthic Nutrient Regeneration in Bivalve-Dominated Tidal Flat). However, field studies on the relationship between porewater nutrient concentrations and macrofaunal communities come often from isolated surveys (17) or from transplantation/manipulation experiments (8,9). In particular, evidence of a coupling between the seasonal variability of nutrient concentrations in porewater and macrofauna-influenced upward flux of nutrients is still lacking.

SEASONALITY OF POREWATER NUTRIENT CONCENTRATIONS

We present here relevant results obtained from a multidisciplinary study carried out on a sandflat in the Seto Inland Sea (18–20). Extended information on the environmental characteristics and variability of this flat are reported in our associated papers (21–23). Emerged sediment temperature ranges widely through the year, from 2.8 °C (December) to 30.0 °C (July) in 1995 (Fig. 1).

At an individual sampling station, we investigated the macrofaunal communities (Temporal Scaling of Benthic Nutrient Regeneration in Bivalve-Dominated Tidal Flat) in parallel with the distribution of ammonium, phosphate, and silicate in porewater, monthly from January 1995 to April 1996. All these nutrient species showed marked spatial and temporal patterns and had a 10 to >30-fold variability between layers and months (Fig. 2). Ammonium varied from 75.1 (0–0.5 cm, January 1995) to

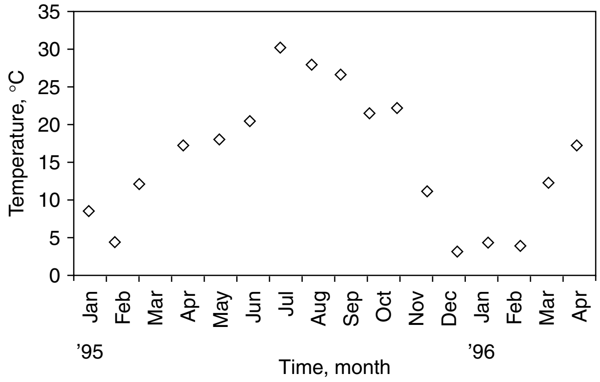


Figure 1. Seasonal variation of sediment temperature.

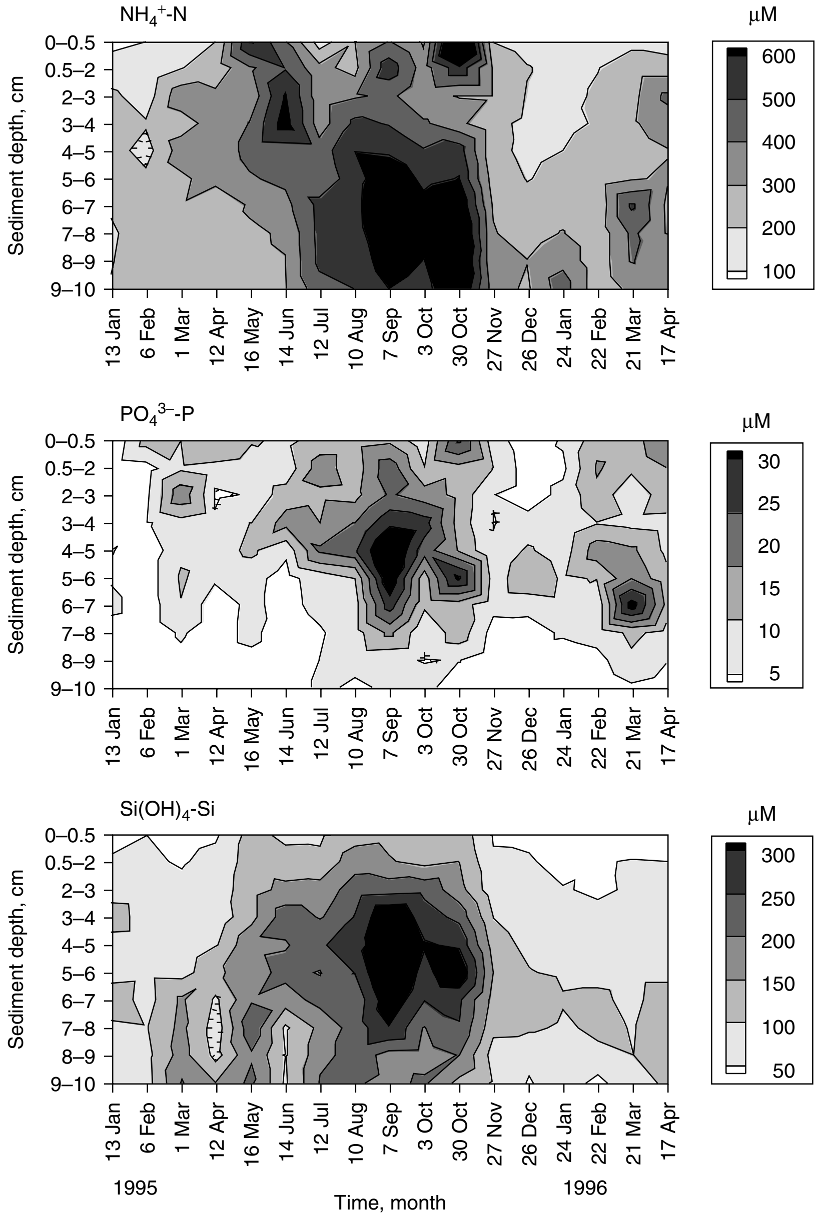

Figure 2. Spatial and seasonal variation of porewater ammonium (NH_4^+-N) (**a**), phosphate (PO_4^{3-}-P) (**b**), and silicate [$Si(OH)_4$-Si] (**c**) concentrations.

908 μM (0–0.5 cm, 30 October 1995), phosphate from 0.9 (0–0.5 cm, January 1995) to 36.9 μM (4–5 cm, September 1995), and silicate from 17.1 (0–0.5 cm, February 1996) to 379 μM (5–6 cm, 30 September 1995).

The spatial and temporal distribution of ammonium, phosphate, and silicate concentrations were consistent with each other. They were lowest in winter, progressively increased through spring and summer in the uppermost layers, and were highest between September and October 1995; a major increase occurred in intermediate layers (i.e., between 3 and 8 cm). Subsequently, minor but noticeable peaks of ammonium and phosphate concentrations were also found in March 1996, up to 518 and 32.7 μM at 6–7 cm, respectively.

For each sampling occasion and nutrient species, we summed the concentrations measured in each layer of the sediment column to be representative of an all-layer monthly pool expressed on a square meter basis. This was obtained by calculating the sediment porosity of each layer from the water content (weight loss on drying at 105°C for 20 h), assuming the bulk density of sediment particles as 2.5 g cm^{-3}. Each volume of porewater was subsequently multiplied by the relevant nutrient concentrations, which were finally expressed as areal depth-integrated values (mmol m^{-2}). Ammonium, phosphate, and silicate concentrations showed a strong correlation with each other (Fig. 3). These results suggest that similar and/or coincident processes may govern the spatial and seasonal variability of major inorganic forms of N, P, and Si in sediment porewater.

We were thus interested in assessing the existence of common environmental factors (i.e., temperature) and/or biological (i.e., macrofauna-influenced) processes that influence the variability of ammonium, phosphate, and silicate in porewater. Ammonium and silicate were highly correlated with temperature (Fig. 4). This could

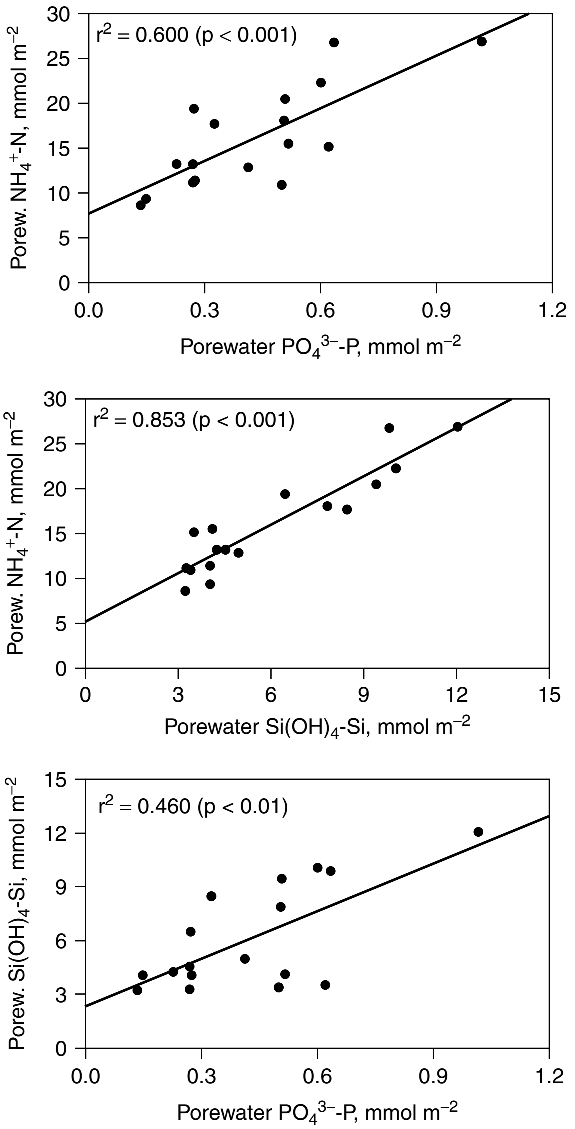

Figure 3. Relationship between porewater ammonium ($NH_4{}^+$-N), phosphate ($PO_4{}^{3-}$-P), and silicate [$Si(OH)_4$-Si] concentrations in the uppermost 10 cm of sediments.

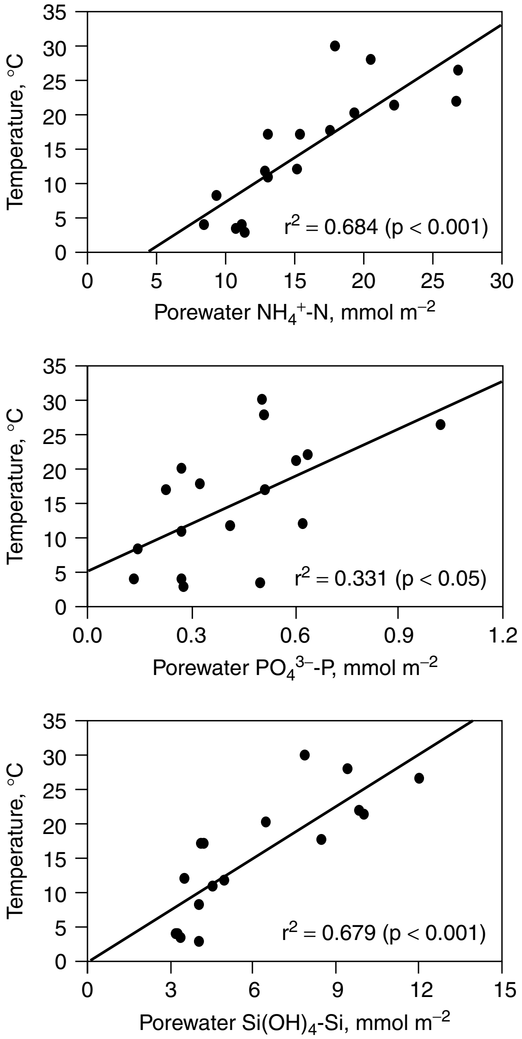

Figure 4. Relationship between porewater ammonium ($NH_4{}^+$-N), phosphate ($PO_4{}^{3-}$-P), and silicate [$Si(OH)_4$-Si] concentrations in the uppermost 10 cm sediments and temperature.

be consistent with previous studies that have focused on the distribution of ammonium and found that it was strongly dependent on seasonal variations in temperature (13,24,25), whereas little combined information is available on the distribution of ammonium, phosphate, and silicate in the sediment column and relevant influencing factors. In our study, for instance, the correlation between temperature and phosphate was significant, yet rather weak. We then tested the hypothesis that the seasonal variation of all three nutrient species could be related to the activity of *in situ* benthic macrofauna.

COUPLING WITH THE EXCRETORY ACTIVITY OF DOMINANT BIVALVES

We based our considerations on previous physiological measurements (Laboratory Experiments On Bivalve Excretion Rates of Nutrients) and scaling up (Temporal Scaling of Benthic Nutrient Regeneration in Bivalve-Dominated Tidal Flat) of nutrient excretion rates by two bivalve species dominant on this flat, *Ruditapes philippinarum* and *Musculista senhousia*. The plots of bivalve excretion rates of ammonium, phosphate, and silicate versus their relevant pool in the porewater showed a highly significant positive correlation in all cases (Fig. 5). These results suggest the importance of the physiological activity of the benthos on the seasonal variability of porewater chemistry. We conclude that the seasonal patterns of nutrient concentrations in the porewater are strongly coupled with the extent of biogenic regeneration of nutrients due to bivalve excretory activity. This study thus provides evidence of the influence of biological processes on the seasonal patterns of porewater nutrient distribution, suggesting a major role of macrofauna not only at the sediment–water interface, but also in the year-round processes that occur within sediments.

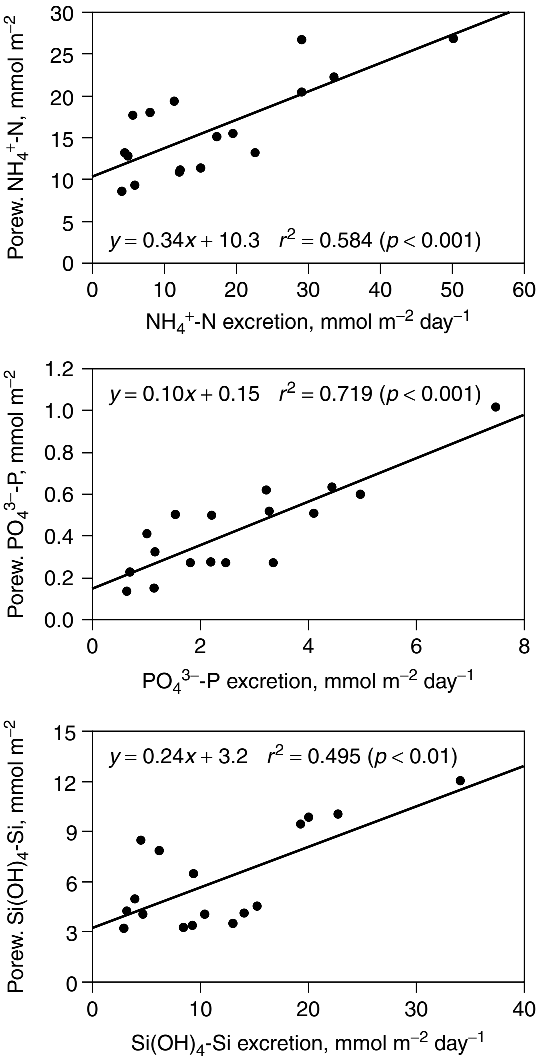

Figure 5. Relationship between porewater ammonium (NH_4^+-N), phosphate (PO_4^{3-}-P), and silicate [$Si(OH)_4$-Si] concentrations in the uppermost 10 cm of sediments and bivalve-influenced upward flux of those nutrients.

MAPPING THE SEA FLOOR OF THE HISTORIC AREA REMEDIATION SITE (HARS) OFFSHORE OF NEW YORK CITY

Bradford Butman
U.S. Geological Survey

Repeated surveys using a multibeam mapping system document changes in the topography and distribution of sediments on the sea floor caused by placement of dredged material, remedial capping, and natural processes.

INTRODUCTION

The area offshore of New York City has been used for the disposal of dredged material for over a century. The area has also been used for the disposal of other materials such as acid waste, industrial waste, municipal sewage sludge, cellar dirt, and wood. Between 1976 and 1995, the New York Bight Dredged Material Disposal Site, also known as the Mud Dump Site (MDS), received on average about 6 million cubic yards of dredged material annually. In September 1997 the MDS was closed as a disposal site, and it and the surrounding area were designated as the Historic Area Remediation Site (HARS) (Figs. 1 and 2). The sea floor of the HARS, approximately 9 square nautical miles in area, currently is being remediated by placing a minimum 1-m-thick cap of clean dredged material on top of the surficial sediments that are contaminated from previous disposal of dredged and other materials. The U.S. Geological Survey (USGS) is working cooperatively with the U.S. Army Corps of Engineers (USACE) to map the sea floor geology of the HARS and changes in the characteristics of the surficial sediments over time.

HIGH-RESOLUTION SURVEYS OF THE SEA FLOOR OF THE HARS

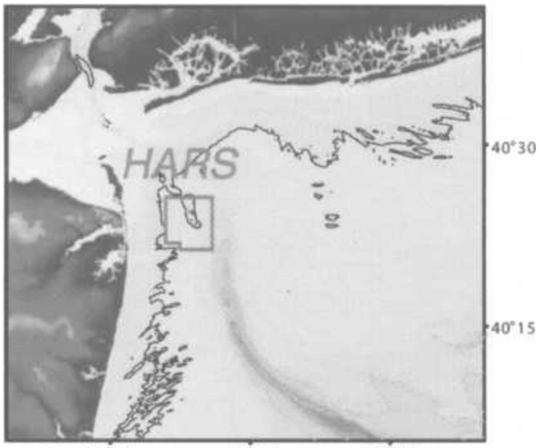

Figure 1. Map showing the area offshore of New York and New Jersey that has been used for the disposal of dredged materials and other wastes since the late 1800's. The Historic Area Remediation Site (HARS) is outlined in red.

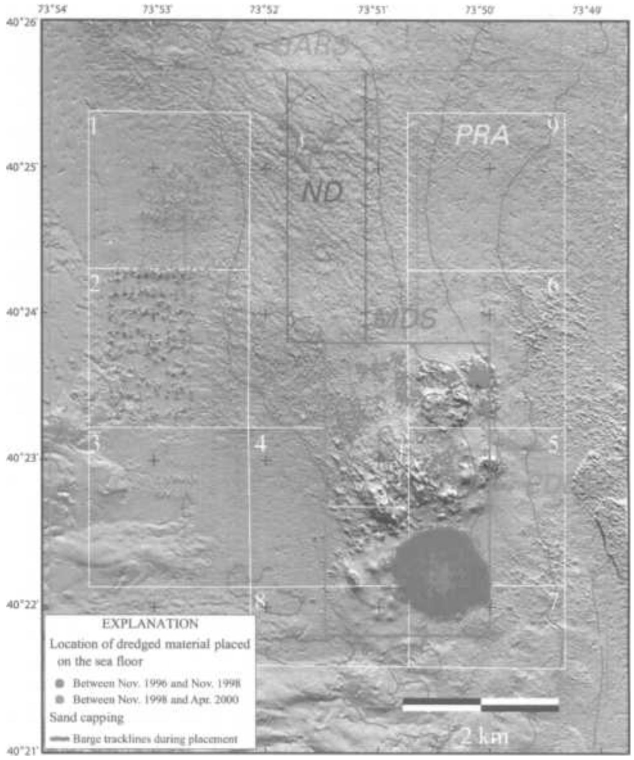

Figure 2. Shaded relief image of the Historic Area Remediation Site (HARS) in April 2000 showing the Primary Remediation Area (PRA, divided into nine cells), the no discharge zone (ND), the former Mud Dump Site (MDS), and the discontinued Cellar Dirt Disposal Site (CDDS). Companion images are shown in Figures 4 and 5. See text for a description of this image and major features. Bathymetric contour interval is 5 m (red lines).

Surveys of the HARS were conducted in November 1996 (prior to the closing of the Mud Dump Site), November 1998 (during early remediation of the HARS), and April 2000 (during continued remediation of the HARS) using a Simrad EM1000 multibeam mapping system (Fig. 3). Survey lines were run approximately 100 m apart to provide full coverage of the sea floor. The EM1000 measured the depth of water (to an accuracy of

---

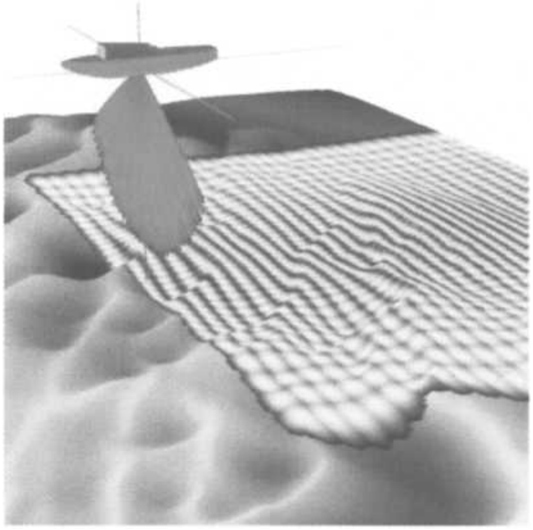

Figure 3. High-resolution multibeam mapping systems use sound from an array of transducers to measure water depth and sediment characteristics of the sea floor. The horizontal resolution of the maps is a few meters, providing an image of the sea floor topography and sediment properties somewhat comparable to an aerial photograph.

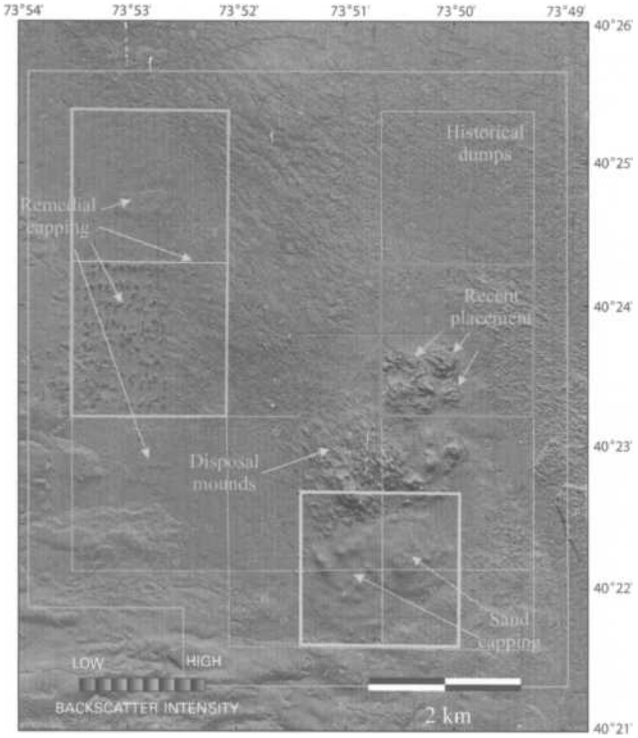

Figure 4. Pseudo-colored backscatter intensity and shaded relief map of the entire HARS in April 2000. The faint north-trending stripes run parallel to the survey tracklines and are artifacts of data collection and environmental conditions. The pink, green, and yellow boxes outline areas shown in Figure 6 to illustrate changes in backscatter intensity between 1996, 1998, and 2000. See text for a description of this image and major features. Bathymetric contour interval is 5 m (red lines).

about 30 cm) as well as the intensity of sound reflected from the sea floor, which is referred to as backscatter intensity. High backscatter intensity generally indicates the presence of rocks and coarse-grained sediments, while low backscatter intensity indicates the presence of finer grained sediments. Direct observations using bottom photographs, video, and grab samples are needed to verify interpretations of the sea floor geology based on backscatter intensity.

IMAGES OF THE HARS SEA FLOOR

In this fact sheet, the topography and backscatter intensity data measured by the multibeam mapping system are presented in three types of images. Each of these images highlights different features and characteristics of the sea floor.

(1) A *shaded relief image* (Fig. 2) visually shows small topographic features (with relief of a few meters) that could not be effectively shown by contours alone at this scale. The image was created by vertically exaggerating the topography four times and then artificially illuminating the relief by a light source positioned 45° above the horizon from the north. In this image, topographic features are enhanced by strong illumination on the north-facing slopes and by shadows cast on the south-facing slopes.

(2) A *shaded relief image, colored by backscatter intensity*, combines the high-resolution view of topography with a measure of sediment characteristics (Figs. 4, 5B, and 6). In these images, the backscatter intensity is represented by a suite of eight colors ranging from blue, which represents low intensity (fine-grained sediments), to red, which represents high intensity (rock outcrops and coarse-grained sediments). These data are draped over the shaded relief image. The resultant image displays light and dark intensities within each color band that result from a feature's position with respect to the light source. For example, north-facing slopes, receiving strong illumination, show as a light intensity within a color band, whereas south-facing slopes, being in shadow, show as a dark intensity within a color band.

(3) A *shaded relief image, colored by bathymetry*, combines the high-resolution view of topography with color to show water depth (Fig. 5A).

THE SEA FLOOR OF THE HARS

Within the HARS, one of the most striking aspects of the sea floor is the variability in backscatter intensity and bottom morphology over distances of a few kilometers or less, caused by both natural and anthropogenic processes. This fact sheet presents companion images showing the sea floor of the HARS as mapped in April 2000 in plan view (Figs. 2, 4, and 6) and in perspective view (Fig. 5). Images of selected areas in 1996, 1998, and 2000 illustrate changes over time (Fig. 6). Major features of the sea floor of the HARS shown in these images include two

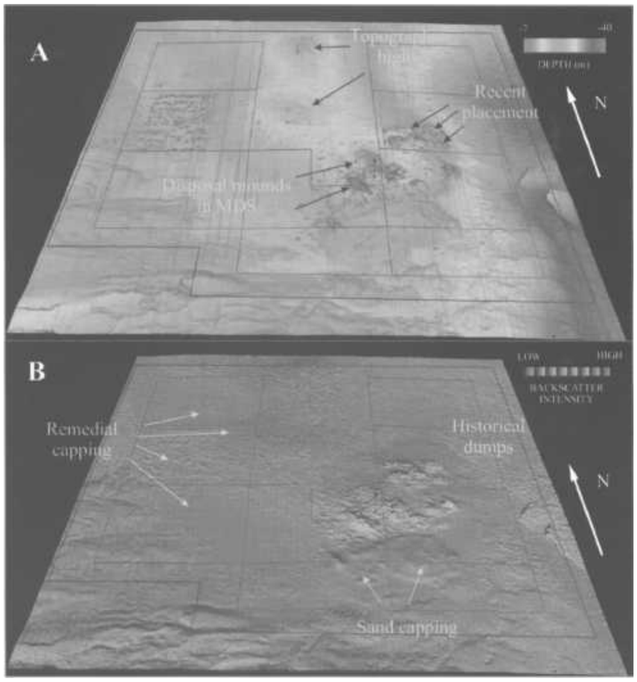

Figure 5. Perspective view of the Historic Area Remediation Site, looking from south to north, based on the multibeam survey carried out in April 2000. A, Shaded relief map with color-coded bathymetry. B, Backscatter intensity draped over shaded relief (see text for a description of the color scheme). The north-trending stripes, running parallel to the survey tracklines, are artifacts of data collection and environmental conditions. The topography, surface features, and the surficial sediments of the HARS have been heavily influenced by the disposal of dredged and other material in this region over the last century, and by recent remedial capping. See text for a description of these images and major features.

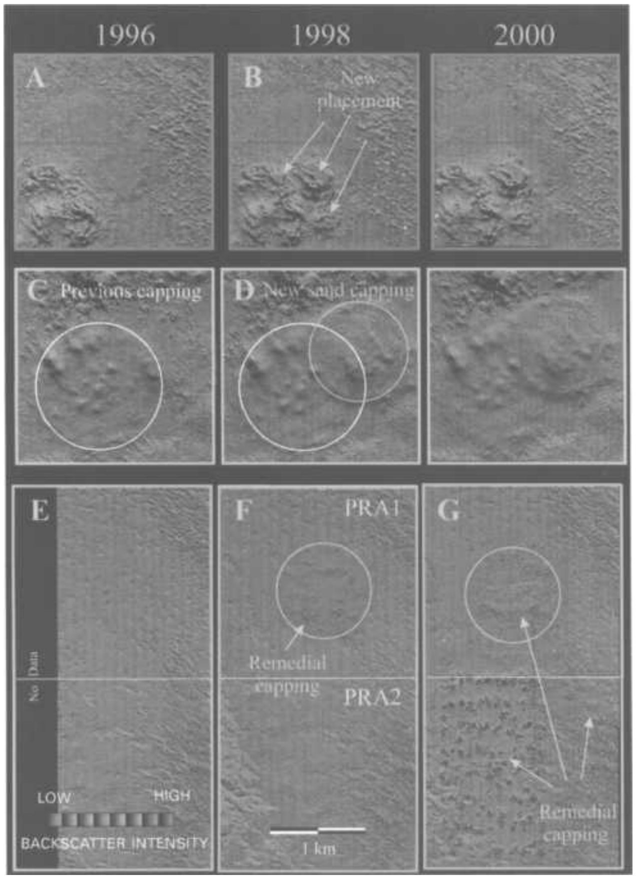

Figure 6. Pseudo-colored backscatter intensity and shaded relief map of parts of the HARS in 1996, 1998, and 2000 (see Fig. 4 for location). These images illustrate changes in the sea floor topography and backscatter intensity that occurred between 1996 and 1998 and between 1998 and 2000 caused by placement of dredged material and by remedial capping. See text for a description of these images and major features.

relatively smooth topographic highs composed of material dumped in the late 1800's and early 1900's ("Topographic highs" in Fig. 5A); mounds of material in the Mud Dump Site ("Disposal mounds in MDS" in Fig. 5A); two circular features where contaminated sediments were placed and then capped with sand, one in the late 1980's, and the other in 1997 ("Sand capping" in Figs. 4 and 5B and "Previous capping" and "New sand capping" in Fig. 6); material deposited between the November 1996 and November 1998 survey ("Recent placement" in Figs. 4 and 5A); many features about 50 m in size interpreted to be individual dumps of material ("Historical dumps" in Figs. 4 and 5B); and material placed as part of remediation activities ("Remedial capping" in Figs. 4, 5B, and 6).

CHANGES IN SURFICIAL PROPERTIES BETWEEN 1996, 1998, AND 2000

Comparison of the topography and backscatter intensity from the three multibeam surveys show how the area changed as a result of dredged material placed before the Mud Dump Site was closed and ongoing remediation of the HARS (see Fig. 2 for locations of placed material from USACE records).

Between 1996 and 1998, changes include (1) mounds of medium backscatter intensity dredged material in the northeastern corner of the MDS, some as high as 6 m, placed between November 1996 and September 1997 (compare panels A and B, Fig. 6); (2) a circular area of low-backscatter intensity material about 1 km in diameter and 2 m thick in the southern part of the MDS associated with sand capping (compare panels C and D, Fig. 6); and (3) a circular area of low backscatter intensity material in PRA1 associated with remedial capping (compare panels E and F, Fig. 6).

Between 1998 and 2000, changes include (compare panels F and G, Fig. 6) (1) increased backscatter intensity in PRA1 due to additional placement of material and consolidation, de-watering, and possible winnowing of the previous cover; (2) a series of crater-like features in the western part of PRA2, 30 to 70 m long and on the order of 20 m wide with elevated rims and central depressions, that were apparently formed as remedial material impacted the soft sediments on the sea floor; and (3) an area of reduced backscatter intensity in the northeastern corner of PRA2 caused by the placement of remedial material.

Resolution limits of the multibeam system, and the amount of material placed over a relatively large area, preclude using the repeated topographic surveys for determining the amount of material placed on the sea floor. However these multibeam data clearly show the overall regional geology and, through comparison of topography and backscatter intensity, document the location of placed material and changes in sediment properties over time.

NOAA AND UNIVERSITY SCIENTISTS STUDY METHYL BROMIDE CYCLING IN THE NORTH PACIFIC

Organization—Australia

As part of a study supported by both NASA and NOAA, scientists from two NOAA laboratories, three universities and CSIRO participated in a research cruise aboard the R/V Ronald H. Brown. The cruise departed Kwajalein, Republic of the Marshall Islands on 14 September 1999 and arrived in Seattle, Washington on 23 October 1999 with stops in Honolulu, Hawaii, Dutch Harbor, Alaska, and Kodiak, Alaska. The objective of this research effort was to obtain reliable measurements of the uptake and emission of methyl bromide and other climatically important halocarbons in tropical to temperate regions of the North Pacific Ocean.

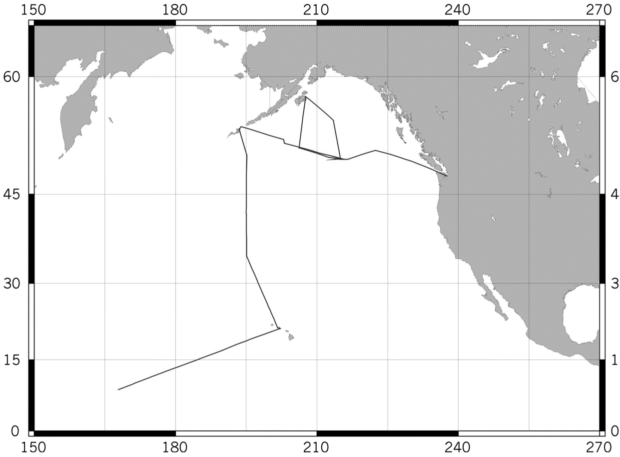

Figure 1. Cruise Track.

Figure 2. Scientists collecting water samples for production and degradation incubations.

Atmospheric methyl bromide (CH_3Br), which is of both natural and anthropogenic origin, has been identified as a Class I ozone-depleting substance in the amended and adjusted Montreal Protocol on Substances that Deplete Stratospheric Ozone. The role of the ocean in regulating the atmospheric burden of this gas is still somewhat uncertain. Methyl bromide is both produced and destroyed in the ocean through chemical and biological processes. The organisms or reactions that produce CH_3Br at rates sufficient to explain its observed concentrations are not known. Degradation has been shown to occur at rates that are faster than can be explained by known chemical degradation reactions, and evidence suggests that this additional degradation is bacterial consumption of CH_3Br. While recent measurements have shown that, on the whole, the ocean is a net sink for CH_3Br, measurement coverage to date has been limited and sporadic, which restricts our ability to map the spatial and temporal variations that are necessary for understanding how the system will respond to perturbations (e.g., Global Warming).

The measurements made during this cruise are designed to help improve our understanding of the role that the oceans play in the cycling of CH_3Br. The program involved instrumentation from two NOAA

---

laboratories and two universities. Measurements were made of the concentrations of CH_3Br and a suite of natural and anthropogenic halocarbons in the air and surface water, degradation rates of CH_3Br in the surface water, production rates of CH_3Br and other natural halocarbons in the surface water, and depth profiles of CH_3Br and other halocarbons. The combined results from these measurements will be used to constrain the budget of CH_3Br in these waters at this time of year. The relative importance of the biological and chemical processes will be examined for tropical and high latitudes. Attempts will also be made to extract relationships between the rates and concentrations measured and satellite measurements in order to develop proxies that can provide global coverage on shorter time scales. At this time, there is insufficient data to examine seasonal and long-term trends in net flux, production, or degradation. Until satellite measurable proxies can be found, additional research cruises are needed to reduce the uncertainty in the global net flux estimate and to map the spatial and temporal variations in the net fluxes, production rates, and degradation rates of CH_3Br and other climatically important halocarbons.

TIDALLY MEDIATED CHANGES IN NUTRIENT CONCENTRATIONS

Paolo Magni
IMC—International Marine Centre
Torregrande-Oristano, Italy

Shigeru Montani
Hokkaido University
Hakodate, Japan

Freshwater runoff during ebb flow and salt water intrusion during the flood may have a major effect on short-term changes in nutrient (ammonium, nitrate+nitrite, phosphate, and silicate) concentrations along an estuary. Time series hourly measurements conducted in a mixed-semidiurnal type estuary (i.e., characterized by two major lower and higher tidal levels) show that these changes are a strong function of both tidal state (e.g., low vs. high tide) and amplitude (e.g., neap vs. spring tide). In particular, the changes in nutrient concentrations are higher during ebb than during flood tide and largest between the lower low tide and the higher high tide of a spring tide. Finally, the importance of investigating simultaneously different stations along the estuarine spine is highlighted, in addition to studying the nutrient distribution based on selected salinity intervals which may reflect only the conditions at a particular tidal state.

BACKGROUND

An important aspect of the high variability of tidal estuaries is related to the effect of the tidal cycle on the physical and chemical characteristics of the water. In particular, on a timescale of hours, freshwater runoff during ebb flow and salt water intrusion during the flood may determine strong changes in salinity and dissolved and particulate compounds. Several studies in riverine and estuarine waters have investigated the distribution of nutrient (e.g., ammonium, nitrate, phosphate, and silicate) concentrations, based on the salinity gradient in the system at a particular tidal state (1–3). Accordingly, plots of nutrients versus salinity are often used to assess the source of different nutrient species, whether from inland, outside the estuary, or within it (3–7).

An evaluation of the distributional pattern of nutrients along an estuary has important ecological implications in relation to the cycling of biophilic elements, such as N (nitrogen), P (phosphorous), and Si (silicon). It is known that numerous processes influence the behavior of nutrients, whether they show conservative mixing or reflect removal or addition along an estuary. Ammonium consumption and ammonium oxidation, for instance, are predominant in the water column, whereas denitrification in sediments is responsible for nitrate removal from the water column (8–10). By contrast, bioturbation and excretion by abundant benthic animals may greatly contribute to the upward flux of regenerated nutrients, such as ammonium and phosphate, which in turn enhance primary production (11,12). Accordingly, it has been shown that regeneration processes within an estuary are consistent with often encountered nonconservative mixing of ammonium (4,8,13,14). This corresponds to the tendency of ammonium concentration to be high at midsalinity ranges, resulting in a poor correlation with salinity. In contrast, nitrate tends to show conservative behavior, as evidence of its riverine origin (2,14,15), although addition (15) or removal (7) is also found. Moreover, it must be considered that in some cases, nitrate versus salinity plots may fail to unravel active nitrate turnover, leading to an approximate balance of sources and sinks (16). As for silicate, a general pattern indicates that estuarine mixing of this nutrient species tends to be conservative (2,7,13). Yet, either silicate removal (7,17) or addition (4) occurs in relation to the development of an algal population in rivers or to a closer interaction with estuarine sediments, respectively, and varies with season (14). A major upward flux of silicate from sediments might also be related to the biological activity and excretory processes of abundant macrofaunal assemblages (18,19).

In addition to these general considerations, the distribution and cycling of nutrients depend strongly on the specific characteristics of each estuary, including water residence time and water depth, nutrient levels, and the extent of salt-water intrusion. Uncles and Stephens (3) showed that saline intrusion was a strong function of the tidal state and a weaker function of freshwater inflow. Accordingly, Balls (2) indicated that conservative mixing of phosphate, is a function of estuarine flushing time, as related to particle–water interaction and chemical speciation (20). In particular, phosphate removal at low salinities may be due to adsorption to iron and aluminium colloidal oxyhydroxides that aggregate and undergo sedimentation (7).

Therefore, it is important that investigations of the distribution of nutrients as a function of salinity are conducted on proper spatial and temporal scales that take into account the extent and variability of salt-water intrusion. Time series surveys represent a valuable approach to quantifying such variability in estuarine waters (21,22). In particular, short-term monitoring surveys during a complete tidal cycle and simultaneous information at different stations can be a powerful tool for evaluating the extent of salt-water intrusion along the estuary and its direct impact on the water chemistry of an estuary. This approach may overcome the limitations of evaluating the distribution and behavior of nutrients based on a particular tidal state at arbitrarily selected salinity intervals. Major drawbacks when working across long distances to cover different salinity ranges include work time to travel between samplings, tidal-water displacements, variations in tidal velocities, and a possible wide range of river discharge. Simultaneous observations at different stations are expected to track changes in nutrient concentrations that occur along the estuarine spine in relation to the extent of salt-water intrusion over time.

Case study

This article reviews the results of 24-hour surveys in a tidal estuary of the Seto Inland Sea, Japan, during a spring tide of May 1995 (13,23). It is aimed to give an example of the effect of freshwater runoff and salt-water intrusion on the spatial and temporal variability of nutrient concentrations during a tidal cycle. The effect of a tide is also evaluated in relation to the *mixed-semidiurnal* behavior (i.e., with pronounced differences between two successive low and high tides) of the estuary. The fieldwork was conducted along a transect line of approximately 1.4 km linking the river to the rear to the subtidal zone. Multiprobe casts were used for hydrologic measurements. Nutrient concentrations were determined every hour in surface waters, simultaneously at a riverine, an intertidal, and a subtidal station, and every two hours at additional depths through the water column at the subtidal station. Details of the sampling scheme and analysis are given in Montani et al. (13) and Magni et al. (23).

At the beginning of the survey, there was a marked salinity gradient along the estuary; surface water salinity was 2.0, 18.5, and 31.3 psu at the riverine, intertidal, and subtidal stations, respectively (Fig. 1). As the lower low tide approached, salinity remained low at the riverine station (Fig. 1a), sharply decreased also at the intertidal station (Fig. 1b) and, subsequently, at the subtidal station (Fig. 1c). By contrast, soon after the lower low tide, salt-water intrusion rapidly caused an abrupt increase in salinity at both the intertidal and the riverine stations, up to >30 psu (Figs. 1a,b). During the flood, there was a homogeneous distribution of high-salinity water along the transect line. At the subtidal station, a major change in salinity as a function of the tidal cycle was also apparent, but restricted to the surface layer, whereas salinity remained constantly >31 psu below the surface (Figs. 1c,d).

The nutrient concentrations were also markedly affected by the tidal cycle. At the beginning of the survey, silicate and nitrate+nitrite concentrations were markedly higher at the riverine station than at the intertidal and subtidal stations, whereas the ammonium concentration was relatively higher at the intertidal station (Figs. 1a, b, c). Approaching the lower low tide, the nutrient concentrations in surface water increased rapidly, especially at the intertidal and subtidal stations. Differently at the riverine station, the ammonium concentrations remained low, suggesting no significant import of this nutrient species through freshwater inflow (Fig. 1a). At the subtidal station, the nutrient concentrations also showed a relatively consistent increase below the surface, yet progressively less noticeable with depth (Fig. 1d).

By contrast, during the flood, as high-salinity water flushed backward into the estuary, the nutrient concentrations dropped to the lowest values at all stations and depths (Figs. 1a, b, c, d); a 7.5-fold and 8.8-fold decrease of silicate and nitrate+nitrite concentrations, respectively, occurred at the riverine station. During the second part of the survey, after the higher high tide, both salinity and nutrient changes were less marked.

Figure 2 summarizes the relationships between salinity and nutrient concentrations. Salinity versus nutrient plots demonstrate that the distributional pattern of nutrients largely varied with station, depth, and the different nutrient species. In particular at the riverine station, silicate and nitrate+nitrite were negatively correlated with salinity; r^2 explained a large portion of total variance (i.e., $r^2 = 0.879$ and 0.796, respectively). By contrast, at this station, ammonium showed a positive correlation with salinity, whereas phosphate did not significantly correlate with salinity. Differently at the intertidal and subtidal stations, the concentrations of all nutrient species in surface waters were negatively and significantly correlated with salinity; levels of confidence varied from $p < .05$ (ammonium) to $p < .001$ (phosphate and silicate).

The variability of both salinity and nutrient concentrations was lowest at the subtidal station below the surface. This test data set (Fig. 2d) indicated that all nutrient species were correlated positively with salinity at a high level of significance ($p < .001$). Relevant plots also highlighted that, within such a restricted variability of salinity, silicate and nitrate+nitrite concentrations comprised narrower values than those of phosphate and ammonium (Fig. 2d). Accordingly, the model equation for the former two nutrient species explained a higher portion of the total variance ($r^2 = 0.423$, and $r^2 = 0.457$, respectively) than that explained by the latter ($r^2 = 0.221$, and $r^2 = 0.245$, respectively).

These results showed that the riverine input was a major source of silicate and, partially, nitrate+nitrite and phosphate. It was also apparent that the increase in nutrient concentrations at the intertidal station and subsequently at the subtidal station, was largest during the first part of the survey (Figs. 1b, c). Companion papers demonstrated that the intertidal zone also plays a major role in nutrient cycling, as a major site of nutrient regeneration within the estuary (12,14,24).

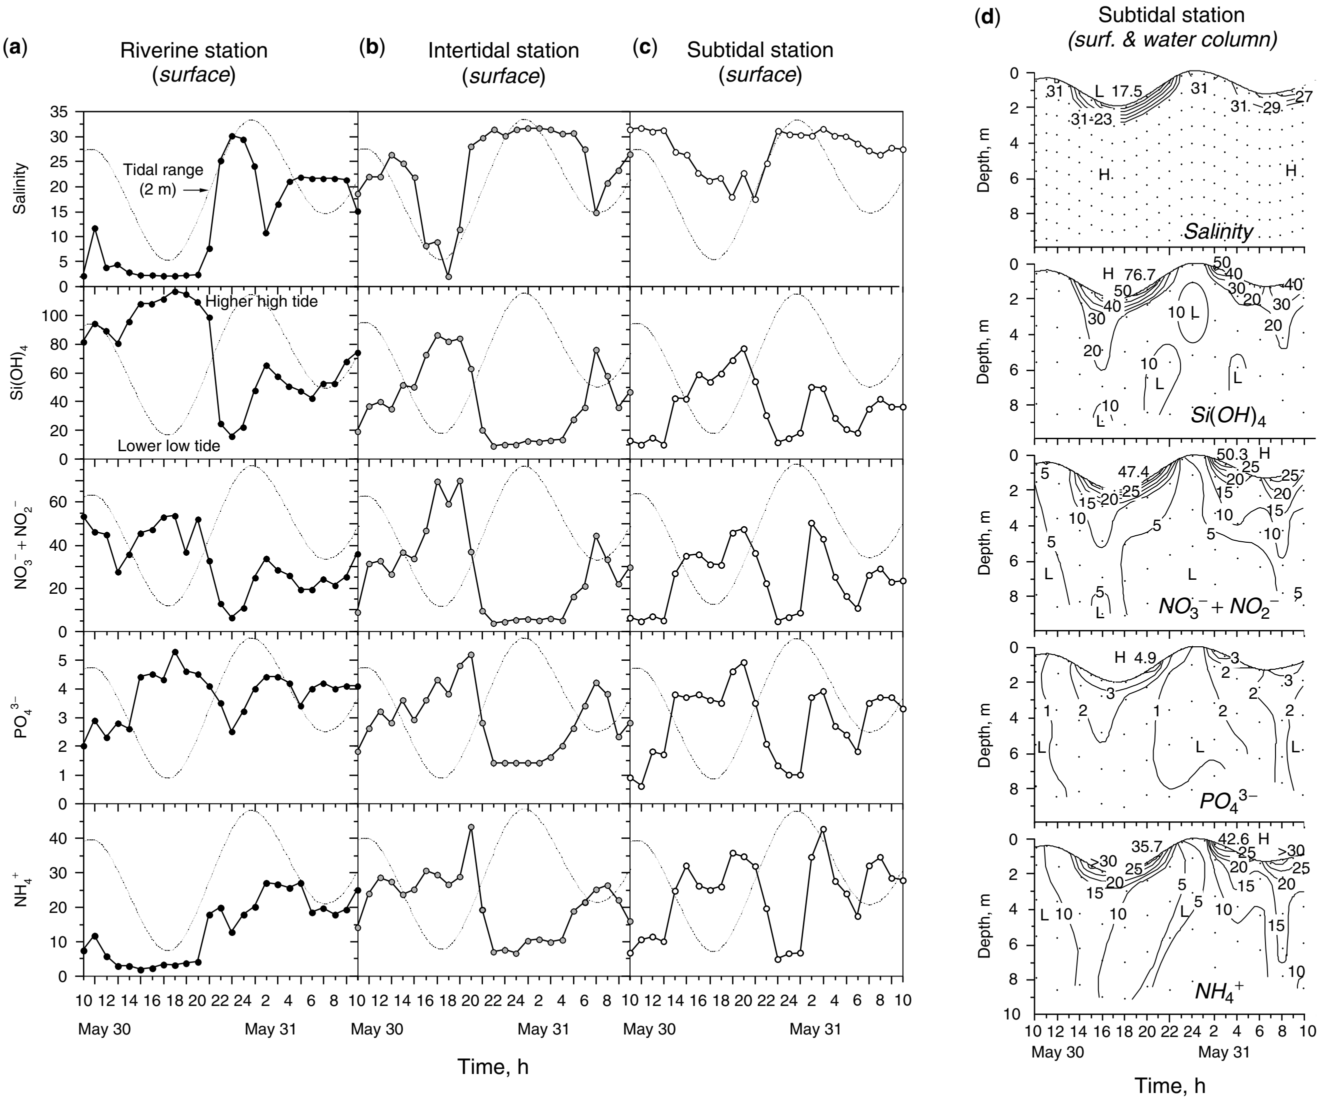

Figure 1. Time series of salinity (psu, practical salinity unit) and nutrient concentration (μM) in surface water at a riverine, intertidal, and subtidal station (Fig. 1a, b, c) and through the water column at the subtidal station (Fig. 1d) during a tidal cycle of a spring tide in a *mixed-semidiurnal* type estuary (Seto Inland Sea, Japan). Data sources: Fig. 1a, b, c from Montani et al. (13) (redrawn from Figs. 4 & 5); Fig. 1d: from Magni et al. (23) (adapted from Figs. 2 & 3).

CONCLUDING REMARKS

This article showed that the effect of salt-water intrusion on the dynamics of nutrients varies strongly both spatially (on relatively short distances) and temporally (on an hour timescale), and that this is much dependent on the tidal state. In particular, it was shown that the effect of tidal amplitude is important in determining the extent of the variations in nutrient concentrations, which were stronger between the lower low tide and the higher high tide. It also indicated that nutrient concentrations were higher during the ebb than during the flood and highest at the surface layer, as strongly correlated inversely with salinity. Finally, this work highlighted the importance of considering simultaneous investigations at different stations along the estuarine spine during a tidal cycle, especially on short distances, besides studying the nutrient dynamics based on selected salinity intervals that may reflect only the situation at a particular tidal state.

THE ROLE OF OCEANS IN THE GLOBAL CYCLES OF CLIMATICALLY-ACTIVE TRACE-GASES

Robert C. Upstill-Goddard
University of Newcastle upon Tyne
Newcastle upon Tyne, United Kingdom

The oceans are important in the global cycles of a range of trace gases that influence atmospheric chemistry and climate. For some of these, the oceans are a net source to the atmosphere, whereas for others, they are a net sink. Major gases of interest are summarized in Table 1, along with their net flux directions and their principal roles in the troposphere and stratosphere. Carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O) are major greenhouse gases: CO_2 currently accounts for more than one-half of enhanced global warming, whereas CH_4 and N_2O, respectively, account for about 15% and 6% (1). Volatile sulphurs are also implicated in climate forcing and they play important roles in atmospheric chemistry. As a result of length restrictions, our discussion focuses only on these gases.

GLOBAL PARTITIONING OF ANTHROPOGENIC CO_2

Several mechanisms contribute to natural CO_2 cycling between the atmosphere and the Earth's surface. The largest natural exchanges occur through respiration and photosynthesis on land and in the oceans, and by solubility-driven uptake in the oceans, and the net result of these exchanges is a natural carbon cycle in overall balance. By comparison with these natural fluxes, the flux of anthropogenic CO_2, which is derived primarily from the burning of fossil fuels, cement production, deforestation, and other land-use changes, is rather small, $\sim 7 \pm 1$ Gt C per year (1) (1 Gt = 1 gigatonne = 10^{15} g), which is nevertheless large enough to significantly disturb the natural CO_2 cycle.

As a result of its unreactive nature, the residence time of CO_2 in the troposphere is of the order of 50–200 years, hence anthropogenic CO_2 tends to accumulate there. In fact, tropospheric CO_2 has risen from about 280 ppmv (parts per million by volume) preindustrially, as determined from ice core studies (2), to approaching 380 ppmv by mid-2004 (http://www.cmdl.noaa.gov/). However, this corresponds to somewhat less than one-half of the known anthropogenic release (1). During the 1980s (the latest decade for which estimates of all carbon sources and sinks are available), the mean rate of tropospheric CO_2 growth was only about 3.3 ± 0.1 Gt C per year, the remainder, about 3.7 ± 1.0 Gt C per year, having been absorbed by "sinks" located in the oceans and within the terrestrial biosphere (1). The fraction of anthropogenic CO_2 absorbed by these sinks is, however, not constant. Large fluctuations are evident in the continuous tropospheric records that date back to the late 1950s (1), and these fluctuations are believed to relate directly to short-term variations in global climate. For example, increased atmospheric growth rates correlate with El Niño climate warming events, whereas cooling periods, such as that which followed the eruption of Mount Pinatubo in the early 1990s, seem to be associated with reduced atmospheric growth. These variations are thought principally to reflect changes in the balance of terrestrial primary production (photosynthesis) versus respiration, decomposition, and the combustion of organic material (3).

High background variability has precluded directly measuring the relative magnitudes of the oceanic and terrestrial CO_2 sinks, hence they have hitherto been estimated using models, often with conflicting results (4). However, recent techniques based on measuring carbon and oxygen isotopes in air (5) now enable the partitioning of anthropogenic CO_2 between these reservoirs to be determined with greater certainty, and it is now generally agreed that the ocean and land sinks are of about the same magnitude (although the uncertainties are large), i.e., about 1.9 ± 0.6 Gt C per year (6).

MECHANISMS OF OCEAN CO_2 UPTAKE

Compared with many other atmospheric trace gases, CO_2 is rather soluble in seawater, where it occurs as three principal dissolved species that together comprise seawater dissolved inorganic carbon (DIC), which are bicarbonate ($HCO_3{}^-$, 91% of DIC), carbonate ($CO_3{}^{2-}$, 8% of DIC), and dissolved CO_2 (1% of DIC).

The capacity of the oceans to absorb atmospheric CO_2 is ultimately buffered by the DIC system. CO_2 uptake results in an increase both in the partial pressure of CO_2 (pCO_2) and in the concentration of $HCO_3{}^-$, which is produced through the reaction of CO_2 with $CO_3{}^{2-}$. With further CO_2 uptake, its conversion to $HCO_3{}^-$ becomes limited by the decreasing $CO_3{}^{2-}$ availability, the result being that more CO_2 remains in solution, further decreasing the capacity for CO_2 uptake at increasing tropospheric levels. As an illustration, for atmospheric CO_2 to rise by about 100 ppmv relative to today, the increase in seawater DIC would only be about 60% of that which has accompanied the approximately 100 ppmv rise in tropospheric CO_2 since the industrial revolution (1,6).

Studies based on the downward penetration of chemical tracers, such as ^{14}C, coupled with simple box models of ocean mixing (7), or more sophisticated General Circulation Models (8), show that tropospheric CO_2 equilibrates with the surface ocean mixed layer rather rapidly, on the order of a few years. In contrast, CO_2 penetration into the deep ocean interior is constrained by relatively slow vertical transport; the whole ocean equilibrates with the atmosphere on a timescale of more than 1000 years. As a result of this slow rate of downward mixing, with few exceptions, anthropogenic CO_2 has yet to penetrate below about 1000 m depth. Transport of CO_2 into the ocean interior occurs via the thermohaline circulation, in which cool surface waters in the high latitude North Atlantic (Greenland Sea) and Southern Oceans sequester CO_2 from the troposphere and sink because of their higher density. This downward transport is balanced in regions where deep water with a high capacity for CO_2 uptake wells up to the surface, such as occurs in parts of the tropics and the Southern Ocean. The sinking waters eventually spread laterally toward the subtropics, giving rise to a relatively uniform distribution of anthropogenic CO_2. Eventually, on the 1000-plus year timescale of deep ocean mixing, the deep CO_2-rich waters formed in this way will again well up to the surface, the principal site for this being the Equatorial Pacific. As this water warms during upwelling, its pCO2 will increase, resulting in CO_2 loss to the atmosphere by out gassing.

One other potential removal process for tropospheric CO_2 is through reaction with $CaCO_3$ contained in deep sea sediments; however, their response time to changes in tropospheric CO_2 is several thousand years (9).

According to some coupled ocean-atmosphere models, one possible consequence of global warming is an increase in the intensity of vertical stratification in the oceans (1), which would reduce the rate of surface to deep water mixing and, consequently, the uptake rate of tropospheric CO_2.

In addition to chemically and physically driven uptake, tropospheric CO_2 is also processed through the so-called "biological pump," in which organic matter produced via photosynthesis and cycled through the upper ocean food-web is ultimately transported downward via sinking organic particles or through vertical biomass migrations. This sinking flux of organic carbon is remineralized or respired back to inorganic carbon at depth with an accompanying release of dissolved inorganic nutrients (principally nitrate and phosphate). Model simulations suggest that without the biological pump, tropospheric CO_2 could be about 150 ppmv higher than at present (1). However, the likely response of the biological pump to increasing tropospheric CO_2 is uncertain. Most current evidence tends to discount increased productivity on the grounds of limitation by the supply of nutrients, which are seasonally depleted in most surface waters. However, extensive regions exist of the subarctic Pacific, equatorial Pacific, and Southern Ocean with abundant nitrate and phosphate throughout the year but with very low phytoplankton productivity, the so-called high-nutrient-low-chlorophyll (HNLC) regions. Their low productivity likely reflects a deficiency in the supply of a minor nutrient such as iron (10). Although predicting climate-induced changes in the supply rate of iron to the oceans is far from straightforward, these regions could conceivably play a significant role in the future ocean uptake of anthropogenic CO_2. It is also conceivable that global warming-induced changes in stratification described earlier could also modify the ocean's biological carbon cycle; however, the consequences of this are difficult to predict given the intrinsic complexity of the system (11).

THE GLOBAL ROLE OF CH_4 AND N_2O

As well as being important greenhouse gases, CH_4 and N_2O play important roles in atmospheric chemistry; N_2O is involved in the stratospheric cycling of NO_x (reactive nitrogen oxides) and ozone (12), and CH_4 takes part in reactions that govern levels of tropospheric ozone and hydroxyl radical ($\cdot$ OH) and stratospheric H_2O (13). Like CO_2, N_2O and CH_4 are currently increasing in the troposphere, both by about 0.3% per year (1). However, the role of the oceans in their global budgets differs from that for anthropogenic CO_2 in two fundamental ways. First, the oceans are a net source of tropospheric N_2O and CH_4, and second, for both, the marine source is one of several global sources whose relative magnitudes remain rather uncertain.

GLOBAL SOURCE UNCERTAINTIES

The marine system is one of two major N_2O sources, the other being terrestrial soils. Combustion, biomass burning, and fertilizers make additional minor contributions. Although the uncertainties are large, the oceans are thought to contribute around 20% of the natural global source (1); however, the contribution is larger with anthropogenic sources included (see below). For CH_4, many more global sources exist, in descending order of magnitude, these are: agriculture, wetlands, fossil fuels, biomass burning, termites, oceans, CH_4 hydrates, and landfills. However, the range of uncertainties is no better than it is for N_2O, ranging from ±100% (e.g., wetlands), to in excess of ±2000% (e.g., CH_4 hydrates) (1). According to these data, marine waters contribute only about 3% of the total CH_4 source to the troposphere, but this may be an underestimate (see below).

SOURCES OF SEAWATER N_2O

In seawater, N_2O develops as a byproduct during microbial nitrification (the conversion of dissolved ammonium, $NH_4{}^+$, to nitrate, $NO_3{}^-$) and as a reactive intermediate during microbial denitrification (the reduction of $NO_3{}^-$ to gaseous nitrogen). Nitrification principally occurs in oxygenated waters, although it is inhibited by light, whereas denitrification is restricted to anoxic sediments and O_2-deficient waters. For these reasons, N_2O production is insignificant in most open ocean surface waters. In extremely O_2-deficient waters, N_2O can be consumed during denitrification because of its use as an electron acceptor by denitrifying bacteria (14). Coupling of the two processes, in which the $NO_3{}^-$ developing from nitrification is consumed by denitrification, occurs both in marine sediments (15) and around the fringes of O_2-depleted waters in the open ocean (16).

The net rate of N_2O production by nitrification and denitrification is influenced by several factors in addition to dissolved O_2 availability, including the supply rates of $NO_3{}^-$ and $NH_4{}^+$, the composition of the microbial ecosystem, and in sediments, physicochemical aspects such as porosity and grain size. Consequently, both processes show pronounced seasonal variability. These aspects, coupled with a nonuniform distribution of N_2O source regions, makes the total marine source of N_2O difficult to quantify.

Current data indicate around two-thirds of the marine source of tropospheric N_2O to derive from the open ocean, with the remainder coming from coastal waters. However, these estimates contain uncertainties resulting from incomplete spatial and seasonal sampling and difficulties related to estimating sea-to-air fluxes.

Open ocean emissions are approximately equally distributed between the northern and southern hemispheres. Most of the N_2O is located below the surface-mixed layer and highest concentrations occur at around 500–1000 m depth, where a high O_2 demand results from the bacterial decomposition of sinking organic particles. Exchange of this water with the atmosphere is usually slow, except during wintertime when the surface-mixed layer deepens because of cooling and wind-driven mixing, entraining waters from below. Regions experiencing strong seasonal upwelling are especially strong sources of tropospheric N_2O, which include the Tropical North Pacific, the Arabian Sea/northwestern Indian Ocean, the equatorial upwelling, and along the coasts of northwest Africa and western central and South America. In these areas, the upwellings bring N_2O-rich waters to the surface along with a plentiful supply of nutrients that fuels high primary productivity. The resultant large downward flux of organic particles gives rise to strongly O_2-deficient waters that replenish the deep water inventory of N_2O through nitrification-denitrification coupling (17). Some areas of the subtropical gyres and the North Atlantic seem to be weak sinks for tropospheric N_2O in winter and weak sources in summer.

The major coastal N_2O source regions are estuaries, open coastal shelf waters being generally at or close to equilibrium with tropospheric N_2O levels. Both water column nitrification associated with high suspended particle populations (18) and sediment denitrification (19) have been identified in estuaries.

Whereas oceanic N_2O emissions are considered to be wholly natural, significant N_2O in coastal waters appears to derive indirectly from anthropogenic activity. In particular, the use of fertilizers is reflected in enhanced transport of nitrogen to coastal waters and a consequent increase in N_2O production and tropospheric flux. As much as 90% of current estuarine N_2O emissions and 25% of continental shelf emissions may be anthropogenic and consistent with the geographic distribution of fertilizer use, human population, and atmospheric nitrogen deposition, more than 80% of these anthropogenic sources are located in the Northern Hemisphere mid-latitudes between 20°N and 66°N (20).

SOURCES OF SEAWATER CH_4

Like N_2O, seawater CH_4 has a microbial source (microbial methanogenesis). Methanogenesis is inhibited by dissolved O_2 and therefore usually occurs in anoxic sediments or in waters that are strongly O_2-depleted. Even so, CH_4 concentrations in the oxygenated surface ocean are on average about 30% above the tropospheric equilibrium value, most likely reflecting methanogenesis by O_2-tolerant methanogens inside bacterially maintained “anoxic microniches” in the guts of zooplankton and/or in particles (21). Consequently, the open ocean represents a small CH_4 source. In addition, regions of much higher CH_4 concentration occur in upwelling areas, associated with enhanced primary productivity as for N_2O (16,22). Based on the available open ocean data, the marine contribution to tropospheric CH_4 is about 10 Tg CH_4 per year, which is equivalent to about 3% of the total global source (1).

Coastal waters have much higher CH_4 concentrations than the open ocean but have, until recently, been excluded from global CH_4 source estimates because of a lack of data. For estuaries, values of 100 to 200 times the background equilibrium value are common. Such CH_4 levels reflect direct inputs from rivers, coastal seawater, underlying sediments, and *in situ* production/consumption from water column methanogenesis and microbial CH_4 oxidation. Recent work suggests that correctly accounting for these regions could increase the estimated marine CH_4 source by around 50% (23).

A potentially even larger CH_4 source may be geologically sourced CH_4 from natural marine seeps, which are most common on shallow continental shelves (24). Seeps are episodic in nature, and the CH_4 fluxes developing from them are predominantly by bubbles, which complicates making accurate measurements. As a result of CH_4 losses because of bubble dissolution and subsequent CH_4 oxidation in the water column, shallow water seeps are much more effective than deep water seeps at contributing CH_4 to the troposphere. Revised source estimates that take account of seep occurrences suggest that the total marine source of tropospheric CH_4 could be as much as 40 Tg yr^{-1} (25). If so, the oceans could be a much more important source of tropospheric CH_4 than previously thought.

VOLATILE SULPHUR COMPOUNDS

The marine system is an important source of sulphur globally; in particular, it is the principal source of biogenic atmospheric sulphate aerosol, which plays important roles in atmospheric chemistry and climate.

The predominant volatile sulphur in surface seawater is dimethyl sulphide (DMS) $[(CH_3)_2S]$, which is a byproduct of algal metabolism and accounts for about 95% of marine sulphur emissions and 20% of total global sulphur emissions (1). DMS is rapidly oxidized by free radicals in the lower troposphere. Sulphur dioxide (SO_2) is the major reaction product and is subsequently transformed to sulphate aerosol through gas-to-particle reactions. This process is hypothesized to impact directly the radiative forcing of global climate, primarily through changes to cloud albedo (26). Carbonyl sulphide (COS) has also been implicated in global climate forcing. Compared with other volatile sulphurs, COS has a long tropospheric residence time of around 2–6 years. Consequently, it is transported into the stratosphere, where its photo-oxidation is believed to be an important source of sulphate aerosol, which is thought to impact Earth's radiation balance (27) and stratospheric ozone levels (28).

DIMETHYL SULPHIDE

A global database of more than 15,000 measurements of surface seawater (29) revealed distinct annual DMS cycles in the open ocean at mid to high latitudes. In the northern hemisphere, open ocean DMS increases during spring–summer, whereas in the southern hemisphere, concentrations peak six months later. These patterns relate to the timing of phytoplankton blooms and seasonal changes in mixed layer depth. In contrast, tropical regions show weak seasonality; DMS is elevated in the upwelling regions off western Africa and South America, but these concentrations are lower than those at high latitudes during summer. On coastal shelves, DMS is spatially and temporally variable, broadly correlating with seasonal primary productivity and the presence of algal blooms associated with upwelling at water mass boundaries (hydrographic fronts) (29). Similar concentrations are found in many estuaries, notable exceptions being those with high concentrations of suspended particles. Seasonal patterns are, however, rather different, with maximum concentrations occurring during late winter/early spring. The available data indicate that coastal regions may be larger emitters of DMS per unit area than the global mean, however, because of its much larger surface area, the open ocean is the most important source of tropospheric DMS (29).

CARBONYL SULPHIDE

Direct marine emissions are thought to account for about 20% of the global COS source (30), although the tropospheric oxidation of marine-derived DMS and carbon disulphide (CS_2) may increase this to as much as 55% (31). COS in seawater primarily develops from the photodecomposition of humic-like colored dissolved organic matter (CDOM) (32), although a small nonphotochemical source has also been inferred. The distribution of sea surface COS, therefore, corresponds closely to the concentration and reactivity of CDOM, which primarily derives from terrestrial sources. Consequently, COS concentrations are highest in estuaries, which are about an order of magnitude higher than those of adjacent coastal waters (32).

COS undergoes hydrolysis removal in seawater at a similar rate to that for its photo-production, hence COS shows a pronounced diel cycle in surface seawater with concentrations peaking in the early afternoon and declining to a minimum just before sunrise (33). Strong seasonal variation also exists. In the mid to high latitude open ocean the balance of photo-chemical production versus hydrolysis removal can lead to these regions becoming a seasonal sink for tropospheric COS (34). Net ocean uptake of COS has also been found in the subtropical ocean gyres (35). Taking account of these findings, the marine COS source is most likely dominated by the contribution from coastal and shelf areas.

PACIFIC MARINE ENVIRONMENTAL LABORATORY—30 YEARS OF OBSERVING THE OCEAN

NOAA—Pacific Marine
Environmental Laboratory

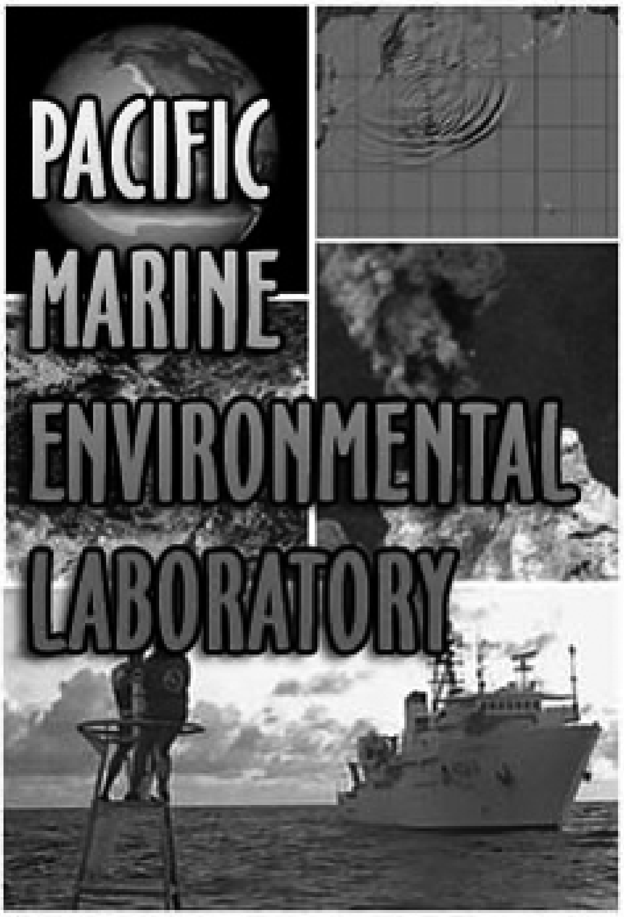
Sept. 29, 2003—Although the NOAA Pacific Marine Environmental Laboratory in Seattle, Wash., celebrates its 30th anniversary this year, its staff has spent 43 years at sea. The figure of 15,654 days at sea was one of the many facts presented during the lab's anniversary celebration in August. That, along with 1,290 published journal articles and 352,000,000 hits on the PMEL Web page indicate that there's a lot going on out on Sand Point.

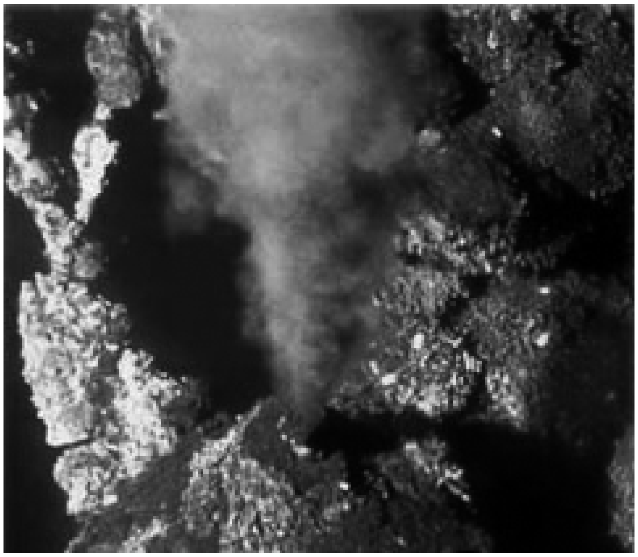
For two-thirds of its life, the lab has been under the direction of Eddie Bernard. An oceanographer by training, Bernard became director in 1983, a decade after the former Pacific Oceanographic Laboratory became PMEL. "We have dedicated people at PMEL who devote a lot of energy and creativity to the work we do," he said.

NATIONAL TSUNAMI MITIGATION PROGRAM

Some of that creativity and energy became evident when in 1994 the U.S. Senate asked NOAA to come up with a plan to reduce the risk of tsunamis to coastal residents. What resulted was the National Tsunami Hazard Mitigation Program, chaired by Bernard and composed of representatives from federal, state and local agencies from West Coast states, Alaska and Hawaii, working to save lives and property. "The National Tsunami Mitigation Program initiated by PMEL is a unique and effective partnership," said Rich Eisner of the California Governor's

---





Office of Emergency Services, one of the program members. “The integration of science and mitigation policy, the warning centers, and local emergency management, and the application of new technologies fostered by PMEL have been successful beyond expectations.” Among the technological innovations is the system of buoys along the West Coast that serve as warning devices, or, as Bernard calls them, “tsunameters.” The tsunami program also includes a public education component that teaches coastal residents what to do in case of a possible tsunami. Signs now indicate evacuation routes and some coastal communities have been designated “TsunamiReady” for their efforts to educate and protect their residents.

UNDERWATER VOLCANOES AND VENTS

As one of NOAA’s “wet” labs, PMEL focuses on a variety of ocean issues. When underwater volcanoes or vents, were first discovered in the Galapagos Islands 26 years ago, PMEL was among the first to start investigating these unusual underwater communities, where unique marine life thrive on the chemical soup spewed from the sea floor. “We may be taking drugs in the future made of enzymes that are more compatible with our bodies than synthetic compounds, which may have side effects,” Bernard said. “What’s spewing from the ocean floor could someday give us resistance to some new strains of infection.”

FISHERIES OCEANOGRAPHY COORDINATED INVESTIGATIONS PROGRAM

PMEL began as a “small research laboratory with emphasis on water quality and environmental impact issues” in the waters off the West Coast extending to the equatorial Pacific Ocean. It now has an international reputation in many areas, especially its ability to collect ocean data and to work collaboratively in projects that cover many disciplines. One example is the Fisheries Oceanography Coordinated Investigations program that assists in forecasting fish stocks to help ensure a reliable supply and lower costs to consumers. “In 1985, Eddie Bernard took a big risk,” said Doug DeMaster of the NOAA Marine Fisheries Service. That risk was offering to establish with the Alaska Fisheries Science Center and his counterpart, William Aron, a cutting-edge, applied

science program across NOAA line offices. Eighteen years after its inception, NOAA's FOCI has published more than 450 scientific articles and was awarded the Department of Commerce Bronze Medal in 2002 for "scientific achievements that have advanced fisheries oceanography and marine ecology and have contributed to building sustainable fisheries in the North Pacific." DeMaster noted, "Today, if you attend a FOCI meeting, you cannot tell which scientists are from NOAA Research and which are from NOAA Fisheries. In 1985, it took vision and courage to blur the lines between line offices. Today, it seems only natural."

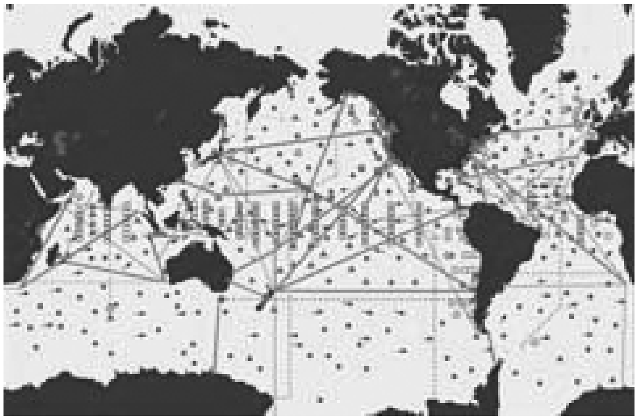
PACIFIC TROPICAL ATMOSPHERE OCEAN ARRAY

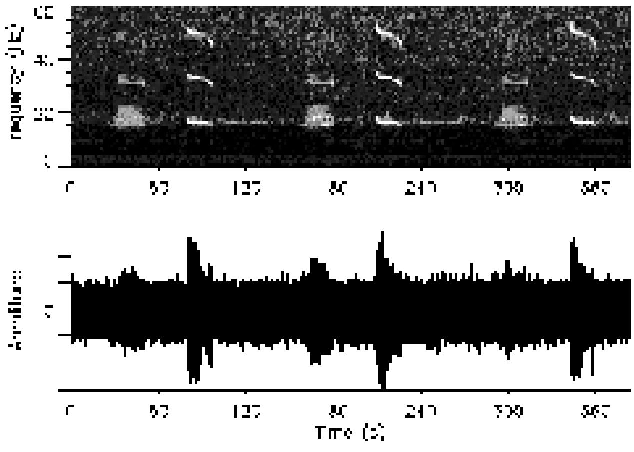
Understanding the natural systems is a key element of the lab. "The ocean is dynamic, it moves all of the time," Bernard said. "We're now in the third generation of observing systems. In the equatorial Pacific, we have the world's longest continuous time series of open ocean data—25 years." The equatorial Pacific also proved to be the place to be if humans wanted early warning of El Niño events. El Niño is a disruption of the ocean-atmosphere system in the tropical Pacific having important consequences for weather around the globe. After the 1982–83 El Niño, considered the most intense in the 20th century, the challenge was given to develop some sort of early warning device so people could prepare for the devastating and beneficial aspects of an El Niño and its counterpart, La Niña. Once again, in 1994, PMEL harnessed the creativity and talent of dedicated scientists and came up with the Pacific Tropical Atmosphere Ocean (TAO) array, the world's largest ocean observing system. Bobbing in the Pacific are 70 buoys measuring and relaying surface wind, sea surface temperature, upper ocean temperatures and currents, air temperature and relative humidity in real-time via satellite. "We knew we were onto something when we linked data from the TAO buoys to the Internet and attracted millions of hits from all over the world," Bernard said. "All it takes is time, money and commitment."

UNDERWATER ACOUSTICAL MONITORING

Always eager to hear what the Earth has to say, PMEL scientists also listen to the planet via underwater acoustical monitoring. Using a variety of methods, including underwater hydrophones, PMEL listens for seismic activity, marine mammals and ship traffic. The systems also have picked up some so-far unidentified sounds. "People tend to think the ocean is quiet beneath the surface," said Christopher Fox, director of the ocean acoustics project. "But it's pretty noisy down there." Some things are easy to identify, Fox said, such as whales and ship traffic. But visitors to the ocean acoustics Web site can listen to such unidentified sounds that the lab has dubbed "Train," "Upsweep," "Whistle" and "Bloop."

After 30 years, PMEL knows that the Earth still holds countless tantalizing secrets. And PMEL scientists and staff are eager to unlock those secrets. "As the planet aspirates, it provides new opportunities," Bernard





said. “It’s an ongoing science experiment with enormous challenges and rewards.”

SEAWATER TEMPERATURE ESTIMATES IN PALEOCEANOGRAPHY

Giuseppe Cortese
Alfred Wegener Institute for
Polar and Marine Research
(AWI)
Bremerhaven, Germany

BACKGROUND

Climatic issues, such as global warming, greenhouse gases release into the atmosphere, and the role mankind plays in affecting the climate of our planet have recently gained international interest.

As a result, political panels and decision-makers are starting to look with growing interest at the results of committees established with the purpose of analyzing past, present, and future climate change.

One of these panels [Intergovernmental Panel on Climate Change (IPCC)], established by the World Meteorological Organization (WMO) and the United Nations Environment Programme (UNEP), regularly publishes reports (available also online at http://www.grida.no/climate/ipcc_tar/) intended for scientists, politicians, and anybody interested in and/or concerned by climate change.

The most powerful tools currently available to the scientific community for the analysis and prediction of climate are computer models, which simulate the functioning of Earth as a complex system. These models differ based on which components of the climate system (atmosphere, ocean, biosphere, cryosphere, etc.) they include and account for, their spatial scale and degree of detail, and on the different sets of physicochemical equations they use to describe and parameterize phenomena taking place at a subgrid spatial scale.

Regardless of setup and characteristics, though, models should be benchmarked against an observational base (e.g., to test how well the model reproduces a known distribution of a climatic variable). Models are moreover usually initialized by a set of observations (to let the incorporated physics modify the starting distribution).

Some of these datasets are readily available in the form of measurements performed over historic timescales: One of the best known examples is the atmospheric CO_2 concentration curve measured at Mauna Loa, Hawaii, since the late 1950s (1).

Other important climatic variables cannot be observed or measured directly, and indirect methods, so-called “proxies,” have been developed to obtain information on them. Some of the methods that estimate seawater temperature on geological timescales are described in the following.

INTRODUCTION

The heat balance of Earth is strongly affected, to a first approximation, by the amount of solar radiation reaching the top of the atmosphere. The motion of currents in the atmosphere and in the ocean redistributes this heat between low and high latitudes, as the low latitudes receive a higher amount of heat compared with the higher latitudes. The ocean can be regarded as the “thermostat” of such a heat machine, because water has a much higher heat capacity compared with air, and because the turnover time for the ocean (thousands of years) is several orders of magnitude higher than for the atmosphere (days). One of the main features of the large-scale circulation in the ocean is the formation of deep waters at high latitudes, in the Weddell and Ross Seas (around Antarctica), and in the Labrador and Greenland/Iceland Seas (in the northern North Atlantic), because of the cooling of enormous amounts of warm surface waters advected to these locations by ocean currents (e.g., the Gulf Stream in the North Atlantic). When these waters move to higher latitudes, they cool, become denser, and sink to the ocean depths, where they start a reversed journey, from high to low latitudes. During this cooling, they also release latent heat and moisture, which help to mitigate the climate of the coastal areas they fringe, including the whole of western Europe.

Indications exist, from geological records and model simulations (2), that during glacial times, this oceanic overturning did not operate with the same intensity as today, and/or that the places where deep waters formed were displaced compared with today. As seawater temperature, together with salinity, determines the density of seawater (and therefore it strongly influences its circulation and sinking characteristics), a variety of methods have been developed to determine this important climatic variable in the distant, geological past.

METHODS

Sediment cores collected from the bottom of the World Ocean represent an ideal archive to trace the history of the ocean. Some of these cores can be accurately dated, and often they contain the fossilized remains of organisms that lived in past oceans, and reacted to changes in their characteristics.

The most useful of these organisms, because of their high fossilization potential, species diversity, and sensitivity to a range of climatic variables, are micro- and nannofossils. As their name implies, these organisms range from nanometer to millimeter size and leave fossilizable body parts, with the most commonly used groups belonging to algae (diatoms, nannoplankton) and protozoans (radiolarians, foraminifera). Most species in these groups live close to the sea surface, and each of them is adapted to a particular set of sea surface water variables, including temperature, salinity, and macro- and micro-nutrient content. Several techniques have been developed to exploit this close link between species occurrences/abundances and past environmental variables. Our first global view of surface water temperatures in the ocean during the Last Glacial Maximum (ca. 18,000 years Before Present) came from one such technique, namely, Q-Mode Principal Component Analysis applied to foraminifer and radiolarian abundance data in sediment cores (3).

Semiquantitative Floral/Faunal Estimates

Some of the first attempts to obtain seawater temperature information from microfossil assemblages tried to derive this value directly from a formula. The latter was based on the presence/absence, in the fossil samples, of species having a well-known distribution in the modern ocean, and being representative of different climatic zones (e.g., equatorial, subtropical, temperate, etc.). This approach, initially developed for diatoms (4), has also been applied to radiolarians (5). Information on species diversities of modern planktonic foraminifera in the Indian Ocean have also been used, in the late 1970s, to estimate ocean paleotemperatures (6).

Transfer Functions

With the expansion of the knowledge about the biogeography of most plankton groups (and the ecological and environmental significance of many species), and the development of computers (allowing the implementation of more sophisticated algorithms and techniques), transfer functions made their breakthrough in paleoceanography. They were first described and applied to planktonic foraminifera by Imbrie and Kipp (7), who illustrated their utilization in paleoclimatology. The species assemblage present in a collection of modern sediment samples (calibration dataset), containing up to several hundreds of samples, is “simplified” into a limited number of faunal factors/assemblages. A multivariate regression is then used to calibrate these simplified assemblages to the desired environmental variable (e.g., surface seawater temperature) measured, in the water column, at the same locations where the surface sediment samples were recovered. The value of the environmental variable at a certain time in the past is estimated by calculating “pseudo-factors” for each of the past samples (i.e., the value the calibrated assemblages have in these samples) and replacing them in the calibration equation. One main assumption of this method is that the considered environmental variable (in our case, surface temperature) plays a major role in influencing the biogeographic distribution of the considered microfossil species, and that it is therefore responsible for most of the variance observed in the calibration dataset. Transfer functions have been successfully applied to past ocean surface temperature reconstructions by using planktonic foraminifera (8–14), radiolarians (15–22), and diatoms (23,24).

Geochemical Methods

Several methods have been recently developed to estimate past ocean temperatures by measuring chemical elements or organic compounds, which are either incorporated in the organism shell or produced during its life cycle. The general approach is to develop a calibration equation by growing the desired species in culture under a variety of environmental conditions, and measuring how its geochemical composition changes. Additionally, a calibration equation can also be obtained by analyzing extensive collections of recent sediments, covering areas where the environmental variables display a wide range. The resulting equation is then applied to fossil samples to derive the past value of the desired variable.

Mg/Ca

The relative amount of magnesium compared with calcium a certain planktonic foraminifera species incorporates in its test depends on temperature, and the Mg/Ca ratio can therefore also be used as a paleo-thermometer. The calibration equation is derived from laboratory culture studies, based on different species, including *Globigerinoides sacculifer* (25), *Globigerina bulloides*, and *Orbulina universa* (26). Revised calibrations and applications to geological records are being continuously developed (27–31). Another paleo-thermometer derived from elemental ratios in foraminifera tests is the Sr/Ca ratio (32).

Alkenones

Several species of nannoplankton, living in the shallower layer of the ocean (less than ca. 50 m depth), produce organic compounds named long-chain (C_{37}-C_{39}) unsaturated ketones, also known as alkenones. The two species being responsible for most of the alkenone production are *Emiliania huxleyi* and *Gephyrocapsa oceanica*. Although it is still not clear what the function of such compounds is, they have become a very useful tool for the estimation of past seawater temperature. It has been demonstrated (33,34) that the three different varieties of the C_{37} unsaturated compounds ($C_{37:2}$, $C_{37:3}$, $C_{37:4}$), characterized by 2, 3, or 4 double bonds, display abundance variations related to seawater temperature. The alkenone unsaturation ratio (35), $U^{k'}{}_{37} = [C_{37:2}]/([C_{37:2}] + [C_{37:3}])$, was calibrated to temperature (36) by growing *E. huxleyi* in culture under a range of temperatures. Since then, alkenones have been widely applied in paleoclimatology (37–45).

Other Methods

Other methods commonly used to estimate past ocean temperatures are as follows the modern analogue technique and its variations (46–51); artificial neural networks (52,53); and the δ^{18}O isotopic composition of planktonic foraminifera (54–58). The study of the isotopic signal stored in corals, although covering shorter time intervals than marine sediment cores, provides excellent temporal resolution archives (down to a few weeks), which allow to analyze seasonal climate variability (59,60).

PHYSICAL OCEANOGRAPHY

Pacific Fisheries Environmental
Laboratory, NOAA

A great deal of the patterns and fluctuations observed in our living marine resources are attributable to the impact of physical processes in the environment on marine

---

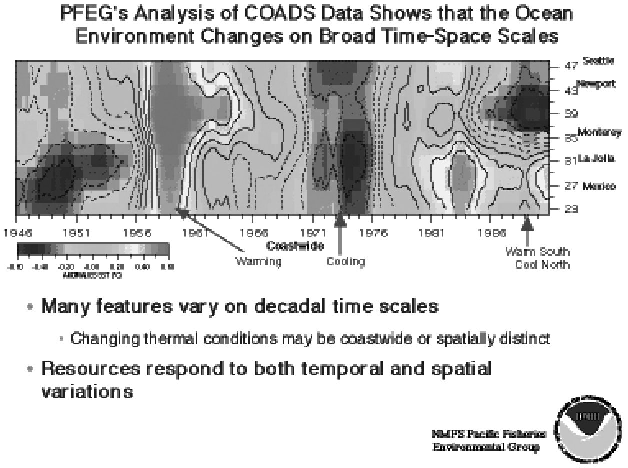
ecosystems and their components. For this reason, PFEL places a strong emphasis on research that examines the role of the physical environmental variability on marine ecosystems in general and commercially important fish stocks specifically. The objectives of the physical oceanography task are:

- perform research on the temporal and spatial scales of environmental variability in eastern boundary current systems in relation to other marine ecosystems
- provide environmental input to SWFSC research programs, particularly the coastal groundfish program
- provide high quality marine information to the research community.

Research is performed at PFEL which integrates environmental and biological data sets, investigating the linkages between environmental variability and fluctuations in the abundance and distribution of marine populations on a continuum of scales (from global, basin-wide spatial scales to the scale of local upwelling centersand on time scales from decades down to days). Physical oceanography research is directed to:

- large-scale climatic variability
- environment/recruitment relationships in eastern boundary current ecosystems
- mesoscale (smaller scale) processes affecting coastal circulation and fisheries recruitment

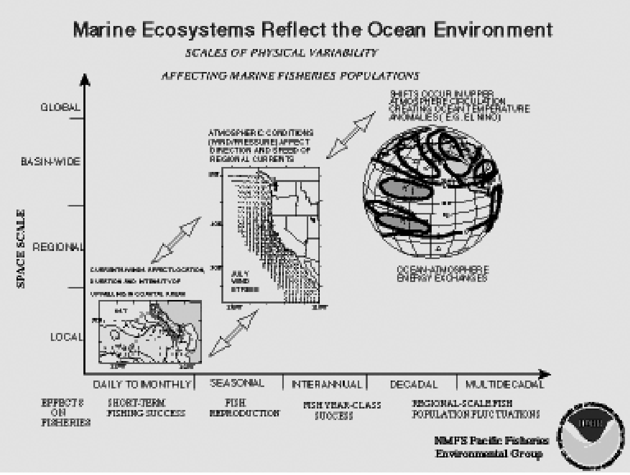
Examples of research on the large-scale variability include studies of recurring temperature changes off the west coast of the U. S. and their effects on groundfish recruitment, and the investigation of environmental changes in the California Current region associated with recent ENSO events. Much of the mesoscale research focuses on relating environmental variability on day-to-year and 5–100 nm scales to patterns and events in the life history of groundfish (e.g., recruitment success). The physical oceanography research program is linked closely to those of the other tasks at PFEG and to research programs at the other SWFSC labs. PFEG scientists also are involved in numerous cooperative studies with oceanographers and fisheries scientists at many federal and state government, academic and privately supported research institutions.



PFEG's Analysis of COADS Data Shows that the Ocean Environment Changes on Broad Time-Space Scales

- Many features vary on decadal time scales
  - Changing thermal conditions may be coastwide or spatially distinct
- Resources respond to both temporal and spatial variations

NMFS Pacific Fisheries Environmental Group



Marine Ecosystems Reflect the Ocean Environment

SCALES OF PHYSICAL VARIABILITY AFFECTING MARINE FISHERIES POPULATIONS

NMFS Pacific Fisheries Environmental Group

Expertise in physical oceanography at PFEG and the linkages to the Navy's Fleet Numerical Meteorology and Oceanography Center (FNMOC) and Naval Postgraduate School, as well as numerous other government, academic, and private research facilities, has historically meant that this task serves regionally, nationally and internationally as a resource to other ocean scientists. Within the SWFSC, many cooperative research programs have been developed and planned. As an example, the task provides physical oceanographic expertise to the Tiburon Laboratory Rockfish Recruitment surveys each spring, to relate ocean variability off central California to rockfish recruitment. PFEG physical oceanographers are asked frequently to attend workshop and present seminars as experts on environmental-fishery linkages, and represent SWFSC, NMFS and NOAA on numerous committees and working groups.

COASTAL WATER POLLUTANTS

Upadhyayula V. K. Kumar
Choa Chu kang Ave-4
Singapore

POLLUTANT INPUT INTO THE MARINE ENVIRONMENT

Among all the diversity of human activities and sources of pollution, we can distinguish three main ways that pollutants enter the marine environment:

- direct discharge of effluents and solid wastes into the seas and oceans (industrial discharge, municipal waste discharge, coastal sewage, and others);
- land runoff into the coastal zone, mainly from rivers;
- atmospheric fallout of pollutants transferred by the air mass onto the sea surface.

Certainly, the relative contribution of each of these channels to the combined pollution input into the sea will be different for different substances and in different situations. At present, the signs and consequences of human activity can be found everywhere on Earth. One of the typical features of marine pollution is global spreading of a number of contaminants. Numerous data undoubtedly indicate the existence of a large-scale (global) field of background contamination of the hydrosphere.

Another important feature of marine pollution is the existence of increased pollution levels in the enclosed seas and coastal waters, compared with the open ocean.

Contamination levels also increase during the transition from the southern parts of all oceans to the north, where the main industrial centers and main pollution sources are concentrated. Besides the general distribution pattern of pollution sources, there are two other factors explaining the relative stability of global pollutant distribution in the world ocean: the relative confinement of large-scale water circulation within the limits of each hemisphere and the predominance of the zonal transport of the traces in the atmosphere.

Another distinctive and repeatedly registered feature of the general picture of contaminant distribution in the marine environment is their localization at the water–atmosphere and water–bottom sediment boundaries. Practically everywhere and for all trace components (primarily for oil hydrocarbons), their concentrations are considerably (usually hundreds and thousands of times) higher in the surface microlayer of water and in the upper layer of bottom sediments. These boundaries provide the biotopes for the communities of hyponeuston and benthos, respectively.

The existence of elevated levels of contaminants in zones of high bioproductivity is extremely alarming ecologically. These zones include the water layer up to 100 m from the water surface (photic layer) and boundaries of natural environments (water–atmosphere and water–bottom sediment, as previously mentioned), as well as enclosed seas, estuaries, and coastal and shelf waters. In particular, in shelf and coastal zones, which occupy 10% of the world ocean surface and less than 3% of its volume, the most intense processes of bioproduction, including the self-reproduction of the main living resources of the sea, take place. The main press of anthropogenic impact is also concentrated here.

The number and diversity of pollution components is growing as well. Contaminants that are globally distributed are combined here with hundreds and thousands of ingredients of local and regional distribution. Most of these substances are wastes and discharges from different local industries and activities.

Based on the extreme diversity of marine pollution components, the variety of their sources, the scales of distribution, and the degree of hazards, these pollutants can be classified in different ways, depending on their composition, toxicity, persistence, sources, volumes, and so on.

TYPES AND FORMS OF WATER POLLUTION

Water pollution is attributed to various sources and can be broadly divided into three categories: domestic, industrial, and radioactive wastes, which can be categorized in the following forms: (1) thermal pollution; (2) the addition of pathogenic organisms, leading to public health hazard; (3) oil pollution; (4) the addition of inert, insoluble mineral material; (5) the addition of biodegradable organic material that will result in the depletion or complete removal of dissolved oxygen; (6) toxicity due to the presence of synthetic organic compounds and salts of heavy metals; (7) enhanced eutrophication; (8) acid deposition or discharges; and (9) radioactivity.

Domestic Sewage

The objectionable features of domestic sewage are its population of pathogenic bacteria; its high content of organic matter, which gives it a high oxygen demand; its nutrient content, which gives it the potential of supporting large populations of algae and other plants, which in turn may be as objectionable as the sewage itself; and the obvious aesthetics. The first and last of these can be overcome by proper treatment in biological sewage treatment plants, but the effluent from these plants is generally rich in nutrients. So, the effluent discharged into nearby inshore waters may result in large objectionable weed crops and other plants. An additional difficulty of disposing of domestic sewage and even the effluents from sewage treatment plants in the sea is that the density of the sewage is invariably less than that of seawater. Thus, the sewage tends to float on the surface unless introduced in a region of strong currents, will mix with seawater, and is diluted only slowly.

Industrial Wastes

These can be highly varied in composition and present a variety of special problems. The wastes may be toxic to plants or animals. They may be highly acidic or basic. If they contain large quantities of organic matter, their BOD may be objectionably high. Surface-active ingredients such as detergents may cause objectionable foaming or disrupt normal bacterial populations. The settable chemicals tend to settle to the seabed, react with mineral content there, and change the entire infrastructure of the seabed itself, which is causing accumulation of heavy metals in the sediments of several seas.

Pathogens

A variety of pathogenic organisms, including viruses, bacteria, protozoa, and parasitic worms, exist in seawater and can cause diseases in plants, animals, and people. Impacts include human illness, seafood contamination, and recreational beach closures. Pathogens are discharged to coastal waters through both point and nonpoint sources, especially from insufficiently treated sewage that is released from septic systems on land and on ships and from agriculture and storm water runoff. Higher concentrations tend to occur after storms and related overflow of sewer systems, making it difficult to interpret trends and temporal fluctuations.

Nutrients

Important parameters for monitoring nutrient pollution in coastal waters include the following: nitrogen and phosphorus concentrations, maximum bottom dissolved oxygen levels, extent and duration of anoxic and hypoxic conditions, extent of SAV, chlorophyll-*a* concentrations, turbidity, and duration and extent of algal blooms (by type). Some parameters are important in assessing the vulnerability of an area to pollutants, such as nitrogen and phosphorus, or in determining baseline conditions of the area.

Oil

Petroleum residues can contaminate marine and coastal waters through various routes: accidental oil spills from tankers, pipelines, and exploration sites; regular shipping and exploration operations, such as exchange of ballast water; runoff from land; and municipal and industrial wastes. Although the main global impact is due to tar balls that interfere with recreational activities at beaches, the impact of petroleum hydrocarbon concentrations on marine organisms in the neuston zone in the ocean—particularly fish eggs and larvae—requires more attention. Large-scale oil spills from tankers often make the headlines; yet, nonpoint sources, such as regular maritime transportation operations and runoff from land, are actually considered the main contributors to the total oil discharge into the ocean, although conclusive statistics are lacking. Runoff and routine maintenance of the oil infrastructure, it is estimated, account for more than 70% of the total annual oil discharge into the ocean. Both the number and amount of *accidental* oil spills have been monitored and seem to have declined in the past decade. A single catastrophic event can, however, influence the statistics significantly *and* have a localized, yet tremendous impact on the ecosystem.

Tables 1 and 2 show the variety of oil pollution sources and give expert estimates of the scales of distribution and impact of each of these sources on the marine environment. Even though these estimates can vary up to one to two orders of magnitude (especially for natural oil sources, atmospheric input, and river runoff), the main anthropogenic flows of oil pollution into the marine environment come from land-based sources (refineries, municipal wastes, and river runoff) and transportation activity (tanker oil transportation and shipping). Polycyclic aromatic hydrocarbons (PAHs),

Table 1. Sources and Scale of Oil Pollution Input Into the Marine Environment

	Environment		Scale of Distribution and Impact		
Types and Source of Input	Hydrosphere	Atmosphere	Local	Regional	Global
Natural:					
Natural seeps and erosion of bottom sediments	+	−	+	?	−
Biosynthesis by marine organisms	+	−	+	+	+
Anthropogenic:					
Marine oil transportation (accidents, operational discharges from tankers, etc.)	+	−	+	+	?
Marine nontanker shipping (operational, accidental, and illegal discharges)	+	−	+	?	−
Offshore oil production (drilling discharges, accidents, etc.)	+	+	+	?	−
Onland sources: sewage waters	+	−	+	+	?
Onland sources: oil terminals	+	−	+	−	−
Onland sources: rivers, land runoff	+	−	+	+	?
Incomplete fuel combustion	−	+	+	+	?

Note: +, −, and ? mean, respectively, presence, absence, and uncertainty of corresponding parameters.

especially benzo(a)pyrene, enter the marine environment mostly from atmospheric deposition.

Table 2 illustrates the general trend of declining total input of oil pollution into the world ocean over the years. The global situation reflected in this table certainly may differ at the regional level, which depends on natural conditions, the degree of coastal urbanization, the population density, industrial development, navigation, oil and gas production, and other activities. For example, in the North Sea, offshore production input reached 28% of the total input of oil pollution in last decade, instead of the "modest" 2% on the world scale shown in Table 2, which equaled the annual input of more than 23,000 tons of oil products at the background of their general changeable flow of 120,000–200,000 tons a year in the North Sea. One can expect similar situations in other regions of intensive offshore oil and gas development, for example, in the Gulf of Mexico, Red Sea, Persian Gulf, and Caspian Sea. The persistent pollution in oil production areas in the Caspian Sea or the amounts of annual discharges (about 40 million tons of produced waters polluted by oil products) during offshore drilling in the Gulf of Mexico. At the same time, no reliable balance estimates exist for these regions.

The continental shelf of the Gulf of Mexico is also distinctive for intense seepage of natural liquid and gaseous hydrocarbons, which can lead to formation of oil slicks and tar balls on the sea surface, which makes assessing and identifying anthropogenic oil pollution more difficult. In any case, the input of oil hydrocarbons from natural sources into the Gulf of Mexico is larger than in many other areas.

In the Baltic Sea, the Sea of Azov, and the Black Sea, the leading role in oil input most likely belongs to land-based sources, which are dominated by river inflow. The Danube River alone annually brings about 50,000 tons of oil to the Black Sea, half of the total oil input of about 100,000 tons.

Observations in the Caribbean basin, where annually up to 1 million tons of oil enter the marine environment, showed that about 50% of this amount came from tankers and other ships. In the Bay of Bengal and the Arabian Sea, oil pollution inputs from tanker and other ship discharges equal, respectively, 400,000 tons and 5 million tons of oil a year. The most intense tanker traffic exists in the Atlantic Ocean and its seas, which accounts for 38% of international maritime oil transportation. In the Indian and Pacific Oceans, this portion is, respectively, 34% and 28%.

Enforcing stricter requirements on activities accompanied by oil discharges led to a global decline of oil pollution inputs in the marine environment mentioned before. A number of dramatic events show the vulnerability of making an optimistic prognosis about decreasing oil pollution at the regional and global levels. For instance, catastrophic large-scale events took place in the Persian Gulf during and after the 1991 Gulf War. Between 0.5 and 1 million tons of oil were released into coastal waters. Besides, products of combustion of more than 70 million tons of oil and oil products were emitted into the atmosphere. Another large-scale accident occurred in Russia in September–November 1994. About 100,000 tons of oil were spilled on the territory of the Komi Republic, which threatened to cause severe oil pollution for the Pechora River basin and, possibly, Pechora Bay.

It must be remembered that catastrophes, in spite of the obvious consequences and all the attention they attract, are inferior to other sources of oil pollution in their scales and degree of environmental hazard. Land-based, oil-containing discharges and atmospheric deposition of products of incomplete combustion can accordingly give 50% and 13% of the total volume of oil pollution input into the world ocean (see Table 2). These diffuse sources continuously create relatively low but persistent chronic contamination across huge areas. Many aspects of the chemical composition and biological impacts of these contaminants remain unknown.

Persistent Organic Pollutants

Persistent organic pollutants (POPs) consist of a number of synthetic compounds, including industrial polychlorinated biphenyl's (PCBs); polychlorinated dioxins and furans; and pesticides, such as DDT, chlordane, and heptachlor, that do not exist naturally in the environment. A number of POPs often persist in the environment and accumulate through the food chain or in the sediment to a toxic level that is directly harmful to aquatic organisms and humans.

The marine environment collects contaminants from the air, but also from ocean currents, rivers discharging into the ocean, and sea ice that transports POP-laden particles.

Figure 1 presents some examples of contaminant levels in seawater. Hexachlorocyclohexane dominates the picture, except for Russian waters where PCB levels are high, up to 15 nanograms per liter in the Kara Sea. These high levels seem to mirror the high input of PCBs from Russian rivers.

Levels in seawater can also be used to shed light on the mechanisms that transport contaminants to the Arctic. Detailed measurements in the Bering and Chukchi Seas show that hexachlorocyclohexane levels in the water increase along a south–north gradient, which has been suggested as evidence for a cold-condensation theory; those semivolatile contaminants condense out of the atmosphere as temperatures drop. Less volatile contaminants, such as PCBs, DDT, and chlordane, were present at lower levels in the Bering and Chukchi Seas than in more temperate latitudes.

Concentrations of organic contaminants in Arctic marine sediments are, in general, extremely low compared with freshwater sediments, and are ten to a hundred times lower than in the Baltic Sea. The most apparent geographic trends are that concentrations of PCBs, hexachlorocyclohexane, and hexachlorobenzene are higher closer to the shore along the Norwegian coast than in the open sea. They are also higher in gulfs and river mouths along the Russian coast and around Svalbard.

Heavy Metals

Heavy metals exist naturally in the environment, and it is sometimes difficult to distinguish variations developing from anthropogenic inputs and those from the

natural hydrologic cycle and the atmosphere. Among the trace metals commonly monitored are cadmium, copper, mercury, lead, nickel, and zinc. When they accumulate through the food chain at moderate to high concentrations, some of these metals can affect the human nervous system.

The marine environment receives heavy metals from atmospheric deposition, river runoff, and local pollution. The relative importance of these sources will differ between regions. For example, rivers carrying metal-laden sediments deposit almost their entire load in the shelf seas, and only a minor portion reaches the deep ocean. Natural sources of metals are important and, in many cases, it is found that they are the main source to the marine environment.

Mining has contaminated ocean waters with several heavy metals. One documented example is in the fjord outside the Black Angel zinc mine in Greenland, where the levels of lead in the bottom water are up to 200 micrograms of lead per kilogram of water. These high lead levels are also reflected in seaweed, blue mussels, prawns, and in some fish; in capelin, lead levels are up to 5 micrograms per gram in the bone. However, no one has been able to document any biological effects in the fish. Cadmium levels in the water are also high, up to 2.5 micrograms per kilogram of water; but in contrast to lead, the animals in the fjord have cadmium levels close to background.

The cryolite mine in Ivittuut in southern Greenland has also contaminated the nearby water. Lead levels of 18 micrograms per kilogram of water have been measured. At Strathcona Sound in northern Baffin Bay, a lead-zinc mine has released lead, making concentrations in the fjord water one to two orders of magnitude higher than background concentrations in the open ocean. Some of the lead has also been taken up by seaweed and crustaceans. Outside a lead-zinc mine in east Greenland, shorthorn sculpins also have elevated levels of lead, whereas the fish outside the cryolite mine on southern Greenland have not been affected.

The mines at Ivittuut and Strathcona Sound have also contaminated their respective fjords with cadmium, but the levels are much lower than those outside the Black Angel mine. At these sites, the cadmium is not affecting the local sediment, nor are elevated levels found in nearby plants and animals.

Metal levels in Arctic Ocean water away from local sources are generally similar to global background levels. Today's global lead concentrations in oceans are generally more than ten times higher than those in prehistoric times. The levels are consistently higher in surface waters than in deeper layers. One might expect the lead levels in the upper Arctic sediments to mirror this increased long-distance transport, but this does not seem to be the case.

Recent seawater analyses from Pechora Bay and Kara and Laptev Seas show very high lead levels, ranging from 0.16 to 0.5 micrograms per kilogram of water. However, these data require confirmation before any conclusions are drawn.

Filter-feeders such as mussels take up lead from sediment particles. The concentration increases slightly with increasing shell length, indicating a moderate accumulation as the mussel ages. However, lead levels are low in crustaceans as well as in fish. The highest levels, 0.05 micrograms per gram of liver, have been recorded in Orkdalsfjorden in Norway.

Lead does not seem to accumulate in fish-eating birds or in marine mammals. In general, levels in marine mammals are low.

Cadmium Levels are High in Marine Biota. Cadmium levels in seawater fall within what could be considered natural background levels. Moreover, there is no indication from sediments that the levels have increased from preindustrial times, nor have temporal trends been detected.

An interesting phenomenon relating to cadmium is that its concentration increases farther away from the coast,

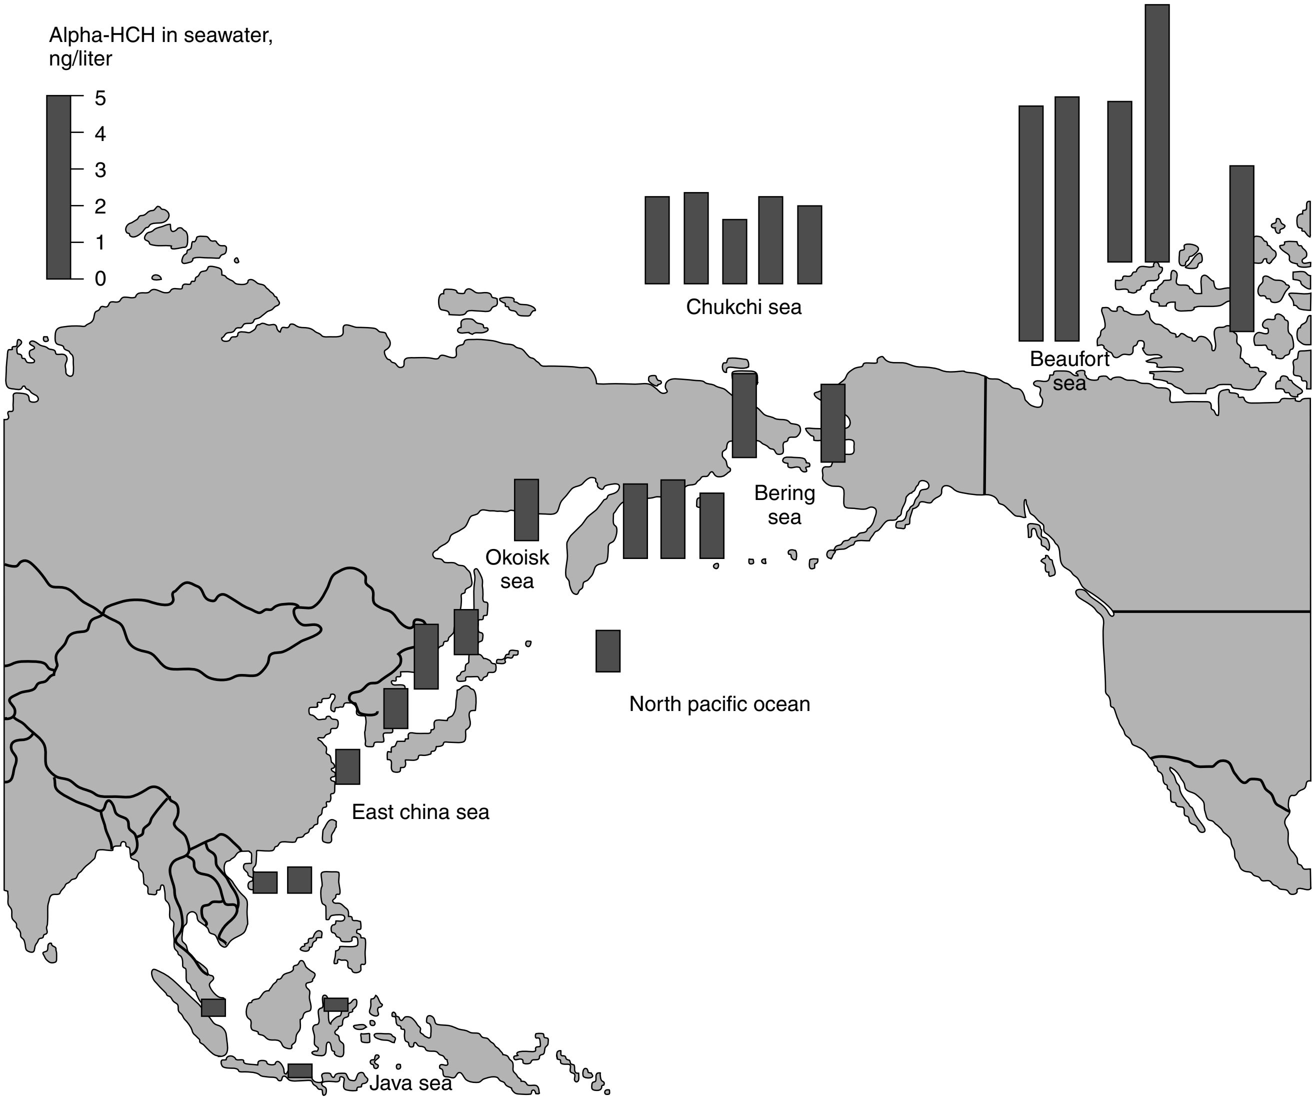

Figure 2. Alpha-hexachlorocyclohexane concentration in seawater increases from south to north, illustrating the cold-condensation effect (1).

which is probably connected with the change in salinity of the water. The result is that cadmium levels in both plants and animals are higher in the open ocean than in the inner region of large fjords, even when there are local sources contaminating the water. Cadmium accumulates with age in mussels and crustaceans. In general, the levels in crustaceans are higher than global background levels but show large variations.

Mercury levels are high and may be increasing. Several sets of data indicate that mercury levels are higher in the upper layers of Arctic marine sediments than in the layers representing preindustrial inputs see the upper right diagram of Fig. 3. Mercury is enriched even in the marine sediments taken at the North Pole. Natural processes may have caused these profiles, but they could indicate that human activities have increased the environmental mobility of existing stores of mercury.

Radioactive Wastes

These can somewhat be divided into high and low level wastes, depending on their activity. Radioactive wastes are characterized by losing their radioactivity with time. Some nuclides lose it quickly; others very slowly. A second consideration is that radioactive elements will enter the biological cycle and therefore the food web. High level radioactive wastes pose a complex problem in their disposal; the low level has been and is being disposed of directly in the sea. Reprocessing plants have added radionuclides to the sea.

Spent nuclear fuel is often processed to recover plutonium. Water used in reprocessing contains a mix of different radionuclides, and some of this contaminated water has been released routinely into the sea. In Europe, three reprocessing plants are relevant to the Arctic because of transport of radionuclides by ocean

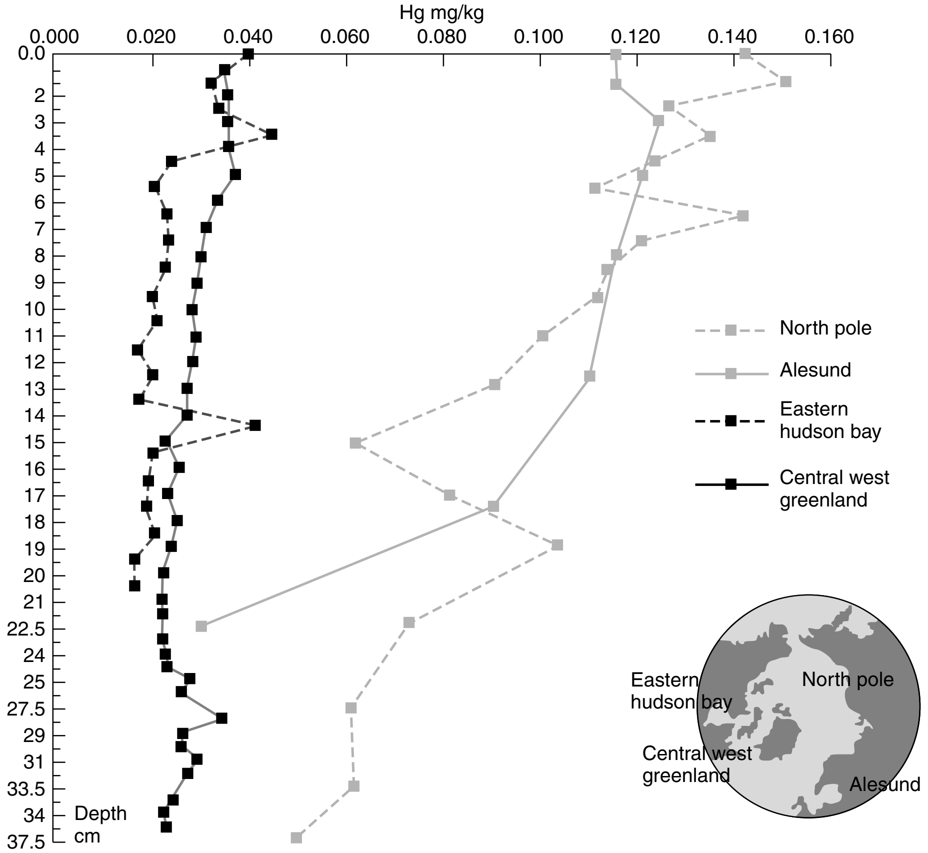

Figure 3. Mercury concentration at different depths in marine sediment cores (1).

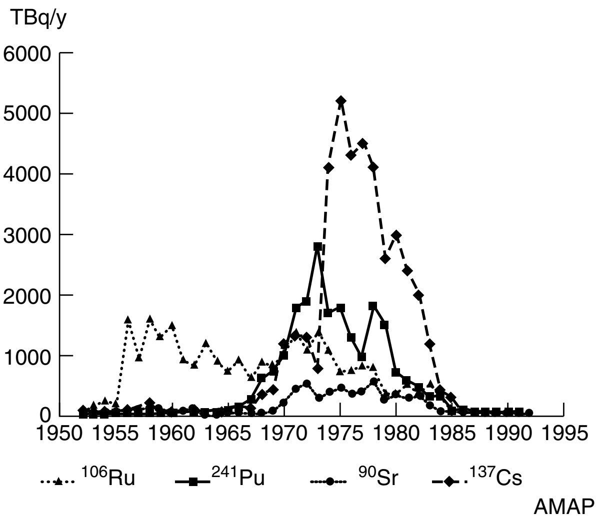

AMAP

currents: Sellafield (formerly Windscale) in Cumbria on the northwest coast of England; La Hague near Cherbourg, France; and Dounreay in northeast Scotland. Sellafield has been the most important source of radionuclides to the Arctic marine environment because of the scale of its discharge. The effluent has been released into the sea and carried north by ocean currents. The releases, which started in 1952, are well documented. Figure 4 indicates the rates of liquid discharges from 1952 to 1992. Cesium-137 dominates. The peak of the release for most radionuclides was in the mid-to-late 1970s.

Underwater Weapon Tests Have Contaminated Chernaya Bay. Chernaya Bay is a fjord inlet, connected to the Barents Sea, on the southwestern coast of Novaya Zemlya. The former Soviet Union used the bay to conduct underwater tests of nuclear bombs in 1955 and 1957 and in the vicinity of the bay in 1961. As a result of these detonations, the bottom sediments of the bay are contaminated by elevated levels of radioactive plutonium and cesium, as well as other radioactive isotopes. However, the mobility of radionuclides in sediment is low and may at present cause only insignificant exposure of people. Exposure of biota is unknown.

Today, the inventory of plutonium in Chernaya Bay is similar to other sites of major plutonium contamination, such as the most contaminated areas of Bylot Sound (where a B-52 bomber crashed) and the Irish Sea in the vicinity of the Sellafield reprocessing plant.

Three underground nuclear detonations were carried out by the United States on Amchitka Island in the Aleutian Islands in 1965, 1969, and 1971. These detonations caused radioactive contamination of deep groundwater and rock around the shot cavities. Long-term monitoring activity is planned for this site to 2025. In 1996, above-ground radioactive contamination was detected at the site.

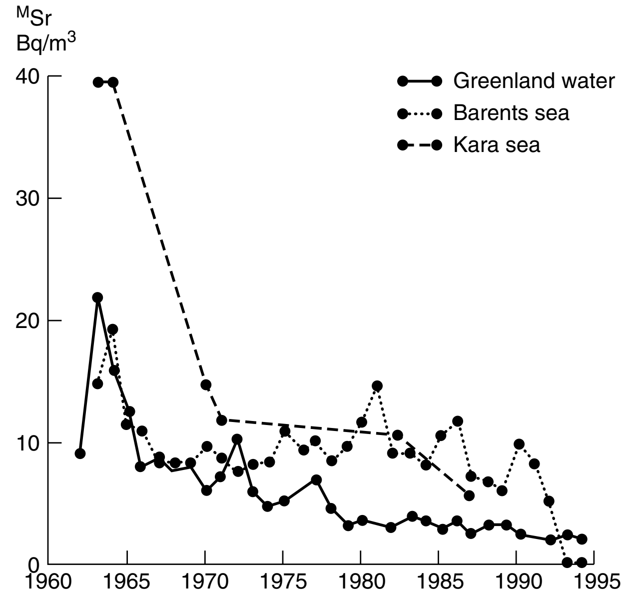

Figure 5. Time trends of activity concentrations of strontium-90 in seawater.

A major direct input of radionuclides into the marine environment has been from European nuclear reprocessing plants, particularly Sellafield on the shore of the Irish Sea. Currents transport the material along the Norwegian coast and into the Arctic Ocean. After 6 to 8 years, some of the contamination leaves the Arctic by way of the East Greenland Current, but much of it stays in the Arctic Basin much longer.

Environmental radiocesium levels have been measured since the early 1970s. As can be seen in Fig. 6, the releases of cesium-137 from Sellafield are virtually mirrored in the levels found in the Barents Sea after a transport time of 4 to 5 years. The peak in concentration in the early 1980s is probably the highest level that has ever occurred in that area of the ocean. The Chernobyl accident in 1986 added cesium to the Arctic Ocean and continues to do so via outflow from the Baltic Sea. Figure 6 shows the recent levels of cesium-137 in seawater around the Arctic. Strontium-90 has been measured in surface seawater collected around Greenland and the Barents Sea; see Fig. 5. During the past 35 years, levels in the waters around Greenland have decreased, approximately half was removed or decayed every 13.5 years. This value is probably representative of the Arctic Ocean as a whole. The highest levels of cesium-137 in people were recorded in the mid-1960s; see the Fig. 6. For the following 20 years, the human body burden decreased by a factor of 3 to 7. However, in 1986, the Chernobyl fallout changed the trend in areas directly affected by the accident.

Assessment of Receiving Waters

The effects of the ocean waste disposal are the result of a complex relation between two variables, concentration and time. The effect of the oceanic environment on the effluent is of critical significance. After discharge to the ocean, the effluent experiences changes in its physical and microbiological properties, which vary, each point as a function of time. An accurate prediction of pollution conditions or environmental impact depends on knowledge of the oceanographic conditions in the area. These conditions vary in time and space. A significant and representative quantitative judgement requires refined statistical analysis. A statistical description of receiving coastal waters should be based on adequate observation of an entire area for a sufficiently long period of time (at least 1 year). The factors operating should be recorded simultaneously to provide a comprehensive picture of the physical and microbiological properties of the area. The data collected should enable probability distributions of the variables to be derived to select a coherent and suitable set of design parameters. Continuous and periodic records should be taken to cover all typical oceanographic conditions at stations strategically located at different sites and should record the following:

(1) Currents (direction and speed) distributed in time/space to permit a comprehensive study of coastal water circulation patterns.
(2) A continuous record of tides and winds in the area.
(3) The density field obtained from time and space distribution of salinity and temperature enabling the stratification conditions of the coastal waters to be determined.
(4) The waves recorded periodically, covering the most critical conditions and enabling a probability distribution of the wave characteristics (height, period, and direction) to be derived for structural design.
(5) Periodic dispersion and diffusion experiments using dye tracers.
(6) Simultaneously with the oceanographic survey a program on bacterial concentration decrease should be carried out, covering typical oceanographic conditions. The experiments should be made *in situ*,

preferably in the existing continuous sewage field. Simultaneously sampling for bacteria and dye tracer direction will enable bacterial die-off rates and dilution to be investigated and the derivation of bacterial concentration decrease from both these effects. During concentration decrease experiments, the water temperature, solar radiation, and other climatic data should be collected.

Mainly tides and winds, to a lesser controlled extent by the density field, govern coastal currents near the shore. A comprehensive study of coastal circulation requires a continuous record of winds and tides and simultaneous measurements of vertical profiles of temperature, salinity, and currents. A detailed vector statistical analysis of the current field is an important requirement. The seasonal or climatological associations between oceanographic and meteorological data and *in situ* bacterial assays are of paramount importance; their interactions determine major design parameters. Statistical analysis of the sewage field is required to predict the seasonal variations in initial dilution and final height of the rise. This analysis should be based on simulations of alternative diffuser discharges at various density stratification conditions.

Oceanic Processes

To assess the oceanic equivalent dilution factors, the following formulations may be used.

Initial Dilution. The initial dilution, RI, and terminal rise height, Y_m, were estimated, assuming that the diffuser is a finite line source of buoyancy flux only, by the equation

$$\mathrm{RI} = \mathrm{FI} \cdot Y_m$$

where $\mathrm{FI} = f(F,\theta)U/q$; in which $f(f,\theta)$ is an experimental factor, which depends on θ and a type of Froude number $F = u3/B$. The current and density stratification are the oceanographic variables that directly interface in the initial dilution. We may consider a critical stratification condition in which this interface extends to a constant depth and the dilution layer increases linearly with the bottom slope according to a relation of the type $Y_m = a + b(x - x_0)$, where x is the distance from a horizontal plume perpendicular to the shore. The subsequent dilutions RM, represent a minor part of the overall receiving water reductions. Thus the total physical dilution can be evaluated as $\mathrm{RF} = \mathrm{RI} \cdot \mathrm{RM}$,

$$\mathrm{RF} = \mathrm{FI}(1 + \mathrm{FM}x)[a + b(x - x_0)]$$

All soluble pollutants experience this composite dilution factor. Small particulate matter will also disperse proportionately. Floatable matter may disperse to a lesser extent, remaining visually detectable and liable to be carried to shore by currents and surface winds. The removal of this material is required, and an initial dilution of 100 is required to provide sufficient emulsification for these materials.

Dilution Equivalent to Bacterial Concentration Decreases. Most experiments on bacterial concentration decrease have been shown to fit Chick's law very satisfactorily. $C(t) = C_0 \cdot 10 - t/T90$, where C_0 = coliform concentration at the origin, and T_{90} = time required for 90% reduction. Thus the dilution equivalent to the concentration decrease may be computed directly from

$$\mathrm{RB} = C_0/C(x) = 10'x/X_{90}$$

where $X_{90} = u \cdot T_{90}$ = distance required for the coliform concentration reduction of 90%.

Dilution Equivalent to Sedimentation. The disappearance rate of coliforms due to sedimentation of solids depends on the degree of removal in the treatment plant. Data collected by experts revealed the fact that T_{90} values decrease as the effluent TSS increases. Therefore, sedimentation effects are already incorporated in the field experimental results for the concentration decrease.

Dilution Equivalent to Treatment. The relation between removal rates and corresponding factor RT is $\mathrm{RT} = 100/[100 - T\ (\%)]$.

Dilution Equivalent to Disinfection. The dilution equivalent to disinfection is evaluated by the equation $\mathrm{RD} = 1/\mathrm{rd}$, where rd is the bacteria reduction factor. Chlorination of less treated sewage produces organic chlorine compounds, which are toxic and deleterious to the environment. Therefore, chlorination may compromise the already recognized ecologically beneficial effects of enrichment of coastal waters by the supply of nutrients and organic matter from those effluents.

Overall Equivalent Dilution. Assuming that $\mathrm{RS} = 1$, the overall equivalent dilution can be evaluated by the equation

$$\mathrm{R}_{\mathrm{total}} = \mathrm{RT} \cdot \mathrm{RD} \cdot \mathrm{RI} \cdot \mathrm{RM}(x) \cdot \mathrm{RB(x)}$$

$$\mathrm{R}_{\mathrm{total}} = \mathrm{RR} \cdot f(F,\theta)(bu/q)[a + b(x - x_0)] \cdot [1 + (KL/b_o)x] \cdot 10'x/u \cdot T_{90}$$

For a given set of parameters, $R_{\mathrm{total}} = \mathrm{CE/CP}$, Q and the oceanic parameters are $u(u,\theta), T_{90}$ and KL are the total equivalent approximation, a linear function of the diffuser length and an exponential quadratic function of the outfall length.

The Effect of Current. Separating the current factors including the current speed u from the above equation, a dilution function may be defined as $Fu = u \cdot 10'x/uT_{90}$, which represents the effect of current on overall oceanic dilution. The figure given shows curves of Fu as a function of u for the various values of the parameter $u_{90} = x/T_{90}$, that is, the velocity for a 90% concentration decrease. It may be seen that the curves show "inflections" that have been connected by the line. The inflection increases as u_{90} decreases or as T_{90} increases. This inflection divides the graph into two domains:

The initial dilution domain (linear)

The concentration decrease dilution factor dilution factor domain (exponential).

For strong currents, the initial dilution is the dominant factor, and for a given T_{90}, the only way to increase Fu is by initial dilution mixing depth, which can be attained by increasing the outfall length. For light currents, the dilution factor equivalent to die-off dominates.

Thus, the current data is collected, as it is useful in the design in

1. analysis of coastal circulation hydrodynamics;
2. prediction of initial dilution;
3. prediction of far field dilution and transport;
4. Prediction of waste field impaction probability.

Thus, a comprehensive oceanographic study is necessary to describe the characteristics of the receiving waters. Therefore, an adequate program of oceanographic investigation *in situ*, including bacterial concentration decrease, is obligatory.

The existence of elevated levels of contaminants in zones of high bioproductivity is extremely alarming ecologically. These zones include the water layer up to 100 m from the water surface (photic layer) and boundaries of natural environments (water–atmosphere and water–bottom sediment, as previously mentioned) as well as enclosed seas, estuaries, and coastal and shelf waters. In particular, in shelf and coastal zones, which occurs in 10% of the world ocean surface and less than 3% of its volume, the most intense processes of bioproduction, including self-reproduction of the main living resources of the sea, take place. The main press of anthropogenic impact is also concentrated here.

EFFECTS OF POLLUTANTS ON MARINE HABITAT

To estimate the hazard of different pollutants, we should take into account not only their hazardous properties, but other factors, too. These include the volumes of their input into the environment, the ways and scale of their distribution, the patterns of their behavior in water ecosystems, their ability to accumulate in living organisms, the stability of their composition, and other properties, such as the extreme diversity of marine pollution components, the variety of their sources, the scales of distribution, and the degree of hazards. Pollutants can be classified in different ways, depending on their composition, toxicity, persistence, sources, volumes, and so on.

To analyze large-scale pollution and its global effects, it is common to distinguish groups of the most widespread pollutants, which include chlorinated hydrocarbons, heavy metals, nutrients, oil hydrocarbons, surface-active substances, and artificial radionuclides. These substances form the so-called background contamination that exists now any place in the hydrosphere.

Depending on the type of impact on water organisms, communities, and ecosystems, the pollutants can be grouped in the following order of increasing hazard:

- substances that cause mechanical impacts (suspensions, films, solid wastes) that damage the respiratory organs, digestive system, and receptive ability;
- substances that provoke eutrophic effects (e.g., mineral compounds of nitrogen and phosphorus, and organic substances) that cause mass rapid growth of phytoplankton and disturb the balance, structure, and functions of water ecosystems;
- substances that have saprogenic properties (sewage with a high content of easily decomposing organic matter) that cause oxygen deficiency followed by mass mortality of water organisms and appearance of specific microflora;
- substances causing toxic effects (e.g., heavy metals, chlorinated hydrocarbons, dioxins, and furans) that damage the physiological processes and functions of reproduction, feeding, and respiration;
- substances with mutagenic properties (e.g., benzo(a)-pyrene and other polycyclic aromatic compounds, biphenyls, radionuclides) that cause carcinogenic, mutagenic, and teratogenic effects.

Some of these pollutants (especially chlorinated hydrocarbons) cause toxic and mutagenic effects. Others (decomposing organic substances) lead to eutrophic and saprogenic effects. Oil and oil products are a group of pollutants that have complex and diverse composition and various impacts on living organisms—from physical and physicochemical damage to carcinogenic effects.

Discharge of heated waters can change the structure and function of coastal marine communities. Impacts of fly ash from coal-fired power plants, hot salty water, and residual chlorine are also important. Dumping of fly ash in coastal waters and into the atmosphere has caused severe impacts on spinner dolphins and mangroves in an area of the south coast of India, and has reportedly changed the number of species of plankton.

Effects of Marine Oil Spills

Oil spills can have a serious economic impact on coastal activities and on those who exploit the resources of the sea. In most cases, such damage is temporary and is caused primarily by the physical properties of oil creating nuisance and hazardous conditions. The impact on marine life is compounded by toxicity and tainting effects resulting from the chemical composition of oil, as well as by the diversity and variability of biological systems and their sensitivity to oil pollution.

Biological Effects of Oil. Simply, the effects of oil on marine life are caused by either the physical nature of the oil (physical contamination and smothering) or by its chemical components (toxic effects and accumulation leading to tainting). Marine life may also be affected by cleanup operations or indirectly through physical damage to the habitats in which plants and animals live.

The main threat posed to living resources by the persistent residues of spilled oils and water-in-oil emulsions ("mousse") is physical smothering. The animals and plants most at risk are those that could come into contact with a contaminated sea surface: marine mammals and reptiles; birds that feed by diving or form flocks on the sea; marine life on shorelines; and animals and plants in mariculture facilities.

The most toxic components in oil tend to be those lost rapidly through evaporation when oil is spilled. Because of this, lethal concentrations of toxic components leading to large-scale mortality of marine life are relatively rare, localized, and short-lived. Sublethal effects that impair the ability of individual marine organisms to reproduce, grow, feed, or perform other functions can be caused by prolonged exposure to a concentration of oil or oil components far lower than will cause death. Sedentary animals in shallow waters such as oysters, mussels, and clams that routinely filter large volumes of seawater to extract food are especially likely to accumulate oil components. Although these components may not cause any immediate harm, their presence may render such animals unpalatable if they are consumed by humans, due to the presence of an oily taste or smell, which is a temporary problem as the components that cause the taint are lost when normal conditions are restored.

The ability of plants and animals to survive contamination by oil varies. The effects of an oil spill on a population or habitat must be viewed in relation to the stresses caused by other pollutants or by any exploitation of the resource. In view of the natural variability of animal and plant populations, it is usually extremely difficult to assess the effects of an oil spill and to determine when a habitat has recovered to its prespill state. In recognition of this problem, detailed prespill studies are sometimes undertaken to define the physical, chemical, and biological characteristics of a habitat and the pattern of natural variability. A more fruitful approach is to identify which specific resources of value might be affected by an oil spill and to restrict the study to meeting defined and realistic aims related to such resources.

Impact of Oil on Specific Marine Habitats. Within each habitat, a wide range of environmental conditions prevails, and often there is no clear division between one habitat and another.

Plankton is a term applied to floating plants and animals carried passively by water currents in the upper layers of the sea. Their sensitivity to oil pollution has been demonstrated experimentally. In the open sea, the rapid dilution of naturally dispersed oil and its soluble components, as well as the high natural mortality and patchy, irregular distribution of plankton, make significant effects unlikely.

In coastal areas, some marine mammals and reptiles, such as turtles, may be particularly vulnerable to adverse effects from oil contamination because of their need to surface to breathe and to leave the water to breed. Adult fish that live in nearshore waters and juveniles in shallow water nursery grounds may be at greater risk to exposure from dispersed or dissolved oil.

The risk of surface oil slicks affecting the sea bed in offshore waters is minimal. However, restrictions on the use of dispersants may be necessary near spawning grounds or in some sheltered, nearshore waters where the dilution capacity is poor.

The impact of oil on shorelines may be particularly great where large areas of rocks, sand, and mud are uncovered at low tide. The amenity value of beaches and rocky shores may require the use of rapid and effective cleanup techniques, which may not be compatible with the survival of plants and animals.

Marsh vegetation shows greater sensitivity to fresh light crude or light refined products, although weathered oils cause relatively little damage. Oiling of the lower portion of plants and their root systems can be lethal, whereas even a severe coating on leaves may be of little consequence especially if it occurs outside the growing season. In tropical regions, mangrove forests are widely distributed and replace salt marshes on sheltered coasts and in estuaries. Mangrove trees have complex breathing roots above the surface of the organically rich and oxygen-depleted muds in which they live. Oil may block the openings of the air breathing roots of mangroves or interfere with the trees' salt balance, causing leaves to drop and the trees to die. The root systems can be damaged by fresh oil that enters nearby animal burrows; the effect may persist for some time and inhibit recolonization by mangrove seedlings. Protection of wetlands, by responding to an oil spill at sea, should be a high priority because physical removal of oil from a marsh or from within a mangrove forest is extremely difficult.

Living coral grows on the calcified remains of dead coral colonies, which form overhangs, crevices, and other irregularities, inhabited by a rich variety of fish and other animals. If the living coral is destroyed, the reef itself may be subject to wave erosion. The proportion of toxic components, the duration of oil exposure, as well as the degree of other stresses, largely determine the effects of oil on corals and their associated fauna. The waters over most reefs are shallow and turbulent, and few cleanup techniques can be recommended.

Birds that congregate in large numbers on the sea or shorelines to breed, feed, or moult are particularly vulnerable to oil pollution. Although oil ingested by birds during preening may be lethal, the most common cause of death is from drowning, starvation, and loss of body heat following damage to plumage by oil.

Impact of Oil on Fisheries and Mariculture. An oil spill can directly damage the boats and gear used for catching or cultivating marine species. Floating equipment and fixed traps extending above the sea surface are more likely to become contaminated by floating oil, whereas submerged nets, pots, lines, and bottom trawls are usually well protected, provided they are not lifted through an oily sea surface. Experience from major spills has shown that the possibility of long-term effects on wild fish stocks is remote because the normal overproduction of eggs provides a reservoir to compensate for any localized losses.

Cultivated stocks are more at risk from an oil spill: Natural avoidance mechanisms may be prevented in the case of captive species, and oiling of cultivation equipment may provide a source for prolonged input of oil components and contamination of the organisms. The use of dispersants very close to mariculture facilities is ill advised because tainting by the chemical or by the dispersed oil droplets may result.

An oil spill can cause loss of market confidence because the public may be unwilling to purchase marine products from the region, irrespective of whether the seafood is actually tainted. Bans on fishing and harvesting marine products may be imposed following a spill to maintain market confidence and to protect fishing gear and catches from contamination.

Mercury levels in marine animals, including bivalves and crustaceans, are generally low, whereas mercury seems to accumulate in fish. The highest values in fish are from northern Canada.

For seals and whales, concentrations often exceed 0.5 micrograms per gram of muscle, especially in older individuals. Livers from ringed seals in the western Canadian Arctic have very high levels of mercury; up to 205 micrograms per gram of liver have been measured. Levels in livers of bearded seals from the Amundsen Gulf are higher than those of both global background and other Arctic areas, as are mercury levels in toothed whales and polar bears. Some of the highest levels, 280 microgram per gram liver (wet weight), have been recorded in pilot whales from the Faroe Islands.

The effects of these mercury levels on the animals are difficult to assess, because some of the mercury may be inactivated by high selenium levels. Moreover, the scientific focus so far has been on tissues relevant for human consumption, and very little information is available on the target organs for mercury, such as the brain. There are no effect studies from the Arctic. However, even for the most exposed animal populations in the western Canadian Arctic and in Greenland, selenium should be abundant enough to protect against mercury poisoning.

Mercury is a major concern because the levels in some animals high in the food chain indicate that the environmental load may have increased in recent years. For example, mercury levels in ringed seals from western Canada show that they accumulated mercury about three times faster during the late 1980s and early 1990s than in the early 1970s. Similar increases have been seen in ringed seals from northwest Greenland taken in 1984 and 1994 and in beluga livers from the western Canadian Arctic. Interpreting these findings is difficult because natural variations that may affect the trends are unknown. Moreover, other data, such as those from Atlantic walrus and ringed seal from central-east Greenland, have not indicated any temporal trends. Very little information is available on temporal trends in Arctic marine fish, but measurements from the Baltic Sea from 1980 to 1993 seem to confirm observations that mercury levels are increasing.

The seas are being polluted by organic and inorganic wastes from sewage, from agricultural and industrial wastes, and from runoff containing oil, hydrocarbons, and heavy metals. All of these contribute to sediment runoff and increased turbidity. Siltation of coral regions is also caused by excessive deforestation and land clearing for commercial crops. Construction and land reclamation has caused changes in water circulation and has increased sedimentation. On the coral reefs, there has been extensive overexploitation of resources by heavy fishing pressure, including very destructive methods such as blasting, coral mining, and cyanide poisoning for live fish collection.

Industrial Pollution

Industrial pollutants that affect coral reefs include nutrients from sewage and organic matter, fertilizer runoff, detergents containing phosphorus, and thermal discharge—the heated water from the cooling systems of power plants and other industries. These all cause nutrient overload, the growth of aquatic plant life, and depletion of dissolved oxygen, or eutrophication, which retards coral growth by decreasing light penetration and changing the dynamics of fish assemblages. Other industrial pollutants include heavy metals and other toxic substances.

The coral reefs bordering major cities throughout Southeast Asia have been largely destroyed. Pollution from oil refineries and drilling platforms, it has been shown, kill reef fish and have negative effects on growth rates, recruitment, and feeding of corals. Thermal pollution from hot water discharge from industrial areas is an additional threat to reef species, many of them cannot withstand sudden and drastic increases in temperature.

Sedimentation. Land-based human activities often cause sedimentation, a major source of reef degradation. As more people move to coastal cities on the South China Sea, there has been a big increase in construction and land reclamation. Land reclamation and sedimentation have been particularly intensive in Singapore. Land was reclaimed by dumping sand and dirt directly onto coral reef flats and shallow water.

These add to the erosion of beaches and sediment runoff that smothers corals and leads to the degradation of a reef. Increased sedimentation also leads to a change in the composition of marine fauna, favoring more resilient species. Sedimentation also comes from soil erosion from unsound agricultural practices, mismanagement of watersheds, exploitation of mangroves, land reclamation and construction, oil drilling, and dumping of terrestrial and marine mine tailings.

Overfishing. Overfishing is a force extremely destructive to corals in the South China Sea. Densities of fish are greatly decreased by overfishing. Coral is damaged by destructive fishing techniques and by removal for trade. It is estimated that 10–15% of the total fish yield in the Philippines comes from coral reef fisheries.

Fishing degrades a reef in several ways. Destructive and illegal fishing methods are common, especially in the Philippines, Indonesia, and Malaysia. These methods include dynamite blasting and cyanide fishing. Overfishing not only depletes fish stocks of target species but also changes the dynamics of the entire reef. Decreases in herbivores can lead to algal blooms that overtop coral growth and can cause mass mortality.

Blooms of noxious algae have increased in the past 20 years worldwide and are being blamed on inputs of excess nutrients due to human activities. Some of these noxious algae produce powerful nerve toxins that can cause massive fish kills or even kill a person who unsuspectingly eats shellfish that was harvested from waters tainted with toxic algae. The case of the "Cell from Hell" now blooming in East Coast waters (North Carolina, Virginia, Maryland) is especially noteworthy. Until recently, *Pfiesteria* was only a curiosity of academic specialists. In the past few years, this organism has been blamed for fish kills unprecedented in their size and has been linked to neurological damage in people who worked or swam in these waters (memory loss, learning difficulties, and decreases in white blood cell content upward of 20% have been recorded in people who were exposed to *Pfiesteria*). Blooms of *Pfiesteria* have been linked to nutrient enrichment of coastal waters due to nonpoint pollution from agriculture. Nutrients in waters allow huge population increases of toxic organisms in water that were unknown or rare. The U.S. EPA has pledged to adopt new standards for nutrient inputs to waters.

It is hard to imagine an organism more bizarre than *Pfiesteria*. When no fish prey are present, it goes into a cyst form and settles to the bottom, lying dormant in the sediments. It can also emerge to form an amoeba that feeds on algae in the water column, and even can become a photosynthetic plankton-like organism, except that it "steals" the chloroplasts of algae from its algal prey and uses photosynthesis only to supplement its nutrient supply in the water column. In the presence of certain species of fish, however, it becomes a "monster" predator capable of mass fish kills. As a "predatory" dinoflagellate, it produces different types of toxins that do an incredible array of damage to fish. Some toxins attack internal organs. Another works on the fish immune system. And one toxin actually strips the skin off of the fish. Those who have witnessed the power of *Pfiesteria* report thousands of fish flopping and thrashing on the water surface, and fish actually beaching themselves, fleeing the water as if on fire.

SUMMARY

The introduction by man, directly or indirectly, of substances or energy into the marine environment (including estuaries) results in such deleterious effects as harm to living resources, hazards to human health, and hindrance to marine activities, including fishing, impairment of quality for use of seawater, and reduction of amenities. As the uses of coastal waters and the ocean have increased, pollution of the ocean waters has increased in turn. River pollution has also had an impact on the ocean as the rivers transport material to the ocean and, as a result, make it the ultimate sink for the world's waste.

The following chart summarizes the sources of wastes and their effects.

Sources and Effects of Marine Pollution.

Type	Primary Source/Cause	Effect
Nutrients	Runoff approximately 50% sewage, 50% from forestry, farming, and other land use. Also airborne nitrogen oxides from power plants, cars, etc.	Feed algal blooms in coastal waters. Decomposing algae depletes water of oxygen, killing other marine life. Can spur algal blooms (red tides), releasing toxins that can kill fish and poison people.
Sediments	Erosion from mining, forestry, farming, and other land-use; coastal dredging and mining.	Cloud water; impede photosynthesis below surface waters. Clog gills of fish. Smother and bury coastal ecosystems. Carry toxins and excess nutrients.
Pathogens	Sewage, livestock.	Contaminate coastal swimming areas and seafood, spreading cholera, typhoid, and other diseases.
Alien species	Several thousand per day transported in ballast water; also spread through canals linking bodies of water and fishery enhancement projects.	Outcompete native species and reduce biological diversity. Introduce new marine diseases. Associated with increased incidence of red tides and other algal blooms. Problem in major ports.
Persistent toxins (PCBs, heavy metals, DDT, etc.)	Industrial discharge; wastewater discharge from cities; pesticides from farms, forests, home use etc.; seepage from landfills.	Poison or cause disease in coastal marine life, especially near major cities or industry. Contaminate seafood. Fat-soluble toxins that bioaccumulate in predators can cause disease and reproductive failure.

Oil	46% from cars, heavy machinery, industry, other land-based sources; 32% from oil tanker operations and other shipping; 13% from accidents at sea; also offshore oil drilling and natural seepage.	Low level contamination can kill larvae and cause disease in marine life. Oil slicks kill marine life, especially in coastal habitats. Tar balls from coagulated oil litter beaches and coastal habitat. Oil pollution is down 60% from 1981.
Plastics	Fishing nets; cargo and cruise ships; beach litter; wastes from plastics industry and landfills.	Discarded fishing gear continues to catch fish. Other plastic debris entangles marine life or is mistaken for food. Plastics litter beaches and coasts and may persist for 200 to 400 years.
Radioactive substances	Discarded nuclear submarine and military waste; atmospheric fallout; also industrial wastes.	Hot spots of radioactivity. Can enter food chain and cause disease in marine life. Concentrate in top predators and shellfish, which are eaten by people.
Thermal	Cooling water from power plants and industrial sites.	Kills off corals and other temperature-sensitive sedentary species. Displaces other marine life.

TRACE ELEMENT POLLUTION

Bobby J. Presley
Texas A&M University
College Station, Texas

INTRODUCTION

All three words in the term “trace element pollution” need to be defined. Defining an element, that is a chemical element, is relatively straightforward. It is a substance consisting entirely of atoms having the same number of protons. All such substances are listed by name and symbol on the periodic charts of the elements found in many science textbooks. Definitions for “trace” and “pollution” are not so straightforward.

It is sometimes convenient to classify the chemical elements making up a complex substance or matrix into major, minor, and trace, based on their relative amounts (concentrations). Most authors designate those elements present in a matrix at one part per million or less by weight as trace elements. Although trace elements are in low concentration in the environment, they can be either essential or harmful to organisms, depending on the element and the circumstances.

A definition of pollution can be inferred from the widely accepted definition of marine pollution given by the United Nations Group of Experts on the Scientific Aspects of Marine Pollution (GESAMP). They say pollution is “the introduction by man, directly or indirectly, of substances or energy to the marine environment resulting in such deleterious effects as harm to living resources; hazards to human health; hindrance of marine activities including fishing; impairment of the quality for use of seawater; and reduction of amenities.” This definition can be applied to all environments, not just to the marine environment.

By the GESAMP definition, pollution must be harmful and must be caused by human activity. In some cases, it is easy to show both a human cause and harm to the environment. In other cases, one or both parts of the definition can be hard to prove. For example, it might be possible to show that the concentration of a trace element, such as mercury, is elevated above normal values in, for example, fish. It might be harder to show harm to the fish or to the consumer of the fish and it might be hard to show that the enrichment is because of human activity. In such a case, it might be better to say contamination has been documented, but not pollution.

ABUNDANCE, DISTRIBUTION, AND BEHAVIOR OF TRACE ELEMENTS

Trace elements occur naturally in the environment. Unlike pesticides, plastics, organic solvents, and other manufactured products, the mere presence of trace elements does not imply pollution, contamination, or even human activity. Sufficiently sensitive analytical techniques can detect some amount of all elements in almost any substance. To determine the amount accurately and precisely is, however, a challenge, and to decide what portion of the element is natural and what portion is because of human activity is an even bigger challenge.

In order to evaluate the significance of trace element occurrences in the environment, information is needed on:

1. Amounts (concentrations) in various compartments (air, soil, water, organisms, etc.).
2. Sources to the environment (both natural and human).
3. Transport mechanism and pathways between compartments (continents to oceans, water to organisms, etc.).
4. Transfer mechanism within compartments (shallow to deep water, fish gill surface to other organs, etc.).
5. Ultimate fate of the element (burial in sediments, mixing throughout the ocean, etc.).
6. Effect of the element on organisms (both short and long term).

As a first step in determining the significance of a given amount of a trace element in a particular environment, it is essential to know the ranges in concentration expected to occur naturally in various media (soil, water, organisms, etc.). Most trace elements were tied up in igneous rocks on the primitive earth. Table 1 gives average concentrations of selected elements in the uppermost part of the earth's crust along with data for organisms, soil, sediment, and water. These values can be considered to be "background" concentrations or at least concentrations not greatly influenced by human activity.

As igneous rocks "weather" to give soil and sediment some fraction of each element in the rock, it becomes dissolved in rivers, lakes, and the ocean. For most trace elements, however, a large fraction is retained in the solids during weathering. For this reason, the natural (background) trace element concentration in soils and sediments varies, depending on the igneous rocks they came from.

Many trace elements behave similarly during weathering, soil formation, erosion, and deposition. For example, fine-grained clay minerals become enriched in most trace elements and quartz sand and carbonate minerals become depleted. It is, therefore, important to have information on the grain size and mineralogy of soils and sediments when evaluating their trace element content. Thus, a given concentration, say 20 ppm Cu, might be background for a clay sediment but be contamination in a sand.

Reliable data on trace elements dissolved in rivers, lakes, and seawater is more difficult to produce than is data on rocks, soil, and sediment. Concentrations are generally a thousand or more times lower (Table 1), and this causes sensitivity and matrix interference problems for even the newest analytical instruments. It is also difficult to avoid contaminating samples with trace elements during

Table 1. Average Concentration of Selected Elements in Various Materials. Values for Sediment, Soil, Crust, Oysters and Fish are μg/g Dry Weight (ppm) Except Ca and Fe in Percent Dry Weight. Values for Water are μg/l (ppb)

Material	Ref.	As	Ba	Ca	Cr	Cu	Fe	Mn	Ni	Pb	V	Hg	Zn
Continental Crust	1	1.5	550	3.00	35	25	3.5	600	20.	20.	60	–	71
Gulf Coast Seds	2	6	–	–	44	10	1.8	330	16	15	–	0.050	60
Gulf Slope Seds	3	8.6	660	11.3	54	27	2.76	300	38	17	100	0.028	81
San Joaquin Soil	4	17.7		1.9	130	34.6		538	88	18.9	112	1.4	106
Sediment Criteria	5	55	–	–	145	390	–	–	50	110	–	1.3	270
Average Seawater	6	1.7			0.2	0.25	0.05	0.2	0.5	0.002	1.5	0.001	0.4
Miss. River Water	7		65			1.5	2.2	1.4	1.5	0.008	1.0		0.27
Seawater Criteria	8	69			1100	4.8			74	210		1.8	90
Fresh Water Criteria	9	340			16	13			470	65		1.4	120
Gulf Oysters	10	10.3			0.57	146	294	14.4	1.77	0.64		0.13	2150
Tuna Fish	11	3.8		100	0.75	2.8	72	0.6	0.5	0.5		4.1	17.4

collection, storage, and analysis. For these reasons, nearly all of the dissolved trace element data published before 1970, and much of the recent data, is unreliable. Much of the published data for both fresh and seawater is too high by factors of up to 100. Only data that has been produced by a lab using a well-documented quality assurance program should be accepted.

Trace element concentrations in organisms are generally intermediate between those in sediments and those in water. However, concentrations vary widely with the specie of organism and with the specific organ within organisms. Livers, for example are enriched in some elements and kidneys in others and some species of organisms are highly enriched in one or another trace element. Trace element concentrations in organisms can also change with season, life stage, health, food supply, etc. Thus, identification of abnormal trace element concentrations is difficult unless reliable data is available for the same organism over a wide area and/or over some time period.

Good general compilations of reliable trace element data for organisms are not as available as are those for soil and sediment. General guidance can be acquired from Furness and Rainbow (7) or similar publications. Many recent journal articles give trace element data for specific organisms from specific locations, but it is not always clear which are background levels.

In addition to natural sources, many different human activities can add trace elements to the environment. Mining and metal processing are classic sources of contamination, but other manufacturing, transportation, and waste disposal practices can also be important. In the United States, the EPA's "Superfund" program has spent many millions of dollars to clean up trace element contamination at dozens of sites around the country. The kinds of practices that led to this gross contamination are very rare today. Environmental regulations and public pressure have caused industry to greatly reduce trace metal releases to the environment. However, as the world population grows, the Earth's surface is increasingly disturbed by agriculture, petroleum production, forestry, urban development, civil conflicts, and war, all of which make trace elements more available for uptake by humans and other organisms.

As discussed above, numerous possible sources exist of trace elements to the environment. It is almost always difficult to determine which possible source is most important for any given element at any given location. Although it is important to identify the source of trace elements, their environmental impact depends not on source but on concentration and behavior. Behavior, including mobility, transport, transfer, and biological uptake, depends strongly on the chemical and physical form of the trace element. In this respect, the size of the trace element specie or the particle with which it is associated is critical, as this will control its transport and settling behavior in air and water. A given trace element will behave differently physically, chemically, and biologically in each of its different forms, and it will partition itself among the various possible forms in response to environmental conditions. It is important to note that many trace elements are "particle-reactive" and will quickly associate with particles if added to the environment in a dissolved form. Trace element concentrations are almost always much higher in particles than in dissolved forms.

Although the behavior of a trace element, including its biological behavior, depends on its form, there is some form of most trace elements that will affect the health of organisms, including humans. At least 20 trace elements have long been known to be essential to health [e.g., (8)]. Diseases because of trace element deficiencies are well known among both humans and other organisms. A number of trace elements such as Cu, Ni, Zn, and Se are essential to life at very low concentrations but toxic at slightly higher concentrations. Good data on trace element concentrations in the environment are needed in order to know whether too little or too much of a giver element is present.

The toxic effects of both essential and nonessential trace elements are well known, in the case of As and Pb, human toxicity has been known for more than 2000 years. For other trace elements, toxic effects are less well recognized. In general, however, for all trace elements, an optimal concentration in the environment and in the organism gives optimal function (growth, reproduction, etc.) and higher or lower concentrations result in less than optimal function and possibly death.

In order for a trace element in the environment to have an effect on an organism, the element must, of course, be taken up by the organism. For plankton and other aquatic plants, this uptake is directly from solution, but for animals, some, or most, of the uptake might be from food or from ingestion of nonfood particles. In any case, at some point the trace element must be in a soluble form and be transferred across cell membranes and possibly transferred to some vital organ within the organism. The form of the trace element is very important in controlling these transfers and the resulting effects, but both environmental conditions (pH, temperature, etc.) and the type of organism and its condition (age, health, etc.) also play a role. Factors that influence the toxicity of trace elements have been discussed by Bryan (9), Luoma (10), and many others, and the large differences in sensitivity to trace elements exhibited by different organisms are well known [e.g., (11)].

ASSESSING BIOLOGICAL IMPACTS

The effect of a trace element on organisms depends on the abundance, distribution, and behavior of the trace element. As discussed above, these are difficult to determine and are subject to complex and incompletely understood processes. The environmental impact of waste disposal or other human activity is, therefore, often controversial. Environmental groups and industry often engage in public fingerpointing and lawsuits over specific activities. Often, more money is spent on lawyers than on attempts to scientifically document impacts. One reason for this is the difficulty in clearly documenting harmful effects in the field, especially at the population or ecosystem level. Laboratory toxicity testing is not easy, but it can usually show dose-response relationships that allow establishment of trace element concentrations above which harmful effects to a given organism are likely to result. Such results are, however, usually difficult to apply to the complex conditions in the field, as is discussed below.

The simplest laboratory toxicity tests are those that use death of the organism as the only indicator of effect. This crude measurement has been much criticized, but it does establish the rough relative toxicity for various trace elements to various organisms. This test will show, for example, that Cu is much more toxic to most plankton than is As. More subtle effects can also be sought in laboratory cultures of various organisms, for example, changes in metabolism, ability to reproduce, find food, grow, etc. A vast amount of literature exists on methods for detecting sublethal effects of toxins on organisms [e.g., (2,12)]. Different sublethal tests often give different results in rating the relative toxicities of different trace elements, but they have the potential for indicating possible long-term effects on organisms that might not show up in short-term acute tests.

Most laboratory toxicity tests use water as free from trace elements, complexing ligands, organic matter, etc. as is possible, so the response of the test organisms can be more clearly related to the trace element added in the test procedure. Consequently, a trace element is almost always less toxic in the environment than it is in the laboratory, because of complexing, adsorption, and other interactions in the environment.

Laboratory toxicity tests, even when they try to imitate the environment by using ambient water, multiple trace elements, varying salinities, temperatures, different life stages of organisms, etc., can never truly duplicate natural conditions. It is useful, then, to look for effects of pollutants in the environment, especially at the population level. This is, however, a difficult task, because of the natural temporal and spatial variability in abundance and health of organisms.

As a result of the relative expense and time involved in toxicity tests, and their sometimes ambiguous results, many environmental assessment programs seek only to determine concentrations of trace elements in the environment and to look for enrichments caused by human activity. If a trace element enrichment is detected, its significance can then be resolved by toxicity testing or detailed ecological field analysis. In any case, trace element enrichments could be sought in air, water, sediment, or organisms.

Water analysis might seem a logical way to detect trace element enrichments in the environment. Furthermore, the significance of trace element concentrations in water can be judged because the US EPA has published values for each element above which harm to organisms is likely (Table 1). However, ambient water, be it river water, groundwater, rainwater, or seawater, is notoriously hard to collect, store, and analyze for trace element content, as was discussed above. Water concentrations can also change over short time scales in some circumstances, which further complicates their use.

Soil or sediment can usually be more easily analyzed accurately for trace element content than can water. Soil and sediment also integrate trace element input over some time scale, so they don't need to be sampled as often as does water. Another advantage of sediment analysis is that it gives a historical view of pollutant input at sites where sediment is laid down layer by layer, year after year. Dates can be assigned to the different layers by use of radio-isotopes, pollen identification, or other means. Furthermore, sediment layers from prehistoric times give a background value for each trace element that can be compared with values in near-surface layers in order to quantify human-induced enrichments.

Recognizing gross sediment contamination is easy. Any sediment that is several-fold higher in a given trace element than the average crustal abundance of that element is contaminated unless some unusual mineralogy exists. However, it is harder to recognize subtle contamination because of difficulties in establishing an exact background concentration for a given location. Values from prehistoric depths in the sediment column are a possible background, as noted above. Another background is sediment well away from any point source of pollutant input. In using either of these methods, care should be taken to compare similar sediment types or to compare element to element concentration ratios rather than absolute concentrations (13).

Another problem with using sediment data is that only some unknown fraction of the trace element in the sediment is likely to be available to organisms, which has been much discussed in the literature [e.g., (14)], especially in conjunction with disposal of dredge spoil [e.g., (15)]. Many authors have suggested leaching sediments with dilute acids or other solutions [e.g., (14)] in order to remove only the trace element that could potentially be removed by an organism. Another suggestion that has been much debated is the ability of sulfide in the sediment to limit availability of trace elements to organisms [e.g., (16)]. Thus, although it generally agreed that only a fraction of the total trace element in sediments is available to organisms, no consensus exists on how to measure that fraction.

Long and Morgan [(2) and elsewhere] suggest another way to identify sediment that is potentially harmful to organisms because of chemical contamination. They compiled published matching biological health and chemical data from numerous field, laboratory, and modeling studies. The data was then ranked from the lowest to the highest contaminant concentration where any adverse biological effect was reported. From the ranking they derived two guideline concentrations for each contaminant. These two values separate the data into values that (1) rarely, (2) occasionally, or (3) frequently cause adverse biological effects. These derived values have been widely used in monitoring programs. See Table 1 for some of the actual values.

If both water and sediment offer analytical and data interpretation challenges, would it not be better to analyze organisms in order to assess trace element contamination? Certainly, advantages to this approach exist. For one thing, there is no question as to whether the element is available to organisms. For another, concentrations are often high enough to make analyses relatively easy, at least for common trace elements such as Cu and Zn. There are, however, problems, for example, deciding what organisms to analyze. It is not practical to analyze every organism at a given location, or even to analyze a representative specie from each major taxonomic group. What, then, should be analyzed?

Farrington (17) summarized the rationale for using common mussels (*Mytilus* sp.), various oyster species (*Crassostrea* and *Ostrea*), and other bivalves as "sentinel" organisms in monitoring studies in the marine environment. This approach has resulted in a very large worldwide data set for trace elements in bivalves. In the United States, the National Oceanic and Atmospheric Administration's "National Status and Trends Program" (NS&T) has been analyzing bivalves from the entire U.S. coastline since 1986 and has produced an especially useful and high-quality data set. As a result of the NS&T and similar data, bivalves should be the first choice for organisms to analyze in marine environmental monitoring programs. Many different kinds of plants and animals have been used in nonmarine environmental monitoring studies, everything from plankton and moss to polar bears. It all depends on what is available and the purpose of the monitoring. In general, organisms that have low natural variability in trace element concentration and are geographically widespread and easy to collect should be selected.

Data from good, long-term environmental monitoring programs can help answer the question "are things getting better or worse." Since strict environmental laws took effect in the United States in the 1970s, billions of dollars have been spent on pollution-control devices and cleanup of polluted sites. Have the efforts worked? (O'Connor (18,19) looked for temporal trends in the NS&T data discussed earlier. He found that for 2744 combinations of 14 chemicals and 196 collection sites over a 10-year time period, only 88 increases and 348 decreases in concentration are significant at the 95% confidence level. Chance alone predicts 69 increases and 69 decreases, so by this analysis, it is quite possible that no real increases occurred over that 10-year period and environmental quality along the U.S. coastline may have improved. This finding is consistent with observations of other environmental scientists. At least for chemical contaminants, environmental laws have worked and the U.S. environment is cleaner now than it was in the 1970s.

CORAL REEFS AND YOUR COASTAL WATERSHED

U.S. Environmental Protection
Agency—Oceans and Coastal
Protection Division

Coral reefs are among the world's richest ecosystems, second only to tropical rain forests in plant and animal diversity. However, they are extremely sensitive environments that have special temperature, salinity, light, oxygen, and nutrient requirements. If environmental conditions fall outside the acceptable range of these requirements, the health and dynamics of a coral reef community can be severely disrupted. That's why coral communities are sensitive indicators of water quality

---

and the ecological health of the coastal watershed. They respond to alterations within the entire coastal watershed, such as changes in freshwater flows and nutrient inputs. Consequently, pollution from the destruction and alteration of surrounding coastal watersheds can directly affect the health and productivity of a coral reef.

WHAT ARE CORAL REEFS AND WHAT DO THEY DO?

Coral reef ecosystems are unique, biologically diverse systems recognized as valuable economic and environmental resources. Many people think coral reefs are made of plants or rocks, but they are actually made of animals! A coral polyp is a delicate, limestone-secreting animal. The limestone serves as a skeleton that either is embedded within the living tissue of the coral or encloses the animal. A coral reef is made up of colonies of these coral polyps. There are several benefits of coral reefs.

- Coral reefs are an important recreational and aesthetic resource for people visiting or living in coastal areas. People use coral reefs for fishing, underwater photography, scuba diving, and snorkeling.
- Coral reefs provide protection for harbors and beaches, which are often found behind reefs because the reefs provide natural protection from heavy wave action caused by coastal storms.
- Coral reefs are home to a number of species of fish and other marine species, including many that we rely on for food and economic purposes.
- Coral reefs also serve as a laboratory for students and scientists to study and learn about complex ecological and biological processes. In addition, the reefs yield many biological treasures that are increasingly being recognized as natural sources of biomedical chemicals.

SOME IMPACTS ON CORAL REEFS

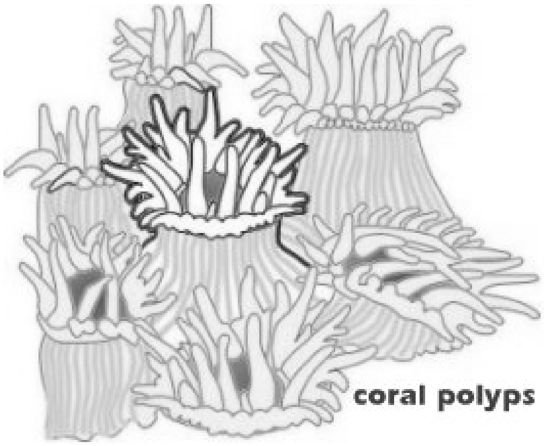
Coral reef habitats are extremely sensitive to disturbances, such as various forms of pollution and physical contact. Pollution of coastal watersheds poses a threat to the existence of coral reefs. Impacts can result from activities occurring near the reef itself or from areas within the coastal watershed that drain to the reef. Disturbances and pollution can lead to diseases in coral such as bleaching (when the algae that give corals their color die). Natural occurrences, such as hurricanes, can adversely impact coral reefs through high-energy storm surges and the resulting resuspension of sediment. However, reefs are usually able to recover from natural disturbances.

People using the reef can have an adverse impact on reef resources. Portions of a coral reef can be broken by the impact of boat anchors and boat groundings. Divers and snorkelers can harm the reef by simply touching it or by removing the corals. Suntan oil from swimmers and snorkelers can harm or even kill sensitive corals. Dragging hooks, fishing line, and nets across the coral reef, as well as placing and recovering lobster traps on reefs, can be damaging. Overfishing also harms coral reefs by removing important species that eat the algae growing on corals. When these fish species are removed, the algae overgrow the corals, smothering them.

Marine debris, trash floating on the ocean or resting on the ocean floor, comes from many sources, including boaters, divers, improper disposal of trash on land, storm water runoff to rivers and streams, ships and other vessels, and offshore oil platforms. Marine debris can harm fish species and other aquatic organisms that use the reef. Trash that lands on the reef can kill corals by continually rubbing against it or smothering it.

An excessive amount of *nutrients* from improperly treated sewage, atmospheric deposition, agricultural and urban runoff, and cleaning products high in phosphates can harm coral reef habitats. In excess levels, nutrients overstimulate the growth of aquatic plants and algae. When nutrient levels increase, the delicate balance that exists between corals and algae is destroyed and the algae can overgrow the corals. When this situation is prolonged, the corals are smothered and die beneath the algal carpet. This, in turn, affects the fish and other aquatic organisms using the area, leading to a decrease in animal and plant diversity and affecting use of the water for fishing and swimming.

Some of the leading causes of nearshore coral decline can be related to *land development* and nearshore



construction that are not environmentally sensitive. Sediment, silt, and other suspended solids wash off plowed fields, construction and logging sites, urban areas, strip-mined land, and eroded stream banks when it rains. Increases in coastal sediment are also caused by construction of seawalls, docks, and marinas; land-clearing; boats running through shallow waters, disturbing and suspending silts with their propellers; and snorkelers and divers kicking up sediment. Sediment can block sunlight that is essential for the survival of some corals, which live in a very close relationship with microscopic plants (algae) that require sunlight to survive. In addition, heavy sedimentation can bury corals, inhibiting their growth or killing them.

Pathogens are disease-causing microorganisms such as viruses, bacteria, and parasites. Pathogens are harmful to corals, causing disease and scarring in many species. These microorganisms enter water bodies from sources such as: inadequately treated sewage, storm water drains, septic systems, runoff from livestock pens, and boats that discharge sewage.

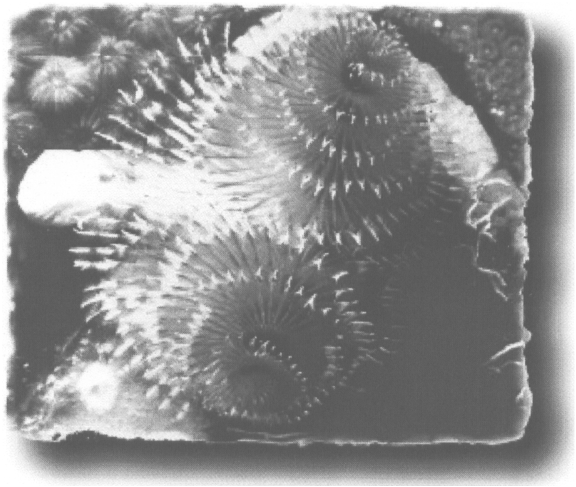
Coral reefs are vulnerable to the introduction of a wide variety of *toxic substances*, including metals (such as mercury and lead), toxic organic chemicals (such as PCBs and dioxin), pesticides, and herbicides found in sources like industrial discharges, urban and agricultural runoff, mining activities, and runoff from landfills. Some toxic substances bind to sediment and are transported to coastal waters through sedimentation. These toxic substances can cause scarring, death, or reproductive failure in fish, shellfish, and other marine organisms. In addition, they can accumulate in fish tissue, leading to fish consumption advisories. The sensitivity of corals makes them especially vulnerable to the introduction of toxic substances.

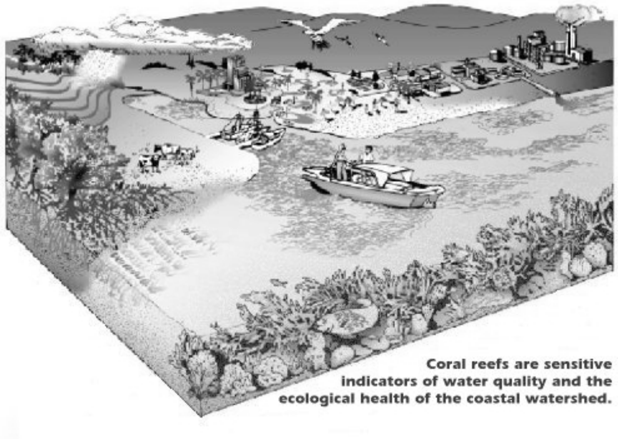
WHAT IS EPA DOING TO PROTECT CORAL REEFS?

International Coral Reef Initiative

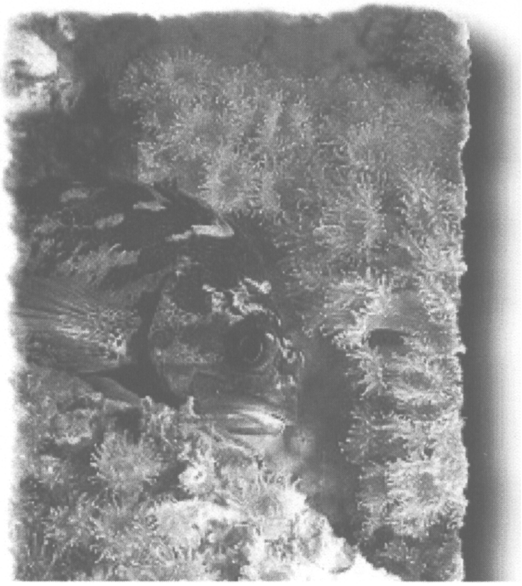
In 1994, EPA, along with the State Department, the National Oceanic and Atmospheric Administration, and the Department of the Interior, formed an international coalition to coordinate information and bring higher visibility to the need for coral reef ecosystem preservation. The coalition became the *International Coral Reef Initiative* (ICRI), which now includes a membership of more than 90 countries.

EPA's Watershed Approach. EPA has joined with others to promote the Watershed Approach nationally as a means to further restore and maintain the physical, chemical, and biological quality of our nation's waters, including coral reefs. By addressing issues on a watershed scale, those areas that pose the greatest risk to human and ecological health can be targeted, several pollutants can be addressed at one time, the public can be involved in cleaning up the environment and protecting coral habitats, and integrated solutions for environmental protection can be considered. This is particularly important given the contribution of activities and sources of pollution within the larger watershed to the decline of coral reefs. Through the Watershed Approach, integrated coastal zone management tools and watershed concepts can be applied in the development of comprehensive management and conservation plans. The Watershed Approach aims





Coral reefs are sensitive indicators of water quality and the ecological health of the coastal watershed.



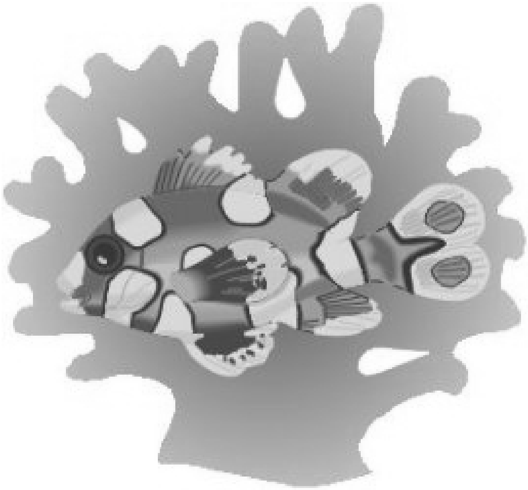
to determine protective approaches for controlling identified stressors to coral reef ecosystems. EPA's *Coastal Watershed Protection Strategy* specifically provides technical assistance and support to priority coastal watersheds, such as *National Estuary Programs* (NEPs) and other coastal waters identified by states.

Other EPA Programs. In assisting coastal states with the development of their *Coastal Nonpoint Pollution Control Programs*, EPA and other federal agencies developed guidance specifying management measures for sources of nonpoint pollution (diffuse runoff of pollutants) in coastal waters. In its program, a state or territory describes how it will implement nonpoint source pollution controls. EPA also works with other federal agencies to protect human health and coral reefs by reducing marine debris. The efforts include the establishment of the *National Marine Debris Monitoring Program*, which looks at the origins and amounts of marine debris deposited along U.S. coasts. EPA and the Coast Guard work together to regulate the transportation of municipal and commercial waste on vessels and to issue regulations for the manufacture, maintenance, and efficiency of marine sanitation devices (boat toilets), as well as the establishment of "no discharge zones" for vessel sewage. EPA also regulates the discharge of pollutants from facilities into sensitive marine waters. EPA assists states in the development of *water quality standards* designed to protect human health and aquatic life. This assistance includes the development of criteria for water quality that accurately reflects the most up-to-date scientific knowledge about the effects of pollutants on aquatic life, such as corals, and human health.

What Can You Do to Help Protect Coral Reefs?

You can do several things to help protect coral reefs and your coastal watershed:

- *Be Informed and Involved*. Learn about coral reefs and their importance to your coastal watershed. Participate in training or educational programs that focus on reef ecology. Be an informed consumer; ask the store owner or manager from what country the coral was taken and whether that country has a management plan to ensure that the harvest was legal and sustainable over time. Support the creation and maintenance of marine parks and reserves. Become a citizen volunteer. As a volunteer you might be involved in taking water quality measurements, tracking the progress of protection and restoration projects, or reporting special events like fish kills and storm damage. Volunteer for a reef cleanup or a beach cleanup. If you don't live near a coast, get involved in your local watershed program. Report dumping or other illegal activities.
- *Take Responsibility for Your Own Backyard*. Determine whether additional nutrients or pesticides are needed before you apply them, and look for alternatives to fertilizers and pesticides where the chance of runoff into surface waters might occur. Even if you live far from a coral reef ecosystem, these products might ultimately affect the waters that support coral. Consider selecting plants and grasses with low maintenance requirements. Water your lawn conservatively; the less water you use, the less runoff will eventually find its way into the oceans.
- *Practice Good Housekeeping*. Learn about procedures for disposing of harmful household wastes so they do not end up in sewage treatment plants that can't treat them or in landfills not designed to receive hazardous materials. Around the house, keep litter, pet waste, leaves, and grass clippings out of street gutters and storm drains to prevent their entrance into streams that might flow to reefs. Use the minimum amount of water needed when you wash your car to prevent waste and runoff. Never dump any household, automotive, or gardening wastes into a storm drain. They might end up on the reef. Take used motor oil, paints, and other hazardous household



- materials to proper collection sites such as approved service stations or designated landfills. Always follow label directions for the use and disposal of household chemicals. Keep your septic tank in good working order. The improper disposal of wastes and hazardous materials can lead to water quality problems and harm to the sensitive coral reef habitats.
- *Respect the Reef*. Help keep the reef healthy by following local guidelines, recommendations, regulations, and customs. If you dive, don't touch the coral. Keep your fins, gear, and hands away from the coral since this contact can hurt you and will damage the delicate coral animals. Stay off the bottom because stirred-up sediment can settle on corals and smother them. Avoid entering sensitive habitat areas with your boat or other motorized watercraft. Maintain your boat engine to prevent oil and gas leaks. Keep all waste produced during your excursions in a safe place to be disposed of properly when you're back on land. If you go boating near a coral reef, don't anchor your boat on the reef. Use mooring buoy systems if they are available. Maintain and use your marine sanitation devices properly. Conserve energy and keep your auto in good running condition. By conserving energy, harmful air emissions leading to air deposition are minimized.

SEA LEVEL AND CLIMATE

Richard Z. Poore
Christopher Tracey
U.S. Geological Survey
Reston, Virginia

Richard S. Williams, Jr.
U.S. Geological Survey
Woods Hole, Massachusetts

INTRODUCTION

Global sea level and the Earth's climate are closely linked. The Earth's climate has warmed about 1 °C (1.8 °F) during the last 100 years. As the climate has warmed following the end of a recent cold period known as the "Little Ice Age" in the 19th century, sea level has been rising about 1 to 2 millimeters per year due to the reduction in volume of ice caps, ice fields, and mountain glaciers in addition to the thermal expansion of ocean water. If present trends continue, including an increase in global temperatures caused by increased greenhouse-gas emissions, many of the world's mountain glaciers will disappear. For example, at the current rate of melting, all glaciers will be gone from Glacier National Park, Montana, by the middle of the next century (Fig. 1). In Iceland, about 11 percent of the island is covered by glaciers (mostly ice caps). If warming continues, Iceland's glaciers will decrease by 40 percent by 2100 and virtually disappear by 2200.

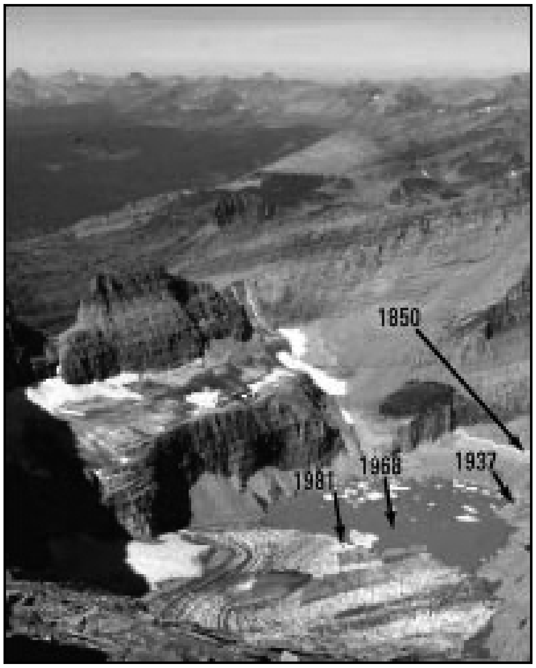


Figure 1. Grinnell Glacier in Glacier National Park, Montana; photograph by Carl H. Key, USGS, in 1981. The glacier has been retreating rapidly since the early 1900's. The arrows point to the former extent of the glacier in 1850, 1937, and 1968. Mountain glaciers are excellent monitors of climate change; the worldwide shrinkage of mountain glaciers is thought to be caused by a combination of a temperature increase from the Little Ice Age, which ended in the latter half of the 19th century, and increased greenhouse-gas emissions.

Most of the current global land ice mass is located in the Antarctic and Greenland ice sheets (Table 1). Complete melting of these ice sheets could lead to a sea-level rise of about 80 meters, whereas melting of all other glaciers could lead to a sea-level rise of only one-half meter.

GLACIAL-INTERGLACIAL CYCLES

Climate-related sea-level changes of the last century are very minor compared with the large changes in sea level that occur as climate oscillates between the cold and warm intervals that are part of the Earth's natural cycle of long-term climate change.

Table 1. Estimated Potential Maximum Sea-Level Rise from the Total Melting of Present-Day Glaciers. [Modified from Williams and Hall (1993). See also http://pubs.usgs.gov/factsheet/fs50-98/]

Location	Volume (km^3)	Potential Sea-Level Rise (m)
East Antarctic ice sheet	26,039,200	64.80
West Antarctic ice sheet	3,262,000	8.06
Antarctic Peninsula	227,100	.46
Greeland	2,620,000	6.55
All other ice caps, ice fields, and valley glaciers	180,000	.45
Total	32,328,300	80.32

During cold-climate intervals, known as glacial epochs or ice ages, sea level falls because of a shift in the global hydrologic cycle: water is evaporated from the oceans and stored on the continents as large ice sheets and expanded ice caps, ice fields, and mountain glaciers. Global sea level was about 125 meters below today's sea level at the last glacial maximum about 20,000 years ago (Fairbanks, 1989). As the climate warmed, sea level rose because the melting North American, Eurasian, South American, Greenland, and Antarctic ice sheets returned their stored water to the world's oceans. During the warmest intervals, called interglacial epochs, sea level is at its highest. Today we are living in the most recent interglacial, an interval that started about 10,000 years ago and is called the Holocene Epoch by geologists.

Sea levels during several previous interglacials were about 3 to as much as 20 meters higher than current sea level. The evidence comes from two different but complementary types of studies. One line of evidence is provided by old shoreline features (Fig. 2). Wave-cut terraces and beach deposits from regions as separate as the Caribbean and the North Slope of Alaska suggest higher sea levels during past interglacial times. A second line of evidence comes from sediments cored from below the existing Greenland and West Antarctic ice sheets. The fossils and chemical signals in the sediment cores indicate that both major ice sheets were greatly reduced from their current size or even completely melted one or more times in the recent geologic past. The precise timing and details of past sea-level history are still being debated, but there is clear evidence for past sea levels significantly higher than current sea level.

POTENTIAL SEA-LEVEL CHANGES

If Earth's climate continues to warm, then the volume of present-day ice sheets will decrease. Melting of the current Greenland ice sheet would result in a sea-level rise of about 6.5 meters; melting of the West Antarctic ice sheet would result in a sea-level rise of about 8 meters (Table 1). The West Antarctic ice sheet is especially vulnerable, because much of it is grounded below sea level. Small changes in global sea level or a rise in ocean temperatures could cause a breakup of the two buttressing ice shelves (Ronne/Filchner and Ross). The resulting surge of the West Antarctic ice sheet would lead to a rapid rise in global sea level.

Figure 2. Wave-cut terraces on San Clemente Island, California. Nearly horizontal surfaces, separated by step-like cliffs, were created during former intervals of high sea level; the highest terrace represents the oldest sea-level high stand. Because San Clemente Island is slowly rising, terraces cut during an interglacial continue to rise with the island during the following glacial interval. When sea level rises during the next interglacial, a new wave-cut terrace is eroded below the previous interglacial terrace. Geologists can calculate the height of the former high sea levels by knowing the tectonic uplift rate of the island. Photograph by Dan Muhs, USGS.

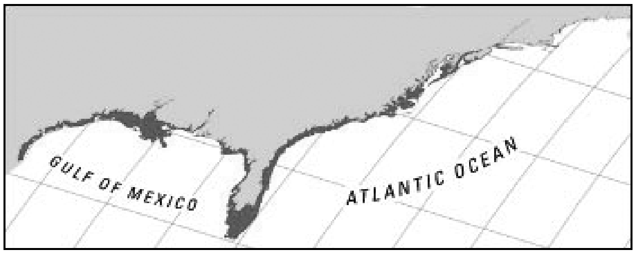

Figure 3. Red shows areas along the Gulf Coast and East Coast of the United States that would be flooded by a 10-meter rise in sea level. Population figures for 1996 (U.S. Bureau of the Census, unpublished data, 1998) indicate that a 10-meter rise in sea level would flood approximately 25 percent of the Nation's population.

Reduction of the West Antarctic and Greenland ice sheets similar to past reductions would cause sea level to rise 10 or more meters. A sea-level rise of 10 meters would flood about 25 percent of the U.S. population, with the major impact being mostly on the people and infrastructures in the Gulf and East Coast States (Fig. 3).

Researchers at the U.S. Geological Survey and elsewhere are investigating the magnitude and timing of sea-level changes during previous interglacial intervals. Better documentation and understanding of these past changes will improve our ability to estimate the potential for future large-scale changes in sea level.

THE PERMANENT SERVICE FOR MEAN SEA LEVEL

S. Jevrejeva
S. Holgate
P.L. Woodworth
Proudman Oceanographic Laboratory
Birkenhead, United Kingdom

Mean sea level (MSL) is the average level of the sea, relative to the level of the land on which the measurements are being made, recorded over an extended period such as a month, year, or the lunar nodal period of 18.6 years by an instrument called a tide gauge (or coastal sea level recorder). MSL data are used in a wide range of scientific applications including studies into climate change, ocean circulation variability and geology, as well as in practical applications such as surveying and the establishment of national leveling datums.

The Permanent Service for Mean Sea Level (PSMSL) is the global data bank for such MSL information, and it has since 1933 been responsible for the collection, publication, analysis, and interpretation of sea level data from the global network of tide gauges. It is based at the Proudman Oceanographic Laboratory (POL) in Liverpool, U.K. and is a member of the Federation of Astronomical and Geophysical Data Analysis Services (FAGS) established by the International Council for Science (ICSU). The PSMSL is supported by FAGS, the Intergovernmental Oceanographic Commission of the United Nations Educational, Scientific and Cultural Organisation (IOC/UNESCO), and NERC.

The database of the PSMSL contains almost 53,000 station-years of monthly and annual mean values of sea level from nearly 2000 tide gauge stations around the world received from almost 200 national authorities (see Fig. 1). On average, approximately 2000 station-years of data are entered into the database each year. All data are readily available from the PSMSL website: www.pol.ac.uk/psmsl.

Data for all stations are included in the PSMSL METRIC (or total) dataset. The METRIC monthly and annual means for any one station-year are necessarily required to be measured to a common datum, although, at this stage, datum continuity between years is not essential. The year-to-year datum checks become essential, however, if the data are subsequently to be included in the PSMSL 'Revised Local Reference (RLR)' component of the dataset. The RLR dataset contains records for which time series analysis of sea level changes can be performed. Long records from this dataset have been the basis of all analyses of secular changes in global sea level during the last century. The geographical distribution of longer RLR records contains significant geographical bias toward the Northern Hemisphere, a situation that is being rectified by means of international collaboration.

Aside from its central role of operation of the global sea level data bank, the PSMSL has a responsibility as a member of FAGS to provide the sea level community with as full a Service as possible with regard to the acquisition, analysis, and interpretation of sea level data. Consequently, the PSMSL provides a range of advice to tide gauge operators and data analysts. It has occupied a central planning and management role in the development of the Global Sea Level Observing System (GLOSS) of the IOC. Through GLOSS and via other routes, the PSMSL provides advice and training to national sea level authorities and individual sea level scientists and technologists. In addition to the provision of training materials (e.g., tide gauge operation manuals), the PSMSL supplies software packages suitable for tidal data analysis and quality control purposes.

In addition to the training courses associated with GLOSS, the PSMSL has every few years hosted important study groups and international conferences on sea level science. The study groups have concerned themselves with topics such as the use of global positioning system (GPS) receivers at tide gauge sites to determine the local rates of vertical land movement and have been held under the auspices of the International Association for the Physical Sciences of the Ocean (IAPSO) Commission on Mean Sea Level and Tides (CMSLT), the scientific body to which

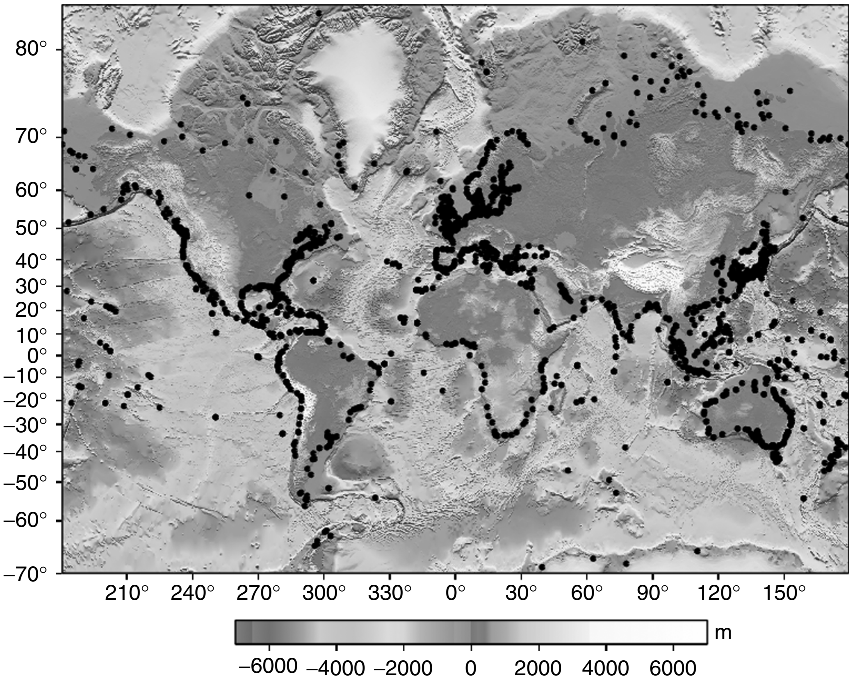

Figure 1. Distribution of PSMSL stations.

the PSMSL reports formally. The PSMSL hosted a major Symposium in Vienna in 1991 as part of the International Union of Geodesy and Geophysics (IUGG) Congress, an international conference at the Linnean Society in London in 1993 as part of its 60th anniversary celebrations, co-organized "Tidal Science 96" at the Royal Society in London in 1996, and took a major part in "A Celebration of UK Sea Level Science" at the Royal Society in 2004. The proceedings of each of these conferences have since been published. A further major conference is planned in 2008 for the PSMSL 75th anniversary.

Probably the most important recent scientific publications with which the PSMSL is associated are those of the First (1990), Second (1995), and Third (2000) Scientific Assessments of Intergovernmental Panel on Climate Change (IPCC). The PSMSL Director has been a lead author for the sea level chapters in each of the IPCC studies. Major conclusions have been that global sea level has indeed risen by approximately 10–20 cm during the past century and may rise by amounts several times larger during the next 100 years.

The PSMSL is conscious that developments in technology have expanded the field of sea and land level studies. During the 1990s, satellite radar altimetry and GPS recording become established techniques, whereas space gravity offers the potential for being an effective source of sea-level-related information in the future. Therefore, the PSMSL maintains full participation with altimeter and space gravity working groups in view of the importance of those techniques to sea level research. PSMSL personnel have Principal Investigator status for the TOPEX/Poseidon, Jason, ERS, and Envisat altimeter missions, in addition to the GRACE and GOCE space gravity projects. The major challenge for the future, to which the PSMSL is committed, is to see the established tide gauge and new space-based techniques closely linked within one coherent global sea level monitoring system.

MARINE AND ESTUARINE MICROALGAL SEDIMENT TOXICITY TESTS

Ignatio Moreno-Garrido
Luís M. Lubián
Julián Blasco
Institute of Marine Sciences of Analucia
Cadiz, Spain

The term microphytobentos refers to the microscopic algae that live on the submerged (temporary or not) floor in fresh water, estuarine, or marine environments. Microphytobenthos are mainly composed of mobile, pennate diatoms and cyanophytes. In marine and estuarine environments, those organisms can be found in habitats such as salt marshes, submerged vegetation beds, intertidal (sand or mud) flats, or subtidal sediments where light permits microalgal growth. As the presence of these photosynthetic organisms is not always evident, MacIntyre et al. (1) borrowed the term "secret garden" from the homonymous book published in 1888 and written by Frances Hodgson Burnett (1849–1874), in order to make a literary allusion to microphytobenthos. In fact, habitats where microphytobentos are the only primary producers are recognized as "unvegetated" areas, but the concentration of chlorophyll *a* in the upper 0.5 cm of the sediments where those organisms live generally exceed the depth-integrated chlorophyll in the entire overlying water column (2). In some cases, chlorophyll from microphytobenthos can be up to six orders of magnitude higher than that for the overlying water (3). Nevertheless, some authors estimate that primary production in the bottom would be lower than in the free plankton in spite of that exceptional data (4). But in some habitats, biomass from benthic microalgae can match or even exceed biomass of bacteria present in the same space (5). Thus, microphytobenthos necessarily play a key role in the benthic trophic webs (6–8). In certain biocenosis, the organisms of the microphytobenthos are the main—sometimes the only—source of carbon for grazers or bacteria (7,9,10). The microphytobenthos are also very important in relation to the stability of coastal and estuarine sediments. Although some cyanobacteria can show hydrophobicity as a mechanism to attach sediment particles or other cells (11), the main strategy of microphytobenthos to keep attached to the sediment is the production of agglutinant molecules [carbohydrates (CH) or exopolysaccharides (EPS)] (12–15). The presence of these molecules has important trophic implications, but their role in the maintenance of the structure of the upper part of the sediment is also important (16–19), because the film of adherent substances produced by microphytobenthos increases the sediment stability. Toxicants such as herbicides can alter microphytobenthic growth and the production of CH and EPS can be diminished. A loss of sediment stability can induce an increase in the turbidity of the water and a higher rate of deposition of fine particles on submerged higher plants or macroalgae, thus reducing even more the primary production of the whole and adjacent systems (20).

The importance of sediments in accumulation of xenobiotics in coastal and estuarine environments has been pointed out. Most chemical contaminants entering marine or estuarine environments eventually accumulate in sediments due to different reasons, including higher salinity values that diminish solubility of such substances in water. Sediment can act as a sink for these substances but also as a subsequent source for the same (25). On the other hand, and except in cases of extreme contamination, chemical data by themselves do not predict hazard (21,22). Thus, bioassays are needed to assess the potential toxicity of sediments.

In spite of the importance of microphytobenthos, few efforts have been made to develop standard toxicity test on these organisms. Guidelines from the SETAC (23) and recent revisions (24–27) about toxicity testing on benthic organisms offer good information on macro and meiofauna but completely ignore microphytobenthos. The reason for this "exclusion" cannot be found in the lack of importance of benthic microalgae, because of all the reasons expressed above. Probably the most important reasons for the scarcity of work on microphytobenthos ecotoxicology are the difficulties that this biological material cause.

First, it is not easy to efficiently remove microphytobenthos from sediments. Size and weight of microalgae on the sediment match part of the sediment particles mixed with them. There are descriptions of techniques that use the migration capacity of the microphytobenthic organisms in order to remove them from sediment. It is well known that microphytobenthos vertically migrate through the sediment as a function of the light and tide conditions. During low tide and light conditions, cells unbury and remain at the surface of the sediment, but during high tide or night conditions, microphytobenthic cells bury themselves again, in order to avoid being removed by the current or waves or grazed during nonphotosynthetic conditions (1,28,29). This vertical movement can be exploited to make cells migrate through a plankton net separated from the sediment by one or more lens tissue papers (8). Other authors improved on this method by covering the plankton net with a few millimeters of silica powder, where living mobile cells accumulate (30). Less effective seems to be the technique that uses the adherent capacity of microphytobenthos for removing cells by the disposition of a cover glass on the sediment (19). It is supposed that cells will attach to the cover glass, but it is not easy to ensure the efficiency and repeatability of the technique. Another approach is to take cores (made of Plexiglas, PVC, or other materials) (31) from the upper sediment and resuspend subsamples of the previously sliced sediment in order to directly count (and taxonomically identify) cells by light microscopy (4). This latter method ensures the integration of all species (motile or not). The use of fluorescence microscopy can help in distinguishing photosynthetic cells from debris: with a blue filter and a barrier filter of 530 nm, chlorophyll emits a bright red fluorescence that clearly reveals cells and facilitates their localization and count, something that is difficult if this technique is not used (32,33) (Fig. 1). Other techniques use density differences to separate diatoms from debris by centrifugation in a Percoll gradient (34). Although this technique seems to be good for isolating cells, the percentage of cell recovery is low (near 5% of total population in natural locations).

Due to the difficulties of handling cells among the sediment, several works were limited to analyzing photosynthetic pigments or photosynthesis in the upper sediments (35–37) as biomarkers for the microphytobenthic biomass. The analysis of degraded pigment molecules in sediments can be useful as a biomarker for grazing pressure (38).

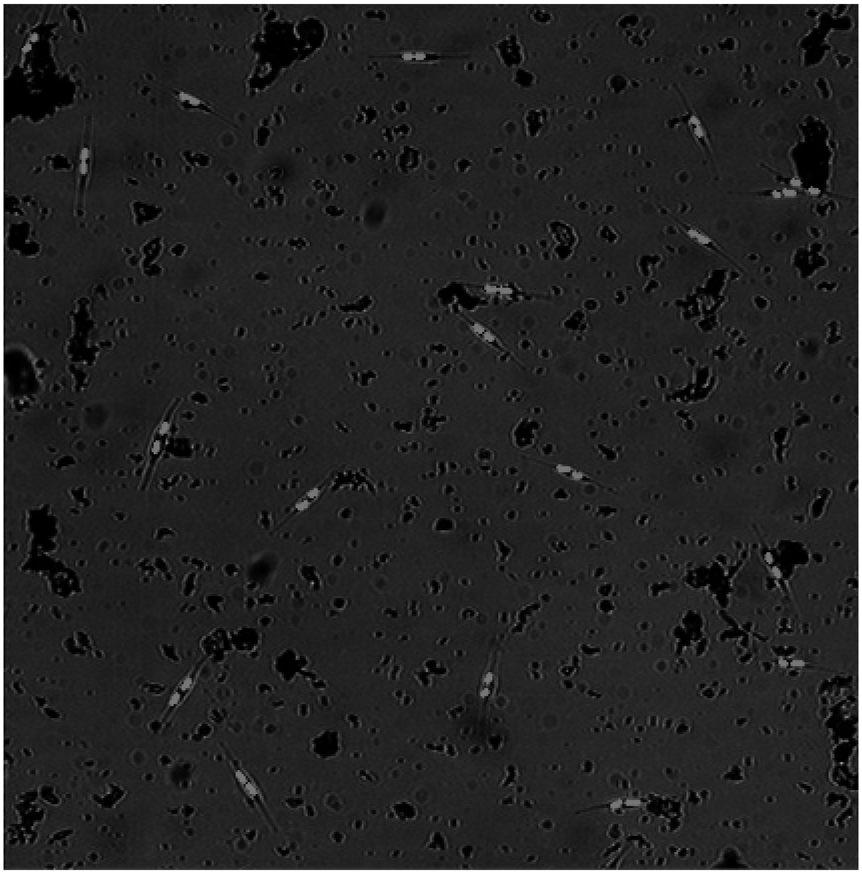

Figure 1. Cells of the diatom *Cylindrotheca closterium* among sediment particles, observed under fluorescence microscopy. Using a barrier filter of 530 nm, the two chloroplasts of each cell are bright red, facilitating the counting and location of the algal cells.

But difficulties in handling microphytobenthos do not end there. The disposition in "patches" of microphytobenthos in field locations is evident, providing a spatial heterogeneous distribution of the cells (39,40). This spatial distribution is sometimes conditioned by the presence of ridges and runnels (41) in the sediment surface, provoked by the natural dynamics of the ecosystem. This must be taken into account when estimations of microphytobenthic organism density are intended to be developed in actual locations (15). Delgado (4) described spatial heterogeneity in the delta of the Ebro River as being insignificant over distances between 10 cm and 10 m. Another consideration is that in emerged (low tide) conditions, there is a process of gradual compaction of sediment due to dewatering, which implies a higher density but a lower content of total pigments, exopolysaccharides, or individuals (42).

In spite of all this, *in situ* or *in vitro* bioassays involving microphytobenthos should be considered as powerful tools to determine potential toxicity of sediments (24). Some efforts have been made in this direction. Wong et al. (43) described a microalgal toxicity test on sediments from the coast of Hong Kong, but they used a planktonic (and not benthic) species (the chlorophyte *Dunaliella salina*) that, additionally, belongs to a genus that demonstrates strong resistance to toxicants. Abalde et al. (44) did not find growth inhibition of populations of *D. tertiolecta* at levels of 8 $\text{mg} \cdot \text{L}^{-1}$ Cu, and Moreno-Garrido et al. (45) found that *D. salina* was the most resistant species to Cu and Cd among the assayed microalgal strains. Each microalgal species shows different sensitivity for toxicants, but there are references showing similar (on the same order of magnitude) sensitivities for very different taxons (46). In this respect, *Isochrysis galbana*, *Cylindrotheca (Nitzschia) closterium*, and *Nannochloropsis species* showed similar responses to water soluble fraction of petroleum. Phytoplankton (free swimming or floating microalgae), periphyton (microalgae growing on solid substrate), and epipsammon (microalgae growing more or less attached to sand) showed comparable toxicity sensitivity responses to paraquat and simazine (47). Other works describe sediment toxicity tests on elutriates or extracts (48). Tolun et al. (49) described experiments where natural sediment toxicity tests on *Phaeodactylum tricornutum*, based on elutriates and bulk exposure, are compared: in the case of elutriates, the authors found different degrees of growth inhibition, although for direct exposure to sediments all organisms died, supporting the idea that direct exposure to sediment will give more realistic (or more sensitive) responses because part of the toxicants could not be extracted in elutriates or extracts (50). A very interesting approach to sediment toxicity tests on benthic algae was that made by Dahl and Blank (31), in which epipsammic communities were transported to a laboratory where they were kept and used in subsequent measurements of metabolic activities and short-term toxicity tests. Cairns et al. (51) defended the use of microorganisms in toxicity tests, because they can show very high sensitivities to toxicants and thus should be included in regulatory-proposed guidelines. But incorporation in those guidelines of multispecies tests that could be more "environmentally realistic" are very slow, fundamentally because of methodological questions (regarding replication and reproducibility). On the other hand, predictions based on multispecies tests are no more accurate than those based on monospecific bioassays, which are cheaper and more reproducible than a multispecies bioassay (51).

As far as we know, the first attempts to develop a standardized, repeatable protocol for sediment toxicity testing involving a microphytobenthic strain and direct exposure of microalgal cells to sediment have only recently taken place (32,33). In those works, populations of the benthic diatom *Cylindrotheca closterium* were exposed to sediment spiked with heavy metals or tensides. The test also considers the effect of particle size distribution on growth of the tested microalgal strain, which could mask actual responses of algae to present toxicants in other experiments such as those described by Tolun et al. (49). The test is simple, repeatable, and cheap, and it does not require special facilities other than those found in any laboratory. It is based on the 72-h algal growth inhibition test from OECD (52), adapted to sediments and marine or estuarine habitats. *Cylindrotheca closterium*, formerly known as *Nitzschia closterium*, demonstrated to be a good subject in other toxicity bioassays and there is a good pool of previous information about this species (53–58). This species is cosmopolitan for temperate coastal waters, ubiquitous, easy to handle in the laboratory, fast growing, sensitive to toxicants, and presents very low nutrient requirements. Nevertheless, other species have been assayed and compared with *C. closterium* in order to detect toxicity in natural sediments. EC_{50} values were calculated for three benthic diatoms exposed to sediment obtained from six different locations from Aveiro Lagoon (Portugal). Those values are shown in Table 1. Locations I, II, and VI were less toxic to microalgae than locations III, IV, and V, since *C. closterium* is slightly more sensitive than the other two species assayed for the majority of the samples. When a chemical analysis of the samples was performed and a similarity analysis carried out crossing toxicity values with possible substances involved (heavy metals, C, N, PCBs), it was found that some heavy metals (Sn, Zn, Hg, Cu, and Cr) had a great effect (Sn the greatest), as shown by the more than 50% of similarity between samples that showed significant growth inhibition for the benthic diatoms assayed (unpublished data).

Other recent work from Adams and Stauber (59) also describes a whole-sediment toxicity test on a benthic microalgal diatom (*Entomoneis* cf. *punctulata*). In this case, a flow cytometer is used to detect viability of living algae by the use of a fluorochrome (fluorescein diacetate,

Table 1. EC_{50} Values for Sediments from Six Locations at the Aveiro Lagoon (Portugal) and Three Benthic Diatoms

	Sample Sites					
Algal Species	I	II	III	IV	V	VI
P. tricornutum	N.I.[a]	N.I.	27	51	62	N.I
C. closterium	92	90	62	31	61	N.I.
Navicula sp.	N.I.	N.I.	64	71	65	N.I.

[a] If 100% of the sediment does not exhibit a growth inhibition value of 50%, EC_{50} is denoted as N.I. (no inhibition).

FDA). In this technique, used previously (60) to determine the toxic response in planktonic microalgal cells, FDA absorbed by living or dead cells is only hydrolyzed by nonspecific esterases inside the living cells. Hydrolyzed FDA is converted into fluorescein and can be detected by flow cytometry techniques. Although the FDA technique is less sensitive than growth inhibition measurements (60), flow cytometry opens a wide field of possibilities for microalgal toxicity testing on sediments, because several different fluorochromes can be used to measure quite different cellular parameters used as biomarkers.

MARINE STOCK ENHANCEMENT TECHNIQUES

JANA DAVIS
Smithsonian Environmental
Research Center
Edgewater, Maryland

The United Nations estimates that 28% of all ocean fishery stocks are overexploited or severely depleted, and another 47% is fully exploited (1). Included in this statistic are species that are long-lived and short-lived, open-ocean and coastal, migratory and sedentary. About 75% of fishery stocks are unable to withstand further exploitation, so only 25% of stocks remain to satisfy the increasing human demand, as human population grows, for fishery products.

As a result of the pressure on fishery populations and the degradation of many of these resources, a suite of fishery management techniques have been developed. One such technique, stock enhancement, is broadly defined as the (human) activity by which the population of a species is increased. In contrast, more traditional management techniques generally focus on limiting human activities that reduce the population of a species.

Traditional measures may focus on reducing fishing effort, for example, by limiting the number of days fishermen can fish, restricting the amount of gear a fishermen can use, regulating the type of gear a fisherman can deploy, or setting restrictions on the types of individuals caught by size or gender. Not only does this latter method serve to reduce catch, it strives to shift the pressure away from more reproductively important individuals toward those with less likely contributions to the next generation over the course of their lifetimes.

GOALS OF STOCK ENHANCEMENT: A NONTRADITIONAL MANAGEMENT TECHNIQUE

The technique of stock enhancement, while often used in concert with more traditional catch-reducing techniques, does not describe limitations to human activities but rather the active improvement of a fishery stock. Enhancement efforts can encompass many approaches. The population can be bolstered both by increasing carrying capacity (the number of individuals that can be supported by their habitat) or by increasing the number of individuals themselves (2,3). The former method is effective only when the factor limiting population is related to habitat, food, or some other resource. The latter method, a special case of aquaculture, is effective only when the habitat can hold more individuals than it does at present.

The key to success in stock enhancement is to identify the factor(s) that limit the population in question and then increase the level of that factor. Incorrect identification of this factor could lead to wasted time, money, and energy. Consider the hypothetical case of a coral reef fish. If the fish population is not habitat-limited, but is recruitment-limited, adding more coral reef habitat would likely serve only to spread out the population spatially. No additional recruits would be available to settle on the new habitat substrate. On the other hand, if the fish is habitat-limited, adding additional individuals will not increase the ultimate population, as there would be no space for them to occupy.

Enhancement directed toward habitat-limited populations has included efforts to enhance stocks of both fish, especially salmonids, and invertebrates (4–7). Often these cases are referred to as “habitat restoration,” stressing the action rather than the consequence. Most often when people refer to “stock enhancement,” they are referring to hatchery-raised individuals, usually juveniles, that are released into the wild to bolster recruitment-limited populations directly. These added juveniles are raised outside of the system, for example, in, an aquaculture facility or a field pen. The juveniles may be offspring of wild parents collected from the field (8) or offspring from generations of parents held in captivity (9).

The goal of stock enhancement is to raise the individuals beyond the initial phase of high early life-history mortality and then release them into the wild. The stage at which they are released is determined through economic optimization, survivorship maximization, or a combination of both. Maintaining individuals, especially heterotrophs, in a hatchery or a pen is expensive. The expense tends to increase as organisms grow. One might calculate the optimum release size or age as a trade-off between the cost of maintaining an individual in the hatchery and the survivorship advantage that the hatchery offers. Often, as individuals grow, the survivorship advantage of the hatchery environment over the natural environment begins to reverse. Many organisms are cannibalistic when held in extremely high densities (10), a trend that increases as organisms grow. Disease transmission also becomes a problem at high densities. Lowering densities requires an expensive solution of creating more tank or pen space. Therefore, at a certain point, mortality rates are actually lower if the organisms are released into the wild than if held in the hatchery.

The optimum release point is different for each species. For example, Kemp’s ridley sea turtles are released at the age of 1 year (11). Blue crabs are released at the age of 2 to 3 months (12). Individuals that are never released but harvested in the hatchery are part of a complete aquaculture program such as, for example, farm-raised salmon, catfish, or shrimp (13,14).

In populations truly at risk, the goal of stock enhancement is not simply to provide more fish to catch. Ideally, after release, these hatchery-reared individuals contribute to the spawning stock and have a potential exponential impact on overall population generation after generation, depending on the degree of recruitment limitation. In these cases, a purely economic model to predict optimum size at release is not appropriate. Stock enhancement therefore has a potential role beyond fishery application and into the realm of threatened or endangered species protection.

STOCK ENHANCEMENT EXAMPLES

Stock enhancement techniques have been applied to many types of organisms worldwide. Finfish populations have been the most common recipients of hatchery-raised juveniles, including many salmon from both the Atlantic and Pacific (15,16), Japanese flounder (17), Hawaiian mullet (18), Nassau grouper (19), and Chesapeake Bay striped bass (20), just to name a few. Holothurians have been hatchery-raised for stock enhancement (21). Bivalves, such as quahogs (22) and soft-shell clams (23), and gastropods, such as abalones (24) and queen conch (25), have been the subject of stock enhancement efforts. Finally, crustaceans are beginning to receive more attention as possible stock enhancement targets; programs have been initiated for decades with American and

European lobsters (26,27), more recent programs for prawn (28) and the Japanese swimming crab (3), and a new exploratory program established for the Chesapeake Bay blue crab (8).

Stock enhancement efforts extend worldwide. In Japan, stock enhancement programs are in place for at least 34 finfish and 12 crustaceans (3). Programs relying on various specific techniques exist in South America, North America, Africa, Europe, Asia, Australia/New Zealand, and in the developed world as well as the developing world (29–31).

Specific techniques to optimize stock enhancement depend on the life-history traits of the species. Sessile organisms may be enhanced by seeding areas with young individuals (32). Depending on how closely the success of the enhancement effort is to be monitored, more mobile species may be released into isolated areas where they can be followed, similar to the idea of stocking freshwater lakes (8,28). For extremely mobile open-ocean species, juveniles are released into the open ocean (3), and even if tagged, large numbers cannot be followed over time.

PROBLEMS OF STOCK ENHANCEMENT

Enhancement has been a controversial management method for several reasons (15,29,33). First, hatchery-raised animals may not survive well in the wild. The hatchery environment can offer conditions very different from the natural environment: food is likely to be different, the method of foraging is different, and therefore the hatchery-raised organisms may have mortality-threatening inexperience with natural prey after their introduction into the wild. They may similarly be inexperienced in avoiding predators. Holding tanks may restrict movement, may have unnatural substrates, may have unnatural light regimes, or may have different flow regimes. As a result of all of these differences, stock enhancement efforts, often funded by the taxpayer, may not be successful (34). Many studies have noted differences in hatchery-raised and wild individuals in factors such as behavior, morphology, growth rates, and therefore survivorship (17,35,36).

A second concern is that hatchery-raised individuals may be too successful. Hatchery animals may compete with and displace wild animals (2,37). If at any point the population becomes habitat-limited, rather than recruitment-limited (or if the stock enhancement effort pushes the population over the carrying capacity), the survivorship of wild individuals may actually decrease. The ultimate result would then be a decline in the population of wild individuals, even if the overall population has increased.

A third concern is that hatchery-raised organisms may carry diseases into the wild, affecting the survivorship of wild individuals. Fourth, increases in stock size due to hatchery successes may provoke a rise in fishing effort and therefore greater pressure on the remaining wild individuals (34,38). Stock enhancement efforts are generally performed in concert with traditional management techniques, such as lowering catch and/or restricting catch to certain segments of the population. However, if the human population increases, pressure may be put on managers to reduce fishing regulations. Again, the ultimate result would be a decline in the survivorship rates of wild individuals, even if overall population has increased.

Finally, and perhaps the reason for the controversy generating the most attention in recent years is genetics, or "gene dilution." Even if efforts in the hatchery are expended to obtain brood stock from many different parents, genetic variability in the brood stock is unlikely to approach that of the wild parental stock. The offspring produced will be more similar to each other than the offspring of wild stock. Opponents of stock enhancement fear that releasing genetically relatively homogenous hatchery individuals will reduce genetic variability in wild populations as hatchery and wild individuals interbreed. The ultimate result after several to many generations might be a decline in population because lack of genetic diversity can limit a population's response to environmental change.

The controversy over stock enhancement has been fueled by the fact that most enhancement efforts have not been studied quantitatively (37,41,42). Quantitative, hypothesis-driven study did not begin until the late 1980s (43). However, now that the necessity to understand better the outcomes of enhancement programs has been recognized, in many cases the enhancement process has been refined. Methods to select better candidate species have been developed (44). Advances in tagging techniques have allowed better assessment and comparison of hatchery and wild animal survivorship (44). Most importantly, calls have been made for quantitative study of small-scale enhancement efforts before investment in large-scale programs begins (42,43).

OPTIMIZING STOCK ENHANCEMENT SUCCESS

Stock enhancement is becoming a more often commonly used method for addressing declines in fished species. Many of the problems identified above can be addressed to a comfortable degree before the program is initiated. For example, several programs are considering conditioning individuals to limit the differences between hatchery-raised and wild organisms before release into the wild (12,45,46). In this way, survivorship rates of hatchery organisms are increased, along with the output per enhancement program dollar spent.

In addition, carrying capacities of targeted release areas can be determined before programs are initiated to (1) determine whether the case is appropriate for stock enhancement and (2) determine optimum release densities of hatchery-raised organisms. Certain microhabitats within a targeted release region may have higher carrying capacity and greater food or refuge resources than others, and therefore distribution of hatchery-raised organisms can be optimized.

Methods of determining whether stock enhancement is successful are more difficult. Determining success requires knowledge about how well hatchery-raised organisms survive, how well wild organisms survive to allow comparison, and the contribution of hatchery organisms to the total population. As programs are developed, a wide range of survivorship and contribution values have been reported. For example, survivorship to fishery size was 3–4% for stocked panaeid shrimp (28), 21% for red drum in Texas (47), and up to 30% for Japanese flounder (3). Even among programs for the same species, values range widely. For example, in some European lobster programs, no hatchery-raised lobsters were recaptured in the fishery, and in others, 10–35% of landed lobsters were of hatchery origin (37).

Often the steps to quantify the success of a stock enhancement program take years of scientific study and require laborious study efforts, such as tagging and resampling individuals over time. Such efforts have been deemed mandatory by critics of stock enhancement programs before public monies are used to support these efforts to bolster fishery stocks, one of the world's most important natural resources.

PHYSICAL AND CHEMICAL VARIABILITY OF TIDAL STREAMS

Paolo Magni

Shigeru Montani
Hokkaido University
Hakodate, Japan

This article focuses on the variability of major hydrologic parameters of tidal streams that occur on different temporal and spatial scales within an individual estuary. Rapid changes in water temperature and salinity take place on a timescale of <1 hour, as a strong function of the tidal state (e.g., low vs. high tide) and amplitude (e.g., spring vs. neap tide). Large day–night fluctuations of dissolved oxygen (DO) concentration are also demonstrated and discussed in relation to the extent of *in situ* biological processes. In addition, the variability of these parameters is evaluated seasonally at controlled low tide. Finally, the year-round distribution of nutrient concentrations (i.e., ammonium, phosphate, silicate, and nitrate+nitrite) in low tide ebbing water is presented and compared with the variability in nutrient concentrations in the sediment porewater of an adjacent exposed sandflat.

SHORT-TERM (HOUR) VARIABILITY

A tidal stream crossing the interidal zone of an estuary in the Seto Inland Sea, Japan, was selected to describe daily fluctuations in water temperature, salinity, and DO concentration (1). Continuous measurements lasting 24 to 28 hours were made during two different tidal cycles, a spring tide of May 1995 and a neap tide of May 1996, using a CTD recorder (Alec AST-1000) placed about 10 cm from the bottom sediment (2,3).

Rapid and drastic changes in the selected parameters occurred during both surveys in 1995 (Fig. 1a) and 1996 (Fig. 1b). Major differences between the two surveys were also found, consistent with spring–neap tidal contrasts (4). Fluctuations in water depth were stronger in the 1995 survey than in the 1996 survey due to a larger amplitude in the tidal cycle during a spring tide (Fig. 1a). In particular, two major lower and higher tidal levels, typical of *mixed-semidiurnal* estuaries, occurred on May 30–31, 1995, as predicted by the local Maritime Safety Agency (2); the maximum tidal range was ca. 2 m (Fig. 1a).

Accordingly, the temporal changes in salinity were largest during the 1995 survey; salinity dropped from >31 to 2.0 psu, coincident with the lower low tide, and rapidly increased up to >31 psu again before the following higher high tide (Fig. 1a). At the subsequent higher low tide, the decrease in salinity was less marked, and minimum values were about 25 psu. An overall more restricted fluctuation of salinity occurred in the 1996

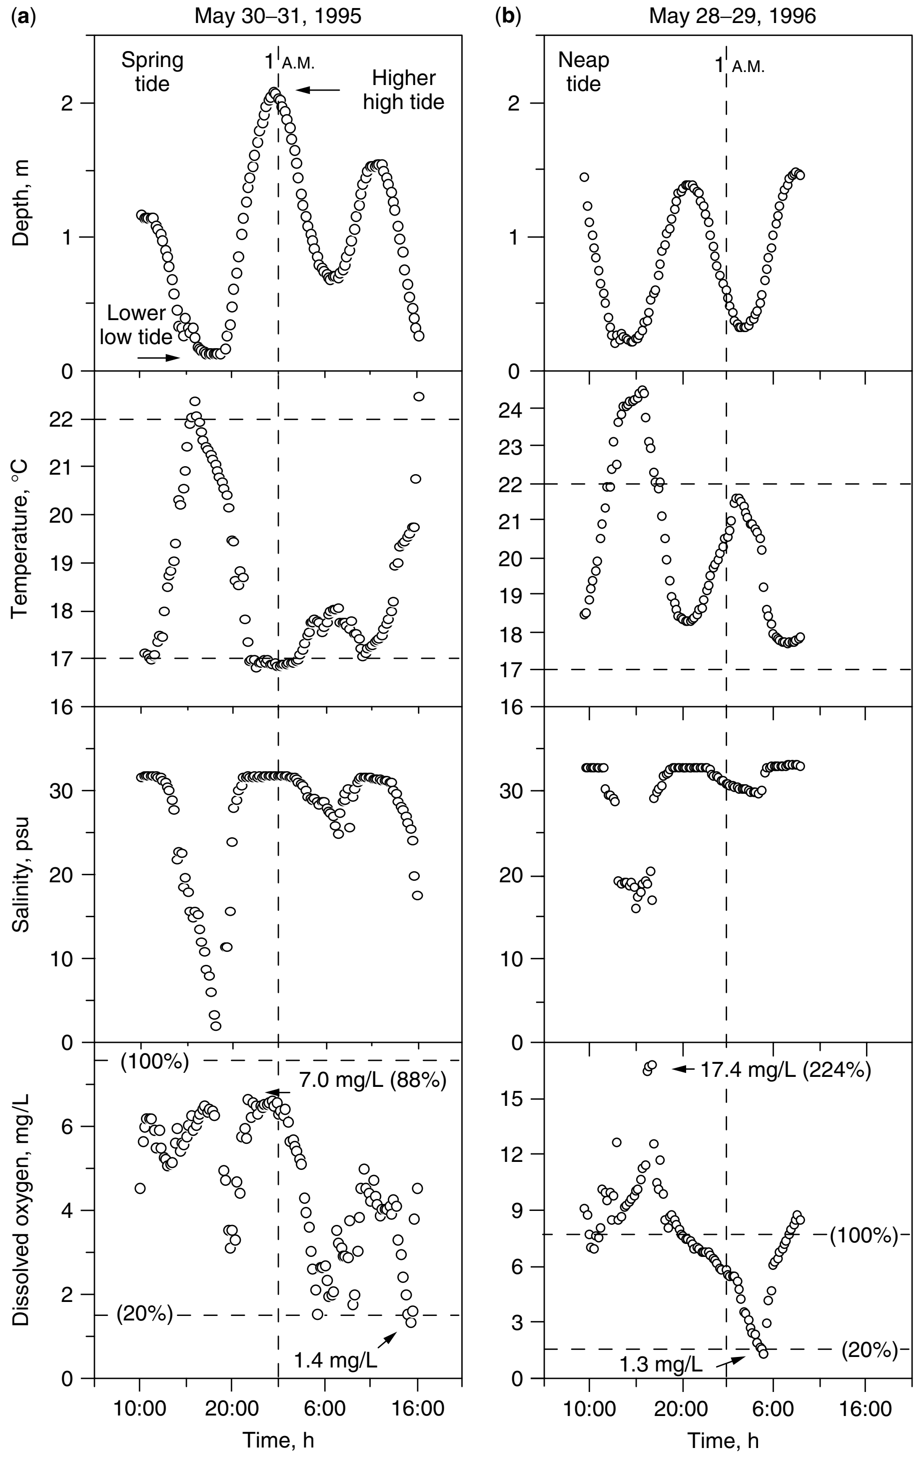

Figure 1. Daily fluctuations of water depth, temperature, salinity and dissolved oxygen (DO) concentration of a tidal stream in an estuarine intertidal zone (Seto Inland Sea, Japan). Measurements were made using a CTD cast placed ca. 10 cm from the bottom sediment at the end of May of 2 consecutive years (a: 1995; b: 1996). Relevant sensors were logged every 15 min. Notes: horizontal dashed lines in temperature and DO boxes individuate major differences within the same range of values (17–22 °C and 20–100% of air saturation, respectively) recorded in the 2 years. In DO boxes, absolute minimum and maximum values are also indicated. The vertical dashed line is arbitrarily depicted at 1 A.M. to highlight the temporal differences in tidal state and amplitude between the two surveys.

survey, consistent with the reduced amplitude of the tide (Fig. 1b) and a rainfall regime more limited in spring 1996 than in spring 1995 (1). These results show that saline intrusion is a strong function of tidal state (e.g., low vs. high tide) and amplitude (e.g., spring vs. neap tide). They also demonstrate that tidal streams may experience, within a few hours, strong changes in salinity that cause very different habitat conditions at the same location in an estuary. These may vary from oligohaline (0.51–5 psu) to euhaline (30.1–40 psu) conditions, in agreement with salinity ranges given by the Venice Conference (5).

The daily fluctuation in water temperature varied according to the tidal cycle and showed a temporal pattern opposite to that of salinity during both surveys (Fig. 1a, b). The range of temperature was relatively larger in May 1996 (17.7–24.5 °C) than in 1995 (16.9 °C–22.3 °C). In both cases, it was apparent that warmer waters were brought into the estuary by the freshwater runoff during ebb flow. These results are consistent with the period and site of measurements; physical processes of heat transfer in spring–summer (and water cooling in winter) are most effective in the upper and shallower riverine zone of the estuary (1).

Dissolved oxygen (DO) concentration was subjected to strong daily fluctuations, partly as a function of the tidal state (and water depth). The two surveys also showed major differences (Figs. 1a and b). In the 1995 survey, DO concentration was mostly within normoxic values, ranging from 1.4 mg/L to 7.0 mg/L. Differently in the 1996 survey, DO concentration showed a larger variation, in much higher values up to 17.4 mg/L.

Elevated DO concentrations are related to ecosystem processes of primary production (6). It is known that shallow lagoons and coastal areas dominated by seagrass or macroalgae are subjected to oversaturation of DO (i.e., >100% of air saturation), especially during the warm period (7,8). Viaroli et al. (7) reported DO oversaturation up to 150% in the near-bottom water of a coastal lagoon dominated by the macroalga *Ulva*. This was followed by the outbreak of a dystrophic crisis, complete anoxia through the water column at some stations of the lagoon. The development of large amounts of macroalgae (*Ulva* sp.) also tends to occur in the estuarine sand flat of this study coincident with increasing temperature and solar radiation during the spring. Extended beds of macroalgal biomass were present during the field measurements of the 1996 survey (personal observations). Accordingly, during the daytime measurements of May 28, DO concentration rapidly rose to oversaturation; a major increase of >200% of air saturation occurred between 16:00 and 16:30 (Fig. 1b), indicating a period of major oxygen production by macroalgae. Similar to the extremely high DO values found in this study, Piriou & Ménesguen (9) reported that the *in vitro* growth of *Ulva* under light saturation and nutrient enrichment raised the DO concentration to 22 mg/L, 4 hours after the experiment started.

By contrast, during nighttime, a progressive decrease in DO concentration occurred, down to hypoxic values of <1.4 mg/L or <14% of air saturation (10). Subsequently, at the next daylight of May 29, the DO concentration was back to normoxic values, reaching oversaturation (Fig. 1b). Differently during the 1995 survey, a much reduced macroalgal biomass was found that tended to be rapidly flushed away by heavy rainfall in spring 1995 (1). This was associated with a more a restricted range of DO concentration that never reached oversaturation during the daytime; whereas, similar to the 1996 survey, hypoxic values occurred during nighttime (Fig. 1a, b). Thus, the different extent of macroalgal coverage indicated how a large DO fluctuation might strongly depend on the extent of biological processes, such as photosynthesis and primary production in the presence of light and respiration at night.

SEASONAL VARIABILITY

This section presents the results of monthly measurements of water temperature, salinity, and DO concentration at controlled low tide on the same tidal stream where the short-term measurements of May 1995 and May 1996 were conducted (see above section and Fig. 1). Between January 1995 and April 1996, the water temperature varied from 3.6 °C ± 0.3 (December) to 29.0 °C ± 1.8 (July) (Fig. 2). Statistically significant differences were demonstrated for the specific geographical area (latitude 34°21′ N, longitude 43°21′E) between a warm period (May–October, water temperature 23.5 ± 4.2 °C) and a cold period (November–April, water temperature 10.0 ± 4.4 °C) (1).

The seasonal variability in low-tide salinity (Fig. 2) was consistent with the results obtained from the short-term measurements of May 1995 and May 1996 during a complete tidal cycle (Fig. 1). In particular, the salinity recorded during the seasonal survey was lowest on May 16, 1995 at 4.6 ± 1.5 psu (Fig. 2). Accordingly, the short-term measurements of May 1995 showed a salinity decrease during low tide to <5 psu (Fig. 1a). By contrast, reduced rainfall during the second half of 1995 and the first half of 1996 (1) corresponded to a progressive increase in salinity in the low-tide stream water during that period. In particular, salinity was >25 psu between the end of September 1995 and April 1996 and reached the highest values in November 1995 at 31.4 ± 1.1 psu (Fig. 2). Consistently, also during the short-term measurements of May 1996, the decrease in salinity during low tide was more limited than that found in May 1995 (Fig. 1a, b).

The DO concentration also varied greatly from 5.4 ± 1.7 mg/L (September 1995) to 15.1 ± 1.1 mg/L (April 1996)

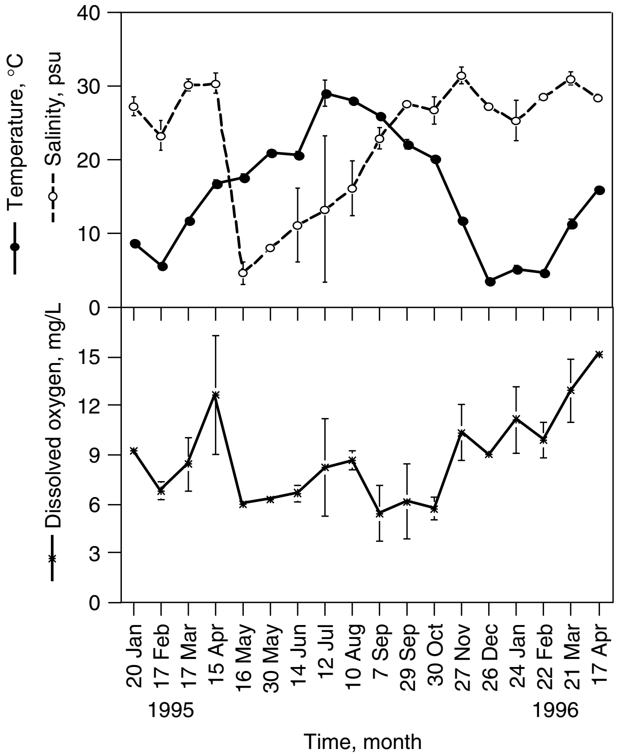

Figure 2. Seasonal variability in temperature, salinity, and dissolved oxygen (DO) concentrations in estuarine ebbing waters during a daytime low tide (Seto Inland Sea, Japan). Data source: Reference 1 (partially redrawn from Fig. 2, as mean values ± standard deviation of Stns. H1 and H2) (with kind permission of Kluwer Academic Publishers).

(Fig. 2). The temporal distribution of the DO concentration highlighted that, after a progressive increase from February 1995 (6.8 ± 0.5 mg/L) to April 1995 (12.6 ± 3.6 mg/L), a noticeable drop in DO concentration to 6–7 mg/L occurred in late spring, May 1995. This tended to persist throughout the following months (Fig. 2). In the second part of the seasonal survey, the DO concentration progressively increased again from relatively low values of 5.7 ± 0.7 mg/L^{-1} in October 1995 to 15.1 mg/L in April 1996 (Fig. 2). The temporal variability of the DO concentration was also consistent with the differences found during the short-term measurements. In particular, the DO level hardly reached oversaturation during the short-term measurements of spring 1995 (Fig. 1a), but it was up to >200% of air saturation in spring 1996 (Fig. 1b).

Nutrients

Nutrients, such as ammonium ($NH_4{}^+$-N), nitrate+nitrite ($NO_3{}^- + NO_2{}^-$-N), phosphate ($PO_4{}^{3-}$-P) and silicate [$Si(OH)_4$-Si], play a major role in controlling the growth, abundance, and structure of primary producers in the ocean (11,12). A qualitative and quantitative evaluation of their distribution represents therefore a fundamental step in assessing the dynamics of biophylic elements (e.g., carbon, nitrogen, phosphorus, and silicon) and the system processes of production and respiration (6). The variability in nutrient concentrations in transitional aquatic systems, such as estuaries and tidal streams, is related to the close interaction between water chemistry, tidal hydrology, and sedimentary processes (1,13,14).

Several approaches have been undertaken on different temporal and spatial scales to evaluate such variability. Time-series surveys of nutrient distribution have been carried out in relation to the ebb–flood tidal state (15–18) and the spring–neap tidal amplitude (4,19,20) or by controlled sampling regimes, such as around high tide (16,21). Other studies in coastal marine systems have used either intact cores (22,23) or *in situ* chambers (24) to quantify the nutrient flux at the sediment–water interface. However, a satisfactory evaluation of the actual physicochemical and biological processes from field enclosed experiments may be controversial because of the nonnatural state of the system, which is shielded from large water movements (25,26). This is particularly true in intertidal environments that are subjected to strong hydrodynamic tidal energy and are more rapidly and directly influenced by "external" variables (e.g., rainfall) and *in situ* benthic processes (e.g., nitrogen uptake by primary producers and release by macrozoobenthos) (27–33).

This work provides an example of the variability of nutrient concentrations in tidal stream water, consistent with large seasonal changes in temperature, salinity, and DO concentration (Fig. 2). A comparison with the nutrient concentrations in the sediment porewater from an adjacent sand flat exposed at low tide is given; it shows how major differences may occur between two closely interacting compartments of an estuary.

The seasonal distribution of nutrient concentrations in ebbing water and in sediment porewater is depicted in Fig. 3, and their annual range of variability is given in Table 1. Ammonium and phosphate concentrations

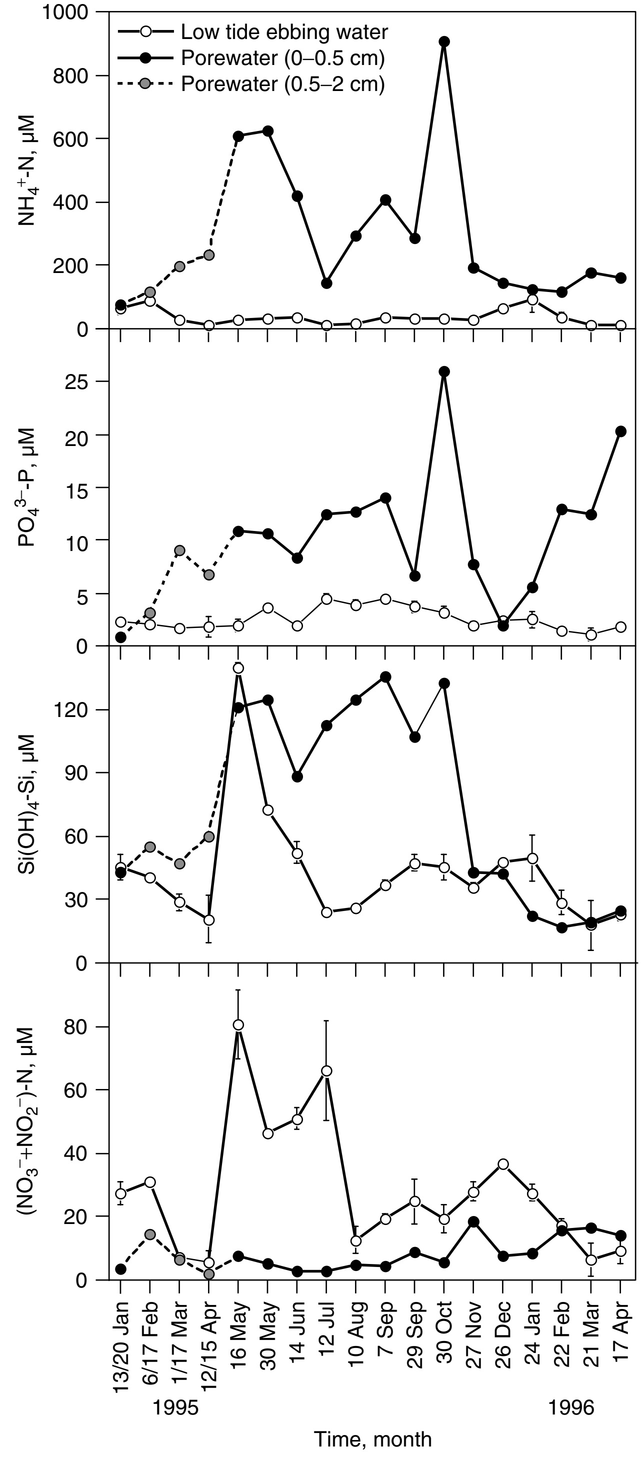

Figure 3. Seasonal variability in nutrient concentrations in estuarine ebbing waters and surface (0–0.5 cm) sediment porewater on an adjacent sand flat measured during a daytime low tide (Seto Inland Sea, Japan). Grey circles refer to porewater nutrient concentrations in subsurface (0.5–2 cm) sediments. On the horizontal axis, two different days from January 1995 to April 1995 refer to the dates of porewater (first day) and ebbing water (second day, see also Fig. 2) sampling. Data sources: ebbing water, data from Reference 1 (partially redrawn from Fig. 3, as mean values ± standard deviation of Stns. H1 and H2) (with kind permission of Kluwer academic Publishers).

Table 1. Annual Minimum and Maximum Values (± Standard Deviation and Period of The Year) of Nutrient Concentrations (μM) in Low Tide Ebbing Water and in the Porewater of Surface (0–0.5 cm) Sediments from an Adjacent Emerged Sand Flat (Seasonal Variation in Fig. 3)

	Ebbing Water		Sediment Porewater	
	Minimum	Maximum	Minimum	Maximum
NH_4^+	10.2 ± 6.8 (Apr ′95)	90.8 ± 39.2 (Jan ′96)	75.1 (Jan ′95)	908 (Oct 30, ′95)
PO_4^{3-}	1.1 ± 0.6 (Mar ′96)	4.5 ± 0.4 (Jul ′95)	0.9 (Jan ′95)	26.0 (Oct 30, ′95)
$Si(OH)_4$	17.9 ± 11.7 (Mar ′96)	139.6 ± 2.5 (May 16, ′95)	17.1 (Feb ′96)	135.7 (Sept 7, ′95)
$NO_3^- + NO_2^-$	5.7 ± 3.5 (Apr ′95)	80.7 ± 11.0 (May 16, ′95)	2.8 (Jul ′95)	18.6 (Nov ′95)

in ebbing water are much lower than those found in porewater in all seasons and on most occasions. However, a noticeable peak of ammonium concentration in ebbing water was observed during the colder months (December–February), coincident with a general decrease in ammonium concentration in the porewater. To some extent, this was also true for phosphate, which showed relatively lower values in porewater than in ebbing water in January 1995 and December 1995 (Fig. 3). Silicate concentration tended to follow a pattern similar to that of ammonium and phosphate, especially between spring and late summer. However, the extent of the differences in silicate concentration between porewater and ebbing water was more limited in autumn and spring. For the study area examined, it is suggested that a diffusive upward flux of nutrients from sediments, if solely based on the water–sediment concentration gradients (29,34) would be relatively limited, yet highly variable with season.

Different from the spatial distribution of ammonium, phosphate, and silicate, nitrate+nitrite concentration was higher in ebbing water than in porewater; major peaks occurred during periods of enhanced rainfall, as indicated by the sharp decrease in salinity on May 16 (Fig. 2). This is consistent with previous companion studies that demonstrated that freshwater input is a major contributor of nitrate+nitrite to the estuary of this work (1,2).

Finally, it can be highlighted that low nitrate concentration in porewater, further decreasing through the sediment column, commonly occurs due to numerous processes within sediment, such as nitrate ammonification and/or denitrification processes (35,36).

BLACK WATER TURNS THE TIDE ON FLORIDA CORAL

NASA—Goddard Space Flight Center

In early 2002, a patch of “black water” spanning over 60 miles in diameter formed off southwestern Florida and contributed to severe coral reef stress and death in the Florida Keys, according to results published from research funded by NASA, the U.S. Environmental Protection Agency and the National Oceanic and Atmospheric Administration (NOAA). The “black water” contained a high abundance of toxic and non-toxic microscopic plants.

Chuanmin Hu and other colleagues at the Institute for Marine Remote Sensing of the University of South Florida (USF), St. Petersburg, Fla., and colleagues from the Florida Fish and Wildlife Conservation Commission (FFWCC) and the University of Georgia, co-authored an article on this phenomenon that appeared as the cover

---

story of a recent issue of the American Geophysical Union's Geophysical Research Letters.

"The water appeared black in satellite imagery because the concentration of the microscopic plants and other dissolved matters were high," Hu said. Because plants and dissolved matter absorb sunlight, they reduce the amount of light normally reflected from the ocean. When a red-tide bloom occurs the water takes on various hues of red or brown. While not all microscopic plants contribute to red tides, the darker hue created by both the plankton and the harmful algal blooms made the water appear black when seen from the satellite.

When Hu and his colleagues examined the data collected by divers from the dark water area in the Florida Keys, they discovered a 70 percent decrease in stony coral cover, a 40 percent reduction of coral species, and a near-elimination of sponge colonies at two reef sites after the dark water passed. By examining satellite images and field survey data, the authors concluded that the coral reef ecosystem was stressed by microscopic organisms and toxins contained in the dark water.

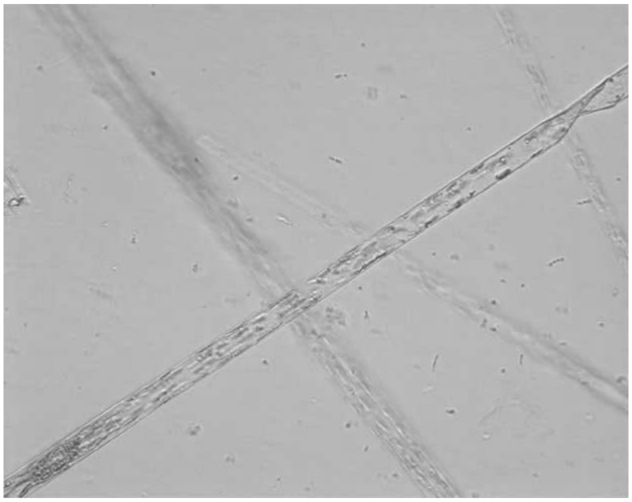

Figure 3. Microscopic image of a dinoflagellate, called Rhizosoleniacea, a cause for Red Tide. Rhizosoleniaceae blooms occur seasonally off Florida's Gulf coast due to freshwater outflow from the Everglades. Courtesy Florida Marine Research Institute.

The "black water" event caused alarm among local fishermen, divers, and the public, as the color of the water was unusual and fish seemed to avoid this large area of dark water. Satellite instruments such as the Sea-viewing Wide Field-of-view Sensor (SeaWiFS) aboard Orbimage's SeaStar satellite and the Moderate Resolution Imaging Spectroradiometer (MODIS) aboard NASA's Terra and Aqua satellites provide information on ocean color that allows scientists to monitor the health of the water and the shallow benthic (ocean bottom) environment. The SeaWiFS and MODIS measurements of the dark water led to a number of investigations to help clarify the issues and to provide answers to the public's concerns.

During January 2002, SeaWiFS detected the dark-colored water in the Florida Bight, just southwest of the Everglades. In fall 2001, the SeaWiFS images showed an extensive red tide off Florida's central west coast, near Charlotte Harbor.

Red tides occur every year off Florida and are known to cause fish kills, coral stress and mortality, and skin and respiratory problems in humans. They are caused by high concentration of microscopic plants called dinoflagellates. Other microorganisms called cyanobacteria can also cause harmful algal blooms. The waters containing this red tide migrated to the south along the coast.

Winter storms caused large amounts of fresh water to drain from the Everglades into Florida Bight (the curve in

the shoreline from the Keys north to Everglades National Park on the mainland), carrying high levels of nutrients such as silicate, phosphorus, and nitrogen to the sea. These caused a bloom of the microscopic marine plants known as diatoms in the same patch. The bloom turned the water dark and the "black water" patch re-circulated for several months in a slow clockwise motion off southwest Florida in the Florida Bight. Slowly, the dark water drifted farther south and toward the Florida Keys. By May 2002, the "black water" had moved through passages in the Florida Keys, dispersing into the Atlantic and the Gulf Stream.

SHALLOW WATER WAVES

Stefano Pagliara
Pietro Chiavaccini
Universitá di Pisa
Pisa, Italy

INTRODUCTION

Shallow water conditions happens when the ratio of water depth d to the wave length L is less than 1/25, i.e., $d/L < 0.04$. In this condition, there is a combination of high wave steepness, and ratios of wave height to water depth are close to unity. Shallow water waves approaching the coast are subjected to refraction, shoaling, and breaking.

THE SHALLOW WATER THEORIES

The Linear Theory

The linear wave theory (1), in which the nonlinear terms of the equation of motion are omitted, describes water motion by two nondimensional parameters, the relative depth d/L and the wave steepness H/L, which represent respectively the influence of the depth on wave characteristics (celerity, length, and height) and the measure of the wave dimension in respect of height. For large values of relative depth, the linear theory cannot be applied.

Wave profile in linear theory is defined by

$$\eta = a\cos(kx-\omega t) = a\cos\left(\frac{2\pi x}{L}-\frac{2\pi x}{T}\right) \tag{1}$$

The celerity is

$$C = \frac{L}{T} = \left(\frac{gT}{2\pi}\right)\tan h\left(\frac{2\pi d}{L}\right) = \sqrt{\left(\frac{gL}{2\pi}\right)\tan h\left(\frac{2\pi d}{L}\right)} \tag{2}$$

In shallow water, as $\frac{d}{L}\to 0 \tan h\left(\frac{2\pi d}{L}\right)\to\frac{2\pi d}{L}$ and celerity becomes dependent only on depth

$$C = \sqrt{gd} \tag{3}$$

Wave train propagates with a speed different from the celerity, called group velocity, defined by

$$C_G = nC = \frac{1}{2}\left[1+\frac{2\pi d}{L}\frac{1}{\operatorname{senh}\left(\frac{2\pi d}{L}\right)}\right]C \tag{4}$$

In shallow water, the group velocity becomes $C_G = C$ because $n\to 1$, so wave train propagates with the same speed of the single waves of the train.

In reality, a wave approaching the coast is modified by the bottom: its height grows and loses characteristics of linearity, which implies a more detailed formulation.

The nonlinear theories, used more to describe shallow water waves, are the cnoidal wave theory and the solitary wave theory.

The Cnoidal Wave Theory

The theory of cnoidal waves was first developed by Korteweg and de Vries (2) and can be used to described unidirectional waves in shallow water, where $d/L < 1/8$ and $Ur > 20$. If the water height is small, the cnoidal wave profile becomes the sinusoidal one.

The cnoidal wave is periodic with the profile given by

$$\eta(x,t) = hCn^2\left[2K(\kappa)\left(\frac{x}{L}-\frac{t}{T}\right),\kappa\right] \tag{5}$$

where $K(k)$ is the complete elliptic integral of the first kind of modulus k, $Cn(r)$ is the Jacobian elliptic function, and h is the vertical coordinate of the water surface about the trough level at the horizontal coordinate. To simplify the use of *cnoidal* theory, Wiegel (3) developed graphs and table of easy appliance.

The Solitary Wave Theory

The solitary wave is a progressive wave consisting of a single crest and is not oscillatory as the other examined. The wave form is (4)

$$\eta(x,t) = H\sec h^2\left(\sqrt{\frac{3H}{4d^3}}(x-Ct)\right) \tag{6}$$

where C (wave celerity) is defined by

$$C = \sqrt{gd}\left(1+\frac{H}{2d}\right) \tag{7}$$

According to the dispersion relation of the linear wave theory, the celerity of water waves in shallow water (Eq. 3) is smaller than solitary wave phase velocity because of the inclusion of terms that depend on H/d.

The solitary wave describes enough well waves approaching shallow water, even if wave period or wave length are not associated with the theory. When the wave pass from deep to shallow water their crests peak up and are separated by flat troughs appearing like a series of solitary waves. Solitary theory appears reasonable even if the periodicity is neglected, because in shallow water the period is not particularly significant, but rather the water depth becomes important.

As the solitary wave advances into shallow water, its height increases, the crests becomes greater and sharper, the trough becomes longer and flatter: in this condition, a wave is well represented by solitary waves. The solitary wave is not an oscillatory wave, as those obtained with other theories, but a translation one. Water particles, as a wave passes, are subjected to a translation in wave direction, whereas in the oscillatory waves it moves forward and backward, remaining after a period in its original position.

Wave profiles, according to the theories illustrated above, are presented in Fig. 1.

WAVE REFRACTION AND SHOALING

Waves passing from deep to shallow water are subjected to refraction in which the direction of their travel changes in such a way that approaching the coast the crests tends to become more parallel to the depth contours (Fig. 2). To determine the variation of the wave direction, Snell's law can be applied

$$\frac{\sin\theta_1}{C_1} = \frac{\sin\theta_2}{C_2} = \text{cons} \tag{8}$$

where q_1 and q_2 are the angles between adjacent wave crests and the respective bottom contours, whereas C_1 and C_2 are the wave celerity at the two depths.

With a regular bottom (straight and parallel contours), the relation can be applied directly between the angle at any depth and the deep water angle approach.

With an irregular bottom, wave refraction may cause a spreading or a convergence of the wave energy. This effect can be easily illustrated taking in account the wave rays (Fig. 2), defined as the lines drawn normal to the wave crests and directed in the wave advance. If the wave rays spread, the wave crests become longer and the energy flux, assumed constant between two rays, must be extended over a greater length. The opposite (energy concentration) happens if the waves rays converge.

Actually, the calculations of the rays are made by software based on models such as a mild slope, parabolic, or Boussinesq wave model.

Another effect of the change in the wave length in shallow water is that the wave height increases. This effect is the consequence of the energy conservation in

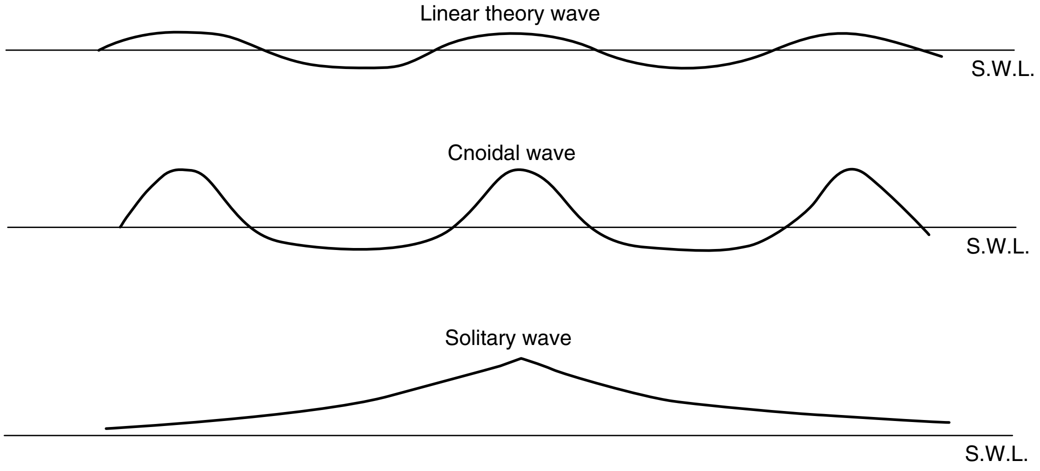

Figure 1. Wave profiles.

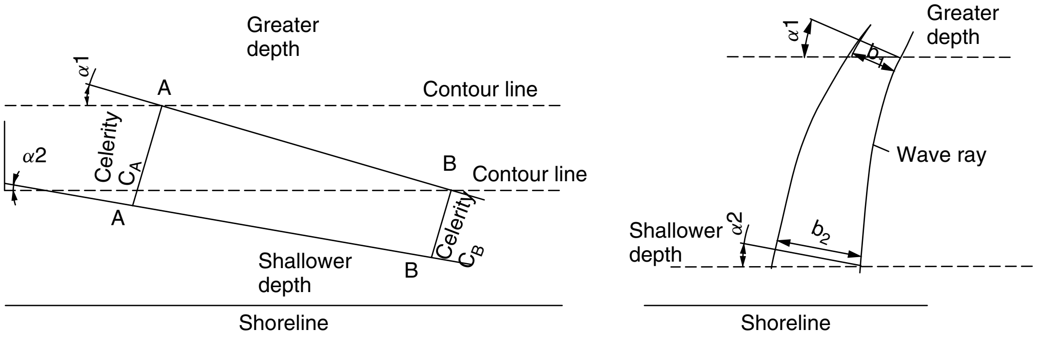

Figure 2. Wave refraction and wave rays.

concert with the decrease of the celerity approaching the shallow water. This phenomenon is referred to as shoaling.

The effects of shoaling and refraction in water can be expressed by the following formula:

$$H = H_0 K_s K_r \tag{9}$$

where H_0 is wave height in deep water, K_s is the shoaling coefficient

$$K_s = \sqrt{\frac{C_{G0}}{C_G}} = \sqrt{\frac{1}{2n \tan h \dfrac{2\pi d}{L}}} \tag{10}$$

with $n = \dfrac{1}{2}\left(1 + \dfrac{2\pi d}{L}\dfrac{1}{\operatorname{senh}\left(\dfrac{2\pi d}{L}\right)}\right)$ and K_r is the refraction coefficient

$$K_r = \sqrt{\frac{b_0}{b}} \tag{11}$$

where b_0 and b are the distance between two adjacent rays, respectively, in deep water and at a generic depth. For straight and parallel contours lines, the refraction coefficient becomes

$$K_r = \sqrt{\frac{\cos\theta_0}{\cos\theta}} \tag{12}$$

WAVE BREAKING

Waves shoaling causes the increasing of wave height until its physical limit because of steepness of wave H/L. When this limit is reached, the wave breaks and dissipates energy. Battjes (5) has shown that the breaking wave characteristics can be correlated to a parameter, called surf similarity x, which is defined as

$$\xi = \frac{\tan\beta}{\sqrt{\dfrac{H_0}{L_0}}} \tag{13}$$

where $\tan b$ is the beach slope and H_0 and L_0 are the wave height and length in deep water, respectively.

Three common type of breakers are recognized (Fig. 3):

- spilling ($x < 0.5$), in which each wave gradually peaks until the wave becomes unstable and cascades down as white water, bubbles, and foam;
- plunging ($0.5 < x < 3.3$), in which the shoreward face of the wave becomes vertical, curls over, and plunges forward and downward as an intact mass of water;
- surging ($3.3 < x < 5$), in which the base of the wave, while it is peaking up, finds the shore, and then the crest collapses and disappears.

When the surf similarity x is >5, reflection happens and no breaking occurs.

According to Galvin (6), a fourth breaker, called collapsing, intermediate between plunging and surging types, exists.

It is difficult to identify which type of breaker can verify, because it depends on the individual heights and interactions of the waves. Plunging and surging breakers can be seen on a beach during the same storm. However, spilling breakers are typical of very low sloping beaches with waves of high steepness values; plunging waves occur in steeper beaches and waves of intermediate steepness; surging, instead, is associated with high gradient beaches with waves of low steepness.

The breaking happens when the water particle velocity is greater than wave celerity. According to solitary wave theory, this condition is described by (7)

$$\left(\frac{H_b}{d_b}\right)_{\max} = 0.78 \tag{14}$$

where the subscript b denotes the breaking.

Laboratory tests pointed out that Equation (14) is verified more for oscillatory waves than solitary wave. However, it is considered fundamental to express the relation between the relative depth and the breaking condition.

Other parameters playing a role in wave breaking exist, such as beach slope and bottom roughness. An empirical relation considers the beach slope m (8):

$$\left(\frac{H_b}{d_b}\right)_{\max} = 0.75 + 25m - 112m^2 + 3870m^3 \tag{15}$$

in which as the slope increases, the breaking happens more and more nearshore.

Another expression was developed by Goda (9)

$$\left(\frac{H_b}{d_b}\right)_{\max} = 0.17\frac{L_0}{d_b}\left[1 - \exp\left(-\frac{15\pi d_b}{L_0}(1 + 15m^{4/3})\right)\right] \tag{16}$$

where L_0 is the deep water wave lenght.

For irregular waves (waves with different height and period), Kamphuis (10) proposed two criteria based on

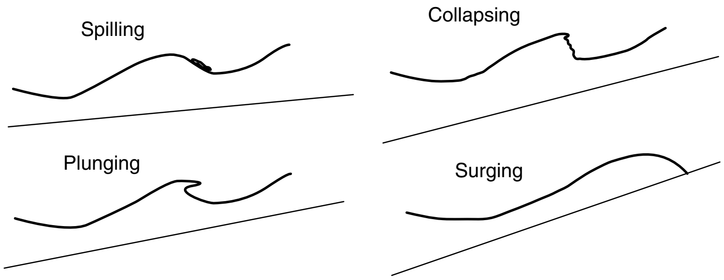

Figure 3. Breaking types.

extensive model tests

$$H_{sb} = 0.095e^{4m}L_{bp}\tan h\left(\frac{2\pi d_b}{L_{bp}}\right) \tag{17}$$

$$\frac{H_{sb}}{d_b} = 0.56e^{3.5m} \tag{18}$$

where H_{sb} is the significant wave breaking, L_{bp} the breaking wave length, and d_{b} is the breaking depth.

WATER WAVES

Nai Kuang Liang
National Taiwan University
Taipei, Taiwan

INTRODUCTION

As one stands at the coast, an endlessly moving succession of irregular humps and hollows can be seen reaching to the shore. This is the water wave generated by wind. There are different kinds of water waves, which are driven by different forces. Beside wind waves, the tide and the tsunami are other well-known water waves. Different Water waves are distinguished by their wavelength, which is defined as the length between successive humps. The wavelength of a wind wave is shorter and is easily recognized.

A water wave is an important physical phenomenon in an ocean, sea, or lake. It influences beach morphology, maritime structures, and human activities very much. Because the wind varies tremendously, a typhoon or hurricane may generate huge waves. This storm usually causes disasters. Tidal and wind waves contain a lot of energy. Electric power can be generated by them.

BASIC CHARACTERISTICS OF A WATER WAVE

The water wave was studied mathematically in the nineteenth century as a form of oscillatory wave. In 1847, Stokes (1) published his famous paper entitled "On the theory of oscillatory waves." Stokes' wave theory has been widely used till now. The elements of an oscillatory wave are wave height, wave period, and wavelength. The wave height H is the distance between the wave crest and trough. The wavelength L is the distance between successive crests, and the wave period T the time difference between successive crests. In deep water, the water depth H is larger than the half of the wavelength L. After Stokes, L is a function of the wave period T in the following equation:

$$L = \frac{gT^2}{2\pi} \tag{1}$$

The wave celerity C is then

$$C = \frac{L}{T} = \frac{gT}{2\pi} \tag{2}$$

in which g is the earth's gravitational acceleration. Obviously, the celerity C is proportional to the wave period T. The water depth is less than $L/2$, so then the wave particle movement touches the bottom. Tides and tsunamis usually are shallow water waves or long waves. Equations 1 and 2 become the following:

$$L = \frac{gT^2}{2\pi}\tanh\left(\frac{2\pi h}{L}\right) \tag{3}$$

$$C = \frac{gT}{2\pi}\tanh\left(\frac{2\pi h}{L}\right) \tag{4}$$

A wave contains kinetic and potential energy. The average energy E per unit sea surface area is the following:

$$E = \frac{1}{8}\rho g H^2 \tag{5}$$

The wave energy propagates in a group velocity, Cg, which is given by the following equation (2):

$$Cg = \frac{C}{2}\left(1 + \frac{4\pi h/L}{\sinh 4\pi h/L}\right) \tag{6}$$

The wave energy flux P is as follows:

$$P = E \cdot Cg \tag{7}$$

A real ocean wave is not oscillatory, as Stokes' theory described, but irregular in a stochastic process. Pierson (3,4) introduced the technique of communication engineering to the ocean wave and proposed the random wave theory. The ocean wave would be a superposition of sinusoidal wave components of different directions, amplitudes, frequencies, and angular phases, in which the phase is a random variable of equal probability density between—π and π. Then the ocean wave can be represented by a power spectrum. However, for convenience, engineers usually use the significant wave to represent the ocean wind wave. For a group of N wave heights measured at a point, waves are ordered from the largest to the smallest and assigned a number from 1 to N to them. The significant wave height $H_{1/3}$ is defined as the average of the first (highest) $N/3$ wave heights (5). The order of the wave period is accompanied by its wave height as a pair. The significant wave period $T_{1/3}$ is defined as the average of the first $N/3$ wave periods.

WIND WAVE FORECASTING

During the Second World War, two famous American oceanographers, Dr. H.U. Sverdrup and Dr. W.H. Munk, were assigned by the U.S. Navy to develop a wind wave forecasting scheme for the Normandy landing operations. The work was originally completed in 1943 and classified and published in 1947(6). Later, the scheme was extensively patched and amended by Bretschneider(7). Therefore, the scheme has been named the SMB method. In the SMB method, the wind speed, wind duration, and fetch are the main parameters, where fetch is defined as the wind blowing distance in the water area.

Modern ocean wave modeling was initiated in 1956 and extensively developed and revised (8). So far it is still developing. The basic concept is the evolution of energy spectrum F governed by the energy balance equation:

$$\frac{df}{dt} = S_{\text{in}} + S_{\text{nl}} + S_{\text{ds}} \tag{8}$$

in which S_{in} is the energy input flux from wind to wave spectrum components, S_{nl} the energy flux exchange due to nonlinear wave–wave interaction, and S_{ds} the energy flux output due to dissipation. The present operating ocean models are WOM, NWW3, etc.

TYPHOON WAVE

The typhoon or hurricane is an atmospheric eddy that originates in tropical or subtropical ocean regions. The typhoon wind speed is usually very high so that the typhoon wave plays a significant role in the design of coastal and offshore structures. Because the wind velocity changes rapidly, the generation process within typhoons is complicated. Parametric typhoon or hurricane wave prediction models were developed (9,10), which pointed out that the maximum wave exists at the right side of the typhoon center as one faces the forward direction.

The radius of a typhoon is about 200–400 km. When a typhoon is still far away from a location, the swell may arrive because the swell energy propagates usually faster than the typhoon moves. The typhoon can be regarded as a point source of wave generation. If Person A, who does not move, throws balls to Person B at a fixed time interval and the speed of the ball relative to the ground is constant, then Person B receives balls at the same time interval. If Person A moves toward Person B, Person B receives balls at a shorter time interval. If the ball is like energy, Person A throws more energy flux to Person B, as Person A moves toward Person B. This is the same as the well-known Doppler effect. As a whistling train moves toward an observer, the sound heard by the observer is higher in frequency than the actual whistle at the source. The observer receives more sound energy flux. As shown in Equation 7, wave energy flux P is wave energy $E \times$ group velocity Cg, which is proportional to the wave period. The wave energy is proportional to H^2 (Equation 5). Because the typhoon wave moving speed has little effect on the swell period, then the swell height is enhanced, as the typhoon approaches a station (11). There were cases where swell heights were larger than those inside the typhoon because the moving velocity was close to the group velocity of the swell.

WOODS HOLE: THE EARLY YEARS

Northeast Fisheries Science
Center—NOAA

The beginning of Woods Hole dates back to the early 17th century. Five years before the settlement of Jamestown,

---

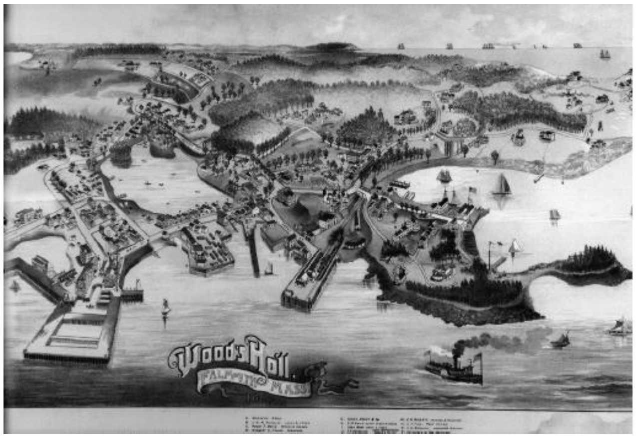
Virginia, and 18 years before the Pilgrims landed at Provincetown and Plymouth, Bartholomew Gosnold coasted along Cape Cod and Marthas Vineyard, and about May 31, 1602, he is believed to have landed at what is now known as Woods Hole. The Town of Falmouth, of which Woods Hole is presently a part, was first settled in 1659–61 when several persons were granted permission to purchase land. The date of the settlement of Woods Hole took place 17 years later. The town (Falmouth) was incorporated on June 4, 1686, and called Succonessett, the name which later, probably in 1694, was changed to Falmouth. On July 23, 1677, the land around Little Harbor of Woods Hole was divided among the 13 settlers in "lots of 60 acres upland to a share" and an "Indian deed" confirming the land title was signed by Job Notantico on July 15, 1679. Fishing, hunting, and sheep breeding were the principal occupations of the early settlers and their descendents. Later on a grist mill was built and salt was made by solar evaporation of sea water in pans built along the banks of Little Harbor.

These quiet, rural conditions, devoid of adventure, persisted until about 1815, when Woods Hole became an important whaling station from which ships operated on the high seas. The whaling industry in the United States became a very profitable business, and Woods Hole was a part of it. In 1854, the total receipts for the American whaling fleet amounted to $10.8 million, the largest part of this amount resulted from whaling carried out by Massachusetts captains. Woods Hole participated in these activities and prospered. It is known that between 1815 and 1860, not less than nine whaling ships were making port at the Bar Neck wharf, which was located where the U.S. Navy building of the Woods Hole Oceanographic Institution now stands. The place was busy processing oil and whalebone and outfitting ships. A bake house for making sea biscuits for long voyages stood next to the present "Old Stone Building" built in 1829 as a candle factory. This conspicuous old landmark on Water Street of Woods Hole, identified by an appropriate bronze plaque, now serves as a warehouse for the Marine Biological Laboratory for storing preserved zoological specimens. About 1860, whaling became less profitable and Woods Hole entered into the second phase of its economic life which was dominated by the establishment and operation of a new commercial venture known as the Pacific Guano Works.

During the years from 1863 to 1889, when the *Pacific Guano Works* was in operation the life of Woods Hole centered around the plant which was built at Long Neck near the entrance to what is known now as Penzance Point. Many large sailing vessels carrying sulphur from Italy, nitrate of soda from Chile, potash from Germany, and many schooners under the American flag loaded with guano and phosphorus from the Pacific Coast of South America were anchored in Great Harbor waiting for their turn to unload their cargoes. The number of laborers regularly employed by the Guano Company varied from 150 to 200 men, mostly Irishmen brought in under contract. Several local fishermen found additional employment as pilots for guano ships. The company maintained a store where various goods such as leather, lead pipe, tin, coal, wood, and other items were bought and sold. The store acted also as a labor housing agency. Through efforts of the business manager of the Guano Company, the Old Colony Railroad was persuaded to extend its branch from Monument Beach to Woods Hole. The establishment of well-organized and reliable transportation to Boston was an important factor in the future life of the community.

The Pacific Guano Works was established by the shipping merchants of Boston who were seeking cargo for the return voyage of their ships. The guano deposits of one of the Pacific islands seemed to furnish this opportunity. As soon as the joint stock company was organized in 1859 with the capital of $1 million, arrangements were made almost immediately by which the newly formed concern came into possession and control of Howland Island. This island is located in the middle of the Pacific Ocean at longitude 177 deg. W., a short distance north of the Equator, about 1, 500 miles true south from Midway Island of the Hawaiian archipelago. At the same time appropriate plant and docking facilities were built at Woods Hole and 33 large sailing ships became available for hauling guano. Unlike the well-known guano islands off the coast of Peru, Howland Island is located in the zone of abundant rainfall. Consequently, the guano deposits of the island were leached of organic components and consisted of highly concentrated phosphate of lime.

Fertilizer produced by the company was made by restoring the lost organic matter of the phosphate rock



1887 Map of Woods Holl (Fisheries is bottom left) by adding the right proportion of organic constituents which were obtained from menhaden, pogy, and other industrial fish which abound in Cape Cod waters. The rock was pulverized and purified by washing; fish brought in by local fishermen were first pressed to extract oil, and the residue digested with sulphuric acid, washed, and dried. Acid was produced locally from sulphur imported from Sicily, and the digestion of fish flesh was carried out in large lead-lined vats. The plant was well equipped with machinery needed for the process and even had a chemical laboratory where chemists made the necessary analyses. Various sheds for storage and drying, barracks for laborers, and a business office completed the facilities.

When the deposits of phosphate rock on Howland Island were exhausted, the company acquired title to the Greater and Lesser Swan Islands from the U.S. Government. These islands are located in the Caribbean Sea at latitude 17 deg. N. and longitude 83 deg. W. off the coast of Honduras. The islands are only 400 miles from Key West, Florida, and 500 miles from New Orleans. They contained good-quality phosphate rock and being much closer to Woods Hole greatly reduced the voyage time and cost of delivery. Further expansion of the company consisted in the acquisition of Chisolm's Island near the coast of South Carolina, construction of a plant for cracking and washing phosphate rock on the Ball River side of the island, and establishment of a processing plant in Charleston, S.C. From the initial production (in 1865) of 7, 540 sacks of fertilizer weighing 200 pounds each, the output reached 11, 420 tons in 1871 and continued to grow until the combined annual production in 1879 of the works at Woods Hole and Charleston reached from 40, 000 to 45, 000 tons of guano fertilizer.

Spencer Baird, Secretary of the Smithsonian Instution and first commissioner of the U.S. Commission of Fish and Fisheries arrived in Woods Hole in 1871. Baird was greatly impressed by the idea of utilizing menhaden and other fishes for the production of guano fertilizer and considered it a worthwhile project. In a letter dated October 18, 1875, to John M. Glidden, treasurer of the Pacific Guano Works Company, Baird urged him "to make a display of your wares at the centennial (in Philadelphia), as this is one of the most important interests in the United States." He writes further that "there is no species (of fish) worked up elsewhere comparable to the movement with the menhaden, or pogy, as to numbers and the percentage of oil. The combination, too, of the pogy scrap with the South Carolina phosphates and the guanos of the West Indies and of the PacificA are also quite novel, and as being especially an American industry, are eminently worthy of full appreciation."

While the scientists, agriculturalists, and stockholders of the company thought very highly of the guano works, the existence of a malodorous plant was not appreciated by the residents of Woods Hole who suffered from a strongly offensive odor whenever the wind was from the west. Woods Hole might have continued to grow as one of the factory towns of Massachusetts but, fortunately for the progress of science and good fortune of its residents (except those who invested their savings in the shares of Pacific Guano Works), the company began to decline and became bankrupt in 1889.

Cessation of business and heavy monetary losses brought financial disaster to many residents of Woods Hole. The gloom prevailing in the village after the closing of the guano works began to dissipate, however, with the development of Woods Hole as a place of scientific research and with the increasing tourist trade. The factory buildings were torn down, the chimney which dominated the Woods Hole landscape was dynamited, and over 100,000 pounds of lead lining the acid chambers were salvaged. Large cement vats and the remnants of the old wharf remained; in the following years the latter became a favored place for summer biologists to collect interesting marine animals and plants.

The years from 1871 to the death of Baird in 1887 were the formative period of the new era of *Woods Hole as a scientific center*. In historical documents and in old books the present name Woods Hole is spelled in a different way. The old name "Woods Holl" is considered by some historians of Cape Cod to be a relic of the times prior to the 17th century when the Norsemen visited the coast. The "Holl", supposed to be the Norse word for "hill", is found in the old records. The early settlers gave the name "Hole" to inlets or to passages between the islands, such as "Robinson's Hole" between Naushon and Pasque Islands, or "Quick's Hole" between Pasque and Nashawena Islands, and Woods' Hole between the mainland and Nonamesset Island. In 1877 the Postmaster General ordered the restoration of the original spelling "Wood's Holl", which remained in force until 1896 when the United States Post Office changed it back to Woods

Hole and eliminated the apostrophe in Wood's. The change was regretted by the old timers and by C. O. Whitman who had given the specific name "hollensis" to some local animals he described.

At the time of his arrival at Woods Hole in 1871, Baird was well known to the scientific circles of this country and abroad as a naturalist, student of classification and distribution of mammals and birds, and as a tireless collector of zoological specimens. He maintained voluminous correspondence with the scientists in the United States and Europe, and was Permanent Secretary of the recently organized American Association for the Advancement of Science. To the general public he was known as a contributor to a science column in the New York Herald and author of many popular magazine articles. His newly acquired responsibilities as Commissioner of Fisheries greatly added to his primary duties as Assistant Secretary of the Smithsonian Institution which was primarily responsible for the establishment of the National Museum in Washington. As a scientist, Baird belonged to the time of Louis Agassiz, Th. H. Huxley, and Charles Darwin. Like Agassiz he attended medical college but never completed his studies, although the degree of M. D. honoris causa was later conferred upon him by the Philadelphia Medical College.

In the words of Charles F. Holder, "he was a typical American of the heroic type. A man of many parts, virtues, and intellectual graces, and of all the zoologists science has given the world.... he was most prolific in works of practical value to man and humanity."

Commissioner Baird attended many Congressional hearings and conferences with state officials and fishermen at which the probable causes of the decline of fisheries were discussed and various corrective measures suggested. From the lengthy and frequently heated discussions and evidence presented by the fishermen and other persons familiar with the fisheries problems, he became convinced that an alarmingly rapid decrease in the catches of fish had continued for the last 15 or 20 years. Such a decline was particularly noticeable in the case of scup, tautog, and sea bass in the waters of Vineyard Sound. It was logical, therefore, that the new Commissioner of Fisheries would select for his initial activities the New England coastal area where the fishing industry was of greatest importance as a politico-economical factor. Woods Hole, however, was not a significant fishing center.

In the "Fisheries and Fishlng Industry of the United States" prepared and edited by Goode (1884–87) for the 1880 Census, the fishing activity at Woods Hole is described in the following words: "Of the male inhabitants only seven are regularly engaged in fishing, the remainder being employed in the guano factory, in farming and other minor pursuits.... There is one ship carpenter in Wood's Holl, but he finds employment in his legitimate business only at long intervals. Of sailmakers, riggers, caulkers, and other artisans there are none. Four men are employed by Mr. Spindel, during the height of the fishing season, in icing and boxing fish. The boat fishery is carried on by seven men from April until September, inclusive. Only three species of fish are usually taken, namely, scup, tautog, and sea bass. The total catch of each fisherman is about 15 barrels, or about 2400 pounds. In addition about 6,720 lobsters are annually taken."

Before selecting a location for permanent headquarters for the work on fishery management and conservation, Baird undertook extensive explorations of the fishing grounds off the entire New England Coast. Section 2 of the Joint Resolution Number 8 of Congress gave the Commissioner full authority to carry out the necessary research. In part it reads as follows "and further resolved, That it shall be the duty of the said Commissioner to prosecute investigations and inquiries on the subject, with the view of ascertaining whether any and what diminution in the number of the food-fishes of the coast and the lakes of the United States has taken place; and, if so, to what causes the same is due; and also, whether any and what protective, prohibitory, or precautionary measures should be adopted in the premises; and to report upon the same

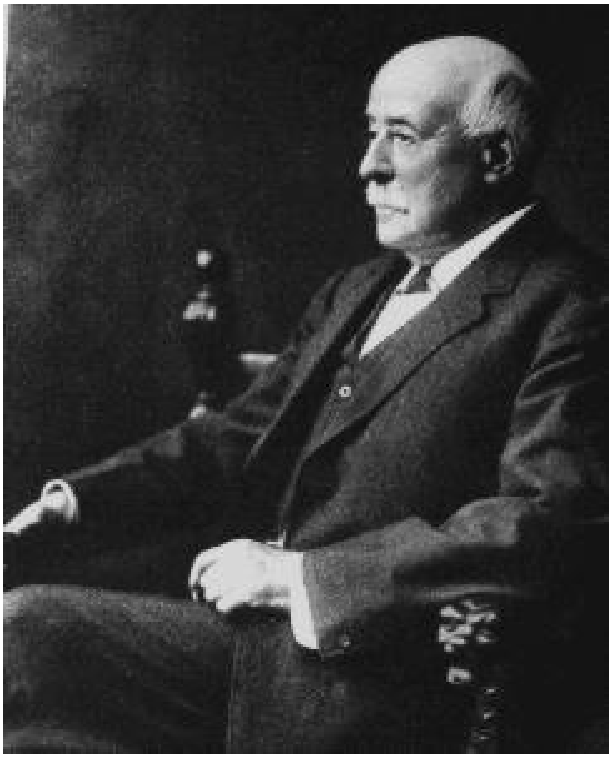
to Congress." Section 4 of the same Resolution contains an important clause which authorizes the Commissioner of Fisheries "to take or cause to be taken, at all times, in the waters of the seacoast of the United States, where the tide ebbs and flows, and also in the waters of the lakes, such fish or specimens thereof as many in his judgement, from time to time, be needful or proper for the conduct of his duties as aforesaid, any law, custom, or useage of any State to the contrary notwithstanding."

The significant words "where the tide ebbs and flows" were interpreted by Baird in a very broad scientific sense which extended the authority for his investigations to the offshore areas of the open ocean.

Pounds and weirs were most frequently accused by the public as destructive methods of fishing responsible for the decline in the abundance of food fishes along the coast. Although Baird gave very serious consideration to the possible destructiveness of fixed nets, traps, pounds, pots, fish weirs, and other stationary apparatus, he was fully aware of the complexity of the factors which may cause the decline in fish populations. He discusses this difficult problem in a paper entitled "Report on the condition of the sea fisheries of the south coast of New England" and published as the first section of the voluminous First Report of the Commissioner of Fish and Fisheries for 1871. Of the causes which may have contributed to the decrease of summer shore fisheries of the south side of Massachusetts and Rhode Island, a fact which he considered as well established by the testimonies of competent persons, he lists the following: (1) decrease or disappearance of the food of commercial fishes; (2) migration of fishes to other localities; (3) epidemic diseases and "peculiar atmospheric agencies, such as heat, cold, etc."; (4) destruction by other fishes; (5) man's activities resulting in the pollution of water, in overfishing, and the use of improper apparatus.

The biologist of today will recognize in this statement Baird's broad philosophical approach to the major problem of fishery biology. The outlined program combined oceanographical and meteorological investigations with the studies of biology, ecology, parasitology, and population dynamics of various fish species. Baird's program of research is as comprehensive and valid today as it was 90 years ago.

No time was lost in initiating this program. Woods Hole was selected as the base of the sea coast operations during the first summer and Vinal N. Edwards became the first permanent federal employee of the fisheries service. In spite of the insignificance of local fisheries, this locality offered a number of advantages which were recognized by Baird. Communication with Boston, New York, and Washington was good and promised to be better with the expected opening of the railroad branch in 1872. Being centrally located in relation to principal fishing grounds of New England and having good dock facilities and water of sufficient depth for sea going vessels, Woods Hole was a suitable base for visiting the offshore grounds. Furthermore, it was believed that the alleged decrease in food fishes was most clearly manifested in the region around Vineyard Sound. The small yacht Mazeppa of the New Bedford Custom House and the revenue-cutter Moccasin attached to the custom-house at Newport, R.I., were placed at the disposal of Baird; and the Light-House Board granted permission to occupy some vacant buildings and the wharf at the buoy-station on the west bank of Little Harbor. The Secretary of the Navy came to Baird's assistance by placing at his command a small steam launch which belonged to the Boston Navy Yard and by giving many condemned powder tanks which could be used for the preservation of specimens. Nets, dredges, tanks, and other gear were provided by the Smithsonian Institution. Cooperation of the various governmental agencies was authorized by Congress which in Section 3 of the Resolution specified that "the heads of the Executive Departments be, and they are hereby directed to cause to be rendered all necessary and practicable aid to the said Commissioner in the prosecution of the investigations and inquiries aforesaid."



This provision of the law was of great value. It is apparent, however, that the success in obtaining cooperation authorized by law depended a great deal on the personal characteristics of Baird, his great ability of getting along with people, and his remarkable power of persuasion, These qualifications played the major role in his success in organizing the Commission's work and also in obtaining the cooperation of scientists as well as that of fishermen and businessmen.

The investigation during the first summer consisted primarily in collecting large numbers of fishes and studying their spawning, rate of growth, distribution, and food. In the course of this work nearly all the fish pounds and traps, some 30 in number, in the vicinity of Woods Hole, were visited and their location recorded. There was no difficulty in obtaining the owners' permission to examine these installations and to collect the needed specimens. Altogether 106 species of fish were secured, photographed, and preserved for the National Museum. Of this number 20 or more species had not previously been known from Massachusetts waters. Information gained in this manner was supplemented by the testimonies of various fishermen who presented their ideas either for or against the use of traps and pounds. Among them was Isaiah Spindel, who at the request of Baird, prepared a description of a pound net used at Woods Hole and explained its operation. In the following years Spindel became an influential member of the group of local citizens who supported Baird's plan of establishing a permanent marine station at Woods Hole.

The ship Moccasin under the command of J. G. Baker was engaged in taking samples of plankton animals, in determining the extent of beds of mussels, starfish, and other bottom invertebrates, and in making temperature observations.

One of the principal collaborators in the studies conducted at Woods Hole in 1871 was A. E. Verrill of Yale University, a professor whom Baird appointed as his assistant and placed in charge of the investigations of marine invertebrates. Dredging for bottom animals during the first summer was carried out on a relatively small scale from a chartered sailing yacht Mollie and a smaller vessel used in the immediate vicinity of Woods Hole. Extensive collections were made by wading on tidal flats exposed at low water.

Zoological work attracted considerable interest among the biologists of this country. Many of them stopped at Woods Hole for greater or lesser periods and were encouraged by Baird to use the facilities of the Fish Commission. The group included such well known men as *L. Agassiz*, A. Hyatt, W. G. Farlow, Theodore Gill, Gruyure Jeffries of England, and many others. The first year's work extended until the early part of October. Before returning to Washington, Baird commissioned Vinal N. Edwards of Woods Hole to continue the investigation as far as possible. By the end of the first year a general plan of study of the natural histories of the fishes and the effect of fishing on fish populations was prepared with the assistance of the well-known ichthyologist, Theodore N. Gill. His old "Catalogue of the fishes of the Eastern Coast of North America from Greenland to Georgia", was revised and the next text including the recently collected data concerning the Massachusetts fishes, appeared in the First Report of the U.S. Commissioner of Fish and Fisheries. The plan of investigation suggested by Gill was adopted by Baird as a guide for the work of his associates for the purpose of "securing greater precision in the inquiries." The plan is composed of 15 sections, such as Geographical distribution, Abundiance, Reproduction, etc., with detailed subdivisions under each one. A questionnaire containing 88 different items was included in order to facilitate the inquiries conducted among the fishermen. The scope of the highly comprehensive program is complete enough to be useful today; marine biologists of today would probably only rephrase it, using modern terminology. During the first year of operations conducted at Woods Hole, Baird and his associates laid down the foundation of the new branch of science which we now call fishery biology or fishery science.

AN ANALYSIS OF THE INTERNATIONAL MARITIME ORGANIZATION–LONDON CONVENTION ANNUAL OCEAN DUMPING REPORTS

Christine Dickenson
Iver W. Duedall
Florida Institute of Technology
Melbourne, Florida

Trends are analyzed for types and quantities of permitted wastes, primarily dredged material, sewage sludge, and industrial waste, to be dumped at sea by member countries to the London Convention (LC) from 1992 and 1995 through 1998. In 1972, the Inter-Governmental Conference on the Dumping of Wastes at Sea led to the creation of the London Dumping Convention (now called the London Convention) to help regulate the dumping of wastes at sea. The act of dumping, as defined by the LC, is international disposal at sea of any material and in any form, from vessels, aircraft, platforms, or other artificial structures. The first consultative meeting of the LC contracting parties was held in 1976 by the Inter-Governmental Maritime Consultative Organization [now called the International Maritime Organization (IMO)]. During this meeting, the procedure for the reporting of permits issued, on an annual basis, for dumping at sea by contracting parties, was determined. The IMO-LC annual reports on permitted wastes list the number of permits issued by member countries, the types and quantities of wastes permitted for dumping at sea, and the location and designation of dump sites. Now with nearly 25 years of dumping records available, we are able to see trends in permitted dumping activity. In 1976, the first year of permitted dumping records, the combined amount of permitted wastes was nearly 150 million tons. In the last four years (1995 through 1998), where data are available, the total amount of wastes permitted to be dumped by the LC contracting parties as between 300 and 350 million tons. Currently, a majority of these wastes are being disposed of in the East Asian Seas and the North Sea and the largest quantity of waste being dumped is dredged material. Although the disposal of wastes at sea is considered to be a major issue, it is only responsible for about 10% of the total anthropogenic contaminants entering the ocean. Unfortunately, the long-term impacts of this dumping in the ocean are still largely unknown.

INTRODUCTION

"Historically, most coastal countries used the sea for waste disposal. It was generally the most economic way to manage waste, since land usually had, and still has, a high price tag while the sea has no private owner in the normal sense. In addition, dilution processes served the illusion that dumping at sea does not cause any permanent damage. So why risk contaminating land or drinking water with wastes if the sea was close by?" (1). "Accurate worldwide records on the amounts of wastes disposed at sea prior to 1976 are virtually impossible to obtain" (1). However, as a result of the international activities leading to the creation of the London Dumping Convention (LC) in 1972, information is now available on the number of permits issued by many countries for disposal at sea, their dumpsite locations, and the kinds and quantities of wastes that have been dumped (1).

According to the LC, the most common form of ocean dumping today is disposal from ships or barges (1,2). Wastes are loaded on these vessels and then taken to the dumpsites. Dumpsites are chosen based on the kind of waste and the ocean's properties at each site (2). Liquid wastes are generally disposed of in more dispersive environments, where mixing will rapidly dilute the dumped material. Solid wastes, on the other hand, are usually disposed of in less dispersive near-shore sites to keep the solids confined.

Here we specifically analyze trends in types and quantities of permitted wastes to be dumped at sea by member countries to the LC from 1992 and 1995 through 1998. The types of wastes that have been dumped in the ocean include industrial waste, sewage sludge, dredged material, incineration at sea, and radioactive wastes. Industrial waste may include both liquid and solid wastes and it may contain such items as acid-iron waste, fish-processing liquids, metal refinery wastes, and gas pipeline flushing wastes (2). An overall reduction in the dumping of these types of wastes has been achieved over the years by switching to alternative disposal methods, reusing wastes, and creating cleaner production technologies. The dumping of industrial wastes at sea has been prohibited since 1996 (3). "Sewage sludge is an anaerobic waste product from treatment of municipal wastewater. The sludge is in aqueous form containing about 3% suspended particles by weight" (2). Alternatives for the disposal of sewage sludge at sea include incineration, deposit on land, and agriculture use (3). "Dredged materials range from clean sands to heavily contaminated fine grained materials" (2). "Physical properties of dredged materials, including grain size, bulk density, water content, and geotechnical characteristics, are especially variable due to the kind or type of sediment being dredged, which is itself dependent on geological and watershed characteristics, as well as to the operational procedures used in dredging and disposal" (2). Incineration at sea is defined as the burning of liquid chlorinated hydrocarbons as well as other halogenated compounds in which all ash is dumped into the sea (3). This type of dumping was phased out early in 1991. The dumping of radioactive wastes, however, might be the most harmful practice of all. Although the dumping of high level radioactive wastes has never been allowed under the London Convention, it has still occurred in some cases, and even though a moratorium was placed on the dumping of low level radioactive wastes in 1983, this type of dumping still occurred (3,4). It was not until 1994 that this act became legally binding. Finally, the other waste category includes such wastes as inert geological materials, decommissioned vessels, scrap metals, and fish wastes (3).

METHODS

Annual reports on permitted dumping at sea by contracting parties were obtained from the IMO-LC (5). There is approximately a three-year delay before the most recent year's records are put into report format and published. Older records that only existed in hard copy form had to be entered into Excel spreadsheets to create a new database. Early on, it was decided that all wastes would be reported in tons to make comparisons from year to year easier. Many of the older reports had wastes recorded in cubic meters. These records were converted into tons by multiplying the cubic meters by the density of the waste (1.3 g/cm^3 for dredged material and other varying factors as indicated by each permit). Newer records, however, were received in Excel format and, for the most part, they were already converted into tons, making them very easy to add to the database.

The primary categories of wastes of importance to this study include dredged material, sewage sludge, industrial waste, and other matter. From the 1992 and 1995 through 1998 reports (5), it was desired to find out which waste was being dumped in the largest quantity, as well as which countries were dumping the most wastes and which water bodies were receiving the most wastes. The more recent data is compared to earlier reports from 1976 to 1985. Comparisons of the different sources of pollutants in the oceans and comparisons between land dumping and sea dumping are also made. Then the past, as well as the future, of ocean dumping can be assessed.

RESULTS

Tables in the IMO-LC annual reports (5) on permitted wastes (IMO, 1992, 1995–1998) list the number of permits issued to member countries, the types and quantities of wastes permitted for disposal at sea, and the location and designation of dumping sites. It is important to know that these reports are reflective of what has been permitted to be dumped and not of what has actually been dumped. The accuracy of these records, therefore, is somewhat questionable (1). It is also important to remember that not all of the contracting parties report their activities every year and some reports from contracting parties may be incomplete (2). For example, in 1995, thirty-eight of the seventy-five contracting parties registered did not report their activities. There is also no way of knowing how much noncontracting parties are dumping (2).

In 1992, 473 million tons were reported as permitted for disposal at sea. In the last four years (1995 through 1998) where data are available, the total amount of wastes permitted to be dumped by the LC contracting parties was 351 million tons in 1995, 312 million tons in 1996, 309 million tons in 1997, and 348 million tons in 1998. Figure 1 illustrates these data.

As seen in Fig. 2, a majority of these wastes are being disposed of in the East Asian Seas (Fig. 3) and the North Sea (Fig. 4). The "other areas" category is represented mostly by the United States and its disposal in the Gulf of Mexico (Fig. 5).

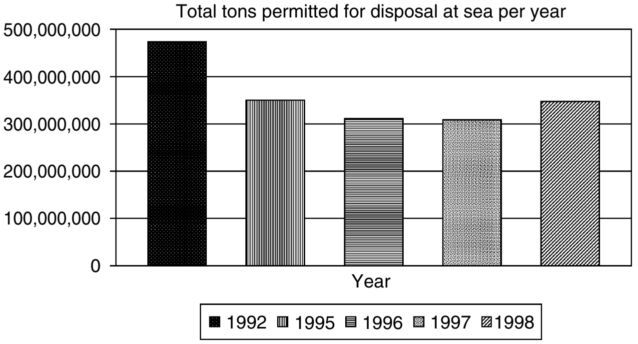


Figure 1. London Convention permitted dumping from 1992 and 1995 through 1998.

The countries responsible for dumping the most wastes, in descending order, are China, the United States, Hong Kong, the United Kingdom, Germany, and Belgium (Table 1).

As shown in Fig. 6, the largest quantity of waste being dumped is dredged material. At 327 million tons in 1998, it is the largest quantity by far, with sewage sludge coming in as the next highest quantity with only 15 million tons.

DISCUSSION

In 1976, the first year of permitted dumping records, the combined amount of permitted wastes was nearly 150 million tons (1). By 1985, this amount had grown to approximately 300 million tons (1). This apparent doubling, however, partly corresponds to an increase in the number of contracting parties to the LC. It is also important to remember that not all of the contracting parties report their activities every year and some reports from contracting parties may be incomplete. Therefore, it is not possible to provide a highly accurate interpretation of these data and the reader should be cautioned that any analysis must be considered approximate.

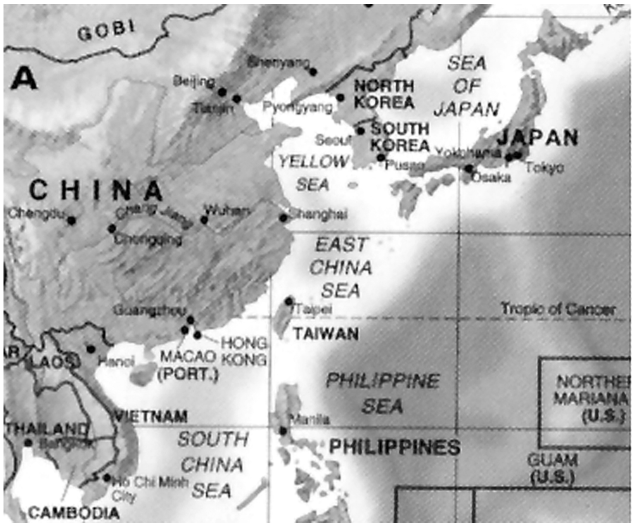

Figure 3. China and Hong Kong dumping in the East Asian Seas. (From Ref. 6).

Looking back to the data in Fig. 1, waste disposal in the ocean seems to continue to increase into the early 1990s with 473 million tons in 1992. However, by 1995 through 1998 this amount had leveled off to between 300 and 350 million tons. This decrease could be representative of the many changes in policy occurring within the LC in the 1990s to intentionally decrease the amount of waste disposed of in the ocean (3). It is also known that a major dredging project took place in Hong Kong in the early 1990s in order to expand the airport there (3). This may explain why the amount of waste dumped in 1992 was so high. The East Asian Seas section of Fig. 2 supports this theory, with data from 1992 being much higher than in the following years. Yearly fluctuations like this occur due to the variation in maintenance dredging and new works associated with shipping activities (3).

According to the IMO-LC web page, "in early 1991, incineration at sea operations came to a halt, ahead of

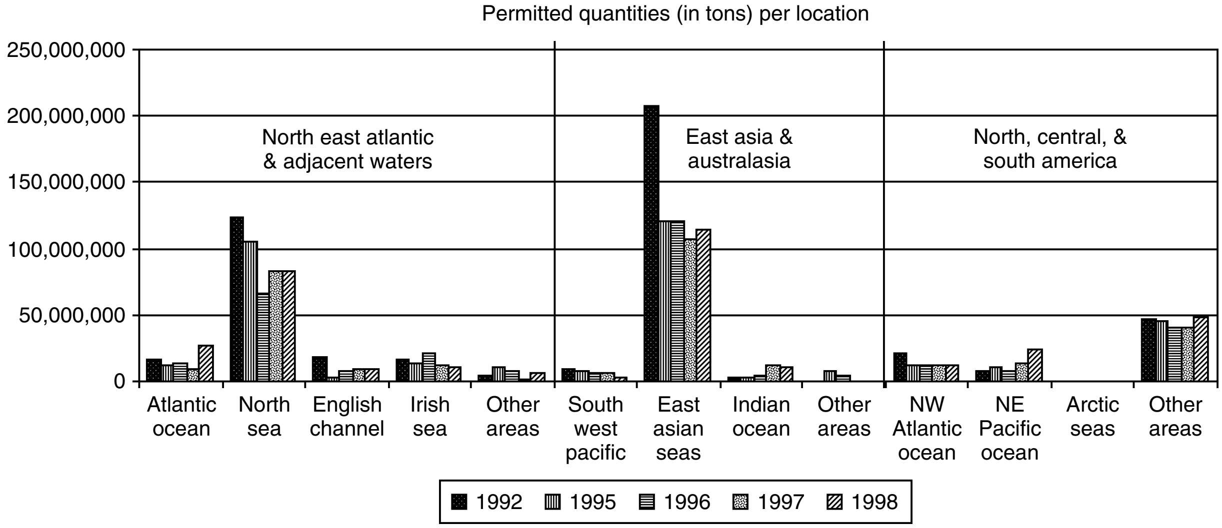

Figure 2. Locations of dumping sites with their respective amounts of wastes dumped.

Table 1. Highest Combined Tons for 1992 and 1995–1998

Rank	Country	Tons
1	China	295,482,060
2	United States	293,272,190
3	Hong Kong	285,437,056
4	United Kingdom	246,759,318
5	Germany	132,149,000
6	Belgium	127,507,436

the agreed global deadline of December 31, 1992…. In 1990, contracting parties to the LC agreed to phase-out sea disposal of industrial waste effective by January 1, 1996…. In 1993, contracting parties started a detailed review of the LC, leading to the adoption of a few crucial amendments…. These amendments consolidated in a legally binding manner the prohibition to dump all radioactive wastes or other radioactive matter and of industrial wastes, the latter as per January 1, 1996, as well as the prohibition of incineration at sea of industrial wastes and of sewage sludge" (3).

According to reports by contracting parties, no permits for the dumping of industrial waste have been issued since 1996. Before this phase-out, Japan and the Republic of Korea were responsible for most of the industrial waste being dumped (3). The amount of sewage sludge being dumped at sea decreased in the early 1990s, reflecting the phase-out of this practice by several countries, Ireland and the United Kingdom being the most recent. Currently, only Japan, the Philippines, and the Republic of Korea dispose of sewage sludge at sea (3).

Figure 5. The United States dumping in the Gulf of Mexico and the northwest Atlantic. (From Ref. 6).

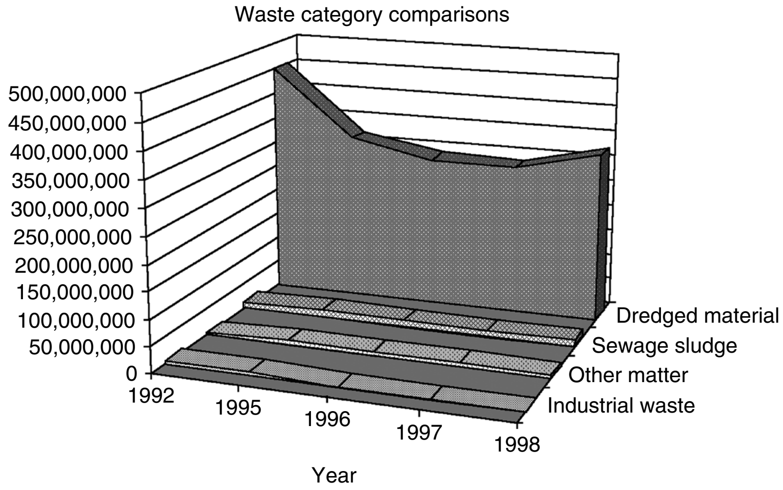

Figure 6. Dredged material, by far, makes up the largest quantity of waste being dumped at sea.

Dredged material makes up the majority of what is being dumped at sea (see Fig. 6). Unlike other wastes, the amount of dredged material dumped each year tends to fluctuate greatly due to variable maintenance dredging and new works associated with shipping activities (3). For example, there were huge dredging efforts going on in Hong Kong with the extension of the airport there in 1992. One hundred forty-four million tons of dredged material were permitted to be disposed of at sea that year by Hong Kong. Arguably, this could be responsible for the 1994 anomaly of the combined total of 473 million tons, meaning that the average amount of wastes dumped annually actually leveled out to between 300 and 350 million tons much earlier than the later 1990s.

The interactions of the wastes dumped at sea with seawater and the toxicity of these wastes to organisms, including humans, are of great importance to the scientific community. Although the long-term effects of disposal at sea are unknown, many studies have looked at some of the short-term effects, particularly in relation to radioactive wastes that have been dumped. Studies conducted in the Arctic by the IAEA and the U.S. Congress Office of Technology Assessment found that (1) releases from dumped objects were small and confined to the immediate vicinity of the dumped objects, (2) projected future doses to the general public were small, (3) doses to marine organisms were insignificant in the context of populations, and (4) remediation on radiological grounds was not warranted (7). A study by Hill et al. (8) assesses the possible effects of 40 years of dredging, and how it might have affected benthos in the Irish Sea. Zooplankton and micronekton communities, off eastern Tasmania, as studied by Bradford et al. (9), were found to be affected by the presence of a warm-core eddy instead of jarosite wastes dumped within the vicinity. As de La Fayette (7) said, it is difficult to draw conclusions from data that has been collected because more research, monitoring, and prevention projects are still needed for us to understand all of the factors that are involved in knowing how, when, and where ocean stored wastes might affect us and the environment.

Although such concern is felt about disposal at sea, it is not the largest contributor of pollutants to the oceans. As seen in Fig. 7, the IMO-LC puts it in fourth place, making up only 10% of the total pollutants in the oceans. Runoff and land-based discharges are the largest source, making up 44%. Even maritime transportation, at an estimated 12%, pollutes the oceans more than dumping does.

In an attempt to compare ocean dumping to disposal in landfills, we look at the United States. According to Zero Waste America (10), in 2001, 409 million tons of municipal waste were generated in the United States. Of that, 278 million tons were disposed of in landfills. Table 2 illustrates dumping on land and in the ocean by the United States during 1992 and 1995 through 1998.

Those five years of ocean dumping, totaling 293 million tons, is only 15 million tons more than what was disposed of in landfills in 2001 alone. In conclusion, we note that much more waste is being disposed of in landfills than in the ocean. Therefore, shouldn't we be more concerned about the land?

CONCLUSION

Although the environmental impacts of dumping at sea are still largely unknown, it is comforting that the LC is moving in a positive direction toward more regulations for the better protection of our oceans. With industrial

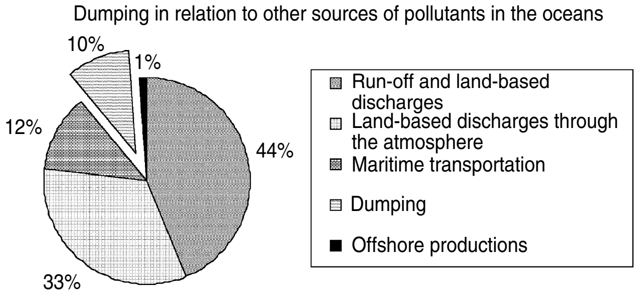

Figure 7. At 10%, dumping ranks fourth compared to the other sources of pollutants in the ocean.

Table 2. Ocean Dumping versus Land Dumping in the United States

	Tons in Millions	
Year	Land	Ocean
1992	241	67

1998	238	69

Data taken from Reference 10.

waste already phased out and sewage sludge on its way to becoming completely phased out, that leaves dredged material and "other matter" as the future of ocean dumping. Other matter mostly makes up inert geological material from mining and excavations; bulky wastes such as steel equipment, scrap metal, and concrete; fish wastes; obsolete ammunition and explosives; discontinued oil platforms; spoiled food; and other random wastes. This category may also eventually be phased out, but dredged material will most likely continue to be dumped since this form of waste, in the normal sense, either came "from the ocean floor" or somewhere close to it being that two-thirds of dredged material is connected with maintenance operations to keep harbors, rivers, and other waterways from being blocked up. Unfortunately, according to the IMO-LC, about 10% of dredged material is moderately to heavily contaminated from a variety of sources including shipping, industrial and municipal discharges, and land runoff. Whether we find somewhere to dispose of dredged material on land, or we continue to dispose of it in the sea, it will continue to affect our environment.

Acknowledgments

We are grateful to Rene Coenen, Office of the London Convention, International Maritime Organization, for kindly providing the LC dumping records. We are also thankful to Ruth Caulk and Melissa Sheffer for assisting in the preparation of the ocean dumping spreadsheets.

MARINE SOURCES OF HALOCARBONS

Robert M. Moore
Dalhousie University
Halifax, Nova Scotia, Canada

Halogenated gases are important in the atmosphere by virtue of their ability to carry chlorine, bromine, and iodine to high altitude, where they can act as efficient catalysts of ozone destruction. The effect on ozone of chlorine release in the stratosphere by certain manufactured chlorofluorocarbons is well known, but naturally occurring halogen carriers account for a part of the background cycle of ozone breakdown. The oceans constitute an enormous reservoir of dissolved halogens in the form of halide ions, but the transport of this material to the upper atmosphere is inefficient because sea salt particles, introduced to the atmosphere as sea spray from breaking waves and bubble-bursting, have short lifetimes, being readily washed out by rain. For this reason the relatively minute concentrations of dissolved halogenated gases, such as methyl chloride occurring in surface seawater at concentrations around 10^{-10} M, have the potential to drive significant transport of chlorine into the upper atmosphere. Since the role of anthropogenic chlorine and bromine gases in stratospheric ozone depletion was recognized, there has been renewed interest in the ocean as a source of halogenated trace gases. The emission of iodine compounds from the ocean has more recently been shown to be potentially important in aerosol production as well as in affecting ozone concentrations over the ocean (1).

The fluxes of trace gases such as those between the ocean and atmosphere is most commonly calculated from concentration measurements in the surface ocean and the overlying atmosphere together with empirical relationships between gas exchange coefficients and wind velocity (2). Supersaturation of a gas at the sea surface with respect to the atmosphere will support an outward flux, the magnitude of which is strongly dependent on wind speed, and to a lesser extent on temperature. Gas fluxes can be highly variable spatially and seasonally, and, in general, estimated global fluxes will have a substantial degree of uncertainty due to the sparseness of the concentration measurements combined with a large uncertainty in the exchange velocity. Ideally, gas fluxes would be calculable based on a firm understanding of the processes governing both the production and loss of the gas in the upper ocean and the processes controlling gas exchange. This remains a distant goal, and current studies are directed at developing an understanding of these processes.

Some of the first measurements made of halogenated methanes in seawater suggested that the ocean could be the predominant source of methyl chloride accounting for most of the 4 million tonnes that must be added annually to the atmosphere to support the observed concentrations (3). More recently, it has been demonstrated that, in the case of methyl chloride, the ocean is just one of many sources (including biomass burning, woodrot fungi, and vegetation) and can probably account for only about 15% of the total flux to the atmosphere (4). In contrast, the ocean is still recognized to be the most important source of atmospheric methyl iodide.

Impetus for the study of sources of methyl bromide came with the discovery of the efficiency with which bromine could catalyze stratospheric ozone loss, working either directly or in concert with chlorine. This led to concern about the possible role of methyl bromide, manufactured for use as a fumigant, in observed ozone loss. The existence of natural sources and sinks for methyl bromide made it more difficult to quantify the deleterious effect of the anthropogenic component. Extensive studies of the distribution of methyl bromide in the oceans and of its flux across the air–sea interface in different regions demonstrated the existence of both production and loss processes within the ocean (5). The balance between these determines whether a particular region will emit CH_3Br to the atmosphere or take it up. A major oceanic sink results from the reaction between CH_3Br and chloride ion, the rate being strongly dependent on temperature. Other losses include chemical hydrolysis and also biological uptake. Bromine is carried to the atmosphere by many other gases produced in the ocean, notably bromoform and dibromomethane (6).

Early studies pointed to an association between certain halogenated compounds in seawater, such as methyl iodide, and coastal beds of macrophytes. The more general phenomenon of organohalogen production by seaweeds has long been known, and a wide range of halogenated organic compounds of varying molecular weight and complexity have been identified (7). The focus here is on halogenated compounds that play a role in atmospheric chemistry, so these are typically volatile compounds. Two such compounds that have been shown to have major sources in macrophytes are di- and tribromomethane (CH_2Br_2 and $CHBr_3$). The latter has been found to occur within certain seaweeds at concentrations up to the percent level. It is apparent that haloperoxidase enzymes are involved in the biosynthesis of organohalogens by macrophytes.

In spite of the variety and abundance of halogenated methanes in seaweeds and the flux of halogen to the atmosphere that can thus be supported in the coastal zone, the overall importance of these algae on an oceanwide scale is small on account of their limited distribution (8), although, in the case of bromoform and dibromomethane, Carpenter and Liss, (9) estimated that macrophytes are a major source. For this reason there has been interest in the possible production of the same compounds by marine microalgae, which are ubiquitous in the sunlit waters of the world's oceans. An approach that has been adopted with some success to study this question has been the use of laboratory cultures of specific algae. This has demonstrated the capacity of a range of phytoplankton of different algal classes to produce compounds such as CH_3I, CH_2Br_2, $CHBr_3$, and CH_2I_2 (10,11), although species vary in the spectrum of compounds that they produce as well as in the production rates. There has been some progress in elucidating the production mechanism of these compounds with the identification of haloperoxidase enzymes in a few phytoplankton species (11). However, much uncertainty remains regarding the oceanic source of methyl chloride, bromide, and iodide. For although there are published studies that point to the capacity of some phytoplankton to produce methyl halides (12), the measured rates when normalized to biomass concentrations have typically been found to be quite inadequate to account for the observed fluxes from the ocean into the atmosphere (10). This may be due in part to the limitations of laboratory studies of phytoplankton cultures: relatively few species can be grown successfully in the laboratory and the conditions are very dissimilar to those in the ocean itself. Alternative possible explanations include the involvement of microbial processes (13), zooplankton, and photochemistry, or a combination of sources. One laboratory study has provided some evidence for the production of methyl iodide in seawater irradiated with simulated sunlight (14), but it has yet to be demonstrated that this process is significant in the ocean.

Open ocean studies of halocarbon distributions show that there is no simple correlation with phytoplankton biomass, quantified as chlorophyll *a* concentration. This means that the production of a particular compound cannot be attributed uniformly to all species of phytoplankton. More success has been obtained in studies that measured a series of photosynthetic pigments and evidence is forthcoming from one such study that CH_3Br has a source in Prymnesiophytes (15).

Measurements of dissolved methyl halides in the ocean typically show relatively high concentrations in the surface mixed layer, frequently with a maximum directly beneath, declining to levels at or near detection limits in deep waters (16). Such profiles are broadly consistent with a source at or near the surface and net consumption at greater depths. The maximum may be explained as occurring in a zone of production beneath the surface mixed layer that is poorly ventilated, so with reduced emission to the atmosphere. However, certain halocarbons have quite different distributions with depth. The chlorofluorocarbons such as CFC11 and CFC12 may have higher concentrations below the surface and at intermediate depths, with levels diminishing to low values in some of the deepest waters of the ocean. These distributions are well understood to be the result of transport of these anthropogenic gases from the atmosphere either by direct exchange at the surface or via downward mixing and advection of cold, dense, ventilated waters to intermediate and abyssal depths. There is now evidence that some halocarbons that have relatively short atmospheric lifetimes (e.g., dichloromethane and tri- and tetrachloroethylene) are also introduced to the ocean by the same processes, and that these gases have much longer lifetimes in the ocean than in the atmosphere. This apparently explains the presence of dichloromethane in the near bottom waters of the Labrador Sea (17).

Chloroform is likely to undergo the same processes but may have an additional *in situ* source.

Loss processes occurring in the ocean can be inferred for most organohalogens by their lower concentrations at depth than at the surface. They have been studied most thoroughly for methyl bromide and, for this compound, are known to include bacterial removal and chemical loss through hydrolysis and reaction with chloride ion (18). Other loss processes affecting a range of halogenated compounds apparently exist in waters that are depleted in dissolved oxygen (19). It should be noted a loss process for one halocarbon might represent a source for another: thus, reaction of both CH_3Br and CH_3I with chloride ion yields CH_3Cl. The photocatalyzed loss of CH_2I_2 is a source of CH_2ICl.

Continued measurement of halocarbons both in the ocean and atmosphere will improve our knowledge of the magnitude, geographic distribution, and seasonality of their fluxes, but a greater challenge is likely to be identifying more accurately their sources. That knowledge is essential if we hope to be able to predict how the fluxes of these atmospherically reactive gases may change in the future.

FOOD CHAIN/FOODWEB/FOOD CYCLE

Andrew Juhl
Lamont–Doherty Earth
Observatory of Columbia
University
Palisades, New York

A representation of the feeding relationships of the organisms, or groups of organisms, within an ecological community will be shown here. By showing which organisms feed on which other organisms, the pathways of energy flow through the ecosystem can be followed. "Food chain" is an older term and is currently less used than "foodweb" or "food cycle." The newer terms were coined to acknowledge the complexity of feeding relationships within most ecosystems. Examples of marine planktonic and intertidal foodwebs will be used below to illustrate specific points, but the concepts are applicable to any ecosystem.

The simplest food chain is organized in a strict hierarchy with primary producers (organisms that generate organic matter by fixing inorganic carbon, usually through photosynthesis) eaten by herbivores (primary consumers), the herbivores eaten by carnivores (secondary consumers), on to tertiary consumers, quaternary consumers, and soon. Each level within the food chain is termed a trophic level. Figure 1 shows an example of a very simple food chain for a planktonic ecosystem where phytoplankton are the primary producers, eaten by zooplankton herbivores. Zooplankton, in turn, are eaten by fish. Each group of organisms is represented by a shape, and the feeding connection and direction of energy flow are shown with an arrow. Simple food chains have heuristic value and are the basis of many quantitative ecosystem models. However, they can be criticized for oversimplification and for missing major groups of organisms.

One step toward a more realistic picture of an ecosystem is to disaggregate the trophic levels. Ideally, each level

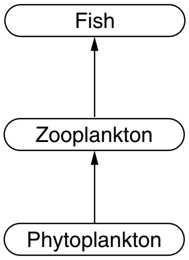

Figure 1. A simple food chain for a planktonic ecosystem.

could be broken down into its constituent species. One problem to consider is whether rare species should be depicted. A food chain diagram could include any feeding relationship that occurs within a system, whether common or unusual. This could lead to so many boxes and connecting arrows that any heuristic value would be jeopardized. In addition, the required information to fully disaggregate species groups may not be available. For example, microorganisms can be difficult to distinguish to the species level. Practical considerations often lead researchers to lump microorganisms into size classes and functional groups (e.g., primary producers >2 μm, 2–20 μm, <20 μm). In practice, the degree of aggregation of species is dictated by the objectives that motivate construction of the food chain diagram.

It is also more realistic to deemphasize the hierarchy implied by trophic levels. Deviations from strict trophic levels are common in aquatic ecosystems. For example, omnivorous species can prey on different trophic levels. A planktonic copepod may sometimes feed on small zooplankton, acting as a secondary consumer. The same copepod may also feed on phytoplankton, thereby acting as a primary consumer (1). Mixotrophy is another complication, common in planktonic ecosystems. Mixotrophic organisms can operate as primary producers, yet they may also consume other primary producers, or even consumers (2). Some aquatic organisms can occupy different trophic levels during different developmental stages. For example, eggs and early larval stages of the copepod *Acartia tonsa* are fed upon by the heterotrophic dinoflagellate *Protoperidinium* cf. *divergens* (3). However, adult *A. tonsa* feed voraciously on the dinoflagellate (4). This is an example of an "ontogenetic niche," or a niche that changes as the organism develops (5). Accommodating such complexities is one reason why the term "foodweb" is generally preferred over "food chain" (see Fig. 2). The many arrows necessary to accurately depict feeding relationships within most ecosystems resemble a web more than a linear chain.

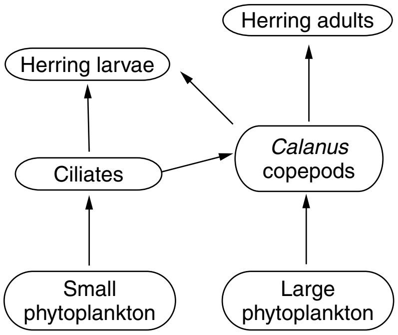

Figure 2. A more complex foodweb for the planktonic ecosystem in Fig. 1. Some groups are taxonomically identified, others are separated by size. The copepods are omnivorous, feeding on both phytoplankton and ciliates. Different feeding roles are shown for adult and larval herring.

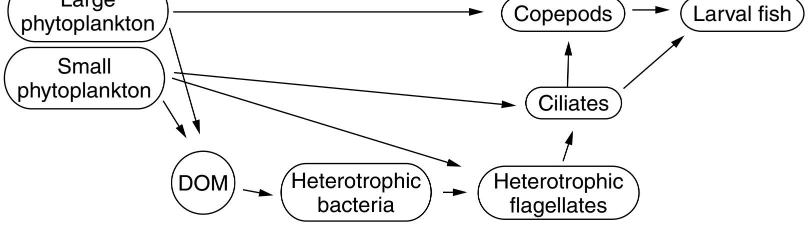
Decomposers are frequently neglected when foodweb diagrams are constructed (6,7), and yet organic production from all trophic levels eventually cycles through decomposers. As the importance of heterotrophic bacteria and microzooplankton to planktonic biogeochemical cycles began to be realized during the 1970s and 1980s, depictions of plankton foodwebs began to include bacterial decomposers and their consumers in what has become known as the "microbial loop" (8,9) (see Fig. 3). Including decomposers in foodwebs of other ecosystems would certainly be more realistic, although it may not be necessary for every research goal.

QUANTITATIVE FOODWEBS

Even a complicated foodweb diagram is a qualitative description of an ecosystem and may only be representative of a single point in time. One approach to making the foodweb quantitative is to include an estimate of the energy flux along each pathway (10). Energy produced at the foodweb base will be dissipated at successive trophic levels. Knowing or assuming the energy dissipation at each step allows an estimate of the maximum production possible at higher trophic levels. For example, maximum potential fisheries production of the world's oceans has been derived from global estimates of planktonic primary production (11,12). In these analyses, different areas of the world's oceans were assumed to have simple food chains of varying length, resulting in variable efficiency of energy transfer until a trophic level with harvestable biomass was reached. Ocean regions with short food chains had greater fishery production per unit primary production than areas with long food chains.

Figure 3. A planktonic foodweb that includes a representation of the "microbial loop" as an alternate pathway from phytoplankton to larger organisms. The loop, shown with thicker arrows, begins with phytoplankton producing dissolved organic matter (DOM). DOM feeds heterotrophic bacteria that are preyed upon by small, unicellular predators (heterotrophic flagellates and ciliates). These protists are food for copepods and larval fishes.



The biological components of many ecosystem models can also be viewed as attempts to make quantitative foodwebs. Models of plankton ecosystems (13,14) are usually not based on energy transfer. Instead, fluxes to and from organisms, and the standing biomass of the organisms, are expressed in units of an important element, often nitrogen, phosphorus, or carbon. Nevertheless, the flux pathways between organisms describe a food chain or foodweb.

Assigning interaction strengths to particular pathways is another approach to making foodwebs less qualitative. One can define strong or weak interactions within a foodweb that are not necessarily related to the flux of energy or material mediated by those interactions. A strong interaction is indicated if removal of one component species leads to pronounced change in the overall community (15). Alternately, removal of a species may cause little change, indicating a weak interaction. The definition of pronounced change is subjective; however, local extinctions and other large shifts in species diversity of a community would likely be acceptable demonstration that a pronounced change had occurred. For example, Paine (16) described two foodwebs for Pacific rocky intertidal communities, one for a coastal region of Washington State, the other for an Alaskan bay. The same 44 species or groups were present in both areas but the interaction strengths were quite different. In Washington, experimental removal of the starfish *Pisaster ochraceus* led to competitive elimination of multiple species of sessile invertebrates and benthic algae. The excluded species were replaced by the blue mussel, *Mytilus californicus*. When the starfish was present, it prevented the mussel from excluding the other species. Thus, the strong interaction between *Pisaster* and *Mytilus* was critical to maintaining a diverse intertidal community, although *Pisaster* preyed on many species and the bulk of its energy came through paths without *Mytilus*. Additional strong interactions within the foodweb were found, but removal of some species had little or no effect on the remaining community. By contrast, in Alaska, *Pisaster* only weakly interacted with other species.

A predator like *Pisaster* (in Washington), whose presence maintains community diversity by preventing competitive exclusion, is known as a “keystone” predator (17). Many other aquatic predators have since been described as keystone predators, including sea otters (18), mosquito larvae (19), and largemouth bass (20).

GENERAL PROPERTIES OF FOODWEBS

In the search for general rules of ecology, it is not surprising that compilations of documented foodwebs have been studied to determine whether foodwebs of different ecosystems share common properties. Certainly, the basic trophic structure with primary producers, one or more levels of consumers, and decomposers is common to vastly different ecosystems. Examples of other properties that might follow general rules include the ratio of predatory to prey species, the number of links per species, the fraction of total species in each trophic level, and the fraction of omnivorous species (21–23). Empirical foodwebs have also been investigated with respect to more abstract metrics, such as connectance—the ratio of actual links within a foodweb to the number of topologically possible links (21,24,25). However, the search for general properties within compilations of foodwebs has been criticized because, as mentioned above, the individual foodwebs used as raw data in such studies are frequently incomplete and overaggregated (6,7,26). The problems associated with documented foodwebs cannot be denied; however, it has been argued that some rules are sufficiently robust to overcome the biases (27).

The search for general rules relating to foodwebs is also approached using theoretical foodweb models. A theoretical foodweb uses a system of equations to represent the interactions of different organisms within an idealized ecosystem. Properties such as the number of links per species and connectance can be modified in different versions of the model. The stability of each resultant system of equations can be examined as various properties of the foodweb are modified (24,27,28). Theoretical foodwebs rapidly provide results for experiments that are difficult or impossible to conduct with real organisms. However, if the system of equations used does not adequately represent a natural condition, extrapolating results to the real world may be problematic.

Whether qualitative or quantitative, foodwebs are models of how the organisms within a community interact. They focus on feeding relationships, neglecting other modes of interaction, such as competition. Like any model, they are open to a variety of criticisms. It is important to recognize that it is not desirable for a model to contain all the complexities of nature; there would otherwise be no advantage to creating the model. Rather, a model should capture those aspects of nature that are necessary for understanding the question at hand. So long as that context is maintained, foodwebs will continue to be one of the most useful tools for teaching, studying, and understanding ecological communities.

PLANKTON

ANDREW JUHL
Lamont–Doherty Earth
Observatory of Columbia
University
Palisades, New York

INTRODUCTION

Plankton are aquatic organisms living in the water column that drift, float, or swim only weakly. The term derives from the Greek word *planktos*, meaning "to drift or "to wander." It is a descriptive classification, implying a certain type of lifestyle, rather than characteristics associated with taxonomy, size, or ecological role. The following information focuses on marine plankton, but much of the information is directly applicable to freshwater plankton.

Plankton can be contrasted with nekton, aquatic organisms capable of vigorous swimming (such as large fishes, squids, and marine mammals), and with benthos, those aquatic organisms that live on or at the bottom. It is generally thought that organisms classified as plankton do not have much ability to control their horizontal position relative to large-scale currents. However, there are no hard rules defining how strongly an organism may swim and still be considered planktonic. The boundaries between plankton, nekton, and benthos are nebulous. In fact, some organisms can be placed in each of the groups during different developmental stages. For example, the blue crab, *Callinectes sapidus*, has a planktonic larval stage (1). After 30+ days as plankton, these larvae settle to the bottom, becoming benthic juveniles (2). Although they spend most of their adult life on the bottom, blue crab adults swim surprisingly well (*Callinectes* translates to "beautiful swimmer") and females will traverse long distances to spawn (3). Despite a loose definition, plankton is a meaningful term that describes one of the most common aquatic lifestyles.

CATEGORIES OF PLANKTON

The organisms that comprise plankton are exceedingly diverse. Many Archaea and Eubacteria (the two major taxonomic groups of bacteria), most algal divisions, and most animal phyla have some representatives that are planktonic. Plankton also range in size from less than 1 μm (bacterioplankton) to several meters across (some jellyfish and colonies of planktonic tunicates). The range of taxa and sizes results in very different ecological roles for different plankton. Several categorization schemes are commonly used to organize the diversity of plankton into groups that share particular properties.

Phytoplankton, Zooplankton, and Bacterioplankton

Phytoplankton are photosynthetic plankton, mostly single-celled, microscopic algae that use light energy to fix carbon dioxide dissolved in water. This process makes solar energy available to them for their own biochemical needs. When they are eaten by other organisms, and when they release dissolved organic matter into the water, the energy becomes available to nonphotosynthetic organisms. Phytoplankton are therefore considered the base of most aquatic foodwebs (primary producers). Phytoplankton commonly include photosynthetic prokaryotes (cyanobacteria) and photosynthetic eukaryotes, such as diatoms, dinoflagellates, cryptophytes, and chlorophytes.

Zooplankton are eukaryotic, planktonic heterotrophs. They are usually phagotrophic, meaning that they ingest particles. However, there are examples of osmotrophic zooplankton (feeding on dissolved organic matter) (4).

Also, many eggs and larvae that are temporarily planktonic do not feed, but only use stored energy reserves. Both examples would still be considered zooplankton. Common zooplankton include single-celled, heterotrophic protists, such as ciliates and choanoflagellates, and multicellular animals, such as copepods and euphausiids.

Gelatinous zooplankton are a subcategory of zooplankton. Although taxonomically diverse, they share a body composition that is jellylike, mostly lacking hard, structural components. Their bodies have very high water content and are often transparent. Cnidarian medusae known as "jellyfish" are the most commonly known examples. Additional examples of gelatinous zooplankton are found in the ctenophores, mollusks (heteropods), and urochordates (planktonic tunicates such as salps, doliolids, and larvaceans). Although there are small gelatinous forms, the largest zooplankton are all gelatinous. Because of their fragile body plan, gelatinous zooplankton are difficult to collect quantitatively. Their importance to marine ecosystems may therefore be underestimated. Gelatinous zooplankton are rare in fresh water.

Bacterioplankton, or planktonic bacteria, includes representatives of both Eubacteria and Archaea. Photosynthetic bacteria are sometimes included within this category, creating an overlap with phytoplankton. Generally, however, the category implies heterotrophic bacteria. Heterotrophic bacterioplankton are osmotrophs. They either take up dissolved organic matter freely available in the water, or they use external enzymes to solubilize organic matter from particles, making it available for transport into their cells.

Holoplankton Versus Meroplankton

Organisms that are planktonic their entire lives are holoplankton. The term derives from the Greek word *holos*, meaning "entirely." Meroplankton are organisms that are planktonic during only a portion of their lives. The Greek word *meros* means "mixed." Most meroplankton are larval forms that are benthos or nekton as adults. For example, many fish larvae are planktonic. As they grow and their swimming ability improves, they eventually become nekton. Similarly, many mollusks have planktonic larvae that eventually settle to the bottom and become benthos. Because ecological conditions for the plankton are often very different from those facing the adults, meroplanktonic larvae often do not resemble the adults. In numerous cases, meroplanktonic larval stages were first scientifically described as distinct species; only later was the connection to the adult stage realized. Organisms that are entirely planktonic except for a benthic resting stage, such as some cladocerans or dinoflagellates, are still generally considered holoplanktonic.

Plankton are also commonly separated based on size. Viruses are abundant in aquatic environments and may be the smallest plankton, for those who consider viruses to be living. Bacterioplankton are the smallest cellular plankton and may be less than 1 μm in length. The largest plankton are cniderian medusae (jellyfish) that may be more than a meter across the bell, with tentacles that extend over many meters. Planktonic tunicate colonies (especially Pyrosomes) can also be many meters across, although the individuals within the colony are only millimeters to centimeters in length.

Size categories are arbitrary, but Sieburth (5) described the following categories currently used by many researchers: picoplankton (organisms 0.2–2 μm in length), nanoplankton (2–20 μm), microplankton (20–200 μm), mesoplankton (0.2–20 mm), macroplankton (2–20 cm), and megaplankton (20–200 cm). Viruses would be considered femtoplankton. These size categories are often combined with other categories. For example, picophytoplankton and mesozooplankton are common terms in oceanographic literature.

COLLECTING AND STUDYING PLANKTON

In general, the number of individuals per unit volume of water increases as planktonic organisms decrease in size. Nevertheless, natural waters are typically a very dilute suspension of even the smallest organisms and concentrating the organisms is often necessary for analyses. High numbers of small organisms (pico-, nano-, microplankton) can be collected simply by taking a water sample with a bucket or a hydrographic bottle. Concentrating such small organisms by filtration is often done after water collection. The filter pore size used determines the smallest organisms collected on the filter surface. Use of different filter pore sizes allows separation of the plankton sample into several size classes. Larger organisms (microplankton and up) may be too rare for quantitative collection in a whole-water sample. They are often collected by dragging plankton nets through the water. Plankton nets typically have a defined mesh size so that only organisms larger than the mesh will be collected. Plankton nets therefore size fractionate and concentrate before collection. A larger mesh net will filter a greater volume of water before it becomes clogged and ineffective. Larger mesh nets can also be dragged through the water more rapidly. It is therefore important to match the net mesh with the size, concentration, and swimming ability of the organisms one desires to collect. Because of their small size, taxonomic identification of most plankton requires microscopic examination after collection.

Buckets, bottles, nets, and microscopes are still used to study plankton, but these traditional approaches are now complemented with a myriad of advanced techniques. For example, on the smallest scales, methods of molecular biology can be used to study gene expression in individual cells of picoplankton (6). On the largest scales, the global distribution of phytoplankton can be studied in satellite images (7).

SPATIAL PATTERNS OF PLANKTON

The dominant large-scale horizontal pattern in plankton abundance is a decline as one goes away from the coast. One may have to travel tens to hundreds of miles offshore for this pattern to become clear. Nevertheless, the central areas of the oceans that are furthest from land generally have the lowest abundance of plankton, while coastal areas have the highest. This is true for all types of plankton (8–10). However, it should be kept in mind that many species of plankton are adapted to live in open-ocean environments. Therefore, certain planktonic species may actually be more abundant in the open ocean than nearer the coast. Exceptions to the general offshore pattern in plankton abundance can be caused by mesoscale eddies (11,12), oceanographic fronts (13,14), upwelling zones (15), and other phenomena (16). Although areas far from shore tend to have low plankton abundance, the diversity of species can be very high by comparison to coastal locations (17).

By definition, plankton have a limited ability to control their horizontal movement. Horizontal patterns of plankton abundance are therefore regulated by environmental factors external to the organism: currents, light, temperature, nutrient availability, and so on. These factors also contribute to vertical patterns in plankton abundance. However, individual behavior is also important in forming vertical patterns because many planktonic organisms do have the ability to control their vertical position within the water column.

Because light from the sun is rapidly absorbed by water, and because phytoplankton need light to photosynthesize, actively growing phytoplankton are restricted to the upper portion of the water column. In coastal waters, sufficient light for photosynthesis may only penetrate the top few meters (or less). In these conditions, vertical phytoplankton abundance often directly correlates with light; the highest phytoplankton abundance is at the surface, with a sharp decline as depth increases (9). This pattern is mostly caused by higher phytoplankton growth where more light is available. In addition, some phytoplankton can swim enough to change their vertical position in the water column (by as much as 10 m/d) (18). Similarly, other phytoplankton species are positively buoyant due to gas or lipid inclusions. Therefore, high phytoplankton abundance near the surface can sometimes be due to upward movement of phytoplankton (19,20). By contrast, in the open ocean, while sufficient light for photosynthesis is generally found within the upper 100–200 m, phytoplankton abundance is usually low near the surface. Highest phytoplankton abundance in open-ocean waters often occurs in a subsurface layer (9,21). Although light levels are always highest near the surface, phytoplankton also require inorganic nutrients to grow, just like other plants. In offshore regions, low phytoplankton abundance near the surface is generally attributable to low nutrient availability. Greater phytoplankton stocks can be supported at deeper depths where both nutrients and light are available.

Different phytoplankton species are often found at different depths (22,23) and may be specialized to live under the conditions associated with certain depth strata (24,25). However, vertical mixing from tides, winds, surface cooling, internal waves, and other physical processes can homogenize the vertical patterns of phytoplankton abundance and species composition.

Because zooplankton do not require light, they can be found at all ocean depths. However, greater zooplankton abundance is generally found in the surface waters where phytoplankton occur. This should not imply that zooplankton and phytoplankton abundances are necessarily directly related. While many zooplankton feed on phytoplankton, many feed on bacteria or other zooplankton. Correlations between zooplankton and phytoplankton abundance patterns can be direct and causal for some groups of zooplankton, that is, for zooplankton that feed on phytoplankton. However, other zooplankton are only indirectly, or coincidentally, associated with phytoplankton.

Many common mesozooplankton, especially crustacean mesozooplankton such as copepods and euphausiids, vertically migrate between the deeper and upper water layers on a daily basis. Such diel vertical migrations of zooplankton may cover several hundred meters each way (26). The most compelling explanation for this behavior is that the zooplankton migrate down during the day to avoid predation, then rise to the upper layers at night to feed (27,28). At night, migrating zooplankton are less likely to be detected by predators in the surface layers that depend on sight (such as fishes) to catch prey. Darkness, whether due to depth or time of day, provides one of the few opportunities to hide in the relatively featureless, planktonic habitat. Although daily vertical migrations are common in both fresh and marine waters throughout the world, it should be pointed out that most zooplankton species probably do not vertically migrate. Many species live out their lives associated with a particular depth strata (29). For example, Marlow and Miller (30) found that only around 10% of zooplankton species in the oceanic Gulf of Alaska vertically migrated. However, those vertically migrating species made up a large fraction of the total zooplankton biomass. Even species that do vertically migrate can change their migration pattern in response to local conditions (31) or over the course of development (32).

TEMPORAL PATTERNS OF PLANKTON

The abundance of plankton varies seasonally in many places, especially in higher latitude waters where seasonality is most pronounced. A pattern observed in many temperate lakes, estuaries, and the open North Atlantic Ocean is the spring phytoplankton bloom (33–35). The cycle begins with low phytoplankton abundance in winter. In spring or early summer, phytoplankton abundance increases dramatically (a bloom). The zooplankton biomass often also increases, although there may be a time lag between the increase in phytoplankton and the later increase in zooplankton. Eventually, the stocks of both phyto- and zooplankton decline to moderate levels that are sustained through the summer. A second bloom can occur in autumn, before plankton levels decline again for the winter.

Much research effort has focused on describing and understanding seasonal patterns of plankton exemplified by the spring-bloom cycle. It provides the best known temporal pattern in plankton stocks. However, in many lower latitude waters and the open North Pacific Ocean, seasonal cycles are either absent (36), subtle (37,38), or complicated by the impact of episodic events such as upwelling, mesoscale eddies, or storms (11,15,39).

Temporal patterns of plankton in polar seas are often dictated by the timing of sea ice melt (40,41).

GLOBAL IMPORTANCE OF PLANKTON

Although most planktonic organisms are individually small and seemingly ineffectual, plankton are important in aggregate because of their ubiquitous occurrence on this mostly water-covered planet. Outstanding examples of the global importance of plankton include their roles in the production of aquatic resources that humans value, in the Earth's climate, in oxygen production, and in sediment formation. Aquatic ecology and global biogeochemical processes cannot be understood without considering the role of plankton.

As the base of the aquatic foodweb, plankton are a critical food resource for aquatic organisms that are valuable to humans. The connection may be direct, as when valuable species such as oysters and anchovies feed on phytoplankton. The connection may also be indirect, for instance, if a commercially valuable predatory fish, such as a tuna, eats the anchovies. Either way, the occurrence of valued species is often coincident with the distribution of plankton. Large, motile species such as large fishes, seabirds, and whales concentrate their activities in locations where plankton are most abundant (42–44). This dependence of larger organisms on plankton means that commercial fisheries yield can be extrapolated from production of the plankton (45,46). Areas with higher plankton production have much greater fisheries yield.

Plankton influence the Earth's climate by removing carbon dioxide from the atmosphere. Carbon dioxide is the main atmospheric gas responsible for the "greenhouse" effect that regulates the Earth's temperature. Photosynthesis by phytoplankton fixes carbon dioxide from the atmosphere, transforming the carbon into organic compounds. Most of the carbon fixed by phytoplankton during photosynthesis is grazed by zooplankton and respired, releasing carbon dioxide back to the atmosphere (47,48). Nevertheless, some of the fixed carbon sinks to the deep ocean as the cells and bodies of plankton, zooplankton fecal matter, and other organic aggregates. Although the standing biomass of phytoplankton is less than 1% of the biomass of terrestrial plants (49), the amount of carbon fixed by phytoplankton and land plants is roughly equal (49,50). Because carbon fixation is coupled to the release of oxygen, phytoplankton are also responsible for approximately half of the Earth's oxygen production. It is estimated that one-third of the carbon fixed by phytoplankton eventually sinks to the deep ocean, effectively removing the carbon from the atmosphere for thousands of years (51). Determining the amount of carbon removed by plankton from the atmosphere and transported to the deep ocean, and predicting how that process may change in the future, are major questions in climate research.

Phytoplankton also influence climate by releasing sulfur compounds to the atmosphere. They are thought to be the main natural source of volatile sulfur compounds to the troposphere (52), mostly in the form of dimethylsulfide. The pathways leading to dimethylsulfide release from the oceans are incompletely understood, but phytoplankton primarily release the precursors to dimethylsulfide when their cells are ruptured during autolysis, viral attack, or grazing by zooplankton. Enzymes of phyto- and bacterioplankton then transform the released precursors to dimethylsulfide, which is released to the atmosphere. The sulfur aerosols stemming from dimethylsulfide of phytoplankton scatter incoming solar radiation. These aerosols also act as cloud condensation nuclei, further increasing atmospheric backscatter of solar radiation. Therefore, phytoplankton (and their interactions with other planktonic organisms) alter cloud formation and the amount of solar radiation reaching the Earth's surface (53).

A fraction of the carbon fixed by phytoplankton becomes a component of deep-sea sediments, removing it from the atmosphere for millions of years (54). Other inorganic structural components of plankton, such as the silicate tests of diatoms and radiolarians, and the calcareous shells of coccolithophores, pteropods, and foraminifera, also contribute to ocean bottom sediments. Over 60% of the ocean bottom is covered with sediments that are primarily planktonic in origin (55). Over geological time, such sea-bottom sediments, formed in previous ages, have been uplifted. Thus, even the peaks of mountains can be composed of material that originated from plankton.

MAJOR IONS IN SEAWATER

Marie de Angelis
Humboldt State University
Arcata, California

Seawater contains all of the natural elements. However, its composition is dominated by relatively few ionic species. These species, which comprise >99.8% of the mass of the total dissolved salts in the ocean, are known as the major ions and are defined as dissolved species having a concentration in seawater of >1 mg kg^{-1} (1 ppm) (Table 1). Na^+ and Cl^- alone account for 86% of all dissolved chemical species in seawater.

The source of Cl^-, and most anions in seawater, is *outgassing* of the Earth's interior, or *volcanic emissions*. The majority of the major cations are derived from the effects of continental weathering and are delivered to the ocean via rivers. The gross composition of seawater is the result of the partitioning of elements between continental rock and seawater over geologic time. The major ions represent the more soluble elements, which have preferentially partitioned into seawater.

The major ions are found to occur in nearly constant ratios to each other throughout most of the world's oceans. That is, although the salinity or the total amount of salt dissolved in seawater varies from location to location in the ocean, the ratios of the major ions to each other remains nearly constant, which is true from ocean to ocean as well as from surface to deep waters (Table 2).

Table 1. Major Ions in Seawater

Major Ion	g kg^{-1} Seawater at Salinity of 35.000 ppt	% by wt	g ion/g Cl^-
Chloride, Cl^-	19.353	55.30	1
Sodium, Na^+	10.781	30.77	0.5561
Sulfate, $SO_4{}^{2-}$	2.712	7.75	0.1400
Magnesium, Mg^{2+}	1.284	3.69	0.0668
Calcium, Ca^{2+}	0.4119	1.18	0.0213
Potassium, K^+	0.399	1.14	0.0206
Bicarbonate, $HCO_3{}^{2-}$	0.126	0.41	0.0075
Bromide, Br^-	0.0673	0.19	0.0035
Boron, B (as $B(OH)_3$	0.0257	0.013	0.00024
Strontium, Sr^{2+}	0.00794	0.023	0.00041
Fluoride, F^-	0.00130	0.0037	0.00006

Concentrations are presented in terms of g of ion per kg of seawater, % by weight in seawater, and the weight ratio g ion per g Cl^-.

Table 2. Ion to Chloride Ratios in Various Oceans and Selected Seas for Na^+ and K^+

Ocean or Depth Interval	Na^+/Cl^-	K^+/Cl^-
Atlantic	0.5552	0.0206
Pacific	0.5555	0.0206
Indian	0.5554	0.0207
Red Sea	0.5563	0.0206
Mediterranean	0.5557	0.0206
0–100 m	0.5554	0.0206
700–1500 m	0.5557	0.0206
>1500 m	0.5555	0.0206
MEAN	0.5555$^+$/–0.0007	0.0206$^+$/–0.0002

Also shown are ion to chloride ratios for selected depth intervals in the world ocean. Mean values are for the world ocean over all depth intervals.

This observation is known as "The Rule of *Constant Proportions*" or conservative behavior. As Cl^- is the single most abundant ionic species in seawater, the Rule of Constant Proportion is usually expressed as the ratio of major ions to chloride ion (e.g., Na^+/Cl^-). Exceptions to this rule exist for calcium (Ca^{2+}), strontium (Sr^{2+}), and bicarbonate ($HCO_3{}^{2-}$) as a small fraction of the total concentration of these species participate in biological reactions resulting in slight variations of ion/Cl^- ratios between surface and deep water.

The *residence time* (τ) of a chemical species in the ocean can be defined as the average time an individual atom for a given element remains in seawater before being permanently removed. Assuming that the major source of dissolved salts to the ocean is from riverine input, residence time of a given ion can be calculated as the total mass (in g) of ion in the ocean (M_{ocean}) divided by the mass of ion delivered by rivers annually ($Flux_{in}$) (in g yr^{-1}).

$$\tau(\text{years}) = \frac{M_{ocean}}{Flux_{in}}$$

Flux $_{in}$ can be estimated from the average concentration of the ion in the world's rivers (in g L^{-1}) multiplied by the total volume of river water entering the ocean annually (in L yr^{-1}). M_{ocean} can be estimated from mean seawater concentrations (in g L^{-1}) multiplied by the volume of the ocean (in L). The residence times for the major ions calculated by this method are extremely large, on the order of millions to hundreds of millions of years (Table 3).

The long residence times of major ions reflects the relatively low reactivity of these chemical species. Except

Table 3. Mean Seawater and River Water Concentrations and Residence Times for Several Major Ions

Species	Mean SW (mg L^{-1})	Mean RW (mg L^{-1})	$\frac{SW}{RW}$	τ (10^6 years)
Cl^-	19, 350	5.75	3, 365	123
Na^+	10, 760	5.25	2, 090	75
Mg^{2+}	1, 294	3.35	386	14
$SO_4{}^{2-}$	2, 712	8.25	338	12
K^+	399	1.3	307	11
Ca^{2+}	412	13.4	31	1.1
Br^-	67	0.02	3, 350	123

for Ca^{2+}, Sr^{2+}, and ${HCO_3}^{2-}$, no biological processes exist that accelerate the removal of these species to the oceanic sediment. The main removal mechanisms for major ions are kinetically slow reactions such as precipitation or incorporation into clay minerals in the sediment or oceanic crust. Thus, major ions are conservative or remain in constant proportion to each other because the major ions have very long residence times relative to either the residence time of water in the ocean (40,000 years) or the oceanic circulation time (1000 years). Even if the salt content (salinity) of seawater changes from location to location in the ocean, the ratios of the major ions do not change because they react on much longer time scales than the removal or addition of water by precipitation or evaporation. As the residence time of major ions greatly exceeds the average oceanic circulation time of approximately 1000 years, no change is seen in major ion concentrations from ocean to ocean or between surface water and deep water

The major ion composition of river water and seawater are different (Table 3). The composition of present-day river water reflects the weathering of continental rock, whose composition reflects the long-term partitioning of chemical species between the continents and seawater. The composition of seawater with respect to its major ion composition is not believed to have changed over the past several million years despite the constant input of river water of different composition. The oceans are believed to be at steady-state equilibrium with respect to the major ions. That is, the composition of seawater remains constant because the flux of major ions into the ocean equals the flux of major ions out of the ocean.

Although the major source of major ions is river input, hydrothermal circulation of seawater through oceanic basalt, particularly at relatively low temperatures, may be a significant source of some major cations (Na^+, K^+). To achieve steady-state equilibrium, the sum of the sinks or fluxes out of major ions must balance the input from rivers. Several processes, most occurring at extremely slow rates over large areas of the oceanic seafloor, have been identified as sinks for major ions. These processes include: (a) Cation exchange in which clay minerals within the oceanic sediment as well as clays delivered to the oceans by rivers exchange cations in seawater to form new clay minerals relatively enriched in Na, K, and Mg at the expense of Ca. (b) Trapping and eventual burial of seawater within interstitial water of marine sediments. This process removes the more concentrated ions in seawater (Na, Cl). (c) Evaporite formation during some periods of Earth's history, in which large deposits of minerals derived from seawater have formed when seawater was trapped and evaporated from shallow, closed basins. Although the areal extent of such basins is limited at the present time, formation of evaporites is an important removal mechanism for some major ions, including Na, Cl, and ${SO_4}^{2-}$, over geologic time. (d) *Sea spray* transported to land can result in net removal of Na and Cl. (e) *Reverse weathering* involving reactions between ions in seawater and cation-poor aluminosilicates derived from continental weathering. This process results in the formation of new cation-rich clay minerals and CO_2, resulting in the net removal of Na, K, and Mg from seawater. (f) *Hydrothermal circulation* involving the reaction of major ions between seawater and oceanic basalt is a net sink for Mg^{2+} and ${SO_4}^{2-}$.

TSUNAMI

Tsunami (also called Seismic Sea Wave, and popularly, Tidal Wave), an ocean wave produced by a submarine earthquake, landslide, or volcanic eruption. These waves may reach enormous dimensions and have sufficient energy to travel across entire oceans. From the area of the disturbance, the waves will travel outward in all directions, much like the ripples caused by throwing a rock into a pond. The time between wave crests may be from 5 to 90 minutes, and the wave speed in the open ocean will average 450 miles per hour.

Tsunamis reaching heights of more than 100 feet have been recorded. As the waves approach the shallow coastal waters, they appear normal and the speed decreases. Then, as the tsunami nears the coastline, it may grow to great height and smash into the shore, causing much destruction.

1. Tsunamis are caused by an underwater disturbance—usually an undersea earthquake. Landslides, volcanic eruptions, and even meteorites can also generate a tsunami.
2. Tsunamis can originate hundreds or even thousands of miles away from coastal areas. Local geography may intensify the effect of a tsunami. Areas at greatest risk are less than 50 feet above sea level and within one mile of the shoreline.
3. People who are near the seashore during a strong earthquake should listen to a radio for a tsunami warning and be ready to evacuate at once to higher ground.
4. Rapid changes in the water level are an indication of an approaching tsunami.
5. Tsunamis arrive as a series of successive "crests" (high water levels) and "troughs" (low water levels). These successive crests and troughs can occur anywhere from 5 to 90 minutes apart. They usually occur 10 to 45 minutes apart.

The Tsunami Warning System, a cooperative international organization and operated by the United States Weather Service, has been in operation since the 1940s. The headquarters of the center is located in Hawaii. An associated Alaska Regional Tsunami Warning System is located in Alaska. Tsunami prediction essentially

Figure 1. Network of tide and seismograph stations that are part of the Tsunami Warning System, headquartered in Hawaii. (*National Oceanic and Atmospheric Administration*.).

commences with earthquake monitoring and prediction information. Inputs from these systems are linked with information from a series of tide monitoring installations. Locations of tide stations and of seismograph stations in the Tsunami Warning System are shown in Fig. 1.

When inputs indicate conditions are favorable for a tsunami, a watch is issued for the probable affected area. Warnings are issued when readings from various tidal stations appear to match the seismographic information. Because of the complexity of the factors involved and a large degree of uncertainty nearly always present, there is a tendency to issue watches and warnings as a safety precaution even though a tidal wave of significance may not develop. Unfortunately, after awhile, persons in likely areas to be affected grow callous to watches and tend to ignore them. A tsunami that hit Hilo, Hawaii in 1960 killed 60 residents even though they had been warned of the coming event an ample 6 hours in advance of the strike.

This, however, was not the reason for the most devastating Tsunami in history which occurred on December 26, 2004 in the Indian Ocean as a result of a 9.0 earthquake off the shore of Banda Aceh, Indonesia. The resulting Tsunami quickly hit the Indonesian coastline, but hours later struck Sri Lanka, India, The Maldives, and later yet, Keyna and Somalia on the East coast of Africa. More than 150,000 lives were lost because no network existed to communicate the likely result of the 9.0 quake in the Indian Ocean. No such event had occurred in this area of the world in over 120 years since Kakatoa erupted in 1883.

Twenty three earthquake monitoring stations picked up the seismic shocks in Indonesia itself, and the U.S. Geological Survey's worldwide monitoring system, with 120 stations, pinpointed the quake immediately. However, on that fateful Sunday, the few warning telephone calls that were made went unanswered. Thus, lack of communication, more than lack of technology, caused the extreme loss of life.

The material destruction, however, touching so many countries, was a result of the movement of the Earth's crust beneath the Indian Ocean extending along a fracture believed to have been 600 miles in length, ultimately creating a tidal wave nearly 1000 miles long.

Such horror can never again touch the Indian Ocean nations as they continue to build a Tsunami Watch System containing all the elements of the early warning capability that has existed in the Pacific Ocean since the middle of the 20th century.

In the late 1970s, scientists suggested an improved method for making tsunami predictions. For a number of years, specialists have suggested that better analysis and interpretation of seismic waves produced by earthquakes may improve the prediction of tsunamis. Seismic waves range from very short-period waves that result from the sharp snap of rocks under high stress to very long-period waves, due mainly to the slower movements of large sections of the ocean floor. Many researchers believe that tsunamis result mainly from the vertical movement of these large blocks, leading to a tentative conclusion that the strength of seismic waves of very long period may be the best criterion for an earthquake's ability to generate a tsunami.

Part of the problem is that most seismographs installed in the system are not very sensitive to very long-period waves, and thus a given earthquake cannot be analyzed effectively in terms of its potential for producing a tsunami. Equipment has been refined so that, today, shorter period waves are used to locate an earthquake and 20-second waves are used to calculate the magnitude. However, some scientists feel that the true magnitude of some earthquakes can only be determined by measuring the characteristics of longer waves, such as 100-second waves. Brune and Kanamori (University of California at San Diego) have observed that the Chilean earthquake of 1960 had a magnitude of 8.3 when calculated on the basis of 20-second waves, but its magnitude was 9.5, or more than 10 times larger in wave amplitude and more than 60 times larger in energy released, when calculated by Kanamori's method, which attempts to include the energy release represented by very long-period seismic waves. Other scientists are coming to the viewpoint that many warnings could be omitted if predictions were based on longer waves. Two of the first long-period seismographs incorporated in the Tsunami Warning System were installed in Hawaii and on the Russian island of Yuzhno-Sakhalinsk, which is northeast of Vladivostok. Later, an installation was made at the Alaska Warning Center in Palmer. Whether the latest reasoning proves successful must await a number of years of experience with the earthquakes of the future and the resulting tsunamis.

CONTINUING TSUNAMI RESEARCH

During the 2000s, research pertaining to the fundamentals of tsunamis and the development of mathematical models of the phenomenon continues. Considerable attention is being directed to specific regions, including the west coasts of Mexico and Chile, the southwestern shelf of Kamchatka (Russia) and, in the United States, the generation of tsunamis in the Alaskan bight and in the Cascadia Subduction Zone off the west coasts of Washington (Puget Sound) and Oregon.

Research also is being directed toward the development of simple and more economic warning systems, particularly in the interest of the developing countries, the coasts of which border on the Pacific Ocean.

The Tsunami Warning System previously described requires millions of dollars for equipment, maintenance, and operation, well beyond the means of some countries. Also, some scientists believe that more localized equipment installations could possibly serve local shore communities better while costing less. These observations, however, do not challenge the need and validity for the larger tsunami network. The National Oceanic and Atmospheric Administration (NOAA) has developed a system costing in the range of $20,000 that can be installed and operated by non experts. The system has been undergoing trials at Valparaiso, Chile, a city that has been struck by nearly 20 tsunamis within the past two centuries. A sensor (accelerometer) is installed in bedrock under the city and can measure tectonic activity in excess of 7.0 on the Richter scale. These measurements are interlocked with level sensors.

Researchers B.F. Atwater and A.L. Moore (University of Washington), in their attempts to model earthquake and tsunami activity in the area over the last thousand years, have reported what they believe to have been a large earthquake on the Seattle fault some time between 1000 and 1100 years ago. The researchers report, "Water surged from Puget Sound, overrunning tidal marshes and mantling them with centimeters of sand. One overrun site is 10 km northwest of downtown Seattle; another is on Whidbey Island, some 30 km farther north. Neither site has been widely mantled with sand at any other time in the past 2000 years. Deposition of the sand coincided—to the year or less—with abrupt, probably tectonic subsidence at the Seattle site and with landsliding into nearby Lake Washington. These findings show that a tsunami was generated in Puget Sound, and they tend to confirm that a large shallow earthquake occurred in the Seattle area about 1000 years ago."

Simulations of tsunamis from great earthquakes on the Cascadia subduction zone have been carried out by M. Ng, P.H. Leblond, and T.S. Murty (University of British Columbia). A numerical model has been used to simulate and assess the hazards of a tsunami generated by a hypothetical earthquake of magnitude 8.5 associated with rupture of the northern sections of the subduction zone. The model indicates that wave amplitudes on the outer coast are closely related to the magnitude of sea-bottom displacement (5 meters). The researchers observe, "Some amplification, up to a factor of 3, may occur in some coastal embayments. Wave amplitudes in the protected waters of Puget Sound and the Straits of Georgia are predicted to be only about one-fifth of those estimated on the outer coast."

METEOROLOGY

BALLOONING AND METEOROLOGY IN THE TWENTIETH CENTURY

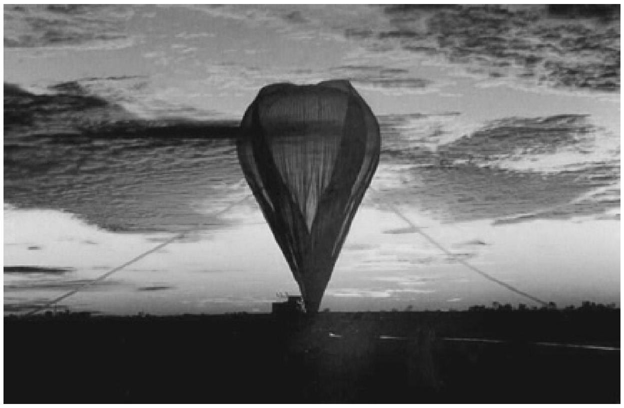
LINDA VOSS
U.S. Centennial of Flight Commission

Balloons are ideal for gathering meteorological information and have been used for that purpose throughout their history. *Meteorological* measurements of wind and air pressure have gone hand in hand with the earliest balloon launches and continue today. Balloons can climb through the denser air close to the Earth to the thinner air in the upper atmosphere and collect data about wind, the different layers of the atmosphere, and weather conditions as they travel.

The first meteorological balloon sondes, or "registering balloons," were flown in France in 1892. These balloons were relatively large, several thousand cubic feet, and carried instruments to record barometric pressure (barometers), temperature (thermometers), and humidity (hygrometers) data from the upper atmosphere. They were open at the base of the balloon and were inflated with a lifting gas, which could be hydrogen, helium, ammonia, or methane. The lifting gas in the balloon exited through the opening as the balloon expanded during its ascent and the air became thinner and the pressure dropped. At the end of the day, as the lifting gas cooled and took up less space, the balloon descended very slowly. The meteorologists had to wait until the balloon descended all the way to Earth to

A balloon equipped for meteorological observations. A German balloon ascent in the late 1800s. 17 Balloon Equipped for Meteorological Observations.

Two men performing balloon tests for the U.S. Weather Bureau.



A zero-pressure balloon being inflated at Alice Springs, Australia.

Weather balloons are used daily to carry meteorological instruments to 20 miles (30 kilometers) and above into the atmosphere to measure temperature, pressure, humidity, and winds. The balloons are made of rubber and weigh up to 2.2 pounds (one kilogram). More than 200,000 weather soundings are made with such balloons worldwide each year.

FIG. 2. FIRST ASCENSION IN AMERICA, ST. LOUIS, SEPTEMBER 15, 1904

Preparing to launch America”s first “ballon-sonde.” Since this first launch on September 15, 1904, in St. Louis, Missouri, literally millions of weather balloons have been launched by the National Weather Service and its predecessor organization. From: The Principles of Aerography, by Alexander McAdle, 1917.

retrieve their instruments, which often had drifted up to 700 miles (1,126 kilometers) from their launch point.

The German meteorologist Assmann solved the problem of drifting balloons and retrieval of instruments in 1892 by introducing closed rubber balloons that burst when they reached a high altitude, dropping the instruments to Earth by parachute much closer to the launch site. These balloons also had fairly constant rates of ascent and descent for more accurate temperature readings. Assmann also invented a psychrometer, a type of hygrometer used to measure humidity in the air that laboratories generally use.

In the 1930s, meteorologists were able to get continuous atmospheric data from balloons when the radiosonde was developed. A radiosonde is a small, radio transmitter that broadcasts or radios measurements from a group of instruments. Balloons, usually unmanned, carry the transmitter and instruments into the upper atmosphere. The radiosonde transmits data to Earth while measuring humidity, temperature, and pressure conditions.

Today, three types of balloons are commonly used for meteorologic research.

Assmann’s rubber, or neoprene, balloon is used for measuring vertical columns in the atmosphere, called vertical soundings. The balloon, inflated with a gas that causes the balloon to rise, stretches as it climbs into thin air, usually to around 90,000 feet (27,400 meters). Data is taken as the balloon rises. When the balloon has expanded from three to six times its original length (its volume will have increased 30 to 200 times its original amount), it bursts. The instruments float to Earth under a small parachute. The neoprene balloon can either carry radiosondes that transmit meteorological information or be tracked as a pilot balloon, a small balloon sent aloft to show wind speed and direction. Around the world, balloons equipped with radiosondes make thousands of soundings of the winds, temperature, pressure, and humidity in the upper atmosphere each day. But these balloons are launched and tracked from land, which limits what the radiosondes can measure to less than one-third of the Earth’s surface.

Zero-pressure plastic (usually polyethylene) balloons were first launched in 1958. They carry scientific instruments to a predetermined atmospheric density level. Zero-pressure balloons are the best for extremely high altitudes because the balloons can be lighter and stress on them can be distributed over the surface of the balloon.

About the same time, the Air Force Cambridge Research Laboratories (AFCRL) started working on super-pressure balloons, which were made from mylar. The development of mylar plastic films and advances in electronic miniaturization made constant-altitude balloons possible.

Mylar is a plastic that can withstand great internal pressure. The mylar super-pressure balloon does not expand as it rises, and it is sealed to prevent the release of gas as the balloon rises. By the time the balloon reaches the altitude where its density equals that of the atmosphere, the gas has become pressurized because the heat of the sun increases the internal gas pressure. However, because mylar can withstand great internal pressure, the volume of the balloon remains the same. By carefully calculating the weight of the balloon and whatever it is carrying, the altitude at which the balloon will achieve equilibrium and float can be calculated. As long as the pressure inside the balloon remains the same, it will remain at that altitude.

These balloons could be launched to remain aloft at specified altitudes for weeks or months at a time.

Moreover, satellites could be used to track and request data from many balloons in the atmosphere to obtain a simultaneous picture of atmospheric conditions all over the globe. Another advantage of super-pressure balloons is that, since they transmit their data to satellites, they can gather data from over oceans as well as land, which is a limitation of balloons equipped with radiosondes.

The AFCRL program resulted in the Global Horizontal Sounding Technique (GHOST) balloon system. With GHOST, meteorologists at last achieved their goal of semipermanent platforms floating high in the atmosphere.

Eighty-eight GHOST balloons were launched starting in March of 1966. The GHOST balloons and their French counterpart, EOLE, (the name Clement Ader used for one of his aircraft—named after the Greek god of the wind) used strong, plastic super-pressure balloons to trace air circulation patterns by drifting with the wind at constant density altitudes. Many super-pressure balloons were aloft at a time, grouped at constant density levels. Each balloon had a sensing device and transmitting system for gathering information on its position and weather data and transmitted atmospheric and weather data to weather satellites. They first transmitted their data to the NASA *Nimbus-4* meteorological satellite in 1970.

In 1966, a GHOST balloon circled the Earth in 10 days at 42,000 feet (12,801 meters). By 1973, NASA had orbited scientific instrument packages aboard sealed balloons at altitudes up to 78,000 feet (23,774 meters). Other GHOST balloons remained aloft for up to a year. The program lasted for 10 years.

The ultimate of the super-pressure balloons was the balloon satellite *Echo I.* Launched into space in 1960, the balloon inflated to a sealed volume by residual air, benzoic acid, and a chemical called anthraquinone.

Constant-altitude, super-pressure balloons continue to fly over the oceans and land surfaces. These balloons have been relied on for decades to provide extensive knowledge of global meteorology and improve worldwide weather forecasting.

BAROMETRIC EFFICIENCY

Todd Rasmussen
The University of Georgia
Athens, Georgia

Water levels in wells are often observed to fluctuate as the air pressure changes. Blaise Pascal described this effect in 1663 (1) and was the first to attribute the water level changes in wells to changes in atmospheric pressure. He noted that water levels declined as the barometric pressure increased, and vice versa.

The barometric efficiency, BE, is used to relate changes in water levels, ΔW, to changes in barometric (air) pressure, ΔB:

$$BE = -\frac{\Delta W}{\Delta B} \tag{1}$$

where consistent units (e.g., feet of water, mm of Hg, hPa) are used for both water levels and barometric pressure (2,3).

To understand why this relationship exists, we can conceive of an aquifer that is entirely isolated from the atmosphere. Such an aquifer maintains a constant total head, $H = H_o$, within the aquifer and is entirely unaffected by atmospheric pressure changes. Water level elevations, W, in the aquifer are measured in an open borehole.

The total head within the well is the sum of the water level elevation plus the barometric pressure exerted on the water surface, $H = W + B$. If the total head within the well is equal to the total head within the aquifer, $H_o = W + B$, and the total head within the aquifer is constant, then the water level varies inversely with barometric pressure, $W = H_o - B$.

The change in water level is just the negative of the change in barometric pressure, $\Delta W = \Delta(H_o - B) = -\Delta B$, so that the barometric efficiency is 100 percent, $BE = -\Delta W/\Delta B = -(-\Delta B)/\Delta B = 1$.

A second example assumes that the total head in the hypothetical aquifer increases with barometric pressure, $H = H_o + B$, so that the head in the aquifer goes up and down over time. In this case, the water levels in the well remain unchanged, and the barometric efficiency of the aquifer is zero.

These two extremes are shown in Fig. 1. Note that the barometric pressure is identical in both cases. In the left figure, the barometric efficiency is 100%, so that the water level varies inversely with barometric pressure. The total head is the sum of the barometric pressure and water levels, so it remains unchanged. In the right figure, the barometric efficiency is zero, so that the water level is unaffected by barometric pressure changes and the total head varies directly with barometric pressure.

Most aquifers lie between these two extremes, however, and the actual response depends, in large part, on whether the aquifer is confined or unconfined. Both of these cases are described below.

CONFINED AQUIFERS

For confined aquifers, Jacob (4) showed that increasing the load on the ground surface increases the load on the aquifer. This additional weight is either carried by the mineral grains or by the water within the aquifer pores. If the entire weight is borne by the mineral grains, and these grains do not deform with the increase in load, then the total head within the aquifer remains unchanged, and the barometric efficiency is 100%.

The barometric efficiency is smaller if some of the weight is carried by the fluid. A very low barometric efficiency in confined aquifers occurs when the fluid within the aquifer bears most of the weight. Examples of such aquifers include poorly consolidated sedimentary aquifers or horizontal fractures that extend great distances.

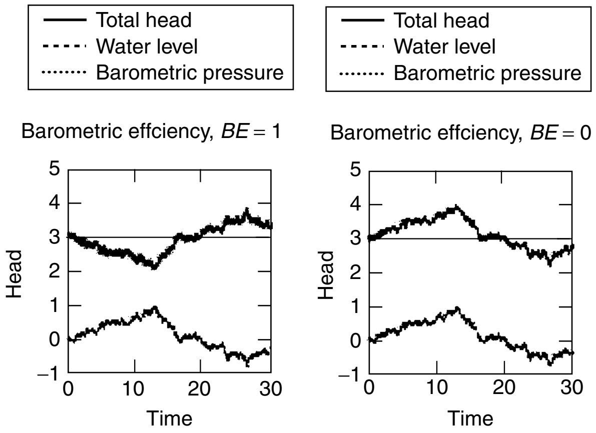

Figure 1. Effect of barometric pressure on water levels in wells. Both figures show barometric pressure (lower, dashed line), total head (solid line), and water levels (dotted line). Left figure shows effects when the barometric efficiency is 100%, $BE = 1$, and right figure shows effects when the barometric efficiency is zero, $BE = 0$.

Figure 2 shows the extreme conditions. In the left figure, the entire increase in load caused by an increase in barometric pressure is carried by the mineral grains. In this case, the pore fluids are not affected by the increase in load, the total head remains unchanged, and water levels drop in an amount equal to the increase in barometric pressure. In the right figure, the mineral grains do not carry the load and the fluid carries the increased load, causing an increase in total head.

In confined aquifers, the barometric response is virtually instantaneous. A change in barometric pressure should cause an immediate change in water levels in wells. Water levels in large-diameter wells may not respond immediately, however, because of the time required for water levels to adjust to the new level. Instead of a rapid

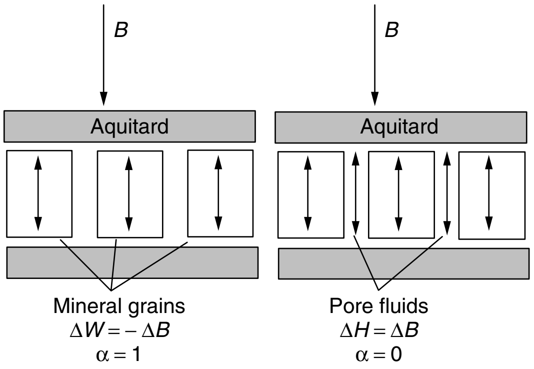

Figure 2. Effect of barometric pressure on total head in confined aquifers. The mineral grains carry the load in the left figure, whereas the pore fluids carry the load in the right figure. Most confined aquifers, however, are intermediate between these two extremes.

response to pressure changes, a slow response may be found in these wells.

This phenomena is called *borehole storage* and is a function of the diameter of the borehole, the length of the screened interval relative to the aquifer thickness, the aquifer hydraulic properties (e.g., transmissivity and storativity), and the rate at which the barometric pressure is changing.

The effects of borehole storage can be eliminated by placing a packer in the well below the water surface, but above the screened interval, which eliminates the need for the water level to change in response to changes in barometric pressure. Some change in volume may result from the slight compressibility of water, but this effect is very small. A gauge-type pressure sensor (i.e., internally vented to the atmosphere) is then placed below the packer to measure the water pressure.

Several techniques are available for estimating the confined aquifer barometric efficiency, including linear regression and Clark's Method (5). Clark's method is an unbiased technique for estimating the barometric efficiency that performs well when a water level trend is present in the data (6). Regression provides a better estimate, but only when the trend function can be accurately specified (7).

UNCONFINED AQUIFERS

Barometric pressure changes commonly do not affect water levels in wells located in shallow, unconfined aquifers, which is because the air pressure moves rapidly through the unsaturated zone and causes an immediate increase in total head within the aquifer.

In deeper unconfined aquifers, however, the typical response to barometric pressure changes is to see an immediate inverse response (i.e., an increase in barometric pressure causes an equivalent and opposite water level response), followed by a slow decay back to the original water level (5,8,9).

To understand this complex response, we focus on how total head responds to barometric pressure changes. Initially, no increase in total head within the unconfined aquifer occurs because the water held within pores is not confined by an overlying confining unit. The total head within the aquifer can rise over time, however, as air diffuses downward through the unsaturated zone.

The total head in the unconfined aquifer increases once the air pressure change reaches the water table. The time required for the total head to respond to barometric pressure changes is a function of the depth of the water table and the air diffusivity within the unsaturated zone. The air diffusivity is higher in coarse, dry soils and is lower in wet soils or in soils with a low air permeability.

As the water level response in observation wells is the total head minus the barometric pressure, the fact that the total head does not change initially means that a rapid water-level response occurs to barometric pressure changes. In fact, the barometric efficiency is one in wells with a deep unsaturated zone—or where the air permeability of the unsaturated zone is low—followed by a gradual decrease as air diffuses downward to the water table.

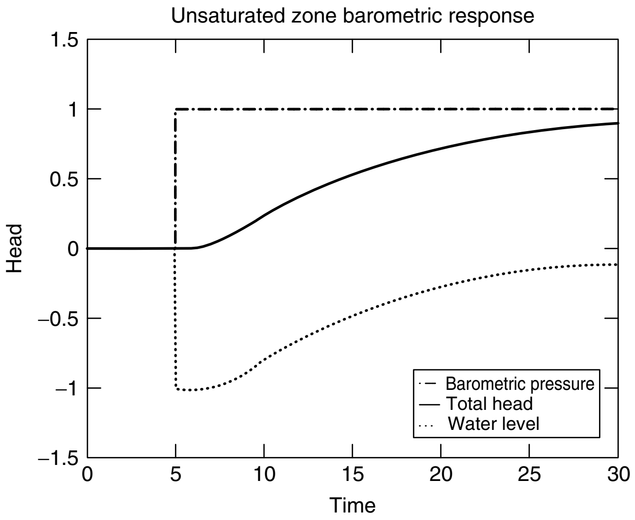

Figure 3. Effect of barometric pressure on total head and water levels in confined aquifers. The barometric pressure in this example takes a step from zero to one at $t = 10$. The total head slowly rises as the barometric pressure makes its way through the unsaturated zone. The water levels initially fall to maintain the constant total head, but then return to normal once the barometric pressure signal reaches the water table.

This concept is illustrated graphically in Fig. 3. Note that the barometric pressure is simplified to a simple step change from zero to one. The total head does not initially respond, but slowly rises over time as the barometric pressure moves through the unsaturated zone and eventually reaches the water table. The observed water level in a well placed in this aquifer responds immediately (as long as borehole storage can be neglected), but eventually decays back to its original level

The barometric efficiency of unconfined aquifers is not single valued like the confined aquifer barometric efficiency. Instead, the response includes a delay that can be estimated using regression deconvolution (5,9). The resulting response can be used to estimate the unsaturated air diffusivity of the unsaturated zone.

CERES: UNDERSTANDING THE EARTH'S CLOUDS AND CLIMATE

NASA—Langley
Research Center

The Clouds and the Earth's Radiant Energy System (CERES) instrument is one of several launched aboard the Earth Observing System's (EOS) Aqua spacecraft in 2002. Scientists use observations from the CERES instrument to study the energy exchanged between the Sun; the Earth's atmosphere, surface and clouds; and outer space.

The CERES Aqua instruments are the fourth and fifth CERES instruments in orbit. NASA launched the first CERES instrument aboard the Tropical Rainfall Measuring Mission satellite or TRMM in November 1997. Results of the TRMM mission show that the first CERES provided better measurement capabilities than any previous satellite instrument of its kind. Two other CERES instruments are currently orbiting the Earth on the EOS Terra spacecraft, launched in late 1999. Early CERES Terra results give new insights into the effects of clouds on climate and how the climate system changes from decade to decade. Two CERES instruments on each of the Terra and Aqua spacecraft will provide global coverage of energy radiated and reflected from the Earth. Scientists use measurements from both satellites' orbits to improve observations of the daily cycle of radiated energy.

NASA Langley Research Center manages the CERES mission. Langley's highly successful Earth Radiation Budget Experiment (ERBE) provided the foundation for the design of the CERES instrument. ERBE used three satellites to provide global energy measurements from 1984 through the 1990s. The TRW Space & Electronics Group in Redondo Beach, Calif., built all six CERES instruments.

WHAT CERES WILL MEASURE

CERES measures the energy at the top of the atmosphere, as well as estimate energy levels in the atmosphere and at the Earth's surface. Using information from very high resolution cloud imaging instruments on the same spacecraft, CERES will determines cloud properties, including altitude, thickness, and the size of the cloud particles. All of these measurements are critical for advancing the understanding of the Earth's total climate system and the accuracy of climate prediction models.

BALANCING THE EARTH'S ENERGY BUDGET

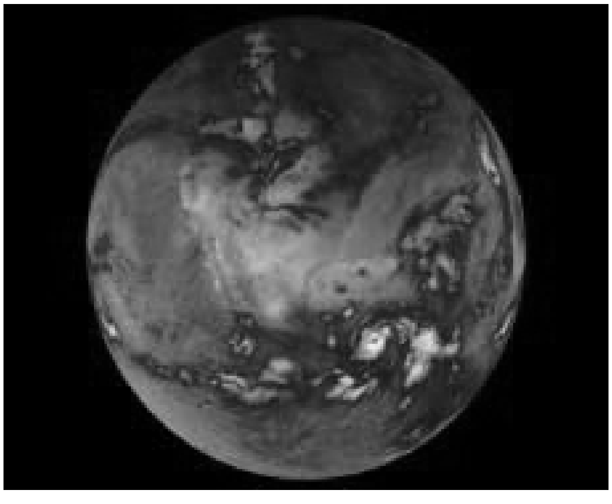
The balance between Earth's incoming and outgoing energy controls daily weather and climate (long-term weather patterns). Sunlight or solar energy is the planet's only incoming energy source. Heat emitted from the sunlight reflected by the Earth's surface, atmosphere and clouds make up the planet's outgoing energy. Scientists have been working for decades to understand this critical energy balance, called the Earth's "energy budget."

The energy received from the Sun is at short wavelengths, while the energy emitted by the surface of the Earth, the atmosphere and clouds is at long wavelengths. Greenhouse gases in the atmosphere absorb the long wavelength energy or heat emitted by the Earth. Increases in the amounts of greenhouse gases produced by both natural processes or human activities can lead to a warming of the Earth's surface. Such changes may, in turn, alter the planet's daily weather and climate.

Clouds and small particles in the atmosphere called aerosols also reflect some sunlight back into space. Major sources of aerosols include windblown dust, emissions from the burning of fossil fuels, such as gasoline, and the burning of forests and agricultural fields.

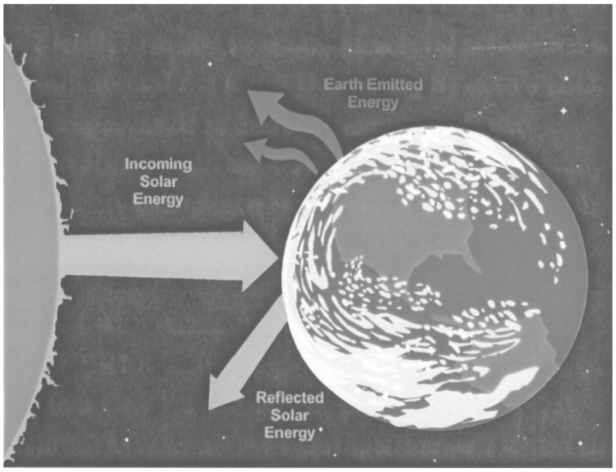
CLOUD EFFECTS

One of the most intriguing questions facing climate modelers today is how clouds affect the Earth's climate



CERES detects low (blue and white) to high (yellow) amounts of emitted heat

---



Earth's radiation budget is the balance between incoming and outgoing energy

and vice versa. The U.S. Global Change Research Program classifies understanding the role of clouds and the Earth's energy budget as one of its highest scientific priorities. Understanding cloud effects requires a detailed knowledge of how clouds absorb and reflect sunlight, as well as how they absorb and re-emit outgoing heat emitted by the planet. For example, low, thick clouds primarily reflect incoming solar energy back to space causing cooling. Thin, high clouds, however, primarily trap outgoing heat and produce warming. To date, satellite studies have found that clouds have an overall cooling effect on the Earth.

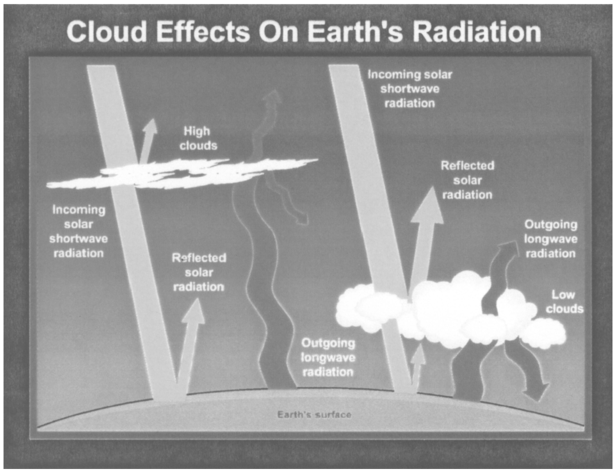
Analyses of satellite data also indicate that clouds which form over water are very different from clouds which form over land. These differences affect the way clouds reflect sunlight back into space and how much heat emitted from the Earth the clouds absorb and re-emit. For example, over the equator in the eastern Pacific Ocean during El Niño events, there is a significant decrease in the amount of energy emitted by the Earth due to increased cloudiness. El Niño events occur when portions of the eastern Pacific Ocean become considerably warmer than normal, causing an increase in cloudiness over the region. These changes can affect weather patterns around the world.

WATER VAPOR EFFECTS

Water vapor in the atmosphere also impacts our daily weather and climate, though scientists are only beginning to understand how this complex mechanism works. Water vapor acts like a greenhouse gas and absorbs outgoing heat to warm the Earth. Because water vapor also condenses to make clouds, additional water vapor in the atmosphere also may increase the amount of clouds.

FUTURE MISSIONS

One additional CERES instrument is available to fill the gap between Aqua and the next generation of highly accurate Earth radiation budget measurements. These



observations are expected to be made on the National Polar-orbiting Operational Environmental Satellite System (NPOESS) starting around 2010. To continue the 22-year record of global energy measurements, the next CERES mission should launch in 2007.

EDUCATIONAL OUTREACH

As a CERES instrument passes overhead, students worldwide are observing clouds and then sending their observations to NASA Langley's Atmospheric Sciences Data Center (ASDC). At the ASDC, scientists store data for further analysis by the CERES science team. The student observations are part of a global educational outreach program called the Students' Cloud Observations On-Line (S'COOL) project. Since the project began five years ago, S'COOL has reached over 1,000 schools in all 50 states and 57 other countries on five continents.

COMMERCIAL APPLICATIONS

CERES supports commercial applications by providing data about weather and sunlight at the Earth's surface for the renewable energy industry via an innovative Web site (http://eosweb.larc.nasa.gov/sse/). The Surface Meteorology and Solar Energy Project maintains the site. In the first three years of operation, the number of registered users of the Web site, including major energy companies, financial institutions and federal agencies, has grown to over 2,000 from nearly 100 countries. With 35,000 hits per month since January 2001, SSE is the most accessed Web site at the ASDC.

CHINOOK

Arthur M. Holst
Philadelphia Water Department
Philadelphia, Pennsylvania

Wind is defined as the movement of air. Although we commonly define wind as a gentle breeze or a harsh gust of cold air, there is a wind phenomenon that can increase the temperature instead of lowering it. It is called a Chinook wind. Chinooks are most commonly associated with the Rocky Mountain range in North American but can also be found in the Swiss Alps and the Andes. They can increase temperatures high enough to melt the snow in their path as they travel down the mountainside. The Chinook wind falls under the classification of katabatic wind, which means that it moves downhill.

The name “Chinook” was taken from the Chinook Indians that lived along the Rocky Mountains until the early 1800s when the tribe became extinct due to disease. Although the tribe died off, their legends and tales live on. One such legend is that of the Chinook wind, which in its literal translation means “snow-eater.”

It is possible for a Chinook to take place anytime during the year, but its effects are much more dramatic during the winter months. Chinook winds cause dramatic increases in the temperature on the eastern side of the Rockies and can send temperatures into the fifties and sixties. A temperature change of this magnitude can take anywhere from an hour to a day. The heat produced is a reaction formed from the change of gas to liquid in the atmosphere. These warm gusts of air then cause the evaporation of any snow on the ground, hence the name snow-eater. There is no definite length of time that a Chinook will last. On average, it can last hours or days.

Chinooks are the end result of the warm moist air of the Pacific Ocean moving up and down the Rocky Mountains. A westerly wind collects the warm moist air in the Pacific Ocean and carries it to the coast where it meets the western side of the Rockies. As the air makes its way up the mountain, the air becomes cooler, and the precipitation is squeezed out of it. Through this process warm, dry air is produced as it makes its way down the eastern side of the mountain. This process is repeated over and over again on each mountain that is in the way of the wind and each time produces warmer, dryer air. The air that makes its way down the last mountain is extremely dry and warm. This wind is called the Chinook wind. These warm gusts of air can reach speeds up to 100 mph.

The results from Chinook winds are both positive and negative. Chinook winds cause evaporation of the snow covering the ground, so the length of the grazing season is extended. A longer grazing season decreases the need to stock up on feed for animals. A negative result is the decreased amount of precipitation due to the quick evaporation of snow. Less precipitation causes hardships in planting.

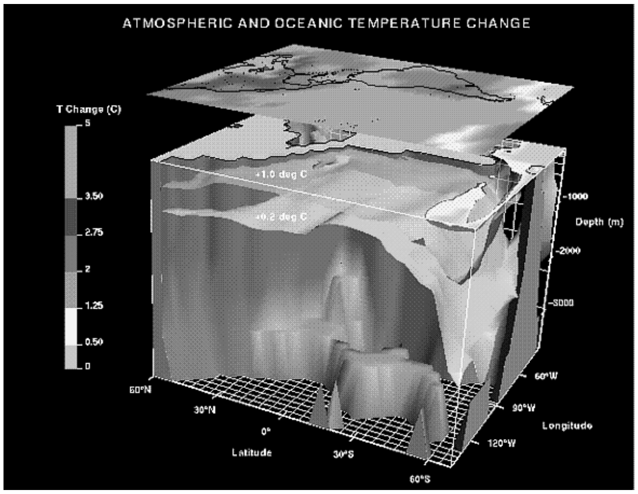
GLOBAL CLIMATE CHANGE

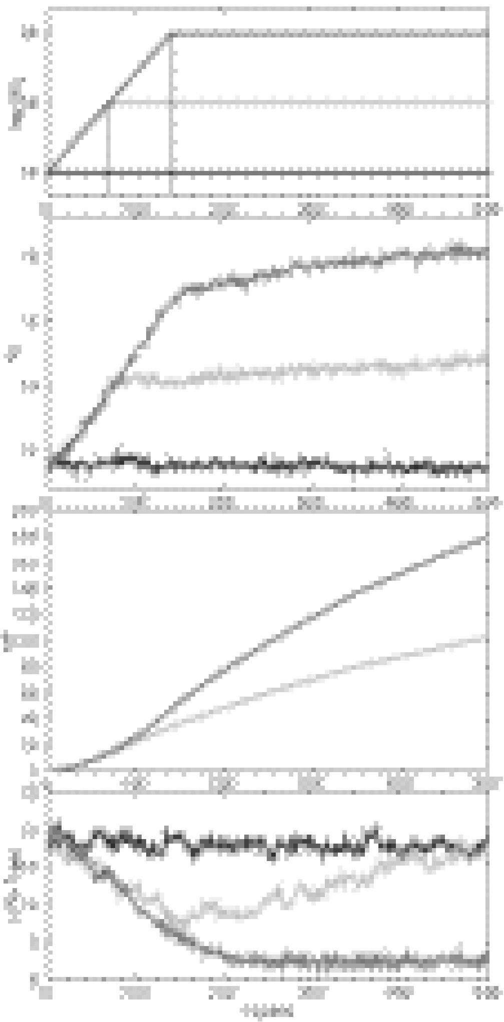
Geophysical Fluid Dynamics
Laboratory—NOAA

In 1967, two GFDL scientists, Syukuro Manabe and Richard Wetherald, published what is now regarded as the first credible calculation of the effect of increased carbon dioxide on the climate. They calculated that a doubling of atmospheric carbon dioxide would warm the earth's surface by about 2 °C. This result laid the foundation for what has become an international, multi-disciplinary research effort on global warming.

Manabe, in collaboration with oceanographer Kirk Bryan and other scientists at GFDL, has continued to lead the international effort to develop the coupled ocean-atmosphere climate models that are crucial to understanding and predicting the impact of greenhouse gases.



Three-dimensional view of projected surface air temperature and ocean warming (°C) due to greenhouse gases as calculated by a low-resolution GFDL coupled ocean-atmosphere climate model. The top panel shows the surface air temperature change over North and South America and surrounding regions. The three-dimensional box illustrates the depth to which a 1 °C and 0.2 °C warming has penetrated in the model's Pacific Ocean. The gray surface depicts the model's ocean floor. Note the deep mixing of the ocean warming signal in the southern hemisphere ocean near Antarctica. The temperature changes are projections of the warming due to greenhouse gases by the latter half of the twenty-first century in the absence of further increases in sulfate aerosol forcing. Results shown are based on years 61–80 of a transient CO_2 increase experiment (+1% per year compounded). [*Source*: adapted from Syukuro Manabe and Ronald Stouffer, Nature, 15 July 1993.]



Impact of increasing CO_2 on the earth's climate as simulated in a GFDL coupled ocean-atmosphere climate model. Shown are timeseries of: a) prescribed CO_2 concentration on a logarithmic scale in comparison to present levels; b) global mean surface air temperature (°C); c) global mean increase of sea level (cm) due to thermal expansion; and d) intensity of the North Atlantic Ocean's meridional overturning circulation (10**6 m**3/sec). The labels "Control", "$2xCO_2$", and "$4xCO_2$" refer to separate experiments where CO_2 either remains constant (Control), or increases at 1% per year (compounded) to double ($2xCO_2$) or quadruple ($4xCO_2$) the current concentration. Note that the sea level rise estimates do not include the effect of melted continental ice sheets. With this effect included, the total rise could be larger by a substantial factor. [*Source*: Syukuro Manabe and Ronald Stouffer, Nature, 15 July 1993.]

A PROBLEM FOR CENTURIES TO COME?

In a recent paper, published 26 years after Manabe's pioneering one-dimensional CO_2 sensitivity study, he and Ron Stouffer of GFDL used a three-dimensional coupled ocean-atmosphere model to examine possible CO_2-induced climate changes over several centuries. Earlier studies had focused on shorter time horizons.

In their scenario, CO_2 quadruples over a period of 140 years, then no longer increases. This perturbation is enough to cause the ocean's global thermohaline circulation to almost disappear in the model. The global thermohaline circulation is important because it is responsible for a large portion of the heat transport from the tropics to higher latitudes in the present climate. In addition, sea level continues rising steadily for centuries after the CO_2 increase is halted. From this perspective, global warming can no longer be viewed as just as a problem of our own lifetimes, but as a legacy—with uncertain consequences—now being passed forward to many future generations.

EVALUATING CLIMATE MODELS

GFDL scientists, including Tony Broccoli and Tom Delworth, are searching for innovative ways to evaluate climate models and to distinguish between human-induced climate change and natural climate variability. Measurements of the current climate, historical observations, and glimpses of earth's climate during the ice ages and other past climates all provide opportunities to test climate models. Through research on climate models and observations, scientists at GFDL will continue to evaluate and refine the climate models that will be needed to help answer critical policy-relevant questions about global warming and its consequences.

OBSERVATIONS OF CLIMATE AND GLOBAL CHANGE FROM REAL-TIME MEASUREMENTS

David R. Easterling
Thomas R. Karl

(from *Handbook of Weather, Climate, and Water: Dynamics, Climate, Physical Meteorology, Weather Systems, and Measurements*, Wiley 2003)

INTRODUCTION

Is the planet getting warmer?
Is the hydrologic cycle changing?
Is the atmospheric/oceanic circulation changing?
Is the weather and climate becoming more extreme or variable?
Is the radiative forcing of the climate changing?

These are the fundamental questions that must be answered to determine if climate change is occurring. However, providing answers is difficult due to an inadequate or nonexistent worldwide climate observing system. Each of these apparently simple questions are quite complex because of the multivariate aspects of each question and because the spatial and temporally sampling required to address adequately each question must be considered on a global scale. A brief review of our ability to answer these questions reveals many successes, but points to some glaring inadequacies that must be addressed in any attempt to understand, predict, or assess issues related to climate and global change.

IS THE PLANET GETTING WARMER?

There is no doubt that measurements show that near-surface air temperatures are increasing. Best estimates suggest that the warming is around 0.6 °C (+−0.2 °C) since the late nineteenth century (1). Furthermore, it appears that the decade of the 1990s was the warmest decade since the 1860s, and possibly for the last 1000 years. Although there remain questions regarding the adequacy of this estimate, confidence in the robustness of this warming trend is increasing (1). Some of the problems that must be accounted for include changes in the method of measuring land and marine surface air temperatures from ships, buoys, land surface stations as well as changes in instrumentation, instrument exposures and sampling times, and urbanization effects. However, recent work evaluating the effectiveness of corrections of sea surface temperatures for time-dependent biases, and further evaluation of urban warming effects on the global temperature record have increased confidence in these results. Furthermore, by consideration of other temperature-sensitive variables, e.g., snow cover, glaciers, sea level and even some proxy non-real-time measurements such as ground temperatures from boreholes, increases our confidence in the conclusion that the planet has indeed warmed. However, one problem that must be addressed is that the measurements we rely upon to calculate global changes of temperature have never been collected for that purpose, but rather to aid in navigation, agriculture, commerce, and in recent decades for weather forecasting. For this reason there remain uncertainties about important details of the past temperature increase and our capabilities for future monitoring of the climate. The IPCC (1) has summarized latest known changes in the temperature record, which are summarized in Fig. 1.

Global-scale measurements of layer averaged atmospheric temperatures and sea surface temperatures from instruments aboard satellites have greatly aided our ability to monitor global temperature change (2–4), but the situation is far from satisfactory (Hurrell and Trenberth, 1996). Changes in satellite temporal sampling (e.g., orbital drift), changes in atmospheric composition (e.g., volcanic emissions), and technical difficulties related to overcoming surface emissivity variability are some of the problems that must be accounted for, and reduce the confidence that can be placed on these measurements (5). Nonetheless, the space-based measurements have shown, with high confidence, that stratospheric temperatures have decreased over the past two decades. Although perhaps not as much as suggested by the measurements from weather balloons, since it is now known that the data from these balloons high in the atmosphere have an inadvertent temporal bias due to improvements in shielding from direct and reflected solar radiation (6).

IS THE HYDROLOGIC CYCLE CHANGING?

The source term for the hydrologic water balance, precipitation, has been measured for over two centuries in some locations, but even today it is acknowledged that in many parts of the world we still cannot reliably measure true precipitation (7). For example, annual biases of more than 50% due to rain gauge undercatch are not uncommon in cold climates (8), and, even for more moderate climates, precipitation is believed to be underestimated by 10 to 15% (9). Progressive improvements in instrumentation, such as the introduction of wind shields on rain gauges, have also introduced time-varying biases (8). Satellite-derived measurements of precipitation have provided the only large-scale ocean coverage of precipitation. Although they are comprehensive estimates of large-scale spatial precipitation variability over the oceans where few measurements exist, problems inherent in developing precipitation estimates hinder our ability to have much confidence in global-scale decadal changes. For example, even the landmark work of Spencer (10) in estimating worldwide ocean precipitation using the microwave sounding unit aboard the National Oceanic and Atmospheric Administration (NOAA) polar orbiting satellites has several limitations. The observations are limited to ocean coverage and hindered by the requirement of an unfrozen ocean. They do not adequately measure solid precipitation, have low spatial resolution, and are affected by the diurnal sampling inadequacies associated with polar orbiters, e.g., limited overflight capability. Blended satellite/*in situ* estimates also show promise (11); however, there are still limitations, including a lack of long-term measurements necessary for climate change studies.

Information about past changes in land surface precipitation, similar to temperature, has been compared with other hydrologic data, such as changes in stream flow, to ascertain the robustness of the documented changes of precipitation. Figure 1 summarizes some of the more important changes of precipitation, such as the increase in the mid to high latitude precipitation and the decrease in subtropical precipitation. Evidence also suggests that much of the increase of precipitation in mid to high latitudes arises from increased autumn and early winter precipitation in much of North America and Europe. Figure 2 depicts the spatial aspects of this change, reflecting rather large-scale coherent patterns of change during the twentieth century.

Other changes related to the hydrologic cycle are summarized in Fig. 1. The confidence is low for many of the changes, and it is particularly disconcerting relative to the role of clouds and water vapor in climate feedback effects.* Observations of cloud amount long have been made by surface-based human observations and more recently by satellite. In the United States, however, human observers have been replaced by automated measurements, and neither surface-based or spaced-based data sets have proven to be entirely satisfactory for detecting changes in clouds. Polar orbiting satellites have an enormous difficulty to overcome related to sampling aliasing and satellite drift (12). For human observers changes in observer schedules, observing biases, and incomplete sampling have created major problems in data

*An enhancement or diminution of global temperature increases or decreases due to other causes.

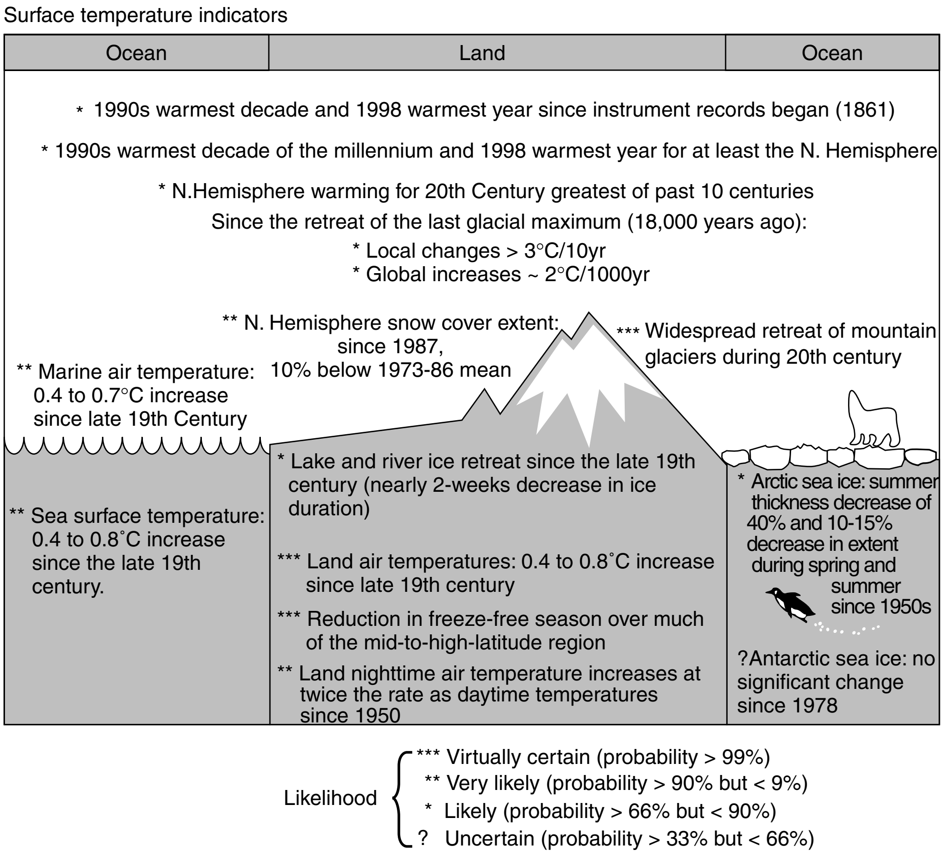

Figure 1. Schematic of observed variations of selected indictors regarding (**a**) temperature and (**b**) the hydrologic cycle (based on Ref. 1).

interpretations, now compounded by a change to new automated measurements at many stations. Nonetheless, there is still some confidence (but low) that global cloud amounts have tended to increase. On a regional basis this is supported by reductions in evaporation as measured by pan evaporimeters over the past several decades in Russia and the United States, and a worldwide reduction in the land surface diurnal temperature range. Moreover, an increase in water vapor has been documented over much of North America and in the tropics (1).

Changes in water vapor are very important for understanding climate change since water vapor is the most important greenhouse gas in the atmosphere. The measurement of changes in atmospheric water vapor is hampered by both data processing and instrumental difficulties for both weather balloon and satellite retrievals. The latter also suffers from discontinuities among successive satellites and errors introduced by changes in orbits and calibrations. Upper tropospheric water vapor is particularly important for climate feedbacks, but, as yet, little can be said about how it has varied over the course of the past few decades.

IS THE ATMOSPHERIC/OCEANIC CIRCULATION CHANGING?

Surprisingly, there is a considerable lack of reliable information about changes in atmospheric circulation, even though it is of daily concern to much of the world since it relates to day-to-day weather changes. Analyses of circulation are performed every day on a routine basis, but the analysis schemes have changed over time, making them of limited use for monitoring climate change. Moreover, even the recent reanalysis efforts by the world's major numerical weather prediction centers, whereby the analysis scheme is fixed over the historical record, contains time-varying biases because of the introduction of data with time-dependent biases and a changing mix of data (e.g., introducing satellite data) over the course of the reanalysis (13). Even less information is available on measured changes and variations in ocean circulation.

A few major atmospheric circulation features have been reasonably well measured because they can be represented by rather simple indices. This includes the El Niño–Southern Oscillation (ENSO) index, the North Atlantic Oscillation (NAO) index, and the Pacific–North American (PNA) circulation pattern index. There are interesting decadal and multidecadal variation, but it is too early to detect any long-term trends. Evidence exists that ENSO has varied in period, recurrence interval, and strength of impact. A rather abrupt change in ENSO and other aspects of atmospheric circulation seems to have occurred around 1976–1977. More frequent ENSOs with rare excursions into its other extreme (La Niña) became much more prevalent. Anomalous circulation regimes associated with ENSO and large-amplitude PNA patterns persisted in the North Pacific

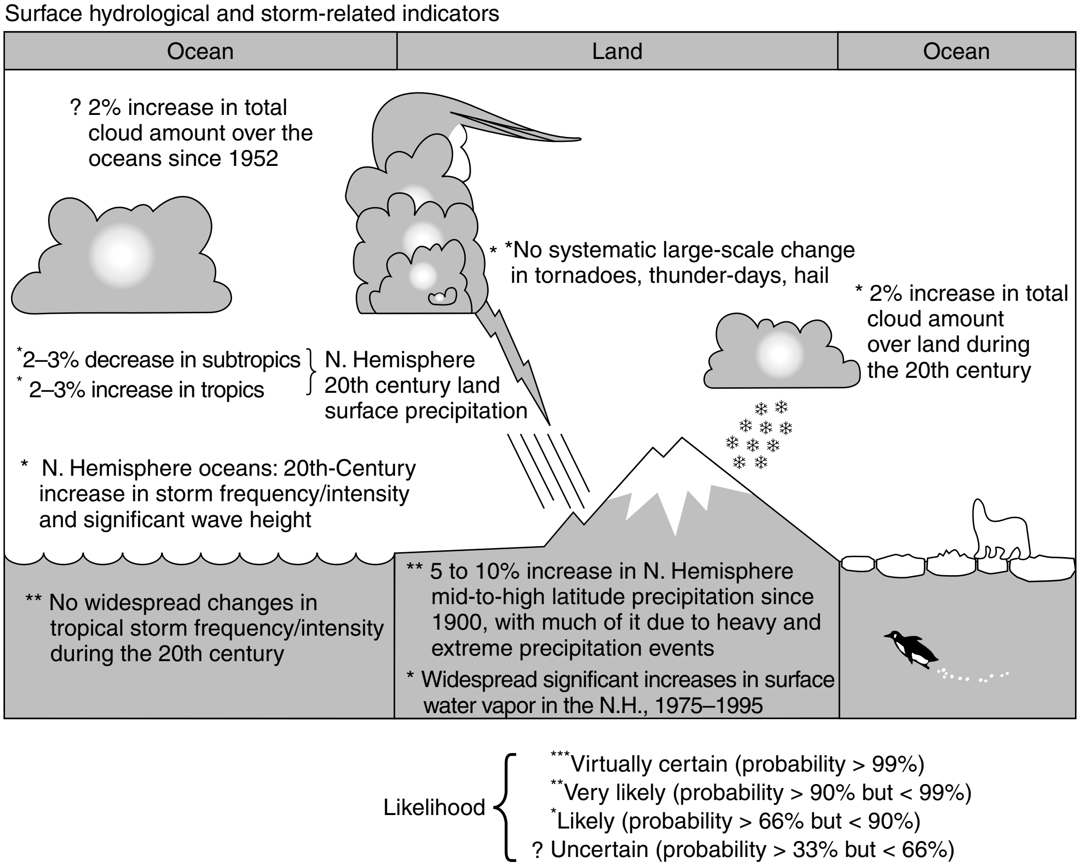

Figure 2. Precipitation trends over land 1900–1999. Trend is expressed in percent per century (relative to the mean precipitation from 1961–1990) and magnitude of trend is represented by area of circle with green reflecting increases and brown decreases of precipitation.

from the late 1970s into the late 1980s, affecting temperature anomalies. Moreover, the NAO has been persistent in its association with strong westerlies into the European continent from the late 1980s until very recently when it abruptly shifted. As a result, temperature anomalies and storminess in Europe have abruptly changed over the past 2 years compared to the past 7 or 8 years.

Increases in the strength of the Southern Hemisphere circumpolar vortex during the 1980s have been documented (14,15) using station sea level pressure data. This increase was associated with a delayed breakdown in the stratospheric polar vortex and ozone deficit in the Antarctic spring. A near-global sea level pressure data set has been used to identify changes in circulation patterns in the Indian Ocean. Allan et al. (16) and Salinger et al. (17) find that circulation patterns in the periods 1870–1900 and 1950–1990 were more meridional than those in the 1900–1950 period, indicating intensified circulation around anticyclones. These changes may be related to changes in the amplitude of longwave troughs to the south and west of Australia and the Tasman Sea/New Zealand area and a subsequent decrease in precipitation in Southwest Australia (18,19).

IS THE WEATHER AND CLIMATE BECOMING MORE EXTREME OR VARIABLE?

Climate and weather extremes are of great interest. Due to inadequate monitoring as well as prohibitively expensive access to weather and climate data held by the world's national weather and environmental agencies, only limited reliable information is available about large-scale changes in extreme weather or climate variability. The time-dependent biases that affect climate means are even more difficult to effectively eliminate from the extremes of the distributions of various weather and climate elements. There are a few areas, however, where regional and global changes in weather and climate extremes have been reasonably well documented (20).

Interannual temperature variability has not changed significantly over the past century. On shorter time scales and higher frequencies, e.g., days to a week, temperature variability may have decreased across much of the Northern Hemisphere (8). Related to the decrease in high-frequency temperature variability there has been a tendency for fewer low-temperature extremes, but widespread changes in extreme high temperatures have not been noted.

Trends in intense rainfall have been examined for a variety of countries. Some evidence suggests an increase in intense rainfalls (United States, tropical Australia, Japan, and Mexico), but analyses are far from complete and subject to many discontinuities in the record. The strongest increases in extreme precipitation are documented in the United States and Australia (21).

Intense tropical cyclone activity may have decreased in the North Atlantic, the one basin with reasonably consistent tropical cyclone data over the twentieth century, but even here data prior to World War II is difficult to assess regarding tropical cyclone strength. Elsewhere, tropical cyclone data do not reveal any long-term trends, or if they do they are most likely a result of inconsistent analyses. Changes in meteorological assimilation schemes have complicated the interpretations of changes in extratropical cyclone frequency. In some regions, such as the North Atlantic, a clear trend in activity has been noted, as also in significant wave heights in the northern half of the North Atlantic. In contrast, decreases in storm frequency and wave heights have been noted in the south half of the North Atlantic over the past few decades. These changes are also reflected in the prolonged positive excursions of the NAO since the 1970s.

IS THE RADIATIVE FORCING OF THE PLANET CHANGING?

Understanding requires a time history of forcing global change. The atmospheric concentration of CO$_2$, an important greenhouse gas because of its long atmospheric residence time and relatively high atmospheric concentration, has increased substantively over the past few decades. This is quite certain as revealed by precise measurements made at the South Pole and at Mauna Loa Observatory since the late 1950s, and from a number of stations distributed globally that began operating in subsequent decades. Since atmospheric carbon dioxide is a long-lived atmospheric constituent and it is well mixed in the atmosphere, a moderate number of well-placed stations operating for the primary purpose of monitoring seasonal to decadal changes provides a very robust estimate of global changes in carbon dioxide.

To understand the causes of the increase of atmospheric carbon dioxide, the carbon cycle and the anthropogenic carbon budget must be balanced. Balancing the carbon budget requires estimates of the sources of carbon from anthropogenic emissions from fossil fuel and cement production, as well as the net emission from changes in land use (e.g., deforestation). These estimates are derived from a combination of modeling, sample measurements, and high-resolution satellite imagery. It also requires measurements for the storage in the atmosphere, the ocean uptake, and uptake by forest regrowth, the CO$_2$ and nitrogen fertilization effect on vegetation, as well as any operating climate feedback effects (e.g., the increase in vegetation due to increased temperatures). Many of these factors are still uncertain because of a paucity of ecosystem measurements over a sustained period of time. Anthropogenic emissions from the burning of fossil fuel and cement production are the primary cause of the atmospheric increase.

Several other radiatively important anthropogenic atmospheric trace constituents have been measured for the past few decades. These measurements have confirmed significant increases in atmospheric concentrations of CH$_4$, N$_2$O, and the halocarbons including the stratospheric ozone destructive agent of the chloroflourocarbons and the bromocarbons. Because of their long lifetimes, a few well-placed high-quality *in situ* stations have provided a good estimate of global change. Stratospheric ozone depletion has been monitored both by satellite and ozonesondes. Both observing systems have been crucial in ascertaining changes of stratospheric ozone that was originally of interest, not because of its role as a radiative forcing agent, but its ability to absorb ultraviolet (UV) radiation prior to reaching Earth's surface. The combination of the surface- and space-based observing systems has enabled much more precise measurements than either system could provide by itself. Over the past few years much of the ozonesonde data and satellite data has been improved using information about past calibration methods, in part because of differences in trends between the two observing systems.

Figure 3 depicts the IPCC (9) best estimate of the radiative forcing associated with various atmospheric constituents. Unfortunately, measurements of most of the forcings other than those already discussed have low or very low confidence, not only because of our uncertainty about their role in the physical climate system, but because we have not adequately monitored their change. For example, estimates of changes in sulfate aerosol concentrations are derived from model estimates of source emissions, not actual atmospheric concentrations. The problem is complicated because of the spatially varying concentrations of sulfate due to its short atmospheric lifetime. Another example is measurements of solar irradiance, which have been taken by balloons and rockets for several decades, but continuous measurements of top-of-the-atmosphere solar irradiance did not begin until the late 1970s with the *Nimbus*

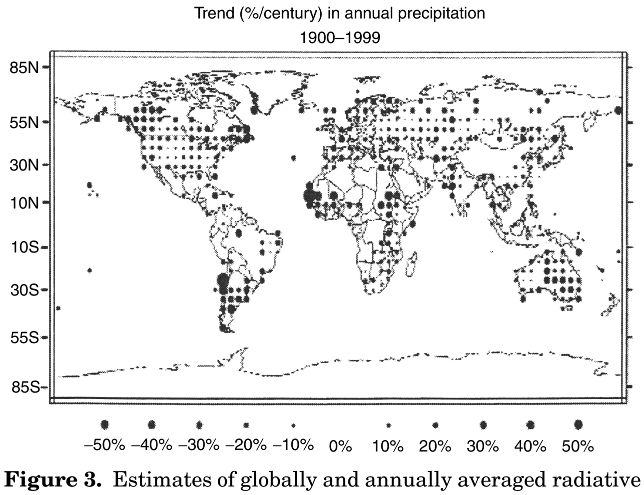

Figure 3. Estimates of globally and annually averaged radiative forcing (in W/m_{-2}) for a number of agents due to changes in concentrations of greenhouse gases and aerosols and natural changes in solar output from 1750 to the present day. Error bars are depicted for all forcings (from Ref. 1).

7 and the Solar Maximum Mission satellites. There are significant absolute differences in total irradiance between satellites, emphasizing the critical need for overlaps between satellites and absolute calibration of the irradiance measurements to determine decadal changes. Spectrally resolved measurements will be a key element in our ability to model the effects of solar variability, but at the present time no long-term commitment has been made to take these measurements. Another important forcing that is estimated through measured, modeled, and estimated changes in optical depth relates to the aerosols injected high into the atmosphere by major volcanic eruptions. The aerosols from these volcanoes are sporadic and usually persist in the atmosphere for at most a few years. Improved measurements of aerosol size distribution and composition will help better understand this agent of climate change.

WHAT CAN WE DO TO IMPROVE OUR ABILITY TO DETECT CLIMATE AND GLOBAL CHANGE?

Even after extensive reworking of past data, in many instances we are incapable of resolving important aspects concerning climate and global change. Virtually every monitoring system and data set requires better data quality, continuity, and fewer time-varying biases if we expect to conclusively answer questions about how the planet has changed, because of the need to rely on observations that were never intended to be used to monitor the physical characteristics of the planet of the course of decades. Long-term monitoring, capable of resolving decade-to-century-scale changes, requires different strategies of operation.

In situ measurements are currently in a state of decay, decline, or rapid poorly documented change due to the introduction of automated measurements without adequate precaution to understand the difference between old and new observing systems. Satellite-based systems alone will not and cannot provide all the necessary measurements. Much wiser implementation and monitoring practices must be adopted for both space-based and surface-based observing systems in order to adequately understand global change. The establishment of the Global Climate Observing System (GCOS) is a high priority (22), and continued encouragement by the World Meteorological Organization (WMO) of a full implementation of this system in all countries is critical. Furthermore, in the context of the GCOS, a number of steps can be taken to improve our ability to monitor climate and global change.

These include:

1. Prior to implementing changes to existing environmental monitoring systems or introducing new observing systems, standard practice should include an assessment of the impact of these changes on our ability to monitor environmental variations and changes.
2. Overlapping measurements in time and space of both the old and new observing systems should be standard practice for critical environmental variables.
3. Calibration, validation, and knowledge of instrument, station, and/or platform history are essential for data interpretation and use. Changes in instrument sampling time, local environmental conditions, and any other factors pertinent to the interpretation of the observations and measurements should be recorded as a mandatory part of the observing routine and be archived with the original data. The algorithms used to process observations must be well documented and available to the scientific community. Documentation of changes and improvements in the algorithms should be carried along with the data throughout the data archiving process.
4. The capability must be established to routinely assess the quality and homogeneity of the historical

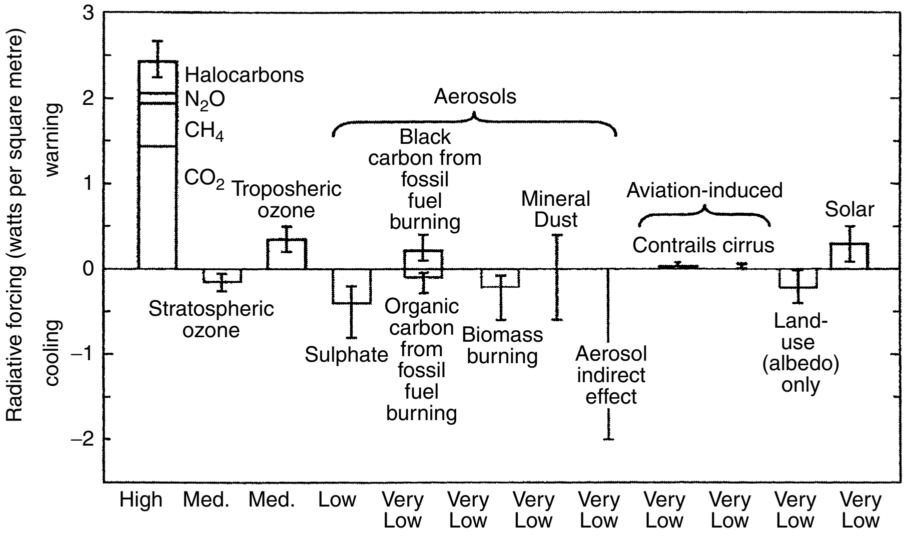

Figure 4. Global, annual-mean radiative forcings (Wm^{-2}) due to a number of agents for the period from pre-industrial (1750) to the present. The height of the vertical bar denotes the central or "best" estimate, no bar indicates that it is not possible to provide a "best" estimate. The vertical line indicates an estimate of the uncertainty range and the level of scientific understanding is a subjective judgement about the reliability of the forcing estimate based on such factors as assumptions, degree of knowledge of the physical/chemical mechanisms, etc. (From Ref. 1).

database for monitoring environmental variations and change, including long-term high-resolution data capable of resolving important extreme environmental events.

5. Environmental assessments that require knowledge of environmental variations and change should be well integrated into a global observing system strategy.
6. Observations with a long uninterrupted record should be maintained. Every effort should be made to protect the data sets that document long-term homogeneous observations. Long term may be a century or more. A list of prioritized sites or observations based on their contribution to long-term environmental monitoring should be developed for each element.
7. Data-poor regions, variables, regions sensitive to change, and key measurements with inadequate temporal resolution should be given the highest priority in the design and implementation of new environmental observing systems.
8. Network designers, operators, and instrument engineers must be provided environmental monitoring requirements at the outset of network design. This is particularly important because most observing systems have been designed for purposes other than long-term monitoring. Instruments must have adequate accuracy with biases small enough to resolve environmental variations and changes of primary interest.
9. Much of the development of new observation capabilities and much of the evidence supporting the value of these observations stem from research-oriented needs or programs. Stable, long-term commitments to these observations, and a clear transition plan from research to operations, are two requirements in the development of adequate environmental monitoring capabilities.
10. Data management systems that facilitate access, use, and interpretation are essential. Freedom of access, low cost, mechanisms that facilitate use (directories, catalogs, browse capabilities, availability of metadata on station histories, algorithm accessibility and documentation, on-line accessibility to data, etc.), and quality control should guide data management. International cooperation is critical for successful management of data used to monitor long-term environmental change and variability.

OVERVIEW: THE CLIMATE SYSTEM

Robert E. Dickinson

(from *The Handbook of Weather, Climate, and Water: Dynamics, Climate, Physical Meteorology, Weather Systems, and Measurements*, Wiley 2003)

The climate system consists of the atmosphere, cryosphere, oceans, and land interacting through physical, chemical, and biological processes. Key ingredients are the hydrological and energy exchanges between subsystems through radiative, convective, and fluid dynamical mechanisms. Climate involves changes on seasonal, year-to-year, and decadal or longer periods in contrast to day-to-day weather changes. However, extreme events and other statistical measures are as, or more, important than simple averages. Climate is seen to impact human activities most directly through the occurrence of extremes. The frequency of particular threshold extremes, as, for example, the number of days with maximum temperatures above 100 °F, can change substantially with shifts in climate averages.

THE ATMOSPHERE

The atmosphere is described by winds, pressures, temperatures, and the distribution of various substances in gaseous, liquid, and solid forms. Water is the most important of these substances. Also important are the various other radiatively active ("greenhouse") gases, including carbon dioxide and liquid or solid aerosol particulates. Most of the mass of the atmosphere is in the troposphere, which is comprised of the layers from the surface to about 12 km (8 km in high latitudes to 16 km at the equator) where the temperature decreases with altitude. The top of the troposphere is called the tropopause. Overlying this is the stratosphere, where temperatures increase with altitude to about 50 km or so (Fig. 1). The tropospheric temperature decreases with altitude are maintained by vertical mixing driven by moist and dry convection. The temperature increases with altitude in the stratosphere in response to increasing heating per the unit mass by ozone absorption of ultraviolet radiation. The variation of temperature structure with latitude is indicated in Fig. 2. The troposphere is deepest in the tropics because most thunderstorms occur there. Because of this depth and stirring by thunderstorms, the coldest part of the atmosphere is the tropical tropopause. In the lower troposphere temperatures generally decrease from the equator to pole, but warmest temperatures shift toward the summer hemisphere, especially in July. Longitudinally averaged winds are shown in Fig. 3. Because of the geostrophic balance between wind and pressures, winds increase with altitude where temperature decreases with latitude. Conversely, above about 8 km, where temperatures decrease toward the tropical tropopause, the zonal winds decrease with altitude. The core of maximum winds is referred to as the jet stream. The jet stream undergoes large wavelike oscillations in longitude and so is usually stronger at a given latitude than in its longitudinal average. These waves are especially noticeable in the winter hemisphere as illustrated in Fig. 4.

GLOBAL AVERAGE ENERGY BALANCE

Solar radiation of about 342 W/m^{-2} entering Earth's atmosphere is absorbed and scattered by molecules. The major gaseous absorbers of solar radiation are water vapor in the troposphere and ozone in the stratosphere. Clouds and aerosols likewise scatter and absorb. Clouds are the dominant scatterer and so substantially enhance the overall planetary reflected radiation, whose ratio to incident solar radiation, about 0.31, is referred to as *albedo*. Thermal infrared radiation, referred to as *longwave*, is controlled by clouds, water vapor, and other greenhouse gases. Figure 5 (4) illustrates a recent estimate of the various terms contributing to the global

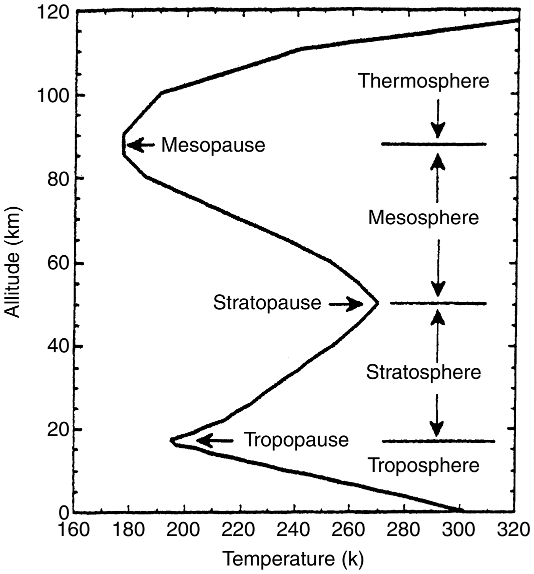

Figure 1. Main zones of the atmosphere defined according to the temperature profile of the standard atmosphere profile at 15°N for annual-mean conditions (1).

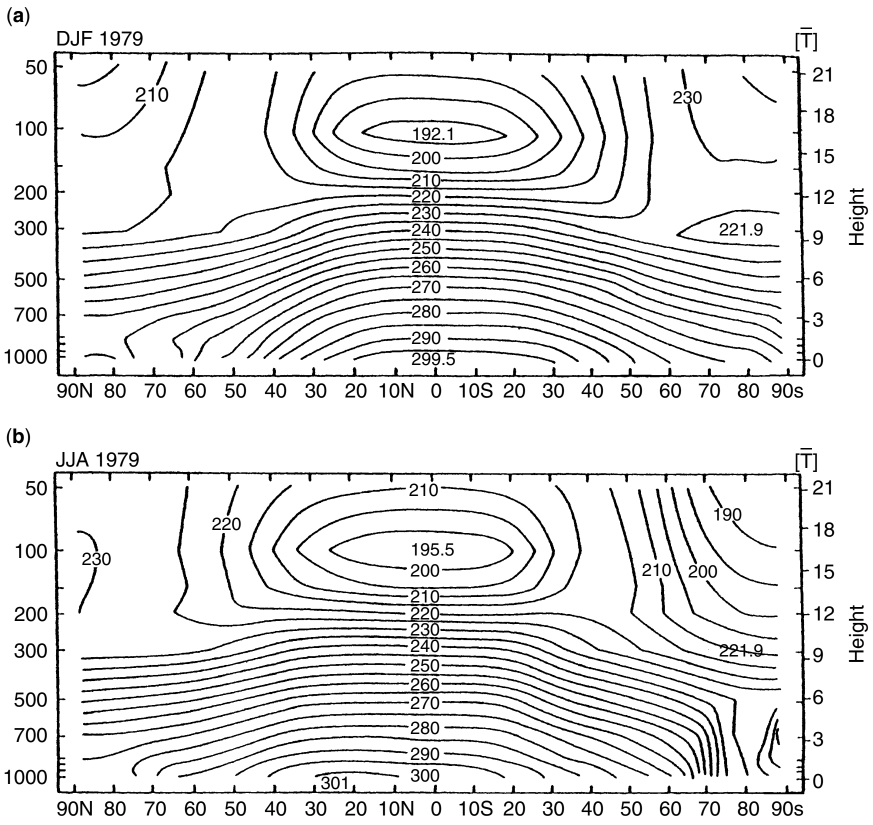

Figure 2. Zonal mean meridional cross sections of temperature during two seasons. (*a*) December 1978–February 1979 and (*b*) June–August 1979. Height scale is approximate and the contour interval is 5 K (2).

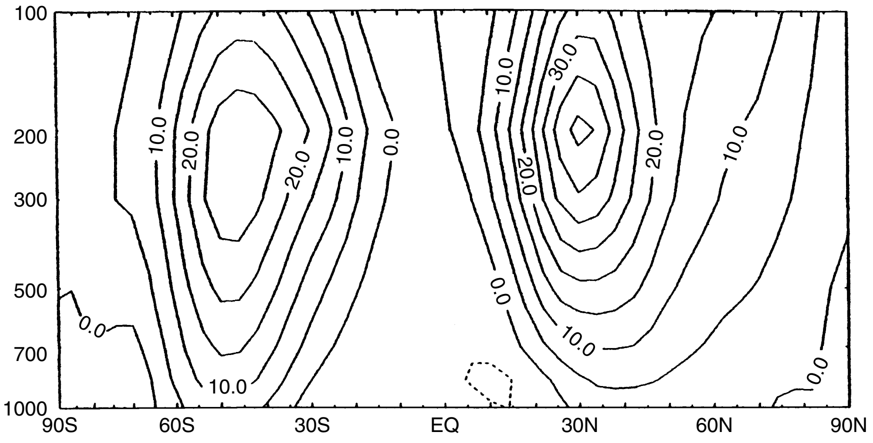

Figure 3. Meridional cross sections of longitudinally averaged zonal wind (top panels, m/s) for DJF (3).

energy balance. The latent heat from global average precipitation of about 1.0 m per year is the dominant nonradiative heating term in the atmosphere.

Because of the seasonally varying geometry of Earth relative to the sun, and the differences in cloudiness and surface albedos, there are substantial variations in the distribution of absorbed solar radiation at the surface and in the atmosphere, as likewise in the transfer of latent heat from the surface to the atmosphere. This heterogeneous distribution of atmospheric heating drives atmospheric wind systems, either directly or through the creation of available potential energy, which is utilized to maintain random occurrences of various kinds of instabilities, such as thunder-storms and wintertime cyclonic storm systems. These dynamical systems hence act to redistribute energy within the atmosphere and so determine the distributions of temperature and water vapor. Likewise, the balances at the surface between fluxes of radiative, latent, and thermal energies determine surface temperatures and soil moistures. The properties of the near-surface air we live in are determined by a combination of surface and atmospheric properties, according to processes of the atmospheric boundary layer. Thus climatic anomalies in surface air may occur either because of some shift in atmospheric circulation patterns or through some modification of surface properties such as those accompanying deforestation or the development of an urban area.

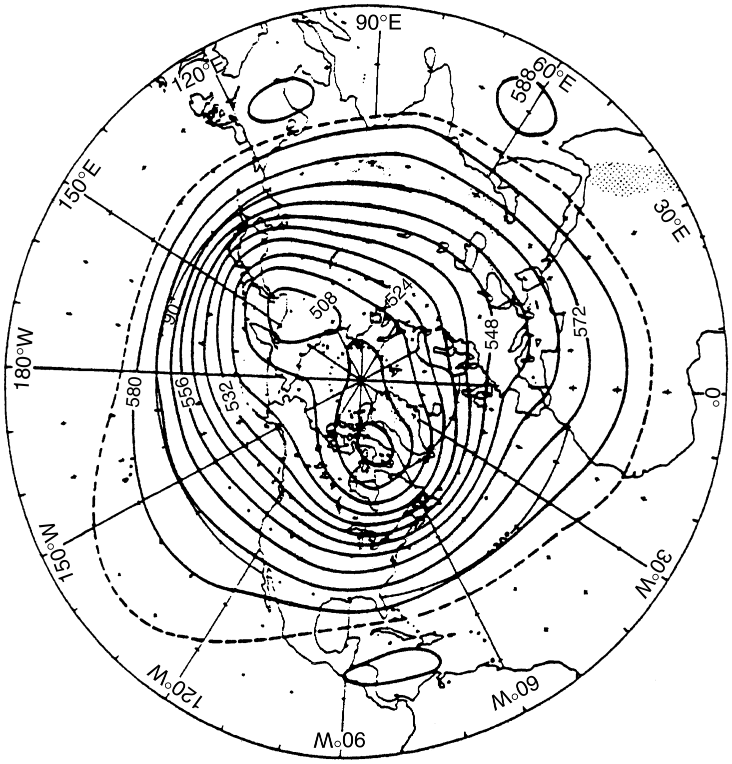

Figure 4. Mean 500-mb contours in January, Northern Hemisphere. Heights shown in tens of meters (3).

THE ATMOSPHERIC BOUNDARY LAYER

The term *boundary layer* is applied in fluid dynamics to layers of fluid or gas, usually relatively thin, determining the transition between some boundary and the rest of the fluid. The atmospheric boundary layer is the extent of atmosphere that is mixed by convective and mechanical stirring originating at Earth's surface. Such stirring is commonly experienced by airplane travelers as the bumps that occur during takeoff or landing, especially in the afternoon, or as waves at higher levels in flying over mountainous regions. The daytime continental boundary layer, extending up to several kilometers in height, is most developed and vigorously mixed, being the extent to which the daytime heating of the surface drives convective overturning of the atmosphere. The land cools radiatively at night, strongly stabilizing the atmosphere against convection, but a residual boundary layer extends up to about 100 m stirred by the flow of air over the underlying rough surface. This diurnal variation of fluxes over the ocean is much weaker and the boundary layer is of intermediate height. The temperature of the atmosphere, when stirred by dry mixing, decreases at a rate of 9.8 K/km. Above the boundary layer, temperatures decrease less rapidly with height, so that the atmosphere is stable to dry convection. A layer of clouds commonly forms at the top of the daytime and oceanic boundary layers and contributes to the convection creating the boundary layer through its radiative cooling (convection results from either heating at the bottom of a fluid or cooling at its top). Also, at times the clouds forming near the top of the boundary layer can be unstable to moist convection, and so convect upward through a deep column such as in a thunderstorm.

ATMOSPHERIC HYDROLOGICAL CYCLE

The storage, transport, and phase changes of water at the surface and in the atmosphere are referred to as the hydrological cycle. As already alluded to, the hydrological cycle is closely linked to and driven by various energy exchange processes at the surface and in the atmosphere. On the scale of continents, water is moved from oceans to land by atmospheric winds, to be carried back to the oceans by streams and rivers as elements of the land hydrological cycle. Most of the water in the atmosphere is in its vapor phase, but water that is near saturation vapor pressure (relative humidity of 100%) converts to droplets or ice crystals depending on temperature and details of cloud physics. These droplets and crystals fall out of the atmosphere as precipitation. The water lost is replenished by evaporation of water at the surface and by vertical and horizontal transport within the atmosphere. Consequently, much of the troposphere has humidities not much below saturation. Saturation vapor pressure increases rapidly with temperature (about 10% per kelvin of change). Hence, as illustrated in Fig. 6, the climatological concentrations of water vapor vary from several percent or more when going from near-surface air to a few parts per million near the tropical tropopause. Water vapor concentrations in the stratosphere are close to that of the tropical tropopause, probably because much of the air in the lower stratosphere has been pumped through the tropical tropopause by moist convection.

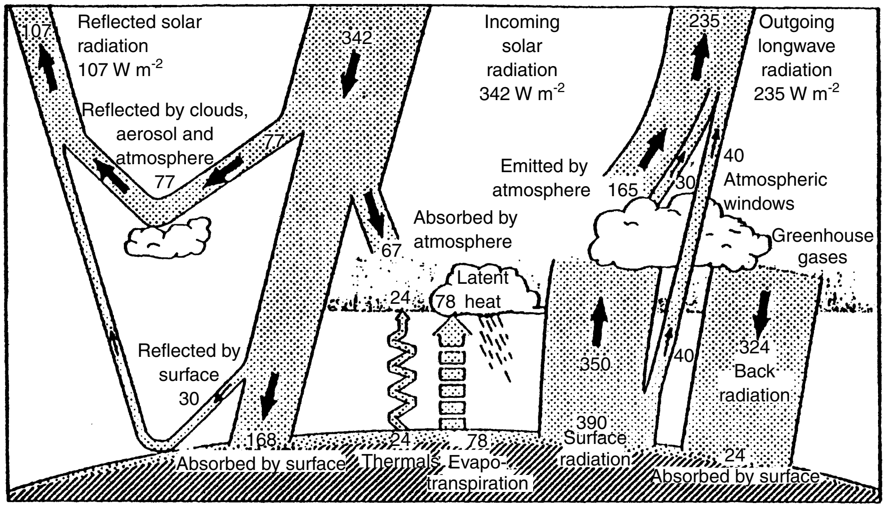

Figure 5. Earth's annual global mean energy budget based on the present study. Units are W/m² (4).

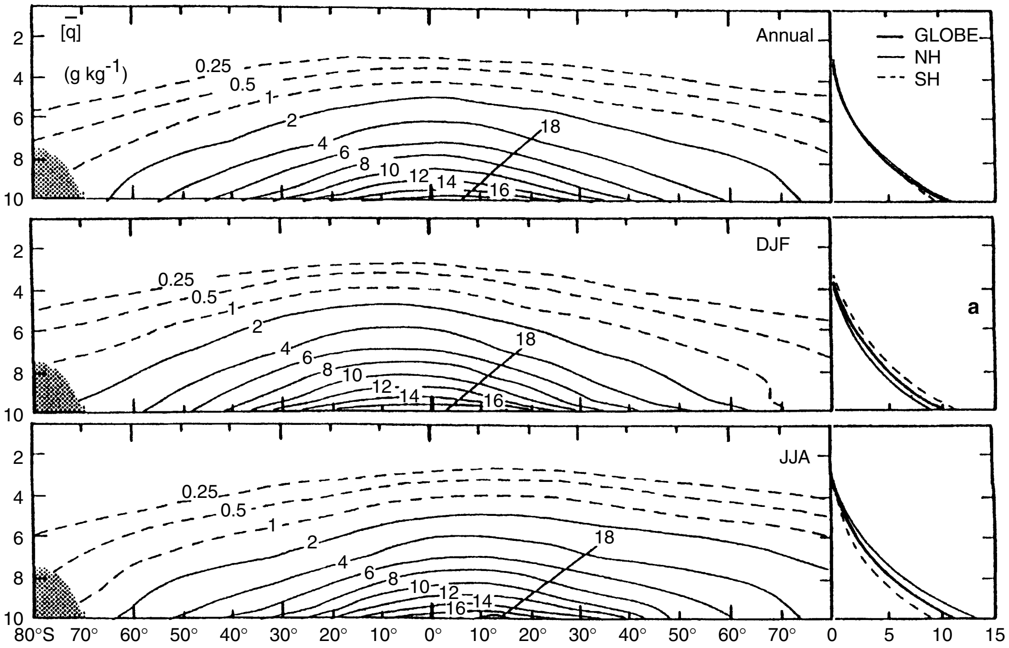

Figure 6. Zonal mean cross sections of the specific humidity in g/kg for annual, DJF, and JJA mean conditions. Vertical profiles of hemispheric and global mean values are shown on the right (5).

CLIMATE OF THE STRATOSPHERE

The dominant radiative processes in the stratosphere are the heating by absorption of solar ultra violet (UV) radiation and cooling by thermal infrared emission from carbon dioxide and, to a lesser extent, ozone molecules. The stratospheric absorption of UV largely determines how much harmful UV reaches the surface. Ozone in the upper troposphere and lower stratosphere additionally adds heat by absorption of thermal emission from the warmer surface and lower layers. The stratosphere, furthermore, enhances the greenhouse warming of CO_2 in the troposphere through substantial downward thermal emissions to the troposphere.

How changes of ozone change stratospheric and tropospheric radiative heating depends on the amounts of overlying ozone and, for thermal effect, on pressure and radiative upwelling depending on underlying temperatures.

Besides radiative processes, stratospheric climate is characterized by its temperature and wind patterns and by the chemical composition of its trace gases. At mid-stratosphere, temperature increases from winter pole to summer pole with an accompanying eastward jet stream in the winter hemisphere extending upward from the tropospheric jet steam. This wind configuration allows planetary wave disturbances to propagate into the stratosphere, contributing significant temporal and longitudinal variabilities. Conversely, the westward jet, found in the summer stratosphere attenuates wave disturbances from below, and so is largely zonally symmetric, changing only with the seasonal heating patterns.

THE CRYOSPHERE

The term *cryosphere* refers to the components of the climate system dominated by water in its frozen phase, that is, in high latitudes and extratropical winter conditions. Elements include snow, its distribution and depths, sea ice, its distribution and properties, high-latitude ice caps, and temperate glaciers. The largest volume of frozen water is stored in ice caps, and glaciers. This storage acts to remove water from the oceans. How it changes with climate change is, hence, of interest for determining changing sea levels.

Ice is highly reflective of sunlight, especially in crystal form. The loss of solar heating because of this high albedo acts to substantially reduce high-latitude temperatures especially in spring and early summer where near-maximum solar radiation sees white snow-covered surfaces. This high albedo can be substantially masked by cloud cover and, over land, tall vegetation such as conifer forests.

THE OCEAN

Oceans are a major factor in determining surface temperatures and fluxes of water into the atmosphere. They store, release, and transport thermal energy, in particular, warming the atmosphere under wintertime and high-latitude conditions, and cooling it under summer and tropical conditions.

How the oceans carry out these services depends on processes coupling them to the atmosphere. Atmospheric winds push the oceans into wind-driven circulation systems. Net surface heating or cooling, evaporation, and precipitation determine oceanic densities through controlling temperature and salinity, hence oceanic buoyancy. This net distribution of buoyancy forcing drives "thermohaline" overturning of the ocean, which acts to transport heat. Climate of the surface layers of the ocean includes the depth to which waters are stirred by waves and net heating or cooling. Heating acts to generate shallow warm stable layers, while cooling deepens the surface mixed layers. Under some conditions, convective overturning of cold and/or high-salinity water can penetrate to near the ocean bottom.

CLIMATE AND SOCIETY

Michael H. Glantz

(from *The Handbook of Weather, Climate, and Water: Atmospheric Chemistry, Hydrology, and Societal Impacts*, Wiley 2003)

At the turn of the twentieth century, scholars who wrote about the interplay between climate and society did so based on their perceptions of climate as a boundary constraint for the development prospects of a society. Perceptions of climate were used as an excuse to dominate societies in Africa, Asia, and Latin America. As a result, climate–society studies soon became viewed as a colonial ploy to control populations in developing areas in the tropics. Perhaps the most cited book in this regard was written by Ellsworth Huntington, *Climate and Civilization*, published in 1915 (1). In his view, inhabitants of the tropics were destined to accept lower levels of economic and social development because their climate setting was not conducive to lively (i.e., productive) human activity or an aggressive work ethic. According to Huntington, tropical climate was the main culprit causing people in the tropics to be less productive than people in temperate regions. Huntington argued that the temperate climate has an energizing effect on humans. With the growing belief that such an argument was racist in intent, Huntington's work was challenged, and discussion of the various ways in which climate might influence human behavior was stifled for decades, notwithstanding a few notable exceptions. One such exception is entitled *Climate and the Energy of Nations* (2) in which Markham referred to the "air-conditioning revolution," a revolution based on the development and spread of a new technology into the tropical areas. Markham asserted that technology brings islands of temperate-zone climate into the tropics, thereby generating a more aggressive work ethic.

Following the end of World War II and the onset of the Cold War between Soviet-style communism and Western capitalism and democracy, attention of governments turned to Cold War conflicts, avoidance of nuclear war, searches for allies, and decolonization. The major Cold War nations were in a competition to show that *their* approach to economic development was the only way for the newly independent countries to follow. A main stated objective was their intent to assist these countries to become food secure based on the nation's resources. Consideration of climate was making its way back into the discussions of economic development in developing countries. Once again interest was raised with regard to climatic constraints to economic development in tropical countries.

In the 1950s and 1960s, attention focused on decolonization and political development of the newly independent states (e.g., 3). In the mid-1970s, a World Bank report about the economic prospects for developing countries—*The Tropics and Economic Development: A Provocative Inquiry into the Poverty of Nations*—hinted at the economic, social, and political problems caused by climate variability from one year to the next. Its author (4) noted that recurrent droughts in northeast Brazil are a chronic constraint on the region's economic development prospects. His reference to interannual climate variability was brief and unelaborated. However, climate as a boundary constraint was starting to give way to climate as something that societies might be able to forecast and cope with, at least in its extremes.

In the 1970s, attention focused on how the vagaries of weather exposed hundreds of millions of people to hunger and, depending on the socioeconomic situation in a particular country, to famine as well (e.g., 5,6). Thus, there was a growing number of examples of the notion that climate was not really a boundary constraint to the level of development that a people or culture could expect to attain. This notion began to give way to the belief that variability in climate, from one year to the next or one decade to the next, could be coped with so as to soften the impacts of climate variability and weather extremes on agriculture and livestock and, more generally, on the productivity of the land's surface (e.g., 7,8).

Recall that the 1970s was a disruptive decade with respect to climate: 5 years of drought in the West African Sahel (5); failure of the Soviet harvest and subsequent large-scale, low-cost grain purchases by the Soviet Union in the early 1970s (9); the global food crisis (10); talk of a possible return to an ice age (e.g., 11,12); the Ethiopian famine (13); drought-related coups in sub-Saharan Africa; drought in the wheat-producing Canadian prairie provinces (7); the first drop in global fish catches since the end of World War II (10), and so forth.

A devastating 5-year drought from 1968 to 1973 in the West African Sahel and its associated death and environmental destruction in the region drew attention to the impacts on household and village responses to prolonged, multiyear droughts. Widespread droughts around the globe in 1972–1973, famines in West Africa and Ethiopia, blamed for the most part on an El Niño event, along with the drop in fish landings, prompted the U.N. Secretary General to convene a series of UN-sponsored world conferences on food (1974), population (1974), human settlements (1976), water (1977), desertification (1977), climate (1979) and technology (1979).

Thus, toward the middle of the 1970s, at least five new major climate-related scientific issues emerged: the effect of chlorofluorocarbons (CFCs) on the ozone layer in the stratosphere, talk of an impending Ice Age suddenly shifted to talk of a human-induced global warming, acid rain, desertification, and El Niño. Each of these issues raised interest in climate–society interactions to higher levels among researchers in different disciplines, government agencies, economic sectors, the media, and the public. Societies around the globe responded (and continue to respond) in different ways to each of these climate-related issues. For example, desertification is an environmental issue that is of great concern to African countries.

North Americans, however, refused to accept the view that desertification could occur in the U.S. West as a result of mismanagement of the land's surface, while noting that *desertification* was the plight of poor developing countries in Africa. The term desertification first appeared in a report on the destruction of dry forests in central Africa by a French forester (14). Since then, the concept of desertification has been expanded to include such land degradation processes as soil erosion, wind deflation, soil salinization, water logging, livestock overgrazing, and soil trampling. While many of these processes were exposed during the prolonged drought in the West African Sahel and then labeled as desertification, it is not difficult to show that similar processes also take place in the U.S. West.

The acid rain issue was addressed in the United States with the implementation by the U.S. Congress of a decade-long national assessment called NAPAP (National Acid Precipitation Assessment Program). Stratospheric ozone depletion was addressed globally in the 1980s with the development of international legal instruments culminating in the Montreal Protocol of 1987 and, later, amendments to it (15).

It was in the early 1970s, 1972–1973 to be exact, that an El Niño event (defined briefly as an invasion of warm water from the Western Pacific into the central and eastern equatorial Pacific Ocean) attracted global attention. An event in 1982–1983, the biggest in a century until that time, captured the full attention of the scientific community and various governments as a natural phenomenon that spawned hazards around the globe. Such hazards included, but were not limited to, droughts, floods, frosts, fires and food shortages, famine, and disease. Ever since the mid-1970s, research funding of El Niño–related research has been growing along with international interest in the phenomenon and its societal and environmental impacts. The extraordinary El Niño event of 1997–1998 helped to make El Niño and its cold counterpart, La Niña, household words throughout much of the world. Only at the end of the twentieth century did La Niña events become of serious interest to the El Niño research and forecasting communities (16). This belated interest is even more surprising given the scientific observation that tropical storms and hurricanes in the Atlantic Basin and in the Gulf of Mexico tend to increase in number during La Niña events and drop in number during El Niño events.

Global warming is an environmental issue that arose out of discussions and governmental and scientific concerns about the possibility of a global cooling. It was first suggested in 1896 by Swedish chemist Arrhenius (17,18) that the burning of coal by human societies would add enough extra carbon dioxide into the air to eventually heat up Earth's atmosphere by a few degrees Celsius. This issue was revisited in the 1930s by Callendar (19), who thought that a human-induced global warming of the atmosphere could stave off the imminent recurrence of an ice age. The issue was again revisited in the 1950s when global warming was looked at in neutral terms, as an experiment that societies were performing on the chemistry of the atmosphere, for which the outcome is unknown (20).

It was not until the mid-1970s that human-induced global warming began to be viewed as an adverse event for future generations of human societies and ecosystems that might not be able to adapt to the rate of warming expected to occur. The cause of the warming was attributed to the increasing amounts of greenhouse gases (CO_2, CFCs, CH_4, NO_x, collectively referred to as GHGs) being emitted into the atmosphere as a result of human activities. Carbon dioxide is a product of the burning of fossil fuels, and its amount in the atmosphere has been rising since the onset of the Industrial Revolution in the late 1700s. Tropical deforestation also contributes carbon dioxide to the atmosphere. Tropical forests have served as sinks for carbon dioxide, pulling it out of the air and storing it. When trees are felled, decompose or burned, the stored carbon is emitted into the air.

Chlorofluorocarbons (CFCs), a greenhouse gas as well as a stratospheric "ozone eater," are man-made chemicals first discovered in the 1920s for use as a refrigerant. Methane resulting from livestock rearing (e.g., cattle, pigs) and from the increasing number of landfills is another greenhouse gas. Nitrous oxides are used by farmers in fertilizers and have been widely applied to agricultural lands around the globe in increasing amounts since the end of World War II. Of these major greenhouse gases, carbon dioxide is seen at the main culprit in the global warming debate.

Current scientific research suggests that the level of climate change that might be expected (at current rates of greenhouse gas emissions) is on the order of 1.5 to 4.5 °C by the end of the twenty-first century (21–23). Concerned with the prospects of a changing global climate, many nations have come together to call for a technical assessment of the state of the science through the Intergovernmental Panel on Climate Change (IPCC).

The degree of warming, however, is dependent on numerous factors: the rate at which GHGs continue to be emitted into the atmosphere, the shift by societies to alternative energy sources, the rate of tropical deforestation, the residence time of GHGs in the atmosphere (several of these gases will remain in the atmosphere for decades to centuries), the development of methods to sequester carbon (i.e., taking it from the atmosphere and binding it in some way in Earth's land surface, vegetation, or oceans), and so forth. Some degree of global warming is inevitable, given the residence time of the GHGs already emitted into the atmosphere. This means that societies around the globe, from local to national, must attempt to ascertain how a warmer global climate regime might affect regional and local climates. Will there be more extreme climate events (such as droughts, floods, frosts, fires) or fewer? These societies must also seriously consider nationally, as well as collectively in cooperation with other countries, the most effective way(s) to cope with the potentially adverse impacts of some degree of human-induced global warming.

Coping mechanisms for climate change likely to occur decades in the future can be divided into three categories: preventive, mitigative and adaptive measures. *Preventive* measures are designed to prevent the increased buildup of GHGs in human-induced global warming, acid rain, desertification, and El Niño. Each of these issues raised interest in climate–society interactions to higher levels among researchers in different disciplines, government agencies, economic sectors, the media, and the public. Societies around the globe responded (and continue to respond) in different ways to each of these climate-related issues. For example, desertification is an environmental issue that is of great concern to African countries.

Climate-related surprise is not a black-and-white condition. People are hardly ever either totally surprised or never surprised. There are shades of surprise with regard to human responses to the same climate-related event. They can be hardly surprised, mildly surprised, somewhat surprised, very surprised, extremely surprised or totally surprised (NB: each of these examples was taken from the scientific literature). Myers (24, p. 358) introduced the interesting notion of "semisurprised." Thus, surprise may best be described in "fuzzy" terms with the degree of surprise dependent on several intervening variables such as personal experience, core beliefs, expectations, or knowledge about a phenomenon or about a geographic location.

One could argue that there are knowable as well as unknowable surprises (25). Knowable refers to the fact that some climate surprises can be anticipated (24). For example, certain parts of the globe are drought prone. It is known that drought will likely recur. What is not known is exactly when it will take place, how long it will last, how intense it will be, or where its most devastating impacts are likely to occur. El Niño is in this category. While we have now come to expect these events to recur, we do not know when that will happen or what it will be like. The uncertainty then cascades down the "impacts chain," and as we speculate about likely impacts of an El Niño, the degree of uncertainty will increase.

Take, for example, the 1997–1998 El Niño. Even with the best monitoring and observing system in the world focused on minute changes in various aspects of the tropical Pacific Ocean, forecasters and modelers were unable to predict the onset of one of the biggest El Niño events in the past 100 years. Nor were they able to predict the course of development of that event. They were better than in earlier times, however, at predicting some of its impacts on societies in certain parts of the globe, especially those where the influences of changes in the sea surface temperatures in the tropical Pacific are known to be strong.

Societies (and their scientists) are on a learning curve with regard to the various ways that climate variability and climate change might affect climate-related human activities. They must avoid becoming complacent as a result of a belief that they fully understand atmospheric processes or their impacts. They must accept that there will be climate surprises in the future, even if the global climate does not change. They must learn from past experiences on how best to cope with the vagaries of climate (26).

Many countries now realize that climate-related problems do not stop at international boundaries. There are many transboundary issues that demand regional (if not international) cooperation, given that countries share river basins, inland seas, airsheds, the global atmosphere as well as the onslaught and impacts of extreme meteorological events such as droughts, floods, and tropical storms.

While climate-related anomalies cannot be prevented, societal preparation for, and response to, their adverse impacts can be improved through better knowledge of the direct and indirect ways in which atmospheric processes interact with human activities and ecological processes. The enhancement of such knowledge will lead to better forecasts as well as better computer modeling of the interactions among land, sea, and air. A society forewarned of climate-related hazards is forearmed to cope with those hazards more effectively.

WHAT IS CLIMATOLOGY?

National Drought Mitigation
Center

"CLIMATE IS WHAT YOU EXPECT. WEATHER IS WHAT YOU GET."

Weather is the condition of the atmosphere over a brief period of time. For example, we speak of today's weather or the weather this week. Climate represents the composite of day-to-day weather over a longer period of time.

People in Minneapolis–St. Paul expect a white Christmas, and people in New Orleans expect very warm, humid summers. And a traveler going to Orlando, Florida, in March will not pack the same kind of clothing as a traveler going to Vail, Colorado, in March. These examples show how climate influences our daily lives. Additionally:

- Our houses are designed based on the climate where we live.
- Farmers make plans based on the length of the growing season from the last killing freeze in the spring to the first freeze in the fall.
- Utility companies base power supplies on what they expect to be the maximum need for heating in the winter and the maximum need for cooling in the summer.

A climatologist attempts to discover and explain the impacts of climate so that society can plan its activities, design its buildings and infrastructure, and anticipate the effects of adverse conditions. Although climate is not weather, it is defined by the same terms, such as temperature, precipitation, wind, and solar radiation.

Climate is usually defined by what is expected or “normal”, which climatologists traditionally interpret as the 30-year mean. By itself, “normal” can be misleading unless we also understand the concept of variability. For example, many people consider sunny, idyllic days normal in southern California. History and climatology tell us that this is not the full story. Although sunny weather is frequently associated with southern California, severe floods have had a significant impact there, including major floods in 1862 and 1868, shortly after California became a state. When you also factor in severe droughts, most recently those of 1987–94, a more correct statement would be that precipitation in southern California is highly variable, and that rain is most likely between October and April.

The misconception that weather is usually normal becomes a serious problem when you consider that weather, in one form or another, is the source of water for irrigation, drinking, power supply, industry, wildlife habitat, and other uses. To ensure that our water supply, livelihoods, and lives are secure, it is essential that planners anticipate variation in weather, and that they recognize that drought and flood are both inevitable parts of the normal range of weather.

HOW DOES CLIMATOLOGY HELP US PREPARE FOR DROUGHT?

Climatology provides benchmarks, such as the drought of record. The drought of record is the drought remembered as having the greatest impact on a region. Most of us are not consciously aware of how much the climate fluctuates from one decade or century to the next. One way for reservoir managers, municipal water suppliers, and other planners to check reality is to compare expectations of water supply against a region’s drought of record. But caution is necessary here: although the weather conditions could recur, the impacts would likely be very different. For most of the country, the drought of record was 30 to 60 years ago, and population concentrations and water use patterns have shifted substantially since then. Planners need to consider and watch out for a variety of problems and misconceptions.

Specifically, climatology answers crucial questions such as:

- How often does drought occur in this region?
- How severe have the droughts been?
- How widespread have the droughts been?
- How long have the droughts lasted?

Examining water supplies and understanding the impact of past droughts help planners anticipate the effects of drought:

- What would happen if the drought of record occurred here now?
- Who are the major water users in the community, state, or region?
- Where does our water supply come from and how would the supplies be affected by a drought of record?
- What hydrological, agricultural, and socioeconomic impacts have been associated with the various droughts?
- How can we prepare for the next drought of record?

CLOUD SEEDING

Arthur M. Holst
Philadelphia Water Department
Philadelphia, Pennsylvania

Cloud seeding is the deliberate treatment of certain clouds or cloud systems to affect the precipitation process within those clouds. The treating of clouds can alter weather conditions, thus cloud seeding is also called weather modification. The technology that led to cloud seeding has been developed only during the past 60 years. Yet as this technology becomes more efficient, increased worldwide application of cloud seeding for practical use is likely to continue into the future.

THE CLOUD SEEDING PROCESS

To understand how cloud seeding works, one must understand some facts about the weather. All air in the atmosphere contains moisture. Warm air rises from the earth’s surface and begins to cool. As the air cools, the moisture condenses into tiny droplets that make up clouds. A cloud is almost 100% air. The tiny droplets composing clouds are not heavy enough to fall to the ground until they merge with millions of other droplets at temperatures below 32 °F and interact with dust, salt, or sand particles.

One type of cloud seeding, known as cold cloud seeding, introduces silver iodide and other agents to enhance ice crystallization in clouds colder than 32 °F. This is often called as the static seeding effect. Once the droplets within the clouds freeze, the resulting ice crystals grow at the expense of the water droplets surrounding them, a process called sublimation. Other crystals grow through contact with neighboring droplets; this is known as riming. Through these two processes, the tiny crystals form snowflakes. If these snowflakes are heavy enough, they fall from the clouds and, depending on the temperatures below, will come to the earth as snow, raindrops, or a mixture.

The other type of cloud seeding, warm cloud seeding, produces rainfall from clouds that are above 32 °F. This process involves introducing additional condensation nuclei (salt particles), which cause additional water droplets to condense within the clouds. If the collision of these particles makes the droplets heavy enough, precipitation can fall from the clouds. In each case, it will usually take the clouds 20 to 30 minutes to produce rain, making it crucial to monitor cloud movement.

USES OF WEATHER MODIFICATION

The primary goal of most weather modification projects is to increase levels of precipitation or to suppress fog or hail. Water agencies, local municipalities, farmers, ranchers, hydroelectric power facility operators, ski resort owners, and others sponsor cloud seeding activities. To date, cloud seeding has successfully stimulated precipitation in more than 50 countries. More than half of the United States now has some type of regulation concerning cloud seeding programs.

More recently, cloud seeding has been used to suppress certain damaging effects of weather. Airports have employed programs to disperse fog levels and increase flight visibility. And in areas damaged by hail, programs have been undertaken to decrease hailstorms.

As technology continues to enhance the weather modification process, it can be assumed that more entities will sponsor cloud seeding programs. Cloud seeding technology is highly portable and very flexible to changing weather conditions. For those who use it, cost/benefit ratios are typically very favorable.

EFFECTIVENESS OF CLOUD SEEDING

From the earliest experiment, which produced just a few droplets of rain, cloud seeding has progressed to make some significant and valuable impacts on weather. Various studies have documented the effects of different programs. For the most part, these programs are overwhelmingly successful. To augment precipitation, well-designed and well-conducted projects yield an average winter precipitation of 5 to 20% more in continental regions and 5 to 30% more in coastal areas; they have yielded as much as 100% more in warm weather. Increases depend on a variety of factors, including spatial coverage of suitable cloud systems and the frequency of different systems.

ENVIRONMENTAL HEALTH CONCERNS OF WEATHER MODIFICATION

To date, no significant environmental problems have been attributed to cloud seeding programs, though government agencies, private firms, and research institutions have conducted many studies. Researchers believe that any negative effects are minimal because relatively little seeding material is used compared to the large surface area that is targeted. For example, the most common seeding material, silver iodide, will yield a concentration of less than 0.1 microgram per liter in rainwater or snow. The U.S. Public Health Service states that the acceptable amount of silver iodide in water is 50 micrograms per liter.

One other common question about cloud seeding is whether the stimulation of rainfall in one area results in decreased rainfall in other areas. It does not. Clouds are inefficient in the way they gather and distribute moisture. They never gather or release all the moisture that is available; rather, clouds gather only about 1% of the moisture in the atmosphere. Even if a seeding program tripled the efficiency of cloud formation, the cloud would still contain only about 3% of the moisture, leaving 97% available. Furthermore, some analyses of precipitation data downwind from seeding projects have indicated small increases in precipitation. To date, no scientific studies have shown that some areas receive precipitation at the expense of their neighbors.

FUTURE OF CLOUD SEEDING

Despite all of the advances made during the past 60 years, weather modification continues to receive relatively little support. Many states and the federal government acknowledge and regulate cloud seeding, but few provide significant funding for weather modification studies or projects. Most scientists insist that more research must be done and more data must be gathered before weather-changing programs garner public trust on a larger scale. However, most researchers are optimistic that new studies and technological advances will continue to advance the science of weather modification.

CONDENSATION

Aldo Conti
Frascati (RM), Italy

Condensation is the physical process by which a vapor changes to its liquid state. Condensation happens when the temperature of the vapor decreases below the so-called dew point. In physics, this sort of process is called a phase change because the matter involved changes its state (i.e., from gaseous to liquid, in this case). Water condensation is evident in our atmosphere; it produces fog, mist, dew, clouds, and rain, depending on the conditions. It can be seen on a cold sheet of glass, where condensed water forms a maze of droplets.

Condensation depends mainly on temperature, and it is a process that happens at the molecular level. When the temperature is high, the molecules in a vapor have plenty of energy and collide at high speed, which means that the molecules bounce immediately and do not stay together long enough to establish a bond. In this situation, the vapor remains. But when the temperature, and therefore the speed, decreases, then the molecules can stick to each other. The result is a droplet of liquid. Condensation is ruled not only by temperature, but by pressure as well, which is the reason why one speaks about dew point and not dew temperature. As a general rule, the dew point temperature increases with pressure.

Condensation, with evaporation, is very important in the water cycle of the earth. By condensation, water falls back as rain, hail, or snow and becomes available again for human use.

COSMIC WATER

D.L. Marrin
Hanalei, Hawaii

Once believed by science to be the substance that distinguished the earth from the rest of the universe, it is now understood that water is ubiquitous in the cosmos—not only as ice and vapor, but also as liquid. Sophisticated scientific instruments can detect cosmic water on the basis of the light, or other electromagnetic, waves that it absorbs and emits (1). Unlike the legendary "waters of chaos" that gave rise to the material world, water's component hydrogen and oxygen atoms owe their existence to the Big Bang and to the stars, respectively.

HYDROGEN AND OXYGEN

Hydrogen is both the simplest and the most abundant atom in the universe. It represents about 75% of the atomic mass in the cosmos. The word *hydrogen* literally means "water-forming" according to the Greek language from which it is derived. Hydrogen atoms are generally traced back to the so-called Big Bang, when a tremendous amount of energy was released and subsequently expanded into what we call our universe. As the newborn universe began to cool, subatomic and atomic particles (e.g., quarks, protons, electrons) were initially created and later drawn together by a number of fundamental forces to form atoms. Possessing one proton and one electron, hydrogen is believed to have been the first atom created. As more hydrogen atoms were created in the early universe, they coalesced into dense gas clouds that contained much of the conventional matter.

Oxygen is the third most abundant atom in the cosmos—behind hydrogen and helium. Because helium is a very inert (nonreactive) atom, water is sometimes described as an interaction between the two most abundant "reactive" atoms in the cosmos. Unlike hydrogen, the origins of the oxygen atom are rooted in dying stars rather than in the Big Bang. As stars near the end of their stellar life, they begin to cool and to switch from hydrogen to helium as a source for nuclear fusion. The cooling stars then enter a phase where they become increasingly dense as intense gravitational energy compresses them into an extremely unstable state that may explode during the final stages of compression (2). This explosion or *supernova* releases the outer layer of the star, which contains many common heavier atoms (e.g., oxygen, carbon), into space as interstellar clouds. Dust grains comprising these clouds are composed of both silicate (oxygen-rich) and carbonaceous (carbon-rich) minerals that are available to react with hydrogen (1).

INTERSTELLAR SPACE

In the interstellar realms of galaxies, water exists predominantly as ice—adhering to the tiny particles that comprise the ubiquitous dust and gas clouds. Water is the primary molecular ice attached to these particles, although methane, carbon monoxide, and water–ammonia mixtures may also be present depending on physical conditions in the gas clouds (3). Water ice in the 10 K temperatures and vacuum conditions of interstellar space is what physical chemists refer to as *amorphous ice* or *glassy water*; it is relatively unstructured compared to the highly crystalline ices that are formed at higher temperatures (e.g., those characteristic of the earth's surface and atmosphere). Amorphous ice is so unstructured that it can flow, not unlike a viscous version of liquid water (4). Some astrophysicists posit that the simple organic molecules responsible for biological life may have been created in this strange ice (4). As interstellar temperatures rise above 150 K (as often occurs near stars), amorphous ice irreversibly transits to more familiar crystalline ice. The various phases and molecular structures of water as a function of temperature are shown in Table 1.

Although water's component atoms are plentiful in interstellar dust and gas clouds, creation of molecular water requires either converting O and OH species directly to water ice on the surfaces of dust grains or producing water vapor via heat energy—usually in the form of stellar radiation (5). The latter process requires that water vapor adhere to dust grains, where the newly formed water molecule is protected from the same ionizing radiation that created it. Scientists currently believe that stars facilitate the creation of water vapor and also that water vapor assists in the birthing of stars. Stars are being born and are dying on an ongoing basis, such that star birthing regions (e.g., the Orion Cloud Complex of the Milky Way Galaxy) generate up to 20% of a galaxy's luminosity as gas and dust clouds are gravitationally compressed into newborn stars. Recent data indicate that these cloud complexes contain an extremely high concentration of water vapor, which has been estimated of the order of 1 part in 2000 (6). The superabundance of water in stellar nurseries (about 20 times greater than that in similar interstellar clouds)

Table 1. Representative Temperature Ranges and Cosmic Locations for the Three Phases of Water

Location	Temperature, K[a]	Phase	Comments
Stellar surfaces	4000 to 50,000	None	Water molecules do not exist. Only hydrogen and oxygen atoms or plasma.
Stellar/planetoid surfaces	<3500	Vapor	Water exists at the surface of cool stars and in cooler regions of some hot stars.
Some planetoids	273 to 373 (at 1 atmosphere)	Liquid	Few places in the cosmos possess the requisite temperatures and pressures.
Interplanetary/interstellar space	>100	Solid (crystalline)	Crystalline ices possess both a cubic and a more common hexagonal structure.
Interstellar space	10 to 150	Solid (amorphous)	The depths of interstellar space are cold enough to produce glassy water.

[a] These temperatures, which are measured on the Kelvin scale, are only approximate and vary depending on environmental conditions (e.g., pressure, rate of cooling or heating).

may permit the gas and dust to cool sufficiently so that condensation can proceed and stars are eventually formed.

As hot winds (in the form of shock waves) are sent out during stellar birthing, the cloud must be cooled—initially by molecular hydrogen and subsequently by water and other simple gases (7). Water vapor is created during the interstellar cloud shocks as oxygen reacts explosively with hydrogen, causing the water vapor concentration to increase substantially during star birthing. Scientists have theorized one of two eventual fates for water created in star birthing. One is that the intense heat of the fledgling star rapidly dissociates water into its component atoms. The other is that the water is deposited on dust grains that later form the star's planetoids. The origin of earthly water is usually attributed to either this second process or the impact of large comets, which are believed to have been more prevalent during the earth's early history.

STARS

Two of the brightest supergiants in our galaxy, Betelgeuse and Antares, have water in their *photospheres*, which constitutes the visible portion of a star (8). A star's photosphere is where its gases transit from opaque to transparent, permitting us to see the stars that are located closest to the earth. This stellar water is actually present within the star itself, not simply as a component of the surrounding dust and gas cloud from which the star was birthed. Aging supergiant stars release massive amounts of water as they die; however, the exact source and role of this water are not yet known.

In addition to cool stars, water has been discovered in the photosphere of at least one hot or *main sequence* star—the Sun. Water cannot exist on the surface of the Sun, where temperatures of 6000 K dissociate the water molecule into its component hydrogen and oxygen atoms. Water can exist in the dark centers of sunspots, where temperatures are less than 3500 K (9). Sunspots are relatively calm solar regions where strong magnetic fields filter out the energy emanating from the intense interior, rendering them both the coolest and darkest regions of the Sun. Water is a major player in determining a star's *radiative opacity*, which describes the extent to which light escapes from stars into interstellar space (10). In this role, water impedes the outward flow of radiation from stars by absorbing energy within certain wavelengths and, thus, renders the star more opaque than it would otherwise appear.

COMETS AND METEORS

Comets are one of the few interstellar objects that are commonly associated with water, predominantly as ice. Comets are composed primarily of water ice that incorporates many of the other simple molecules in interstellar dust and gas clouds (e.g., carbon monoxide, methane, ammonia). Comets are most easily recognized by their unmistakable tails, which can extend millions to hundreds of millions of kilometers behind the icy body of the comet. The tail consists of dust and ionized particles (mostly water ice) that are always transported away from the Sun by the *solar wind*, which is an ionized stream of particles consisting predominantly of protons and electrons. The ionization of water ices is the primary mechanism influencing the properties of a comet's tail, including the steam jets that release tons of water vapor per second from the comet. It is now believed that these steam jets result from solar-induced changes in ice's molecular geometry (e.g., a transition from the amorphous to crystalline structure). Large comets are generally accepted as a source of planetary water, but controversy surrounds the hypothesis that many small comets hitting the planet's upper atmosphere also contribute significantly to the volume of water on the earth.

The first liquid water in the solar system, it was projected, made its appearance on meteors just 20 million years after our Sun and its debris emerged from the interstellar dust and gas cloud (11). Although liquid water is rarely present on the surface of meteors today, the chemical interaction of water with primitive rocks produced carbonate minerals, suggesting that the chemical processes of water evaporation and condensation were among the earliest in the solar system. Recently, a small meteorite found in southwestern North America contained actual liquid water within its salt crystals, which were believed to have been created from the original interstellar cloud that gave rise to the solar system.

PLANETOIDS

Most planet-sized bodies in our solar system (and probably in others) are now known or suspected to contain water in some form. A number of recent missions have revealed a Martian landscape that almost certainly indicates the large-scale flow of liquid water. The surface features of Mars (e.g., flood plains, river beds, mud deposits) suggest the recent presence of liquid water and also the mineralogy of Martian rocks could have resulted only from aqueous processes. Moreover, it has been hypothesized that Mars may have also once possessed surface oceans. The Jovian moon, Europa, is another of the solar system planetoids that probably contains liquid water located tens of kilometers beneath its icy surface. The liquid water underlying Europa's surface ice is believed to be an ocean containing saltwater that may be similar in composition to the seawater of the earth's oceans. Unlike the earth, the heat required to maintain water in a liquid phase on Europa is believed to originate from an internal source such as volcanic activity rather than from the heat of the Sun.

Data collected from the Infrared Space Observatory indicate the presence of water in the upper atmospheres of our solar system's gas giant planets and on one of Saturn's moons (1). The source of water in these planet's atmospheres is attributed to comets or to water-containing interplanetary dust. Based on recently developed techniques for measuring a suite of stellar characteristics (e.g., orbital velocity, position, brightness), the search for planets has been extended beyond our solar system to other star systems in the galaxy (12). Various planets have been identified orbiting stars in the constellations of Leo, Pegasus, Virgo, and Ursa Major that probably possess surface temperatures ranging from slightly less than 100 °C down to −100 °C. Planets or moons characterized by this temperature range could possess water in solid, gaseous, and liquid phases.

THE WATER CYCLE

NASA—Goddard Space Flight
Center

INTRODUCTION

As seen from space, one of the most unique features of our home planet is the water, in both liquid and frozen forms, that covers approximately 75% of the Earth's surface. Believed to have initially arrived on the surface through the emissions of ancient volcanoes, geologic evidence suggests that large amounts of water have likely flowed on Earth for the past 3.8 billion years, most of its existence. As a vital substance that sets the Earth apart from the rest of the planets in our solar system, water is a necessary ingredient for the development and nourishment of life.

HYDROLOGIC HISTORY

The notion that water is continually circulating from the ocean to the atmosphere to the land and back again to the ocean has interested scholars through most of recorded history. In Book 21 of the lliad, Homer (ca. 810 B.C.) wrote of "the deep-flowing Oceanus, from which flow all rivers and every sea and all springs and deep wells." Thales (ca. 640 B.C.–ca. 546 B.C.) and Plato (ca. 427 B.C.–347 B.C.) also alluded to the water cycle when they wrote that all waters returned by various routes to the sea. But it wasn't until many centuries later that scientific measurements confirmed the existence of a water (or hydrologic) cycle. Seventeenth century French physicists Pierre Perrault (1608–1680) and Edmond Mariotte (1620–1684) separately made crude precipitation measurements in the Seine River basin in France and correlated these measurements with the discharge of the river to demonstrate that quantities of rainfall and snow were adequate to support the river's flow.

WATER, WATER, EVERYWHERE

Water is everywhere on Earth and is the only known substance that can naturally exist as a gas, liquid, and solid within the relatively small range of air temperatures and pressures found at the Earth's surface. In all, the Earth's water content is about 1.39 billion cubic kilometers (331 million cubic miles) and the vast bulk of it, about 96.5%, is in the global oceans. Approximately 1.7% is

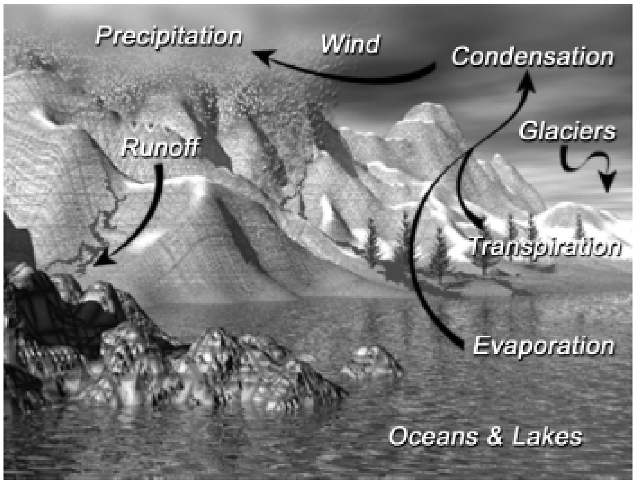

Figure 1. In the hydrologic cycle, individual water molecules travel between the oceans, water vapor in the atmosphere, water and ice on the land, and underground water.

stored in the polar icecaps, glaciers, and permanent snow, and another 1.7% is stored in groundwater, lakes, rivers, streams, and soil. Finally, a thousandth of 1% exists as water vapor in the Earth's atmosphere (Table 1).

A MULTI-PHASED JOURNEY

The hydrologic cycle describes the pilgrimage of water as water molecules make their way from the Earth's surface to the atmosphere, and back again. This gigantic system, powered by energy from the sun, is a continuous exchange of moisture between the oceans, the atmosphere, and the land (Fig. 1).

Studies have revealed that the oceans, seas, and other bodies of water (lakes, rivers, streams) provide nearly 90% of the moisture in our atmosphere. Liquid water leaves these sources as a result of evaporation, the process by which water changes from a liquid to a gas. In addition, a very small portion of water vapor enters the atmosphere through sublimation, the process by which water changes from a solid (ice or snow) to a gas. (The gradual shrinking of snow banks, even though the temperature remains below the freezing point, results from sublimation.) The remaining 10% of the moisture found in the atmosphere is released by plants through transpiration (Fig. 2). Plants take in water through their root systems to deliver nutrients to their leaves, then release it through small pores, called stomates, found on the undersides of their leaves. Together, evaporation, sublimation, and transpiration, plus volcanic emissions, account for all the water vapor in the atmosphere. While evaporation from the oceans is the primary vehicle for driving the surface-to-atmosphere portion of the hydrologic cycle, transpiration is also significant. For example, a cornfield 1 acre in size can transpire as much as 4000 gallons of water every day.

After the water enters the lower atmosphere, rising air currents carry it upward, often high into the atmosphere,

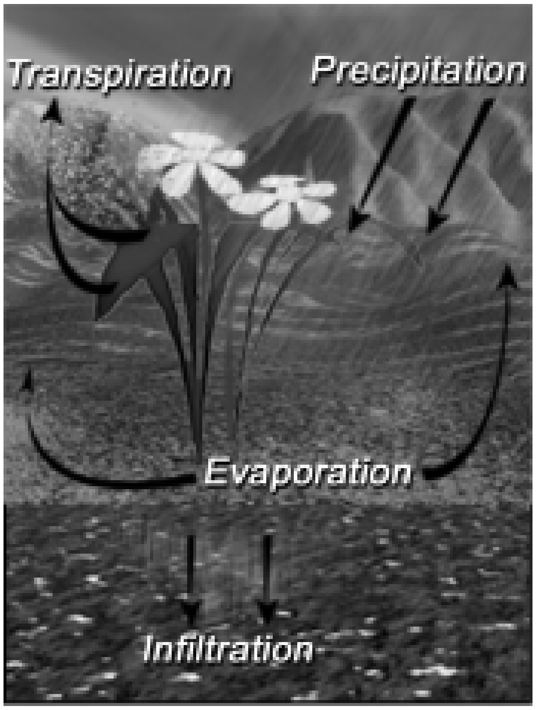

Figure 2. Plants return water to the atmosphere through transpiration. In this process, water evaporates from pores in the plant's leaves, after being drawn, along with nutrients, from the root system through the plant.

where the air cools and loses its capacity to support water vapor. As a result, the excess water vapor condenses (i.e., changes from a gas to a liquid) to form cloud droplets, which can eventually grow and produce precipitation (including rain, snow, sleet, freezing rain, and hail), the primary mechanism for transporting water from the atmosphere back to the Earth's surface.

When precipitation falls over the land surface, it follows various routes. Some of it evaporates, returning to the atmosphere, and some seeps into the ground (as soil moisture or groundwater). Groundwater is found in two layers of the soil, the "zone of aeration," where gaps in the soil are filled with both air and water, and, further down, the "zone of saturation," where the gaps are completely filled with water. The boundary between the two zones is known as the water table, which rises or falls as the amount of groundwater increases or decreases (Fig. 3). The rest of the water runs off into rivers and streams, and almost all of this water eventually flows into the oceans or other bodies of water, where the cycle begins anew (or, more accurately, continues). At different stages of the cycle, some of the water is intercepted by humans or other life forms.

Even though the amount of water in the atmosphere is only 12,900 cubic kilometers (a minute fraction of Earth's total water supply that, if completely rained out, would cover the Earth's surface to a depth of only 2.5 centimeters), some 495,000 cubic kilometers of water are cycled through the atmosphere every year, enough to uniformly cover the Earth's surface to a depth of 97 centimeters. Because water continually evaporates, condenses, and precipitates, with evaporation on a global basis approximately equaling global precipitation, the total amount of water vapor in the atmosphere remains approximately the same over time. However, over the continents, precipitation routinely exceeds evaporation, and conversely, over the oceans, evaporation exceeds precipitation. In the case of the oceans, the routine excess of evaporation over precipitation would eventually leave the oceans empty if they were not being replenished by additional means. Not only are they being replenished, largely through runoff from the land areas, but, over the past 100 years, they have been over-replenished, with sea level around the globe rising by a small amount. Sea level rises both because of warming of the oceans, causing water expansion and thereby a volume increase, and because of a greater mass of water entering the ocean than the amount leaving it through evaporation or other means. A primary cause for increased mass of water entering the ocean is the calving or melting of land ice (ice sheets and glaciers).

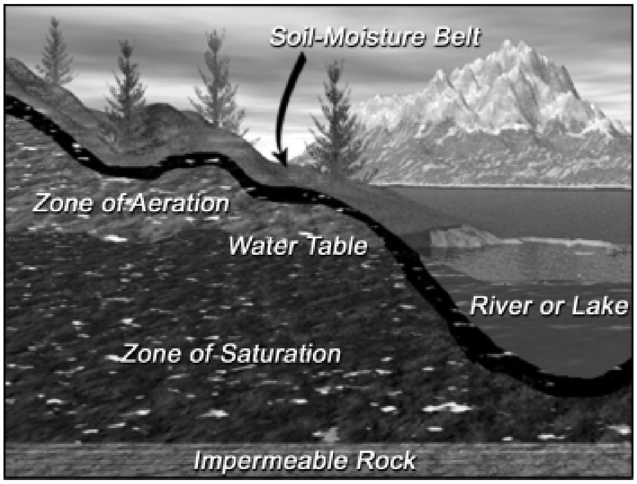

Figure 3. The water table is the top of the zone of saturation and intersects the land surface at lakes and streams. Above the water table lies the zone of aeration and soil moisture belt, which supplies much of the water needed by plants.

Throughout the hydrologic cycle, there are an endless number of paths that a water molecule might follow. Water at the bottom of Lake Superior may eventually fall as rain in Massachusetts. Runoff from the Massachusetts rain may drain into the Atlantic Ocean and circulate northeastward toward Iceland, destined to become part of a floe of sea ice, or, after evaporation to the atmosphere and precipitation as snow, part of a glacier. Water molecules can take an immense variety of routes and branching trails that lead them again and again through the three phases of ice, liquid water, and water vapor. For instance, the water molecules that once fell 100 years ago as rain on your great grandparents' farmhouse in Iowa might now be falling as snow on your driveway in California.

THE WATER CYCLE AND CLIMATE CHANGE

Amongst the highest priorities in Earth science and environmental policy issues confronting society are the potential changes in the Earth's water cycle due to climate change. The science community now generally agrees that the Earth's climate will undergo changes in response to natural variability, including solar variability, and to increasing concentrations of greenhouse gases and aerosols. Furthermore, agreement is widespread that these changes may profoundly affect atmospheric water vapor concentrations, clouds, and precipitation patterns. For example, a warmer climate, directly leading to increased evaporation, may well accelerate the hydrologic cycle, resulting in an increase in the amount of moisture circulating through the atmosphere. Many uncertainties remain, however, as illustrated by the inconsistent results given by current climate models regarding the future distribution of precipitation.

THE AQUA MISSION AND THE WATER CYCLE

As mentioned earlier, the hydrologic cycle involves evaporation, transpiration, condensation, precipitation, and runoff. NASA's Aqua satellite monitors many aspects of the role of water in the Earth's systems, and will do so at spatial and temporal scales appropriate to foster a more detailed understanding of each of the processes that contribute to the hydrologic cycle. These data and the analyses of them nurture the development and refinement of hydrologic process models and a corresponding improvement in regional and global climate models, with a direct anticipated benefit of more-accurate weather and climate forecasts.

Aqua's contributions to monitoring water in the Earth's environment involves all six of Aqua's instruments: the Atmospheric Infrared Sounder (AIRS), the Advanced Microwave Sounding Unit (AMSU), the Humidity Sounder for Brazil (HSB), the Advanced Microwave Scanning Radiometer-Earth Observing System (AMSR-E), the Moderate Resolution Imaging Spectroradiometer (MODIS), and Clouds and the Earth's Radiant Energy System (CERES). The AIRS/AMSU/HSB combination provides more-accurate space-based measurements of atmospheric temperature and water vapor than have ever been obtained before, with the highest vertical resolution to date as well. Since water vapor is the Earth's primary greenhouse gas and contributes significantly to uncertainties in projections of future global warming, it is critical to understand how it varies in the Earth system.

The water in clouds is examined with MODIS, CERES, and AIRS data; and global precipitation is monitored with AMSR-E. The cloud data includes the height and areal coverages of clouds, the liquid water content, and the sizes of cloud droplets and ice particles, the latter sizes being important to the understanding of the optical properties of clouds and their contribution to the Earth's albedo (reflectivity). HSB and AMSR-E, both making measurements at microwave wavelengths, have the ability to see through clouds and detect the rainfall under them, furthering the understanding of how water is cycled through the atmosphere.

Frozen water in the oceans, in the form of sea ice, is examined with both AMSR-E and MODIS data, the former allowing routine monitoring of sea ice at a coarse resolution and the latter providing greater spatial resolution but only under cloud-free conditions. Sea ice can insulate the underlying liquid water against heat loss to the often frigid overlying polar atmosphere and also reflects sunlight that would otherwise be available to warm the ocean. AMSR-E measurements allow the routine derivation of sea ice concentrations in both polar regions, through taking advantage of the marked contrast in microwave emissions of sea ice and liquid water. This continues with improved resolution and accuracy, a 22-year satellite record of changes in the extent of polar ice. MODIS, with its finer resolution, permits the identification of individual ice floes, when unobscured by clouds.

AMSR-E and MODIS also provide monitoring of snow coverage over land, another key indicator of climate change. Here too, the AMSR-E allows routine monitoring of the snow, irrespective of cloud cover, but at a coarse spatial resolution, while MODIS obtains data with much greater spatial detail under cloud-free conditions.

As for liquid water on land, AMSR-E provides an indication of soil moisture, which is crucial for the maintenance of land vegetation, including agricultural crops. AMSR-E's monitoring of soil moisture globally should permit, for example, the early identification of signs of drought episodes.

THE AQUA SPACECRAFT

Aqua is a major mission of the Earth Observing System (EOS), an international program centered in NASA's Earth Science Enterprise to study the Earth in detail from the unique vantage point of space. Focused on key measurements identified by a consensus of U.S. and international scientists, EOS is further enabling studies of the complex interactions amongst the Earth's land, ocean, air, ice and biological systems.

The Aqua spacecraft circles the Earth in an orbit that ascends across the equator each day at 1:30 p.m. local time and passes very close to the poles, complementing the 10:30 a.m. measurements being made by Terra, the first of the EOS spacecraft, launched in December 1999. The instrument complement on Aqua is designed to provide information on a great many processes and components of the Earth system, including cloud formation, precipitation, water vapor, air temperature, cloud radiative properties, sea surface temperature, surface wind speeds, sea ice concentration and temperature, snow cover, soil moisture, and land and ocean vegetation. The individual swaths of measurements will be compiled into global images, with global coverage of many variables being obtained as frequently as every two days or, with the help of numerical models, combined every 6 or 12 hours into comprehensive representations of the Earth's atmospheric circulation and surface properties. In combination with measurements from other polar orbiting satellites, Aqua measurements also provide accurate monthly-mean climate assessments that can be compared with and assimilated into computer model simulations of the Earth's climate.

The Earth Observing System has three major components: the EOS spacecraft, an advanced ground-based computer network for processing, storing, and distributing the collected data (the EOS Data and Information System); and teams of scientists and applications specialists who study the data and help users in universities, industry, and the public apply it to issues ranging from weather forecasting and climate prediction to agriculture and urban planning.

CYCLONES

Arthur M. Holst
Philadelphia Water Department
Philadelphia, Pennsylvania

Cyclones are hazardous weather conditions characterized by extreme gusts of wind moving in a circular pattern, low pressure, and intense rain. They form over tropical or subtropical waters; however, some can reach land, where they have in the past inflicted great amounts of damage on buildings and communities.

Based on wind strength, cyclones are given various names. Tropical depressions have maximum surface winds of less than 39 mph. Those cyclones whose maximum winds are between 39 and 74 mph are known as tropical storms. Upon attaining 74-mph surface winds, a cyclone is known as one of a number of names that are all regional equivalents of the same type of storm.

The names of cyclones are typhoon (in the NW Pacific Ocean), hurricane (in the North Atlantic, NE Pacific, and South Pacific Ocean), tropical cyclone (in the SW Indian

Ocean), severe cyclonic storm (in the North Indian Ocean), and severe tropical cyclone (in the SW Pacific and SE Indian Oceans). Cyclones always build over tropical seas. There are seven basins in which the majority of tropical cyclones form: the Atlantic Basin, the North Indian Basin, the Southwest Indian Basin, the Southeast Indian-Australian Basin, the Australian-Southwest Pacific Basin, the Northwest Pacific Basin, and the Northeast Pacific Basin. Heat gives cyclones their energy, and thus the water over which a cyclone forms must be at least as warm as 80°F (i.e., tropical). Other conditions necessary for a cyclone include a fast cooling atmosphere, moisture in the middle troposphere area, a distance of more than 300 miles from the equator to be influenced by the Coriolis force, and minimal vertical wind shear. This vertical wind shear is the result of differences between winds in the lower and upper portions of the atmosphere. However, the main contributor to the formation of a cyclone is a disturbance in the form of a thunderstorm or group of showers. When all of these factors come together, conditions are right for a tropical cyclone, although the presence of each of these factors does not guarantee the formation of a cyclone. Cyclones are spontaneous; a minute variation in one variable can be the difference between a hurricane and a thunderstorm.

The circular area in the center of a cyclone, known as the "eye," has conditions quite different from those in the region surrounding it. Calmness and a light breeze characterize the eye. Temperatures are generally higher than those in the surrounding area, and the sky is usually very clear.

Since the 1970s, cyclones have been regularly named by various people and agencies, depending on where the cyclones originated. They are named to ensure ease of description among newscasters, weatherpeople, and the general public. Names are often taken from rotating lists, one name for each letter of the alphabet. When an exceptional cyclone occurs, its name is taken out of use ("retired") to avoid confusion.

Strong cyclones often cause extensive damage to whatever they encounter. Damage can range from crop destruction to total devastation of building structures, depending on the severity of the cyclone. They become most dangerous as they hit land and spawn tornadoes. These are formed when tropical cyclones begin to lose their power. The diameter of a tropical cyclone is measured in kilometers; the diameter of a tornado is measured in meters. In 1980, one of the most destructive cyclone-spawned tornadoes in the United States caused nearly $100,000,000 worth of damage to the Austin, Texas, area. Along with destruction, cyclones (and the subsequent tornadoes) cause death. Large objects lifted from the path of the extreme wind are tossed about like lethal weapons. In 1964, twenty-two people were killed by a tornado that hit the Los Angeles area in the United States. The most damaging cyclone in history was Hurricane Andrew, which caused over $26 billion in damage to the Southeastern United States. The most deadly cyclone ever may have been the Bangladesh Cyclone, which killed at least 300,000 people in 1970. One of the ways in which a hurricane will cause damage is through the storm surge. This is the name given to the phenomenon whereby sea level in the area of a cyclone rises due to cyclonic winds.

Once a cyclone reaches 74 mph maximum winds and is considered a hurricane, it's intensity is rated by the Saffir–Simpson Scale, used since the 1970s by the National Oceanic and Atmospheric Administration (NOAA). Hurricanes are referred to as category one, category two, category three, category four, or category five. Category one hurricanes have winds between 74 and 95 mph. They cause negligible damage to buildings and other structures, although they can damage mobile homes and road signs. They carry a storm surge of about 5 feet. Category two hurricanes have maximum winds of 96–110 mph. They can cause minor damage to buildings and sizable damage to mobile homes and trees. Their storm surge is usually around 7 feet. Category three hurricanes have winds from 111–130 mph. They cause noticeable damage to buildings and trees; buildings near the shoreline are often destroyed by flooding. Evacuation of certain low-lying areas can be necessary for category three hurricanes, and their storm surge ranges from 9–12 feet. Category four hurricanes have winds between 131 and 155 mph. These hurricanes can cause massive damage to smaller structures. They destroy trees and mobile homes utterly. Evacuation of large areas can be necessary, as the storm surge can reach up to 18 feet. Category five hurricanes are the most powerful; they have maximum sustained winds of more than 155 mph. Residential as well as industrial structures are often destroyed. Damage is catastrophic, and major evacuations usually take place. The storm surge exceeds 18 feet above normal.

Cyclones can range from relatively simple tropical storms to devastating hurricanes whose winds swirl at furious speeds. Their effects can be disastrous and long-lasting.

WATER CYCLE

Arthur M. Holst
Philadelphia Water Department
Philadelphia, Pennsylvania

The water cycle—a series of steps through which virtually all water on earth is constantly cycling. The names of these steps vary, but they generally follow this order: storage, evaporation, transpiration, condensation, precipitation, infiltration, and runoff.

Due to the nature of the water cycle, there is really no “beginning” or “end”, but for simplicity, the cycle can be said to begin at the storage stage. Storage is the storing of water on, in, and above the earth. There are about 340 million cubic miles of water on the earth. This water is stored in many places: glaciers, seas, rivers, lakes, polar ice caps, and all living things on the planet. The largest percentage of water, approximately 97.25%, exists as salt water in the ocean. Water is also stored in the earth’s atmosphere and as groundwater. Groundwater in the top few miles of the earth’s crust is easily obtainable, whereas groundwater further down is chemically attached to rocks and usually cannot be accessed.

Evaporation is an essential way in which water is transferred from the earth to the atmosphere. During evaporation, water molecules change from a liquid state directly into a gaseous state, known as water vapor. Changes in temperature and air pressure on the earth cause millions of gallons of water to evaporate into the atmosphere each day. The majority of the water that is transferred into the atmosphere is primarily in a liquid state before the change; however, a small percentage of new water vapor comes from ice. The process of water changing state from a solid directly to a gas is called sublimation. Sublimation occurs on glaciers and polar ice sheets. When the sun strikes these massive ice structures, the temperature and pressure allow no room for a liquid, only a solid and a gas.

Transpiration is another way that water is transferred into the atmosphere. Although similar in process to evaporation, transpiration differs because the medium from which the water comes is not earth, it is plants. Transpiration is the process through which water absorbed from the ground by plant roots evaporates into the atmosphere. After the plants absorb the water from the soil, the water moves up through the veins of the plant, eventually reaching the leaves (or the plant’s equivalent). These leaves have pores, or stomata, which allow water to evaporate. Large forests can release massive amounts of water into the atmosphere through transpiration.

Once the water has been transferred into the atmosphere by either evaporation or transpiration, the molecules will eventually condense. This process is called condensation. Condensation is the reciprocal process of evaporation. During condensation, water changes state from a gas to a liquid. Once again, a change in either temperature or pressure initiates the change. Condensation is most visible in the formation of dew, fog, and clouds. Dew usually appears in the morning and is water that has condensed on any solid object during the rapid temperature change that occurs from day to night. If the water vapor is dense enough around objects when the temperature change happens, dew is formed. Fog is really a low level cloud formation. When the conditions are right, fog is formed on or near the ground. The only difference between fog and cloud formations is their locations with reference to the earth. Clouds form when water vapor in the atmosphere encounters a critical temperature or air pressure, causing the water vapor to change state into a liquid. Water molecules then “stick together” causing physical cloud structures to emerge. When the molecules in the cloud that are stuck together reach a certain critical mass, they release the moisture causing precipitation to begin.

Precipitation is the process by which water is transferred from the medium of the atmosphere to the medium of the earth. Precipitation literally comes in all shapes and sizes, including rain, snow, and ice. The differentiating factor that determines the form water takes when precipitating is air temperature. The lower the temperature, the more likely it is that the precipitation will be either snow or ice (the closer the temperature is to the freezing point of water, 32 °F or 0 °C the more likely). Droplets of rain form around small particles of dust or dirt to form a cohesive raindrop as a vehicle for the trip to the earth.

Regardless of the form it takes on its descent, water will take one of two paths once it arrives on the earth’s crust. It will either seep into the ground or flow into larger bodies of water such as streams, seas, oceans, and rivers. The former process is infiltration, and the latter is runoff. Infiltration restores groundwater to the water table that has been lost from wells. During the infiltration process, the water is purified by cascading amongst rocks and minerals that draw impurities out of the water.

Water that does not infiltrate the earth’s crust runs off into streams, rivers, seas, and oceans. Runoff replenishes bodies of water that have lost water due to evaporation. Runoff can occur either above the land or below it. Large amounts of water can run across the land immediately after precipitation. Smaller amounts of water run through the ground and along the water table until they reach a larger body of water.

So thusly does the water complete its cycle throughout the different media of the earth. This process is essential for the survival of life on the earth because it allows water to permeate every accessible region of the crust and atmosphere, thereby allowing life to flourish wherever water exists.

DEGREE DAY METHOD

Carlos D. Messina
University of Florida
Gainesville, Florida

An adequate description and prediction of plant development is critical for understanding plant growth and its responses to the environment. Only then we can assess the impact of a changing environment on plant productivity and survival, understand plant adaptation, design adequate agricultural production systems, and optimize natural resources management. Of particular importance for water resource management are the effects of plant ontogeny on plant water use and productivity throughout the regulation of leaf area. This determines the patterns of plant water demand and the partitioning between transpiration and evaporation components. Therefore, plant development dictates the selection of cultivars that best fit the water availability patterns under dryland conditions, and the amount, frequency and timing for irrigation otherwise.

Plant development is responsive to environmental cues such as photoperiod, water availability, and temperature. Figure 1a shows an example of the close association between ambient temperature and plant development for boll growth duration in cotton. Rameur first suggested in 1735 that the duration of any developmental stage was related to temperature and that this duration can be characterized by a thermometric constant, which can be predicted by the sum of daily air temperatures (2). Since then, several methods based on the concept of normalizing time by temperature to predict developmental rates were developed (2,3) and applied in life sciences. Although we can formulate some hypothesis to explain the relationship between plant development and temperature based on the effects of temperature on circadian oscillations (4), lipid composition and membranes fluidity, and cell division (5), the scientific basis of these empirical methods remains elusive. It was shown, however, that degree day based methods significantly improved the description and prediction of phenological events relative to other approaches based on the time of the year or the number of days (3).

Because of the close coupling between the timescale of plants and temperature, Ritchie and NeSmith (6) proposed that the most appropriate term to describe plant development would be "thermal time" or degree days (DD), whose units are °C-day. The degree day method is based on the effects of temperature on developmental rates, rather than on the duration of a phase. Figure 1b shows the linear relationship between temperature and rate of development, the reciprocal of the duration of the phase in days. The base temperature (T_b), temperature at which the rate of development is zero, is obtained by extrapolating this linear relationship to the intersection with the x-axis:

$$T_b = -\frac{y_0}{\alpha}$$

where y_0 is the intercept and α is the slope of the linear regression equation (Fig. 1b). Then, the rate of development (RD) can be calculated as

$$\mathrm{RD}(t) = \alpha\ (T_a - T_b)$$

where T_a is the mean temperature. Integrating the rate of development in time,

$$\int \mathrm{RD}\, dt = \int \alpha\ (T_a - T_b)\, dt$$

and considering a daily time step ($\Delta t = 1$) for integration, we can estimate the cumulative development (CD) at time n (t_n), provided that $t_0 = 0$, as

$$\mathrm{CD} = \alpha \sum_n (T_a - T_b)$$

For constant temperatures, given that development is complete when CD equals one, the degree days above a certain base temperature for a given phase are

$$\mathrm{DD} = (T_a - T_b)\, n$$

or

$$\mathrm{DD} = \frac{1}{\alpha}$$

For the example of cotton shown in Fig. 1, boll growth requires 1000 °C-days above a base temperature

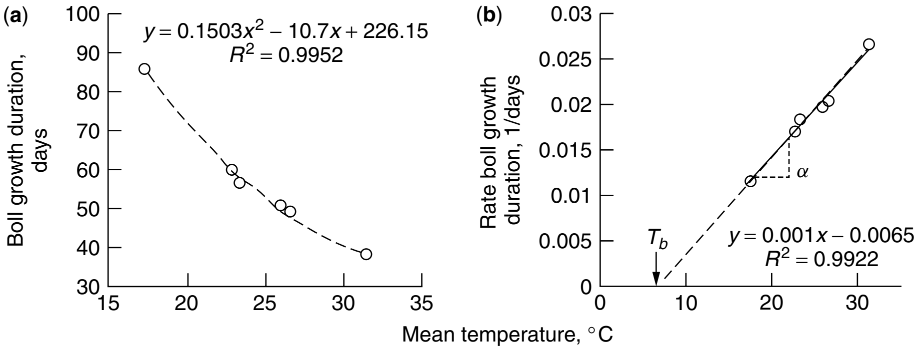

Figure 1. Responses of boll growth duration in cotton (*Gossypium hirsutum*, L.) development to air temperature. (**a**) Boll growth duration, (**b**) rate of boll growth duration (1/d). T_b denotes base temperature (see below), and α is the slope of the regression line. Data is from (1).

of 6.5 °C to reach maturity. Although this formulation for calculating DD is useful for estimating the requirements of the plant to complete a given developmental phase, in natural environments, temperature fluctuates and makes this procedure inadequate. The following canonical form to calculate DD is frequently used:

$$\mathrm{DD} = \sum_{n} \left[\left(\frac{T_{\max} + T_{\min}}{2} \right) - T_{\mathrm{b}} \right]$$

where $T_{\max}$ and $T_{\min}$ are maximum and minimum daily temperatures, n is the number of days of temperature observations, and $[(T_{\max} + T_{\min})/2] = T_{\mathrm{b}}$ when $[(T_{\max} + T_{\min})/2] < T_{\mathrm{b}}$. An alternative method, frequently used in calculating DD for corn, compares $T_{\max}$ and $T_{\min}$ with T_{b} individually before calculating their average. Significant discrepancies in calculated DD between these procedures may arise under some circumstances (3).

These procedures for calculating *DD* are adequate, provided that (1) the daily temperature does not fall below T_{b} and does not exceed an upper threshold for a significant part of the day, (2) the temperature of the growing plant tissue is the same as the air temperature, and (3) the response of the rate of development to temperature is linear over the range of temperature that the crop experiences (5). When these assumptions are not satisfied, alternative approaches are required. For example, McMaster et al. (5) and Vinocur and Ritichie (7) used soil or apex temperatures to calculate DD because the growing points were close to the soil rather than at the height where the temperature is normally measured. In simulation models such as CERES (8), hourly temperatures are approximated from $T_{\max}$ and $T_{\min}$, and if the temperature is below T_{b}, DD is set to zero for that part of the day. For a thorough discussion of the limitations of the degree day method, see Ritchie and NeSmith (5).

The degree day method can be found in the literature in a different mathematical form under the concept of physiological day. This model is generally used to simulate development in legumes and is particularly adequate for incorporating the effects of photoperiod on development (9). The rate of development is calculated as the product of two functions:

$$\mathrm{RD}(t) = f(P) \times f(T)$$

One function accounts for the effects of photoperiod (P) and the other for the effects of temperature (T) on development. The model predicts relative development; the maximum rate of development is standardized to 1.0. At optimum temperature (T_{opt}) and photoperiod ($P < P_{\min}$ in short day species and $P > P_{\max}$ in long day species), the rate of progress in calendar days equals the rate of progress in physiological days. When conditions deviate from the optimum, the rate of progress per day decreases and becomes a fraction of a physiological day. Then, cumulative development is measured in photothermal time units. The effects of the photoperiod on the rate of development are nonlinear:

$$\begin{aligned} f(P) &= 0, && \text{if } P > P_{\max} \\ f(P) &= 1 - \frac{P - P_{\min}}{P_{\max} - P_{\min}}, && \text{if } P_{\min} < P \le P_{\max} \\ f(P) &= 1, && \text{if } P \le P_{\min} \end{aligned}$$

In short day species, the relative rate of development is maximum below a threshold $P_{\min}$, above which the development decreases to zero at $P_{\max}$. Both $P_{\min}$ and $P_{\max}$ are characteristic of the species and cultivar (Table 1). A similar function is used to describe the effects of temperature:

$$\begin{aligned} f(T) &= 0, && \text{if } T \le T_{\mathrm{b}} \\ f(T) &= \frac{T - T_{\mathrm{b}}}{T_{\mathrm{opt1}} - T_{\mathrm{b}}}, && \text{if } T_{\mathrm{b}} < T < T_{\mathrm{opt1}} \\ f(T) &= 1, && \text{if } T_{\mathrm{opt2}} \ge T \ge T_{\mathrm{opt1}} \\ f(T) &= \mathbf{1} - \frac{T - T_{\mathrm{opt2}}}{T_{\mathrm{upper}} - T_{\mathrm{opt2}}}, && \text{if } T_{\mathrm{upper}} > T > T_{\mathrm{opt2}} \\ f(T) &= 0, && \text{if } T \ge T_{\mathrm{upper}} \end{aligned}$$

where T_{opt1} and T_{opt2} define a plateau whose rate of development is maximum. For temperatures above T_{opt2} and below T_{opt1}, the rate of development decreases linearly to zero at T_{upper} and T_{b}, respectively. Table 1 shows characteristic values for selected cereals and legumes.

In this chapter, a derivation of the degree day method is shown along with a mathematical variant that incorporates the effects of the photoperiod. The literature about models that uses degree days is vast, it is not

the intent to review it here. However, the rationale and concept presented here covers most of the models currently used. Summerfield et al. (12) discuss additive photothermal models and Jones et al. (13) provide further details on multiplicative ones. Ritchie and NeSmith (6) and McMaster and Wilhelm (3) discuss some limitations of the degree day method. As emphasized in these previous papers, to obtain reliable and accurate predictions or descriptions of plant development, the parameters and the method used for their estimation must be consistent.

DESERTIFICATION

Aldo Conti
Frascati (RM), Italy

Desertification is a degradation of the top layer of the soil that reduces its ability to support plant life and to produce food. As a result, the soil becomes dusty and dry, and it is easily carried away by erosion, which affects wild and domestic animals, wild plants and crops and, finally, humans. Desertification can be the result of human activities or of natural climate changes. In the latter case, the process is very slow and can take several thousand years to produce its effects. A common misconception about desertification is that it spreads from a desert core. The truth is that land degradation can occur where land abuse has become excessive. If it is not stopped in time, desertification spreads from that spot. Eventually, many of these spots merge and form a large homogeneous area. Another misconception is that desertification is the result of droughts. In fact, well-managed land can recover from even a long period of drought with very little adverse effect as soon as rains return. But it is true that droughts can increase the pace of desertification already taking place.

Desertification is a term that has been in use since at least 1949, when Aubreville, a perceptive and well-informed botanist and ecologist, published a book on *Climate, Forets, et Desertification de l'Afrique Tropicale*. Aubreville observed desertification in tropical Africa and understood immediately that the culprit was not the Sahara desert gaining land. He noticed instead that the main reasons behind desertification were tree cutting, indiscriminate use of fire to clear the land, and cultivation.

Many processes can lead to desertification. Logging, for instance, makes the soil unstable on mountain slopes. Eventually, all the soil runs down as a dangerous landslide or mud river and leaves behind exposed rocks, unable to support any life. What is left behind are barren mountains, particularly evident in China. In Europe, one of the leading causes of desertification is overgrazing. In the past, wild animals used to move following the rainfall, always grazing the richest areas. In modern times, the use of fences prevented these movements, and the result was heavy overgrazing that left the soil exposed to erosion. In many areas, desertification is the result of agriculture. A typical example of this is salinization of soil that happens normally when the soil is overirrigated. The water that is not used by plants evaporates, leaving behind salts that concentrate in the soil. Eventually, the concentration of salts in the soil becomes so high that plants cannot survive, again exposing the land to erosion. In same cases, desertification is the more direct result of urbanization, mining, and recreational activities. In any case, the adverse effects are still the same.

Nowadays, desertification is a serious problem that affects, according to some estimates, up to 30% of dry lands. Worldwide, desertification is making approximately 12 million hectares useless for cultivation every year. But land degradation and desertification are by no means new problems, despite the attention focused on them in recent years. During the first conquest of Africa, it was normal to clear patches of land with fire and then use them to grow crops. After three or four seasons, the land was depleted of nutrients and unable to support any plant life. Moreover, there is some historical evidence that serious and extensive land deterioration was already occurring several centuries before. It started in arid regions, and it had three epicenters: the Mediterranean Sea and other places where destructive changes in soil and plant cover had occurred, but were small in extent or not well known.

Luckily, desertification in many areas has been stopped, but very little effort has been made to restore the land to its original productivity. Today, desertification can be defeated using techniques already known, if financial resources are available and the political will to act is present. For instance, only in the last few decades, satellite images have allowed a better understanding and monitoring of the problem on a large scale.

There are several possible remedies available, even at the local level. The first is to avoid cutting trees or, at least, to replace them with new ones. Plants, a major soil stabilizer, can alone stop erosion. Moreover, the use of available local water and ways to control the salinity of the soil can be very effective. On this topic, genetic engineering is trying to help. Scientists are working on the development of crops that can survive higher salinity, both as a way to use the land and produce food and as a way to save lost soils. Curiously, one of the remedies until now used against desertification is to pollute the soil. In Iran, oil is sprayed over semiarid land with crops. The oil covers the seedlings, retains the moisture, and prevents them from being blown away by the wind until they grow large enough.

As stated at the beginning, desertification is sometimes a slow natural process. As an example, it should be enough to say that 20,000 years ago, the Sahara Desert was a lush forest. This is proved by the fossils of the animals that used to live in this forest. Moreover, pictures taken using radar from the Space Shuttle allow us to identify numerous dry riverbeds under a few meters of sand. This is already happening again due to the global warming on the earth. Many deserts are expanding, even though it is not possible to find a human reason for that. Desertification seems to threaten, in particular, all countries in the Mediterranean region. The coasts of North Africa are already disappearing into the sand, but the same might start happening in Europe. The heat wave of 2003 caused lots of problems. In Italy, many crops were heavily affected, and in the whole Mediterranean region, but in particular in Spain and Portugal, large areas of forest were destroyed by fires.

DEW

ALDO CONTI
Frascati (RM), Italy

Dew forms when water condenses on objects on the surface near the ground and forms a thin layer or many droplets. Dew forms normally during the night when the air temperature decreases and approaches the dew point. Objects on the surface cool down, too, by radiative cooling, facilitating the condensation of small droplets of water. Dew formation is helped by the high humidity of the bottom layer of air, close to the surface. This layer can supply the needed water and prevent the evaporation of the dew already deposited. Strong winds can inhibit the formation of dew. Turbulence mixes a larger layer of air and creates a more homogeneous distribution of humidity and heat, thus preventing the formation of the right conditions near the ground. Dew forms more easily on surfaces that cool efficiently, like metals, which is the reason that cars are often covered with dew in the morning. But dew is often seen on grass or plants because their transpiration creates a thin layer of very humid air.

Dew is very important in the ecology of many deserts, especially those along the western coasts of Africa and South America. In some of them, water from condensation of dew caused by night cooling often exceeds that of rainfall. But dew can be an interesting source of water for human consumption, too. For instance, data recorded in the Negev desert of Israel, a country where water is really scarce, have shown that dew falls for 200 days each year. Moreover, dew is plentiful on many little islands that, surrounded by water, have high humidity but where no water dwells. Some islands of the Mediterranean Sea suffer from a chronic water shortage, which is the reason that one of the first dew-collecting plants has been built in Ajaccio (Corsica Island in France). It is also interesting to describe an old project studied in India and unfortunately never actually realized. The idea was to pump water at 4.5 °C from the sea at a depth of 500 meters. The pumping scheme called for the use of four 1.2-meter pipes and wind-powered pumps. A heat exchanger of 130,000 square meters could then condense, every day, more than 600 cubic meters of dew.

But many animals and plants have already learned how to survive on dew. A place particularly interesting for this kind of adaptation is the Namib desert in Namibia (Africa). Here, many insects in the early morning sit on top of sand dunes trying to catch some dew (or fog) on their wings and legs. In particular, the beetle *Stenocara* has even modified the surface of its hard shell surface to trap mist more efficiently. This beetle shell is covered with bumps whose peaks are smooth like glass and attract water. The troughs around the bumps are covered with a wax that repels water. The water is therefore collected by the peaks, and when a droplet is big enough to touch the water repelling valley it rolls down to the animal's mouth. Some researchers think that the easy trick of the animal can be used in dew collecting devices. A similar surface can be prepared in many ways, even with an ink-jet printer that sprays hydrophilic ink onto an acetate sheet. Dew-collecting devices have the problem of making the water run off the collecting surface.

Another Namibian creature well adapted to survive on dew is the plant *Welwitschia mirabilis*. Despite its look, it is a close relative of pine trees. It has a short trunk split in two and from each side grows a single leaf that can be several meters long. Welwitschias are among the oldest plants on the earth, and some of them are 1500 years old. The trick that allows this plant to survive in one of the driest deserts of the planet is a two-part root system. Welwitschias have a long root that goes deep in the soil trying to reach the water table and extends for several meters away from the plant. These roots collect all the dew that forms on the top layer of soil. Moreover, all the water that condenses on the leaves forms big drops that eventually run down, so that the plant can water its own roots.

DEW DESERTS

Giora J. Kidron
The Hebrew University of
Jerusalem
Jerusalem, Israel

The term dew deserts denotes deserts that receive dew precipitation throughout the year. Dew is defined as condensation of atmospheric vapor and does not include vapor condensation that stems from the wet ground, i.e., distillation. We term dew desert as a desert that receives at least 10 mm of dew in >0.1 mm of daily precipitation. As a result of dew precipitation, primary production in dew deserts is much higher, affecting the entire food chain.

Like the Atacama Desert in South America, the Namib Desert in South Africa, and the Sonora Desert in Baja California (North America), dew only affects those portions of the desert close to a sea or ocean, i.e., to a large body of water that can serve as an adequate vapor source. As most deserts occupy mainly the interior of the continents, the term applies only to a small part of near sea deserts.

At present, information regarding the extent of dew precipitation within deserts is scarce. Most of the available information pertains to the heart of the Negev Desert where annual precipitation is 90–100 mm (1). There, a total of 33 mm was annually measured (2). Nevertheless, based on rain isohyets and the proximity to a sea or ocean (3), one may hypothesize that parts of the Sahara and the Arabian Peninsula are in fact dew deserts. Certain areas within the fog deserts may also be dew deserts (4–6).

Although daily dew amounts may usually range between 0.1 and 0.3 mm and the total annual sum may be much smaller than that of rain precipitation, the occurrence of a steady and constant source may be of great importance in arid and semiarid zones (7–9). As the threshold for organism activity was found to be 0.03 mm of dew (10), amounts of 0.1–0.3 mm are still sufficient to allow growth activity.

Although small, the dew amounts received may allow the establishment and distribution of many species, otherwise not capable of inhabiting the site. Consequently, higher biomass and higher species diversity may characterize the dew deserts. Biomass increase per millimeter of dew may be much higher than that calculated for rain (7) and that extrapolated, by adding the addition of water from dew to that of rain. The dew may thus be an important source of moisture for the primary food chain in arid and semiarid zones (11).

Many groups of micro-organisms were hypothesized to use dew. Among them, cyanobacteria, hypolithic algae and cyanobacteria that occupy the underside of stones (12,13), and lichens (14,15). Among the lichens are the endolithic lichens, embedded within calcite or dolomite crystals at the upper 1–5 mm of the rock and stone surface (16); epilithic and epedaphic lichens that dwell on the rock and soil surface, respectively (17); foliose (18); and fruticose lichens (18,19). In addition, bugs, ants, and beetles were reported to use dew directly by drinking it (20), whereas isopods and beetles were reported to use it indirectly by consuming wet food (20). When wet, snails in the Negev Desert were reported to successfully graze on endolithic lichens. By doing so, the snails disintegrate the limestone, a weathering phenomenon that can take place only upon rock moistening (21).

Although cyanobacteria, hypolithic algae, and cyanobacteria, epedaphic, endolithic, epilithic, foliose, and fruticose lichens were all hypothesized to use dew, positive evidence for dew use under field conditions was obtained only from endolithic, epilithic, foliose, and fruticose lichens. These lichens were shown to photosynthesize for 2–4 h in the morning following dew in the Negev Desert (Fig. 1) (10,18,22). One should note that whereas lithobiontic lichens (inhabiting rocks and stones) were shown to use dew (22), dew use by micro-organisms inhabiting the soil is still controversial. Whereas Lange et al. (22) and Veste et al. (23) showed the use of dew by epedaphic lichens inhabiting soil and sand, respectively, and indirect evidence, expressed by the development of sexual and vegetative reproduction organs, were also monitored in mosses in the Negev Desert (24), the use of dew by endedaphic cyanobacteria inhabiting sand is not certain. According to Jacobs et al. (25), dew may moisten the surface. However, other reports indicate that dew moistening of the soil is rare (24,26). According to Bunnenberg and Kühn (26), an amount of 0.13 mm of dew at 9 cm above ground amounted to 0.03 mm only at the surface. Similarly, Kidron et al. (24) showed that average dew precipitation of 0.1 mm measured on glass plates at 0.7 cm above ground amounted to only 0.034 mm at the surface. As cyanobacteria need liquid water for growth (27), and the necessary threshold for net photosynthesis was 0.1 mm (28), only rarely sufficient dew will moisten the surface to reach >0.1 mm, and thus the contribution of dew to the growth and development of endedaphic cyanobacteria may be negligible.

The uncertainty regarding the use of dew by certain micro-organisms and at certain habitats is mainly linked to two factors: (a) Does dew condense at all habitats? (b) Is the amount supplied sufficient for use and for net carbon gain? As for the second question, rapid dew evaporation during the morning may result in a net loss of carbon, as was shown for the lichen *Ramalina maciformis* following mornings of low dew precipitation (10).

Whereas the efficiency to which different micro-organisms may use dew may be species-dependent, no controversy exists as to the perquisite conditions necessary, i.e., the capability of the dew to condense at their habitat. This ability depends, of course, on the existence of sufficient moisture in the air. It also depends

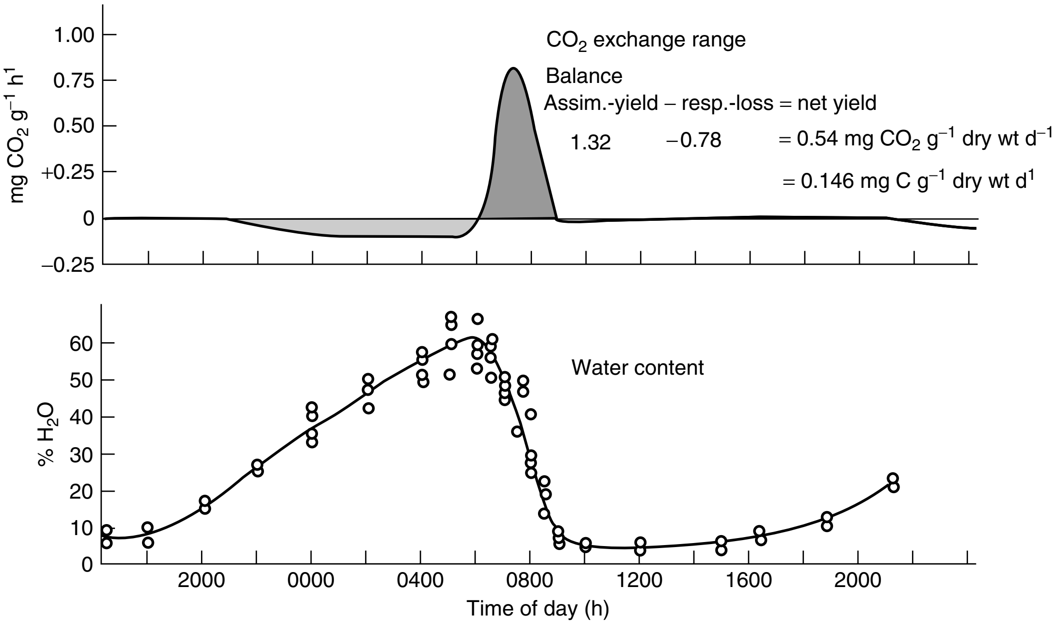

Figure 1. Apparent CO_2 exchange rate (above) and the thalli water content (below) of *Ramalina maciformis* during 24 h in September 1967. Net carbon yield resulted in 0.146 mg C per gram of dry weight a day (18).

on substrate temperatures that will dictate whether the dew point temperature, necessary for vapor condensation, will be reached.

Once reached, dew condensation will take place. As dew was found to condense at a more or less constant rate (29), the time during which the dew point is reached may dictate, to a large extent, the overall amount of dew that will be condensed. Furthermore, as phototrophic microorganisms necessitate light hours for photosynthesis, the length of time during which dew is available may dictate, to a large extent, the overall net gain of organic carbon owing to dew use. Thus, variables that may affect dew condensation and dew duration should be considered once dew availability in different habitats is examined. Factors such as topographical elevation, height above ground, aspect, location along the slope, and angle may all affect dew condensation.

Recent dew measurements carried in the Negev Desert aimed to examine the role of the above-mentioned factors. Thus, in order to obtain continuous dew amounts and duration, a simple and inexpensive method was adapted. The Cloth-Plate Method (CPM) consists of 10 × 10 × 0.2 glass plates glued at their bottom to 10 × 10 × 0.5 cm plywood plates, thus creating an identical substratum (30). Velvet-like cloth (6 × 6 × 0.15 cm) are attached each afternoon to the center of the glass plate and collected throughout the following morning into glass jars that are immediately sealed and then weighed in a nearby lab, oven dried (in 70 °C) and then weighed again, and their moisture content is calculated. By placing plates next to each other within a certain habitat, the CPM facilitates inexpensive large-scale continuous measurements (Fig. 2). The readings are also not affected by wind, as might be the case with some other devices (31).

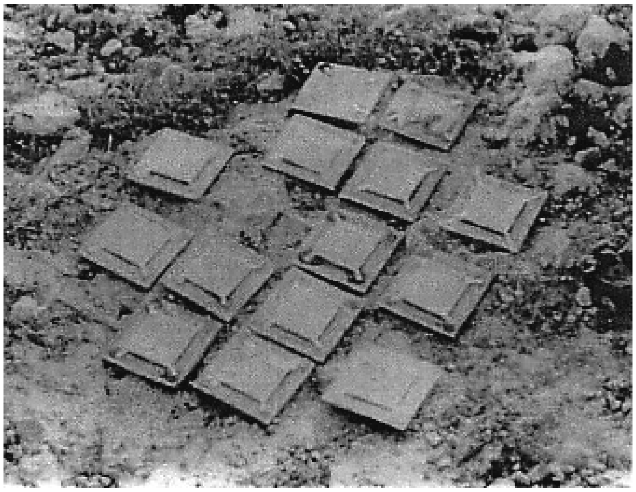

Figure 2. Dew measurements by the CPM in the Negev Highlands.

The CPM was used to assess the possible role of altitude and distance from the sea. When simultaneous measurements at three locations at 250, 550, and 1000 m above sea level being 37, 55, and 98 km from the Mediterranean Sea were carried out in the Negev Desert, positive correlations between dew and fog amounts and altitude were found (Fig. 3). Dew precipitation, as well as fog precipitation, increased with altitude, with the most elevated location receiving more than twice the amount obtained at the topographically lowest location, which was the case, although the most elevated location was also the farthest away from the Mediterranean Sea, i.e., from a vapor source. The data thus indicate that, within 100 km from the sea, topographical height may compensate for the increase in distance from the vapor source. In this regard, one should note that elevation plays a major role in controlling dew and fog precipitation also in the Atacama Desert (4).

The CPM facilitates careful analysis of dew precipitation. When continuous dew measurements were carried out, a typical condensation and evaporation pattern was obtained during the morning hours (Fig. 4). Dew condensation was found to continue also after dawn and sunrise, explained by radiation-induced air turbulence (30). As for the relationship between dew amounts and height above ground, dew values showed high variability (33,34). When dew was measured on a hilltop in the Negev Highlands at 0.7, 10, 20, 30, 40, and 50 cm above ground, maximal values were recorded at 10 cm above ground (Fig. 5). The findings reflected two effects: the warming effect of the soil as a result of a nocturnal heat flux that rises from the deeper horizons of the soil, responsible for the decrease in dew values near the ground (31,34,35), and the air turbulence at height, resulting from higher wind velocities, responsible for lower dew values farther away from the ground (35,36).

High variability in dew amounts and duration was also found in the Negev Desert when dew was measured at 0.7 and 40 cm above ground along limestone slopes (approximately 50 m long) of four aspects (north, south, east, and west) within a second-order drainage basin (Fig. 6). Whereas at 0.7 cm above ground, the hilltops and the bottom parts of the northern and western aspects received the highest amounts, the wadi beds received approximately half these values (Fig. 6a). The lowest values were received at the south-facing midslope (located at the lee side of the prevailing north north-west winds), being approximately a quarter of the maximal values recorded. At 40 cm above ground, a reverse trend was obtained with the south-facing midslope and the wadi beds receiving the highest values (Fig. 7). And thus, whereas the 0.7 cm above-ground results were not in accordance with the classical model that predicts high dew values at the wadi beds (because of nocturnal katabatic wind) and higher amounts at the lee side of the wind, i.e., at the south-facing slope (because of undisturbed inversion), the 40 cm above ground measurements corresponded to the classical model. The discrepancy was explained by the overwhelming impact of the rock surface temperatures on the dew values at 0.7 cm above ground, with south-facing rock surfaces being 3–8 degrees higher than the north-facing rock surfaces throughout the night. As for the higher amounts of dew received at 0.7 cm above ground at the hilltops in comparison with the wadi

beds, it was hypothesized that the afternoon winds act as a cooling agent, facilitating a much earlier drop in surface temperatures (and thus reaching much faster the necessary dew point temperature) at the wind-exposed hilltops (37).

Aspect and slope location also dictate dew duration, seen as being of even greater ecological importance to organisms than the maximal amount (38–40). Generally, a positive correlation between dew amounts and duration was found (34,37), and thus, by affecting dew amounts, aspect and slope position also affect dew duration (Fig. 6b). Nevertheless, dew duration was also affected by slope location and aspect beyond these relations. Although condensation was found to take place in all habitats also after sunrise (for usually 0.5–1.0 h after sunrise), condensation at the sun-sheltered habitats of the bottom north- and west-facing slopes continued for up to 1.5 h following sunrise (41). As a result of the higher maximal values and the limited desiccation effect of the sun in these habitats, these habitats were characterized by longer dew duration.

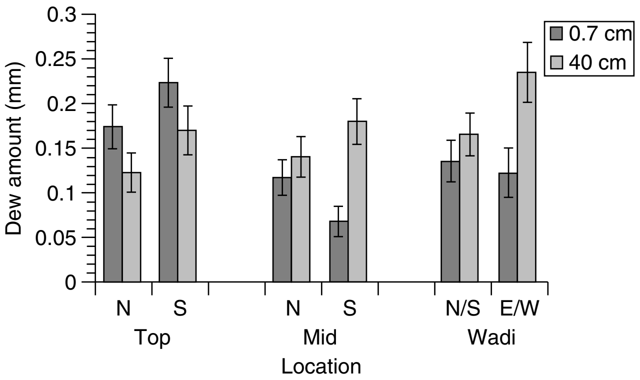

Figure 7. Dew measurements at 0.7 and 40 cm above ground at three habitats within a second-order drainage basin in the Negev Desert. N = northern exposure, S = southern exposure, Wadi N/S = wadi between the northern and southern exposure, Wadi E/W = wadi between the eastern and western exposures (37).

The substrate angle is another factor found to affect dew amounts and duration. When cloths were attached to 50 × 50 × 10 cm wooden boxes, having sides of different angles (30, 45, 60, 75, and 90°) placed at different aspects (facing north, south, west, and east) on a hilltop, a decrease in dew amounts with an increase in angle, from 30° to 90°, was found and dew amounts were positively correlated with $\cos(\theta)$ (Fig. 8). Thus, dew amounts obtained at an angle of 90° was approximately a quarter of the values obtained at a horizontal surface and at an angle of 30°, both of which received similar values. This difference was explained by the slower rate of nocturnal cooling that takes place with an increase in angle in accordance with the lower proportion of sky seen by the substrate (43). No preferential condensation in accordance with aspect was found. Nevertheless, dew duration was aspect-dependent with a decrease in duration following the order west>north>south>east (Fig. 9). Thus, daylight dew duration was approximately double at the west-facing sun-sheltered angle than at the sun-exposed east-facing aspect.

The variability in dew amounts and duration may have important consequences for micro-organisms. For

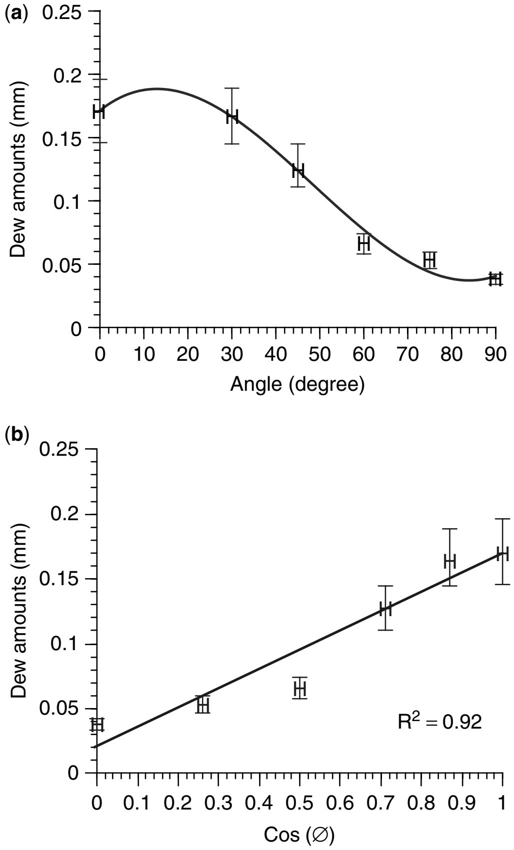

Figure 8. The relationships between dew amounts with (**a**) angle (in degrees) and (**b**) cos(θ) as measured in the Negev Desert (42).

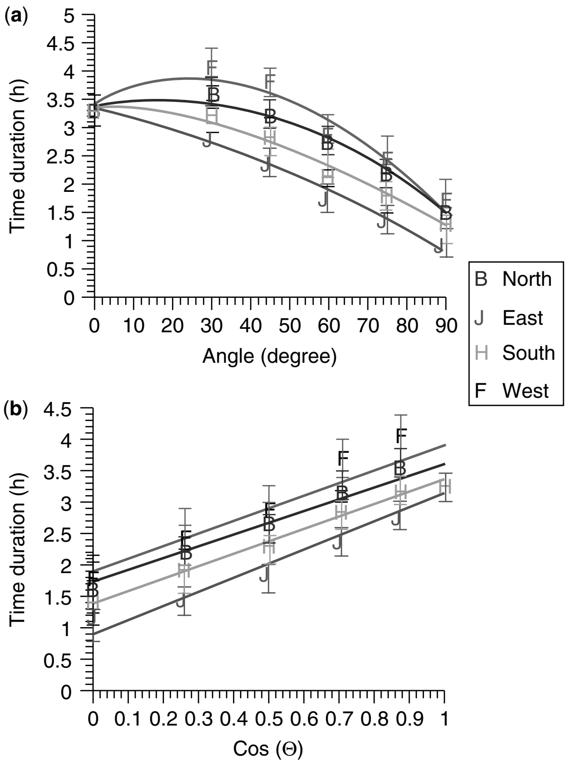

Figure 9. The relationships between dew duration with (**a**) angle (in degrees) and (**b**) cos(θ) in the Negev Desert (42).

most micro-organisms, the ability to use dew is primarily a function of the amount condensed and the duration during which dew is available, both of which are habitat-dependent. Thus, when cloths were attached to different substrates, high variability in dew amounts was received on loose cobbles, partially embedded cobbles, and rock surfaces (Fig. 10). Loose cobbles that rapidly cool at night were found to receive approximately twice the amounts of embedded cobbles and more than 4 times the amounts condensed on a nearby rock (44). Whereas the cobbles were primarily inhabited by endolithic lichens, the rock surfaces were mainly inhabited by epilithic lichens. Similarly, lichen growth on loose cobbles was controlled by angle-induced dew. Thus, the top of loose cobbles, inhabited by lichens, received approximately twice the amount condensed on the uninhabited side of the cobble (45). Consequently, dew contribution to the ecosystem biomass may be highly important. For instance, in research conducted by Kappen et al. (22,46) in the Negev Desert, the biomass of lichens (with *Ramalina maciformis* predominating) in the northern aspect was over 200 g m^{-2}, three to five times as much than at the other aspects. Although some of the differences can certainly be attributed also to use of rain-induced moisture, the fact that the main water source for *Ramalina maciformis* and other endolithic and epilithic lichens in the Negev Desert was dew pointed to the importance of dew on lichen biomass. The difference in lichen cover of the sun-sheltered and the sun-exposed slopes points also to the role of dew in lichen distribution (47). As lichens may serve as food for snails, the whole food chain may be affected by dew precipitation.

Dew precipitation may also affect vascular plants. The effect may not always be positive, as dew may hasten plant fungal infection (7,48). Dew may preferentially accumulate on leaves because of their lower temperature (0.5–2 °C lower in comparison to the ambient air) (35,36) and thus, wet the leaves for several hours during the morning (34).

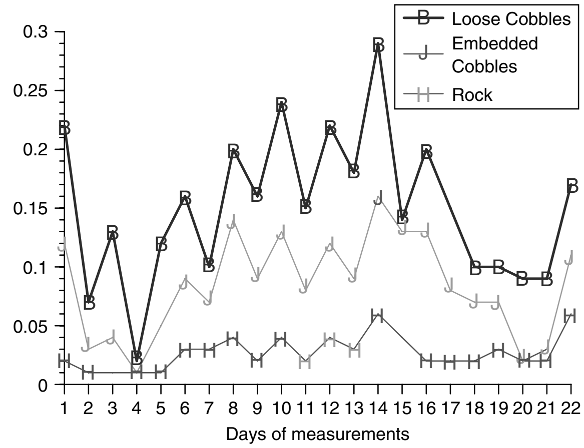

Figure 10. Simultaneous dew amounts as obtained on loose and embedded cobbles inhabited by endolithic lichens, and rock surface inhabited by epilithic lichens (44).

However, no conclusive evidence of direct dew use by vascular plants is yet available, and the research conducted on this topic is controversial (7,8,31,49,50). Dew, however, may have an indirect effect, facilitating stomata opening (51), longer hours of photosynthesis (39), reducing transpiration (7), and affecting flowering (7). Dew may facilitate seedling survival (52), recovery from wilting (34), plant growth (34), and yield (34,53). By affecting micro-organisms and plant growth, and by facilitating insect survival (20), dew also indirectly affects the nutrient cycling (54) and soil-forming processes (55), which in turn has an important impact on the ecosystem and may thus call for a specific awareness of the dew deserts.

DEW POINT

Aldo Conti
Frascati (RM), Italy

The dew point is the temperature to which air must be cooled at constant pressure until it reaches saturation and the water, or any other vapor, begins condensing. The result is the formation of fog. When the dew point falls below freezing, it is called the frost point. In this case, water forms ice crystals directly. The dew point is also a good indicator of the amount of water contained in the air. The more humid the air, the higher the dew temperature. The dew point is often reached in the evening, when the air cools down, which is why fog is more common in the evening, or why one normally finds that dew or frost are common in the morning but disappear as soon as the temperature increases.

Dew point and relative humidity can be measured with an instrument called a wet- and dry-bulb psychrometer. The dry bulb is a normal thermometer that measures the actual air temperature. The wet bulb is another thermometer, but has a bulb wrapped in a piece of cloth dampened by a string that dips into a bottle of distilled water. Unless the air is so humid that it is very close to saturation, the wet bulb thermometer measures a lower temperature, because it is cooled by the evaporation of water. The difference between the dry-bulb and wet-bulb temperatures is called the wet-bulb depression. It is then possible to calculate the dew point as a function of the wet-bulb depression and of the dry-bulb temperature.

To calculate the dew point starting from the psychrometer readings, the first step is to calculate the saturation vapor pressure in millibars, corresponding to the dry- and wet-bulb temperature:

$$E_{\mathrm{s}} = 6.11 \times 10.0[7.5T/(237.7 + T)]$$

$$E_{\mathrm{swb}} = 6.11 \times 10.0[7.5T_{\mathrm{wb}}/(237.7 + T_{\mathrm{wb}})]$$

where T and T_{wb} are the readings of the dry- and wet-bulb temperatures.

Now we are ready to calculate the actual mixing ratio of the air:

$$W = [(T - T_{\mathrm{wb}})(C_{\mathrm{p}}) - L_{\mathrm{v}}(E_{\mathrm{swb}}/P)]/[-(T - T_{\mathrm{wb}})(C_{\mathrm{pv}}) - L_{\mathrm{v}}]$$

where C_{p} = specific heat of dry air at constant pressure (J/g)~1.005 J/g
C_{pv} = specific heat of water vapor at constant pressure (J/g)~4.186 J/g
L_{v} = Latent heat of vaporization (J/g)~2500 J/g
T = air temperature in °C
T_{wb} = wet bulb temperature in °C
E_{swb} = saturation vapor pressure at the wet-bulb temperature (mb)
P = atmospheric pressure at the surface ~1013 mb at sea level

We can now use the following formula to obtain the saturation mixing ratio for the air:

$$W_{\mathrm{s}} = E_{\mathrm{s}}/P$$

$$\mathrm{RH} = W/W_\mathrm{s}$$

Now we can use the relative humidity to calculate the actual vapor pressure (E) of the air as follows:

$$E = \mathrm{RH} \times E_\mathrm{s}$$

The dew point temperature is then

$$T_\mathrm{d} = [-430.22 + 237.7 \times \ln(E)]/[-\ln(E) + 19.08]$$

Let us now assume a psychrometer that gives the following readings at a pressure of 1013 mbar:

$$T = 30\,^\circ\mathrm{C}$$

$$T_\mathrm{wb} = 20\,^\circ\mathrm{C}$$

Then,

$$E_\mathrm{swb} = 23.34\ \mathrm{mbar}$$

$$E_\mathrm{s} = 42.31\ \mathrm{mbar}$$

The mixing ratio becomes

$$W = 0.019$$

$$W_\mathrm{s} = 0.042$$

The relative humidity is then,

$$\mathrm{RH} = 0.45\ (\text{or } 45\%)$$

The actual vapor pressure is then,

$$\mathrm{E} = 18.95\ \mathrm{mbar}$$

and the dew point is

$$T_\mathrm{d} = 16.7\,^\circ\mathrm{C}$$

Instead of going through all these formulas, it is possible to use tables that give the dew point temperature as a function of the readings for different pressures.

DROUGHTS

Arthur M. Holst
Philadelphia Water Department
Philadelphia, Pennsylvania

A drought is a period of time during which weather is in one way or another excessively dry. A drought's severity is determined by the degree of moisture deficiency in the affected area, as measured by various methods. Droughts are a standard, recurring, and normal feature of long-term climate. There are four generally accepted categories of drought: meteorological, socioeconomic, hydrologic, and agricultural.

Meteorological droughts involve a lack of precipitation during a given time period. Their specific definition depends mostly on the region in question; a lack of precipitation for some areas would be excessive precipitation in others. Some regions receive rain year-round, and some receive virtually none. Likewise, some regions receive precipitation consistently throughout the year, and others have seasonal precipitation patterns. A departure from any of these climatological characteristics as abnormally low precipitation can cause a meteorological drought. Meteorological droughts are usually measured in terms of their duration and in contrast to established precipitation averages for specified time periods for a specified area. This type of drought generally precedes the other three types.

Agricultural droughts need not involve a severe lack of precipitation. They are marked by damage to crops and plants due to insufficient water supplies. Because water from rain and snow is more likely to run into creeks and rivers instead of filtering into the soil due to human intervention, agricultural droughts can sometimes occur in spite of noticeable rainfall. Depending on a plant's species and stage of growth, it needs varying amounts of water from the soil; when the majority of crops cannot obtain the amount of water they need, an area is said to be undergoing an agricultural drought. This type of drought is most damaging to farmers and those in poor countries, and it generally comes after the onset of a meteorological drought.

A hydrologic drought involves water shortages in reservoirs, lakes, and streams due to lack of precipitation. These droughts are measured by stream flow and water levels in local reservoirs. Local climate is not the only factor that causes a hydrologic drought; altered land usage, dams, and degraded soil quality can all have effects as well. Reduced precipitation in one area can cause a hydrologic drought in another because various areas are hydrologically connected by their rivers, lakes, and other bodies of water. The primary cause of this type of drought is generally a meteorological drought; hydrologic droughts usually come some time after agricultural droughts.

The final category of drought is socioeconomic. This type of drought, like the other three, involves a lack of precipitation. It occurs when reduced precipitation causes a shortage of water as related to the demands of the local populace. The socioeconomic drought is the only type of drought that has a major effect on the general population, and it is generally the last of the four types to occur.

Aside from lack of rain, the three most important variables to look at during a drought are air temperature, humidity, and circulation patterns in the atmosphere. Atmospheric circulation patterns that produce little or no precipitation are often associated with droughts. Climate abnormalities are another component of a drought. Precipitation levels that would be considered a drought in one area are normal in another that has a different climate. To understand the cause of a drought, scientists study the circulation patterns of the atmosphere across global distances, using computer-generated atmospheric simulator models.

Droughts also have direct effects on communities that experience this phenomenon. Both water quality and cost are negatively affected by droughts. Changes in the taste and odor of drinking water can also occur. Those who draw their water from wells may have to drill more deeply to reach the lowered level of the water table.

During a drought, water conservation is important. Restrictions on watering gardens, washing cars, and using sprinkler systems are applied when a drought emergency or warning is in effect. There are generally three stages of drought preparedness: drought watches, drought warnings, and drought emergencies. During a drought watch, no restrictions are enforced, but citizens are encouraged to curb water usage because the possibility of drought has been established for an area. During a drought warning, restrictions are still not enforced, but citizens are instructed to reduce water usage further in response to impending drought conditions. The final stage is a drought emergency. This is the most serious stage, often involving mandatory water usage guidelines to ensure that sufficient water is available for critical needs. At this stage, officials try to avoid local shortages by evenly distributing the water available.

Droughts can have a great impact in many ways. There are three main types of impact they can have: economic, social, and environmental. A lack of water in the soil for crops can cause farmers great financial difficulty. The resulting decrease in crop production has a ripple effect on the economy, causing short-term and long-term problems. One of the biggest short-term problems is unemployment. Certain industries can also be affected by long-term problems. For instance, loss of tax revenue can hinder tourism. Brush and trees can become very dry, and an outbreak of destructive fires can result. Drought can harm the logging industry, fisheries, and hydroelectric power generation, all economic effects. It can also cause insect problems in agriculture, as well as erosion and disease. Environmental effects include reduced biodiversity, degraded air quality, and perhaps most importantly, devastating forest fires. Social impacts include induced emigration, rampant famine, and, indirectly, greater poverty. These are merely a few of the multitude of impacts, direct and indirect, that drought can have.

DROUGHT INDICES

Michael J. Hayes
Climate Impacts
Specialist—National Drought
Mitigation Center

INTRODUCTION

Drought indices assimilate thousands of bits of data on rainfall, snowpack, streamflow, and other water supply indicators into a comprehensible big picture. A drought index value is typically a single number, far more useful than raw data for decision making.

There are several indices that measure how much precipitation for a given period of time has deviated from historically established norms. Although none of the major indices is inherently superior to the rest in all circumstances, some indices are better suited than others for certain uses. For example, the Palmer Drought Severity Index has been widely used by the U.S. Department of Agriculture to determine when to grant emergency drought assistance, but the Palmer is better when working with large areas of uniform topography. Western states, with mountainous terrain and the resulting complex regional microclimates, find it useful to supplement Palmer values with other indices such as the Surface Water Supply Index, which takes snowpack and other unique conditions into account.

The National Drought Mitigation Center is using a newer index, the Standardized Precipitation Index, to monitor moisture supply conditions. Distinguishing traits of this index are that it identifies emerging droughts months sooner than the Palmer Index and that it is computed on various time scales.

Most water supply planners find it useful to consult one or more indices before making a decision. What follows is an introduction to each of the major drought indices in use in the United States and in Australia.

PERCENT OF NORMAL

Overview: The percent of normal is a simple calculation well suited to the needs of TV weathercasters and general audiences.

Pros: Quite effective for comparing a single region or season.

Cons: Easily misunderstood, as normal is a mathematical construct that does not necessarily correspond with what we expect the weather to be.

The percent of normal precipitation is one of the simplest measurements of rainfall for a location. Analyses using

---

the percent of normal are very effective when used for a single region or a single season. Percent of normal is also easily misunderstood and gives different indications of conditions, depending on the location and season. It is calculated by dividing actual precipitation by normal precipitation—typically considered to be a 30-year mean—and multiplying by 100%. This can be calculated for a variety of time scales. Usually these time scales range from a single month to a group of months representing a particular season, to an annual or water year. Normal precipitation for a specific location is considered to be 100%.

One of the disadvantages of using the percent of normal precipitation is that the mean, or average, precipitation is often not the same as the median precipitation, which is the value exceeded by 50% of the precipitation occurrences in a long-term climate record. The reason for this is that precipitation on monthly or seasonal scales does not have a normal distribution. Use of the percent of normal comparison implies a normal distribution where the mean and median are considered to be the same. An example of the confusion this could create can be illustrated by the long-term precipitation record in Melbourne, Australia, for the month of January. The median January precipitation is 36.0 mm (1.4 in.), meaning that in half the years less than 36.0 mm is recorded, and in half the years more than 36.0 mm is recorded. However, a monthly January total of 36.0 mm would be only 75% of normal when compared to the mean, which is often considered to be quite dry. Because of the variety in the precipitation records over time and location, there is no way to determine the frequency of the departures from normal or compare different locations. This makes it difficult to link a value of a departure with a specific impact occurring as a result of the departure, inhibiting attempts to mitigate the risks of drought based on the departures from normal and form a plan of response (1).

STANDARDIZED PRECIPITATION INDEX (SPI)

Overview: The SPI is an index based on the probability of precipitation for any time scale.

Who uses it: Many drought planners appreciate the SPI's versatility.

Pros: The SPI can be computed for different time scales, can provide early warning of drought and help assess drought severity, and is less complex than the Palmer.

Cons: Values based on preliminary data may change.

Developed by: T.B. McKee, N.J. Doesken, and J. Kleist, Colorado State University, 1993.

Monthly maps: http://www.drought.unl.edu/monitor/spi.htm; http://www.wrcc.dri.edu/spi/spi.html.

SPI Values	
2.0+	extremely wet
1.5 to 1.99	very wet
1.0 to 1.49	moderately wet
−.99 to .99	near normal
−1.0 to −1.49	moderately dry
−1.5 to −1.99	severely dry
−2 and less	extremely dry

The understanding that a deficit of precipitation has different impacts on groundwater, reservoir storage, soil moisture, snowpack, and streamflow led McKee, Doesken, and Kleist to develop the Standardized Precipitation Index (SPI) in 1993. The SPI was designed to quantify the precipitation deficit for multiple time scales. These time scales reflect the impact of drought on the availability of the different water resources. Soil moisture conditions respond to precipitation anomalies on a relatively short scale. Groundwater, streamflow, and reservoir storage reflect the longer-term precipitation anomalies. For these reasons, McKee et al. (2) originally calculated the SPI for 3-, 6-, 12-, 24-, and 48-month time scales.

The SPI calculation for any location is based on the long-term precipitation record for a desired period. This long-term record is fitted to a probability distribution, which is then transformed into a normal distribution so that the mean SPI for the location and desired period is zero (3). Positive SPI values indicate greater than median precipitation, and negative values indicate less than median precipitation. Because the SPI is normalized, wetter and drier climates can be represented in the same way, and wet periods can also be monitored using the SPI.

McKee et al. (2) used the classification system shown in the SPI values table to define drought intensities resulting from the SPI. McKee et al. (2) also defined the criteria for a drought event for any of the time scales. A drought event occurs any time the SPI is continuously negative and reaches an intensity of −1.0 or less. The event ends when the SPI becomes positive. Each drought event, therefore, has a duration defined by its beginning and end, and an intensity for each month that the event continues. The positive sum of the SPI for all the months within a drought event can be termed the drought's "magnitude".

Based on an analysis of stations across Colorado, McKee determined that the SPI is in mild drought 24% of the time, in moderate drought 9.2% of the time, in severe drought 4.4% of the time, and in extreme drought 2.3% of the time (2). Because the SPI is standardized, these percentages are expected from a normal distribution of the SPI. The 2.3% of SPI values within the "Extreme Drought" category is a percentage that is typically expected for an "extreme" event (Wilhite 1995). In contrast, the Palmer Index reaches its "extreme" category more than 10% of the time across portions of the central Great Plains. This standardization allows the SPI to determine the rarity of a current drought, as well as the probability of the precipitation necessary to end the current drought (2).

The SPI has been used operationally to monitor conditions across Colorado since 1994 (4). Monthly maps of the SPI for Colorado can be found on the Colorado State University website (http://ulysses.atmos.colostate.edu/SPI.html). It is also being monitored at the climate division level for the contiguous United States by the National Drought

Mitigation Center and the Western Regional Climate Center (WRCC). You can download the SPI program and sample files here.

PALMER DROUGHT SEVERITY INDEX (THE PALMER; PDSI)

Overview: The Palmer is a soil moisture algorithm calibrated for relatively homogeneous regions.

Who uses it: Many U.S. government agencies and states rely on the Palmer to trigger drought relief programs.

Pros: The first comprehensive drought index developed in the United States.

Cons: Palmer values may lag emerging droughts by several months; less well suited for mountainous land or areas of frequent climatic extremes; complex—has an unspecified, built-in time scale that can be misleading.

Developed by: W.C. Palmer, 1965.

Weekly maps: http://www.cpc.ncep.noaa.gov/products/analysis_monitoring/regional_monitoring/palmer.gif.

Palmer Classifications	
4.0 or more	extremely wet
3.0 to 3.99	very wet
2.0 to 2.99	moderately wet
1.0 to 1.99	slightly wet
0.5 to 0.99	incipient wet spell
0.49 to −0.49	near normal
−0.5 to −0.99	incipient dry spell
−1.0 to −1.99	mild drought
−2.0 to −2.99	moderate drought
−3.0 to −3.99	severe drought
−4.0 or less	extreme drought

In 1965, W.C. Palmer developed an index to measure the departure of the moisture supply (5). Palmer based his index on the supply-and-demand concept of the water balance equation, taking into account more than just the precipitation deficit at specific locations. The objective of the Palmer Drought Severity Index (PDSI), as this index is now called, was to provide measurements of moisture conditions that were standardized so that comparisons using the index could be made between locations and between months (5).

The PDSI is a meteorological drought index, and it responds to weather conditions that have been abnormally dry or abnormally wet. When conditions change from dry to normal or wet, for example, the drought measured by the PDSI ends without taking into account streamflow, lake and reservoir levels, and other longer-term hydrologic impacts (6). The PDSI is calculated based on precipitation and temperature data, as well as the local Available Water Content (AWC) of the soil. From the inputs, all the basic terms of the water balance equation can be determined, including evapotranspiration, soil recharge, runoff, and moisture loss from the surface layer. Human impacts on the water balance, such as irrigation, are not considered. Complete descriptions of the equations can be found in the original study by Palmer (5) and in the more recent analysis by Alley (7).

Palmer developed the PDSI to include the duration of a drought (or wet spell). His motivation was as follows: an abnormally wet month in the middle of a long-term drought should not have a major impact on the index, or a series of months with near-normal precipitation following a serious drought does not mean that the drought is over. Therefore, Palmer developed criteria for determining when a drought or a wet spell begins and ends, which adjust the PDSI accordingly. Palmer (5) described this effort and gave examples, and it is also described in detail by Alley (7). In near-real time, Palmer's index is no longer a meteorological index but becomes a hydrological index referred to as the Palmer Hydrological Drought Index (PHDI) because it is based on moisture inflow (precipitation), outflow, and storage, and does not take into account the long-term trend (6).

In 1989, a modified method to compute the PDSI was begun operationally (8). This modified PDSI differs from the PDSI during transition periods between dry and wet spells. Because of the similarities between these Palmer indices, the terms *Palmer Index* and *Palmer Drought Index* have been used to describe general characteristics of the indices.

The Palmer Index varies roughly between −6.0 and +6.0. Palmer arbitrarily selected the classification scale of moisture conditions based on his original study areas in central Iowa and western Kansas (5). Ideally, the Palmer Index is designed so that a −4.0 in South Carolina has the same meaning in terms of the moisture departure from a climatological normal as a −4.0 in Idaho (7). The Palmer Index has typically been calculated on a monthly basis, and a long-term archive of the monthly PDSI values for every climate division in the United States exists with the National Climatic Data Center from 1895 through the present. In addition, weekly Palmer Index values (actually modified PDSI values) are calculated for the climate divisions during every growing season and are available in the *Weekly Weather and Crop Bulletin*. These weekly Palmer Index maps are also available on the World Wide Web from the Climate Prediction Center at http://www.cpc.ncep.noaa.gov/products/analysis_monitoring/regional_monitoring/palmer.gif.

The Palmer Index is popular and has been widely used for a variety of applications across the United States. It is most effective measuring impacts sensitive to soil moisture conditions, such as agriculture (1). It has also been useful as a drought monitoring tool and has been used to trigger actions associated with drought contingency plans (1). Alley (7) identified three positive characteristics of the Palmer Index that contribute to its popularity: (1) it provides decision makers with a measurement of the abnormality of recent weather for a region; (2) it provides an opportunity to place current conditions in historical perspective; and (3) it provides spatial and temporal representations of historical droughts. Several states, including New York, Colorado, Idaho, and Utah, use the Palmer Index as one part of their drought monitoring systems.

There are considerable limitations when using the Palmer Index, and these are described in detail by Alley (7) and Karl and Knight (6). Drawbacks of the Palmer Index include:

- The values quantifying the intensity of drought and signaling the beginning and end of a drought or wet spell were arbitrarily selected based on Palmer's study of central Iowa and western Kansas and have little scientific meaning.
- The Palmer Index is sensitive to the AWC of a soil type. Thus, applying the index for a climate division may be too general.
- The two soil layers within the water balance computations are simplified and may not be accurately representative of a location.
- Snowfall, snow cover, and frozen ground are not included in the index. All precipitation is treated as rain, so that the timing of PDSI or PHDI values may be inaccurate in the winter and spring months in regions where snow occurs.
- The natural lag between when precipitation falls and the resulting runoff is not considered. In addition, no runoff is allowed to take place in the model until the water capacity of the surface and subsurface soil layers is full, leading to an underestimation of runoff.
- Potential evapotranspiration is estimated using the Thornthwaite method. This technique has wide acceptance, but it is still only an approximation.

Several other researchers have presented additional limitations of the Palmer Index. McKee et al. (4) suggested that the PDSI is designed for agriculture but does not accurately represent the hydrological impacts resulting from longer droughts. Also, the Palmer Index is applied within the United States but has little acceptance elsewhere (9). One explanation for this is provided by Smith et al. (10), who suggested that it does not do well in regions where there are extremes in the variability of rainfall or runoff. Examples in Australia and South Africa were given. Another weakness in the Palmer Index is that the "extreme" and "severe" classifications of drought occur with a greater frequency in some parts of the country than in others (1). "Extreme" droughts in the Great Plains occur with a frequency greater than 10%. This limits the accuracy of comparing the intensity of droughts between two regions and makes planning response actions based on a certain intensity more difficult.

CROP MOISTURE INDEX (CMI)

Description: A Palmer derivative, the CMI reflects moisture supply in the short term across major crop-producing regions and is not intended to assess long-term droughts.

Pros: Identifies potential agricultural droughts.

Developed by: W.C. Palmer, 1968.

Weekly maps: http://www.cpc.ncep.noaa.gov/products/_analysis_monitoring/regional_monitoring/cmi.gif.

The Crop Moisture Index (CMI) uses a meteorological approach to monitor week-to-week crop conditions. It was developed by Palmer (11) from procedures within the calculation of the PDSI. Whereas the PDSI monitors long-term meteorological wet and dry spells, the CMI was designed to evaluate short-term moisture conditions across major crop-producing regions. It is based on the mean temperature and total precipitation for each week within a climate division, as well as the CMI value from the previous week. The CMI responds rapidly to changing conditions, and it is weighted by location and time so that maps, which commonly display the weekly CMI across the United States, can be used to compare moisture conditions at different locations. Weekly maps of the CMI are available as part of the USDA/JAWF Weekly Weather and Crop Bulletin (http://www.usda.gov/oce/waob/jawf/wwcb.html).

Because it is designed to monitor short-term moisture conditions affecting a developing crop, the CMI is not a good long-term drought monitoring tool. The CMI's rapid response to changing short-term conditions may provide misleading information about long-term conditions. For example, a beneficial rainfall during a drought may allow the CMI value to indicate adequate moisture conditions, while the long-term drought at that location persists. Another characteristic of the CMI that limits its use as a long-term drought monitoring tool is that the CMI typically begins and ends each growing season near zero. This limitation prevents the CMI from being used to monitor moisture conditions outside the general growing season, especially in droughts that extend over several years. The CMI also may not be applicable during seed germination at the beginning of a specific crop's growing season.

SURFACE WATER SUPPLY INDEX (SWSI; PRONOUNCED "SWAZEE")

Description: The SWSI is designed to complement the Palmer in the state of Colorado, where mountain snowpack is a key element of water supply; calculated by river basin, based on snowpack, streamflow, precipitation, and reservoir storage.

Pros: Represents water supply conditions unique to each basin.

Cons: Changing a data collection station or water management requires that new algorithms be calculated, and the index is unique to each basin, which limits interbasin comparisons.

Developed by: Shafer and Dezman, 1982.

The Surface Water Supply Index (SWSI) was developed by Shafer and Dezman (12) to complement the Palmer Index for moisture conditions across the state of Colorado. The Palmer Index is basically a soil moisture algorithm calibrated for relatively homogeneous regions, but it is not designed for large topographic variations across a region and it does not account for snow accumulation and subsequent runoff. Shafer and Dezman designed the SWSI to be an indicator of surface water conditions and described the index as "mountain water dependent", in which mountain snowpack is a major component.

The objective of the SWSI was to incorporate both hydrological and climatological features into a single index value resembling the Palmer Index for each major river basin in the state of Colorado (Shafer and Dezman 1982). These values would be standardized to allow comparisons between basins. Four inputs are required within the SWSI: snowpack, streamflow, precipitation, and reservoir storage. Because it is dependent on the season, the SWSI is computed with only snowpack, precipitation, and reservoir storage in the winter. During the summer months, streamflow replaces snowpack as a component within the SWSI equation.

The procedure to determine the SWSI for a particular basin is as follows: monthly data are collected and summed for all the precipitation stations, reservoirs, and snowpack/streamflow measuring stations over the basin. Each summed component is normalized using a frequency analysis gathered from a long-term data set. The probability of non-exceedence—the probability that subsequent sums of that component will not be greater than the current sum—is determined for each component based on the frequency analysis. This allows comparisons of the probabilities to be made between the components. Each component has a weight assigned to it depending on its typical contribution to the surface water within that basin, and these weighted components are summed to determine a SWSI value representing the entire basin. Like the Palmer Index, the SWSI is centered on zero and has a range between −4.2 and +4.2.

The SWSI has been used, along with the Palmer Index, to trigger the activation and deactivation of the Colorado Drought Plan. One of its advantages is that it is simple to calculate and gives a representative measurement of surface water supplies across the state. It has been modified and applied in other western states as well. These states include Oregon, Montana, Idaho, and Utah. Monthly SWSI maps for Montana are available from the Montana Natural Resource Information System (http://nris.state.mt.us/wis/SWSInteractive/).

Several characteristics of the SWSI limit its application. Because the SWSI calculation is unique to each basin or region, it is difficult to compare SWSI values between basins or regions (13). Within a particular basin or region, discontinuing any station means that new stations need to be added to the system and new frequency distributions need to be determined for that component. Additional changes in the water management within a basin, such as flow diversions or new reservoirs, mean that the entire SWSI algorithm for that basin needs to be redeveloped to account for changes in the weight of each component. Thus, it is difficult to maintain a homogeneous time series of the index (8). Extreme events also cause a problem if the events are beyond the historical time series, and the index will need to be reevaluated to include these events within the frequency distribution of a basin component.

RECLAMATION DROUGHT INDEX

Description: Like the SWSI, the RDI is calculated at the river basin level, incorporating temperature as well as precipitation, snowpack, streamflow, and reservoir levels as input.

Who uses it: The Bureau of Reclamation; the State of Oklahoma as part of their drought plan.

Pros: By including a temperature component, it also accounts for evaporation.

Cons: Because the index is unique to each river basin, interbasin comparisons are limited.

Developed by: The Bureau of Reclamation, as a trigger to release drought emergency relief funds.

RDI Classifications	
4.0 or more	extremely wet
1.5 to 4.0	moderately wet
1 to 1.5	normal to mild wetness
0 to −1.5	normal to mild drought
−1.5 to −4.0	moderate drought
−4.0 or less	extreme drought

The Reclamation Drought Index (RDI) was recently developed as a tool for defining drought severity and duration, and for predicting the onset and end of periods of drought. The impetus to devise the RDI came from the Reclamation States Drought Assistance Act of 1988, which allows states to seek assistance from the Bureau of Reclamation to mitigate the effects of drought.

Like the SWSI, the RDI is calculated at a river basin level, and it incorporates the supply components of precipitation, snowpack, streamflow, and reservoir levels. The RDI differs from the SWSI in that it builds a temperature-based demand component and a duration into the index. The RDI is adaptable to each particular region and its main strength is its ability to account for both climate and water supply factors.

Oklahoma has developed its own version of the RDI and plans to use the index as one tool within the monitoring system designated in the state's drought plan. The RDI values and severity designations are similar to the SPI, PDSI, and SWSI.

DECILES

Description: Groups monthly precipitation occurrences into deciles so that, by definition, "much lower than normal" weather cannot occur more often than 20% of the time.

Who Uses It: Australia.

Decile Classifications	
Deciles 1–2: lowest 20%	much below normal
Deciles 3–4: next lowest 20%	below normal
deciles 5–6: middle 20%	near normal
deciles 7–8: next highest 20%	above normal
deciles 9–10: highest 20%	much above normal

Pros: Provides an accurate statistical measurement of precipitation.
Cons: Accurate calculations require a long climatic data record.
Developed by: Gibbs and Maher, 1967.

Arranging monthly precipitation data into deciles is another drought-monitoring technique. It was developed by Gibbs and Maher (14) to avoid some of the weaknesses within the "percent of normal" approach. The technique they developed divided the distribution of occurrences over a long-term precipitation record into tenths of the distribution. They called each of these categories a *decile*. The first decile is the rainfall amount not exceeded by the lowest 10% of the precipitation occurrences. The second decile is the precipitation amount not exceeded by the lowest 20% of occurrences. These deciles continue until the rainfall amount identified by the tenth decile is the largest precipitation amount within the long-term record. By definition, the fifth decile is the median, and it is the precipitation amount not exceeded by 50% of the occurrences over the period of record. The deciles are grouped into five classifications.

The decile method was selected as the meteorological measurement of drought within the Australian Drought Watch System because it is relatively simple to calculate and requires less data and fewer assumptions than the Palmer Drought Severity Index (10). In this system, farmers and ranchers can only request government assistance if the drought is shown to be an event that occurs only once in 20–25 years (deciles 1 and 2 over a 100-year record) and has lasted longer than 12 months (15). This uniformity in drought classifications, unlike a system based on the percent of normal precipitation, has assisted Australian authorities in determining appropriate drought responses. One disadvantage of the decile system is that a long climatological record is needed to calculate the deciles accurately.

THE EARTH OBSERVING SYSTEM: AQUA

NASA—Goddard Space
Flight Center

EARTH SYSTEM SCIENCE

Beginning in the 1960s, NASA pioneered the study of the atmosphere from the unique perspective of space

---

with the launch of its Television Infrared Observation Satellite (TIROS-1). Thanks to new satellite and computer technologies, it is now possible to study the Earth as a global system. Through their research, scientists are better understanding and improving their forecasting of short-term weather phenomena.

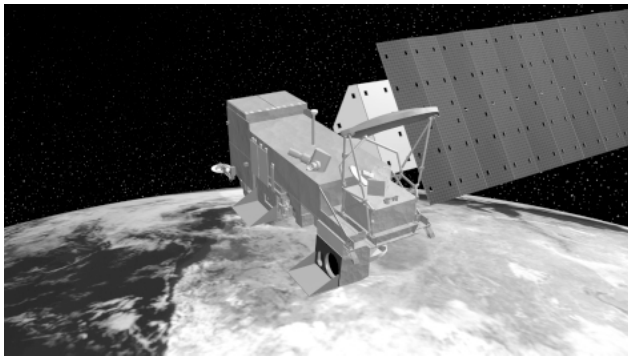
Long-term weather and climate prediction is a greater challenge that requires the collection of better data over longer periods. Since climate changes occur over vast ranges of space and time, their causes and effects are often difficult to measure and understand. Scientists must obtain long-term data if they are to reach a full understanding of the interactions among the Earth's physical and biological systems. NASA's Earth Observing System (EOS) will help us to understand the complex links among air, land, water and life within the Earth system.

WHAT IS AQUA?

NASA's commitment to studying the Earth as a global system continues with the Aqua spacecraft (originally called EOS PM-1), representing a key contribution by NASA to the U.S. Global Change Research Program. Aqua carries six state-of-the-art instruments to observe the Earth's oceans, atmosphere, land, ice and snow covers, and vegetation, providing high measurement accuracy, spatial detail, and temporal frequency. This comprehensive approach to data collection enables scientists to study the interactions among the four spheres of the Earth system—the oceans, land, atmosphere, and biosphere.

Aqua, Latin for "water," is named for the large amount of information that the Aqua spacecraft will collect about the Earth's water cycle. In particular, the Aqua data will include information on water vapor and clouds in the atmosphere, precipitation from the atmosphere, soil wetness on the land, glacial ice on the land, sea ice in the oceans, snow cover on both land and sea ice, and surface waters throughout the world's oceans, bays, and lakes. Such information will help scientists improve the quantification of the global water cycle and examine such issues as whether or not the cycling of water might be accelerating.

In addition to information about the water cycle, Aqua also provides information on many additional elements of the Earth system. For instance, Aqua enables studies of the fluxes of radiation from the Sun and from the Earth that combine to constitute the Earth's radiation balance. It also enables studies of small particles in the atmosphere termed "aerosols" and such trace gases in the atmosphere as ozone, carbon monoxide, and methane. The trace gases each have a potential contribution to global warming, whereas the aerosols are more likely to have a cooling effect. Aqua also provides observations on vegetation cover on the land, phytoplankton and dissolved organic matter in the oceans, and the temperatures of the air, land, and water. All of these measurements have the potential to contribute to improved understanding of the changes occurring in the global climate and the role of the interactions among the various elements of the climate system.



One of the most exciting of the potential practical benefits likely to derive from the Aqua data is improved weather forecasting. Aqua carries a sophisticated sounding system that allows determination of atmospheric temperatures around the world to an accuracy of 1° Celsius in 1-km-thick layers throughout the troposphere, the lowest portion of the atmosphere. The troposphere extends to an altitude of about 10–15 km, depending on location, and contains most of the global cloud cover. The anticipated 1° Celsius accuracy far exceeds current accuracies from satellite observations and, in conjunction with the moisture profiles also obtainable from the Aqua sounding system, offers the potential of improved weather fore-casting. NASA is working with the U.S. National Oceanic and Atmospheric Administration and the European Centre for Medium-Range Weather Forecasts to facilitate the incorporation of the Aqua data in their weather forecasting efforts.

INTERNATIONAL COLLABORATION

Aqua is a joint project of the United States, Japan, and Brazil.

THE SPACECRAFT

The spacecraft was designed and built by TRW in Redondo Beach, California. Aqua is based on TRW's modular, standardized AB1200 common spacecraft bus. This design features common subsystems scalable to the mission-specific needs of Aqua as well as future missions. Instrument payloads can be attached on a "mix and match" basis without changing the overall design or subsystem support requirements.

THE INSTRUMENTS

The Atmospheric Infrared Sounder (AIRS), built by BAE Systems, was provided by NASA's Jet Propulsion Laboratory in Pasadena, California. AIRS is the highlighted instrument in the AIRS/AMSU-A/HSB triplet centered on measuring humidity, temperature, cloud properties, and the amounts of greenhouse gases throughout the atmosphere. AIRS/AMSU-A/HSB will improve weather forecasting, establish the connection between severe weather and climate change, examine whether the global water cycle is accelerating, and detect the effects of greenhouse gases.

The Advanced Microwave Scanning Radiometer for EOS (AMSR-E), built by Mitsubishi Electronics Corporation, was provided by Japan's National Space Development Agency. AMSR-E measures precipitation rate, cloud water, water vapor, sea surface winds, sea surface temperature, ice, snow, and soil moisture.

The Advanced Microwave Sounding Unit (AMSU-A), built by Aerojet and provided by NASA's Goddard Space Flight Center (GSFC) in Greenbelt, Maryland, obtains temperature profiles in the upper atmosphere (especially the stratosphere) and will provide a cloud-filtering capability for tropospheric temperature observations. The EOS AMSU-A is part of the closely coupled AIRS/AMSU-A/HSB triplet.

The Clouds and the Earth's Radiant Energy System (CERES), built by TRW, was provided by NASA's Langley Research Center in Hampton, Virginia. This instrument measures the Earth's total thermal radiation budget, and, in combination with Moderate Resolution Imaging Spectro-radiometer (MODIS) data, provides detailed information about clouds. The first CERES instrument was launched on the Tropical Rainfall Measuring Mission (TRMM) satellite in November 1997; the second and third CERES instruments were launched on the Terra satellite in December 1999; and the fourth and fifth CERES instruments was on board the Aqua satellite launched in May 2002. The pairs of CERES on both Terra and Aqua satellites allow coincident measurements by one CERES scanning in lines perpendicular to the path of the satellite and by the other CERES scanning in lines at various angles with respect to the satellite's path.

The Humidity Sounder for Brazil (HSB), built by Matra-Marconi, was provided by Brazil's Instituto Nacional de Pesquisas Espaciais, the Brazilian Institute for Space Research. The HSB obtains humidity profiles throughout the atmosphere. The HSB is the instrument in the AIRS/AMSU-A/HSB suite that allows humidity measurements even under conditions of heavy cloudiness and haze.

MODIS, built by Raytheon Santa Barbara Remote Sensing, was provided by GSFC. MODIS is a 36-band spectroradiometer measuring visible and infrared radiation and obtaining data that is used to derive products ranging from vegetation, land surface cover, and ocean chlorophyll fluorescence, to cloud and aerosol properties, fire occurrence, snow cover on the land, and sea ice cover on the oceans. The first MODIS instrument was launched on board the Terra satellite.

Aqua was launched in May 2002 aboard a Delta 7920-10L launch vehicle from Vandenberg Air Force Base, California. The stowed spacecraft is 8.8 ft (2.68 m) × 8.2 ft (2.49 m) × 21.3 ft (6.49 m). Deployed, Aqua is 15.8 ft (4.81 m) × 54.8 ft (16.70 m) × 26.4 ft (8.04 m). The spacecraft, at launch, weighed 6784 lbs with a full propellant load of 508 lbs and is powered by 4.6 kilowatts of electric power from its solar array.

Aqua was launched into a circular 680-km orbit. Over a period of days after separation from the launch vehicle, it was commanded by the ground to raise its orbit to the prescribed 705-km (438-mile) orbit. This was necessary in order to allow for proper phasing of Aqua with other spacecraft in orbit and the polar ground stations used for communications. The spacecraft was ultimately be positioned in a near-polar (98°) orbit around the Earth in synchronization with the Sun, with its path over the ground ascending across the equator at the same local time every day, approximately 1:30 p.m. The early afternoon observation time contrasts with the 10:30–10:45 a.m. equatorial crossing time (descending in this case) of the Terra satellite. The two daytime crossing times account for why the Terra and Aqua satellites were originally named "EOS AM" and "EOS PM," respectively. The combination of morning and afternoon observations allows studies concerning the diurnal variability of many of the parameters discussed above.

MANAGEMENT

Overall management of the Aqua mission is located at GSFC, which is managing the integration and testing of the spacecraft. The Aqua data is processed, archived, and distributed using distributed components of the Earth Observing System Data and Information System (EOSDIS). EOSDIS also provides the mission operations systems that perform the functions of command and control of the spacecraft and the instruments. NASA's Kennedy Space Center is responsible for the launch operations, including Boeing's Delta launch vehicle and the prelaunch integrated processing facility. The U.S. Air Force is responsible for all range-related matters. GSFC manages EOS for NASA's Earth Science Enterprise (ESE), headquartered in Washington, DC.

DATA PROCESSING AND DISTRIBUTION

Aqua provides a major part of a 15-year environmental dataset focusing on global change. The Aqua instruments produce more than 750 gigabytes of data per day, which is equivalent to 75 personal computer hard disks at 10 gigabytes each per day. This massive amount of information is handled using EOSDIS, in addition to its present accumulation of nearly 3000 gigabytes per day.

EOSDIS provides the high-performance computing resources needed to process, store, and rapidly transmit terabytes (thousands of gigabytes) of the incoming data every day. EOSDIS has several distributed sites that perform these functions: Distributed Active Archive Centers (DAACs) that process, store and distribute the data, and Science Investigator-led Processing Systems that process the data and send them to the DAACs for storage and distribution. EOSDIS uses an "open" architecture to allow insertion of new technology while enabling the system to support the changing mission and science needs throughout the EOS Program.

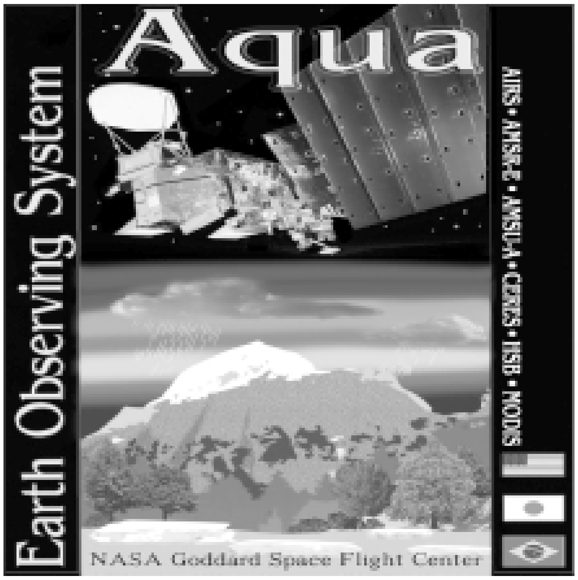
GOALS AND OBJECTIVES

NASA's ESE identified several high-priority measurements that EOS should make to facilitate a better understanding of the components of the Earth system—the atmosphere, the land, the oceans, the polar ice caps, and the global energy budget. The specific objectives of Aqua include:

- producing high-spectral resolution obtaining 1 K/ 1 km global root-mean-square temperature profile accuracy in the troposphere by 1 year after launch;
- extending the improved TRMM rainfall characterization to the extra tropics;
- producing global sea surface temperature daily maps under nearly all sky conditions for a minimum of 1 year;
- producing large-scale global soil moisture distribution for regions with low vegetation;
- producing calibrated global observations of the Earth's continents and ocean surfaces 150 days after the mission is declared operational;
- capturing and documenting three seasonal cycles of terrestrial and marine ecosystems and atmospheric and cloud properties;
- producing three sets of seasonal/annual Earth radiation budget records;
- producing improved measurements of the diurnal cycle of radiation by combining Aqua measurements with Terra measurements for months of overlap;
- producing combined cloud property and radiation balance data to allow improved studies of the role of clouds in the climate system; and,
- capturing, processing, archiving, and distributing Aqua data products, by 150 days after the mission is declared operational.

A NEW PERSPECTIVE

Complemented by Terra, aircraft and ground-based measurements, Aqua data enable scientists to distinguish between natural and human-induced changes. The EOS series of spacecraft are the cornerstone of NASA's ESE, a long-term research effort to study the Earth as a global environment.



More information on EOS and the science related to it can be found at the EOS Project Science Office website at http://eospso.gsfc.nasa.gov and at the Earth Observatory website at http://earthobservatory.nasa.gov. Further information on Aqua can be found at http://aqua.nasa.gov

ENTROPY THEORY FOR HYDROLOGIC MODELING

Vijay P. Singh
Louisiana State University
Baton Rouge, Louisiana

INTRODUCTION

Entropy theory has recently been employed in a broad range of applications in hydrology, and new applications continue to unfold. This paper revisits entropy theory and its application to hydrologic modeling.

Hydrologic systems are inherently spatial and complex, and our understanding of these systems is less than complete. Many of the systems are either fully stochastic or part stochastic and part deterministic. Their stochastic nature can be attributed to randomness in one or more of the following components that constitute them: (1) system structure (geometry), (2) system dynamics, (3) forcing functions (sources and sinks), and (4) initial and boundary conditions. As a result, a stochastic description of these systems is needed, and entropy theory enables the development of such a description.

Engineering decisions concerning hydrologic systems are frequently made with less than adequate information. Such decisions may often be based on experience, professional judgment, rules of thumb, crude analyses, safety factors, or probabilistic methods. Usually, decision-making under uncertainty tends to be relatively conservative. Quite often, sufficient data are not available to describe the random behavior of such systems. Although probabilistic methods allow for a more explicit and quantitative accounting of uncertainty, their major difficulty occurs due to the lack of sufficient or complete data. Small sample sizes and limited information render estimation of probability distributions of system variables by conventional methods difficult. This problem can be alleviated by using entropy theory that enables determining the least biased probability distributions based on limited knowledge and data. Where the shortage of data is widely rampant, as is normally the case in many countries, entropy theory is particularly appealing.

Since the development of entropy theory by Shannon in the late 1940s and of the principle of maximum entropy (POME) by Jaynes in the late 1950s, there has been a proliferation in applications of entropy. The real impetus to entropy-based modeling in hydrology was, however, provided in the early 1970s, a great variety of entropy-based applications have since been reported, and new applications continue to unfold. This article aims to revisit entropy theory and to underscore its usefulness for both modeling and decision-making in hydrology.

ENTROPY THEORY

Entropy theory is comprised of three main parts: (1) Shannon entropy, (2) the principle of maximum entropy, and (3) the principle of minimum cross entropy. Before discussing these parts, it will be instructive to discuss briefly the meaning of entropy.

Meaning of Entropy

Entropy originated in physics. It is an extensive property like mass, energy, volume, momentum, charge, or number of atoms of chemical species, but unlike these quantities, it does not obey a conservation law. The entropy of a system is an extensive property, so the total entropy of the system equals the sum of the entropies of individual parts. The most probable distribution of energy in a system is the one that corresponds to the maximum entropy of the system. This occurs under the condition of dynamic equilibrium. During evolution toward a stationary state, the rate of entropy production per unit mass should be minimum, compatible with external constraints. This is the Prigogin principle. In thermodynamics, entropy is decomposed into two parts: (1) entropy exchanged between the system and its surroundings and (2) entropy produced in the system. According to the second law of thermodynamics, the entropy of a closed and isolated system always tends to increase. In hydraulics, entropy is a measure of the amount of irrecoverable flow energy that the hydraulic system expands to overcome friction. The system converts a portion of its mechanical energy to heat energy which then is dissipated to the external environment. Thus, the process equation in hydraulics expressing the energy (or head) loss, it can be argued, originates in the entropy concept.

Entropy has been employed in thermodynamics as a measure of the degree of ignorance about the true state of a system. If there were no energy loss in a hydraulic system, the system would be orderly and organized. The energy loss and its causes make the system disorderly and chaotic. Thus, entropy can be interpreted as a measure of the amount of chaos within a system. Algebraically, it is proportional to the logarithm of the probability of the state of the system. The constant of proportionality is the Boltzmann constant, and this defines Boltzmann entropy.

Shannon Entropy

Shannon (1) developed the entropy theory for expressing information or uncertainty. To understand the informational aspect of entropy, we perform an experiment on a random variable X. There may be n possible outcomes $x_1, x_2, \ldots, x_n$, whose probabilities are $p_1, p_2, \ldots, p_n$; $P(X = x_1) = p_1, P(X = x_2) = p_2, \ldots, P(X = x_n) = p_n$. These outcomes can be described by

$$P(X) = (p_1, p_2, \ldots, p_n); \ \sum_{i}^{n} p_i = 1; p_i \geq 0, i = 1, 2, \ldots, n \tag{1}$$

If this experiment is repeated, the same outcome is not likely, implying that there is uncertainty as to the outcome of the experiment. Based on one's knowledge about the outcomes, the uncertainty can be more or less. For example, the total number of outcomes is a piece of information, and the number of those outcomes of nonzero probability is another piece of information. The probability distribution of the outcomes, if known, provides a certain amount of information. Shannon (1) defined a quantitative measure of uncertainty associated with a probability distribution or the information content of the distribution in terms of entropy, $H(P)$ or $H(X)$, called Shannon entropy or informational entropy as

$$H(X) = H(P) = -\sum_{i=1}^{n} p_i \ln p_i = E[-\ln p] \tag{2}$$

If the random variable X is continuous, then Shannon entropy is expressed as

$$\begin{aligned} H(X) &= -\int_0^{\infty} f(x) \ln[f(x)]\, dx \\ &= -\int \ln[f(x)]\, dF(x) = E[-\ln f(x)] \end{aligned} \tag{3}$$

where $f(x)$ is the probability density function (PDF) of X, $F(x)$ is the cumulative probability distribution function of X, and E [.] is the expectation of [.].

Thus, entropy is a measure of the amount of uncertainty represented by the probability distribution and is a measure of the amount of chaos or of the lack of information about a system. If complete information is available, entropy = 0; otherwise, it is greater than zero. The uncertainty can be quantified using entropy by taking into account all different kinds of available information. Shannon entropy is the weighted Boltzmann entropy.

Principle of Maximum Entropy

In search of an appropriate probability distribution for a given random variable, entropy should be maximized. In practice, however, it is common that some information about the random variable is available. The chosen probability distribution should then be consistent with the given information. There can be more than one distribution consistent with the given information. From all such distributions, we should choose the distribution that has the highest entropy. To that end, Jaynes (2) formulated the principle of maximum entropy (POME), a full account of it is presented in a treatise by Levine and Tribus (3). According to POME, the minimally prejudiced assignment of probabilities is that which maximizes entropy subject to the given information, that is, POME takes into account all of the given information and at the same time avoids considering of any information that is not given.

If no information about the random variable is available, then all outcomes are equally likely, that is, $p_i = 1/n$, $i = 1, 2, 3, \ldots, n$. It can be shown that Shannon entropy is maximum in this case and may serve as an upper bound of entropy for all cases involving some information. In a more general case, let the information available about P or X be

$$p_i \geq 0, \sum_{i=1}^{n} p_i = 1 \tag{4}$$

and

$$\sum_{i=1}^{n} g_r(x_i) p_i = a_r \quad r = 1, 2, \ldots, m \tag{5}$$

where m is the number of constraints, $m + 1 \leq n$ and g_r is the rth constraint. Equations 4 and 5 are not sufficient to determine P uniquely. Therefore, there can be many distributions that satisfy Eqs. 4 and 5. According to POME, there will be only one distribution that will correspond to the maximum value of entropy, and this distribution can be determined using the method of Lagrange multipliers which will have the following form:

$$p_i = \exp[-\lambda_0 - \lambda_1 g_1(x_i) - \lambda_2 g_2(x_i) \ldots - \lambda_m g_m(x_i)] \quad i = 1, 2, \ldots, n \tag{6}$$

where λ_i, $i = 0, 1, 2, \ldots, m$, are Lagrange multipliers that are determined by using the information specified by Eqs. 4 and 5.

Because the POME-based distribution is favored over those with less entropy among those that satisfy the given constraints, according to Shannon entropy as an information measure, entropy defines a kind of measure on the space of probability distributions. Intuitively, distributions of higher entropy represent more disorder, are smoother, are more probable, are less predictable, or assume less. The POME-based distribution is maximally noncommittal with regard to missing information and does not require invoking ergodic hypotheses.

Principle of Minimum Cross Entropy

According to Laplace's principle of insufficient reason, all outcomes of an experiment should be considered equally likely, unless there is information to the contrary. On the basis of intuition, experience, or theory, a random variable may have an a priori probability distribution. Then, Shannon entropy is maximum when the probability distribution of the random variable is one which is as close to the a priori distribution as possible. This is called the principle of minimum cross entropy (POMCE) which minimizes Bayesian entropy (4). This is equivalent to maximizing Shannon entropy.

To explain POMCE, let us suppose that we guess a probability distribution for a random variable x as $Q = \{q_1, q_2, \ldots, q_n\}$ based on intuition, experience, or theory. This constitutes the prior information in the form of a prior distribution. To verify our guess, we take some observations $X = (x_1, x_2, \ldots, x_n)$ and compute some moments of the distribution. To derive the distribution $P = \{p_1, p_2, \ldots, p_n\}$ of X, we take all the given information and make the distribution as near to our intuition and experience as possible. Thus, POMCE is expressed as

$$D(P, Q) = \sum_{i=1}^{n} p_i \ln \frac{p_i}{q_i} \tag{7}$$

where the cross entropy D is minimized. If no a priori distribution is available and if, according to Laplace's principle of insufficient reason, Q is chosen as a uniform distribution U, then Eq. 7 takes the form

$$D(P, U) = \sum_{i=1}^{n} p_i \ln \left[\frac{p_i}{1/n}\right] = \ln n \left(\sum_{i=1}^{n} p_i \ln p_i\right) \tag{8}$$

Hence, minimizing $D(P, U)$ is equivalent to maximizing Shannon entropy. Because D is a convex function, its local minimum is its global minimum. Thus, a posterior distribution P is obtained by combining a prior Q with the specified constraints. The distribution P minimizes the cross (or relative) entropy with respect to Q, defined by Eq. 7, where the entropy of Q is defined as in Eq. 2. Cross-entropy minimization results asymptotically from Bayes' theorem.

JOINT ENTROPY, CONDITIONAL ENTROPY, AND TRANSINFORMATION

If there are two random variables X and Y whose probability distributions are $P(x) = \{p_1, p_2, \ldots, p_n\}$ and $Q(y) = \{q_1, q_2, \ldots, q_n\}$, which are independent, then Shannon entropy of the joint distribution of X and Y is the sum of the entropies of the marginal distributions expressed as

$$H(P, Q) = H(X, Y) = H(P) + H(Q) = H(X) + H(Y) \tag{9}$$

If the two random variables are dependent, then Shannon entropy of the joint distribution is the sum of the marginal entropy of one variable and the conditional entropy of the other variable conditioned on the realization of the first. Expressed algebraically,

$$H(X, Y) = H(X) + H(Y \mid X) \tag{10}$$

where $H(Y|X)$ is the conditional entropy of Y conditioned on X. The conditional entropy can be defined as

$$H(X|Y) = -\sum_{i=1}^{n} \sum_{j=1}^{m} p(x_i, y_j) \ln(p(x_i \mid y_j) \tag{11}$$

It is seen that if X and Y are independent, then Eq. 10 reduces to Eq. 9. Furthermore, the joint entropy of dependent X and Y will be less than or equal to the joint entropy of independent X and Y, that is, $H(X, Y) \leq H(X) + H(Y)$. The difference between these two entropies defines transinformation $T(X, Y)$ or $T(P, Q)$ expressed as

$$T(X, Y) = H(X) + H(Y) - H(X, Y) \tag{12}$$

Transinformation represents the amount of information common to both X and Y. If X and Y are independent, $T(X, Y) = 0$. Substitution of Eq. 10 in Eq. 12 yields

$$T(X, Y) = H(Y) - H(Y|X) \tag{13}$$

Equation 13 states that stochastic dependence reduces the entropy of Y.

ENTROPY AS A MODELING TOOL

Although entropy theory has been applied in recent years to a variety of problems in hydrology, its potential as a decision-making tool has not been fully exploited. A brief discussion follows highlighting this potential. Fundamental to the concepts presented below is the need for probability distributions that can be derived by using entropy theory.

Information Content of Data

One frequently encounters a situation in which one exercises freedom of choice, evaluates uncertainty, or measures information gain or loss. The freedom of choice, uncertainty, disorder, information content, or information gain or loss has been variously measured by relative entropy, redundancy, and conditional and joint entropies employing conditional and joint probabilities. As an example, in the analysis of empirical data, the variance has often been interpreted as a measure of uncertainty and as revealing gain or loss in information. However, entropy is another measure of dispersion—an alternative to variance. This suggests that it is possible to determine the variance whenever it is possible to determine entropy measures, but the reverse is not necessarily true. However, variance is not the appropriate measure if the sample size is small.

To measure correlation or dependence between any two variables, an informational coefficient of correlation r_0 is defined as a function of transinformation, T_0, as

$$r_0 = [1 - \exp(-2T_0)]^{0.5} \tag{14}$$

The transinformation, given by Eq. 14, expresses the upper limit of common information between two variables and represents the level of dependence (or association) between the variables. It represents the upper limit of transferable information between the variables, and its measure is given by r_0. The ordinary correlation coefficient r measures the amount of information transferred between variables under specified assumptions, such as linearity and normality. An inference similar to that of the ordinary correlation coefficient, r, can be drawn by defining the amount (in percent) of transferred information by the ratio T/T_0, where T can be computed in terms of ordinary r.

Criteria for Model Selection

Usually, there are more models than one needs, and so a model has to be chosen. Akaike (5) formulated a criterion, called the Akaike information criterion (AIC), for selecting the best model from amongst several models as

$$\mathrm{AIC} = 2\log(\text{maximized likelihood}) + 2k \tag{15}$$

AIC provides a method of model identification and can be expressed as minus twice the logarithm of the maximum likelihood plus twice the number of parameters used to find the best model. The maximum likelihood and entropy are uniquely related. When there are several models, the model that gives the minimum value of AIC should be selected. When the maximum likelihood is identical for two models, the model that has the smaller number of parameters should be selected, for that will lead to a smaller AIC and comply with the principle of parsimony.

Hypothesis Testing

Another important application of entropy theory is testing of hypotheses (6). By using Bayes' theorem in logarithmic form, an evidence function is defined for comparing two hypotheses. The evidence in favor of a hypothesis over its competitor is the difference between the respective entropies of the competition and the hypothesis under test. Defining surprisal as the negative of the logarithm of the probability, the mean surprisal for a set of observations is expressed. Therefore, the evidence function for two hypotheses is obtained as the difference between the two values of the mean surprisal multiplied by the number of observations.

Risk Assessment

In common language, risk is the possibility of loss or injury and the degree of probability of such loss. Rational decision-making requires a clear and quantitative way of expressing risk. In general, risk cannot be avoided, and a choice has to be made between risks. There are different types of risk, such as business risk, social risk, economic risk, safety risk, investment risk, and occupational risk. To put risk in proper perspective, it is useful to clarify the distinction between risk, uncertainty, and hazard.

The notion of risk involves both uncertainty and some kind of loss or damage. Uncertainty reflects the variability of our state of knowledge or state of confidence in a prior evaluation. Thus, risk is the sum of uncertainty plus damage. Hazard is commonly defined as a source of danger that involves a scenario identification (e.g., failure of a dam) and a measure of the consequence of that scenario or a measure of the ensuing damage. Risk encompasses the likelihood of converting that source into the actual delivery of loss, injury, or some form of damage. Thus, risk is the ratio of hazard to safeguards. By increasing safeguards, risk can be reduced, but it is never zero. Awareness of risk reduces risk, so awareness is part of safeguards. Qualitatively, risk is subjective and is relative to the observer. Risk involves the probability of a scenario and its consequence resulting from the occurrence of the scenario. Thus, one can say that risk is probability and consequence. Kaplan and Garrick (7) analyzed risk using entropy.

HYDROLOGIC MODELING USING ENTROPY THEORY

A historical perspective on entropy applications in environmental and water resources is given in Singh and Fiorentino (8) and Singh (9). Harmancioglu and Singh (10) discussed the use of entropy in water resources. A brief synopsis of entropy-based applications follows.

Derivation of Probability Distributions

Frequency distributions that satisfy the given information are often needed. Entropy theory is ideally suited to that end. POME has been employed to derive a variety of distributions; some have found wide applications in environmental and water resources. Many of these distributions have been summarized in Singh and Fiorentino (8) and by Singh (9). Let $p(x)$ be the probability distribution of X that is to be determined. The information on X is available in terms of constraints given by Eq. 2. Then, the entropy-based distribution is given by Eq. 6. Substitution of Eq. 5 in Eq. 2 yields

$$\exp(\lambda_0) = Z = \sum_{i=1}^{n} \exp\left[-\sum_{j=1}^{m} \lambda_j g_j(x_i) \right] \tag{16}$$

where Z is called the partition function and λ_0 is the zeroth Lagrange multiplier. The Lagrange parameters are obtained by differentiating Eq. 16 with respect to the Lagrange multipliers:

$$\begin{aligned} \frac{\partial \lambda_0}{\partial \lambda_j} &= -a_j = E[g_j], \quad j = 1, 2, 3, \ldots, m \\ \frac{\partial^2 \lambda_0}{\partial \lambda_j^2} &= \mathrm{Var}[g_j] \\ \frac{\partial^2 \lambda_0}{\partial \lambda_j \partial \lambda_k} &= \mathrm{Cov}[g_j, g_k] \\ \frac{\partial^3 \lambda_0}{\partial \lambda_j^3} &= -\mu_3[g_j] \end{aligned} \tag{17}$$

where E[.] is the expectation, Var [.] is the variance, Cov [.] is the covariance, and is the third moment about the centroid, all for g_j.

When there are no constraints, then POME yields a uniform distribution. As more constraints are introduced, the distribution becomes more peaked and possibly skewed. In this way, entropy reduces from a maximum for the uniform distribution to zero when the system is fully deterministic.

Parameter Estimation

It is desirable to estimate parameters of a distribution in terms of the given constraints. Entropy theory accomplishes precisely that. Singh (11) described POME-based estimation for a number of probability distributions used in hydrology and environmental and water resources. He also discussed a comparison of the POME-based method with the methods of moments, maximum likelihood estimation, and some others. The comparison shows that the POME-based method is comparable to some methods and is better than others.

Entropy-Spectral Analysis for Flow Forecasting

Maximum entropy spectral analysis (MESA) was introduced by Burg (12). It has several advantages over conventional spectral analysis methods. It has short and smooth spectra that have high-degree resolutions (13). The statistical characteristics that are used in stochastic model identification can also be estimated using MESA, thus permitting integration of spectral analysis and computations related to stochastic model development. Ulrych and Clayton (14) reviewed the principles of MESA and the closely related problem of autoregressive time series modeling. Shore (15) presented a comprehensive discussion of minimum cross-entropy spectral analysis.

The relationship between spectrum $W(f)$ with frequency f of a stationary process $x(t)$ and entropy $H(f)$ can be expressed as

$$H(f) = \frac{1}{2}\ln(2\,w) + \frac{1}{4\,w}\int_{w}^{+w} \ln[W(f)]\,df \tag{18}$$

where w is the frequency band. Equation 18 is maximized subject to the constraint equations given as autocorrelations until log m:

$$\rho(n) = \int_{w}^{+w} W(f)\exp(i_2\pi f n \Delta t)\,df, \qquad m \le n \le +m \tag{19}$$

where Δt is the sampling time interval and $i = (-1)^{1/2}$. Maximization of Eq. 19 is equivalent to maximizing

$$H(f) = \int_{w}^{+w} \ln[W(f)]\,df \tag{20}$$

which is known as Burg entropy. The spectrum $W(f)$ can be expressed in terms of the Fourier series as

$$W(f) = \frac{1}{2\,w}\sum_{n=\infty}^{\infty} \rho(n)\exp(i2\pi n f \Delta t) \tag{21}$$

Substituting Eq. 21 in Eq. 20 and maximizing lead to MESA.

Jaynes (16) has shown that MESA and other methods of spectral analysis, such as Schuster, Blackman–Tukey, maximum likelihood, Bayesian, and autoregressive (AR, ARMA, or ARIMA) models are not in conflict and that AR models are a special case of MESA. Krstanovic and Singh (17,18) employed MESA for long-term stream flow forecasting. Krstanovic and Singh (19,20) extended the MESA method to develop a real-time flood forecasting model. Padmanabhan and Rao (21,22) applied MESA to analyze rainfall and river flow time series. Rao et al. (23) compared a number of spectral analysis methods with MESA and found that MESA is superior. Eilbert and Christensen (24) analyzed annual hydrologic forecasts for central California and found that dry years might be more predictable than wet years. Dalezios and Tyraskis (25) employed MESA to analyze multiple precipitation time series.

Regional Precipitation Analysis and Forecasting

The Burg algorithm or MESA can be applied to identify and interpret multistation precipitation data sets and to explore spectral features that lead to a better understanding of rainfall structure in space and time (25).

Then, multistation rainfall time series can be extrapolated to develop regional forecasting capabilities.

Grouping of River Flow Regimes

An objective grouping of flow regimes into regime types can be employed as a diagnostic tool for interpreting the results of climate models and flow sensitivity analyses. By minimizing an entropy-based objective function (such as minimum cross entropy), a hierarchical aggregation of monthly flow series into flow regime types can, therefore, be effectively performed, which will satisfy chosen discriminating criteria. Such an approach was developed by Krasovskaia (26) who applied it to a regional river flow sample for Scandinavia for two different formulations of discriminating criteria.

Basin Geomorphology

Entropy plays a fundamental role in characterizing landscape. Using entropy theory for the morphological analysis of river basin networks, Fiorentino et al. (27) found that the connection between entropy and the mean basin elevation is linearly related to basin entropy. Similarly, the relation between the fall in elevation from the source to the outlet of the main channel and the entropy of its drainage basin, it was found, is linear and so also was the case between the elevation of a node and the logarithm of its distance from the source. When a basin was ordered following the Horton–Strahler ordering scheme, a linear relation was found between drainage basin entropy and basin order. This relation can be characterized as a measure of basin network complexity. Basin entropy, it was also found, is linearly related to the logarithm of the magnitude of the basin network. This relation led to a nonlinear relation between the network diameter and magnitude where the exponent, it was found, is related to the fractal dimension of the drainage network.

Design of Hydrologic Networks

The purpose of measurement networks is to gather information in terms of data. Fundamental to evaluating these networks is the ability to determine if the networks are gathering the needed information optimally. Entropy theory is a natural tool for that determination. Krstanovic and Singh (28,29) employed the theory for space and time evaluation of rainfall networks in Louisiana. The decision whether to keep or to eliminate a rain-gauge was based entirely on the reduction or gain of information at that gauge. Yang and Burn (30) employed a measure of information flow, called directional information transfer index (DIT), between gauging stations in the network. The value of DIT varies from zero, where no information is transmitted and the stations are independent, to one where no information is lost and the stations are fully dependent. Between two stations of one pair, the station that has the higher DIT value should be retained because of its greater capability of inferring information at the other side.

Rating Curve

Moramarco and Singh (31) employed entropy theory to develop a method for reconstructing the discharge hydrograph at a river section where only water level is monitored and discharge is recorded at another upstream section. The method, which is based on the assumption that lateral inflows are negligible, has two parameters linked to remotely observed discharge and permits, without using a flood routing procedure and without the need of a rating curve at a local site, relating the local river stage to the hydraulic condition at a remote upstream section.

CONCLUDING REMARKS

Entropy theory permits determining of the least biased probability distribution of a random variable, subject to the available information. It suggests whether or not the available information is adequate and, if not, then additional information should be sought. In this way, it brings the model, the modeler, and the decision-maker closer. As an objective measure of information or uncertainty, entropy theory allows communicating with nature, as illustrated by its application to the design of data acquisition systems, the design of environmental and hydrologic networks, and the assessment of the reliability of these systems or networks. In a similar vein, it helps better understand the physics or science of natural systems, such as landscape evolution, geomorphology, and hydrodynamics. A wide variety of seemingly disparate or dissimilar problems can be meaningfully solved by using entropy.

EVAPORATION

THEODORE A. ENDRENY
SUNY-ESF
Syracuse, New York

Evaporation of water is a solar energy driven phase change from liquid to vapor that maintains the hydrologic cycle by transferring liquid water at the earth's surface to water vapor in the atmosphere, where it may lift, condense, and precipitate to earth as liquid water. In this discussion, evaporation is defined to include the closely associated transpiration process as a subcategory. The coupled processes are often called as evapotranspiration, or ET, where transpiration focuses on the transport of liquid water through the plant roots, stem, and leaf prior to evaporation through the leave's stomata. Further, when the discussion does not make a clear distinction between potential and actual evaporation, potential should be assumed. Potential evaporation refers to the amount of water that available energy and diffusion processes can transfer into atmospheric vapor, which is typically greater then the amount actually transferred due to limits on soil water volumes and resistances in the path.

PHYSICAL CONTROLS ON EVAPORATION

Evaporation is effectively a two-step process that first, requires that water changes phase to a vapor state and second, requires that the vapor is transported by advection and/or diffusion into unsaturated air. The phase change alone does not completely satisfy the requirement for evaporation when dynamic equilibrium exists at the boundary between liquid and vapor and condensation of the vapor saturated air returns liquid water to the surface to maintain no net water loss. Transport, therefore, ensures removal of the water vapor and a net loss of heat and mass from the liquid surface. In the vapor state, evaporated water is invisible to the human eye, which detects wavelengths between 0.4 and 0.7 μm, but is detectable in other areas of the electromagnetic spectrum. As such, though clouds are derived from and contain evaporated water, they are not vapor and instead reveal condensed water droplets that geometrically scatter light.

The first step in changing the phase of water from liquid to vapor requires an input of solar energy, which is stored at the surface and supports nighttime evaporation. Nearly 52% of solar energy absorbed at the earth's surface is used for vaporization. This energy is called latent heat of vaporization, or λ, and is a function of water temperature. When the phase changes directly from frozen water to vapor, known as sublimation, a greater amount of energy is required. Phase changes require energy to separate the hydrogen bond based, attractive intermolecular forces holding water molecules in an organized pattern and close proximity. Latent heat is a name that suggests dormant, or invisible, and is used to indicate that, unlike the measurable effect of sensible heat on air temperature, the solar energy used in evaporation remains ‘hidden’ from thermometer measurement.

As an example, at the standard pressure of 1013.3 milibar (mb), heating liquid water from 0 to 100 °C requires 4186.8 joules (J) of heat per kilogram of water per degree C temperature change and is detectable with a thermometer. In contrast, the latent heat of vaporization converting 100 °C water into 100 °C vapor does not have a measurable impact on water temperature. The latent heat, in megajoules per kilogram ($\mathrm{MJ\,kg^{-1}}$), required per °C of water temperature, T, is given as

$$\lambda = 2.501 - 0.002361 \cdot T$$

It is apparent that the majority of heat input to evaporate water, whether at 0 °C or 99 °C, is that for the phase change. A relatively constant 1350 $\mathrm{Js^{-1}\,m^{-2}}$ stream of solar energy entering the earth’s upper atmosphere provides energy to evaporate water just like a stove can boil and evaporate water. When 50% of this solar constant strikes the earth’s surface after atmospheric attenuation (e.g., scattering and reflection), it requires approximately 1 hour and 10 minutes to generate the latent heat needed to evaporate 1 kg of water at 20 °C.

Latent heat, though not detectable as affecting air temperature, is stored with the vapor in greater vibrational, rotational, and translational movement of vapor molecules. The removal of this vapor from the liquid, therefore, causes a measurable loss of energy and temperature from the remaining liquid, producing a cooling effect. A familiar example of this process is that wet skin, from sweat or a shower, cools faster in moving rather than still air because the wind speeds evaporation that takes heat from the body. Knowing that heat is used for evaporation, it is now clear that a covered pot will boil faster than a counterpart uncovered pot do to a lower loss of heat to the net evaporation of water. Heat stored in vapor is later released back into the environment when the vapor vibrational speeds slow, and it condenses into water, called latent heat of condensation. When vapor passes directly to solid frozen water, called deposition, a greater amount of heat stored in rotational, vibrational, and translational molecular movement is released into the environment.

The second physical step in evaporation is transport by advection and/or diffusion, which provides the net movement of water molecules from the liquid water surface of soil, plants, or lakes to atmospheric vapor. Vapor and wind gradients exert the principal controls on removal of water vapor beyond the saturated layer of air that maintains condensation–evaporation equilibrium dynamics. Fundamental barriers to transport beyond the layer of dynamic equilibrium include stagnant air and saturated air above the evaporating surface, conditions readily created within and at the surface of soil and plant systems. Net evaporation therefore increases with steeper wind and saturation gradients, which are defined as the change in wind or saturation with distance above the evaporating surface. Work on fluid velocity and turbulence gradients in the mid-1900s by Prandtl and von Karman has been used to estimate momentum, sensible heat, and vapor transport from wind speed measurements.

Estimates of atmospheric wind and vapor conditions above the evaporating surface provide important data for estimating wind and saturation gradients and predicting barriers to vapor transport and net evaporation. Meteorological stations are frequently equipped with anemometers and thermometers at 2 meters (m) above the ground surface to help establish the wind and vapor gradients controlling evaporation. Wind profiles, it is assumed, begin with stagnant air at the no-slip boundary, or zero-plane displacement height, and increase logarithmically. In a landscape broken by tree canopies, a 2 m wind measurement may be inadequate to represent observations. Research has shown that dynamic turbulence and eddies created by such forested heterogeneity result in increased wind and evaporation rates that exceed the estimated atmospheric potential.

Based on Dalton’s work on individual pressures of multiple atmospheric gases summing to the observed atmospheric pressure, vapor is often reported as a partial pressure and can be derived from measurements of temperature. In the following equation, vapor pressure is reported in kilopascals (kPa) and temperature in °C. Initially dry warm air can absorb more water than initially dry cold air before reaching saturation.

$$e = 0.6108 \exp\left(\frac{17.27\,T}{237.3 + T}\right)$$

The dry-bulb temperature is used to estimate the total amount of vapor the air could absorb prior to saturation; the dew point temperature represents the temperature to which the air must cool for total saturation. When the dry-bulb and dew point temperatures are equal, the air is fully saturated. The ratio of actual to saturated vapor pressures is the relative humidity. The dew point temperature is estimated by using a psychrometer that measures the difference between dry-bulb and wet-bulb thermometers, called the wet-bulb depression, together with lookup tables relating wet-bulb depression to dew point temperature. The dry-bulb is a normal thermometer measuring air temperature, but a moist piece of cloth typically covers the wet-bulb, and evaporation of the water from the cloth causes the temperature to drop. Chilled mirrors hygrometers, hair hygrometers, and vapor pressure sensors are also used to detect the vapor content in the air.

EVAPORATION MEASUREMENT AND ESTIMATION

Evaporation is fundamental to both energy and water balances, yet despite the importance of evaporation to hydrologic assessment of the paths, quantities, and quality of water in the lithosphere, biosphere, and atmosphere, the complexity of the process has prevented easy or exact techniques for measuring and estimating it. The relative accuracy of yearly river basin evaporation estimates is high, as the estimate time frame and spatial area become smaller, but the simple application of energy and water balance models to solve for evaporation becomes less tractable. A variety of measurement and estimation techniques have been developed for these smaller scales, such as hourly, daily, and monthly evaporation from reservoirs, farm fields, and single plants.

In general, evaporative fluxes from the land surface are more difficult to measure than from open water, given that an immeasurable number of irregular, tiny and unique soil and leaf surfaces are involved in this phase change and that suction gradients draw water to this evaporating interface from unobserved reserves of unknown volume. Fluxes from open water, though relatively homogeneous, still provide challenges when subsurface inflows and outflows are poorly understood and significant and wind and water advected energy influencing evaporation is heterogeneously distributed. Hence, the numerous methods developed for estimating evaporation are categorized based on the type of surface, availability of water, and the importance of stored energy, water-advected energy, and air-advected energy.

Actual evaporation can be measured by using a water balance approach, a turbulent-transfer approach, a potential evaporation approach, or a water quality approach. The water balance approach can function with measurements of a mass balance being kept for a water pan, such as a the Class-A Pan of the National Weather Service, a soil and plant system, such as in a weighing lysimeter, or of a small, enclosed atmosphere. Turbulent-transfer methods, which derive evaporation from estimates of momentum or heat flux, can provide estimates for larger heterogeneous areas, but assume that the air sampled by the field instrumentation used for the Bowen ratio or eddy-correlation method is well mixed to represent the upwind land area by a given fetch. Water quality methods include techniques that track concentrations of dissolved solids, which enrich when evaporation removes the water solvent, and isotope tracer studies that show heavier isotopes are enriched by preferred evaporation of lighter isotopes. Sap flow monitoring in trees provides another technique to measure the flux of water from the ground to the atmosphere.

Mathematical estimates of evaporation rates have been approached by using an equally wide variety of techniques and include temperature-based, aerodynamic-based, radiation-based, and combination-based methods. Temperature-based methods, such as the monthly time-step Thornthwaite equation, use air temperature and length of day, as well as an assumed humidity, to compute the potential evaporation, and they have been adapted to suit several different climates and regions. Aerodynamic methods assume that solar radiation is not limiting and consider only wind speed and turbulence as controls on the transport of water vapor away from the surface. Radiation-based methods likewise assume that wind turbulence and eddies are not limiting and use measured incoming radiation and the latent heat of vaporization to compute evaporation flux. A popular form of this equation is the Priestly–Taylor, which increased it by a factor of 30% to account for added aerodynamic transfer. The combination method, known most extensively for the Penman–Monteith equation, uses air temperature, net radiation, wind speed, and relative humidity vapor gradients to derive minute by minute and daily evaporation rates.

HYDROLOGIC IMPACTS OF EVAPORATION

Observations of terrestrial river discharge reveal that more water precipitates on land than evaporates from land and that more water evaporates from oceans than precipitates on oceans. Precipitation totals may vary from year to year, but evaporative demands are rather steady, which creates a greater relative fluctuation in river discharge than in precipitation. This is illustrated by considering a 20% decrease in annual precipitation from 100 to 80 cm, where 50 cm went to evaporation in both years, and discharge dropped by 40% from 50 to 30 cm. Evaporation and its impact on liquid and vapor water volumes and the partitioning of solar energy into latent and sensible heat create and maintain a range of climatic conditions, from microclimates on the scale of a tree canopy to macroclimates that describe the global distribution of plants.

The volume of water evaporated from the ocean and land surface is greatest at the meteorological equator, or intertropical convergence zone (ITCZ), and smallest at the poles, which is the result of a similar longitudinal distribution of insolation intensity. Sinking Hadley cell air at the 30° latitude belts, which warms to absorb greater amounts of water vapor, is the cause of a belt of deserts in this region. The distribution of incoming solar radiation, which is greatest at the equator and smallest at the poles, is the driving force explaining the meridional (across lines of latitude) distribution of evaporation. Wind transport of this evaporated vapor from the equatorial region to the midlatitudes and poles, where latent energy is released to the atmosphere as sensible heat during condensation, is one of only a few processes that help to maintain the earth's energy balance.

Global water balance numbers reveal that a relatively small volume of evaporated vapor resides in the atmosphere. The earth's atmosphere has a volume of 12,900 km^3, and contains just 0.001% of all global water. As evaporated vapor, it receives 71,000 $\text{km}^3\,\text{yr}^{-1}$ from land, 1000 $\text{km}^3\,\text{yr}^{-1}$ from lakes, and 505,000 $\text{km}^3\,\text{yr}^{-1}$ from oceans, and this flux rate into its total volume equals a residence time of 8.2 days, or just over a week before evaporated water precipitates. The atmospheric vapor precipitates at a volumetric rate of 577 $\text{km}^3\,\text{yr}^{-1}$, of which 119,000 $\text{km}^3\,\text{yr}^{-1}$ falls on land. Observation and estimation of river discharge at 47,000 $\text{km}^3\,\text{yr}^{-1}$ was used to deduce the amount evaporated from land, which is 61%

Table 1. Continental Average Estimated Evaporation

Continent	Area, km^2	Evaporation, $\text{mm}\,\text{yr}^{-1}$	Evaporation, %
Antarctica	14,100,000	28	17
Europe	10,000,000	375	57
Asia	44,100,000	420	60
South America	17,900,000	946	60
North America	24,100,000	403	62
Africa	29,800,000	582	84
Australia	7,600,000	420	94
Total Land	148,900,000	480	64

Table 2. Average Estimated Evaporation Based on Studies of Precipitation and Runoff

Watershed by River Name	Continent [Nation(s)]	Basin Size, km^2	Evaporation^a, %
Brahmaputra	Asia (Tibet/Bangladesh)	589,000	35
Irrawaddy	Asia (Burma)	431,000	40
Yangtzekiang	Asia (China)	1,970,000	50
Amazon	South America (six nations)	7,180,000	53
Orinoco	South America (Venezuela)	1,086,000	54
Lena	Asia (Russia)	2,430,000	54
Mekong	Asia (China)	795,000	57
Yenesei	Asia (Russia)	2,599,000	58
Ganges	Asia (China)	1,073,000	58
Saint Lawrence	North America (Canada, U.S.)	1,030,000	67
Amur	Asia (Russia)	1,843,000	68
Congo	Africa (7 nations)	3,822,000	75
Ob	Asia (Russia)	2,950,000	76
Mississippi	North America (U.S.)	3,224,000	79
La Plata	South America (five nations)	2,650,000	80
Average	–	2,224,800	60

[a] Evaporation may include basin transfers because it was not directly measured but derived from precipitation and runoff measurements.

evaporating, and this differs from the continental average of 64% reported in Table 1.

For the continental United States, which contains deserts in Arizona and rain forests in Washington, the average annual percentage of precipitation converted to evaporation is approximately 62%. This value is similar to global patterns but varies considerably from that measured on other continents (see Table 1) and larger watersheds (see Table 2).

The agricultural impact of evaporation is both the cause of nutrient uptake and growth in plants, as well as the loss of soil water and plant stress. Maintenance of optimal water levels in the soil, called field capacity, when gravitational water has drained, is the goal of many irrigation projects. If irrigation causes evaporation to exceed local precipitation, then salts will be drawn to the soil surface, which often creates osmotic gradients at the root interface that kill the agricultural crop. Agricultural irrigation to satisfy the high evaporation demand of sunny agricultural land, such as California's Central Valley, has become a direct competitor for use as a public water supply.

EVAPOTRANSPIRATION

JOSE O. PAYERO
University of Nebraska-Lincoln
North Platte, Nebraska

Liquid water from a surface can be transformed into water vapor by either evaporation or by transpiration. *Evaporation* is the process for converting liquid water to water vapor and removing it from the evaporating surface. *Transpiration* is the vaporization of water contained in plant tissues and the removal of vapor to the atmosphere through leaf stomata (1,2). Evaporation and transpiration occur simultaneously in cropped surfaces, and there is no easy way of quantifying the magnitude of each component. For practical applications, such as irrigation scheduling and irrigation system design, it has been more useful to consider both processes combined. The combination of these two processes is called *evapotranspiration*. The proportion of each component in a cropped surface is affected by factors such as vegetative cover, available water in the soil, and surface wetness. For an annual crop like corn, evaporation is the dominant component of evapotranspiration at the beginning of the season when the soil surface is exposed to solar radiation. As the crop grows and the canopy covers the surface, evaporation is minimized, and transpiration becomes the dominant component.

IMPORTANCE OF EVAPOTRANSPIRATION

Evapotranspiration is an important process in agriculture and other natural sciences, such as hydrology, because it is an important component of the hydrologic cycle. It represents the water that is effectively lost from the earth's surface, and can no longer be controlled by humans. This type of water loss is often called consumptive use. Other types of processes that usually cause water losses from a given area on the earth's surface, such as runoff and deep percolation, do not involve a change in the physical state of water and therefore, water can still be controlled to some degree by humans.

Plants use water as a solvent and transport mechanism for nutrients and other chemicals, as a reagent for the chemical reactions involved in their physiological processes (such as photosynthesis), and as a component of cell cytoplasm, which allows plant tissues to stay turgid. Most of the water consumed by plants, however, is used in evapotranspiration. Evapotranspiration has the important function of regulating the temperature of plants, keeping them cool within a temperature range that favors growth. When the water supply in the soil is limited, for instance, plants respond by closing their stomata. This restricts the rate of evapotranspiration, and the temperature of the canopy tends to increase (3). This increase in canopy temperature has been used to estimate the rate of evapotranspiration of crops and as a way to detect crop water stress for irrigation scheduling (4). Because most of the water consumed by plants is lost in evapotranspiration, it takes a considerable amount of water for a crop to produce one unit weight of dry matter, as shown for different crops in (Fig. 1).

Researchers have shown that crop yield is often linearly related to crop evapotranspiration, up to the point where yield is limited by factors other than water (6). Therefore, if evapotranspiration is limited, yield is usually reduced. For this reason, in regions where rainfall is not sufficient to provide enough water for crops to keep evapotranspirating at a nonlimited rate, irrigation is required to obtain adequate crop yields. The nonlimited rate of evapotranspiration, however, can also be maintained by applying excess water. Application of excess water, however, has been linked to undesired side effects such as drainage problems, salinization of soils, soil erosion, and pollution of surface and groundwaters. In places where irrigation water needs to be pumped, pumping excess water also represents higher production cost. Therefore, it is considered ideal to schedule irrigation according to crop water needs. This requires, among other things, good knowledge of crop evapotranspiration rates.

MEASURING EVAPOTRANSPIRATION

Measuring the rate of evapotranspiration of crops and other surfaces is complex and is a subject that has attracted considerable research. Many methods have been devised to measure and estimate evapotranspiration. *Methods for measuring* evapotranspiration include the use of lysimeters, scintillometers, micrometeorological techniques such as the Bowen ratio and eddy covariance methods, and measurement of sap flow. Methods to measure evapotranspiration usually require expensive instrumentation and specialized training, and therefore have been confined mostly to research applications. Because of this, considerable effort has been devoted to develop methods for estimating evapotranspiration.

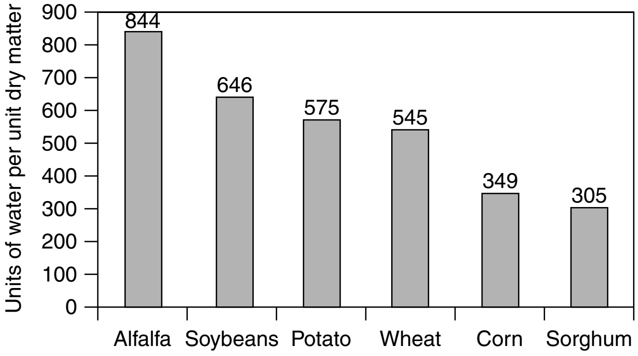

Figure 1. Unit weight of evapotranspirated water needed per unit weight of dry matter produced by different crops (adapted from Ref. 5).

ESTIMATING EVAPOTRANSPIRATION

Methods for estimating evapotranspiration include the use of different kinds of devices and a variety of equations. Devices such as evaporation pans, atmometers, and soil moisture monitoring devices have long been used to estimate evapotranspiration. The use of equations, however, is by far the most common method to estimate evapotranspiration. A great variety of equations have been proposed though the years, ranging from very simple to very complex models (1,7).

Simple models usually try to estimate evapotranspiration based on empirical relationships involving one or several meteorological variables. Complex models consider the physics governing the evapotranspiration process and try to include all factors that significantly contribute to the process (1,8). Complex models can be further divided into single-layer models and multiple-layer models. Single-layer models, such as the Penman–Monteith model, consider the crop canopy as a “big leaf,” taking into account only processes that occur between the top of the canopy and the atmosphere. Multiple-layer models, on the other hand, also take into account those processes that take place below the crop canopy. Multiple-layer models are more theoretically sound than single-layer models, but their complexity makes them impractical for widespread use. Because a single-layer model is sufficiently accurate for most practical applications and relatively simple to apply, it has been proposed as the recommended method for estimating evapotranspiration (9).

Considerable effort has been made to estimate evapotranspiration using inputs obtained from remote sensing platforms, such as satellites or airplanes (1,10,11), and others have even tried to estimate evapotranspiration by measuring the flux of stable isotopes (12). Evapotranspiration, however, is more often estimated from equations that use meteorological data as input, as well as inputs that describe the characteristics of the evaporating surface. This is a convenient method because meteorological data are readily available in most places. Most nations and states support a network of meteorological stations and offer this information to the public in various ways. Meteorological data commonly used to estimate evapotranspiration include solar radiation, air temperature, relative humidity, and wind speed.

A detailed procedure for calculating evapotranspiration has been described by Allen et al. (1). The method involves a two-step process. One step consists of calculating the evapotranspiration rate of a reference crop, either clipped grass or alfalfa, which is usually known as reference evapotranspiration. In older literature, this was also called potential evapotranspiration. It represents a measure of the evaporating demand of the atmosphere for a short, cropped surface that effectively covers the ground, is growing healthily, and is not short of water, that is, a condition in which transpiration is not limited by stress, and the evapotranspiration demand of the atmosphere is met. The second step involves adjusting the reference evapotranspiration to match the conditions of the specific surface or crop being considered. This is done by calculating an adjustment factor, usually known as the crop coefficient. Depending on the accuracy required, calculating crop coefficients can also be a simple or complex process (7,13). Multiplying the reference evapotranspiration by the crop coefficient then results in the evapotranspiration rate for the crop or surface in question.

REQUIREMENTS FOR EVAPOTRANSPIRATION

Procedures used to estimate evapotranspiration try to simplify the complexities of the physical and physiological processes that affect evapotranspiration to a manageable number of quantifiable variables. They try to recognize that for the evapotranspiration process to take place, it is necessary to have

1. energy
2. water
3. space in the atmosphere to hold the water vapor
4. a transport mechanism for the water vapor to move from the surface to the atmosphere.

Evapotranspiration is an energy-driven process. It takes approximately 2.45 megajoules of energy to evaporate 1 kilogram of water at 20 °C. The sun supplies the energy needed for evapotranspiration from the earth's surface. Part of the solar energy that reaches the evaporating surface, however, is reflected back to the atmosphere and cannot be used for evapotranspiration. Of the energy that stays on the evaporating surface, known as net radiation, not all is used in evapotranspiration. The energy balance of a surface also includes energy that is absorbed or released by the soil (soil heat flux), by the air (latent heat flux), and that used in evapotranspiration (latent heat flux). All of these types of heat fluxes take place simultaneously from a given surface, and their proportions depend on the characteristics of the surface and weather conditions.

The amount of energy used for evapotranspiration includes short-wave radiation that comes directly from the sun, long-wave radiation or heat that comes from the surface, and advective heat that is transported horizontally by hot wind to the evaporating surface. The amount of energy available for evapotranspiration varies with latitude, day of the year, time of day, atmospheric conditions, and the characteristics of the surface itself. Figure 2 shows how the theoretical clear-sky solar radiation for different latitudes varies throughout the year. Figure 3 shows how measured solar radiation varies during the day and the effect of cloudiness in reducing the amount of solar energy that reaches the surface. As a general rule, the higher the amount of energy available at the evaporating surface, the higher the evapotranspiration rate, assuming that all other conditions required for evapotranspiration are met.

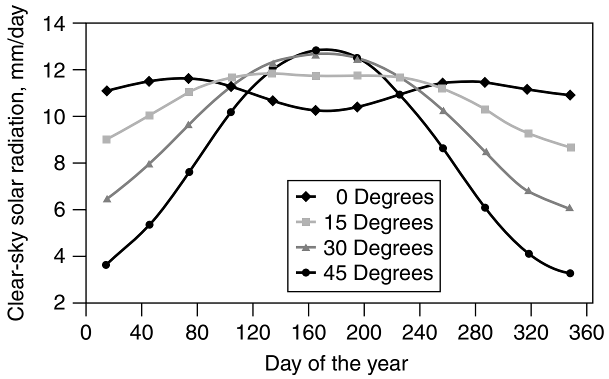

Figure 2. Theoretical clear-sky solar radiation values for different northern latitudes and day of the year at sea level.

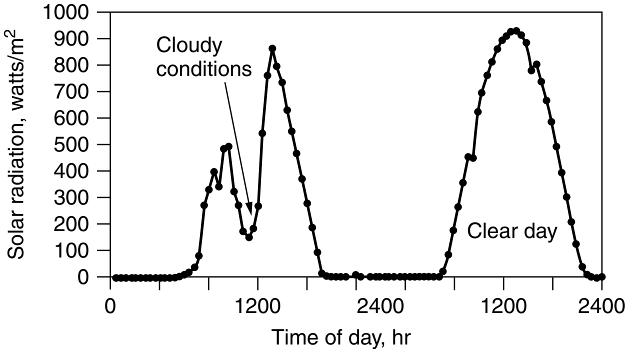

Figure 3. Measured solar radiation in North Platte, NE, on July 15 and 16, 2001.

Water is the next essential requirement for evapotranspiration. If water is not available, the energy available to evaporate water is then used to heat the air and the soil. Under desert conditions, for instance, where energy is usually plentiful, but water is normally very limited, the evapotranspiration rate can be very small. Most of the energy is converted to sensible heat flux, soil heat flux, and a very small portion or none of the energy is converted to latent heat flux. Similarly, when crops are under water stress, the evapotranspiration rate is reduced.

Space in the atmosphere to hold the water vapor is also needed for evapotranspiration to proceed. When water is evaporated from a surface, the water vapor will travel to the atmosphere where it will be stored, provided that the atmosphere is not saturated. If the atmosphere is already saturated, it will not be able to store the additional water vapor, and evapotranspiration will be restricted. The drier the air in contact with the evaporating surface, the more evapotranspiration is enhanced. For this reason, the humidity of the air, usually expressed as relative humidity, is an important factor to consider when estimating evapotranspiration.

The last requirement for evapotranspiration is a transport mechanism for moving water vapor from the surface to the atmosphere. There are two basic transport mechanisms for water vapor. The first is turbulence.

Turbulence is created when air moves horizontally over a rough surface. The friction created by the contact of the air with the rough elements of the surface creates a vertical component of the wind speed, which creates eddies of different sizes. The size of these eddies depends on the roughness of the surface and on the magnitude of the wind speed. These eddies carry the water vapor to the atmosphere. The other transport mechanism is buoyancy. Hot air is less dense that cold air; as the air close to the surface becomes hotter than the air above, it tends to ascend, carrying with it the water vapor. Turbulence is the most important transport mechanism in most instances, so wind speed is a very important factor in determining evapotranspiration. The higher the wind speed and the rougher the surface, the more turbulence, and the higher the evapotranspiration rate will be.

MAGNITUDE OF EVAPOTRANSPIRATION

Evapotranspiration rates are most commonly expressed in units of water depth per unit time, such as millimeters per day (mm day^{-1}) or inches per month (in months^{-1}). Since it takes energy to evaporate water, water depths can also be expressed in terms of energy received per unit area. Therefore, evaportranspiration is often expressed in units of energy per unit area per unit time, such as watts per squared meter (w m^{-2}), or megajoules per squared meter per day (MJ m^{-2} day^{-1}). It can, however, also be expressed in units of energy per unit area, such as watts m^{-2}, or MJ m^{-2} day^{-1}. Many of the factors affecting evapotranspiration are so dynamic that the magnitude of the evapotranspiration rates for a given surface will vary from day to day, from place to place, and throughout the day. Figure 4 shows the calculated daily evapotranspiration rate for corn in North Platte, Nebraska, during the 2000 growing season. It shows the typical large variations in evapotranspiration rate that can be expected from day to day, as a result of normal daily changes in weather conditions. It also shows a seasonal pattern, as a response to the seasonal changes in available energy and to the changing water demand of the crop during its growing cycle.

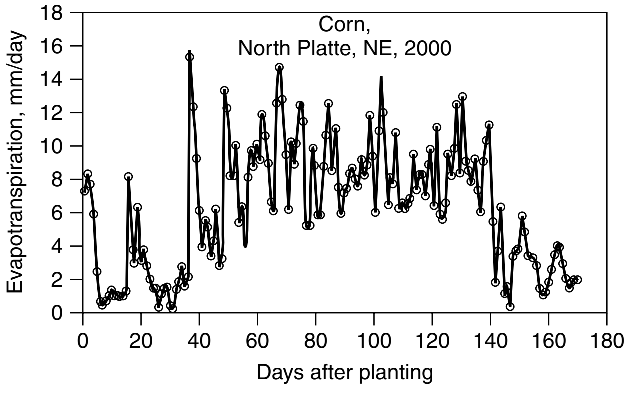

Figure 4. Calculated daily evapotranspiration for corn in North Platte, NE, during the year 2000.

FOG

Arthur M. Holst
Philadelphia Water Department
Philadelphia, Pennsylvania

Fog is a cloud that materializes near the ground or over water. It is a reaction that occurs when the temperature near the ground cools to the temperature required to produce dew and causes the water vapor in the air to become visible in the form of a cloud of precipitation. There are different types of fog, which occur when different variables are involved. The two conditions necessary for fog formation are mild or no winds and air temperatures that are equivalent to the temperature at the dew point. Mild or no winds are important because obstructions in the way of a strong wind can cause it to blow in an up and down motion, which brings warmer air down and pushes the colder air up. Cool air is a requirement for fog formation so wind prevents it from happening.

Fog, like most weather hazards, can cause serious problems for society. The only time this condition is not applicable is when fog forms over water due to the absence of obstructions. In this case, the reverse reaction occurs, and the fog worsens as the wind grows faster. Fall nights are often said to contain the perfect conditions for producing fog. At night, the ground cools which also cools the air directly above it. This reaction causes droplets of water to become suspended in the air resulting in the creation of fog. However, these perfect conditions don't last forever. By morning, the heat from the sun begins to warm the ground, and the fog evaporates.

There are many types of fog, but the four most common are evaporation fog, upslope fog, precipitation fog, and radiation fog which is commonly called ground fog. Evaporation fog is found mostly out at sea, which is why it is also known as "sea fog." It is the reaction of moist air moving over colder water. The fog conditions worsen as the wind speed increases. Upslope fog is produced by moist air that is sent by a strong wind up into mountainous regions. Precipitation fog is created when precipitation in the form of rain or snow hits drier air and causes water vapor to materialize instantly. Radiation fog is seen at night when the ground is cool. The air that comes in contact with the ground also becomes cool and creates water vapor which soaks the ground and causes the formation of dew.

Like most weather hazards, fog can have severe impacts on society. Fog can cause health problems in polluted areas because the water vapor produced can become acidic. Driving through a thick cloud severely reduces a person's visibility and is a major contributor to car accidents. Even worse than the occasional car accident due to fog are the aircraft and boating accidents that can occur. Throughout history, fog has been known as the silent murderer that has taken hundreds of lives at sea in catastrophic boating accidents.

COASTAL FOG ALONG THE NORTHERN GULF OF MEXICO

Timothy Erickson
National Weather Service New Orleans/Baton Rouge Forecast Office
Slidell, Louisiana

INTRODUCTION

Coastal fog is a major problem for all traffic along the United States' coastlines. Lives and large monetary losses have occurred because of coastal fog. These losses have been realized over land, in the air, and on the water. Huge strides have been taken to understand and combat the coastal fog forecasting problem by the National Weather Service. Studies and research continue to improve these fog forecasting techniques. Tens of thousands of people use the Gulf of Mexico as their home or as part of their occupation in many different ways, and billions of dollars in products and property are carried and moved through the channels and river systems to and from the Gulf of Mexico each year. All are affected by coastal fog many times throughout the fall, winter, and spring. This research project took place along the northern Gulf of Mexico from the upper Texas coast to the Mississippi coastline.

METHODOLOGY

The synoptic and mesoscale patterns used in this research were from the fall, winter, and spring of 1998, 1999, 2000, and 2001. Fog was defined as water droplets suspended in the air reducing visibility to one half-mile or less. Shower and thunderstorm activity reducing visibility to these levels was not used. No records exist for fog contributions to the hydrologic cycle. Water contributions caused by fog are dismissed as false tips in rain gauges. The reference to "boundary layer" in this article will be the layer of atmosphere from the surface to the base of the lowest inversion.

Variables used in this research were surface pressure, rainfall, moisture advection, wind direction, wind speed, water temperatures, ambient temperature, and ambient dew point temperature from land observations and production platforms in the northern Gulf of Mexico. Parameters used from previous studies by Johnson and Graschel (1) were air temperature, dew point temperature, wind direction, wind speed, ceiling heights, and visibilities from oil and gas production platforms at an average altitude of 35 ms over the northern Gulf of Mexico. Gulf of Mexico sea surface temperatures were provided by the Tropical Prediction Center oceanographer in Miami, Florida.

SCALES OCCURRING WITH COASTAL FOG

Mesoscale—Widespread

Horizontal range would normally be from 50 to several hundred miles.

Microscale—Locally

Horizontal range could be at a point close to 50 miles.

CONDITIONS THAT HELP PRODUCE COASTAL FOG

Radiative

Heat is transmitted via long wave radiation (infrared) away from Earth. This radiation causes nocturnal cooling of the ground and subsequent atmospheric boundary layer. Radiational cooling is responsible for developing a stable layer near the surface by cooling the layer of air in contact with the ground while leaving a relatively warmer layer immediately above this cooler layer. This stability by warmer air above cooler air with increasing altitude is called an inversion. This feature is important in forecasting the depth of coastal fog. As the radiative process continues, the layer will cool further until saturation is achieved and fog can be produced, given the pressure does not change much during the process.

Coastal Interface. Temperature and moisture gradients are strong where the ocean meets land, especially at night during the fall, winter, and spring. During prime radiational cooling processes, this interface can become moist and stable horizontally from land to water when there is no forcing. These conditions were found when a thin ribbon of fog developed at this interface of land and water. The fog stretched linearly for more than 100 miles and vertically for hundreds of feet. Studies on how this type of fog develops are ongoing but horizontal skew-t sounding-like profiles may be a tremendous help in what is occurring at this land–water junction when this fog forms. No horizontal sounding-like profiles exist, and this is the first mention of such a profile. But if they were available, they could give some valuable insight not only into the coastal "ribbon" fog formation but also where thunderstorms are more likely to develop along with many other variables.

Frontal

This is another inversion producing process. Coastal fog can be developed with the assistance of cold, warm, or stationary fronts.

Cold Frontal. An inversion develops by cooler air displacing warmer air at the surface. The interface where these air masses meet in the vertical is known as a frontal inversion.

Coastal fog formation under a frontal inversion is nonexistent with fast-moving cold fronts, because of stronger winds that cause a deeply mixed layer, along with dry, cold air advection behind the front.

When warm air is lifted by a cold front, it causes displacement and mid-altitude air ahead of the front becomes subsident. This process causes compressional warming, which forms another inversion well ahead of the cold front. As the surface cools at night, the boundary layer becomes stable well ahead of the front. If there has been rain ahead of the cold front with a prefrontal trough, there will be plenty of moisture and a strong inversion that may develop some dense coastal fog. Even without a prefrontal trough or rainfall, the subsidence inversion and gulf moisture ahead of a slow-moving cold front will sometimes be enough to provide conditions promoting dense coastal fog.

Warm Frontal. Relatively cool saturated or nearly saturated air ahead of a warm front is gently displaced by warmer air. The cool air is normally not very deep (100–300 ms) and is topped by warmer air at relatively low altitudes, which causes an inversion to form where the two air masses meet in the vertical. Cooler air cannot hold as much moisture as warm air. As the air ahead of the warm front is already moisture laden, cooler, and stable, water vapor condenses to small particles, which causes fog to form. This result happens frequently along the coast during the cooler months of the year and sometimes far inland. A similar scenario along the coast was also described by Hsu (2). The dynamics of warmer, higher dew point air flowing over cooler waters was described by Kotsch (3) and Mullan (4).

Coastal fog can occur behind warm fronts but is not as common. The air is, by definition of a warm front, warmer than the air ahead of it. The warmer air expands and therefore can hold more water vapor, which will normally dissipate any fog behind a warm front if no overwhelming positive moisture flux is occurring in the warm sector. When this flux occurs, it can be far too great for even the warm air to hold and the water vapor will condense, which causes fog to form. During research, this result occurred only when an inversion was still present behind a warm front.

Stationary and Slow Moving Fronts. These types of fronts are aggressive at developing coastal fog, which can occur in two ways ahead of a cold front that becomes stationary or slow moving. One is when moisture is not displaced and wind speeds are very light behind the trough preceding the cold front. The second is when the wind fetch is well over the marine environment and it brings warm moist air back over cooler waters or land. Warm frontal fog conditions were explained above.

Two unusual fog days occurred as post-cold frontal events. A cold front passed through the southern Louisiana coastal region, and dew points and dry bulb temperatures cooled. Coastal fog then began to develop over many sites from east central Texas to south central Louisiana. The air mass change was more negative for the dry bulb temperature than for the dew point temperature, and the cold front slowed from about 10 knots to less than 5 knots as it reached the coastline. This decrease caused the air behind the front to become saturated. Frontal forcing weakened, and consequently northerly winds weakened and created perfect conditions for coastal fog development. Post-cold frontal fog is rare, but when it does occur, visibilities can plummet to less than one quarter of a mile quickly.

Hsu's (2) description on frontal fog production is similar to this research. Johnson and Gracshel (1) called frontal fog "mixing fog."

Maritime (Sea Fog)

When fog develops via any process over any large marine area, it is called marine or sea fog. Marine fog may be stationary or be advected elsewhere. It is during the advection process that coastal fog occurs.

Dormant. As the cooler boundary layer air over land "drains" offshore, it causes stability to decrease, which makes mixing possible. The warm gulf gives off water vapor to the cooler air, which causes the vapor to condense, making water droplets. This process quickly deteriorates when only little "drainage" is occurring. Latent heat released because of condensation warms the marine boundary layer too fast, which makes the stability in this layer neutral. Fog will form in the near shore waters if this latent heating can be exhausted through the top of the maritime boundary layer. Fog development caused by this process does not occur often. When it does, the fog stays near the coast, rarely moving anywhere because of the very slow, almost laminar flow of air moving off land. When this type of fog affects the shoreline, it is also called coastal fog. The other processes mentioned above may produce nonadvective marine fog that stays in the near shore waters.

Advancing. This process in which coastal fog is achieved is the most common. The air in the boundary layer is well mixed but does not entrain air from above the inversion. Fog that forms either onshore or offshore by any process and moves elsewhere is an advective fog. When fog advects from one offshore location to another or to the coast, it is said to be advancing. The most common type of advancing fog is found with post-strong cold front events. Winds from these fronts move the top layer of warm shelf water away from the coast. This water is replaced by cooler upwelled water. A strong temperature gradient exists where the cooler upwelled water meets the warm water offshore. When the next cold front produces return flow from the warmer water offshore, moisture-laden air saturates while moving over the cooler water. Extensive areas of fog or very low cloud ceilings form before moving inland, which causes extremely low visibilities stretching for miles along the coast. When the moisture came in the form of low clouds during research, the cloud deck would often descend to the surface producing very dense coastal fog as well. As warm air overlays cooler water, it produces a stable boundary layer. No vertical mixing occurs by air moving up or down. Mixing was produced solely by wind advancing the fog. The wind did not reach through the inversion layer, and therefore, no entrainment occurred.

A similar scenario was recorded by Binhau (5) and Hsu (2). Their contributions showed this environment to be stable, with surface winds from the southeast through southwest. This scenario holds true for all locations along the northern Gulf of Mexico.

Advective

Anytime fog forms elsewhere and is forced to another location, it is a type of advection fog. A well-mixed boundary layer also exists with advective fog, but again, air from above the inversion is not mixed downward. In some cases, the atmosphere will be capable of supporting fog but it cannot produce it. When this happens, fog may be brought into the area by wind or by the slow movement of an entire layer of air. It is important that this air mass does not mix with air from above the inversion. If this mixture occurs, dry, relatively warmer air will be mixed into the boundary layer, causing the fog to erode.

Conglomerate of Two or More Types from Above

This fog producer is the most common. Two or more of the above processes usually develop fog that forms almost anywhere on Earth. One major variable may occur at the time of fog formation, but most of the time fog is supported by another equal or weaker variable, for example, frontal-induced marine fog. That is, fog develops over the marine environment by a cold front, which brings warm, moist air back over cooler waters. The fog develops mainly because of the marine environment, where it derives its moisture, but it could only do so as a result of forcing by the cold front.

VARIABLES PRESENT DURING COASTAL FOG PRODUCTION

Variables Always Present During Coastal Fog Formation

Negative or Neutral Omega Within or Just Above the Boundary Layer. When lift occurred during the research, fog would dissipate or simply not form. The lift causes mixing through the inversion, which brings dry, relatively warm air into the boundary layer.

Weak or No Positive Vorticity in the Boundary Layer. Coastal fog developed under boundary layer-negative vorticity regimes, but it would not develop under moderate-to-strong positive vorticity in the boundary layer. When weak vorticity occurred within or at the top of the boundary layer, fog would lift and become a low-level cloud ceiling. As the vorticity center moved past, the ceiling would once again descend to the surface, which caused coastal fog to form.

Inversion. An inversion is always present during any and all fog development and duration.

Variables Present During Research for Each Condition

Radiation Fog Variables

Winds 0 to 3 Knots. Radiation fog events are created without mixing through the inversion. Wind greater than 3 knots was found to create too much mixing and dissipated coastal fog during radiative events.

Moisture Advection or Rainfall Within 36 Hours. Moisture is needed for any fog to develop. With no moisture advection, it was found that moisture input from rainfall would be sufficient inside 36 hours. This field was dependant on several variables. These variables included amount of rainfall, ground moisture, insolation, and amount of rainfall coupled with timing. The best results were found with light rain episodes during the early morning with strong insolation during the day.

Neutral or Negative Omega. Neutral or negative lift from some height above down to the top of the boundary layer was always found when coastal fog formed during this research. Positive lift caused mixing through the inversion, which dissipated the fog.

Weak-to-No Boundary Layer Positive Vorticity. Coastal fog formed under negative and neutral vorticity regimes. Coastal fog was either displaced or was not present when moderate-to-strong positive vorticity was found within the boundary layer. Coastal fog was also present with weak positive vorticity, but a few interesting findings occurred. As a weak positive vorticity center moved through the boundary layer, coastal fog would lift, which created a low-level ceiling from 100 to 400 feet. When the vorticity maxima passed, the low-level ceiling would descend to the ground, which caused coastal fog to return. This phenomenon was known for creating "bouncy" fog conditions where visibilities would swing wildly from as little as 0 to as much as 4 miles.

Clear Skies. Clear skies were the overwhelming majority of sky conditions experienced during radiational coastal fog events. The minority sky condition consisted of very high thin cirrus clouds. No radiational coastal fog events occurred during any other cloud conditions.

Outside Downtown Areas. Radiational coastal fog events during this study were found outside the downtown areas of cities. The heat island effect was enough to dissipate any fog trying to form inside these areas.

Moisture Advection or Rain Within 36 Hours. The highest frequency of coastal fog during frontal regimes was found when a prefrontal trough passed. Moisture was input by both the front causing return flow from the marine environment and the prefrontal trough causing rainfall.

Clear Skies or Very High Cloud Ceiling. High cloud ceilings were noted several times throughout the research when frontal-induced coastal fog developed. Winds of 10 to 20 knots were noted above a shallow inversion, which allowed heat from the boundary layer to escape and be carried away.

Surface Winds of 0 to 12 Knots. During radiative conditions, coastal fog only formed when wind speeds were 0 to 3 knots. During advective or advancing conditions, coastal fog was carried to or along the coast when wind speeds were 4 to 12 knots.

No coastal fog formed during this research when wind speeds were greater than 12 knots.

Onshore Winds of At Least 4 Knots and Not More Than 12 Knots. During marine-induced coastal fog, winds were necessary to advance the fog from the marine environment to the coast. But wind speeds greater than 12 knots caused the fog to dissipate by mixing with air above the inversion. When these winds did not reach the top of the boundary layer, no mixing occurred through the inversion and the fog would simply lift, developing a low-level cloud ceiling.

No Moisture Advection. Surprisingly, moisture preconditioning was not necessary when marine fog caused coastal fog. The marine fog was the moisture advection.

Clear or Very High Ceilings. Several cases showed coastal fog production via a low-level cloud deck. When heat was capable of radiating through the inversion at the top of the low-level clouds, the cloud deck lowered or deepened toward the surface through the night, finally reaching the ground, which caused coastal fog to form. It was also noted that the lower the cloud deck, the shorter the time frame coastal fog would develop. A very general rule of thumb was realized when the boundary layer was capable of supporting fog. On average, it took about an hour for the cloud ceiling to descend 100 feet. Cloud bases higher than 1000 feet never reached the surface during marine-induced coastal fog events.

Temperature. Johnson and Graschel (1) found temperature differences of several variables to be important when maritime fog developed. As indicated in their article, "Sea Fog and Stratus: A Major Aviation and Marine Hazard In The Northern Gulf Of Mexico," the differences between water and air temperatures, as well as between water and dew point temperatures, were the most important variables producing marine fog when the right atmospheric conditions were in place. The graphs below show these parameters versus relative humidity (RH) values.

Johnson and Graschel's study (1) as well as this project found RH values of 98% or greater always present with coastal fog.

Figure 1 shows the continental shelf region along the northern Gulf of Mexico, which is shown at the 200-m depth contour. It is also the region where a cool water temperature of 20 °C (68 °F) or less was found to be critical for marine fog development in the northern gulf during the right atmospheric conditions. These findings may not be the same at other locations around the globe because fog development depends on temperature gradients, over water and/or land, which are relative. Water temperature findings close to these were also accomplished by Binhau (5).

Figure 2 shows RH versus (Ta - Tw), where RH is relative humidity and (Ta - Tw) is the difference between the ambient air temperature and the water temperature.

In Fig. 3, in regard to the positive (+) numbers, when the water temperature is cooler than the air temperature, the air must be moving between 4 knots to as high as 12 knots for coastal fog to form. During this process, the moisture-laden warmer air loses its heat to the cooler water. As the air cools to its dew point, condensation takes place. Latent heat is released during the condensation process. The air can lose this added heat to the cooler water below and through the top of the boundary layer

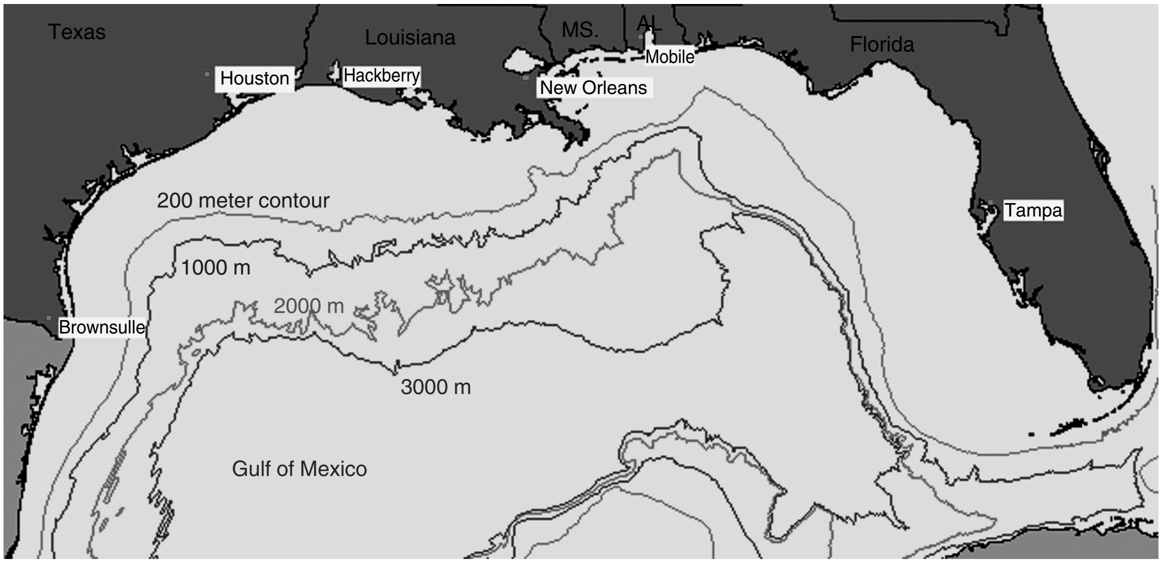

Figure 1. Continental Shelf-Northern Gulf at Mexico.

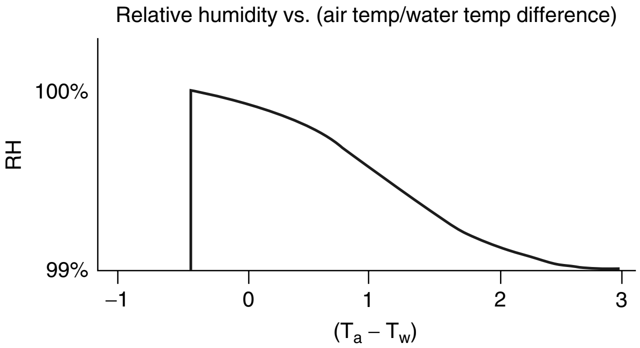

Figure 2. This graph shows the relationship between air temperature and water temperature when coastal fog developed with respect to the lowest relative humidity value found during research.

via long wave radiation, so fog can begin to form. This process is efficient and is the main reason for coastal fog developing from advancing marine fog.

The positive numbers in Fig. 3 show a stable boundary layer also described by Binhau (5) and Hsu (2).

In Fig. 4, in regard to the negative (−) numbers, when the water temperature is warmer than the air temperature, the air must be calm or moving no faster than 3 knots for coastal fog to form. During this process, when coastal tidal marshes exist, a column of cooler dry air will have a net gain of water vapor, which causes the dew point temperature to rise. When the air and dew point temperature are very close, condensation will begin. As a result of condensation, latent heat is released. The column will need to lose this heat through the top of the boundary layer before fog will begin to form. Even though marine fog occurs by this process, it is not an efficient coastal fog producer unless fog initially forms along the coast. Most of the time, fog will develop over the marine environment and be stationary or drift farther offshore.

Negative numbers in Fig. 4 show an unstable boundary layer as described by Binhau (5). Binhau showed that this type of fog may be produced over the marine environment even with northerly winds of 30 knots. But with winds of this magnitude, coastal fog will never develop along the northern gulf coast because the winds would force it out to sea.

Figure 5 shows RH versus (Td − Tw), where RH is relative humidity and (Td − Tw) is the difference between the ambient dew point temperature and the water temperature.

In Fig. 6, in regard to the positive (+) numbers, it is important to remember that the atmosphere as well as the ocean is always trying to reach a state of equilibrium.

When the ambient dew point temperature is higher than the water temperature, water molecules can easily move to and become a part of the ocean surface. Water molecules find it hard to break away from the waters' surface during these conditions, and therefore, a net moisture flux from air to water occurs. The air temperature is always equal to or greater than the dew point. Hence, there will be a transfer of heat from the air to the water as well. This process cools the air temperature, but saturation is difficult to achieve because there is a net loss of water vapor to the water surface. The air continues to cool and dry until temperatures of the water, the air, and the dew point equal or become very close. This process eventually causes saturation and can, but rarely does, cause coastal fog to form when atmospheric conditions are right and (Td—Tw) is zero or very close. Normal occurrences of fog on the positive side of Fig. 6 are when fog develops elsewhere and advances into the area.

In Fig. 7, in regard to the negative(−) numbers, when the water temperature is warmer than the dew point, water molecules can easily break away from the water surface to the air. Regardless of the air temperature,

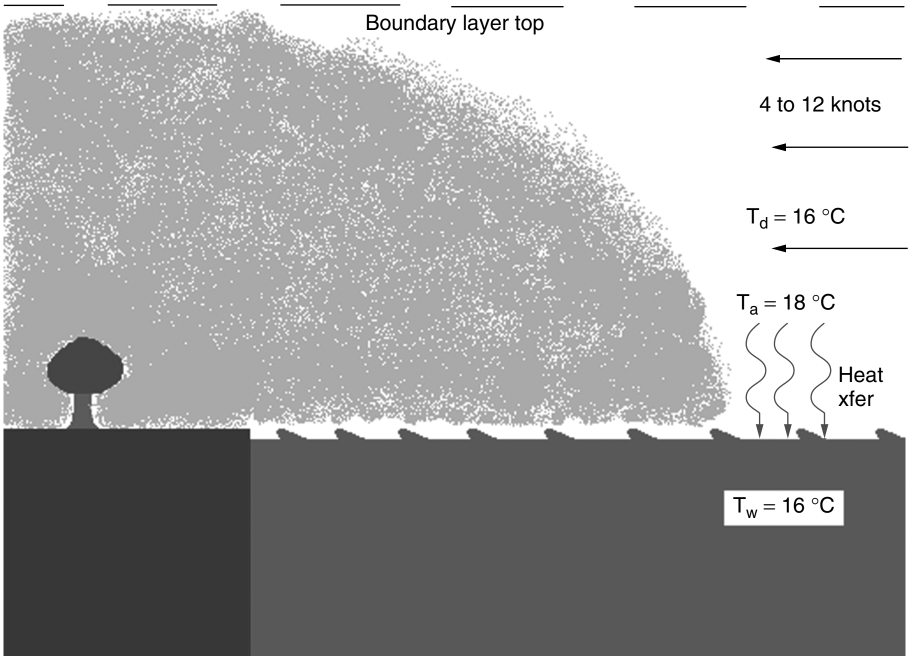

Figure 3. Stable Boundary Layer.

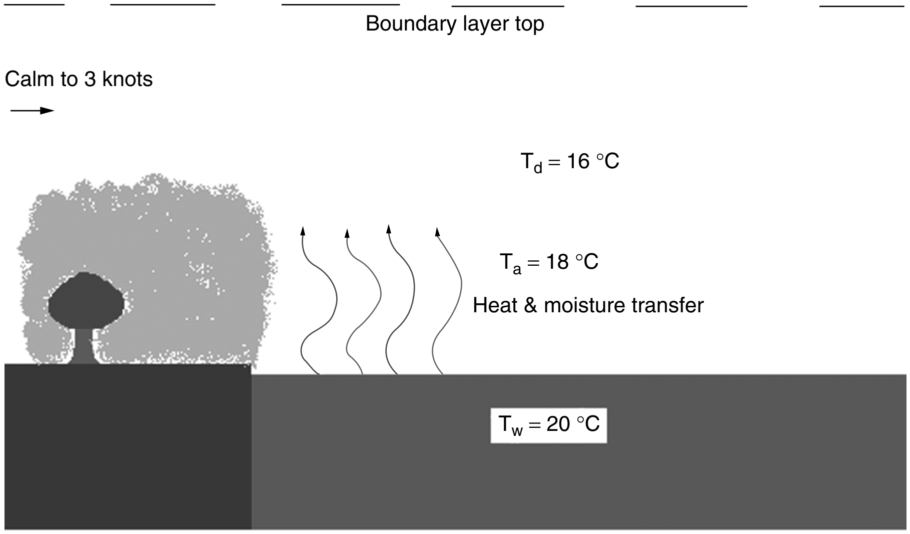

Figure 4. This picture shows a light offshore wind, dew point temperature (Td), air temperature (Ta), and water temperature (Tw).

the water will try to modify it until the water and air temperatures are equal. Even if saturation is achieved, moisture will continue to be added to the air until the dew point is equal to the water temperature. As moisture is added to the air at saturation, condensation begins and latent heat is released to the air until the temperatures of the water, dew point, and air are equal. This saturation can easily develop fog near or offshore. Normally, marine fog produced by this process occurs with little airflow (0–3 knots). After marine fog forms, it can be easily forced to the coast as winds increase ahead of the next cold front. This coastal fog producer is aggressive.

As Fig. 7 depicts, this process occurs with a minimal separation of air, dew point, and water temperatures. When separations are too large, there may be too much

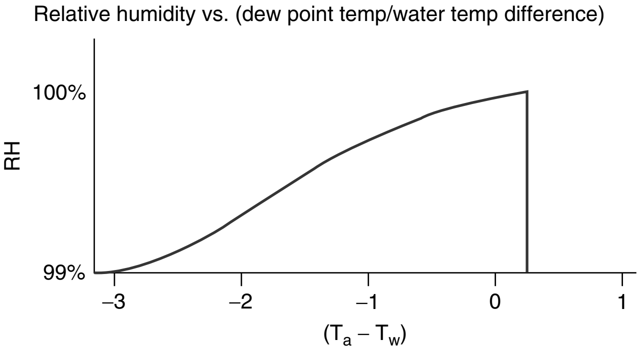

Figure 5. This graph shows the relationship between dew point temperature and water temperature when coastal fog developed with respect to the lowest RH value found during research.

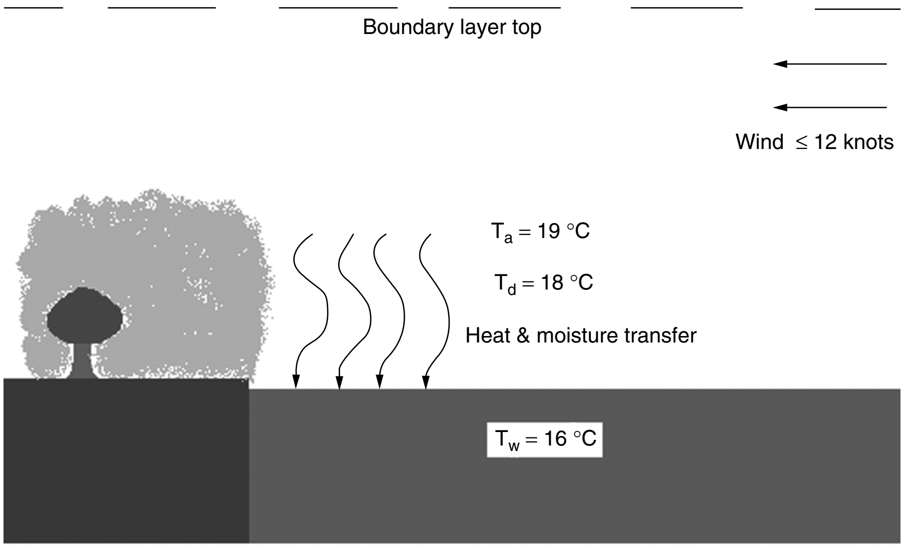

Figure 6. This picture shows winds of 12 knots or less, air temperature (Ta), dew point temperature (Td), and water temperature (Tw).

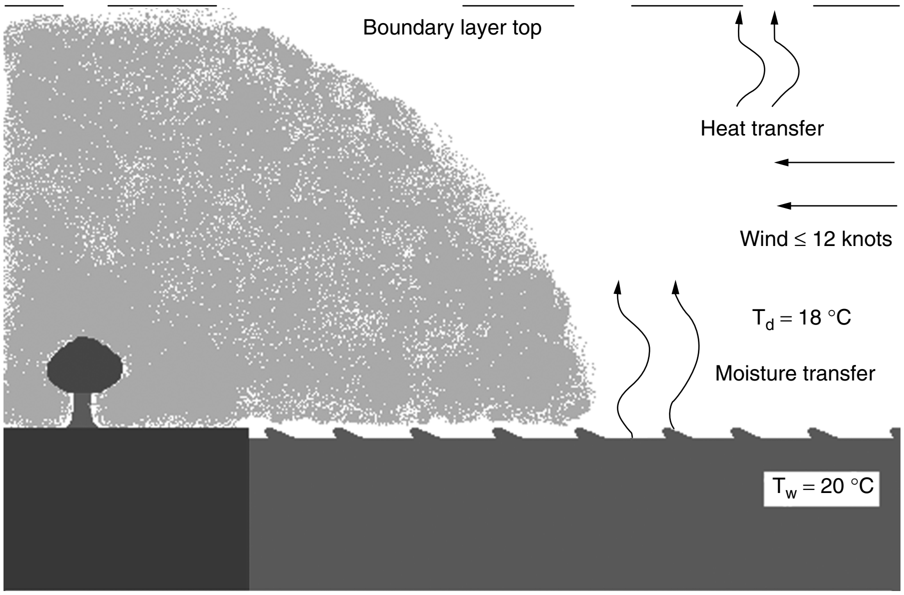

Figure 7. This picture shows wind speeds less than or equal to 12 knots, dew point temperature (Td), and water temperature (Tw).

dry air to modify before the next system brings this air mass back to shore. If the air is moving more than 3 knots, there will be a continual replacement of dry air and/or air from above the inversion may be mixed into the boundary layer and saturation will not be achieved.

Advective Fog Variables

Winds of At Least 4 Knots and Not More Than 12 Knots. Advective fog, which causes coastal fog, is different from advancing marine fog in a couple of ways, i.e., where the fog developed and the wind fetch. Fog that develops onshore and moves to the coast is only known as advective fog. Whenever fog moves to the coast, the wind direction will always be in a direction from the fog to the coastal location. All other variables that are needed for marine fog to advance to the coast are also needed for advective fog.

No Moisture Advection. Even though moisture may be in place, advective fog does not need to have a premoistened atmosphere for coastal fog to be produced. Moisture advection can be induced by the fog moving to the coast.

Clear or Very High Cloud Ceilings. Cloud conditions were found to be the same as for marine fog.

Conglomerate Fog Variables. The variables for each condition associated with coastal fog development have to be present when coastal fog forms under more than one condition.

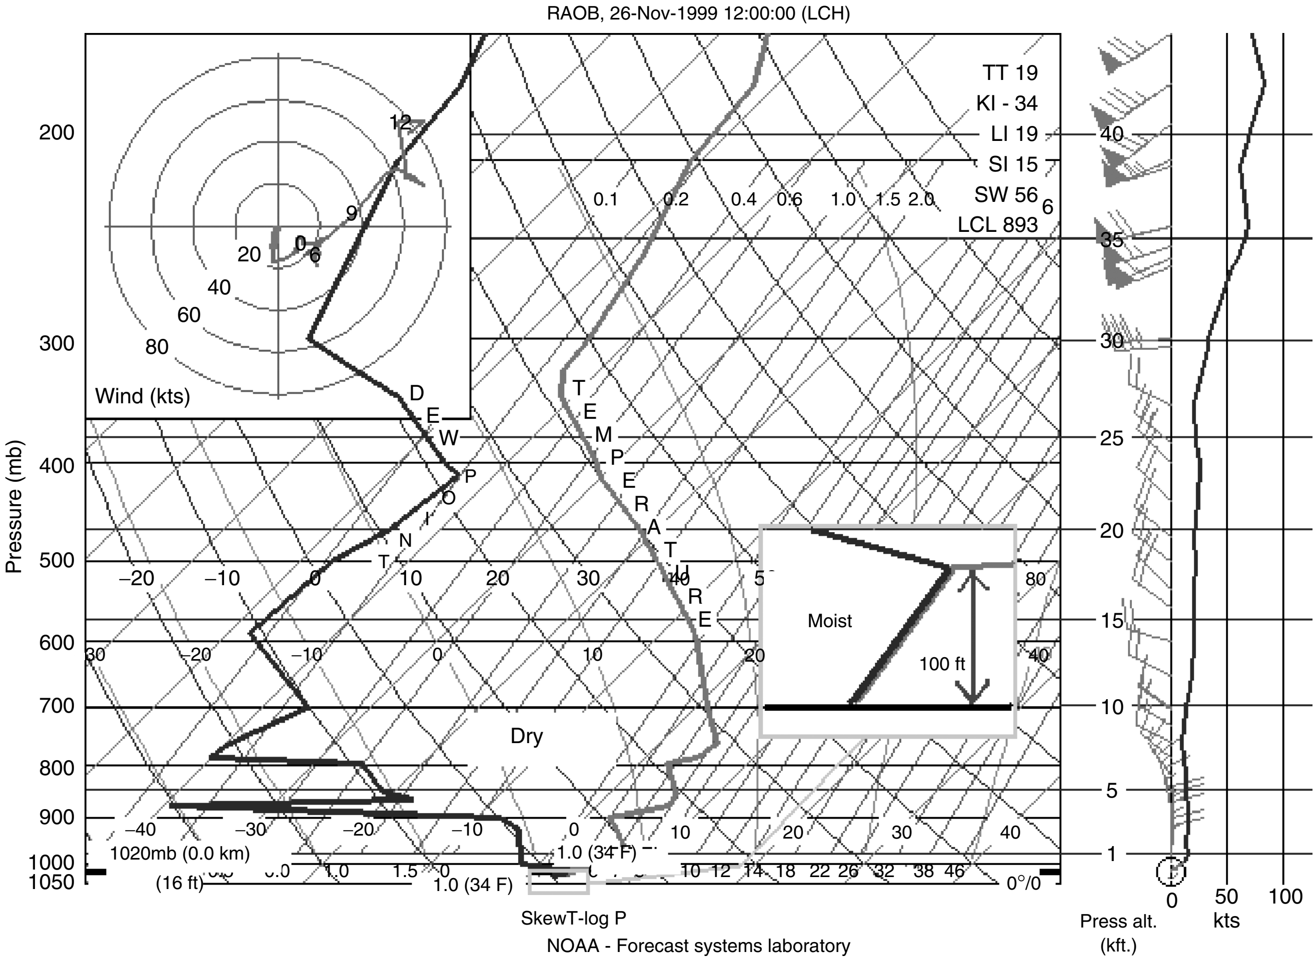

Figure 8. Sounding Profile-Radiative.

SOUNDING PROFILES PRESENT DURING COASTAL FOG

A sounding profile similar to Fig. 8 was always present shortly before and during radiative coastal fog events. This actual sounding shows a very shallow (~100 feet) moist layer capped by three strong inversions.

A sounding profile similar to Fig. 9 was always present shortly before and during advective and maritime coastal fog events. This actual sounding shows a very deep (~1000 feet) moist layer capped by a moderate inversion.

Fog rarely develops beneath the type of inversion in Fig. 10. This actual sounding shows a deep moist layer capped by a frontal inversion; coastal fog occurred before the passage of this cold front, but it quickly dissipated by the time this sounding was taken.

Frontal-induced and conglomerate fog was found with all three types of sounding profiles. Frontal-induced coastal fog occurred more often under the first and second profile types.

Sounding profiles are important for forecasting the depth of coastal fog or any type of fog. Maritime, advective, and frontal-induced coastal fog can only be as deep as the height from the surface to the base of the inversion. These types of fog produced the deepest fog along the coast as well as inland, and consequently they took longer to dissipate.

During research, most radiation-induced coastal fog formed only under a low-level inversion. The inversion could be as high as 100 feet or as low as a few feet from the ground. The inversion was frequently strong. Air parcels were not able to penetrate the inversion, but it would not stop radiative heat transfer from the surface via long-wave radiation. Radiative fog did not always follow the depth rule. It could be from the surface to the base of the inversion deep or as shallow as a few inches, even when the inversion was much higher.

An interesting find during the project was horizontal stability and moisture profiles during radiative fog formation conditions along the coast. The horizontal profile shown below from the coast along with the radiative vertical profile from inland locations were both present when a thin "ribbon" of fog formed along the coast (see Fig. 11). This fog was found to run linearly along the coast and stretched upward for hundreds of feet. The inland vertical sounding did not support such a high

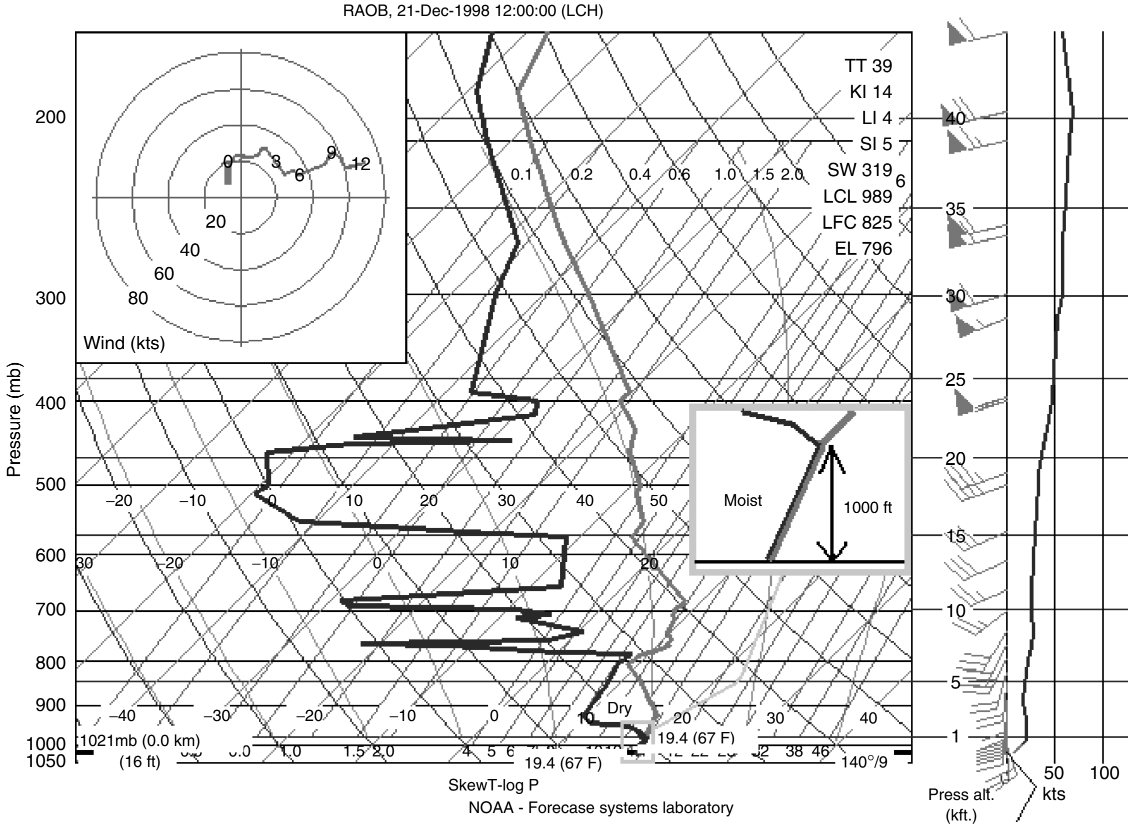

Figure 9. Sounding Profile-Advective.

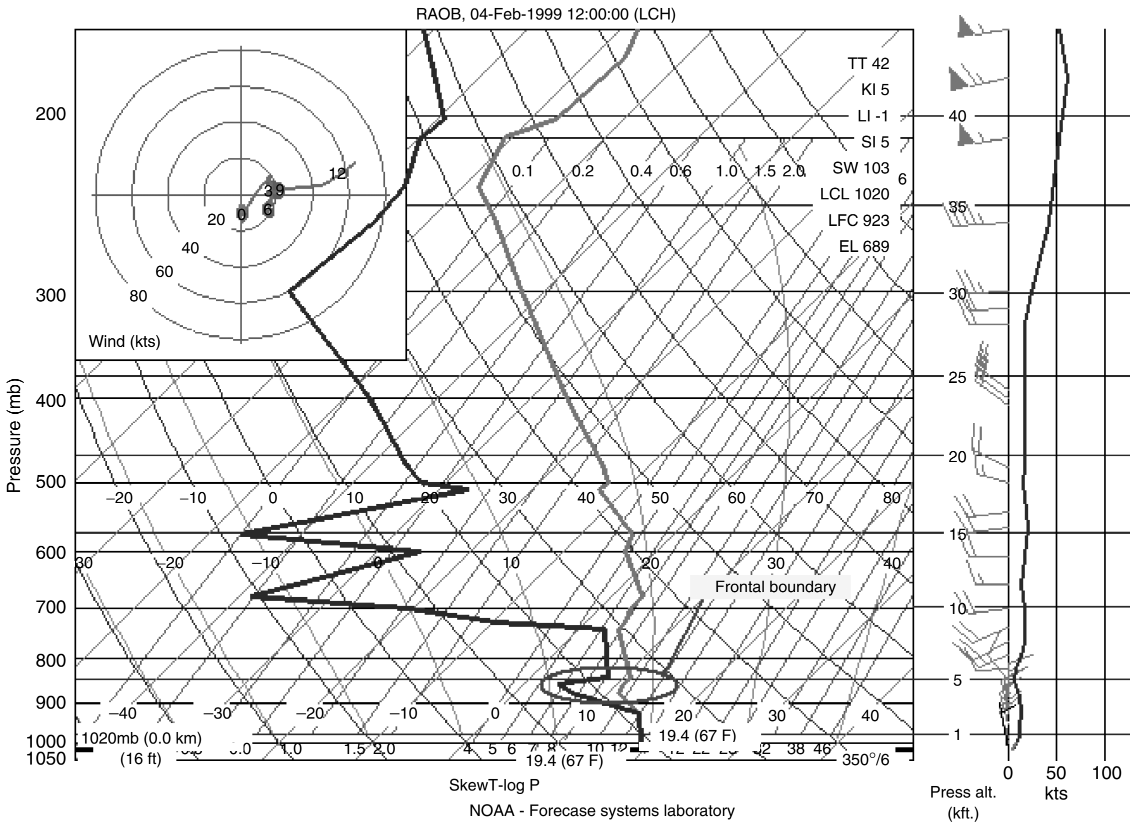

Figure 10. Sounding Profile-Inversion.

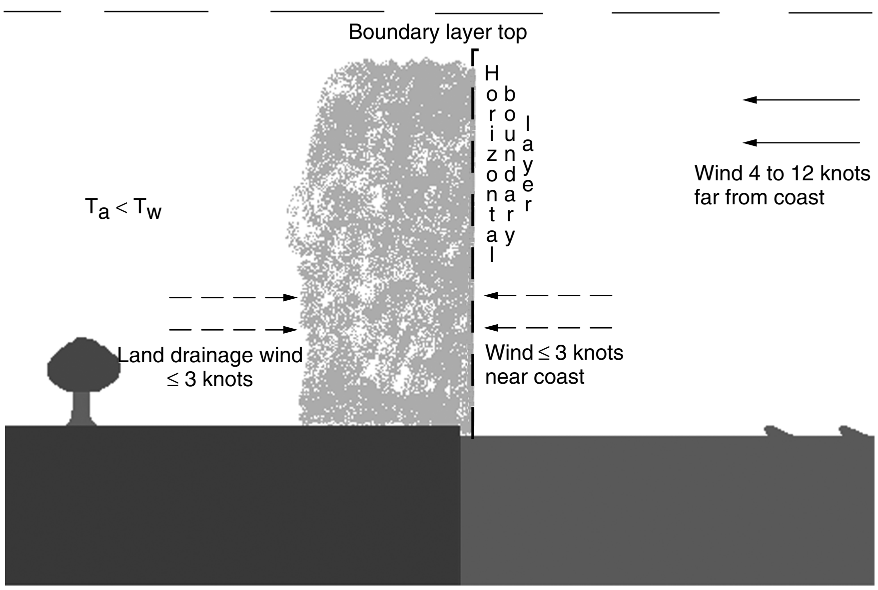

Figure 11. This illustration shows a hypothetical representation on how a very thin ribbon of fog develops at the coast.

depth of coastal fog, but this vertical profile may have been different along the coast because strong moisture and temperature gradients existed. Research into this phenomenon is ongoing.

CONCLUSION

Fog has never received the attention it deserves because it does not make for an explosive story like hurricanes and tornadoes. But fog is blamed for large monetary losses as well as property losses. Each year, fog is blamed for indirectly taking more lives than hurricanes in the United States. Fog also donates a small but significant amount of water to the hydrologic cycle. In some places, such as the western high coast region of South America, fog is the only way insects and grasses receive water.

When fog develops, there is always an inversion in place, which means the boundary layer is disconnected from the remaining atmosphere above with respect to mixing. This process is called decoupling. When the inversion erodes and mixing resumes through this layer, it is said to be coupled. As a result, pollutants released to the environment will remain in the boundary layer during decoupled conditions and will mix out during coupled conditions. Petrochemical plants and other facilities-producing pollutants that are dispersed to the environment can use fog as an indicator for when not to release waste products.

Results during research show there are numerous variables and observations from the microscale environment to consider when forecasting coastal fog conditions. Current National Weather Service numerical models do not solve for microscale conditions, and therefore, forecasters must rely on pattern recognition to resolve these issues.

RAIN FORESTS

Aldo Conti
Frascati (RM), Italy

Rain forests are, by definition, those forests that receive more than 2500 mm of rain each year. Rain forests are characterized by very dense vegetation dominated by tall trees and huge biodiversity. Rain forests exist in many parts of the planet, but most of them are along the equator, where the weather is stable throughout the year and there is never a dry season. Rain forests do not have seasons at all. The amount of rain is almost constant during the year, and the temperature seldom dips below 16 °C. Rain forests cover 7% of the earth's land surface and 2% of its total surface, but are home to more than half of all animal and plant species. Despite the fact that rain forests cover less than 10% of the earth, they support a third of its plant matter. The largest tropical rain forest in the world is the Amazon Rain Forest, which lies in the countries of Brazil, Bolivia, Peru, Ecuador, and Colombia. There are rain forests in Africa, mainly in the Congo, and in Oceania.

The large amount of rain also creates some of the biggest rivers and flood plains of the world.

Unfortunately, rain forests are in danger. They lie mainly in poor countries, where the economic situation forces people to use all resources, which is why most rain forests have shrunk dramatically in size over the last few decades. What is in danger is their huge biodiversity. Some researchers estimate that the Amazon Forest alone might host up to 10 million species of animals, mainly insects. At the rate the forest is disappearing, most of the estimates say that we are losing something like 100 of these species every day, before even being described by science.

Most of the animals in rain forests have adapted to live in the upper level of the canopy, where food is really plentiful. The constant weather means that there are flowers and fruits at any time of the year. The largest group of animals is that of insects that can easily climb trees and often have a highly symbiotic relationship with the plant life of the forest. Ants and termites are the most abundant animal of every rain forest. Animals are very important for the survival of the forest. Underneath the canopy, the wind is not strong enough to disperse efficiently the seeds produced by plants. Plants rely therefore on insects, that very often pick up the seeds and drop them some distance away. But the most important animals for seed dispersal are birds. Birds in rain forests eat mainly fruits, and the seeds can pass through their digestive system unscathed. By the time a bird excretes its load of seeds, it has normally flown a long distance from the plant, which ensures a high level of genetic mixing, healthy and helpful for plants. There are even some seeds that do not germinate unless they have gone through the digestive system of birds. More than one-fourth of all bird species in the world today live in tropical rain forests.

To have an idea of the importance of rain forests, some figures might be interesting. A single square meter of rain forest supports between 45 and 80 kg of biomass, far more than any other biome. This biomass gains more importance considering that most of it is made of carbon removed from our atmosphere. One hectare of rain forest can contain 200 species of trees and more than 40,000 species of insects. In Panama, scientists discovered fully 80% of the world's currently known beetle species on only 19 trees. Once, researchers discovered over 600 new species of beetle by studying a single species of tree.

Although not as rich in species as their Asian or Amazonian counterparts, African rain forests contain more than half of that continent's animal and plant species, even though they cover less than 7% of its total land area.

Because of the huge biodiversity, most species have evolved to occupy very specialized niches of the environment, which means that many species depend on each other and cannot survive without each other. Deforestation and many other human activities disrupt these complicated relationships.

Rain forests could play a crucial role in feeding the whole world's population. Many vegetables and fruits such as bananas and peppers that we consume come from rain forests. Peanuts come from rain forests, as do many drinks (coffee, tea, cola), oils (palm, coconut), flavorings (cocoa, vanilla), and other foods (beans, grains, fish). And many more vegetables are still there ready to be discovered. Moreover, researchers have identified over 200 plants that produce potential cancer fighting substances. And this considering that only 1% of plants have been intensively screened for such properties. Tropical rain forests do not offer only goods. They are a vital part of the hydrogeologic cycle of the planet and act as a global air purifier, absorbing huge amounts of carbon dioxide and releasing oxygen.

Despite their importance, rain forests everywhere are exposed to huge threats. Often, forests are cleared with fire to make room for cultivation. One plot is used for a few years until the soil is exhausted, and then farmers move on to clear another patch, putting the lushest forests in danger of desertification. But other industrial interests, including timber and mining, are taking advantage of rain forests. Part of the danger comes also from animal and plant species introduced from other environments. All these activities result, every year, in a rather large loss of rain forest. It is difficult to estimate the extent of the damage, as data are not plentiful or reliable. Nevertheless, it is true that in some countries, like Madagascar, the whole forest has almost disappeared in a few decades. As a result, human activities might be inducing the most important mass extinction since the fall of dinosaurs 65 million years ago. According to some research, up to 10% of the world's species might disappear in the next 25 years. But the truth is that over 50% of the earth's plants and animal are in danger. Nearly 20% of known endangered vertebrates are threatened by introduced species. Cultures are going extinct, too. Since the turn of the century, 90 tribes of indigenous peoples have been wiped out in Brazil alone. The pace of annihilation is increasing; 26 of those tribes were killed or scattered in the past decade. Everything should be done to halt this loss that many scientists think might affect the earth's climate, too, on a global scale.

FROST

Arthur M. Holst
Philadelphia Water Department
Philadelphia, Pennsylvania

Essentially, a type of dew, frost is ice formed by the condensation of atmospheric water vapor on a surface. It generally occurs at night, and when frost forms, it can sometimes be seen in patterns of ice crystals. Frost can be extremely damaging to outdoor crops and plants. Researchers and weather services throughout the world monitor the effects of damaging frosts. Frost forms on any surface, including cars, grass, and buildings. Frost forms through one of two processes: the formation of dew that subsequently freezes, or deposition, which is the process wherein a gas changes to a solid. In frost formation, this gas is water vapor, and the solid state is ice crystals. These two processes will occur when the air is saturated. Saturation occurs when the air holds as much water vapor as is possible at its temperature and pressure. The temperature at which frost is deposited is known as the frost point temperature.

Condensing water vapor must have something upon which to condense. If the temperature of the ground is below 0 °C, then the deposit will initially be as dew. Over time, this dew will eventually freeze, forming frost. However, if the dew point of the air is below 0 °C, the deposit will be hoarfrost, which is ice that forms directly through deposition, without initially forming as dew. Hoarfrost is also known as black frost, because unlike regular frost, it is not visible as white crystals (normal frost is called white frost).

It is possible for frost to form even if the air temperature is above freezing. Frost formation depends solely on the air's dew point. However, the temperature of a surface affects whether or not dew, frost, or hoarfrost form because colder objects radiate less heat into the air surrounding them, keeping that air's dew point down. The formation of frost is also governed by a process known as radiational cooling. Frost formation requires a surface temperature below 0 °C, so cold surfaces are necessary. At night, certain surfaces will cool much faster than the surrounding air and other surfaces because all objects radiate heat at all times. During the day, objects generally recoup any lost energy from energy received from the Sun. However, at night, objects no longer receive heat radiated by the Sun, and so less energy is generally received, resulting in a rapidly decreasing nighttime temperature. Frost is more likely to form on clear nights because surfaces cool faster when no clouds radiate heat. On cloudy nights, the clouds may radiate enough heat to surfaces to prevent frost from forming.

Frost typically forms under conditions of light or no wind and sufficiently cold temperature. Winds cause air turbulence, and this turbulence mixes the air, which inhibits frost formation. Typically, frost will form more easily overnight because temperatures tend to be lower and the air moves more slowly than it does during the day. Due to radiational cooling, frost forms less often in areas where many buildings, trees, and other objects are; it also forms less often near bodies of water.

Multiple factors are used by scientists and meteorologists to determine whether or not frost will occur on a given night. One is the general weather of that day/night. The situation most favorable to frost formation is a cloudy day followed by a clear night because clouds prevent the Sun from adequately heating the soil. Humidity is also used. If the dew point is over 5.5 °C at night, frosts are unlikely. If it is below 2.2 °C, a frost is highly probable.

In areas where frost forms, local weather services will designate the type of frost that might be deposited in the region. These designations are light, heavy, and killing. A light frost will have no destructive effects on vegetation. A heavy frost is a significant deposit but is not likely to affect the staple vegetation of a region. A killing frost is severely destructive to vegetation and can decimate an entire crop. In the United States, frost warnings will be issued only until October 15th west of a line from Frederick, Maryland, to Charlottesville, Virginia. East of this line, warnings are not issued past November 1st. In the spring, frost warnings are issued only if there is a possibility that crops and other plants could be damaged.

Killing frosts are monitored by weather services, as regions attempt to predict possible arrival dates, so that crop producers can better prepare for their arrival. Various methods can be employed to diffuse the effects of a harmful frost, such as placing small heating systems throughout a crop area, continuously sprinkling water on crops throughout the night, or, on a smaller scale, placing simple screening cloths around a home garden. Farmers and scientists are continuing to experiment with new methods to avoid the harmful effects of black frost on vegetation. Frost harms plants by forming ice in and around cells. The water around the cells is purer than that inside the cell, so it will usually freeze first. Those plants that have greater quantities of solutes within their cells are more resistant to frost and can withstand cold temperatures more easily than those plants with little solute in their water. Plant damage from frost is determined by the type of plant, the stage of growth of the plant, and the length of time the temperature is low enough for frost formation.

FROST DAMAGE

Arthur M. Holst
Philadelphia Water Department
Philadelphia, Pennsylvania

Frost is ice formed by the condensation of atmospheric water vapor on a surface. When low temperatures are present in a certain region, the potential for frost damage to plant life exists in that region. Frost damage can injure plants permanently or slow plant development. Several factors dictate the extent and severity of frost damage to plants in any given region.

Frost damage can have profound effects on agriculture and ecosystems. Frost is most likely to form on a cold, clear night that has been preceded by a cold and cloudy day. Lack of wind is vital to a developing frost. The little heat that was stored in the ground during the day will dissipate more quickly overnight. If the dew point has dropped below freezing, the result, is a heavy frost. As conditions change from day to night, an air temperature drop of 1 °C per hour is a signal that a frost is likely to develop.

Even if the conditions of freezing temperatures and a calm night are present, some areas will be more susceptible to frost damage than others. Fields that have lighter soils, which dry out faster, fail to insulate the soil below. This will prevent the natural warming by soil radiation of the air directly above the soil surface and increase the likelihood that a heavy frost will form. Recently cultivated fields will suffer the same fate. Low-lying valleys, where cold dense air cannot be affected by winds, can be heavily damaged. Areas of a field that are close to the edge of a crop formation are also susceptible. In these areas, grass near a crop formation acts as a blanket or insulator, preventing warm soil from heating cold air directly above it. Finally, areas that have recently been treated with herbicides are more susceptible to frost damage. Herbicide stress on a plant can be compounded by cold stress from the weather, increasing the possibility of frost damage.

Frost damage is evidenced by a variety of symptoms on plants. Plant leaves are the best indicators of frost damage. Frost damage on the youngest leaves of a plant (the top leaves) is often seen as a burn on the tips of the leaves. More severe damage is a darkening of the entire leaf. In the most extreme form, the entire plant takes on a black appearance. This darkening is evidence that the frost penetrated and destroyed cell membranes of the plant. Severe darkening of this kind is sometimes referred to as a “killing frost.” Whether a killing frost has set in on plant life may not be noticeable until a day or two after the frost. If the plant has turned almost completely brown, chances of recovery are not good. However, a closer look may reveal that the lower part of the plant, or the pseudostem, is still green, a good sign that some recovery from the damage may be possible. The three most important factors in determining the ability of plant life to withstand damaging frost are the plant’s maturity, its health prior to a frost, and the weather immediately following the frost. Susceptibility to frost damage increases as plant development increases. As the growing season progresses, the chances of weather conditions conducive to a damaging frost decrease. Young plants are less susceptible to frost damage that will lead to a plant’s death because their growing points are still below ground, insulated from freezing temperatures. However, should frost injury occur at this young stage, it could severely delay growth as the season progresses and affect the overall harvest. More mature plants present more opportunities for frost damage. Mature plants have more exposed leaves and may have growing points above the earth’s surface. Damage to the outside of a mature plant can constrict future growth. Plant health prior to a frost also determines the ability of a plant to recover. If plants have been continually exposed to cold stress, herbicides, excessive moisture, or disease, even the most minimal frost can be debilitating. Finally, the weather following frost damage plays an important role in the plant’s recovery. If warm temperatures follow frost damage, a plant’s ability to recover increases.

Worldwide, 5–15% of all agricultural production is lost to frost damage each year. Frost can also cause a loss of food supplies for an animal species by killing leaves, seeds, and fruits.

THE GLOBAL WATER CYCLE

U.S. Global Change Research
Program

USGCRP-supported research on the global water cycle focuses on: (1) the effects of large-scale changes in land use and climate on the capacity of societies to provide adequate supplies of clean water; and (2) how natural processes and human activities influence the distribution and quality of water within the Earth system and to what extent the resultant changes are predictable. Specific areas include:

---

identifying trends in the intensity of the water cycle and determining the causes of these changes (including feedback effects of clouds on the global water and energy budgets as well as the global climate system); predicting precipitation and evaporation on timescales of months to years and longer; and modeling physical/biological processes and human use of water, to facilitate efficient water resources management.

The USGCRP budget includes $311 million in FY 2003 for research and observations related primarily to the Global Water Cycle. The Global Water Cycle program studies the movements and transformations of water, energy, and water-borne materials through the Earth system and their interactions with ecosystems. The movements and transformations of water are important because they appear to control the variability of the Earth's climate and they provide an essential resource for the development of civilization and the Earth's environment. Figure 1 schematically illustrates the movements and transformations. This cycling involves water in all three of its phases—solid, liquid, and gaseous—and exchanges large amounts of energy as water moves and undergoes phase changes. Therefore, the water cycle operates necessarily on a broad continuum of time and spatial scales.

Water vapor is a greenhouse gas that maintains temperatures in a range required by life on Earth. Many of the uncertainties in the current projections of the effects of the atmospheric buildup of carbon dioxide are related to the feedbacks between the climate and the water cycle. While warmer temperatures enable the atmosphere to hold more water leading to further warming, the complex interactions among changing cloudiness, precipitation patterns, land cover, and decreasing snow and ice cover have limited the quantitative understanding of the links between water and climate warming.

Water is not evenly distributed over the globe, nor is it always accessible for human use. Society is becoming more vulnerable to variations in the water cycle as a result of expanding populations and increasing water use. The increasing demands for water accompanied by the growing economic losses from droughts and floods place pressure on the science community to develop the knowledge and tools needed to manage our limited water resources more effectively. There are large potential paybacks from increased investments in scientific research to improve the monitoring and prediction of the global water cycle variations and in water management applications.

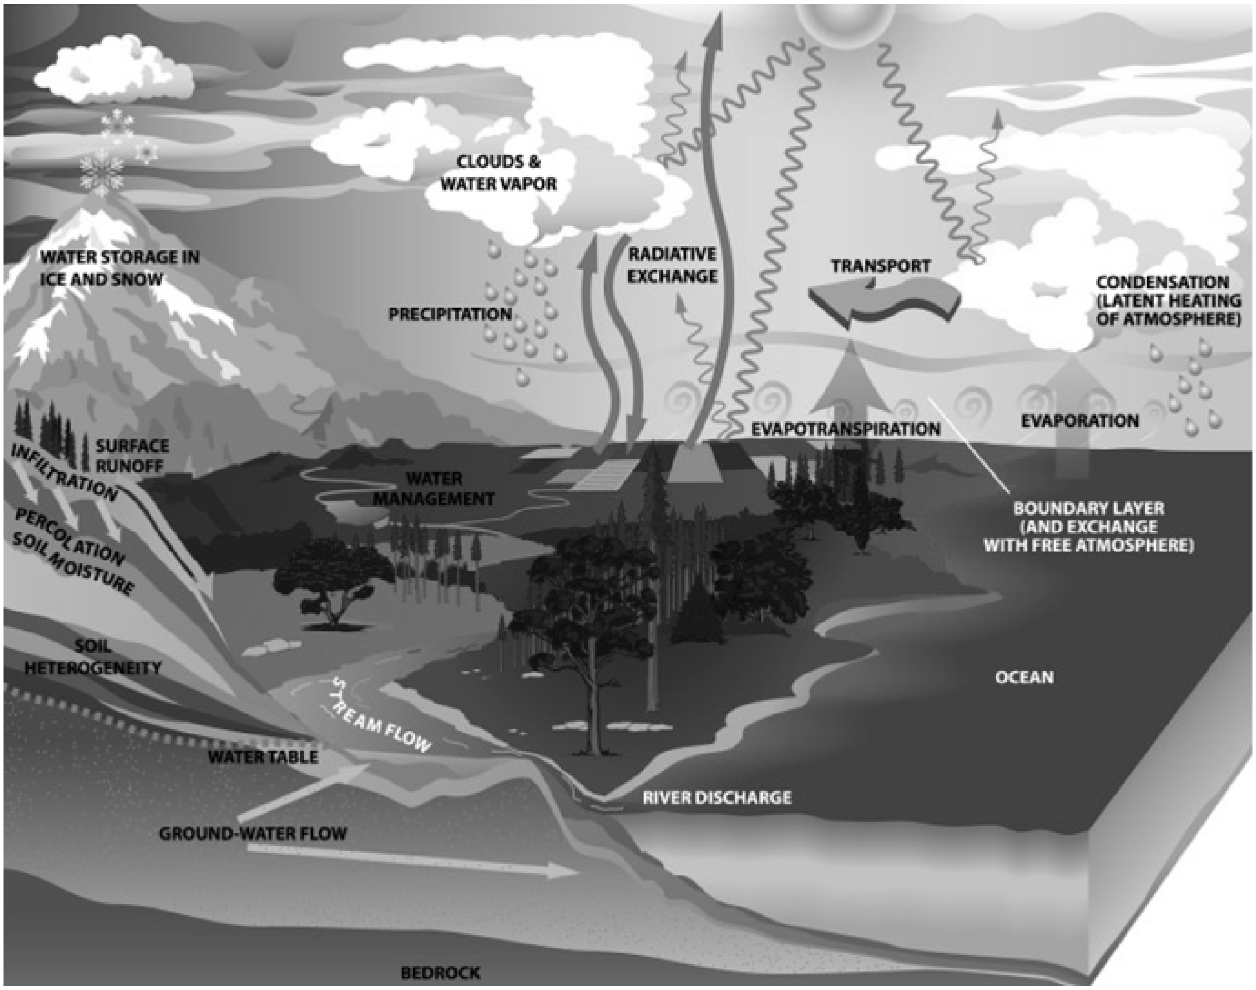

Figure 1. Conceptualization of the water cycle.

On a national basis, near-crisis situations have occurred in several dry southwestern river basins, including the Colorado and Rio Grande, where over-allocation has taken place. Recent drought conditions and rapid development in these basins have exposed the intensity of competition that exists over the available water resources. The development of a capability to predict where water management crises will emerge due to a drought or extended flood conditions is a priority for the Global Water Cycle program. The ability to provide probabilistic forecasts of rainfall and snowfall at various time and space scales is at the center of all potential applications of climate change science and climate information systems. The program has research activities directed at developing experimental predictions that will ultimately benefit society through better protection of human health and assets, and more efficient water system management and infrastructure planning.

Human activity is an integral part of the water cycle. A recent USGCRP-commissioned report, *A Plan for a New Science Initiative on the Global Water Cycle*, issued in 2001, concluded that, among other priorities, there is a pressing need to determine the causes of water cycle variations on both global and regional scales, and to what extent these variations are induced by human activities. In view of this emerging link between water science and water resource issues, the USGCRP global water cycle strategic plan addresses two major questions: (1) What are the effects of large-scale changes in land use and climate on the capacity of societies to provide adequate supplies of clean water, and (2) how do natural processes and human activities influence the distribution and quality of water within the Earth system and to what extent are resultant changes predictable?

Stakeholders are helping to define the Global Water Cycle program at the catchment and larger river basins scales. Users are interested in better forecasts of precipitation, runoff, and soil moisture. Reservoir management decisions require forecast lead times of up to seasons and, in some cases, years. For planning reservoirs, dam recommissioning, and water control infrastructure, and developing new proposals for water law, projections of water variability are required on the decadal to century timescales.

The USGCRP Global Water Cycle program focuses on characterizing, explaining, and predicting variability and long-term changes in the global water cycle and their impacts. To address the issues arising from the intimate role of the water cycle in controlling climate variability on seasonal to multidecadal timescales, the program investigates the pathways of water movement between the biosphere and surface hydrologic systems, the atmosphere, and the oceans, as well as feedback processes between climate, weather, and biogeochemical cycles. Because the biosphere is a substantial regulator of the Earth's carbon cycle, the global water cycle maintains a considerable influence upon the global pathways of carbon. Globally, the cycling of water and its associated energy and nutrient exchanges among the atmosphere, ocean, and land determine the Earth's climate and cause much of climate's natural variability.

A critical contribution of the USGCRP to Federal water activities lies in the benefits that come from drawing together the wide range of programs and expertise from different agencies with the capabilities of the academic community to address these complex issues. The elements of the management structure that the USGCRP has put in place during the past year include: (1) Interagency Global Water Cycle working group, (2) Global Water Cycle scientific steering group, and (3) Global Water Cycle program office. The linkages between the global water cycle, the global carbon cycle, and climate will be explored in the coming year through this strengthened program management structure.

Laboratory

INTRODUCTION

Water vapor is one of the most important components of the Earth's atmosphere. It is the source of precipitation, and its latent heat is a critical ingredient in the dynamics of most major weather events. As a greenhouse gas, water vapor also plays a critical role in the global climate system: it absorbs and radiates energy from the sun and affects the formation of clouds and aerosols and the chemistry of the lower atmosphere. Despite its importance in climate and weather prediction, water vapor has been one of the most poorly measured and least understood components of the Earth's atmosphere. Researchers at FSL and elsewhere are utilizing recent technology to reverse this situation.

The ability to use the Global Positioning System (GPS) to make accurate refractivity measurements under all weather conditions has led to the development of a promising new meteorological observing system for NOAA. The

---

first and most mature application of ground-based GPS meteorology involves the measurement of integrated (total column) precipitable water vapor (IPW) in the atmosphere. The GPS-IPW technique is more advantageous than conventional water vapor observing systems because of its low-cost, high-measurement accuracy, all weather operability, and long-term measurement stability. Further, GPS-IPW requires no external calibration, operates unattended for long periods with high reliability, and is easily maintained. Since GPS-IPW measurements are compatible with satellite data retrievals, they provide an independent method for calibrating and validating global satellite observations.

These positive attributes, however, are accompanied with one major disadvantage: GPS-IPW provides no direct information about the vertical distribution of water vapor in the atmosphere. In an attempt to mitigate this deficiency, researchers at government laboratories and universities around the world are investigating the best ways to use GPS-IPW as a "proxy quantity" for moisture profiles in weather forecasting.

In this article we discuss how IPW is now calculated from GPS signal delays and the potential use of slant-path measurements in numerical weather prediction models. Preliminary results of the effect of GPS-IPW on numerical weather prediction, the demonstration network, data and product availability, and plans for the operational network are also described.

CALCULATING IPW FROM GPS SIGNAL DELAYS

GPS signals are delayed as they pass through the Earth's atmosphere (Fig. 1). The signal delay caused by the presence of free electrons in the ionosphere makes the largest contribution to the total atmospheric delay. Because the ionosphere is a dispersive medium, the velocity of the GPS signals is frequency dependent and its impact can be effectively eliminated by using dual frequency receivers.

Below the ionosphere, in the electrically neutral portion of the atmosphere, refraction (that is, slowing and bending) of the GPS signal is caused by changes in temperature, pressure, and water vapor. Most of this delay occurs in the troposphere, which extends from about 9 km at the poles to about 13 km at the equator. The primarily tropospheric delay consists of a hydrostatic (or dry) component caused by the mass of the atmosphere and a wet component (the wet delay) caused by the dipole moment of the water vapor molecule. The contributions of the wet and dry components of the tropospheric signal delay are in the same proportion as the wet and dry components of the atmosphere.

FSL currently collects GPS observations from a demonstration network of 55 sites (Fig. 2) and processes them to produce IPW measurements every 30 minutes using the scheme shown in Fig. 3.

The first step in obtaining IPW from GPS observations is to determine the zenith-scaled delay caused by the neutral atmosphere. This delay is commonly referred to as the zenith tropospheric delay (ZTD), and is calculated from carrier phase and range observations made by networks of GPS receivers. The calculation is made using GPS analysis software such as GAMIT (GPS At MIT), which in addition to the GPS observations, requires improved satellite orbits and parameters describing the orientation of the Earth in space and time. Next, the ZTD is separated into its wet and dry components using additional observations made by collocated surface meteorological sensors. The zenith- scaled hydrostatic delay (ZHD) is caused by the mass of the atmosphere directly above the site and can be estimated with great accuracy from a surface pressure measurement. The wet signal delay (ZWP) is caused by water vapor along the paths of the radio signals to all satellites in view, about 6 to 8 with the current GPS satellite constellation.

ZWP is calculated simply by subtracting the hydrostatic delay from the tropospheric delay. The resulting wet delay can be mapped into IPW with an error of about 5 degrees using a quantity that is proportional to the mean vapor pressure-weighted temperature of the atmosphere (Tm). Tm may be estimated from a climate model, the surface temperature derived from a numerical weather prediction model, or measured directly using remote sensing techniques. FSL is planning to utilize model-derived Tm estimates operationally.

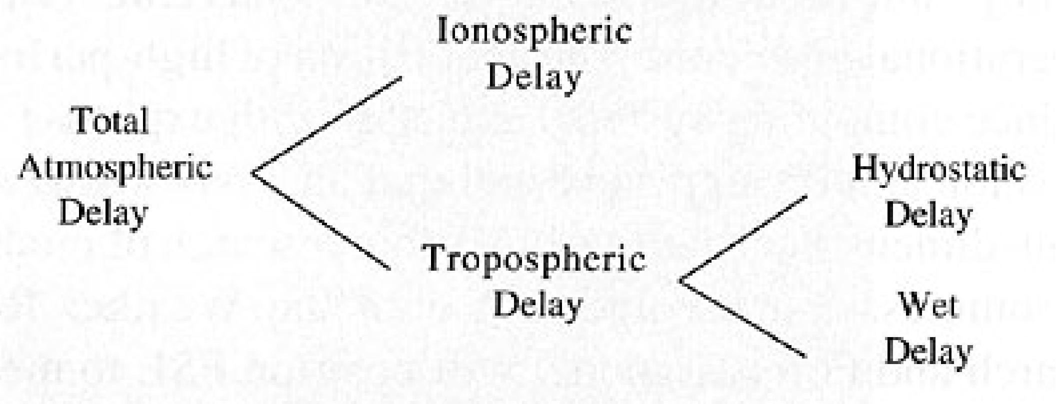

Figure 1. Signal delays caused by the atmosphere.

Figure 2. A map of the NOAA-FSL Global Positioning System Integrated Precipitable Water (GPS-IPW) Demonstration Network (55 sites) as of October 1999.

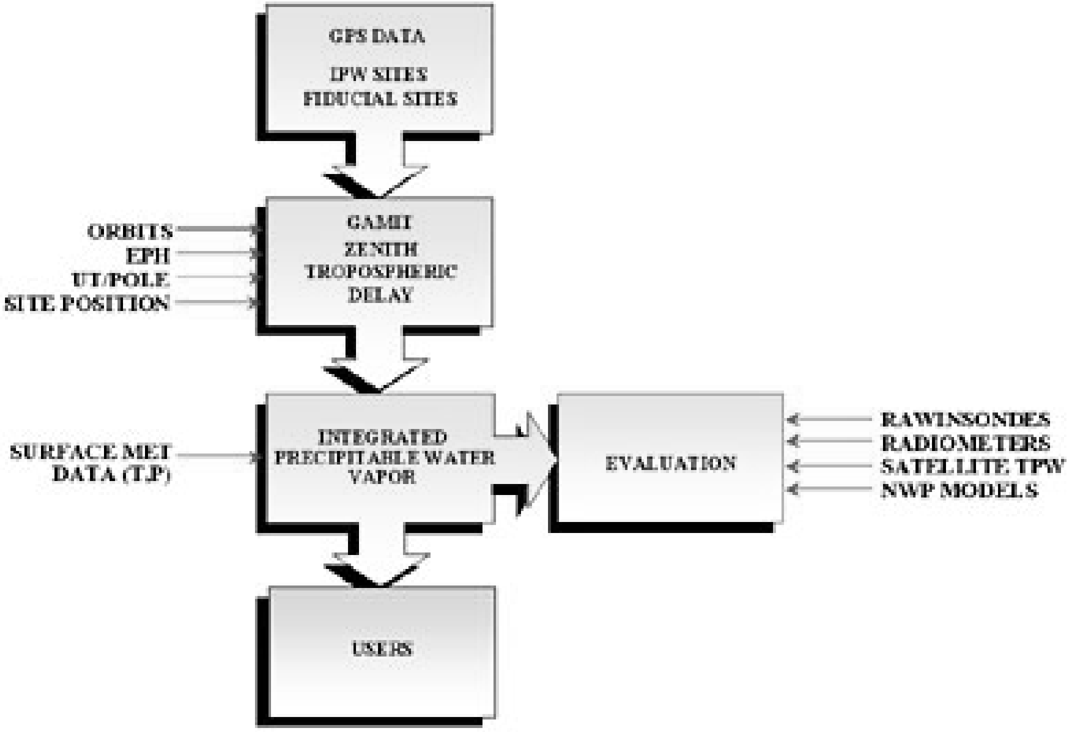

Figure 3. The FSL-developed data processing scheme used to produce IPW measurements.

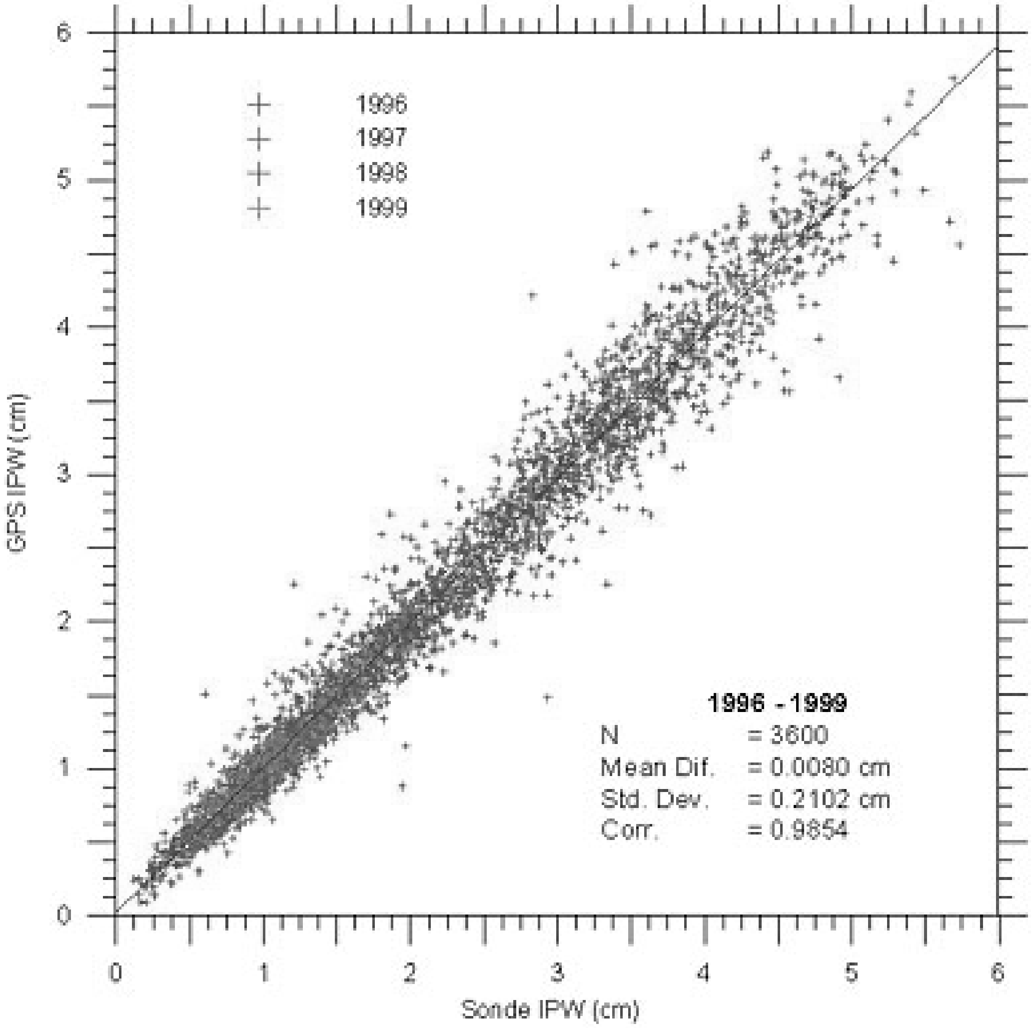

Figure 4. Scatterplot of GPS and rawinsonde observations of integrated precipitable water vapor at the ARM CART site near Lamont, Oklahoma, between January 1996 and September 1999.

Integrated precipitable water calculated from GPS signal delays is physically identical to integrated measurements or retrievals made by other upper-air observing systems including rawinsondes, ground-based microwave water vapor radiometers, or satellite microwave and infrared instruments including sounders and interferometers. Comparisons of GPS and radiosonde-derived total column water vapor have been carried out continuously since 1996 under all weather conditions at the DOE Atmospheric Radiation Measurement site near Lamont, Oklahoma. Results from 3600 comparisons (to September 1999) indicate a mean difference of 0.08 mm and a standard deviation of 2.1 mm (Fig. 4).

SLANT-PATH SIGNAL DELAY MEASUREMENTS

Recent investigations by FSL director A.E. MacDonald and Yuanfu Xie (of the Forecast Research Division) of the potential use of line-of sight estimates of path-integrated water vapor (derived from slant-path GPS signal delay measurements) to retrieve the 3-D moisture field have been very interesting and potentially significant. The experiments involve assimilating simulated slant-path moisture measurements from a wide area network of closely spaced stations into the Quasi-Nonhydrostatic (QNH) model using variational techniques. In recent research, their simulations indicate that it may be possible to recover the three- dimensional structure of the moisture field from a densely spaced network of ground-based GPS receivers making a single line-of- sight, or slant path, measurement of the signal delay to all satellites in view. The configuration of the GPS satellite constellation as seen from Boulder, Colorado, between 1200 and 1300 UTC on 28 September 1999 is shown in Fig. 5. A GPS satellite moves across the sky at the rate of about 30 degrees per hour. Although 10 satellites are visible above the horizon in this example, six to eight would be more typical at any one time.

Making a slant-path signal delay measurement with the same accuracy as a zenith-scaled measurement is

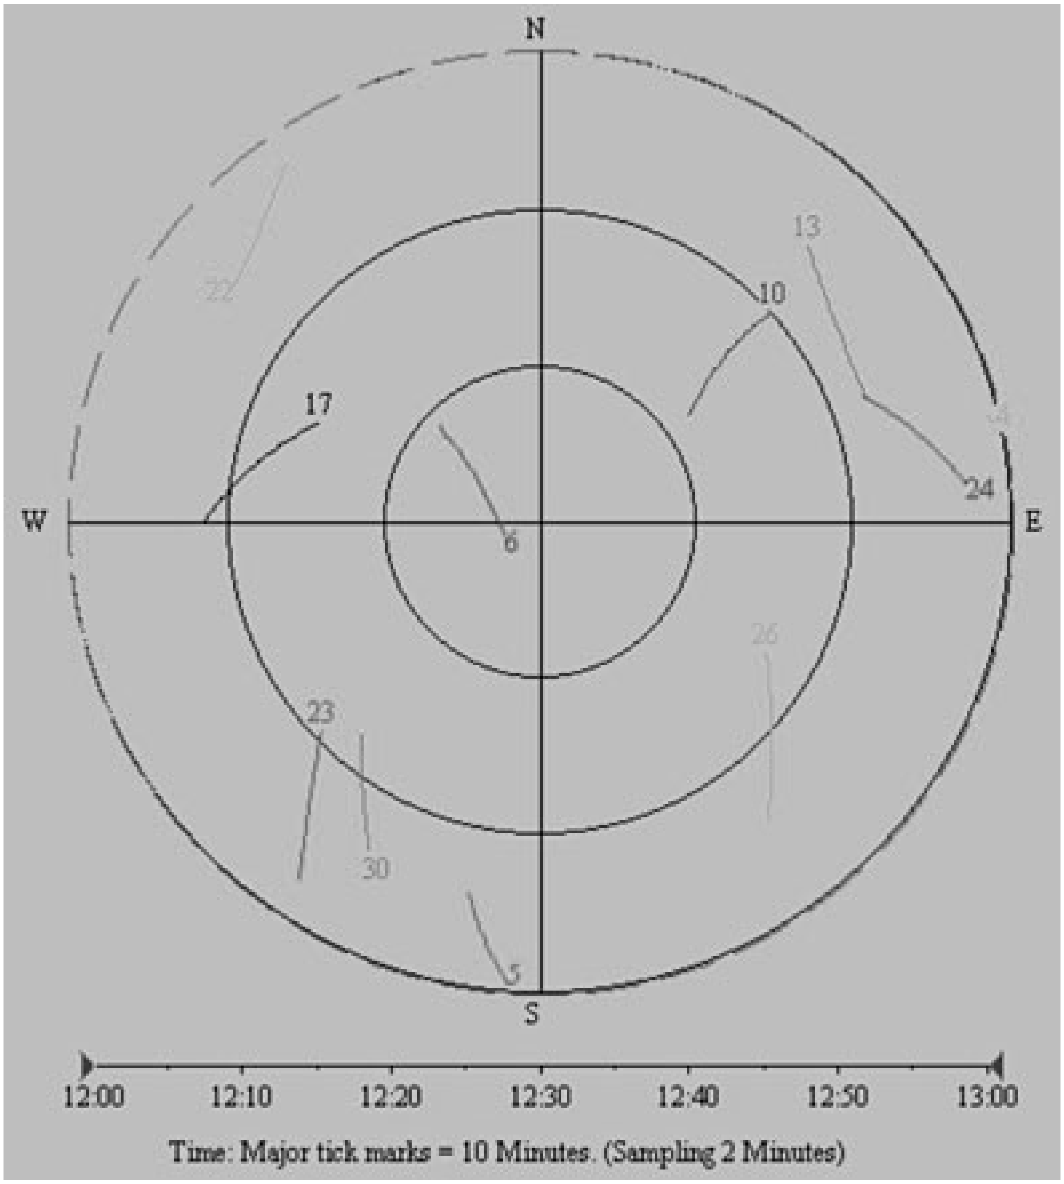

Figure 5. Configuration of the GPS satellite constellation as seen from Boulder between 1200 and 1300 UTC 28 September 1999.

not trivial. The sources of measurement error that are successfully managed through geodetic modeling of the zenith tropospheric signal delay will have to be dealt with in other ways. Although some of the most important information about the structure of the atmosphere can be obtained from low-angle observations, measurement errors increase significantly along with the negative impact of multipath reflections from nearby obstacles as satellites approach the horizon. One way to mitigate these problems is to utilize advanced GPS receivers and antennas that maximize the ability to track satellites under all conditions and reject multipath reflections. Unfortunately, not all problems can be eliminated through the selection of hardware, and advanced data processing techniques will be needed as well.

Research at Scripps Institution and the University of Hawaii into ways to monitor the accuracy of GPS orbit predictions suggests that these techniques can also be used to reduce systematic errors in slant-path signal delay or refractivity measurements to individual satellites.

EFFECT OF GPS-IPW DATA ON THE ACCURACY OF NUMERICAL WEATHER PREDICTION

Since 1997, parallel runs with and without GPS have been carried out using the research version of the Rapid Update Cycle (RUC-2) model to assess how GPS-IPW data affect the accuracy of numerical weather prediction. Results from the first two years using optimal interpolation techniques have been encouraging despite the fact that the observations came from only a limited number of widely spaced sites. Model runs using data acquired from more sites over a larger area through September 1999 confirm improvements

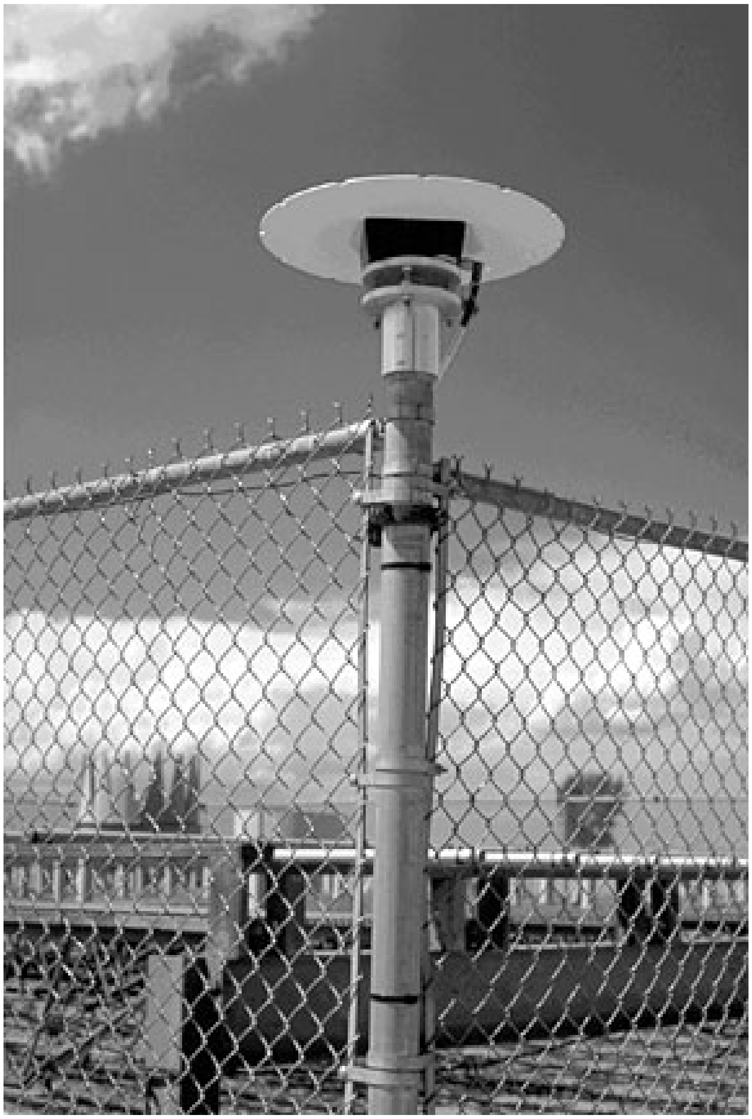

Figure 6. GPW-IPW installation at the NOAA Profiler Network site at Platteville, Colorado.

in forecast accuracy, especially under conditions of active weather. Therefore, NOAA meteorologists expect significant improvements in short-term forecasts of clouds, precipitation, and severe weather when high-resolution numerical weather prediction models routinely use data from a nationwide network of GPS-IPW systems in conjunction with data from other observing systems and advanced data assimilation techniques.

The decision to implement ground-based GPS Meteorology (GPS-Met) as a next-generation upper-air observing system will be supported in part by promising assessments such as this one. In anticipation of a favorable decision, network design and implementation options for a national network of ground-based GPS- IPW systems are being evaluated at FSL.

GPS-IPW DEMONSTRATION NETWORK

The rapid development of the GPS-IPW Demonstration Network for meteorological remote sensing has been made possible by a fortuitous synergy with the positioning and navigational applications of GPS by the U.S. Coast Guard and U.S. Department of Transportation. As of October 1999, the data acquisition component of the demonstration network consisted of 55 GPS-IPW systems operating in the continental United States and Alaska.

Thirty-four systems are currently installed at NOAA Profiler Network (NPN) sites, seven at sites belonging to other NOAA organizations or institutions affiliated with NOAA, 11 belong to the U.S. Coast Guard Maritime Differential GPS (DGPS) system, and three are at the Department of Transportation Nationwide Differential GPS facilities. Typical sites from each organization are illustrated in Figs. 6–9.

In addition to supporting the assessment of GPS as a possible next-generation upper-air observing system, the GPS-IPW Demonstration Network is designed to help NOAA accomplish the following tasks:

- Evaluate the engineering and scientific bases of ground- based GPS-Met, including advanced data acquisition and processing techniques.

Figure 7. GPS-IPW installation at the Scripps Institution of Oceanography at La Jolla, California.

- Develop and test strategies to build, monitor, operate and maintain large networks of GPS reference stations for meteorological remote sensing.
- Develop techniques to acquire, process, and quality control GPS observations and data products.
- Provide observations and derived meteorological products to users (such as forecasters, modelers, researchers) and data archives.
- Transfer ground-based GPS-Met technologies to operational use in weather forecasting and climate monitoring.
- Other possible applications under investigation include calibration and validation of environmental satellite data and improved positioning and navigation services.

All ground-based observing systems in the GPS-IPW Demonstration Network consist of dual-frequency GPS receivers and antennas, and collocated surface meteorological sensors.

These systems are located at sites where shelter, power, and communications are available to operate and collect data from the instruments, and transmit these data in real or near real time to one of two locations. The generalized flow of data and products from the network is illustrated in Fig. 10.

DATA AND PRODUCT AVAILABILITY

GPS and surface meteorological observations from the GPS-IPW Demonstration Network sites are available to the general public in near real time through the NOAA National Geodetic Survey. Information and raw data may be acquired via the Web.

Processed data, including GPS signal delays and integrated precipitable water vapor, are available shortly after improved NAVSTAR GPS satellite orbits and Earth Orientation Parameters are available from one of the International GPS Service (IGS) tracking stations. This usually occurs within 24 hours of the close of the day, but efforts to accelerate the process and make improved orbits available within 1–3 hours are well underway. IPW and other products may be acquired from the FSL Demonstration Division, *GPS-Met Observing Systems Branch*.

Figure 8. GPS-IPW installation at the U.S. Coast Guard Differential GPS site at Cape Canaveral Air Force Station.

PLANS FOR NETWORK EXPANSION AND IMPROVEMENT

Our primary goals in 2000 are to continue to expand the demonstration network, demonstrate distributed data processing using low-cost PCs instead of high-end workstations, and implement real-time data processing.

Expansion of the Demonstration Network. Now that all NOAA Profiler Network sites have been equipped with GPS-IPW systems, expansion of the network will mostly proceed by installing GPS Surface Observing System (GSOS) packages at U.S. Coast Guard Maritime DGPS and Department of Transportation NDGPS sites. Depending on the availability of funds and the status of interagency agreements under review, during the next year we hope to install 21 new systems at DGPS sites (mostly in the Mississippi Valley and Great Lakes regions), 11 NDGPS sites, and one at the Department of Energy ARM facility at Point Barrow, Alaska (Fig. 11).

Implementation of Real-time Data Processing. We define real-time data processing as acquiring and processing GPS and ancillary observations to yield signal delay or IPW calculations within a single numerical weather prediction assimilation cycle. In the case of the Rapid Update Cycle, running operationally at the National Centers for Environmental Prediction, this is approximately 75 minutes.

Real-time data processing techniques are being tested and evaluated in a collaborative effort involving FSL, the Scripps Permanent Orbit Array Center, and the University of Hawaii at Manoa. Techniques involve acquiring data from a subset of the IGS global tracking network and using these observations to produce an improved retrospective orbit with only about 2-hour latency. An orbit prediction that covers the data gap is also made, and it is this short-term prediction that is used to calculate IPW. In theory, the error in a prediction that spans only 2 or 3 hours will be proportionally less than an error made over an interval of 36–48 hours.

Real-time quality control techniques are also under evaluation. The most promising involve continuous monitoring of the relative positions of a number of sites, and using these data to infer changes in orbit

accuracy for specific satellites in the constellation. When a problem is encountered, the satellites are removed temporarily from the ephemerides until an updated orbit can be produced.

Distributed Data Processing. Recent advances in low-cost PC processor speed and memory will be utilized to perform data processing in a fully distributed environment. During this year we have demonstrated the ability to partition a large network into smaller subnetworks, process each independently in substantially less time with no significant loss of accuracy and precision.

Operational GPS-IPW Network Implementation Strategy. The expansion of the GPS-IPW Demonstration Network to about 200 sites, and the transition from retrospective to real-time data processing will enable us to assess the impact of these data on weather forecast accuracy. Based on the results of these studies, a decision to implement ground-based GPS-IPW as a next-generation upper-air observing system for NOAA is expected. The following plan has been developed to expand the demonstration network to an operational network of about 1000 sites with an average station spacing of somewhat less than 100 km (Fig. 12).

- Once transition of the GPS-IPW Demonstration Network to operational status has become a reality, receivers and antennas will be upgraded. Communications will transfer from FTS-2000 to the AWIPS [Advanced Weather Interactive Processing System] communications systems via the Internet.
- GPS receivers will be added to about 800 Automated Surface Observing (ASOS) sites (sample site shown in Fig. 13). The reason for collocating GPS at ASOS sites is to take advantage of the surface meteorological data and site infrastructure, including shelter, power, data communications, field maintenance, and logistics support. This will minimize implementation time and life-cycle cost. The GPS antenna installation at a typical ASOS site will resemble the one at FSL's new location, the David Skaggs Research Center (Fig. 14).
- Data processing hardware, software, and training will be provided to all AWIPS offices (Fig. 15).

CLIMATE AND WATER BALANCE ON THE ISLAND OF HAWAII

James O. Juvik
D.C. Singleton
G.G. Clarke
University of Hawaii
Hilo, Hawaii

INTRODUCTION

The island of Hawaii, with a surface area of only 10,455 km, exhibits a spectacular range of climatic

---

diversity comparable with that found on large continents. Three major factors contribute to this climatic diversity:

1. Topographic relief. The volcanic mountains of Mauna Kea and Mauna Loa reach summit elevations of 4,205 m and 4,168 m, respectively. The attitudinal range provides for a diversity of temperatures, and the mountains themselves are barriers that induce orographic precipitation.
2. Large-scale synoptic wind field. The strong and persistent northeast trade winds interact with the island topography to produce distinctive windward and leeward climates. The associated upper-level trade wind inversion exerts a particularly strong control on mountain precipitation gradients.
3. Local circulation. Differential heating and cooling of the land, water, mountain, and lowland areas on Hawaii give rise to localized wind regimes which add to the island's climatic diversity.

KOPPEN CLIMATIC ZONES

Integrating the attitudinal temperature gradients with the annual, seasonal, and spatially variable rainfall regimes results in a diverse combination of climatic environments. The Koppen climate classification uses monthly temperature and precipitation characteristics in a descriptive system that distinguishes broad regional and global climatic zones. The system has been often criticized for its empirical approach and lack of emphasis on "dynamic processes" (e.g., 1); however, as a "first approximation" the Koppen classification offers useful insights into regional climatic patterns.

Four broad Koppen climatic zones are distinguished on the island of Hawaii. They are organized primarily as concentric attitudinal bands on the mountain slopes. Figure 2 illustrates the spatial distribution of these Koppen climatic types on the island. The map was constructed on the basis of temperature (absolute or extrapolated) and precipitation data from 55 island stations. Discussions of the zones follow.

Humid Tropical Zone (A climates)

Characterized by warm temperatures throughout the year and relatively high annual rainfall, humid tropical climates occupy the lower slopes of the island from sea level to about 450 m (slightly higher in warmer areas of leeward

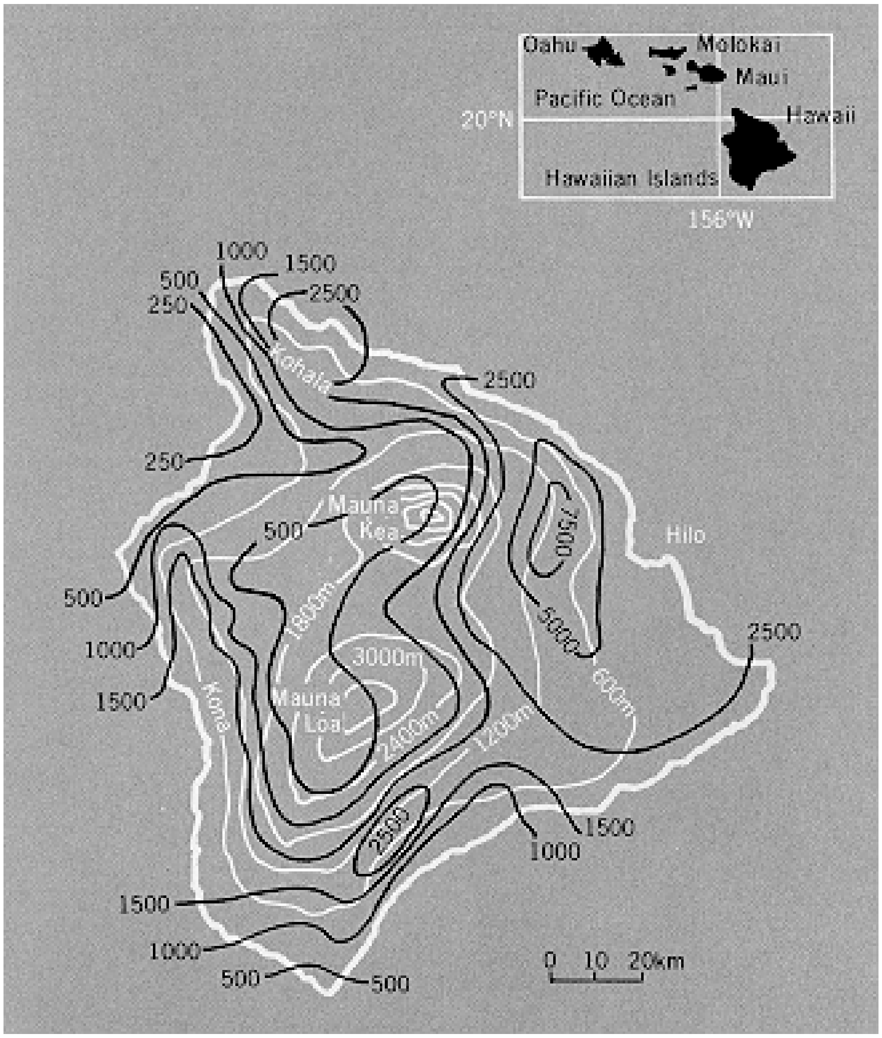

Figure 1. Distribution contours of mean annual rainfall (mm), superimposed on topographic map of the island of Hawaii. (Redrawn from 2,3).

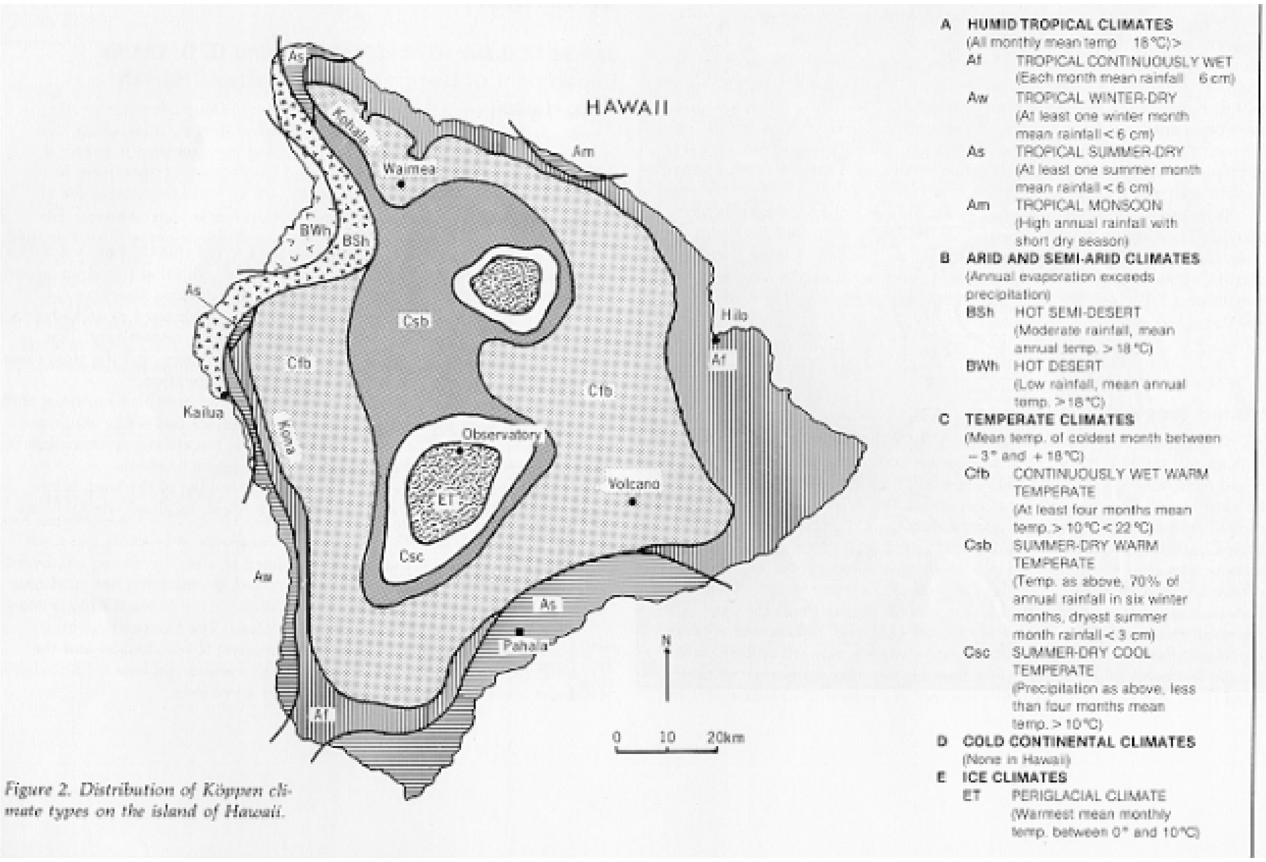

Figure 2. Distribution of Köppen climate types on the island of Hawaii.

Kona). This tropical zone may be further differentiated on the basis of rainfall seasonality. Large-scale synoptic disturbances in winter (mid-latitude cyclonic storms) produce substantial rainfall that is to some extent independent of slope aspect or elevation, and as a result most locations on the island exhibit an absolute winter maximum in rainfall. However, windward areas of Hawaii also receive substantial orographic rainfall throughout the year, with the result that there is no distinct dry season (Af climate). Lowland areas on the island that are transitional in location between windward and leeward receive less orographic rainfall (since they are not oriented normal to trade wind flow) and exhibit a distinctive summer dry season (As climate). Humid summer-dry climates are not common anywhere in the world, since for most tropical locations rainfall is at a maximum in the summer, the result of increased convective instability in the high-sun period. Outside of Hawaii the As climate type occurs only in southern Madras (India) and adjacent northern Sri Lanka.

The leeward or Kona coast of Hawaii contains the only extensive area of summer maximum rainfall in the Hawaiian archipelago (Aw, winter-dry climate). Isolated from the prevailing trade wind flow by intervening high mountains, the Kona coast's dominant circulation pattern is formed by a localized land-sea breeze regime. Increased land surface temperatures in summer strengthen the daily sea breeze regime and increase convective instability, leading to a high frequency of afternoon thundershowers. The vertical structure necessary for thundershower development is further assured by the high mountains, which exclude the trade wind aloft and limit the potential for strong vertical wind shear. The presence of a strong shearing force would otherwise tend to destabilize these leeward convectional cells. Although there is generally a summer rainfall maximum throughout Kona, the Aw climate gives way to Af at elevations above 400 m, where, by virtue of general orographic position, there is adequate precipitation in all months.

Arid and Semi Arid Zones (B climates)

A classic rain shadow desert exists on the leeward side of the Kohala mountains. Smaller and lower (maximum elevation 1,670 m) than Mauna Kea and Mauna Loa, the Kohala mountains are incapable of blocking out trade wind flow to leeward. Having become depleted of moisture during windward ascent, the trades warm adiabatically to leeward, promoting a hot, arid zone. With only 190 mm of annual rainfall, Kawaihae on the leeward Kohala coast is the driest location in the Hawaiian archipelago. The Koppen system distinguishes two climatic subtypes, the true desert (BWh climate) and the semidesert (BSh climate) on the basis of relative aridity. In leeward Kohala the true desert gives way to semi-desert at higher elevations.

[1] The Temperate (C) and Polar (E) climates as originally proposed by Koppen were not applied in high-altitude tropical environments, which, because of their orographic complexity,

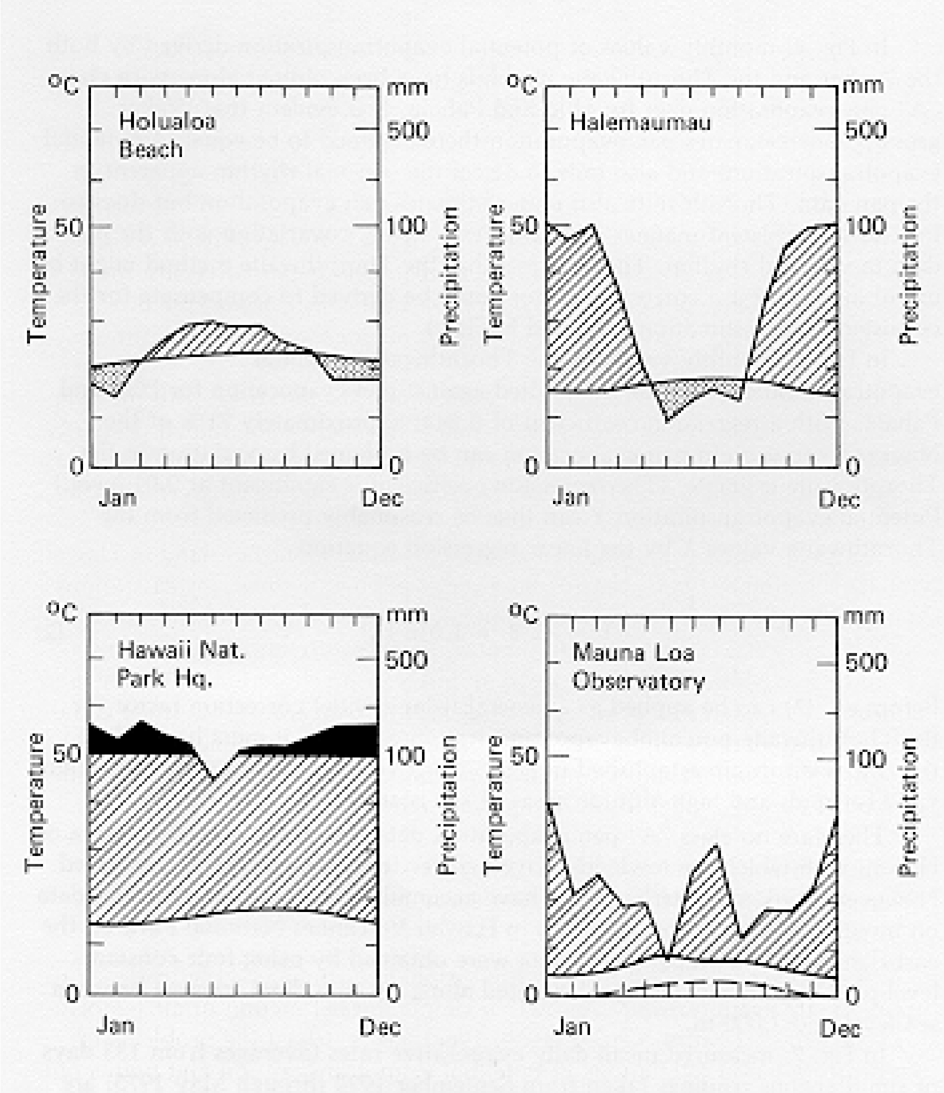

Figure 3. "Walter" climate diagrams for four Hawaii island stations (4).

Temperate Zone (C climates)[1]

Average air temperature in Hawaii decreases with altitude at the rate of about 0.55øC/100 m (Price, 1973). When the criteria of the Koppen classification are used, at elevations above 400–500 m on the mountain slopes, tropical climates grade to temperate as a result of decreasing average temperatures. As a result of the moderating influence of altitude, almost two-thirds of the "tropical" island of Hawaii possesses a temperate upland climate. The majority of this zone is characterized by warm summers and adequate precipitation in all months (Cfb climate). Except for the absence of a stronger season variability the upland Hawaii climates are analogous to those of similar Koppen designation in Pacific coastal areas of North America. Ascending orographic clouds compressed between the rising mountain slope and an upper-air temperature inversion produce frequent ground level mountain fog, an important moisture source for upland vegetation (Juvik and Perreira, 1974). At still higher elevations on Mauna Kea and Mauna Loa (above 2,000 m) there is a tendency toward summer drought. The increased strength and frequency of the trade wind inversion in summer (modal elevation 1,800 m) inhibits the vertical penetration of orographic clouds and precipitation to the higher slopes. This summer-dry zone (Gsb climate) also occurs at a lower elevation in leeward Kohala, Mauna Kea, and Mauna Loa, where summer orographic precipitation is largely absent. Above 2,500 m on both Mauna Loa and Mauna Kea the summer-dry regime changes from warm to cool (Gc climate).

Alpine (periglacial) Zone (E climates)

Above 3,200-m level on Mauna Kea and Mauna Loa all months have a mean temperature below 10 °C, and the climates are classified as periglacial (ET). Nighttime freezing is common throughout the year. Although it

lack of meteorological data, and absence of strong seasonality, were simply designated as highland climates (H). In more recent global and regional climatic maps of the tropics, highland C and E climatic areas are frequently portrayed in order to show approximate attitudinal analogs for these broad latitudinal climatic zones.

exhibits a winter maximum, annual rainfall is very low (200–400 mm) and variable. Above the 3,500-m level, winter snowfall accounts for a substantial portion of the seasonal precipitation. Koppen used the 10 °C (warmest month) boundary to separate the C and E climates on the basis that trees will not normally grow where mean temperatures fall below this level. Hence E climates characterized the treeless arctic tundra. The upper tree line of Mauna Kea (3,000 m) corresponds fairly closely to the C/E boundary mapped in Fig. 2. On Mauna Loa the tree line is much lower for edaphic reasons (recent lava).

WATER BALANCE

The preceding discussion of Koppen climatic zones on Hawaii provides a general overview of the dramatic range in regional climatic diversity found on the island. However, this descriptive approach says little about the direct linkage of climate to physical and biological processes at the earth/atmospheric interface.

An integration of seasonal moisture supply (precipitation) with the evaporation and transpiration demands of the environment (determined primarily by solar energy inputs) provides an index of moisture surplus or deficit. Such indices can illuminate direct process/response relationships between climate and the terrestrial ecosystem.

In an initial survey of water balance climatology on the island of Hawaii, Mueller-Dombois (4) constructed a series of climate diagrams 21 stations (see Fig. 3). This type of diagram, popularized by Walter and Lieth (5), portrays seasonal curves of mean monthly temperature and precipitation. According to Muller-Dombois (6) an index of precipitation efficiency is built into the diagrams by making one degree of temperature (Celsius) equal to two millimeters of precipitation in the scaling of the two ordinates. This is based on the assumption that monthly potential evapotranspiration (in millimeters) is roughly equal to twice the mean monthly temperature (7). Wherever the precipitation curve drops below the temperature curve, a drought season is indicated. Thus the graph is transformed into a water balance diagram with the temperature curve interpreted as an index of potential evapotranspiration.

A serious problem inherent in this graphing technique is the tendency to approximate evapotranspiration with a simple linear function of air temperature (i.e., the 2:1 ratio). Chang (8,9) has reviewed the problems of temperature-based estimations of potential evapotranspiration and points out that solar radiation rather than temperature is the primary forcing function in the evaporative process. Temperature-based estimates of evaporation implicitly assume a strong correlation between temperature and solar radiation. In Hawaii, as a result of advection and the buffering effect of the surrounding marine environment, there is generally poor correlation between solar radiation and temperature. In Hilo, for example, the range in mean monthly air temperature is only 1.4 °C between June (24.2 °C) and December (22.8 °C). By contrast, the receipt of solar radiation in June (563 Ly; see solar radiation data for 1965 from Ref. 10) is more than twice that in December (263 Ly).

It is obvious from the above comparison that temperature-based estimates of evapotranspiration cannot be expected to portray realistically the seasonal fluctuations implied in the radiation data. However, in the absence of a dense network of solar radiation monitoring stations on the island, upon which more sophisticated spatial modeling of evapotranspiration might be based, it is necessary to revert to some form of temperature-derived estimation in a "first approximation" of water balance regimes.

Thornthwaite (11) has developed perhaps the most widely adopted method of estimating potential evapotranspiration. His empirical formula is based essentially on air temperature:

$$E = 1.6\,(10T/I)^a. \qquad (1)$$

Potential evapotranspiration E is computed from mean monthly temperature T and an empiric "heat index" I, which itself is an exponential function of temperature; a is a constant.

To obtain mean monthly evapotranspiration, the values derived from eq. (1) are corrected for mean daylength and number of days in the month. The Thornthwaite equation, although subject to the general limitations of all temperature-based methods, might be expected to give better results than the Walter method in Hawaii,

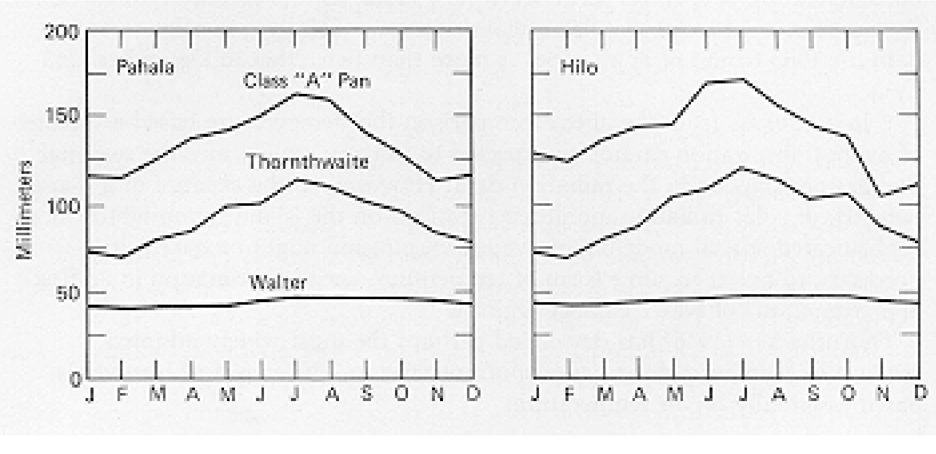

Figure 4. Monthly estimated potential evapotranspiration and measured pan evaporation for Hilo and Pahala data.

since potential evapotranspiration is expressed as an exponential rather than linear function of temperature.

In Fig. 4, monthly values of potential evapotranspiration derived by both the Walter and the Thornthwaite methods have been plotted along with class "A" pan-evaporation data for Hilo and Pahala. It is evident that Walter grossly underestimates pan evaporation (here assumed to be equal to potential evapotranspiration) and also fails to detect the seasonal rhythm apparent in the pan data. Thornthwaite also underestimates pan evaporation but does so in a fairly consistent manner and achieves a strong covariation with the pan data in seasonal rhythm. This suggests that the Thornthwaite method might be useful in Hawaii if a correction factor could be derived to compensate for the consistent underestimation exhibited in Fig. 4.

In Fig. 5, monthly values of the Thornthwaite potential evapotranspiration estimate are plotted against pan evaporation for Hilo and Pahala. With a regression coefficient of 0.844, approximately 71% of the observed variation in pan evaporation can be explained by variation in the Thornthwaite estimate. (The regression coefficient is significant at 0.01 level.) Potential evapotranspiration Y can thus be reasonably predicted from the Thornthwaite values X by the linear regression equation

$$Y = 42.8 + 1.016\ (X) \tag{2}$$

Before eq. (2) can be applied as a general (island-wide) correction factor for the Thornthwaite potential evapotranspiration estimate, it must be verified that the relationship established in Fig. 5 (for two lowland locations) is equally valid for mid- and high-altitude areas of the island.

There are no class "A" pan evaporation data for inland mountain areas of Hawaii with which the lowland-derived correction factor might be compared. However, Juvik and Clarke (12) have accumulated limited experimental data on mountain evaporation gradients in Hawaii Volcanoes National Park on the east flank of Mauna Loa. These data were obtained by using four constant-level pan evaporimeters (Fig. 6) situated along an attitudinal transect between sea level and 2,000 m.

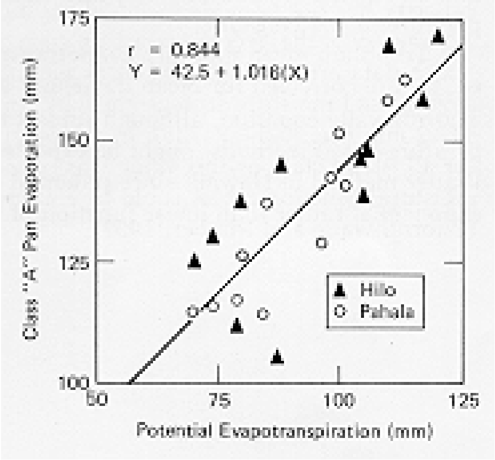

Figure 5. Relationship between monthly class "A" pan evaporation and estimated monthly potential evapotranspiration (Thornthwaite) for Hilo and Pahala data.

In Fig. 7, measured mean daily evaporative rates (averages from 133 days of simultaneous readings taken from September 1974 through May 1975) are plotted against elevation. There is a clear linear decrease in evaporation over the attitudinal range surveyed (approximately 0.72 mm/day/1,000 m). Figure 7 also shows the corrected (eq. 2) Thornthwaite potential evapotranspiration values (mean of 9 months, September to May) derived from temperature-recording stations that occur near the evaporimeter transect. There is good agreement between the Thornthwaite and the evaporimeter values (differences range from 1% to 12%), largely because air temperature also decreases linearly with elevation. On the basis of the close agreement in Fig. 7, the corrected Thornthwaite estimate was considered acceptable to use for all areas of the island

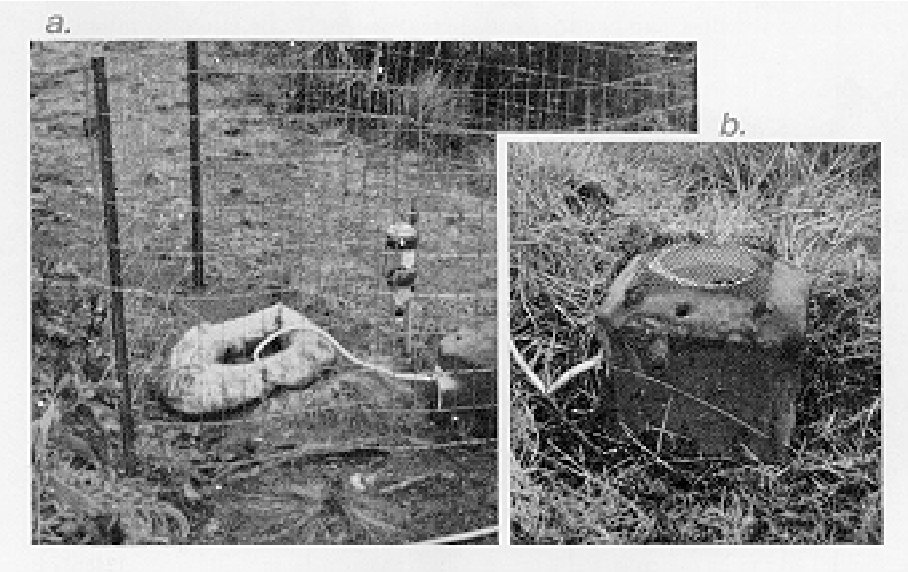

Figure 6. Constant-level pan evaporimeter. a) field installation with inner tube reservoir; b) evaporimeter detail. Note foam insulation around evaporation pan.

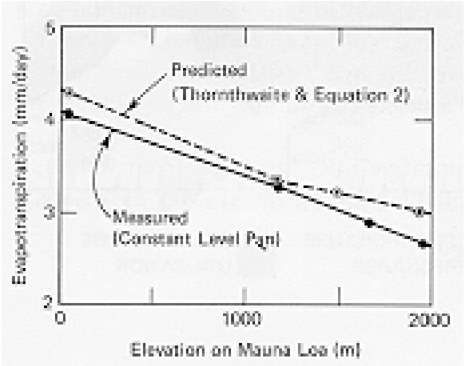

Figure 7. Relationship between measured and predicted evapotranspiration along an attitudinal transect in Hawaii Volcanoes National Park on the east flank of Mauna Loa (pan data from 12).

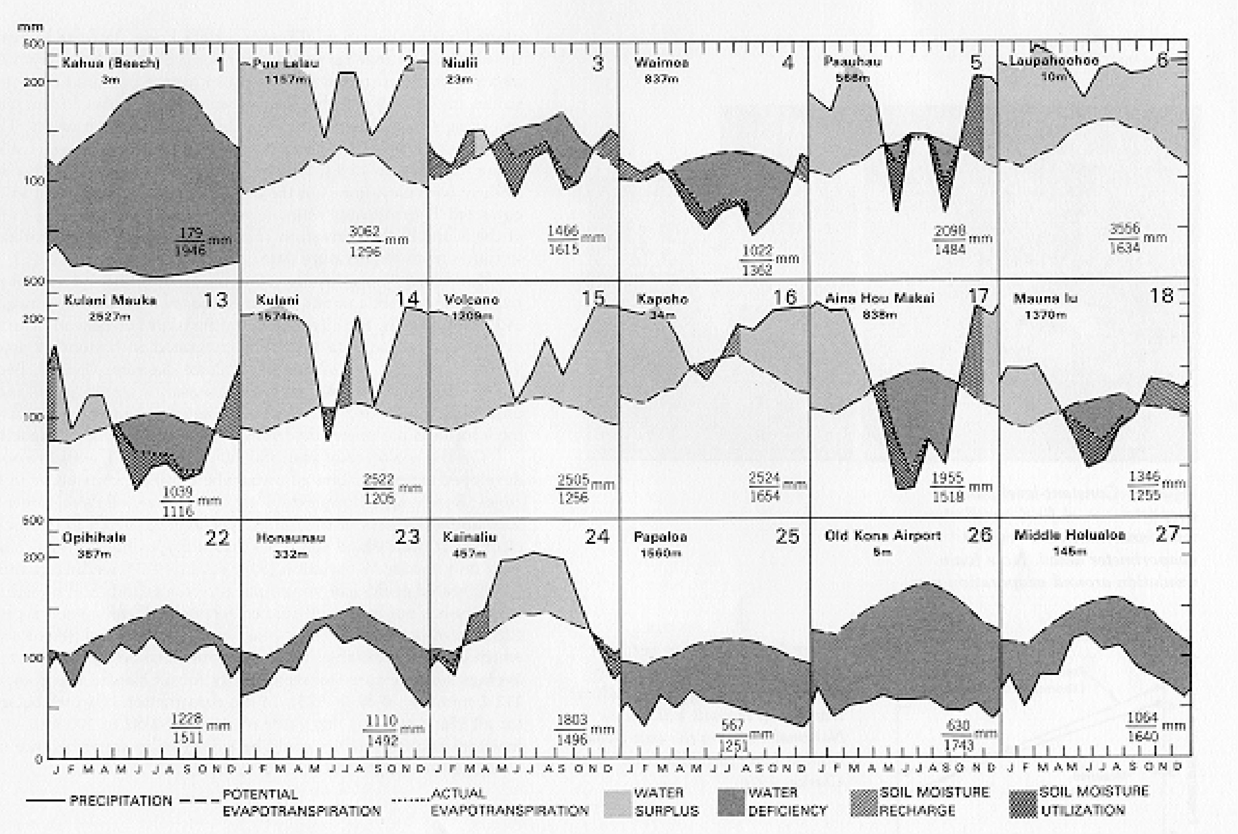
in the derivation of monthly and annual potential evapotranspiration from temperature data.

Corrected Thornthwaite estimates of monthly and annual potential evapotranspiration were computed from standard tables (13) and eq. (2), for 30 stations on the island of Hawaii. The evapotranspiration data were then integrated with monthly precipitation values to produce seasonal water balance diagrams (Fig. 8). Because some of the water surplus received in the wet season is stored as soil moisture for utilization during dry periods, the computation of seasonal water balance must incorporate a parameter describing the moisture storage capacity of the soil.

On the geologically youthful island of Hawaii, soils are not generally well developed except for limited areas where ash deposits occur in high-rainfall zones. Recent lava flows exhibiting little or no soil development cover substantial portions of the island. The average depth to bedrock for 75 different Hawaii island soil types and subtypes has been calculated at 0.89 m with only moderate variation (14), lending quantitative credence to this stated geological youthfulness of the island. Soil moisture storage capacity has not been well studied for most Hawaiian soil types. A value of 125 mm/m is the average moisture capacity for ten different soil types for which data are available. If this is assumed to be representative, then the average soil moisture storage capacity for all Hawaii island locations would be 111.2 mm (i.e., 0.89 × 125). In the construction of water balance diagrams for all island stations this value was rounded off to 100 mm so that standard moisture depletion tables could be employed in water balance calculations (13).

The 30 water balance diagrams constructed for the island depict both steep gradients and pronounced regional differences in seasonal moisture surplus and deficit. In Fig. 8 the difference between annual precipitation and potential evapotranspiration has been mapped in four zones:

1. Annual surplus exceeding 1,000 mm. This zone comprises 20% (2,100 km^2) of the island area and is restricted to the high-rainfall regions of windward Mauna Kea, Mauna Loa, and the summit area of Kohala. The annual moisture surplus in this zone



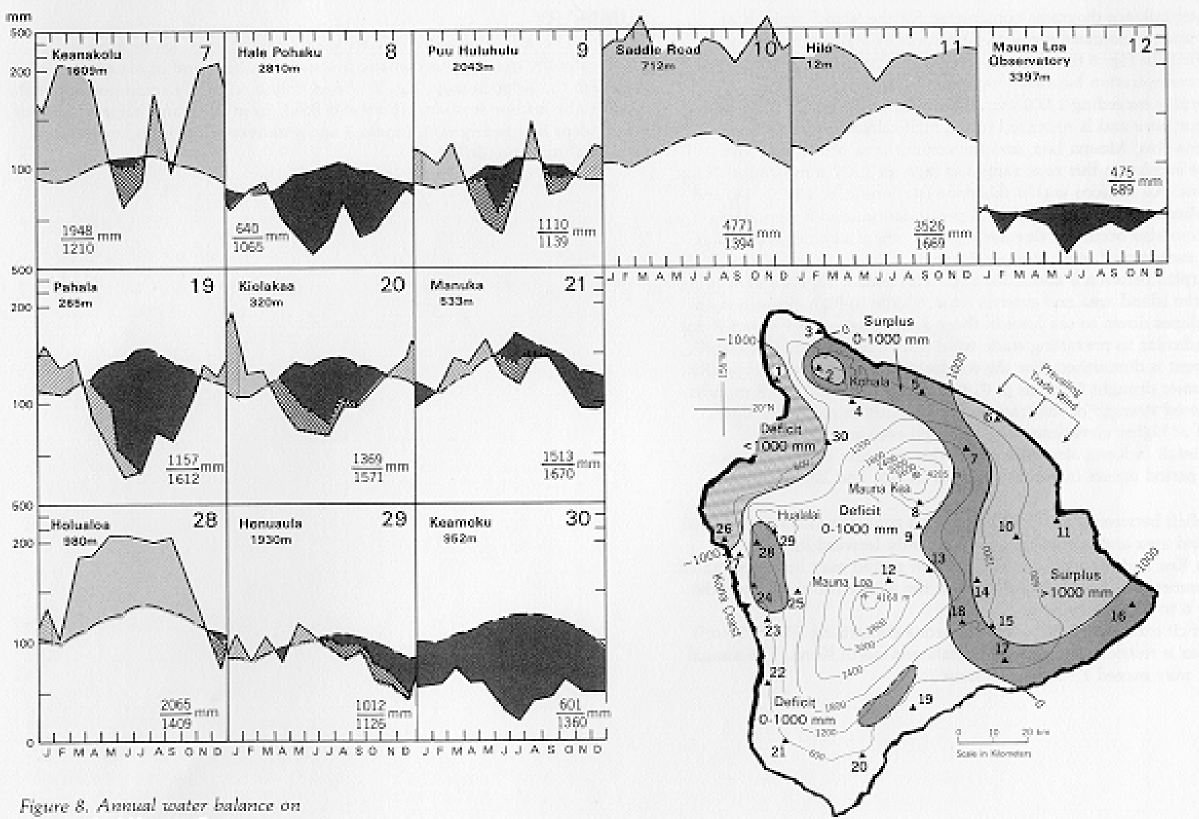


Figure 8. Annual water balance on the island of Hawaii. Ratios are mean annual precipitation over mean annual potential evapotranspiration in millimeters.

ranges as high as 3,377 mm (station 10) at middle elevations. All stations within this zone (stations 2, 6, 10, 11, 14, and 15) exhibit an absolute winter maximum in precipitation, and a secondary summer maximum also occurs at elevated stations where summer orographic precipitation is exaggerated (e.g., stations 2 and 14).

2. Annual surplus between 0 and 1,000 mm. This zone comprises 21% (2,200 km^2) of the island area and extends from middle to high elevations on the windward slopes down to sea level in those areas where slope aspect is not oriented perpendicular to prevailing trade wind flow, and thus the orographic rainfall component is diminished. For the windward stations there is typically a moderate summer drought (stations 5, 7, 9, 13, and 17) from 2 to 5 months long. The increased strength of the trade wind inversion in particular limits summer rainfall at higher elevations. The localized core area of high convectional rainfall in Kona also falls within this moisture zone. However, here the deficit period occurs in winter (stations 24, 28, and 29) and is not severe.
3. Annual deficit between 0 and 1,000 mm. This zone comprises 54% (5,600 km^2) of the island area and occupies a predominantly leeward location on Kohala, Mauna Kea and Mauna Loa. The drought period may be concentrated in either the summer (on the windward side) or the winter (on the Kona side) and is typically 6 to 12 months long.
4. Annual deficit exceeding 1,000 mm. This zone comprising 5% (550 km^2) of the island area is restricted to leeward Kohala and north Kona. The annual moisture deficit may exceed 1,900 mm (station 1).

SUMMARY

The Thornthwaite water balance diagrams and map demonstrate graphically the tremendous climatic diversity on the island of Hawaii. Although the Koppen map (Fig. 2) shows only a relatively small portion of the island to be arid or semi-arid (BWh and BSh), from the water balance analysis it is evident that nearly 60% (zones 3 and 4 above) of the island experiences an annual moisture deficit.

HEAT OF VAPORIZATION

Naraine Persaud

Blacksburg, Virginia

HEAT OF VAPORIZATION

The heat of vaporization (here denoted as L_v) is defined as the heat added (or given off) when unit mass undergoes isobaric phase transformation in any closed two-phase, one-component liquid/vapor system. In engineering and meteorology, L_v is used in a restricted sense to mean the heat of vaporization of the two-phase liquid water/water vapor system. Although much of the subsequent discussion focuses on L_v, for this specific system as an example, the concepts covered are universally applicable to all fluid/vapor systems.

As illustrated below (Fig. 1), for the liquid water/water vapor system, L_v represents the heat gained when unit mass of water in the system evaporates in the isobaric phase transformation H_2O (liquid) → H_2O (vapor). For the reverse phase change H_2O (vapor) → H_2O (liquid), i.e., condensation, L_v is lost from the system. This seemingly simple phase transition H_2O (liquid) ↔ H_2O (vapor) is the fundamental driving process of the earth's hydrological cycle, the working principle of the steam engine that ushered humanity into the industrial revolution along with its (often negative) social and environmental pollution consequences, and the physical mechanism that maintains the body temperature of plants and warm-blooded animals.

In general, the state of any closed two-phase, one-component system is defined by the state variables temperature (T in °K), saturation vapor pressure (P in Pascal), and volume (V in m^3). The behavior of any such system (generally termed as PVT systems) is usually represented as a family of experimental constant temperature curves (isotherms) on a P-V coordinate plane called an Amagat–Andrews diagram. The general shape of these experimental isotherms is illustrated below (Fig. 2).

For the liquid water/water vapor system, the liquid and vapor phases coexist in equilibrium only at P-V coordinates between 2 and 3 along an isotherm, provided

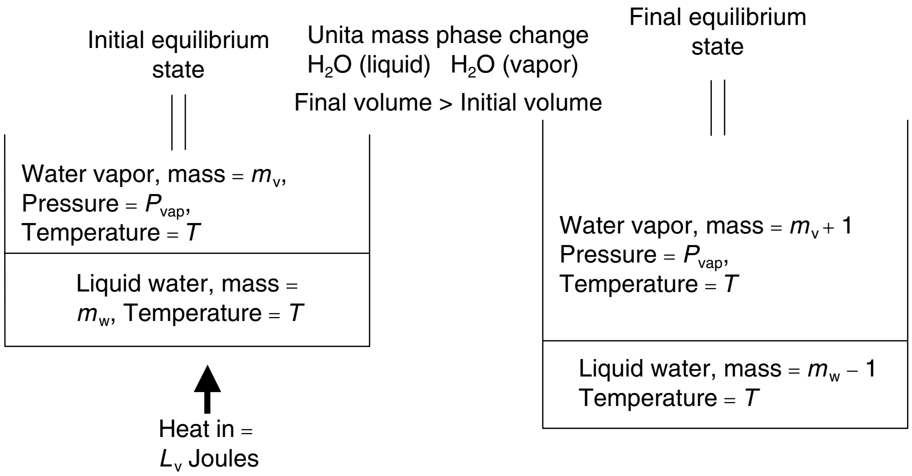

Figure 1. Liquid Water/Water Vapor System.

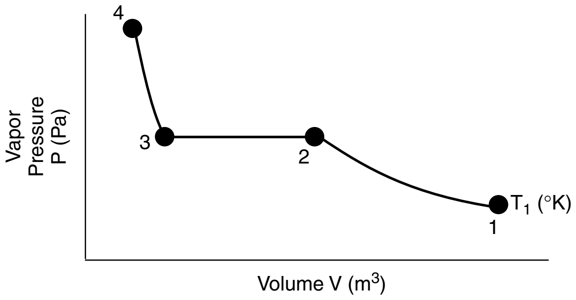

Figure 2. Amagat–Andrews Diagram.

that T_1 is above the triple point temperature of water (0.01 °C, i.e., the temperature at which ice, liquid water, and water vapor can coexist in equilibrium), and below the critical temperature (374 °C, i.e., the temperature above which it is impossible to produce condensation by increasing the pressure). Between 2 and 1, the system can exist as vapor only, and as liquid between 3 and 4. Thus the liquid-vapor phase transition at a given temperature can only take place at constant pressure or vice-versa. Consequently, as shown in Fig. 1, isobaric liquid vaporization and condensation is necessarily an isothermal process, implying that the triple-point saturation vapor pressure is fixed (it is 611 Pa), and so is the saturation vapor pressure at the critical temperature (it is 2.21×10^7 Pa = 218.2 atm). Similar isotherms and parameters exist for all liquid/vapor systems.

This observed behavior of closed two-phase, one-component systems is of course predicted by Gibb's Phase Rule (1), namely $F + N = C + 2$, where F = degrees of freedom, i.e., the smallest number of intensive variables (such as pressure, temperature, concentration of components in each phase) that must be specified to completely describe the state of the system; N = number of phases, i.e., distinct subsystems of uniform chemical composition and physical properties; and C = the number of components, i.e., the number of independent chemical constituents meaning those constituents whose concentration can be varied independently in the different phases. In a liquid/vapor system $P = 2$ and $C = 1$, and therefore $F = 1$, implying only one intensive variable is needed to specify the state of the system. Therefore, temperature and pressure cannot be fixed independently. For the liquid water/water vapor system, this means physically that at a given temperature between the triple point and critical temperature, water vapor will evaporate or condense to achieve the equilibrium saturation vapor pressure as would be evidenced in a complete Amagat–Andrews diagram for water (2,3).

The earth's atmosphere and oceans can be considered as a vast closed two-phase liquid water/moist air system. Consequently, for most practical engineering and meteorological applications, one is interested in the heat of vaporization of the liquid water/moist air system rather than a pure liquid water/water vapor system. Fortunately, the presence of the other gases (collectively called dry air) in the liquid water/moist air system has negligible effect on the saturation vapor pressure. The reason is that the dry air component in the liquid water/moist air system remains unchanged and is always in the gaseous state during phase transition at temperatures and pressures of practical interest. Therefore, it can be considered as a closed subsystem as opposed to the open liquid water and water vapor subsystems. Consequently, results obtained from an analysis of the thermodynamics of the pure system are applicable to the natural liquid water/moist air system.

Energy conservation required under the first law of thermodynamics implies that heat (Q) exchanged reversibly with the surroundings between equilibrium states of any closed two-phase PVT system is consumed by any internal energy change (ΔU) of the liquid and vapor phases associated with the mass change from one phase to the other, and any mechanical work ($\pm P\Delta V$) realized as the volume of the system increases (positive work) or decreases (negative work). Stated mathematically, $Q = \Delta U + P\Delta V$, or in a differential form, $\delta Q = dU + pdV$. Here, P is the saturation vapor pressure (P_{vap} in Fig. 1). As entropy (S) is defined as Q/T, then $\delta Q = TdS$. The first law can therefore be restated in terms of exact differentials as $TdS = dU + PdV$. Dividing by dV at constant T and rearranging gives $dU/dV = T(dS/dV) - P$. Using the Maxwell relation $(\partial S/\partial V)_{\mathrm{T}} = (\partial P/\partial T)_{\mathrm{V}}$ (1), dS/dV can be replaced (for fixed T) by dP/dT. The equation becomes $dU/dV = T(dP/dT) - P$.

At a given pressure and temperature, the internal energy of the system (U in Joules) can be partitioned as $m_{\mathrm{w}}u_{\mathrm{w}} + m_{\mathrm{vap}}u_{\mathrm{vap}}$, where m_{w}, m_{vap} and u_{w}, u_{vap} represent the masses and the specific internal energies (internal energy per unit mass in J kg^{-1}) of the water and water vapor in the system. Similarly, the volume (V in m^3) of the system can be partitioned as $m_{\mathrm{w}}v_{\mathrm{w}} + m_{\mathrm{vap}}v_{\mathrm{vap}}$, where v_{w}, v_{vap} represent the specific volume (volume per unit mass in J kg^{-1}) of the water and water vapor in the system. If, as illustrated in Fig. 1, the system internal energy changes by ΔU from U to $U + \Delta U$ as a result of L_{v} Joules of heat absorption to convert unit mass of water to water vapor, then $U + \Delta U = (m_{\mathrm{w}} - 1)u_{\mathrm{w}} + (m_{\mathrm{w}} + 1)u_{\mathrm{vap}}$, and therefore $\Delta U = (u_{\mathrm{w}} - u_{\mathrm{vap}})$. Similar reasoning shows that, if the volume changes from V to $V + \Delta V$ in the process, then $\Delta V = (v_{\mathrm{vap}} - v_{\mathrm{w}})$. The mechanical work because of volume change is $P\Delta V$, where P (the saturation vapor pressure) is a constant at a fixed temperature. Therefore, the heat absorbed (or released) by the system for isobaric phase transition of unit mass in the liquid water/water vapor system ($L_{\mathrm{v}}$by definition) $= \Delta U + P\Delta V$. Dividing by ΔV gives $\Delta U/\Delta V = (L_{\mathrm{v}}/\Delta V) - P$. Substituting $\Delta V = (v_{\mathrm{vap}} - v_{\mathrm{w}})$ gives $\Delta U/\Delta V = [L_{\mathrm{v}}/(v_{\mathrm{vap}} - v_{\mathrm{w}})] - P$, or in a differential form, $dU/dV = [L_{\mathrm{v}}/(v_{\mathrm{vap}} - v_{\mathrm{w}})] - P$. [It should be noted that because enthalpy (H) is defined as $H = U + PV$, then $\Delta U + P\Delta V = \Delta H$, and therefore L_{v} is the same as the specific enthalpy change ($\Delta h = \Delta H$ per unit mass) for phase transition of unit mass in the liquid water/water vapor system.]

Combining the results for dU/dV from the two previous paragraphs gives $T(dP/dT) - P = [L_{\mathrm{v}}/(v_{\mathrm{vap}} - v_{\mathrm{w}})] - P$, and therefore $T(dP/dT) = L_{\mathrm{v}}/(v_{\mathrm{vap}} - v_{\mathrm{w}})$, which can be rearranged to obtain the general forms of the Clapeyron (Emile Clapeyron, 1799–1864) equation $dP/dT = L_{\mathrm{v}}/[T(v_{\mathrm{vap}} - v_{\mathrm{w}})] = \Delta h/[T(v_{\mathrm{vap}} - v_{\mathrm{w}})]$ or $L_{\mathrm{v}} = [T(v_{\mathrm{vap}} - v_{\mathrm{w}})]dP/dT$.

The Clapeyron equation can be used to obtain L_v at a given temperature T for any liquid provided one can obtain values of $(v_{\text{vap}} - v_w)$ and an accurate representation of dP/dT. Values of $(v_{\text{vap}} - v_w)$ can be obtained from tabulated measurements (3). Alternatively, because $v_{\text{vap}} \gg v_w$ at the low pressures, $(v_{\text{vap}} - v_w)$ can be taken as equal to v_{vap}. Assuming further that at low pressures water vapor behavior closely approximates that of an ideal gas, then $v_{\text{vap}} = RT/P$, where R is the specific gas constant for water $= 8.314/0.018 = 461.9\ \text{J kg}^{-1}\ ^{\circ}\text{K}^{-1}$. The Clapeyron equation becomes $L_v = (RT^2/P)dP/dT$, and this form is referred to as the Clausius–Clapeyron equation (Rudolph Clausius, 1822–1888).

Unfortunately, no single function has been shown to adequately represent vapor pressure data for various liquid/vapor systems over wide ranges of T. For the liquid water/water vapor system, values of dP/dT for a given value of T can be obtained by finite differencing of tabulated values. As an example, consider using the above equation to estimate L_v for water at human body temperature of 37 °C. Tabulated values are $v_w = 1.007\ \text{cm}^3 g^{-1} = 0.01007\ \text{m}^3\ \text{kg}^{-1}$, $v_{\text{vap}} = 22{,}760\ \text{L kg}^{-1}, = 22.760\ \text{m}^3\ \text{kg}^{-1}$, $P = 5.940$ kPa at 36 °C and 6.624 kPa at 38 °C, which gives $(v_{\text{vap}} - v_w) = 22.760 - 0.01007 = 22.75\ \text{m}^3\ \text{kg}^{-1}$. By finite differencing, $dP/dT \approx \Delta P/\Delta T = (6.624 - 5.940)/(38 - 36) = 0.342\ \text{kPa}\ ^{\circ}\text{C}^{-1} = 0.342\ \text{kPa}\ ^{\circ}\text{K}^{-1} = 342\ \text{Pa}\ ^{\circ}\text{K}^{-1}$ (a temperature difference of 1 °C is the same as a difference of 1°K). At $T = 37 + 273.16 = 310.16^{\circ}\text{K}$, $L_v = 310.16^{\circ}\text{K}\,(22.75\ \text{m}^3\ \text{kg}^{-1}) \times 342\ \text{Pa}\ ^{\circ}K^{-1} = 2399\ \text{kJ kg}^{-1}$. The actual value (tabulated as Δh) is $2414\ \text{kJ kg}^{-1}$, an error of <1%.

Sometimes it is more efficient to have semianalytical expressions for $P(T)$ and hence dP/dT. Examples of such expressions for $P(T)$ are the Antoine equation, $\ln P = A + [B/(T + C)]$, and the Rankine equation, $\ln P = A + B/T + C \ln T$, where T is (usually) in °K, and A, B, C are empirical parameters obtained by fitting these equations to experimental data on phase equilibrium for a specific liquid/vapor system for various temperature ranges. Antoine's equation coefficients for the vapor pressure of quite a number of chemical compounds are available online in the NIST Chemistry Webbook (3). This reference lists Antoine coefficients for liquid water based on the vapor pressure data of Bridgeman and Aldrich (4) over several temperature ranges as:

Antoine Equation Coefficient	Temperature Range (°K)			
	273 to 303	304 to 333	334 to 363	344 to 373
A	5.40221	5.20389	5.0768	5.08354
B	1838.675	1733.926	1659.793	1663.125
C	−31.737	−39.485	−45.854	−45.622

These coefficients apply to Antoine's equation in the form $\log_{10} P = A - [B/(T + C)]$ with P in bar and T in °K. At 37 °C, this equation gives $P = 6.280$ kPa compared with the measured tabulated value of 6.274 kPa. The derivative of Antoine equation in this case is $dP/dT = P[2.3026B/(T + C)^2]$, which gives dP/dT at 37 °C $= 6.280 \times 0.0545 = 0.342\ \text{kPa}\ ^{\circ}\text{K}^{-1}$, which is the same as obtained by finite differencing of tabulated values.

For the liquid water/water vapor system, the equation for $P(T)$ developed by Richards (5) covers a wide temperature range and gives estimates for dP/dT close to those obtained by finite differencing of tabulated data. This equation is:

$$P(T) = ae^{f(T_r)}$$

where P is in millibar (mb), e is the base of natural logarithms, $T_r = 1 - \dfrac{373.15}{T}$, T is the temperature in °K, and $a = 1013.25$. The function $f(T_r) = 13.3185T_r - 1.9760\ (T_r)^2 - 0.6445\ (T_r)^3 - 0.1299\ (T_r)^4$. The derivative (with respect to T) is:

$$\frac{dP}{dT} = P\left(\frac{373.15}{T^2}\right)\left(\frac{df(T_r)}{dT_r}\right)$$

At 37 °C, $T_r = -0.2031$, the calculated value of $P = 62.78$, $mb = 6.278$ kPa compared with the tabulated measured value of 6.274 kPa. Using $P = 62.78$, mb gives $dP/dT = 62.78 \times 0.00388 \times \{13.3185 - (2 \times 1.9760 \times -0.2031) - [3 \times 0.6445 \times (-0.2031)^2] - [4 \times 0.1299 \times (-0.2031)^3]\} = 0.2434 \times \{13.3185 + 0.8026 - 0.0797 + 0.0044\} = 0.2434 \times 14.046 = 3.419\ \text{mb}\ ^{\circ}\text{K}^{-1} = 341.9\ \text{Pa}\ ^{\circ}\text{K}^{-1}$, practically the same as the value of $342\ \text{Pa}\ ^{\circ}\text{K}^{-1}$ obtained above from finite differencing of tabulated data.

Applying the Clausius–Clapeyron equation with $P = 6.280$ kPa at 37 °C by the Antoine equation, gives $L_v = 461.9 \times [(310.16)^2/6.280] \times 0.342 = 2{,}420\ \text{kJ kg}^{-1}$ compared with the actual value of $2414\ \text{kJ kg}^{-1}$.

HYDROLOGIC HISTORY, PROBLEMS, AND PERSPECTIVES

JASON A. HUBBART
University of Idaho
Moscow, Idaho

HYDROLOGIC HISTORY

Since humans first settled along the banks of lakes and rivers, there has been a keen interest in the proper management of fresh water resources both as a necessity for life as well as to avoid potential health hazards. Along the Indus in Pakistan, the Tigris and Euphrates in Mesopotamia, the Hwang Ho in China, and the Nile in Egypt, the first "hydraulic engineers" created canals, levees, dams, subsurface water conduits, and wells as early as 5000–6000 years ago. Hydrologic information became vital to these early civilizations. The flow rates and yields of rivers were monitored by the Egyptians as early as 3800 years ago, and rainfall measuring instruments were first used approximately 2400 years ago by Kautilya of India (1).

The idea that a global hydrologic cycle actually exists dates back at least 3000 years when early Greek philosophers such as Thales, Anaxagoras, Herodotus, Hippocrates, Plato, and Aristotle conceptualized the basic ideas governing the process (2). Many initial ideas established by the Greeks about the hydrologic cycle were quite reasonable. However, many of the initial mechanisms concerning the routes by which water returned from the sea and entered rivers were devoid of as much logic. Despite apparent gaps in hydrologic mechanisms, the Romans developed aqueduct systems reflecting an extensive practical understanding of hydrology and hydraulics and did so using the basic hydrologic ideas established and passed along by the Greeks (3). During the Renaissance, Leonardo da Vinci (1500) in France proclaimed, on the basis of field observations, that the waters in rivers come from precipitation. During that time, any unrealistic mechanisms proclaimed by the Greek philosophers concerning the hydrologic cycle were either refuted or modified (4,5). In the seventeenth century, the modern scientific approach to studying the hydrologic cycle was assumed by the Frenchmen Pierre Perault and Edme Marriotte. By the 1670s and 1680s, they had published data and calculations to support the contention that precipitation was the precursor to streamflow. By 1700, Edmun Halley, an English scientist, added to the work of Perault and Marriotte by estimating the quantity of water involved in the hydrologic cycle of the Mediterranean Sea and surrounding lands.

Substantial progress was made during the eighteenth century in applications of mathematics, fluid mechanics, and hydraulics by scientists like Pitot, Bernoulli, Euler, Chezy, and other European professionals. The term "hydrology" arrived at its current meaning around 1750, and by 1800, the work of English physicist and chemist John Dalton solidified the current understanding of the global hydrologic cycle (2).

Until the 1800s, the physical processes governing groundwater flow had confounded scientists and created barriers to understanding the hydrologic cycle. These barriers were eliminated in 1856, when the French engineer, Henry Darcy, introduced his law describing flow through porous media. Other advances in the hydrologic sciences were made throughout the 1800s. Poiseuille, DuPuit, DuBoys, Stokes, Manning, Reynolds, and others contributed substantially to fluid mechanics, hydraulics, and sediment transport during this period of time (3). Also during the 1800s, literary publications began to surface, increasingly frequently in the last half of the century. Many works examined relationships between precipitation and stream flow out of necessity for engineers designing bridges and other structures. During this time, the close association between hydrology and civil engineering was established. Daniel Mead published the first English-language text in hydrology in 1904, and Adolf Meyer followed with his text in 1919. Both texts were written for civil engineers (1). The association of hydrology and civil engineering established during this time, it has been argued, both enhanced as well as possibly inhibited the development of hydrology as a science (6).

The first half of the twentieth century saw great advancements in the hydrologic sciences starting with the addition of the Section of Scientific Hydrology in the International Union of Geodesy and Geophysics in 1922. This was followed by the addition of the Hydrology Section of the American Geophysical Union in 1930. These were the first formal recognitions of the scientific status of hydrology. Many individuals contributed substantially in their areas of hydrologic expertise during the early and middle decades of the twentieth century, including A. Hazen, E. J. Gumbel, H. E. Hurst, and W. B. Langbein in statistical applications of hydrologic data; O. E. Meinzer, C. V. Theis, C. S. Slichter, and M. K. Hubbert who contributed to the development of theoretical and practical aspects of groundwater hydraulics; L. Prandtl, T. Von Karman, H. Rouse, V. T. Chow, G. K. Gilbert, and H. A. Einstein in sediment transport and stream hydraulics; R. E. Horton and L. B. Leopold who contributed greatly to runoff processes and quantitative geomorphology; W. Thornthwaite and H. E. Penman in furthering the understanding of hydroclimatologic processes and modeling evapotranspiration; and A. Wolman and R. S. Garrels who contributed greatly to understanding and modeling water quality. It was not until the 1960s that detailed field studies attempting to understand the physical processes by which water enters streams began to emerge (3).

At the emergence of the twenty-first century, many new breakthroughs in the hydrologic sciences are imminent. In the forthcoming years, breakthroughs will describe the relationships between hydrologic regimes to current and future climate change and the effects of hydrologic processes on landform development. New findings will also include modeling regional evapotranspiration rates and geomorphologic water transport (1).

Population growth and land use changes have resulted in sizable impacts on surface water and groundwater resources. Increasing demands for fresh water has led to water stress in many parts of the world. Increasing quantities of water are used for agriculture, and increasing water quantities withdrawn from subsurface water bodies and large rivers have had significant influences on the water cycle. Population growth and land use changes have led to polluting of surface waters and groundwater resources as well as soil deterioration through erosion, salinization, and of course pollution. The ability to meet challenges of increased demand and to propose mitigating strategies will require intensive studies looking into how population growth and associated land use change and water demands influence the local, regional, and global water cycles.

HYDROLOGIC PROBLEMS AND PERSPECTIVES

Many specific scientific problems or challenges related to hydrologic study exist. These include assessing the impacts that growing populations have on water demand, land use change on groundwater reserves, and river discharges. Once successfully concluded, these assessments must be used as tools for predicting the extent of expected water stress in the coming decades due to changes in the supply and demand of water resources. Scientists must strive to understand the extent to which increased evaporation and transpiration through increased withdrawal of groundwater and surface water will lead to changes in local and global water cycles. There is a growing need for improved understanding of pollutant related flows in groundwaters and the self-cleaning capacities of aquifers and rivers related to different pollutants. Thus, further work is needed to describe the impacts of population growth and land use change on the quality of groundwater reserves, soils, and rivers and also what the effects may be on the natural ecosystems that depend on them.

Studies will be needed to understand landscape processes better, including hill slope forms, channel networks, and the processes responsible for transporting water, sediments, and pollutants. Hydrologic research in past decades has focused attention mainly on modeling the dynamic response of channel networks. Progress in understanding catchment scale flow will require that relevant hill slope flow also be carefully studied. This will likely require collaborative research approaches among hydrologists, geomorphologists, geologists, pedologists, and others to identify scaling relationships in flow domain structures.

There remains a need for improved understanding of the interactions between climate change and the hydrologic cycle. Further understanding and documentation is required to predict apparent changes that have led to an intensification of the hydrologic cycle due to climate change. Critical questions need to be asked concerning current changes observed in water availability and whether critical regions can be identified where the interactions between water availability and human demand become problematic. Conducting this type of research necessitates better understanding of past climates and paleohydrologic behavior. At present, the ability to predict changes in the fluxes of the water cycle under various scenarios of climate change is poor. Therefore, it is desirable to create improved methods of portraying the interactions between water systems and natural and human induced environments.

Due to the inherently complex nature of hydrologic systems, the characterization and subsequent modeling of these systems is a continual challenge to scientists. There are a number of unresolved issues that continue to impede the ability of scientists to analyze and predict behavioral changes of hydrologic systems. One of the most predominant features of hydrologic systems is the spatial heterogeneities and temporal variabilities that occur perpetually and persistently on multiple scales. Modeling physical processes encumbered by such diversity is a constant challenge. For these reasons, theoretical upscaling and downscaling attempts to develop quantitative links among process descriptions at various hydrologic scales has been so arduous. New or modified algorithms need to be devised, which will govern observed variabilities and define constitutive relations for each system. In the past, many empirical observations made on simple systems have been often erroneously applied to more complicated systems. Hydrologic systems are quite complex, and equations valid at one scale are not necessarily valid on higher scales, so one may question the applicability of theories that are originally developed for a simple system and vice versa.

Moreover, hydrologic processes are nonlinear and there tend to be strong couplings among them. As a result, the effect of one process is influenced by the occurrence of other processes, and a negligible effect of one process can lead to significant impacts on another. Clearly, there is a need to develop rigorous physical theories to describe the synergistic relationships of coupled nonlinear hydrologic systems on various scales. Intense study on a small scale is not leading to reliable working policy for addressing watershed processes critical to broad scale water management. As such, work needs to be undertaken designed specifically to improve our ability to model and predict water flows and movement. Finally, these models must also be appropriate and applicable to modeling and accurately predicting of flows and outputs in ungauged basins.

Hydroelectric dams, important for generating electricity, have transformed large fluvial systems into chained lakes. These large waterworks have generated a number of substantial environmental disruptions, including the erection of what are often unsurpassable obstacles for fish, explosive growth of floating aquatic plants, and eutrophication of dam reservoirs. The large development projects that connect watersheds and improve continental navigational networks also affect wetlands. Timber harvesting can likewise have negative effects on the production and regulation of water flows because increased soil erosion rates may increase the amount of suspended sediments, which can affect the quality of the water resources and the functioning of dams and reservoirs. On this basis, studies are needed to clarify the most appropriate management practices for harvesting timber.

Water resource management faces many other monumental problems. Academia needs to understand the current crisis completely to become innovative in producing new technologies and in advocating arrangements to satisfy demand. The sciences must be able to integrate and upscale. The field of ecohydrology (ecology and hydrology) is a testimony to the potential success of integrating sciences and should serve as a model for future interdisciplinary cooperatives. However, from a historical context, academia is easily drawn apart to the point that each discipline often fails to identify with statements of findings produced by other disciplines. The public is poorly served by divided or polarized science. Hydrologists are not unique integrators amongst scientists, but interdisciplinary research is required in hydrology to solve the current water-related problems. The goal of strengthening the identity of hydrology as a discipline is commensurate with hydrology's desire to serve the needs of society better. For example, the general public is much more aware of water problems (too much, too little, too dirty) than of the discipline of hydrology and how it relates to water problems. However, people agree that objectives intended to strengthen the hydrologic sciences will result in hydrology that is better equipped to serve the needs of society. These are therefore compatible ideals, well suited to serve both coalitions.

Hydrologic resources management has evolved through incremental refinements to its current point by using information on precipitation, streamflows, water demands, and other processes based to a high degree on a measurement technology that is often archaic in design. Now, scientific advances offer technologies that can be used to add much more information and provide much greater detail. The academic community is often the source of new science and of new technology designed to organize and disseminate information better. Academia is also often the source of courses and literature intended to inform people and make them comfortable with information resources. The world has a fixed quantity of water to use to satisfy a widening diversity and deepening intensity of human and environmental needs. Therefore, academic must make a concerted effort to inform the general public of the limitations of hydrologic resources.

A system for water resources management must also be sustainable to succeed. It is a major challenge to preserve options in a dynamic world where changes are caused by anthropogenic activities, environmental evolution, and geologic processes. These are the challenges that await educators, scientists, and water resource managers in the future.

Ultimately, a management system that addresses periodic severe crises may be less sustainable than that designed to mitigate long-term contingencies. The greatest difficulty lies in protecting future options as social preferences change. Regardless of origin, scientists, educators, politicians, and lawmakers must all cooperate to meet these challenges.

Hydrology and water use are obviously considered from a variety of perspectives, including social, economic, legal, scientific, and environmental, to determine how differing viewpoints affect the quality and quantity of water supplies. Researchers study pollution carried by water, which includes oceans, rivers, streams, rain, snow, and ice, and devise methods to clean and control it. Some study weather related problems such as flood forecasting, drought management, acid rain, and global warming. Others manage water resources so that the goals of all water users are achieved efficiently while protecting the environment. To extenuate and manage water quality issues adequately, they must be dealt with from all perspectives. Some water quality problems that can be common to entire regions include toxic contamination from industry, waste disposal, and eutrophication from human sewage. Bacterial pollution of water supplies is a perpetual dilemma that has adverse effects on human health. The major concerns centered on high bacterial and organic loads range from poor quality drinking water, eutrophication, and disappearance of aquatic life to food contamination and the prevalence of waterborne diseases.

Rivers can be polluted from a number of different sources. The largest contributors include industrial and urban wastewaters from large cities, wastewater from mining industries, and agricultural runoff. As a result, many river water resources today are chemically and biologically contaminated. Large quantities of agricultural contaminants are likewise disposed of in streams flowing to the sea, where there has been found clear evidence of elevated levels of phosphorous, nitrates, potassium, pesticides such as dichlorodiphenyltrichloroethane (DDT), and highly organic effluents. These elevated levels of pollutant concentrations caused by the indiscriminate discharge of highly pollutant-loaded effluents into waterbodies are also seen in deep underground aquifers, which are often contaminated by the same negligence.

Experiences during the past century have contained many useful lessons that are now being used to shape water management practices to address effectively the threats of water shortages and pollution that are growing worldwide. A half-century ago, water resources planning focused on building facilities to capture and deliver water for beneficial uses and to contain floods to reduce damage. Planners were certain that full resource development would foster economic growth and serve broad social needs. Governments built projects that proved financially costly, environmentally destructive, and politically divisive. Environmental harm increased as projects drained rivers and wetlands and converted forests, meadows, and deserts into fields and cities. Political differences deepened as jurisdictions sought to develop their own water resources with little regard for the needs of neighbors. Disputes mounted among towns, states, and nations. As water resources were more fully developed, projects became larger and more costly, and their adverse environmental impacts became more severe. Fiscal and environmental concerns caused the political process to halt construction as society looked for alternative approaches to basic human needs. Now, water withdrawals are approaching the upper limit to what nature can supply, and freshwater resources are being reduced by pollution and threatened by climate change.

Throughout history, humans have been concerned with the proper management of hydrologic resources. This task has been less than facile simply because water availability and population induced threats vary greatly among locations and over time. There is a need to think more creatively to gain deeper understanding of the inherent heterogeneities and diversities within hydrologic systems. Proper management of water resources will need to address the problems and challenges of growing regional and global populations with complex societies but will also need to sustain the needs of the earth's natural ecosystems.

HUMIDITY—ABSOLUTE

Absolute humidity is one of many measures to quantify the water vapor content of the atmosphere. It is defined as the mass (m_v) of water vapor per unit volume of moist air. It can be denoted as ρ_{v} with SI units of g (vapor) m^{-3} moist air or in corresponding engineering units as lb ft^{-3} or (more commonly) as grain ft^{-3}. Conversion factors are $1\ \mathrm{lb} = 453.6\ \mathrm{g} = 7000\ \mathrm{grain}$ and $1\ \mathrm{m}^3 = 35.31\ \mathrm{ft}^3$. Other terms in use for this quantity are vapor concentration and density of water vapor in a moist air mixture. Absolute humidity is quite often incorrectly used to mean specific humidity, which is the mass of water vapor per unit mass of moist air, and sometimes to mean the mixing ratio, which is the mass of water vapor per unit mass of dry air. Absolute humidity, specific humidity, and mixing ratio are important in the study of evaporation from water bodies, crop transpiration, soil-water balances, and in ventilation and air conditioning engineering applications. These interrelated measures are rarely measured directly.

Absolute humidity can be estimated indirectly in terms of psychrometric measures of atmospheric water vapor content and known physical parameters. The key assumption in making such estimates is that the mixture of gases in moist atmospheric air behaves ideally. With this assumption, a volume (Vm^3) of moist air at a given pressure (P in Pa; usually at $P = 1.013 \times 10^5 Pa = 1$ atm) and temperature T°K obeys the relationship $\mathrm{PV} = \mathrm{nRT}$, where n is the number of moles of mixture and R is the ideal gas constant $= 8.314\ \mathrm{J\ mol^{-1}\ {}^{\circ}K^{-1}}$. The number of moles of mixture can be taken as the mass of mixture/mean molecular weight (M_{wm}) of the mixture, which gives $\mathrm{PV} = \mathrm{mRT}/M_{wm} = mR*T$, where $R* = R/M_{wm}$ and is called the specific ideal gas constant. Dividing both sides by V gives $P = mR*T/V = \rho_m\ R*T$, where $\rho_m = m/V$ is the density of the moist air.

The partial pressure P_i of the ith constituent in a volume V of an ideal gas mixture at temperature T can be defined as the pressure it would exert if it alone occupied the volume V, implying that $P_iV = n_iRT$. As for the entire mixture, the total pressure $PV = nRT$, which implies (by summation over i) that $P = \sum P_i$ and (by division) that $P_i/P = n_i/n$. $P = \sum P_i$ is known as Dalton's Law of Partial Pressures. Similarly, the partial volume V_i of the ith constituent T can be defined as the volume it would occupy if exerted and if it alone existed at the total pressure of the mixture. This definition implies $PV_i = n_iRT$, and therefore $V = \sum V_i$ (know as Amagat's Law) and $V_i/V = n_i/n$. Combinations of these results show that $P_i/P = V_i/V = n_i/n$. As the water vapor content by volume in moist air rarely exceeds 0.04, this result implies that its partial pressure rarely exceeds 0.04 atm.

Application of the foregoing ideal relations to estimate absolute humidity from psychrometric meterological observation would be straightforward if the composition of the atmospheric air were constant. However, this is not so, because the water vapor content by volume (i.e., volume water vapor per unit volume of atmospheric air) is the most variable constituent of the atmosphere. It can vary from as little as $2 \times 10^{-6}\%$ (at high altitudes, in extremely cold conditions such as Antartica, and in deserts) to between 4 and 5% (in warm equatorial regions close to large waterbodies). On the other hand, the other constituents of atmospheric air are relatively constant. Therefore, a quantity measured on a volume V of moist air can be regarded as a combination of the quantity measured on the water vapor (V_v) and dry air (V_d) volume components. Thus, the mass m_m of moist air = mass water vapor m_v + mass of dry air m_d. Similarly, the density of moist air $\rho_m = m_m/V = m_v/V + m_d/V = \rho_v + \rho_d$ where ρ_v (the partial density of the vapor component) is by definition the absolute humidity, and ρ_d is the partial density of dry air in the vapor/dry air mixture. The quantity ρ_v/ρ_m represents the mass of water vapor per unit mass of moist air, i.e., the specific humidity. The total moles $n = n_v + n_d$, and therefore, because mass = moles times molecular weight, $\rho_m = [n_vM_{wv}/V] + [n_dM_{wd}/V]$, where M_{wv} and M_{wd} represent molecular weight of water ($18.016\ \mathrm{g\ mol^{-1}}$) and dry air ($28.97\ \mathrm{g\ mol^{-1}}$), respectively. As the molecular weight of water is less than that of dry air, the foregoing indicates that the density of a given volume V of moist air would be less than the density of the same volume of dry air ($<1.29\ \mathrm{kg\ m^{-3}}$). Indeed, if this were not so, instead of our poetry-inspiring cloudy skies, most of the earth would be blanketed by dense surface fogs most of the time.

Pursuing this line of reasoning, the total pressure P of a volume V of moist air at temperature T would be equal to $P_v + P_d$, where P_v and P_d are the partial pressures of the water vapor and dry air. P_v is usually denoted as e, implying $P_d = P - e$. Applying the ideal gas relations above for a volume V of moist air at atmospheric pressure P and temperature T, $e = \rho_vR_vT$, and therefore ρ_v(the absolute humidity) $= e/R_vT = eM_{wv}/RT$, because $\mathrm{R}_v = R/M_{wv}$ is the specific gas constant for water vapor. Dividing numerator and denominator by M_{wd} (molecular weight of dry air) gives:

$$\rho_v = \frac{e\left(\frac{M_{wv}}{M_{wd}}\right)}{R_v T} = \frac{0.622e}{R_d T}$$

where R_d is the specific gas constant for dry air (=287.04 J $\text{kg}^{-1}\,{}^\circ\text{K}^{-1}$).

Thus, at a given temperature T (in °K), the absolute humidity can be obtained if the vapor pressure e were known.

Observations of humidity are widely reported as relative humidity (RH), which is strictly defined as the quotient of the mixing ratio (w) of actual (vapor unsaturated) air at a temperature T and the mixing ratio ($w*$) in vapor-saturated air at the same temperature. The mixing ratio w is defined as the mass of water vapor per unit mass of dry air, and therefore $w = \rho_v/\rho_d$. Therefore, $RH = \text{w}/w*$. As at a given T, $\rho_d = P_d/(R_d T)$ and $P_d = P - e$, therefore from the above equation for ρ_v, $w = 0.622e/(P - e)$. At saturation, the mixing ratio $w* = 0.622e*/(P - e*)$, where $e*$ is the saturation vapor pressure at temperature T. As e and $e*$ are, in general, small compared with P, $w \approx 0.622e/P$, and $w* \approx 0.622e*/P$, implying that $w/w*$ is very nearly equal to $e/e*$, i.e., the ratio of the vapor pressure in actual (vapor unsaturated) air at a temperature T to the vapor pressure in vapor-saturated air at the same temperature. Therefore, e can be obtained from reported RH values if $e*$ were known.

Many equations exist for estimating $e*$ at a given temperature T°K. Based on thermodynamic theory, $e*$ is a function of T and can be obtained by integrating the Clausius–Clapeyron equation $de*/dT = (0.622\,Le*)/(R_d T^2)$, where L is the latent heat of evaporation (J kg^{-1}) at temperature T, R is the specific gas constant for dry air $= 287.04$ J $\text{kg}^{-1}\,{}^\circ\text{K}^{-1}$, and T is the absolute temperature (°K). As L is a function of T, the Clausius–Clapeyron equation can be integrated for a given function $L(T)$ to obtain $e*(T)$. One such integral is that of Goff and Gratch (1) and Goff (2) that has become the basis for the published Smithsonian and World Meterorological Organization (WMO) standard tables of $e*(T)$. Gibbins (3) reviewed this and many other equations developed for estimating $e*(T)$. One developed by Richards (4) gives values that differ by no more than 0.01% of the tabulated Goff–Gratch standard. This equation is:

$$e*(T) = ae^{f(T_r)}$$

where $e*$ is in millibar (mb), e is the base of natural logarithms, $T_r = 1 - \dfrac{373.15}{T + 273.15}$, T is the temperature in °C, and $a = 1013.25$. The function $f(T_r) = 13.3185T_r - 1.9760\ (T_r)^2 - 0.6445\ (T_r)^3 - 0.1299\ (T_r)^4$. For example, at 20°C, $T_r = -0.2729$, $f(T_r) = -3.7694$, and $e*(20^\circ\text{C}) = 23.372$ mb (=2337.2 Pa) compared with the tabulated standard value of 23.373 mb.

Another computationally less tedious equation for $e*(T)$ commonly used in ventilation and air conditioning engineering calculations is the Magnus equation (also referred to as the Magnus–Teten formula) valid for air temperatures between 0–50°C:

$$e*(T^\circ\text{C}) = 6.112\ \text{e}^{\frac{17.62T}{243.12+T}}$$

where T is the temperature in °C and $e*$ is in mb. This formula gives $e*(20^\circ\text{C}) = 23.325$ mb.

INTRODUCTION

If samples of air collected at different times of the year and over different points of the earth between the surface and 80 km altitude are analyzed, it is observed that the proportions of gases that form air are, except for a few components, nearly constant in all samples.

That fixed composition is nitrogen (N_2), the most abundant gas with 78.08% in volume concentration, oxygen (O_2) with 20.95%, and argon (Ar) with 0.93%. Other less abundant gases, known as trace gases, are helium (He), neon (Ne), hydrogen (H_2), carbon dioxide (CO_2), ozone (O_3), and water vapor (H_2O), accounting for all together less than 0.04% in volume concentration. The atmospheric layer that has this composition is called the homosphere.

Among the trace gases, ozone shows a particular vertical distribution. The greater concentrations are found at altitudes between 20 and 35 km. This layer is known as the ozonosphere. The concentrations near the earth's surface and over 40 km are very low. On the other hand, the ozone concentration is at a maximum in spring and at a minimum in autumn in the Northern Hemisphere.

Water vapor distribution exhibits great spatial and temporal variability. At any given point, the quantity of water vapor varies continuously, and it is always different from one place to another. An image from the Meteosat satellite in the water vapor (WV) channel permits visualizing the spatial variability (Fig. 1). This spatial variability is particularly high in the vertical, such that about 75% of the water vapor in the atmosphere is in the lower 3000 m, and practically all of this trace gas is trapped in the lowest atmospheric layer or troposphere (10–12 km deep). The high spatial and temporal variability of water vapor requires the definition of variables that, having a simple formulation, permit us to quantify its abundance.

Water itself is a very important component because it can exist in three states (solid, liquid, and gas) within the atmospheric temperature range. Many processes in the atmosphere can cause water to change state. Particularly relevant is when water vapor condenses into liquid water because this process is accompanied by a release of heat that can be absorbed by the air. Similarly, when liquid water freezes or water vapor sublimes, latent heat is released. On the contrary, ice melting, ice sublimation, and liquid evaporation imply heat absorption. The quantification of water vapor content is therefore some measurement of the latent heat available to the air, which, if released, can strongly affect the atmospheric stability to vertical motions and dynamic processes such as the development of pressure systems.

In the remainder of this article, some indexes that are used to quantify water vapor content in the atmosphere are described.

VAPOR PRESSURE AND SATURATION VAPOR PRESSURE

The air is a mixture of gases. The pressure exerted by air is the sum of the partial pressures exerted by each of its components (Dalton's law). The partial pressure exerted by water vapor, denoted as vapor pressure (e), is then a measure of the water vapor content in the atmosphere. A state can be represented by a point in a diagram whose coordinates are (temperature, vapor pressure) = (T, e).

For each temperature, a maximum vapor pressure exists that is known as the saturation vapor pressure (e_s). That saturation value cannot be surpassed, and if water vapor in excess occurs, condensation or sublimation results. Figure 2 shows the state curve (T, e_s), with respect to liquid water for temperatures above 0 °C and with respect to supercooled water (e_s) and ice (e_i) below 0 °C. The values of saturation vapor pressure are determined experimentally. A list of values as a function of temperature can be found in Smithsonian Meteorological Table (2). Table 1 includes some e_s values at several temperatures.

Efforts have been carried out to adjust the curve (T, e_s) with respect to liquid water (above and below 0 °C) by an analytic formula. Following is the expression of Tetens (3),

$$e_s(t) = 6.11 * 10\left(\frac{7.5t}{t + 237.3}\right) \quad (1)$$

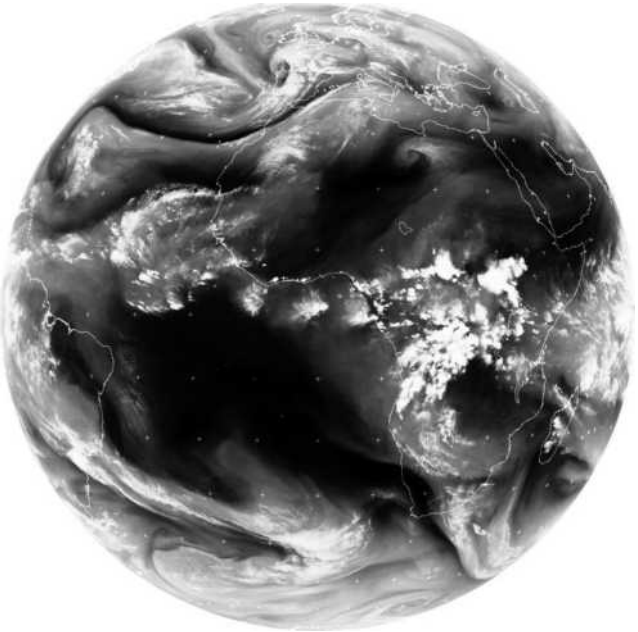

Figure 1. WV image from Meteosat satellite on November 13, 2002 at 1500 UTC (from Dundee University, UK).

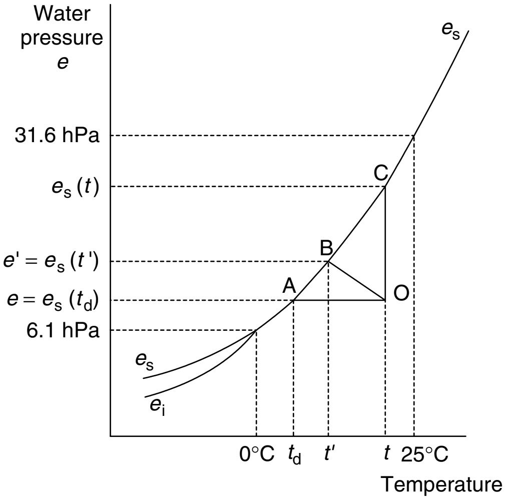

Figure 2. State curve of saturation vapor pressure as a function of temperature. e_s = pressure over a plane surface of liquid water; e_i = pressure over a plane surface of ice. See text for additional information contained in the figure (Diagram is based on Fig. 2 of Reference 1).

Table 1. Values of Saturation Vapor Pressure Over a Plane Surface of Liquid Water at Different Temperatures

t, °C	e_s, hPa
−20	1.2
−10	2.9
0	6.11
10	12.28
20	23.38
30	42.43
40	73.76
50	123.30

Figure 3. Psychrometer. Note the wet thermometer with its bulb covered by wet muslin (photograph courtesy of INM, Spain).

that of Bolton (4),

$$e_s(t) = 6.112 * \exp\left(\frac{17.67t}{t + 243.5}\right) \quad (2)$$

and the modified Clausius–Clapeyron formula,

$$\ln e_s = 53.67957 - \frac{6473.70}{t + 273.16} - 4.8451 \ln(t + 273.16) \quad (3)$$

where t is the temperature in °C and e_s, is the saturation vapor pressure in hPa. The Boltons expression is precise to 0.3% in the range $-35\,^\circ$C to $35\,^\circ$C and the modified Clausius–Clapeyron method to 0.01% between $-40\,^\circ$C and $40\,^\circ$C. Both intervals cover a wide spectrum of temperatures in which condensation phenomena are important. Other more complex formulas for saturation vapor pressure on liquid water and on ice can be obtained by polynomial adjustments (5).

Given an air parcel of state (T, e) represented by point O in Fig. 2, two very simple processes permit the air to reach saturation. Suppose that at constant temperature (t), water vapor is added to the parcel so that the vapor pressure is increased. This process eventually leads to saturation, that is, the vapor pressure would reach $e_s(t)$ (point C in the diagram). Analogously, the temperature could be diminished while maintaining the water pressure constant and a lower temperature (t_d) would be reached in which the water pressure would equal the saturation value, that is, $e_s(t_d) = e$ (point A). The temperature at which this happens is known as the “dew point.” If the temperature decreased further, the vapor pressure would equally decrease following curve e_s and water vapor would condense.

Another saturation mechanism would consist of adding liquid water to the air parcel. That liquid water would evaporate, getting the necessary heat from the same air. The temperature would diminish at the same time that the vapor pressure would increase. Thus, with enough liquid water available, saturation would eventually be reached at some temperature t' (point B in Fig. 2). That temperature, known as the “wet bulb temperature,” is the smallest possible temperature an air mass can acquire by evaporation of water in its body.

DETERMINATION OF VAPOR PRESSURE

The vapor pressure at the surface in the real atmosphere is determined indirectly by the psychrometer. That instrument is composed of two identical thermometers placed in a stationary screen box; one has its bulb dampened in muslin (Fig. 3), called the wet thermometer. The temperature difference between the dry and the wet thermometers depends on the water vapor content of the atmosphere; the smaller the vapor content, the greater the temperature difference. Assuming that the air circulating near the wet thermometer effectively reaches the saturation vapor pressure according to the process explained above, its temperature is simply t′ (Fig. 2), and we refer to the dry bulb temperature as t. The following relation is satisfied:

$$e = e_{\mathrm{s}}(t') - \frac{8c_{\mathrm{p}}}{5Lv}p(t - t') \tag{4}$$

where c_{p} ($c_{\mathrm{p}} = 1005\ \mathrm{Jkg^{-1}K^{-1}}$) is the specific heat of dry air at constant pressure, L_{v} ($L_{\mathrm{v}} = 2501 \times 10^6\ \mathrm{J\ kg^{-1}}$) the latent heat of condensation, and p is the pressure, which permits determination of the vapor pressure e from the dry and wet bulb thermometer readings. Commonly, tables with double entries of t' and $t - t'$ are constructed which permit determination of e (2).

RELATIVE HUMIDITY

Once a vapor pressure value is determined, the whole picture is not complete unless that value is compared to the saturation vapor pressure at the temperature of the air.

Relative humidity (h) is thus defined as the ratio (expressed in a percentage) of the vapor pressure e and the saturation vapour pressure $e_{\mathrm{s}}(t)$ at the corresponding temperature (1,6):

$$h = 100\frac{e}{e_{\mathrm{s}}(t)} \tag{5}$$

Keeping in mind the dew point definition introduced earlier,

$$h = 100\frac{e_{\mathrm{s}}(t_{\mathrm{d}})}{e_{\mathrm{s}}(t)} \tag{6}$$

and $e_{\mathrm{s}}(t_{\mathrm{d}})$ can never be greater than $e_{\mathrm{s}}(t)$. For an interpretation, see Fig. 2. When $h = 100\%$, saturation has been reached and condensation is produced.

Some surfaces exposed to the environment often acquire a temperature that is different from that of the air. For those surfaces, an equivalent relative humidity can be defined as

$$h = 100\frac{e}{e_{\mathrm{s}}(t_{\mathrm{s}})} = 100\frac{e_{\mathrm{s}}(t_{\mathrm{d}})}{e_{\mathrm{s}}(t_{\mathrm{s}})} \tag{7}$$

where t_{s} is now the temperature of the surface. A surface cooler than the air ($t_{\mathrm{s}} < t$), for example, would then promote saturation more easily than the surrounding air. This explains why dew sometimes forms on plant leaves although 100% relative humidity has not been reached in the atmosphere. Analogous expressions could be defined considering the saturation pressure with respect to ice.

Hygrometers are instruments that measure relative humidity directly. Digital hygrometers are generally based on some change in the electrical properties of some material as a function of the relative humidity of the air, whereas analogic hygrometers use the variation of length that the human hair (especially that of a blond woman!) experiences with a change in relative humidity.

If the relative humidity is known, the dew point can be determined by inverting some of the formulas for calculating the saturation vapor pressure (Eqs. 1–3). Conversion tables are also available for that purpose (2).

OTHER HUMIDITY INDEXES

There are several other humidity indexes apart from relative humidity. They are often more useful than the latter for adequate formulation of the moist thermodynamic processes that occur in the atmosphere. The following are emphasized:

Mixing Ratio (*r*)

It is defined as the quantity of water vapor per unit mass of dry air. Its units are therefore $\mathrm{g\ g^{-1}}$ but generally it is expressed in $\mathrm{g\ kg^{-1}}$:

$$r = \frac{m_{\mathrm{v}}}{m_{\mathrm{d}}} \tag{8}$$

Both the water vapor and dry air portions of the sample, which have partial pressures e and $p - e$, respectively, comply with the equation for the ideal gases; then,

$$e = \frac{m_{\mathrm{v}}}{V}R_{\mathrm{v}}T \tag{9}$$

$$p - e = \frac{m_{\mathrm{d}}}{V}R_{\mathrm{d}}T \tag{10}$$

where R_{v} and R_{d} are the specific gas constants of water vapor and dry air, respectively, V is the volume, and T the temperature. Combining Eqs. 9 and 10,

$$r = \frac{m_{\mathrm{v}}}{m_{\mathrm{d}}} = \frac{R_{\mathrm{d}}}{R_{\mathrm{v}}}\frac{e}{p - e} = \varepsilon\frac{e}{p - e} \tag{11}$$

and using the constants $R_{\mathrm{d}} = 287.04\ \mathrm{J\ kg^{-1}\ K^{-1}}$ and $R_{\mathrm{v}} = 461.50\ \mathrm{J\ kg^{-1}\ K^{-1}}$, Eq. 11 is

$$r = 0.622\frac{e}{p - e} \tag{12}$$

Within the interval of temperatures and atmospheric pressures, $e << p$, and therefore

$$r \cong 0.622\frac{e}{p} \tag{13}$$

If the vapor pressure corresponds to its saturation value, then a saturation mixing ratio is defined as

$$r_{\mathrm{s}} \cong 0.622\frac{e_{\mathrm{s}}}{p} \tag{14}$$

that depends only on pressure and temperature.

Using Eqs. 13 and 14, the relative humidity is

$$h = 100\frac{e}{e_{\mathrm{s}}(t)} \cong 100\frac{r}{r_{\mathrm{s}}(t)} \tag{15}$$

Therefore, the numerical values of h deduced from vapor pressure or from the mixing ratio are practically the same.

The exact relation between the relative humidity and the mixing ratio is

$$h = 100\frac{r}{r_{\mathrm{s}}(t)}\frac{1+\dfrac{r_{\mathrm{s}}(t)}{\varepsilon}}{1+\dfrac{r}{\varepsilon}} \tag{16}$$

Specific Humidity (*q*)

Specific humidity is defined as the relation between the vapor mass and the mass of moist air that contains this vapor, that is, the quantity of water vapor per unit mass of moist air:

$$q = \frac{m_{\mathrm{v}}}{m_{\mathrm{r}} + m_{\mathrm{d}}} \tag{17}$$

The units are g g^{-1} although it is generally expressed in g kg^{-1}.

Using the same formulation introduced previously for the mixing ratio,

$$q = \varepsilon\frac{e}{p - e(1-\varepsilon)} \tag{18}$$

And according to the same previous arguments,

$$q \cong \varepsilon\frac{e}{p} \tag{19}$$

and therefore

$$h \cong 100\frac{q}{q_s(t)} \tag{20}$$

The same comments noted earlier for the mixing ratio (r) are valid for the specific humidity in relation to relative humidity.

Knowledge of the specific humidity permits us to calculate the specific parameters for humid air, for example, the specific heat

$$c_{\mathrm{p}}^{'} = (1-q)c_{\mathrm{p}} + qc_{\mathrm{v}} \tag{22}$$

where c_{p} and c_{v} are the specific heats of dry air and water vapor at constant pressure, respectively ($c_{\mathrm{p}} = 1005$ J $\mathrm{kg}^{-1}\mathrm{K}^{-1}$, $c_{\mathrm{v}} = 1.85\ 10^3$ J $\mathrm{kg}^{-1}\mathrm{K}^{-1}$); and the specific gas constant

$$R^{'} = (1-q)R_{\mathrm{d}} + qR_{\mathrm{v}} \tag{23}$$

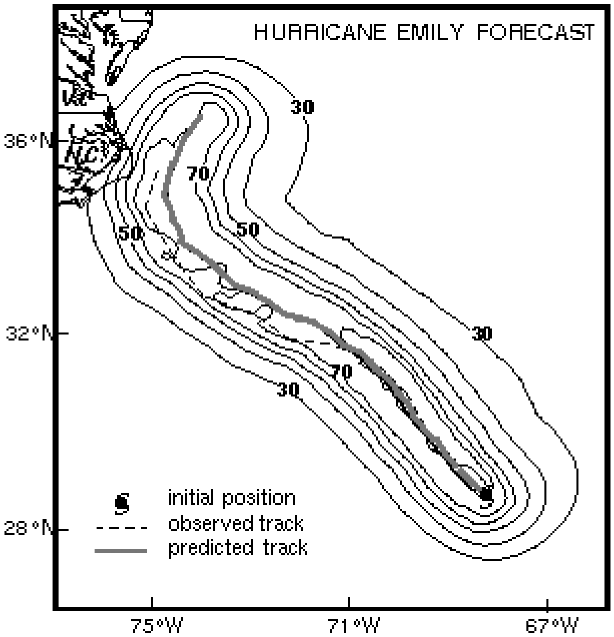
HURRICANES: MODELING NATURE'S FURY

Geophysical Fluid Dynamics
Laboratory—NOAA

Few natural phenomena evoke a greater sense of awe and mystery than hurricanes, the powerful and destructive tropical storms that often menace coastal regions. Scientists at GFDL, led by Yoshio Kurihara, have worked steadily for two decades to develop physically based models that can be used to understand the basic mechanisms producing hurricanes and to predict the movement and intensity of individual storms.

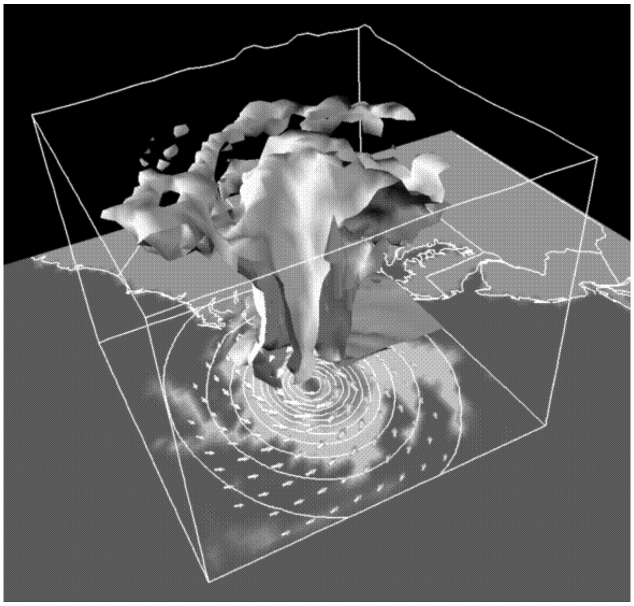
A PREDICTION BREAKTHROUGH

Improvements in hurricane prediction have been made possible by improved observations, models, and methods for incorporating observations into the forecast models. Kurihara and collaborators Bob Tuleya and Morris Bender realized that current weather analyses were inherently inadequate as "initial conditions" for such models. They developed a method to circumvent much



Three-day forecast of Hurricane Emily's track (red line) and intensity produced by the GFDL hurricane model. Thin contours show the maximum predicted wind speed (in knots) during the forecast period. The forecast was available at 8 a.m., Sunday, Aug. 29, 1993. The hurricane caused extensive damage along North Carolina's Outer Banks beginning late Tuesday afternoon (Aug. 31) before recurving to the northeast and out to sea, as predicted by the GFDL model

---



Three-dimensional view of Hurricane Emily near the North Carolina coast as modeled by the dynamical hurricane prediction system developed at GFDL. The view is a 48-hour forecast (valid 8 p.m., August 31, 1993) obtained from the GFDL model. This forecast system provides improved hurricane track predictions roughly two days in advance of hurricane conditions and has the potential to provide useful forecasts of storm intensity and precipitation as well. In the case of Hurricane Emily, the model successfully predicted the occurrence of hurricane-force winds in the Cape Hatteras, N.C. vicinity. In the figure, the three-dimensional "cloud-like" volume (which is sliced vertically through the storm center) depicts the 91% relative humidity surface; the colored shading at the earth's surface shows precipitation (higher values are red); red and white arrows show vertical motions and surface winds, respectively; white contours depict sea-level pressure; the dark blue surface and solid green background represent the Atlantic Ocean and the U.S. East Coast, respectively. Note the "eye-wall" in the relative humidity surface at the storm center and the heavy precipitation north of the storm

of the initial data problem and achieved a breakthrough in hurricane prediction.

The new forecast system achieved a series of remarkably successful forecasts, compared to other available methods for Hurricanes Andrew, Iniki, and Emily. For example, while conventional models predicted that Hurricane Emily (August 1993) would make landfall in the vicinity of Georgia, the GFDL forecast system correctly predicted that the hurricane would deliver a glancing blow to North Carolina's Outer Banks before veering back out to sea. Based on its impressive performance during the 1993 and 1994 hurricane seasons, the model has been adopted as the operational hurricane prediction model at the National Meteorological Center.

HURRICANE EMILY FORECAST

Given the expense and inconvenience of hurricane evacuations and emergency preparations, the public benefits greatly if unnecessary hurricane warnings can be avoided. Furthermore, residents are likely to take hurricane warnings more seriously if the forecasts are shown to be more reliable. With potential damage from a single storm exceeding $25 billion (e.g., Hurricane Andrew in 1992), reliable short-term preparations, while expensive to undertake, can result in large net savings by the public.

A NEW COASTAL FORECAST SYSTEM

In a complementary effort, GFDL is cooperating with scientists at Princeton University and NOAA's National Meteorological Center (NMC) and National Ocean Service (NOS) to develop a coastal forecast system for the East Coast. The system is designed to provide nowcasts and forecasts of currents, storm surges, and other information to coastal residents, the fishing and marine transport industries, and government users. The forecast system uses a high-resolution ocean model–developed by Princeton's George Mellor in collaboration with GFDL–and an atmospheric model from NMC.

HYDROLOGIC CYCLE

Sharad K. Jain
National Institute of Hydrology
Roorkee, India

Vijay P. Singh
Louisiana State University
Baton Rouge, , Louisiana

The hydrologic cycle, the endless circulation of water between the earth, the oceans, and the atmosphere, is fundamental to the study of the waters of the earth. The cycle entails a huge turnover of water driven by the energy of the Sun and gravity. It has a profound influence on the landscape and the earth's climate. The major components of the hydrologic cycle are precipitation, evapotranspiration, interception, infiltration, overland and channel flow, and groundwater flow. Quantitatively, the hydrologic cycle is represented by a mass balance or continuity equation. The relative significance of the terms of this equation depends on the space and timescale. Human activities and the hydrologic cycle are interactive and influence the earth's climate.

INTRODUCTION

The hydrologic cycle is a fundamental concept in hydrology and is amongst a number of cycles known to be operating in nature, such as the carbon cycle, the nitrogen cycle, and other biogeochemical cycles. The National Research Council (1) defines the hydrologic cycle as "the pathway of water as it moves in its various phases to the atmosphere, to the earth, over and through the land, to the ocean and back to the atmosphere." This cycle has no beginning or end, and water is present in all three states, solid, liquid,

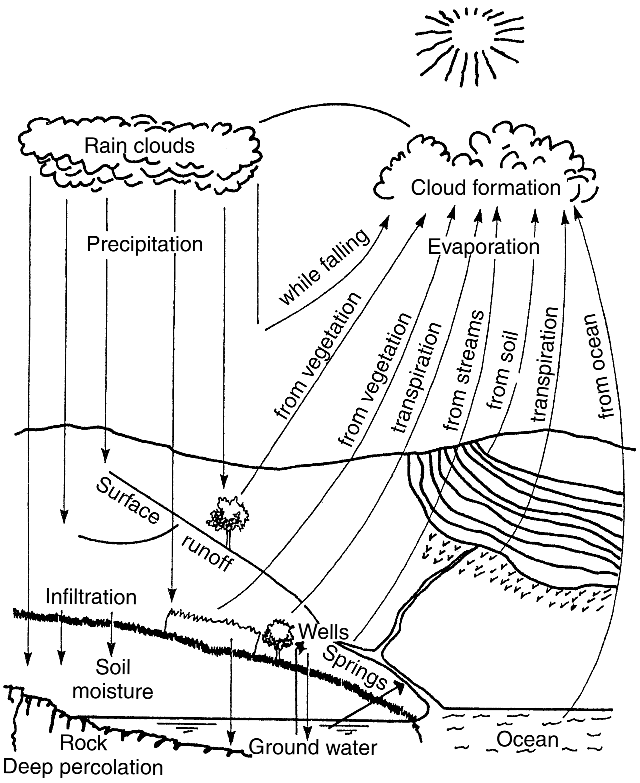


Figure 1. Pictorial representation of the hydrologic cycle (2).

and gas, in the cycle. A pictorial representation of the hydrologic cycle is given in Fig. 1.

The hydrologic cycle, also known as the water cycle, is a concept that considers the processes of motion, loss, and recharge of the earth's waters. It connects the atmosphere and two storages of the earth system: the oceans and the landsphere (lithosphere and pedosphere). The water that is evaporated from the earth and the oceans enters the atmosphere. Water leaves the atmosphere through precipitation. The oceans receive water from the atmosphere by precipitation and from the landsphere through stream flow and groundwater flow. The only way that water leaves oceans is by evaporation. The landsphere receives water by precipitation. The water leaves this sphere by evaporation, transpiration, evapotranspiration, stream flow, and groundwater flow. Evaporation and precipitation are the processes that take place in the vertical plane, whereas stream flow and groundwater flow occur mostly in the horizontal plane.

The exchange of water among the oceans, land, and the atmosphere has been termed 'the turnover' by Shiklomanov (3). This turnover affects the global patterns of the movement of ocean waters and gases in the atmosphere, thereby greatly influencing climate. Besides, water is a very good solvent, and hence, geochemistry is an integral part of the hydrologic cycle. The hydrologic cycle is, thus, the integrating process for the fluxes of water, energy, and the chemical elements (4). Usually, rain and snow are considered the purest form of water, although they may also be mixed with pollutants in the atmosphere. During the journey on the earth, many chemical compounds are mixed with water, and consequently water quality undergoes a change.

The hydrologic cycle can also be visualized as a perpetual distillation and pumping system. In this endless circulation of water, the glaciers and snow packs are replenished, the quantity of river water is replenished, and its quality is restored. From the view point of water use, the land phase of the hydrologic cycle is the most important. The necessity and utility of studying the hydrologic cycle arises because water is essential for the survival of life and is an important input in many economic activities. But water of the desired quality may not be available when needed.

In view of the complexities and extensive coverage, the study of the complete hydrologic cycle is truly interdisciplinary. For instance, the atmospheric part is studied by meteorologists, the pedospheric part by soil scientists, the lithosphere by geologists, and the part pertaining to oceans falls in the domain of oceanographers. The domain of a hydrologist is confined mainly to the land phase, and this in itself is a very large domain. A host of other professionals may be interested in studying the hydrologic cycle, including energy utility managers, chemists, agricultural engineers, public health officers, and inland navigation managers. It is hard to draw lines demarcating various domains in such an interdisciplinary subject, and the boundaries are often blurred. Teams of people from various specialties often work together on a problem dealing with the components of the hydrologic cycle.

COMPONENTS OF THE HYDROLOGIC CYCLE

The hydrologic cycle can be subdivided into three major systems: The oceans are the major reservoir and source of water, the atmosphere functions as the carrier and deliverer of water, and the land is the user of water. The amount of water available at a particular place changes with time because of changes in the supply and delivery. Globally, water movement is a closed system, but locally, it is an open system. A systems representation of the hydrologic cycle is shown in Fig. 2.

The major components of the hydrologic cycle are precipitation (rainfall, snowfall, hale, sleet, fog, dew, and drizzle), interception, depression storage, evaporation, transpiration, infiltration, percolation, moisture storage in the unsaturated zone, and runoff (surface runoff, interflow, and base flow).

Evaporation of water takes place from the oceans and the land surface mainly due to solar energy. The moisture moves in the atmosphere as water vapor which precipitates on land surface or oceans as rain, snow, hail, or sleet. Part of this precipitation is intercepted by vegetation or buildings. Of the amount reaching the land surface, part infiltrates into the soil, and the remaining water runs off the land surface to join streams. These streams finally discharge into the ocean. Some of the infiltrated water percolates deep to join groundwater, and some comes back to the streams or appears on the surface as springs.

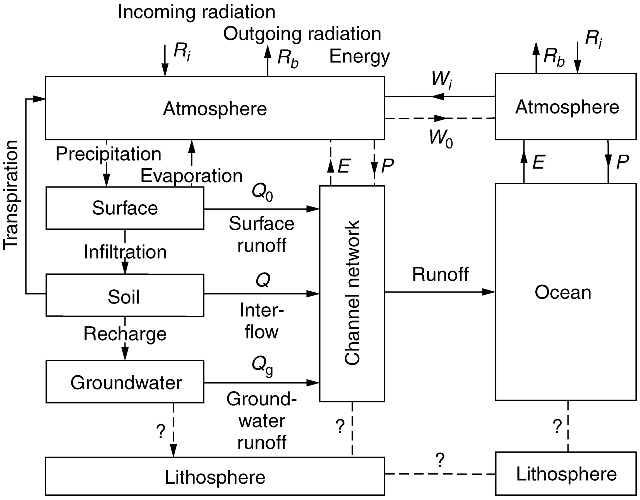

Figure 2. Systems representation of the hydrologic cycle (5).

This immense movement of water is driven mainly by solar energy: the excess of incoming radiation over outgoing radiation. Therefore, the Sun is the prime mover of the hydrologic cycle. The energy for evaporating water from streams, lakes, ponds, oceans, and other open water bodies comes from the Sun. A substantial quantity of moisture is added to the atmosphere by transpiration of water from vegetation. Living beings also supply water vapor to the atmosphere through perspiration. Gravity has an important role in the movement of water on the earth's surface, and anthropogenic activities also have an increasingly important influence on water movement.

An interesting feature of the hydrologic cycle is that at some point in each phase, there usually occur (1) transportation of water, (2) temporary storage, and (3) a change of state. For example, in the atmospheric phase, there is vapor flow, vapor storage in the atmosphere, and condensation or formation of precipitation created by a change from vapor to either the liquid or solid state. Moreover, in the atmosphere, water is in the vapor form, whereas it is mostly (saline) liquid in the oceans.

Scales for Studying the Hydrologic Cycle

Depending on the purpose of study, the hydrologic cycle is studied on many different spatial scales. Horton (6) clearly recognized the diversity of scales when he stated *Any natural, exposed surface may be considered as a unit area on which the hydrologic cycle operates. This includes, for example, an isolated tree, even a single leaf or twig of a growing plant, the roof of a building, the drainage basin of a river system or any of its tributaries, an undrained glacial depression, a swamp, a glacier, a polar ice-cap, a group of sand dunes, a desert playa, a lake, an ocean, or the Earth as a whole* (Quoted in Ref. 4). A qualitative representation of the hydrologic cycle is given in Fig. 3.

From the view point of hydrologic studies, two scales are readily distinct, the global scale and the catchment scale.

Global Scale. From a global perspective, the hydrologic cycle is comprised of three major systems: the oceans, the atmosphere, and the landsphere. Precipitation, runoff, and evaporation are the principal processes that transmit water from one system to the other, as illustrated in Fig. 4. This illustration depicts a global geophysical view of the hydrologic cycle and shows the interactions among the earth (lithosphere), the oceans (hydrosphere), and the atmosphere. Study on the global scale is necessary to understand the global fluxes and global circulation patterns. The results of these studies form important inputs to water resource planning for a national or regional water resource assessment, weather forecasting, and study of climate changes. These results may also form the boundary conditions of small-scale models/applications.

Catchment Scale. While studying the hydrologic cycle on a catchment scale, the spatial coverage can range from a few square km to thousands of square km. The timescale could be a storm lasting for a few hours to a study spanning many years. When the water movement of the earth system is considered, three systems can be recognized: the land (surface) system, the subsurface system, and the aquifer (or geologic) system. The dominant processes of the hydrologic cycle of the land system, are precipitation, evapotranspiration, infiltration, and surface runoff. The land system itself comprises three subsystems: the vegetation subsystem, the structural subsystem, and the soil subsystem. These subsystems subtract water from precipitation through interception, depression, and detention storage. This water is either lost to the atmospheric system or enters the subsurface system. The exchange of water among these subsystems takes place through infiltration, exfiltration, percolation, and capillary rise. Figure 5 shows the schematic of the hydrologic cycle on a global scale in the earth system and a microscale view of the cycle in the land system.

Timescales in the Hydrologic Cycle. The time required for the movement of water through various components of the hydrologic cycle varies considerably. The velocity of stream flow is much higher than the velocity of groundwater. The time-step size for an analysis depends on the purpose of study, the availability of data, and how detailed the study is. The estimated periods of renewal of water resources in water bodies on the earth are given in Table 1. The time step should be sufficiently small so that the variations in the processes can be captured in sufficient detail, but at the same time, it should not put undue burden on data collection and computational efforts.

The range of the spatial and temporal dimensions of many processes related to the hydrologic cycle is shown in Fig. 6.

MATHEMATICAL REPRESENTATION OF THE HYDROLOGIC CYCLE

The quantities of water going through the various components of the hydrologic cycle can be evaluated by the so-called hydrologic equation, which is a simple spatially lumped continuity or water budget equation:

$$I - Q = \Delta S \qquad (1)$$

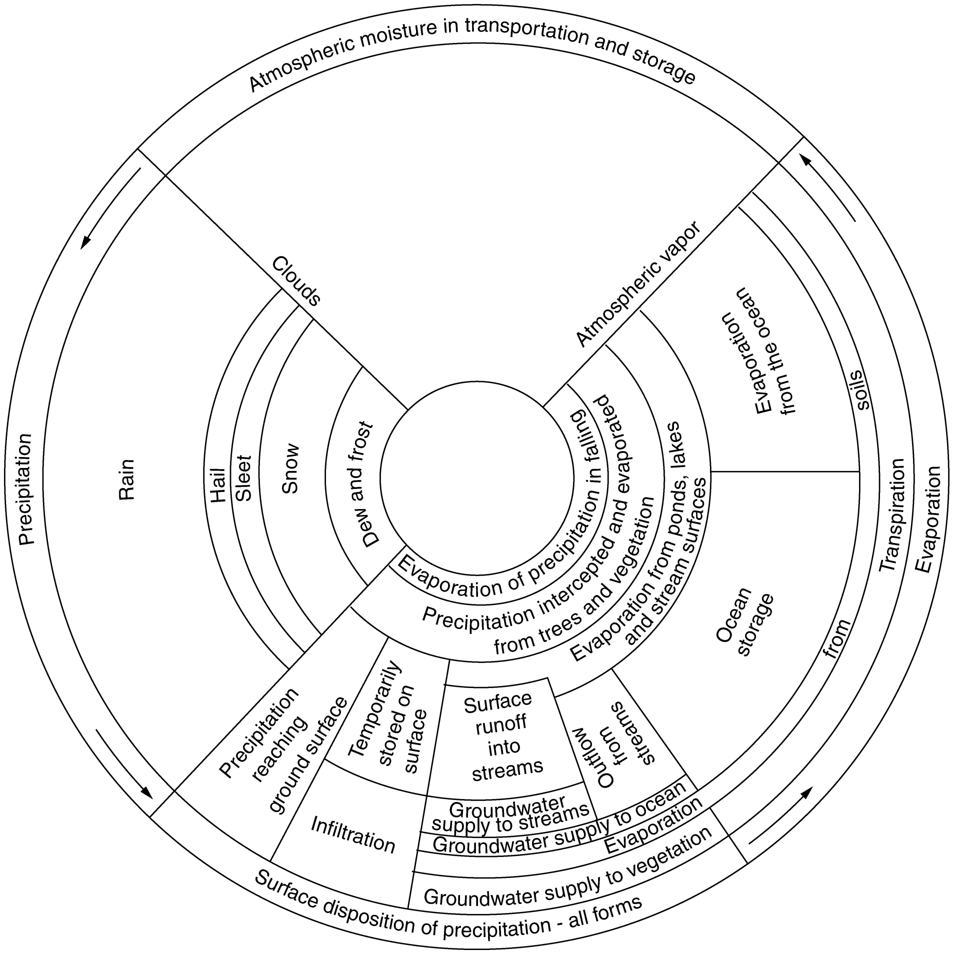

Figure 3. Qualitative representation of the hydrologic cycle (6).

Table 1. Periods of Water Resource Renewal on the Earth[a]

Water of Hydrosphere	Period of Renewal
World ocean	2500 years
Ground water	1400 years
Polar ice	9700 years
Mountain glaciers	1600 years
Ground ice of the permafrost zone	10000 years
Lakes	17 years
Bogs	5 years
Soil moisture	1 year
Channel network	16 days
Atmospheric moisture	8 days
Biological water	Several hours

[a] Reference 3.

where I = inflow of water to a given area during any given time period, Q = outflow of water from the area during the selected time period, and ΔS = change in storage of water in the given area during the time period. If I and Q vary continuously with time, then Eq. 1 can be written as

$$dS(t)/dt = I(t) - Q(t) \tag{2}$$

By integrating, this equation can also be written as

$$\int dS(t) = \int [I(t) - Q(t)]\, dt$$

or

$$\begin{aligned} S(t) - S(0) &= \int_0^t I(t)dt - \int_0^t Q(t)dt \\ &= V_I(t) - V_0(t) \end{aligned} \tag{3}$$

where $S(0)$ is the initial storage at time $t = 0$, $S(t)$ is the storage at time t, and $V_0(t)$ and $V_I(t)$ are volumes of outflow and inflow at time t. Each of the terms of this lumped equation is the result of a number of other terms. They can be subdivided and even eliminated from the equation, depending on the temporal and spatial scale of the study. The continuity equation is one of the governing equations of almost all hydrologic problems. For a watershed, Eq. 1 may be written as

$$P + Q_{\mathrm{SI}} + Q_{\mathrm{GI}} - E - Q_{\mathrm{SO}} - Q_{\mathrm{GO}} - \Delta S - \varepsilon = 0 \tag{4}$$

where P is precipitation, Q_{SI} is surface inflow, Q_{GI} is groundwater inflow, E is evaporation from the watershed, Q_{SO} is surface water outflow, Q_{GO} is groundwater outflow, ΔS is the change in the storage of water in the watershed, and ε is a discrepancy term. For large watersheds, Q_{GI}

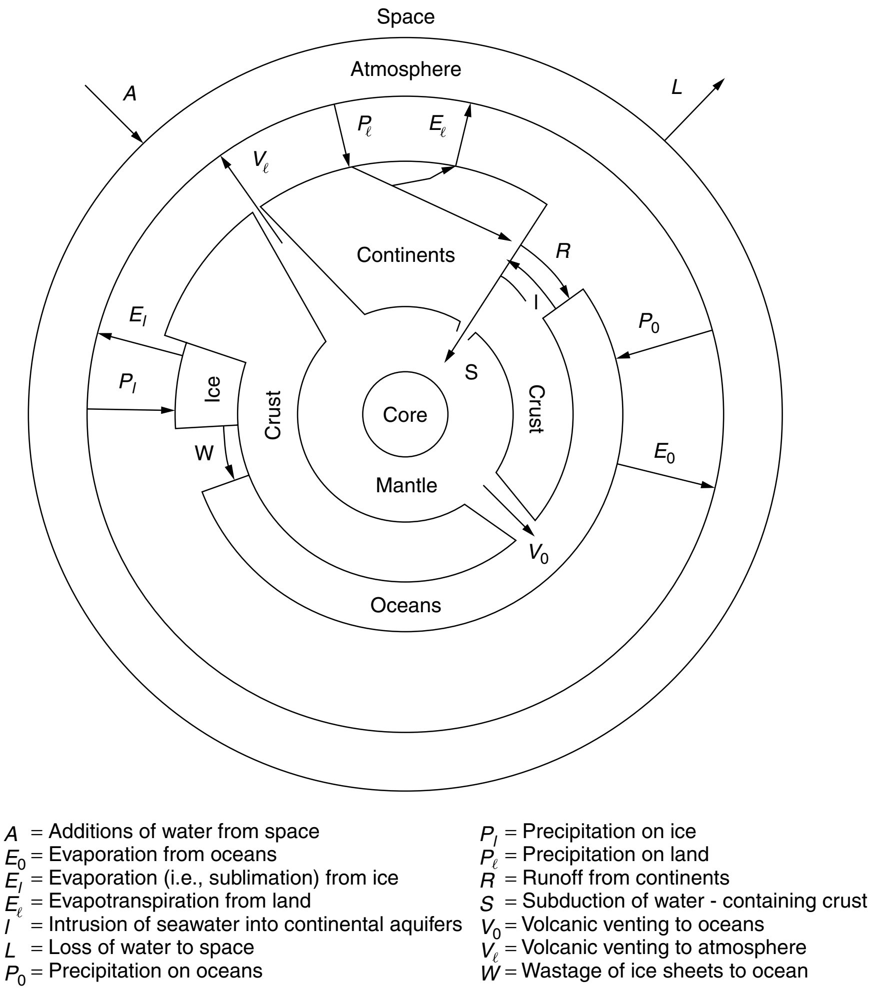

Figure 4. The hydrologic cycle as a global geophysical process (4).

and Q_{GO} are usually negligible. The discrepancy term is included in Eq. 4 because the sum of all other terms may not be zero due to measurement errors and/or simplifying assumptions. However, a small value of the discrepancy term does not necessarily mean that all other terms have been correctly measured/estimated.

Depending on the specific problem, the terms of Eq. 1 may be further subdivided. For example, when applying the hydrologic equation for short time intervals, the change in the total water storage (ΔS) may be subdivided into several parts: changes of moisture storage in the soil (ΔM), in aquifers (ΔG), in lakes and reservoirs (ΔL), in river channels (ΔS_C), in glaciers (ΔS_G), and in snow cover (ΔS_S). Thus, ΔS can be expressed as

$$\Delta S = \Delta M + \Delta G + \Delta L + \Delta S_C + \Delta S_G + \Delta S_S \tag{5}$$

The hydrologic equation may be applied to any time interval; computation of the mean annual water balance for a basin is the simplest because it is possible to disregard changes in water storage in the basin (ΔS), which are difficult to measure and compute. In general, the shorter the time interval, the more stringent are the requirements for measuring or computing the components, and the more subdivided are the terms of Eq. 1. This results in a complex equation which is difficult to close with acceptable errors.

The hydrologic equation may be applied to areas of any size, but the complexity of computation depends greatly on the extent of the area under study. The smaller the area, the more complicated is its water balance because it is difficult to estimate components of the equation. Finally, the components of the hydrologic equation may be expressed in terms of the mean depth of water (mm), as a volume of water (m^3), or as flow rates (m^3/s or mm/s).

Global Water Balance

According to estimates (7), the annual average depth of precipitation on the land surface is about $108 \times 10^3\ \mathrm{km}^3$. Out of this, about $61 \times 10^3\ \mathrm{km}^3$ is returned to the atmosphere as evapotranspiration, and the runoff from land to oceans is $47 \times 10^3\ \mathrm{km}^3$. As far as the water balance of oceans is concerned, the depth of precipitation over them is about $410 \times 10^3\ \mathrm{km}^3$, $47 \times 10^3\ \mathrm{km}^3$ of water is received as runoff from the land, and $457 \times 10^3\ \mathrm{km}^3$ is lost as evaporation. If we consider the water balance of the atmosphere, $457 \times 10^3\ \mathrm{km}^3$ water is received as evaporation from oceans and $61 \times 10^3\ \mathrm{km}^3$ from land. The precipitation over oceans is

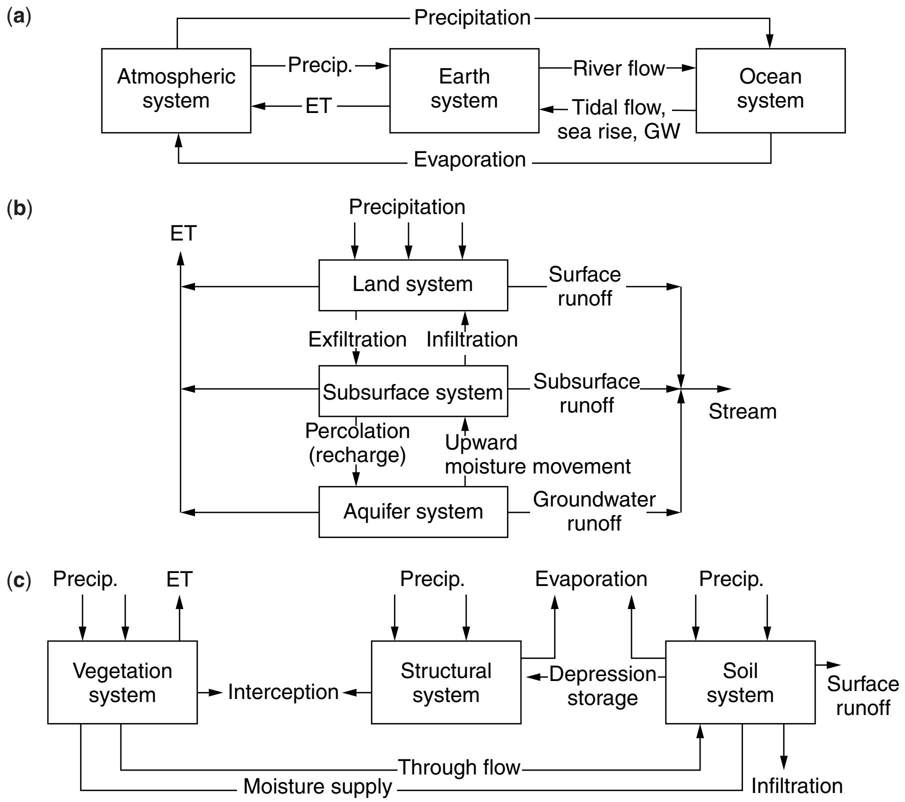

Figure 5. (**a**) A global schematic of the hydrologic cycle (2). (**b**) A schematic of the hydrologic cycle of the earth system (2). (**c**) A detailed schematic of the hydrologic cycle in the land system (2).

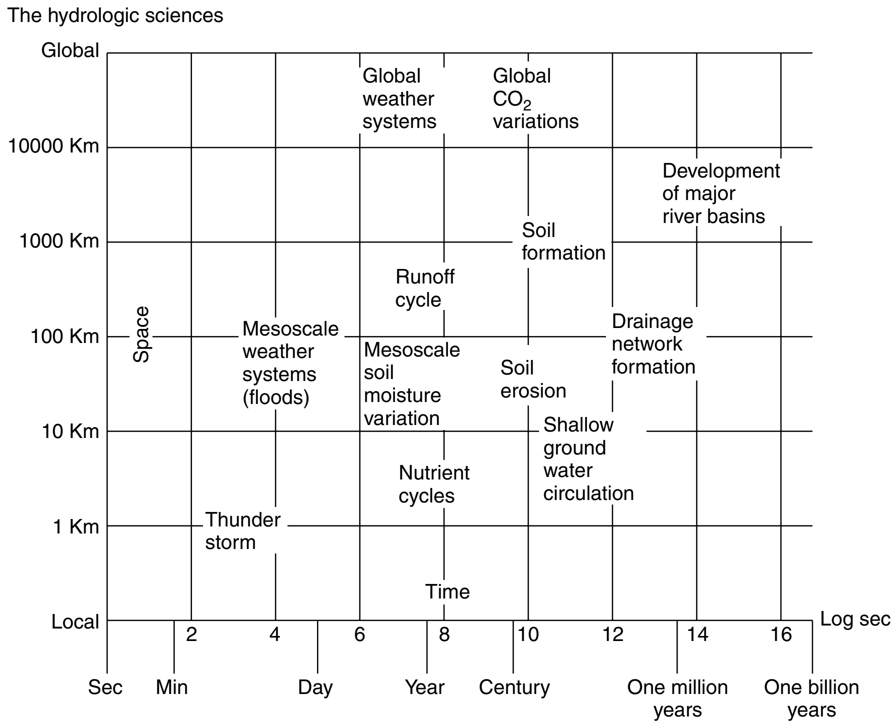

Figure 6. Illustrative range of process scales (4).

410×10^3 km^3, and it is 108×10^3 km^3 over land. Table 2 gives quantitative values of water in various forms on the earth.

The storages and fluxes of the hydrologic cycle are shown in Fig. 7.

INFLUENCE OF HUMAN ACTIVITIES AND LAND-USE CHANGES ON THE HYDROLOGIC CYCLE

Watersheds are subjected to many types of changes, major or minor, for various reasons. Some of them are natural

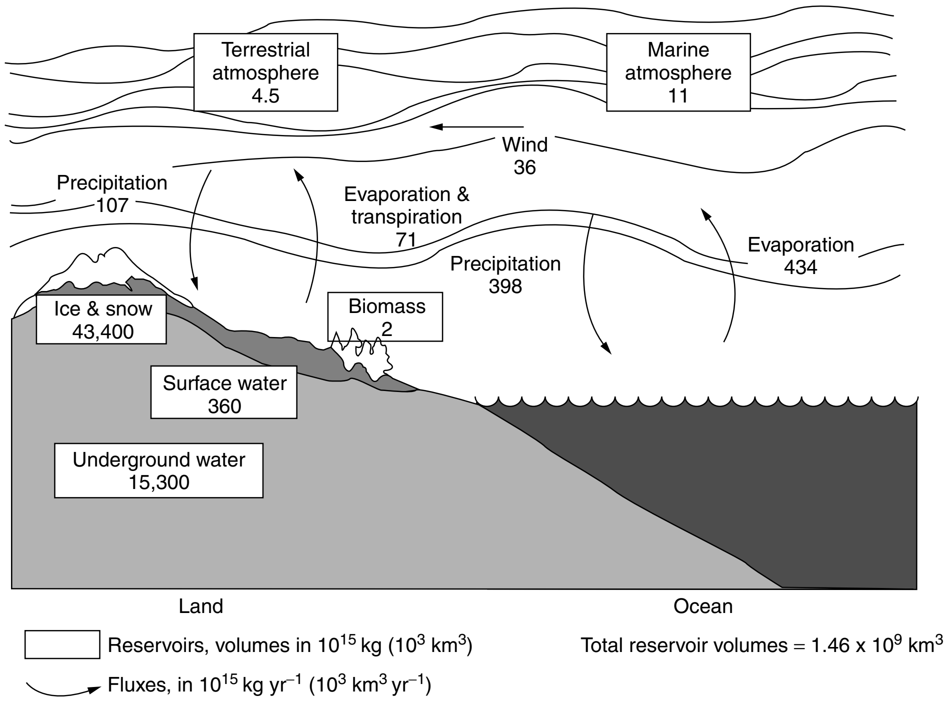

Figure 7. Volumes and fluxes of the global hydrologic cycle (9).

changes, and some are due to human activities. Watershed changes affect virtually all elements of the hydrologic cycle. The quality of water is significantly deteriorating at many places due to industrial and agricultural activities. There has been a growing need to quantify the impact of major human-induced changes on the hydrologic cycle to anticipate and minimize the potential environmental detriment and to satisfy the water resource requirements of society. Even if the water of adequate quantity were present at a place, its use may be limited because of poor quality. The classical and the modern viewpoints of the human role in the hydrologic cycle are shown in Fig. 8.

Most watershed changes can be distinguished as point changes and nonpoint changes. Structural changes, such as dam construction, channel improvement, and detention storage are examples of point changes and affect watershed response in terms of evaporation, seepage, and residence time. Forestry, agriculture, mining, and urbanization are nonpoint land-use changes that affect catchment response. A qualitative discussion of the hydrologic consequences of watershed changes is in order.

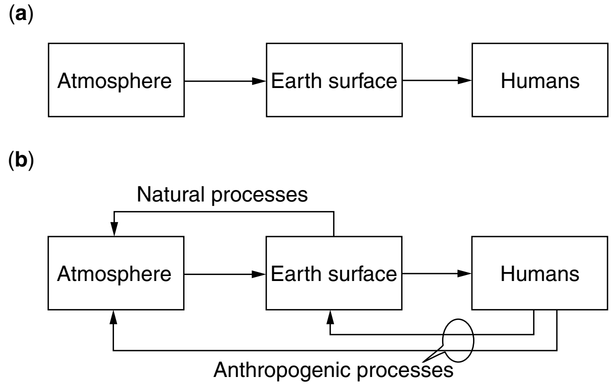

Figure 8. (**a**) Classical viewpoint of the human role in the hydrologic cycle. (**b**) Modern viewpoint of the human role in the hydrologic cycle (1).

Effects of Agricultural Changes

These changes imply that a land area that was forested or barren earlier, is now being cultivated. As a result, the vegetal cover changes; the land slope may be altered a little bit, soil crusting and infiltration characteristics change, and artificial bounds may be placed. The effect of these changes on the hydrologic regime is pronounced and may be multiplicative. Water may be withdrawn from the groundwater zone, or canal irrigation may be introduced leading to noticeable changes in water table behavior. The impacts are also noticed in evapotranspiration, overland flow, channel flow, and infiltration. Fertilizers, pesticides, and insecticides that are applied to crops affect the quality of runoff from agricultural areas.

Effects of Urbanization

A land area that was being used for forestry or agriculture might be transformed into an urban area where houses, roads, parks, parking lots, and sewers are constructed. A large increase in the paved (impervious) surface takes place which considerably reduces infiltration, and the removal of storm water is accelerated. Urban development usually increases the volume and peak of direct runoff for a given rainfall. The time of travel of water is reduced, resulting in lower lag time and a lower time of concentration. However, it is possible to control these effects by providing detention storage or changing the landscape and sizing the storm drains. In brief, the hydrologic effects of urbanization are

Table 2. Water Reserves in Various Phases of the Hydrologic Cycle[a]

	Distribution Area, 10^3 km^2	Volume, 10^3 km^3	Layer, m	Percentage of Global Reserves	
				Of Total Water	Of Freshwater

[a] Reference 8.

1. increased water withdrawals from surface and subsurface water bodies; sometimes demands exceed the available natural resources;
2. increased peak flow and diminishing baseflow of streams;
3. reduced infiltration;
4. increased pollution of rivers and aquifers that endanger the ecology;
5. increased withdrawals from ground water; and
6. changes in local microclimate.

Effects of Forest Activities

These activities may be directed toward planting trees as well as cutting them. The immediate effect of forest activities is change in vegetal cover. When a forested area is deforested and forest litter removed, the interception of precipitation is virtually eliminated. Litter removal changes the infiltration capacity of soil and has a pronounced effect on raindrop impact and resulting soil erosion. When vegetation is lost, evapotranspiration is generally decreased. These changes amount to increased production of direct runoff, reduced surface roughness, and decreased recharge to groundwater. The hydrograph of direct runoff rises more quickly because of the reduced time to peak. However, when additional trees are planted in an area, the effect is reversed, though the impact takes place gradually as the trees grow.

Effects of Structural Changes

Typical structural changes include a dam, a weir, and channel improvement. A dam–reservoir is constructed for many purposes. Regardless of its intended function, it does affect the hydrology of the stream on which it is built. In general, the peak of the outflow from a reservoir is less and the flow may be more even than in the preproject condition. The volume of flow downstream may be considerably less in the afterproject scenario if the reservoir water is diverted elsewhere.

In contrast with reservoirs, channel improvements have an opposite effect. For example, decreasing channel roughness increases flow velocity and hence peak discharge for the same channel size. The removal of vegetation, lining of the channel, and proper maintenance can greatly reduce roughness. Other alterations, such as straightening the channel, maintenance of bands, or increasing slope, significantly affect travel time and flow velocity. Depending on the bed material, infiltration through the bed and banks also modifies flow characteristics.

Impact of Climate Changes on the Hydrologic Cycle

An analysis of measured data series as well as paleoclimatological records suggests that the climate of the earth may be undergoing a significant change. The climatic change may have important impacts on the hydrologic cycle (the converse is also true). The change may be taking place due to natural and human causes. The major changes that could affect climate are changes in vegetation (changes in evapotranspiration, soil moisture, albedo, and radiation balance), increased use of water for day-to-day needs, burning of fossil fuels, and industrial activities. Large-scale water transfers from one basin to another may also cause climate change in the long run. The change manifests itself in changed patterns of spatial and temporal variability in the components of the hydrologic cycle.

The increased emission of greenhouse gases is believed to be the cause of a gradual increase in the earth's temperature. An increase in the temperature of the atmosphere would lead to higher evapotranspiration; changes in precipitation patterns, timing, and distribution; melting of polar ice caps; and recession of glaciers. Higher melting of polar ice and glaciers and thermal expansion of sea water will cause a rise in the seawater level and inundation of islands of low elevations as well as cities adjacent to seas. Another possibility is that an increase in temperature may mean more precipitation, some of which will be snow at the poles, leading to an additional accumulation of ice. The coupled atmosphere–ocean general circulation models are widely used to study the response of climate to various changes. Notwithstanding a large number of studies, what is going to happen and where? is not known with a sufficient degree of certainty and accuracy.

SUMMARY AND CONCLUSIONS

Water is central to the environment and is considered the driver of nature. All studies of water are concerned with some part of the hydrologic cycle. The occurrence and availability of water are closely linked to human development. As a result of many human activities, the features/characteristics of many components of the hydrologic cycle are undergoing changes that are likely to have long-term effects on climate. It is necessary to predict the magnitude and extent of these changes so that the required ameliorative measures can be initiated in time.

HYDROSPHERE

Yoseph Negusse Araya
Open University
Milton Keynes, United Kingdom

INTRODUCTION

The hydrosphere [Greek *hydor* water and *sphera* sphere] refers to the water on or surrounding the surface of the globe, as distinguished from those of the lithosphere (the solid upper crust of the earth) and the atmosphere (the air surrounding the earth). More specifically, the hydrosphere includes the region that includes all the earth's liquid water, frozen and floating ice, water in the upper layer of soil, and the small amounts of water vapor in the earth's atmosphere. The hydrosphere is the major setting for the earth's hydrologic cycle [see Hydrologic Cycle].

ORIGIN OF WATER ON EARTH

The most significant feature of the earth, in contrast to our neighboring planets, is the liquid water that covers more than two-thirds of the planet's surface. This water came about during the early days of the formation of the earth, when the earth's surface cooled down and the oxygen and hydroxides contained in the accreted material, diffused toward the surface. These gases then cooled and condensed to form the earth's oceans. It is believed that since then, there has been little loss or gain in the overall quantity of the hydrosphere, despite minor fluctuations such as gain from continued degassing and infalling comets and loss in the upper layers of the atmosphere caused by ultraviolet light breaking up water molecules.

DISTRIBUTION AND QUANTITY OF WATER ACROSS THE GLOBE

The earth's water has six major reservoirs in which water resides. These include the oceans, the atmosphere (split into two reservoirs, one over the land and one over the oceans), surface water (including water in lakes, streams, and the water held in the soil), groundwater (water held in the pore spaces of rocks below the surface), and snow and ice. The locations of some major reservoirs on earth are shown in Fig. 1.

The approximate contribution of the different components of the reservoirs to the hydrosphere, the annual recycled volumes, and the average replacement periods are shown in Table 1.

Table 1 highlights the enormous disparity between the huge volume of salt water and the tiny fraction of freshwater and, in addition, the long residence time of polar ice and groundwater, as opposed to the brief period for which water remains in the atmosphere. Some 96.5% of the total volume of the world's water, it is estimated, exists in the oceans and only 2.5% as freshwater. Of this freshwater, nearly 70% occurs in the ice sheets and

[b] Excluding groundwater in the Antarctic estimated at 2 million km^3, including predominantly freshwater of about 1 million km^3.

glaciers in the Antarctic, Greenland and in mountainous areas, whereas a little less than 30%, it is calculated, is stored as groundwater in the world's aquifers.

Water moves through the reservoirs by a variety of processes, at different rates, and for unique residence times within any reservoir. This flow of water constitutes the Earth's hydrologic cycle [see HYDROLOGIC CYCLE]. A brief summary of the major processes involved in this movement, along with the amount of water transferred per unit time are shown in Fig. 2.

THE BIOGEOCHEMISTRY OF THE HYDROSPHERE

The quality of natural water in the various reservoirs of the hydrosphere depends on a number of interrelated factors. These factors include geology, climate, topography, biological processes, land use, and the time for which the water has been in residence. Table 2 gives a comparison of major elements in selected reservoirs.

Rainwater has a low concentration of nutrients compared to the other reservoirs because it originates as evaporated water vapor and also has a relatively short residence time in the atmosphere. Even so, it is never pure. The major constituents originate from dissolution of aerosol particles, which are formed from natural processes, such as evaporation of sea spray or human activities, such as burning of fossil fuels. Naturally rain water has a slightly acid pH (about 5.5). This results from the formation of mild carbonic acid, when rainwater reacts with atmospheric carbon dioxide:

$$CO_2 + H_2O \longrightarrow H_2CO_3$$

In areas of high emission of sulfur dioxide or nitrogen oxide gases from industrial activities or fossil fuel burning, hydrolysis of rainwater may result in more acidic rain and a pH as low as 4 [see Acid Rain].

River waters have an intermediate concentration of ions compared to that of rainwater and oceans. The main factor controlling the composition or river water is the weathering reaction between rainfall and rocks through which this water passes. An example is that of calcite in limestone, which reacts with carbonic acid of rainfall, as

$$CaCO_3 + H_2CO_3 \longrightarrow Ca^{2+} + 2HCO_3{}^-$$

Lakes also have an intermediate concentration of ions compared to those of river and seawater. Lake waters constitute a reservoir of freshwater, and their composition depends on four factors: the hydrology (e.g., the relative importance of groundwater or surface water inputs, evaporation), the surrounding geology (e.g., carbonate rocks or granite), temperature-driven circulation patterns, and anthropogenic factors (e.g., acid rain, agricultural fertilizers). In some instances, evaporation of water from lakes formed in closed basins may result in a high concentration of salts, as opposed to areas of high rainfall.

Sea and ocean waters are dominated by sodium and chloride ions, followed by sulfate and magnesium. Surface sea water is alkaline at an average pH of about 8. Seawater tends to have a more or less uniform composition in the major elements. But concentrations of minor constituents, including trace and heavy metals and nutrients, vary with depth and location, resulting in marked differences in biological productivity. Organisms living on the surface of the seawater are also involved in changes in its composition via removal of nutrients and breakdown of organic matter at different depths.

Ground water composition is the result of the rock type in which it is confined (e.g., limy is to calcium as argillaceous is to silica); the chemical processes of dissolution, hydrolysis, oxidation-reduction; and biological processes. Moreover, anthropogenic contaminants such as excess fertilizers and heavy metals may also affect the composition of groundwater.

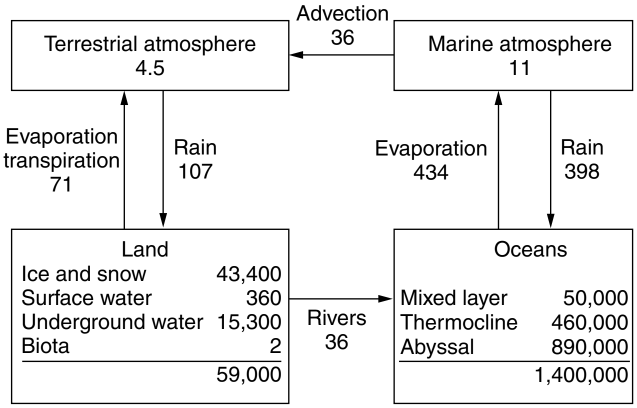

Figure 2. Estimates of global water reservoirs (in 10^{15} kg and 10^{15} kg/yr) global water cycle fluxes (3).

Table 2. Chemistry of Some Hydrospheric Components (in Parts per Million—ppm)[a]

Major Element	Average Seawater	Average Natural River Water	Average Rainwater
Chloride (Cl^-)	19,000	5.75	3.79
Sodium (Na^+)	10,500	5.15	1.98
Sulphate ($SO_4{}^{2-}$)	2,700	8.25	0.58
Magnesium (Mg^{2+})	1,350	3.35	0.27
Calcium (Ca^{2+})	410	13.4	0.09
Potassium (K^+)	390	1.3	0.3
Bicarbonate ($HCO_3{}^-$)	142	52	0.12
Bromide (Br^-)	67	0.02	
Strontium (Sr^{2+})	8	0.03	
Silica (SiO_2)	6.4	10.4	—
Boron (B)	4.5	0.01	
Fluoride (F^-)	1.3	0.1	

[a] References 1 and 4.

Ice is a pure solid and has thus only few impurities in its structure, but particulate matter and gases may be trapped within it. Analysis of successively trapped gases or other anthropogenic substances such as carbon dioxide in polar ice caps, has been used to study consecutive changes in the atmospheric composition of past times.

EFFECT OF HUMAN BEINGS ON THE HYDROSPHERE

During the last 200 or so years, the sharp rise in population, urbanization, industrial development, and intensification of agricultural practices have combined to affect most natural waterbodies of the earth. This is due to the transport of waste products from those activities by surface water, groundwater, and the atmosphere. The scale and intensity of this pollution vary considerably; there are global problems such as the presence of heavy metals, regional problems such as acid rain, and much more localized ones such as groundwater contamination.

Overall, globally, organic material from domestic sewage, municipal waste, and agroindustrial effluent is the most widespread pollutant. The sewage contains

Table 3. The World's Major Water Quality Issues[a]

Issue Scale	Waterbodies Polluted[b,c]	Sector Affected	Time Lag Between Cause and Effect	Effects Extent
Organic pollution	Rivers++ Lakes + Groundwater +	Aquatic environment	< 1 year	Local to district
Pathogens	Rivers ++ Lakes + Groundwater +	Health ++	< 1 year	Local
Salinization	Groundwater ++ Rivers +	Most uses Aquatic environment Health	1–10 years	District to region
Nitrate	Rivers + Lakes + Groundwater ++	Health	> 10 years	District to region
Heavy metals	All bodies	Health Aquatic environment Ocean fluxes	< 1 to > 10 years	Local to global
Organics	All bodies	Health Aquatic environment Ocean fluxes	1–10 years	Local to global
Acidification	Rivers ++ Lakes ++ Groundwater +	Health Aquatic environment	> 10 years	District to region
Eutrophication	Lakes ++ Rivers +	Aquatic environment Most uses Ocean fluxes	> 10 years	Local
Sediment load (increase and decrease)	Rivers + Lakes	Aquatic environment Most uses Ocean fluxes	1–10 years	Regional
Diversion, dams	Rivers + Lakes + Groundwater ++	Aquatic environment Most uses	1–10 years	District to region

[a] References 5 and 6.
[b] +: serious on global scale.
[c] ++: very serious issue on global scale.

pathogens that lead to disease and mortality among the populations using this water.

Moreover, this organic material has also high concentrations of nutrients, particularly nitrogen and phosphorus, which cause eutrophication (i.e., nutrient enrichment) of lakes and reservoirs. This eutrophication promotes abnormal plant growth and oxygen depletion, which destroys aquatic ecosystems. Excess fertilizers from agricultural production areas also have similar consequences.

Acidification of surface waters as a result of acid rain has adverse effects on aquatic life and also human health. Salinization, the high concentration of salts in the soils of irrigated areas, as a result of poor drainage and high evaporative loss also causes water pollution. Sediments in the form of suspended load may affect physical structures, for example, silting up of dams and damage to aquatic life. Table 3 is a summary of these problems by the type of waterbodies polluted and the extent and reach of the effects.

In general, it may be noted that the effect of pollution can reach far beyond the vicinities of its origin. Moreover, the effects may not be noticed until substantial time has elapsed and it is too late. This calls for constant monitoring and control strategies to save the earth's most precious resource, water.

THE HYDROLOGIC CYCLE

Water is more or less constantly moving and changing from one state to another (solid, liquid, or vapor) while interacting with the physical processes in the atmosphere, lithosphere, and biosphere. These changes and movements of water are linked together into a grand scheme called the hydrologic cycle. Components of the hydrologic cycle include the water vapor and clouds in the atmosphere, and also liquid surface waters (oceans, lakes, and streams) on continents as well as groundwater. Other important components of the hydrologic cycle include glacial ice held on continents and water in biomass. Plants and animals are about 70% water by volume. Water evaporates in enormous quantities from the oceans and then falls as precipitation either on land or ocean. That portion which falls on land evaporates, evapotranspires, runs off, or infiltrates by some measure. Eventually, all water ends up back in the ocean. Between the various stages of the hydrologic cycle, water moves between temporary storage areas often called reservoirs. These movements are controlled by climatic conditions, which include rain, snow, wind, and other meteorologic processes.

Various pathways exist in the hydrologic cycle (Fig. 1). In nonvegetated systems, interception processes usually do not occur; however, within vegetated systems, precipitation can be intercepted and lost to evaporation. Some precipitation may reach the ground by stemflow but most often reaches the soil by a process called throughfall. Precipitation that reaches the soil surface can then infiltrate and recharge soil waters. From there, it can percolate through soil to deeper soil layers or groundwater supplies. The rate of evaporation from soils or surface waters (including oceans) can be influenced by several factors, including temperature, relative humidity, and wind.

Warmer air can hold more water vapor, thereby generating increased evaporation rates. Drier air can accept much more water vapor than air that is nearly saturated, and windy conditions generally accelerate evaporation. Transpiration from plants takes place via water loss from the stomata, the gas exchange organs on the leaves of plants. The stomata also act as an important cooling mechanism for plants by means of latent heat absorbed and transferred from the plants. This process also supplies the tensional forces necessary to help draw water into roots from the surrounding soil.

Transpiration is often lumped with evaporation and is then called evapotranspiration. Besides evapotranspiration, water can be converted to water vapor in the atmosphere by sublimation. When water is heated enough, it becomes water vapor, which results in evaporation. Sublimation is the result of ice going directly from a solid to water vapor without passing through a liquid state.

Air can hold only a certain amount of water vapor. The amount depends largely upon temperature; thus, as mentioned, hotter air can hold more water vapor than colder air. When air is saturated with water vapor, the water vapor condenses into droplets of water, forming clouds. When the droplets gain enough mass, they fall to the ground as rain or snow. Water that falls as snow or rain evaporates, sublimates, runs off the ground surface (runoff), or soaks into the ground (infiltration).

Whether the water runs off or infiltrates is controlled by a number of mechanisms including precipitation rate, soil water content, slope, and vegetation.

As rates of precipitation increase, runoff rates tend to increase. In extreme cases, rapid cloudbursts of precipitation can result in flash floods and potential land slides. Prior to rainfall, the relative amount of soil water content can dictate the amount of water that soil can hold before saturation. Generally, more water will infiltrate into dry soil than into wet soil, and more water will run off steeper slopes than off moderate slopes. Vegetation can counteract this process by holding more water than hill slopes by themselves. Hillsides, which have undergone timber harvesting or have been burned, often suffer severely from mudslides and flooding. Runoff processes within the hydrologic cycle include stream flow and groundwater flow, each of which eventually results in flow to ocean reservoirs. Lakes and streams may occur in low points of the landscape due to streamflow, or where the groundwater table emerges above the surface. Other contributors of the runoff process include melting of glacial ice and calving of icebergs into the sea.

Globally, precipitation exceeds evapotranspiration over continents, evaporation exceeds precipitation over ocean reservoirs, and excess water moves from continents to oceans as runoff. The ratio of precipitation rate to evaporation rate can vary dramatically between regions. For example, in tropical rainforests, precipitation may greatly exceed evapotranspiration (1).

Often, rates of hydrologic activity are measured in terms of "mean residence time," or the average amount of time that water remains in its various states. For example, the mean residence time of a water molecule in the atmosphere is very short, usually from days to a week or two. Water tends to move quickly through plant and animal tissues but can be stored in cells for a much longer period of time. It can take weeks to months for water to move through surface drainage networks, depending on the complexity of the geomorphologic network. Water may be stored for months to years in soil water, and individual water molecules may remain in deep groundwater, glaciers, and ocean basins for decades to 10,000 or more years.

Traditionally, quantities of water transferred within the global hydrologic cycle are described in terms of cubic kilometers (km^3) by virtue of the immense quantities held in respective reservoirs. Each km^3 of water contains 10^{12} liters and weighs 10^{15} grams (1). Often, changes in the water cycle are discussed in terms of depth, for example, centimeters per year (cm/yr) or millimeters per hour (mm/hr). Annually, approximately 100 cm of water are evaporated from the surface area of oceans.

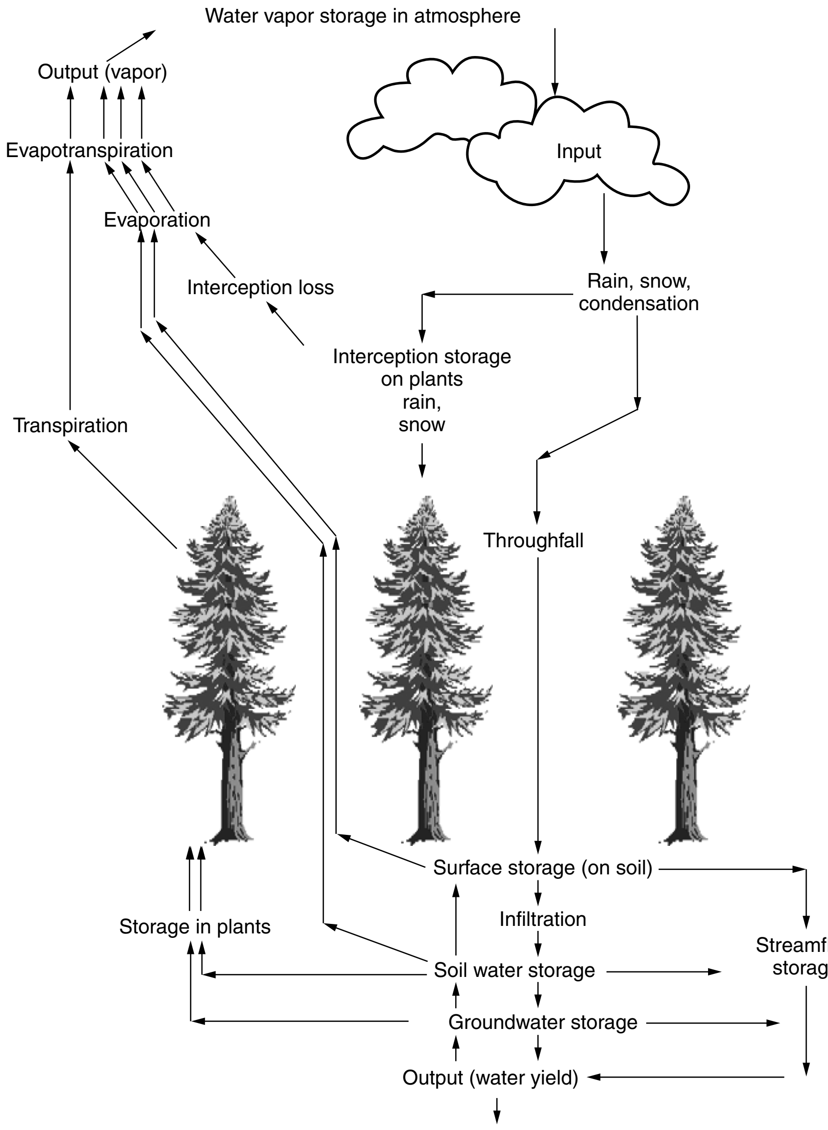

Figure 1. The hydrologic cycle, consisting of water storage compartments and the solid, liquid, and gaseas phases associated within and between each compartment.

Oceans, which also happen to be the dominant pool in the global water cycle, contain approximately 1,350,000 km^3 of water. Of this, approximately 425,000 km^3 are evaporated to the atmosphere each year, 385,000 km^3 are returned directly to the oceans via precipitation, and 40,000 km^3 are delivered to land by rainfall (net transport to land). At any given time, the atmosphere contains about 13,000 km^3 water, or approximately 0.3 cm of rainfall. The large quantities of annual water movement through the atmosphere result in 111,000 km^3 being precipitated upon land and vegetation and 71,000 km^3, either evaporated or transpired (evapotranspiration). Polar and glacial ice reservoirs account for approximately 33,000,000 km^3 water, water held in soils is equal to approximately 122,000 km^3, and groundwaters hold approximately 15,300,000 km^3 (1–3).

WATER RESOURCES

Water resources refer to the supply of groundwater and surface water in a given area. Water resources may also reference the current or potential value of the resource to the community and the environment. The maximum rate at which water is potentially available for human use and management is often considered the best measure of the total water resources of a given region. Approximately 30% of the world's fresh water is in liquid form and therefore potentially accessible for human use and management at any given time (4). The rest is either locked up in polar or glacial ice or water vapor. Of the 30%, almost all is held in groundwaters. Historically, attempts to develop global assessments of available water resources have resulted in limited applicability. The usefulness of resulting aggregated quantities, based on streamflow and population calculations, which lead to measurements in relative abundance and shortages of water regionally, have often been unreliable. The extreme difficulty in preparing a global assessment stems from the general lack of sufficient and reliable information on water availability, quality, and water use in many areas of the world.

Efforts to balance supply and demand and plans for a sustainable future are severely hampered by this lack of reliable information. Studies of water resources leading to meaningful assessments have been found realistic only if conducted regionally or locally. Only then has proper accounting of seasonal and interannual variability of stream flow as well as interactions between groundwater and surface water been appropriately accounted for. Likewise, only then have the potentials for reusing the water as it proceeds downstream and the balance of instream and withdrawal uses been appropriately managed. Reduced scale also allows for the importance of water quality in determining suitability for use and, most importantly, the realistic evaluation of social, economic, and political factors that help determine per capita water use (5–8).

Despite these constraints, some attempts to describe global water use have led to reasonable conclusions. For example, estimates indicate that since 1900, global water withdrawal has increased about ninefold and per capita withdrawal has quadrupled. Globally, the largest use of water is for irrigation (70%); industry uses 20%, and 10% is for direct human consumption (9). As a result, humans now withdraw about 35% of the world's reliable runoff. At least another 20% of this runoff is left in streams to transport goods by boats, dilute pollution, and sustain fisheries and wildlife (10). Obviously, these percentages may vary greatly from one region to another, depending on natural precipitation and the degree of development and human population in the region (9). There may be further variance because the distribution of water resources over the landmass of the earth is uneven and unrelated to population demographics or economic development. Because of these complexities and constraints, humans have attempted to increase available water resources by increasing precipitation in various anthropogenic manners, including cloud seeding. Humans have also attempted to decrease evapotranspiration by modifying vegetation, sometimes genetically. The effects of these manipulations are usually minimal and most often temporary but unfortunately often have serious environmental, social, economic, and legal ramifications (4).

SOCIETY

Water is central to survival. Without it, plant and animal life would be impossible. Water is a central component of the earth's ecosystems and provides important controls on weather and climate. Water is likewise central to economic well-being via delivery of direct precipitation and agricultural irrigation, forestry, navigation, waste processing, and hydroelectricity. There are more than 250 international river basins, and in each basin, water moving across diplomatic boundaries can create sensitive and potentially dangerous political challenges. Our present understanding of climate and the consequences of future climate change (whether natural or anthropogenic), together with population growth and economic development, necessitate that water resources are of increasing interest and importance for the foreseeable future.

Reflecting the impacts of population growth alone, water use is increasing everywhere. If per capita consumption of water resources continues to rise at its current rate, humans could be using over 90% of all available freshwater by the year 2025, leaving just 10% for all other living organisms. This forecast does nothing to reflect the high likelihood of climate change. Many studies point to serious consequences for water resources due to climate change, especially in arid regions. For instance, a 1 °C to 2 °C increase in the mean annual air temperature and a 10% decrease in precipitation can create a 40 to 70% reduction in annual runoff in regions that already experience insufficient moisture. The same is true for water resources of large economic regions. American scientists have calculated that a 2 °C climate warming and a 10% reduction in precipitation, can decrease water resources by 1.5 to 2.0-fold in those regions of the country located in arid climate zones alone.

It is well known that the severity of water management problems is determined by the ratio of available water resources to demand. Based on predicted climate changes, plans for further development in irrigated agriculture, reservoir construction, and most water-consuming types of industry will have to be revised. All such revisions will need to result in the greatest positive impacts on hot arid regions. These regions already have difficulties with water supplies and undergo persistent conflicts between different water users and consumers. Regardless, as water use responds to changing demand with some degree of inertia, regional water availability will be determined primarily by the changing water regime within a given territory. The water management systems of river basins will be complex and will have to be extremely flexible and capable of efficient control over water resources under different climate scenarios. In this respect, the regions with large capabilities in river runoff regulation, as is the case in many parts of the United States of America, Canada, and Europe, will have considerable advantages relative to solving water supply and flood regulation, as opposed to those regions with more natural river systems such as regions located in southern and southeastern Asia and South America.

Relatively little account has been taken of the qualitative or quantitative depletion of water resources due to increasing pollution of natural freshwater sources. On this basis alone, all water resource estimates could be construed as optimistic. The major sources of intensive pollution of waterways and waterbodies are contaminated industrial and municipal wastewater as well as water runoff originating from irrigated areas. This problem can be no more acute than in the industrially developed and densely populated regions where relatively little wastewater purification takes place. It is estimated that in 1995, the volume of wastewater was 326 km^3/year in Europe, 431 km^3/year in North America, 590 km^3/year in Asia, and 55 km^3/year in Africa. Many of these countries discharge large portions of their wastewater containing harmful substances into the hydrologic system with no preliminary purification. Prime water resources are thus polluted and their subsequent use becomes unsuitable, especially as potable supplies. Every cubic meter of contaminated wastewater discharged into water bodies and watercourses can potentially spoil between eight and ten cubic meters of pure water. This means that most parts of the world are already facing the threat of catastrophic depletion of water resources due to pollution alone.

Forecasts of future population, industry, and power generation growth are used to predict water withdrawal and water availability. The values obtained for 2025 are ±10–15% for those regions of predominantly developed countries and ±20–25% for regions with predominantly developing countries. To be able to plan for and properly manage these potential future demands for fresh water, it will be vital to achieve close cooperation between scientists and water resource managers. Scientists from different countries and international organizations will have to collaborate and deal with many problems related to hydrology, climatology, and other related disciplines in an cooperative effort to understand better the complex use and protection of water resources.

In human history, water has been central to society and remains so today. Over time, we have grown more aware of the accelerated growth of industry and population correlated to increased uses of water and how that use relates to the earth's fixed supply. In recent times, it has become clearer that human prosperity and prospects for survival vary with the amount and distribution of fresh, unpolluted water. Each year there are millions more humans but no more water than before (11). The same amount of water exists now as when the earth was formed. Ultimately, although finite in quantity, water is a renewable resource. There can be little argument that exponential population growth coupled with an increasing demand for freshwater is resulting in increasing pressures on the resource. The continued degradation, abuse, and pollution of the environment and its resources may cause irremediable damage to our own health and that of the planet on which all life depends. Despite strong feedback mechanisms between hydrologic and meteorologic processes, which have historically led to poor representations of hydrologic processes, increased understanding will lead to improved management strategies for the future and the various processes of the hydrologic cycle.

ISOHYETAL METHOD

Sharad K. Jain
National Institute of Hydrology
Roorkee, India

Vijay P. Singh
Louisiana State University
Baton Rouge, Louisiana

The isohyetal method is used to estimate the mean precipitation across an area by drawing lines of equal precipitation. The method uses topographic and other data to yield reliable estimates.

INTRODUCTION

An accurate assessment of the mean areal precipitation is needed in many hydrologic analyses. Precipitation observations from gages are point measurements, and precipitation exhibits appreciable spatial variation over relatively short distances. Numerous methods of computing areal precipitation from point measurements have been proposed, such as the arithmetic average method, the Thiessen polygon method, the Isohyetal method, and kriging. The choice of any method depends on the quality and nature of data, precision required (1), the availability of time and resources, and the preference of the analyst.

Let the precipitation data be available at n stations, spread over an area and P_i be the observed depth of precipitation at the ith station. Using a linear interpolation technique, an estimate of the precipitation across the area can be expressed by

$$P* = \sum_{i=1}^{n} P_i W_i \tag{1}$$

where W_i is the weight at the ith station. Spatial averaging techniques differ in the method of evaluating these weights. The weights of an optimal interpolation technique are chosen so that the variance of error in estimation is a minimum.

The simplest technique for computing the average precipitation depth across a catchment is to take an arithmetic average of the observed depths at gauges within the area for the time period of concern. If the gauges are relatively uniformly distributed across the catchment and the precipitation depths do not vary greatly, this technique yields good results. However, gauges are not always uniformly distributed, there may be large variations in precipitation depths, and topography and orography influence storm movement and precipitation. For these reasons, the arithmetic average is not a preferred method; a technique that can take into account the spatial variability of precipitation is needed.

ISOHYETAL METHOD

Isohyets are contours of equal precipitation analogous to contour lines on a topographic map. In the isohyetal method, precipitation values are plotted at their respective stations on a suitable base map, and isohyets are drawn to create an isohyetal map. Isohyetal lines are based on interpolation between rain gauge stations. While constructing isohyets, it is assumed that rainfall between two stations varies linearly, unless abrupt changes in topography indicate otherwise.

Obviously, this method works best when there are a number of rain gauges. In regions of little or no physiographic influence, isohyetal contours may be drawn taking into account the spacing of stations, the quality, and the variability of the data. In regions of pronounced orography, where precipitation is influenced by topography, analysts take into consideration the orographic effects and storm orientation to interpolate between station values, thus making full use of their knowledge of orographic effects and storm morphology. The areas enclosed by two successive isohyets are multiplied by the average of the isohyets to obtain the volume of precipitation needed to compute the average rainfall depth across the basin. However, a more accurate value of mean areal rainfall is obtained if the lengths of the isohyets are measured as well as the area between the isohyets. If b is the length of the lower value isohyet B, a is the length of the higher value isohyet A, and Δi is the isohyet interval $(A-B)$, then it can be shown that mean rainfall r for the segment is

$$r = B + \frac{\Delta i(2a + b)}{3(a + b)} \tag{2}$$

An isohyetal map resembles a topographical map, except that it contains contours of equal precipitation depths. The topographic parameters that are used to draw isohyets are the elevation of the station, the proximity to mountains and their slope, and the proximity to valleys. If linear interpolation between stations is used, the results will be essentially the same as those obtained by methods, such as the Thiessen polygon method. Clearly, the accuracy of the method depends high on the skill of the analyst; an improper analysis may lead to serious errors. This technique of computing the average precipitation is laborious, if done manually, because the precipitation values need to be interpolated, isohyetal lines are to be drawn, and areas are to be measured for each storm.

Steps of the Isohyetal Method

1. The location of each station is plotted on a map of the catchment.
2. The observed depth of precipitation at each station is marked on the map.
3. The increment of isohyets is chosen, depending on the variation of precipitation values and the scale of the map.
4. Isohyets at selected increments are plotted. In flat areas, linear interpolation between observed precipitation depths is performed. If the area has mountains, valleys, etc., isohyets are drawn keeping in view the influence of these features on precipitation.
5. Starting either from the outermost or the innermost isohyet, the average precipitation between two consecutive isohyets is obtained as the arithmetic average of the value of two isohyets. For example, between the 10 and 20 cm isohyets, the average precipitation would be 15 cm.
6. The area between the two isohyets is measured by using a planimeter or by counting the number of boxes (if the map is drawn on graph paper) and using the scale of the map.
7. Multiplying the area between isohyets by the average precipitation gives the volume of precipitation for that area. The total catchment precipitation is the sum of all such values.
8. The average depth of precipitation is obtained by dividing the sum by the area of the catchment:

$$P = \frac{\sum_{i=1}^{n} P_i A_i}{\sum_{i=1}^{n} A_i} \tag{3}$$

where A_i is the area between successive isohyets and P_i is the average precipitation across this area.

Figure 1 shows an isohyetal map for a catchment that was drawn using point rainfall data. The area enclosed by each isohyet was calculated as given in Table 1. To compute the average catchment rainfall, the average isohyetal value is worked out for each isohyet (the maximum observed rainfall was 108 cm and the minimum 38 cm). The average value multiplied by the area enclosed by the corresponding isohyets gives the volume of precipitation for that area. The volumes for different areas are summed and divided by the area of the catchment to get the average catchment rainfall. The computations are shown in Table 1.

Features of the Isohyetal Method

Important features of the isohyetal method are

- This method is widely regarded as the most accurate method for determining the average precipitation across an area.

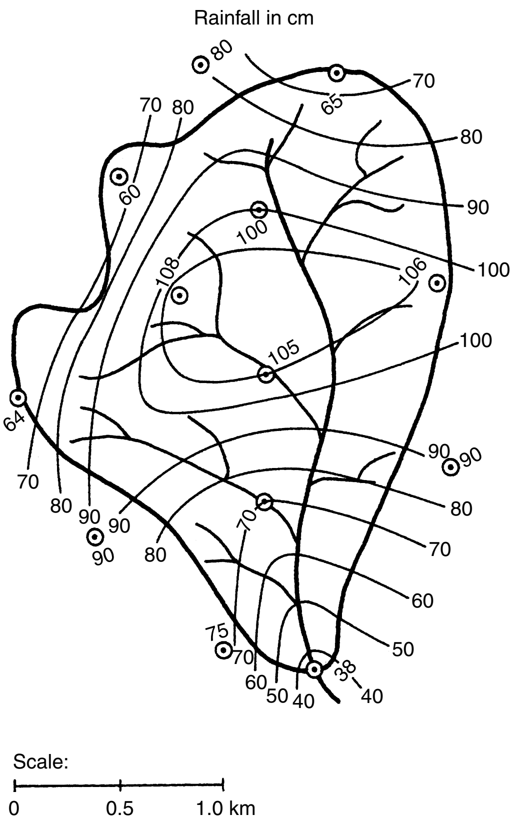

Figure 1. The isohyetal method for computing mean areal rainfall.

Table 1. Estimate of Mean Areal Rainfall by the Isohyetal Method

Isohyet Value, cm	Average Value, cm	Area Enclosed, km^2	Net Area, km^2	Rainfall Volume, km^2-cm
105	106.5	0.79	0.79	84.14
100	102.5	1.52	0.73	74.83
90	95	2.57	1.05	99.75
80	85	3.47	0.90	76.50
70	75	4.50	1.03	77.25
60	65	5.18	0.68	44.20
50	55	5.39	0.21	2.20
<40	39	5.41	0.02	0.78
	Total		5.41	459.65
Average catchment rainfall = 459.65/5.41 = 84.96 cm				

- The isohyetal method permits using available pertinent data, such as orographic features and storm morphology.
- This method is subjective because drawing isohyets depends on the individual analyst. Consequently, there is a potential for mistakes.
- The method is time-consuming.
- The isohyetal method is usually applied in the past tense. It is not generally applied in the present to provide inputs for modeling or forecasting.
- This method can be used for spatial averaging of other variables, such as evapotranspiration and snow depth.

There are many computer softwares (2,3) that can be used to draw an isohyetal map from point data. Most of these use a statistical technique known as kriging. The use of software relieves the hydrologist of the tedious job of drawing a map, interpolating precipitation from point data, and drawing isohyets. But most software follow a mathematical algorithm and do not use topographic or storm features. While manually drawing isohyets, most people use judgment rather than actual calculations in interpolation. An alternative is using a computer to draw the isohyetal map which can be refined by the hydrologist later using additional information, experience, and judgment. This results in a considerable saving of time and provides better results.

WHAT ABOUT METEOROLOGY?

Pacific Northwest National
Laboratory—Shrub-Steppe
Ecology Series

BACKGROUND INFORMATION

Meteorology is the science of the atmosphere. The word meteorology comes from the Greek meteors, which

---

means lofty or elevated and logos, meaning discourse or description. The field of meteorology includes both weather and climate and is concerned with the physical, dynamical (a force producing change or motion), and chemical state of the Earth's atmosphere and interactions between the atmosphere and the Earth's surface. Humans' earliest observations of climate and weather date to hunters, gatherers, and farmers, who studied signs of changing weather in the sky. Today, scientists who study weather are called meteorologists.

Weather and climate are closely related, but big differences exist between them. Weather refers to the condition of the atmosphere at a given time and location. It describes daily local changes in temperature, humidity, wind, clouds, and precipitation (rain, snow). Climate, in contrast, describes the average of these conditions over a long period of time–month, year, or more (annual precipitation, monthly mean, high, and low temperatures) and variability.

WHAT ABOUT THE COLUMBIA BASIN'S CLIMATE?

As you know, the climate of the Columbia Basin tends to be warm and dry. The Cascade Mountains to the west of the Basin greatly influence our climate by means of their "rain shadow" effect, which causes moisture (rain or snow) to be released from the clouds before they reach the area. This limits the amount of precipitation we receive each year. For example, the average rainfall in the lower Columbia Basin is 6 to 7 inches per year, which includes about 13 inches of snow (13 inches of snow equals about 1.5 inches of rain). Because the mountains significantly reduce the amount of moisture in the air, fewer clouds exist in the Columbia Basin, which means more sunshine and very warm temperatures from late spring through early autumn. The average annual temperature recorded at the Hanford Meteorology Station–located on the Hanford Site near Richland–is 53.3 degrees Fahrenheit. The warmest month is July, which averages 76.4 degrees Fahrenheit, while the coolest month is January, which averages 30.5 degrees Fahrenheit. The hottest temperature ever recorded at Hanford was 113 degrees Fahrenheit on August 4, 1961; the coldest was −23 degrees Fahrenheit on February 1 and 3, 1950.

HOW IS WIND CREATED?

In the Columbia Basin, we are all familiar with wind, the kind that can whip up to 50 miles per hour, blowing dust from nearby fields, tumbling trees, and tearing roofs off buildings. But how is wind created? Scientists say it has to do with air pressure. If you have seen what happens to a tire if it's punctured or a balloon when you blow it up and then hold the neck and let the air come back out, you get an idea of this pressure. Air inside a tire or balloon is at high pressure, and air outside of the tire or balloon is at lower pressure. Air comes out of the high-pressure tire or balloon into the lower pressure air of its surroundings. A similar occurrence happens in the Earth's atmosphere. Air moves from regions of high pressure to regions of low pressure (though not in a straight line). This movement of air is what we know as wind. The greater the difference between high pressure and low pressure, the stronger the wind.

WHAT ARE CLOUDS, FOG, RAIN, AND SNOW?

Clouds are formed as air rises into the atmosphere. They are created by very tiny water droplets (it takes a million cloud droplets to make one raindrop). Scientists classify clouds by their shape and by their height (low, medium, and high). Stratus and cumulus are two kinds of low-level clouds. Altostratus and altocumulus are medium-level clouds, and cirrus and cirrostratus are high-level clouds.

Fog is a stratus-type cloud that reaches the ground. As cloud droplets grow, they become heavy and eventually may become so heavy they fall to the ground as rain. In parts of the world where air temperatures are cold enough, water droplets in the clouds freeze into ice crystals and join together into snowflakes. When the snowflakes become big and heavy enough they fall from the clouds–and if the air near the ground remains cold enough (usually near or below freezing) they remain as snowflakes. If the air above and near the ground is too warm, they melt and fall as rain.

WHAT DO METEOROLOGISTS DO?

To become a meteorologist you must go to college and take courses in mathematics, physics, chemistry, and many different courses in meteorology or atmospheric sciences. Meteorologists may have a variety of different jobs. Some meteorologists that many people call "weathermen" may study day-to-day weather events and provide forecasts for the public. Other meteorologists may fly in research aircraft to study clouds, rain, or hurricanes. Meteorologists conducting tornado research may use cars and trucks to try to "chase" these violent storms so they can understand them and provide better forecasts to save lives. Some meteorologists also work mainly in offices with computers. They develop computer models to try to better understand the Earth's atmosphere. Others, primarily interested in research, may work in colleges and universities or in government or private laboratories. Those involved in weather forecasting may work for the government (such as the National Weather Service) or for private weather companies or television/radio stations.

> "Science is constructed of facts as a house is of stones. But a collection of facts is no more a science than a heap of stones is a house."-Henri Poincare
> Keep in mind this fact sheet is intended to be used only as background information to support your effort to encourage inquiry-based science, which parallels the way scientists uncover knowledge and solve problems.

SUGGESTED ACTIVITIES

1. You can have fun determining the monthly average(s) for your community.
   Were you surprised to read that the average temperature at the Hanford Meteorology Station

in July was 76.4 degrees Fahrenheit and 30 degrees Fahrenheit in January? Did you think the average temperature would be higher for our area? Lower?

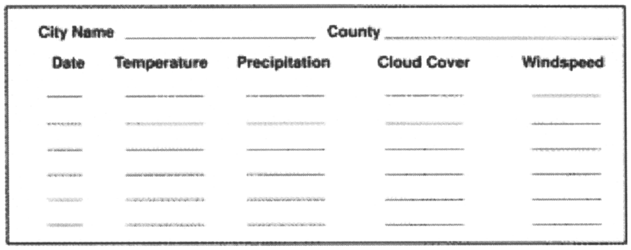
Here's How: You will need a calendar, pencil, calculator, and access to the local newspaper. Each day check the paper for high and low temperature from the previous day.

1. Record both the high and low temperatures on your calendar.
2. At the end of the month, add all the high temperatures for your community and divide by the number of days in the month. Do the same for the low temperatures.
3. What is the average high? Low?

If you track the weather for a year then you can compute a 1-year average (which describes the climate of your community). What was the maximum temperature for the month? For the year? The minimum temperature for the month? For the year? How much hotter than the average was the hottest day? The coolest night? Ask a friend or relative in another city to keep same data on the temperatures in their community. How do the temperatures they record differ from yours? What are some of factors that might influence the temperature?

2. Do you know about weather in other areas of the world?

You will need a local newspaper, a world map, pencil, and paper that has a grid on it (see example below). Each member of your class or family should select a city from the map to track (make sure the city is one whose temperature and other aspects of weather are reported in your paper. As a group, decide how often you will check the temperature, precipitation, humidity, cloudiness, and windiness in the cities you have selected. Remember to record your data on the data sheet. If you are not familiar with the symbols used for the weather in the newspaper, check the key or talk to a teacher or your parent(s). Watch for news on weather phenomena in your city. Share what you have learned about your city at a weekly class or family meteorological meeting. How could this information help you plan a trip? Decide where to live? (Adapted from Nick Walker, The "Weather Dude" Seattle, Washington)



City Name ______________ County ______________

Date	Temperature	Precipitation	Cloud Cover	Windspeed

3. Did you ever wonder how the weather and climate impact plants and animals?

Pick a site in your backyard, or in a park that you can visit on a regular basis. Take along a notebook and sit quietly in the spot you picked. Record in your journal the date, time of day, and the weather (What is the temperature? Is it cloudy, windy, humid?). What animals do you see (insects, birds, fish, mammals)? What are they doing? Where do they go in winter? Can they be found in other habitats? If you can identify the birds, note their names in your notebook. If you don't know the types of birds you see quickly sketch the birds and note any special markings. Later look them up in a bird guide and add the names to your notebook. What plants do you see? Are shoots just starting to emerge from the ground? Are the leaves frostbitten? Visit your favorite spot throughout the year, in different kinds of weather and record your observations in your notebook. Weather and climate influence the life cycle of plants and animals but what other factors influence the plants and animals you observed? How would those plants and animals be affected if the climate changed?

BASIC RESEARCH FOR MILITARY APPLICATIONS

W.D. Bach, Jr.

(from *The Handbook of Weather, Climate, and Water: Dynamics, Climate, Physical Meteorology, Weather Systems, and Measurements*, Wiley 2003)

> If you know the enemy and know yourself, your victory will never be endangered; if you know Heaven and know Earth, you may make your victory complete
>
> —Sun Tzu, The Art of War X, 31 circa 500 BC

The ancient Chinese general succinctly summarizes necessary ingredients for success in war. Understanding that "Heaven" represents the atmospheric environment, the need to know the weather is deeply rooted in military preparation and tactics. History is replete with examples of commanders using weather as an ally or suffering its bad effects. Even with today's modern technology, the dream of an all-weather military has not become a reality. Thus the military continues to seek ways to use the atmosphere as a "combat multiplier" in the order of battle.

MILITARY PERSPECTIVE

The military must understand the atmosphere in which it operates. That understanding will ultimately depend on scientific understanding of the atmospheric processes, an ability to use all of the information available, and an ability to synthesize and display that information in a quickly understandable fashion.

The military's needs for understanding the atmosphere's behavior has changed as a result of geopolitics and advancing technology. On the battlefield, future enemies are more apt to resort to chemical or biological attacks as a preferred method of mass destruction. The atmospheric boundary layer is the pathway of the attack. Increased reliance on "smart" weapons means that turbulent and turbid atmospheric effects will influence electromagnetic and acoustic signals propagating through the boundary layer. Intelligence preparation of the battlespace, a key to successful strategies, depends on full knowledge of the enemy, weather, and terrain. It requires an ability to estimate atmospheric details at specific locations and future times to maximize strategic advantages that weather presents a commander. It also avoids hazards and strategic disadvantages.

A convergent theme of basic research in the atmosphere is the interdependence of research progress in acoustic and electromagnetic propagation with the measurement and modeling of the dynamical boundary layer. The scattering of propagating energy occurs because of fine structure changes in the index of refraction in the turbulent atmosphere. The connection between the two—the refractive index structure function parameter, C_n^2—is proportional to the dissipation rate of the turbulent kinetic energy.

Military operations are often in time (seconds to hours) and space (millimeters to tens of kilometers) scales that are not addressed by conventional weather forecasting techniques. Atmospheric information is required for meteorological data-denied areas. Furthermore the real conditions are inhomogeneous at various scales. Significant adverse effects may have short lifetimes at high resolution. Such breadths of scales make accurate quantification of important boundary layer processes very difficult. Carefully planned and executed experiments in the uncontrolled laboratory of the atmosphere are needed for almost every phase of the research. The combined range of atmospheric conditions and potential propagation types and frequencies that are of interest to the military is too broad to condense into a few nomograms. The propagation studies require intensive and appropriate meteorological data to understand the atmospheric effects. Understanding of heterogeneous atmospheric fields arising from inhomogeneous conditions requires measurements achievable only by remote sensors.

Chemical and biological agents constitute major threats to military field units as well as to civil populations. Electromagnetic propagation and scattering are the principal means of remote or in-place detection and identification of agents. Current models of atmospheric transport and diffusion of the agents over stable, neutral, and convective conditions are marginally useful and based on 40-year-old relationships. Significantly improved models of the transport and diffusion are needed to estimate concentrations and fluctuations at various time and space scales for simulated training, actual combat, and for environmental air quality.

RESEARCH ISSUES

Basic research for the military in the atmospheric sciences comes under two broad, interdependent scientific efforts:

Atmospheric wave propagation, which is concerned about the effects of the atmosphere, as a propagating medium, on the transmission of electromagnetic (EM) or acoustic energy from a source to a receptor, and atmospheric dynamics, which is concerned with quantifying the present and future state of the atmosphere.

Atmospheric Wave Propagation

Electromagnetic and acoustic propagation and scattering is a large subject that addresses problems in both characterizing the battlespace and in detecting targets for engagement and situational awareness. Although there has been much previous research in the general area of wave propagation and scattering, there remains a pressing need for research that specifically address issues related to propagation and scattering in realistic atmospheric environments.

Electro-optical and infrared propagation in the atmosphere is limited by turbulence and by molecular and aerosol extinction by both absorption and scattering. The relative importance of turbulence and extinction is dependent on the wavelength of the radiation and the atmospheric conditions. Modern, high-resolution imaging systems are often turbulence limited, rather than diffraction limited, impairing long-range, high-resolution target acquisition, recognition, and identification. Laser-based systems are limited in their ability to retain spatiotemporal coherence and effectively focus at tactical ranges. Like acoustic signals, electromagnetic signals are primarily useful for target detection or ranging and for remote sensing of the atmosphere itself. Although much research has been done in the area of electromagnetic extinction, and current models are generally good, applications of these models for remote-sensing purposes is an area of active research. A large body of research exists in the area of atmospheric turbulence effects for electromagnetic propagation, but with less conclusive results. Hence understanding of atmospheric turbulence for optical and infrared propagation is still an active area of research.

Understanding of the interaction between propagation and turbulence is rather straightforward in the theoretical sense. Practically, the time scales of the EM propagation interactions with the air are much shorter, $O(10^{-9}$ s) along a path, than the capability to locally sample the atmospheric turbulence or density fluctuations, $O(10^{-1}$ s) and to characterize the turbulence spectra, $O(10^{+3}$ s). Acoustic interactions also occur on short time scales. Second, the turbulent structure of the atmosphere between the source and detector is largely unknown, so the scale of the disturbance is undetermined. Furthermore, with models, grid volume samples are realized at $O(10^{0}$ s) in large eddy simulation models and at $O(10^{2}$ s) in fine mesoscale models. To make the connection between propagation effects, turbulence characteristics, and atmospheric models, new measurement techniques are needed. In careful field campaigns to relate propagation to atmospheric conditions, the biggest problem is independent ground truth.

Atmospheric Dynamics

The military emphasis on global mobility requires weather forecasting support at all scales from global to engagement scales. In recent years, the explosion in computer capacity enabled highly complex numerical weather prediction models on most of these scales. Model accuracy has improved even as complexities are added. Model results have become more accepted as a representation of the atmospheric environment. As computation power increases, finer and finer scales of motion are represented in smaller grid volumes. Lately, large eddy simulations represent dynamics at grid sizes of a few meters in domains of 5 km^2 by 1 km deep.

As the models go to finer scales, the variability imposed by large-scale synoptic and mesoscale influences the Atmospheric Boundary Layer (ABL) is modified by both the cyclical nature of solar radiation and metamorphosis due to the stochastic behavior of clouds and other natural processes as well as anthropogenic causes. The resulting (stable and unstable) boundary layers are sufficiently different that current models of one state do not adequately capture the essential physics of the other or the transition from one state to the other. Accurate predictions become more difficult, principally because the atmosphere is poorly represented. Data are lacking at the scales of the model resolutions. Parameterizations required to close the set of equations are inadequate. Observations are lacking to describe the four-dimensional fields of the forecast variables at the model resolution. The models are unlikely to improve until better theories of small-scale behavior are implemented and observations capable of testing the theories are available.

For the military, techniques to represent the inhomogeneous boundary layer in all environments—urban, forest, mountains, marine, desert—is absolutely essential for mission performance. In most cases, this must be done with limited meteorological data. Furthermore, the military is more frequently interested in the effects—visibility, trafficability (following rain), ceiling—than in the “weather” itself. Nevertheless, without high-quality, dependable models that represent the real atmosphere in time and space, the effects will not be representative.

Basic research attempts to improve modeling capability by increasing the knowledge base of the processes of the atmosphere. Until new measurement capabilities are developed and tested, our ability to characterize the turbulent environment—affecting propagation and dispersion of materials—will be severely limited.

PROTOTYPE MEASUREMENT SYSTEMS

Military basic research has participated in several new techniques to measure winds and turbulence effects in the atmospheric boundary layer. These techniques concentrate on sampling a volume of the atmosphere on the time scales of (at least) the significant energy containing eddies of the atmosphere.

The Turbulent Eddy Profiler, developed at the University of Massachusetts, Amherst, is a 90-element phased-array receiving antenna operating with a 915-MHz 25-kW transmitter. It is designed to measure clear air echoes from refractive index fluctuations. The received signal at each element is saved for postprocessing. These signals are combined to form 40 individual beams simultaneously pointing in different directions every 2 s. In each 30-m range gate of each beam, the intensity of the return, the radial wind speed is computed from the Doppler shift, and the spread of the Doppler spectrum is calculated. These data are displayed to show a four-dimensional evolution of refractive index structures in the boundary layer. Further processing gives estimates of the three components of the wind velocity. Combining the wind vectors with refractive index structures has shown significant horizontal convergence occurring with strong refractive index structures. At 500 m above the ground the volume represented is approximately a 30-m cube.

The Volume Imaging Lidar at the University of Wisconsin measures backscatter from atmospheric aerosols in three dimensions at 7.5-m range resolutions. The evolution of boundary layer structures can be seen in a variety of experiments. Capabilities to estimate horizontal winds at selected altitudes have been developed and demonstrated.

An eye-safe, scanning Doppler lidar operating at 2 μm has been jointly developed with NOAA/ERL/ETL to measure radial wind speeds at 30-m resolution. The error of the measurement is < 0.2 m/s. Various scanning approaches have shown several different evolutions of the morning transition and breakdown of a low-level jet.

Another lidar system has been developed at the University of Iowa to measure the horizontal wind in the boundary layer at about 5-m increments every minute. Teamed with existing FMCW radars, having comparable vertical resolution, should add to meteorological understanding of layers of high refractive index.

CURRENT MEASUREMENT CAPABILITIES

Reliable measures of atmospheric temperature and moisture at high resolution in space and time are still lacking. Some progress has been made but does not yet achieve the resolutions of the wind measurements.

Prototype and existing wind/wind field data do not yet measure the turbulence. Although the Doppler spectrum width is an indicator of the eddy dissipation rate, few researchers or equipment developers report the variable or its spatial variability. To date, none have done so operationally.

CONCLUSIONS

Some progress is being made by the military to develop necessary instrumentation to measured atmospheric fields at high time and spatial resolution. This is motivated by the need to improve the theory and subsequently the models of atmospheric motions at small scales to provide the armed services with reliable models on which to gain superiority over the adversary and successfully complete the mission.

UNCERTAINTIES IN RAINFALL–RUNOFF MODELING

Patrick Willems
Hydraulics Laboratory
Leuven, Belgium

WHY DEAL WITH RUNOFF PREDICTION ERRORS OR UNCERTAINTIES?

Errors and uncertainties in the prediction of rainfall–runoff are often substantial. Consideration of these errors is therefore crucially important. When water decision-making is based on the rainfall–runoff prediction, for instance, by means of rainfall–runoff, uncertainties affect model outcomes and, consequently, the decisions. Hence, good modeling practice provides not only the results of model predictions but also the accuracy of these results. It supplies decision makers with important additional information on the uncertainty in the data and information that they use as a basis for their decisions. After quantification of the runoff prediction errors, water policies can be set up for which the efficiency can be guaranteed up to specified acceptable risk levels. Combined with the uncertainty analysis, a sensitivity analysis provides the modeler and decision maker with information about the importance of various types of model limitations and sources of uncertainty.

RAINFALL INPUT ERRORS AND UNCERTAINTIES

Rainfall is the driving force of the rainfall–runoff process. Therefore, both for watersheds and for urban drainage catchments, the rainfall input errors are one of the most important sources of uncertainty in the runoff prediction process. These errors have therefore been studied extensively in the literature. In general, they can be classified as rainfall measurement errors and errors by the simplification in the real spatial variability of the rainfall.

Rainfall Measurement Errors

Both rain gauge and radar data are subject to errors in the registration of the rainfall intensity (1–6). For rain gauges, this might be caused by:

- *Rain Losses by Wind Effects, Position, and Shelter*. Rain gauges installed above the ground level or in the lee of trees or buildings typically record less rainfall because of stronger wind effects. In comparison with rain gauges installed at ground level in a pit, gauges at higher elevations can have wind-induced losses up to 5–15% (7–9). The presence of a wind shield on the gauge can reduce this influence (10–13).
- *Rain Losses by Wetting and Evaporation*. All gauges using collecting funnels have losses of rain water remaining on the funnel surface without passing into the collecting chamber, which subsequently evaporates.
- *For Tipping Bucket Rain Gauges: Loss of Water During the Tipping Movements of the Buckets*. This bias can be corrected by calibration of the rain gauge (14–18).
- *For Tipping Bucket Rain Gauges: Resolution Error*. This is the error because of resolution of the recorded rainfall intensity, where the resolution corresponds to the volume of one tipping-bucket. This type of error is only important for small rainfall volumes.

Simplification in the Real Temporal and Spatial Variability of Rainfall

Rainfall–runoff models require simplification in the real spatial distribution of the rainfall. Lumped conceptual models require a larger averaging of the rainfall over the catchment in comparison with semidistributed and fully distributed models. The accuracy of areal rainfall estimates strongly depends on the simplification of the rainfall variability in both space and time. For the spatial dimension, the degree of simplification depends on the rain gauge network density more than on the interpolation method. The effect of the rain gauge network density was first studied by McGuinness (19) and afterwards by Bras and Rodriguez-Iturbe (20); Dawdy and Bergman (21); Wilson et al. (22); Troutman (23); Bastin et al. (24); Schilling (25); Lebel et al. (26); Fontaine (27); Peters-Lidard and Wood (28); Roux et al. (29); Yoo and Ha (30); and Lau and Sharpe (31). Areal reduction factors (or more generally, areal correction factors) have been developed for bias correction when areal rainfall estimates are based on rain gauge data (32,33). Uncertainty estimates for such areal correction factors can be found in Willems (34). They are based on simulations with a spatial rainfall generator. One of the problems with the accuracy of the areal correction factors is locating the desired point within the given area. If the point is away from the center of the area, the correction factors may be vastly different in comparison with correction factors based on historical storms located centrally in the catchment. Correction factors based on individual storm events also may not necessarily look like the climatological rainfall patterns for the whole catchment region. The climatological patterns indeed have to be considered with a reasonable level of confidence (35).

When radar data is available, this data can be used in addition to the rain gauge data. Radar data mainly provides detailed information on the spatial coverage and movement of the rain storms. The rainfall intensity registrations are less accurate, mainly because of the ambiguity of Z–R relationships for conversion of radar reflectivity to rainfall rate. Radar data, thus, can be used in a complementary way to the rain gauge data to increase the accuracy of the spatial interpolation (36,37). The accuracy and benefits of radar data depend, however, largely on the type of the radar and on the data processing (38–41).

PROPAGATION OF INPUT ERRORS THROUGH THE MODEL

To calculate the propagation of the rainfall input errors and related uncertainties to the uncertainty in the runoff prediction, different techniques can be used (the same techniques are also used for propagation of errors or uncertainties on other input variables and parameters). The most popular technique is the Monte Carlo method [either using Simple Random Sampling, Importance Sampling (e.g., 42), or Latin Hypercube methods]. These techniques also allow performing sensitivity analysis, on which the relative contribution of uncertain inputs to the output uncertainty is obtained. Alternatives to the Monte Carlo technique are based on analytical variance calculation. Only the first two moments of the error distributions are considered ("first order second method" reliability analysis methods; 43–47). These methods usually involve some degree of simplification of the model response behavior.

The significance of rainfall input on runoff hydrograph properties, such as runoff volumes, time to peak runoff, and peak runoff rates, has been studied extensively in the literature (21,22,48–54).

In a limited number of studies, the importance of the rainfall input errors in comparison with other uncertainty sources is investigated. For urban drainage stormwater modeling, Schilling and Fuchs (55), Lei and Schilling (56), Willems and Berlamont (57), and Van Mameren and Clemens (58) have made such assessment, and concluded that the input of rainfall and the paved catchment area (which is not so accurately known in urban drainage modeling) are by far the most important uncertainty sources. For watersheds, Andréassian et al. (59) have shown that rainfall–runoff models are more sensitive to the spatial rainfall distribution than to the spatial distribution of watershed (land-surface) parameters.

UNCERTAINTIES IN INPUT DATA AND MODEL PARAMETERS

Other inputs in rainfall–runoff models consist of evapotranspiration estimates, but also in geometric catchment characteristics (at least input of the catchment area is needed), and for distributed rainfall–runoff models, geological, soil type, and land-use maps.

When runoff predictions are based on modeling, the uncertainty on the model results does not only originate from model input uncertainties, but also from uncertainties on the model parameters and the model structure.

Model parameters are most often derived from calibration on the basis of simultaneous observations for the model input and model output variables. Parameter uncertainties will then develop when erroneous and/or limited time series of measurements are used for calibration or when the calibration procedure is not optimal. When inputs are biased (systematic deviation from their real values), the calibrated model parameters might also be biased. This problem has been shown, for instance, by Troutman (23,60,61) and Chaubey et al. (62), investigating the effect of rainfall input errors on runoff volumes. It is obvious that parameter uncertainties decrease when a longer time series of observations is used for calibration.

Parameter uncertainties strongly depend on the parameter calibration process. Optimization algorithms are most often used for parameter calibration (63–69). These algorithms also provide information on the confidence limits of the calibrated model parameter values, as they are based on statistical considerations (see the linear regression theory in any basic statistical handbook as the most simple example). The shuffled complex evolution algorithm (SCE-UA) is one of the most advanced algorithms (70,71). Other techniques are based on maximum likelihood estimation [in combination with Kalman filter in the recursive parameter calibration techniques of Jakeman et al. (72) and Young (73)]. Parameter uncertainty estimates were calculated and discussed for hydrological models by Johnston and Pilgrim (74), Kuczera (75), and Kuczera and Mroczkowski (76).

Goodness-of-fit statistics used in the optimization are the mean squared error, the coefficient of efficiency (77), Young's Information Criterion (73), etc.; for an overview, see Legates and McCabe (78).

Parameter optimization may have difficulties because of the different sources of model errors. For complex models, it might be true that different parameter sets give equally acceptable goodness-of-fits. This problem together with related issues are discussed by several authors, and are denoted by the terms "non-uniqueness," "ambiguity," "equifinality," "nonidentifiability," "overparameterization," etc. (79–81). It may, in addition to other parameter optimization problems (such as the presence of many local optima in the objective function), explain underestimations in the parameter uncertainty estimates.

One method for inferring parameter uncertainties (and also for total model uncertainty), at the same time addressing the above-mentioned problem, is the generalized likelihood uncertainty estimator (GLUE) proposed by Beven and Binley (82). After it was used in a number of studies presented in the hydrological literature (e.g., 83–85), it became more and more popular. GLUE rejects the existence of an optimum model and parameter set and assumed that multiple likely models and parameter sets exist [the "equifinality" concept of Beven (81,86,87)]. This approach is opposed to the more classic approach of identifying the true or optimal model in face of uncertainty. Goodness-of-fit statistics in the GLUE approach are used as likelihood measures. A number of parameter sets is generated via sampling, and the performance of each trial assessed through a likelihood measure. When the likelihood measure reaches a lower limit, then the tried parameter set is called nonbehavioral and is rejected. To the behavioral sets, likelihood-based weights can be applied and parameter and model output uncertainties assessed (88). The problem of the GLUE approach is, however, that is does not account for input uncertainties (89), apart from other statistical problems that make the GLUE inappropriate for uncertainty estimation [e.g., subjective likelihood functions are used and no formal representation is made of the model error (66,90)]. It can, at most, be used for identifying the most sensitive parameters of the model.

For all cases where models are calibrated, the uncertainty in individual parameter values strongly depends on the model sensitivity to each specific parameter. Sensitivity analysis was therefore conducted in many studies.

Input and parameters strongly depend on the scale (temporal and spatial). Often, because of averaging effects, the uncertainty is likely to be much smaller for a larger scale average than for a smaller scale average (see also 91).

Model structure uncertainties, as the last type of model uncertainties considered, originate from the modeler's limited understanding of the physical reality. These can be assessed by comparison of different model structures for the hydrological system under study, or based on the analysis of the model residuals (considering model structure uncertainties as rest term after subtraction of the input and parameter uncertainties; see next sections).

MODEL RESIDUALS

The total uncertainty in the model results (the model output) can be quantified by calculation of the standard deviation or variance (squared standard deviation) of the model residuals (differences between modeled and observed runoff values). This variance can be further split up in the mean error (the bias or systematic deviation in the model output) and the random error (representing the uncertainty after bias correction). An illustration is given in the scatterplot of Fig. 1, where residuals are shown for all hydrographs in a runoff series. The mean deviation and the random error standard deviation are represented by the solid and dotted lines. Both may depend on the runoff value; typically, higher errors are found for higher runoff values. Transformation of both axes in the scatterplot can be done to normalize the residuals—to derive a normal distribution for the residuals (Gaussian residuals) independently of the runoff value (homoscedastic residuals). The Box–Cox (BC) transformation (92) is most flexible; as—depending on its parameter value—it can cover the whole range of weak and strong transformations. The strongest transformation in this range is the logarithmic transformation. The logarithmic transformation is useful in case the standard deviation of the residuals is shown proportional to the runoff value. In this case, the model has a constant relative error. In most practical cases, neither the absolute error nor the relative error is constant, and a BC transformation is needed (see applications by 93). Another transformation applied to reach Gaussian residuals is the normal quantile transform (94). In the case of heteroscedastic residuals, dependence between the residuals and the runoff value has to be considered (95–97), which can be done in the easiest way by the use of a meta-Gaussian model where both the residuals and the runoff discharges are transformed into a Gaussian distribution, and the correlation between both is considered (89,94).

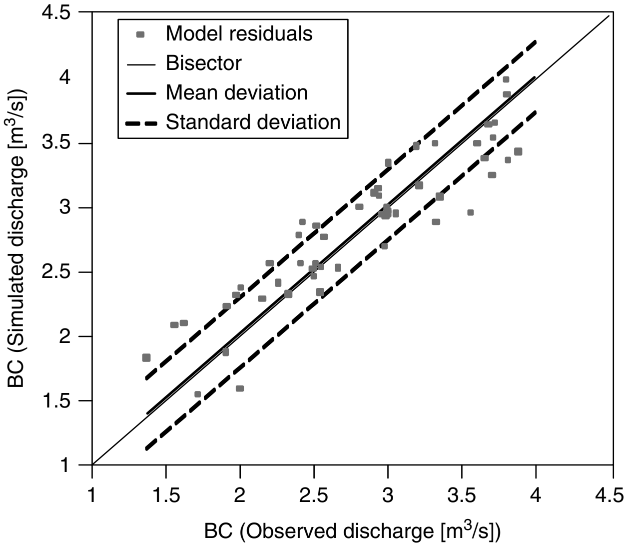

Figure 1. Scatterplot showing model residuals.

SERIAL DEPENDENCE

When runoff series with small timesteps are considered (e.g., hourly or smaller than the recession constants of one of the subflows in the catchment), residuals calculated from runoff values at different timesteps will have a serial dependence. Often, this serial dependence is higher for dry periods in comparison with wet periods, which is caused by the longer recession constant of the baseflow component in comparison with the quick runoff components. To derive independent residuals, a prior selection can be made of nearly independent values from the flow series. These can be peak values during subsequent quick-flow hydrographs, cumulative volumes during these hydrographs, low-flow values during subsequent baseflow recession periods, etc.

Other approaches use the full time series of residuals and describe both the amplitude and the serial correlation by means of stochastic models (98–101). These stochastic models are needed, for instance, on the basis of the recursive parameter estimation techniques.

ERRORS ON RUNOFF OBSERVATIONS

The total residual variance is larger than the total variance of the errors in the model output. Errors on the observed runoff values indeed also take part in the residual variance. These runoff discharges are most often not directly measured, but calculated from river discharge observations. River discharges are most often closely related to the average rainfall–runoff discharge upstream of the river flow monitoring station. Effects of routing along the river and flooding (over bank storage), may explain differences between both. As river flow monitoring stations are only available at a limited number of locations, they are lacking in providing the modeler with a detailed spatial coverage of runoff data. Errors in runoff observations can thus be classified in the following categories:

- errors in the flow data (by uncertainties in the rating curve for limnigraphic stations or in the accuracy of the flow monitoring device);
- differences between the flow at the monitoring station and the upstream runoff because of routing and flooding influences;
- differences between the runoff at a single point along the catchment or river and the average runoff upstream of the flow monitoring station (only relevant for distributed hydrological models).

MODEL ERROR

After compensation for the runoff observation errors, the total variance of the errors in the modeled runoff can be derived from the total residual variance. After calculation of the contribution of the input and parameter uncertainties (by propagation through the model), the remaining uncertainty can then be considered as the model structure uncertainty. When observations are available for some of the submodel output variables, the model structure uncertainties can be decomposed for different submodels.

Such a separate description of the different types of model uncertainties has the advantage that the contributions of the different sources of uncertainty to the total uncertainty in the model output can be quantified and compared. The comparison of the uncertainties resulting from the data, on the one hand, and the uncertainties resulting from the model structure, on the other hand, is especially valuable. Ragas et al. (102) called these two types of uncertainties respectively "operational" and "fundamental" uncertainties. As a general rule, a balance between the two is recommended. Whenever the operational uncertainties dominate, much more attention should be given to data collection than to model structure improvement in an attempt to improve the model results. Whenever the fundamental uncertainties dominate, the reverse is recommended. By comparing the contributions of the different uncertainty sources, efficient measures can thus be determined to reduce the total uncertainty in the model results.

IGNORANCE

Previous paragraphs only consider "quantifiable uncertainty." The real uncertainty may, however, be larger than this quantifiable uncertainty. It indeed might occur that the system structure is depending on specific influences, which were not observed in the past, but which may occur in an unpredictable manner in the future, which is a specific and special type of "lack of knowledge" that we cannot include in our uncertainty predictions because it is not quantifiable. Such additional nonquantifiable uncertainty is usually referred to as "ignorance." Ignorance occurs when we are missing relevant knowledge. Two types of ignorance have to be considered (see also 103):

- *Recognized Ignorance or Accepted Ignorance:* we realize and accept that we are ignorant, and communicate about this;
- *Total Ignorance:* we do not realize this lack of knowledge and are in complete ignorance (or "ignorance about the fact that we are ignorant").

Our confidence in a model may range from being certain (called "determinism" by Harremoës, see Fig. 2) to accepting that we are ignorant (zero confidence,

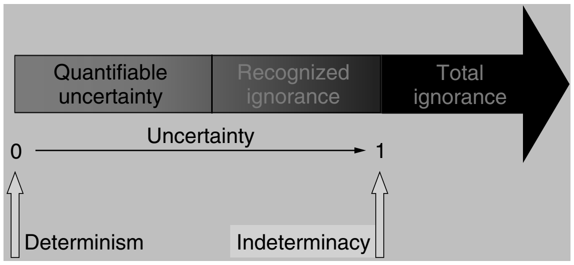

Figure 2. Illustration of the level of uncertainty from the ideal of what we know to total ignorance (103).

"indeterminacy" in Fig. 2). Regardless of our state of confidence, we may be correct or incorrect as a result of ignorance. Nonquantifiable uncertainties, thus, also may contribute to the runoff prediction uncertainty, and may, in some cases, be more serious than the quantifiable uncertainties. Therefore, a need to communicate these uncertainties exists in the decision support (104). When essential processes are not incorporated in the structure of the hydrological model because of insufficient knowledge about the processes, then it would be wrong to forget about this recognizable ignorance and not to communicate this potential source of uncertainty. The communication still can be supported by quantitative information, by running some scenarios on the unknown processes, and to report on the potential results (e.g., epistemic uncertainty, comparing a set of competing models based on different assumptions for the unknown processes).

MONSOON

Arthur M. Holst
Philadelphia Water Department
Philadelphia, Pennsylvania

Cyclic air masses accompanied by either much or little rain, carried by winds that reverse direction semiannually, are called monsoons. The word monsoon comes from the Arabic word "mausim," which is translated as "season." Monsoons occur over almost every continent, but they come in varying degrees of strength, as judged by rainfall production and wind speed. The most powerful and well-known monsoons occur in India and Southeast Asia.

Monsoons are caused by a difference in temperature, and thus air pressure, between landmasses and oceans. They are especially strong in Southeast Asia because the area is geographically conducive to monsoon weather. There is much more land in the Northern Hemisphere, namely, the Asian continent, and there is much more water in the Southern Hemisphere, namely the Indian Ocean. Due to the earth's tilt as it revolves around the Sun, the Northern Hemisphere receives more sunlight during the summer, and the Southern Hemisphere receives more sunlight during the winter. This means that there is always a marked difference between the air temperature over land and the air temperature over the sea in Southern Asia and India. The two variations that result are called wet and dry monsoons. Locally, they are called wet season (summer) and dry season (winter). Wet monsoons occur when the land in the Northern Hemisphere becomes heated by extensive sunlight. Due to convection, the warm air over land rises into the atmosphere, and cooler ocean air slides in to take its place. This cool air carries vast amounts of moisture, which is dropped on the landmass, in this case India and SE Asia.

Dry monsoons occur in the winter when the reverse occurs, and the oceans are heated by sunlight. The air over them rises, and cool air from the land leaves to take its place. This cold air takes moisture with it; thus, there is little rainfall over land.

The precipitation released during the wet season can fall quickly and unpredictably, sometimes resulting in floods, but usually resulting in enormous quantities of much needed rainfall for the farmers and residents of Southeast Asia. Due to this fact, monsoons are integral to the lives and well-being of virtually all of the people who live in India and Southeast Asia, as they have been for millennia. However, despite their importance to the area, they can cause great damage at times, as well. It is not uncommon for abnormal monsoon conditions to result in massive flooding or extended droughts. In fact, a 1987 Indian drought due to variations in the local monsoons was one of the worst of the twentieth century. And parts of India can receive 40 feet of rain or more in a span of less than 4 months.

The monsoon seasons are the distinctive feature of the Southeast Asian climate, but they do exist to lesser degrees elsewhere in the world. Africa, Australia, and the Southwestern United States all undergo minor monsoon seasons during the year. Generally, their monsoon weather is less pronounced than that of Southeast Asia because they do not have its unique geographical properties.

AFRICAN MONSOONS

Mike Bettwy
Goddard Space Flight Center,
NASA

In the world of weather, we've all heard of the "butterfly effect," that is, if a butterfly flaps its wings in China, it will affect the weather in New York a few weeks later. While this may be an exaggeration, a new study offers more evidence of how seasonal weather patterns can impact conditions thousands of miles away.

One cyclic weather pattern is the monsoon—a seasonal reversal in wind direction—caused by the fact that land and ocean heat up at different rates. Land quickly responds to heating, while oceans, with a much larger heat capacity,

This photograph of heavy rainfall in Ghana was taken August 19, 2001 during an ongoing NASA/USAID project. The West African monsoon season typically lasts from May-October, with the largest totals observed during June-September. Click on image to enlarge. Credit: Distinguished Professor, Dr. James W. Jones, University of Florida

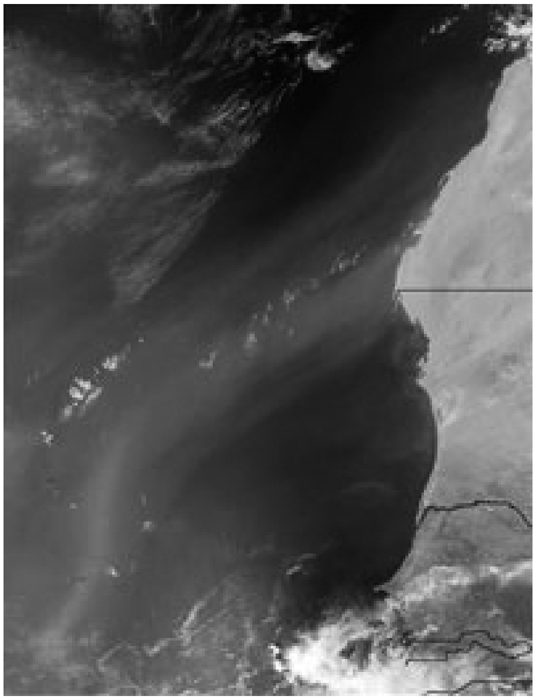
---

take longer to react. The difference in temperature leads to a difference in pressure, ultimately creating a wind shift which changes rainfall patterns. The monsoon system in West Africa is especially important, as it brings vital rainfall to support life and maintain local economies.

Now, new research by NASA and University of Maryland scientists suggests that these naturally occurring annual swings in temperature and pressure create two distinct monsoons in Africa, one in late spring and another in mid-summer. Using data from satellites, including NASA's Tropical Rainfall Measuring Mission (TRMM), researchers were able to detect a distinct northward "jump" in the monsoon from late spring to mid-summer.

In the first episode, large differences in sea surface temperatures between coastal waters and water further out to sea enhances rainfall on the West African Coast. By July, a second monsoon appears. This downpour is related to African Easterly Waves, low-pressure systems that form on the African continent during the summer months. On average, about 60 waves are generated over North Africa each year, and previous research suggests they may kick off small circulations that develop into hurricanes over the North Atlantic Ocean.

Between May and October, about two Easterly Waves per week travel from the African continent onto the cool Eastern Atlantic. These waves generally fall apart, but their remnants do survive and head towards the Western Atlantic and Caribbean, where they regenerate. Only about one in ten Easterly Waves survive to develop into gale-force tropical storms or full-fledged hurricanes. But, almost 85 percent of major hurricanes (wind speeds 111 mph or greater) began as Easterly Waves. Some studies have also suggested that many of the tropical cyclones in the Eastern Pacific Ocean can also be traced back to Africa.



The Moderate Resolution Imaging Spectroradiometer (MODIS), aboard NASA's Aqua satellite, captured this true-color image of Saharan Desert dust blowing southwestward off the coasts of Morocco and Mauritania in West Africa. The light brown plume can be seen wending its way over the Cape Verde Islands in the Eastern Atlantic Ocean. Click on image to enlarge. Credit: NASA/GSFC

While not all Easterly Waves will form into hurricanes, Florida, like Africa, receives a large chunk of its annual rainfall from these storm systems. But other waves that originate to the north of Ghana are dry and pick up debris and dust from Africa's Sahara Desert. A strong high-pressure system over the Atlantic Ocean, known as the Bermuda High, helps steer these waves toward the Florida coast. Easterly Waves tend to be drier in El Niño years, which means they're less likely to produce hurricanes, but more likely to bring pollutants and dust toward the United States.

PERMANENT FROST

Arthur M. Holst
Philadelphia Water Department
Philadelphia, Pennsylvania

INTRODUCTION

The last geographic remnant of the last great Ice Age is permafrost, or permanently frozen ground. Permafrost exists today in many places on the earth, including the northernmost parts of America, Eurasia, and the Antarctic. In the coldest regions, permafrost has developed and existed for millions of years. Today, it covers about 20% of the earth's surface.

Frozen soil or rock that remains at a temperature of 0 °C (32 °F) or below for 2 or more years is permafrost. Permafrost is defined solely by temperature and is not determined by the amount of snow cover, soil moisture content, or its location. Permafrost may contain more than 30% ice or no ice at all, and may be topped by meters of snow cover or no snow at all. The defining characteristic of permafrost is its temperature.

REMAINS OF THE GREAT ICE AGES

What remains from the last Ice Age is nearly one-fifth of the Earth's surface still permanently frozen. During the past 2 million years, the great ice sheets that covered much of the earth's Northern Hemisphere prevented the surface below them from thawing. This freeze seeped deeper and deeper into the earth, forming thick layers of permanently frozen ground, permafrost. As time passed, much of this permafrost thawed due to the end of the Ice Age. As the earth's surface began to warm again, permafrost levels declined. However, across the Northern Hemisphere and in Antarctica, much of the ground remains permanently frozen, even during the summer months. Other permafrost forms when the ground cools enough during the winter to prevent it from thawing in the following summer.

Though the determining characteristic of permafrost is ground temperature, the determining cause is not air temperature but atmospheric climate. Temperature instead affects the distribution and thickness of permafrost.

GEOGRAPHY OF PERMAFROST

Permafrost is located throughout the Northern and Southern Hemispheres. The largest continuous mass of permafrost in the Southern Hemisphere is beneath the thick ice of Antarctica. This colossal mass alone comprises about 9% of the earth's surface. Permafrost is more widespread in the Northern Hemisphere. It is found as far north as Greenland and as far south as the heights of the Himalayas. Most of the Northern Hemisphere's permafrost, which makes up 23% of the hemisphere, occurs in the Eastern Hemisphere in parts of Siberia, eastern Russia, northern parts of Mongolia and China, and in the Tibetan Plateau. Other significant permafrost comprises most of Alaska (85% of the state) and parts of northwestern Canada. More than 50% of the surface of Canada is permafrost. Farther north, permafrost levels decline rapidly as land gives way to the Arctic Ocean; yet, a shelf of permafrost has been discovered even under the sea.

Permafrost is separated into two categories: continuous and discontinuous. Continuous implies permafrost everywhere except underneath bodies of water. Discontinuous permafrost is broken into two subdivisions: widespread and sporadic. In the widespread permafrost zone, 50–90% of the land is permafrost. In the sporadic zone, only 10–50% of the ground is permafrost.

LIFE IN A PERMAFROST REGION

A widely held misconception is that a permafrost zone is barren and inhospitable to any form of plant or animal life. On the contrary, the Arctic permafrost zone is home to a variety of mammals, birds, insects, and evergreen forest plant life that covers much of the Northern Hemisphere's permafrost zone.

In Arctic summers, the terrain is alive with animal life. Insects and other invertebrates inhabit the shallow wetlands. Birds feed from these insects and the plant life; they are provided ideal breeding and nesting grounds during the summer months. Snow geese and tundra swans are among the more common visitors of more than 100 bird species, which also include some hawks, owls, and cranes. Polar bears and caribou are also common in the Arctic's permafrost region. Musk oxen, other species of bears, several rodent species, foxes, squirrels, and hares often accompany these Arctic inhabitants. However, when the brief summer comes to a close and the frigid cold reasserts itself upon the region, most animal life leaves in what is essentially a mass exodus.

The trees and shrubs that grow in permafrost forests are much smaller than those in the south and are far more resistant to freezing conditions. Forests tops are evidenced by species of spruce, birch, and aspen trees, and are carpeted below by shrubs, heath, and moss.

PERMAFROST FEARS

Scientists fear that changes to the permafrost regions pose a serious threat to humans and animals. The Earth's natural warming, or human-influenced global warming, has begun to melt the thick permafrost. Also, removal of vegetation and organic cover, as well as forest fires, can also have temperature-raising effects on permafrost regions, causing further thawing of the Permafrost. If this problem continues, the permafrost could turn into a slush mixture. This would cause permanent damage to buildings, roads, pipelines, and other infrastructure in the Arctic region. In particular, oil pipelines, originally set in solid permafrost, would be disrupted. The results could be disastrous, releasing oil into an already fragile ecosystem. Scientists believe this chain of events has begun, but admit that their investigations still remain at a very early stage. However, in Alaska and other Arctic regions, builders are already taking more precautions before building structures on permafrost.

RADAR USE IN RAINFALL MEASUREMENTS

Theodore A. Endreny
SUNY-ESF
Syracuse, New York

Meteorologists, hydrologists, and other environmental scientists use microwave radar (radio detection and ranging) techniques to observe remotely the location, type, and intensity of atmospheric precipitation. Doppler radar units provide an additional measurement of storm movement and wind rotational strength. Hence, microwave radar units are used for remotely sensing precipitation and winds.

Radar operates by emitting electromagnetic radiation into the air at various scan heights and then detecting the part of that radiation that is reflected back by hydrometeors (e.g., backscattered) to the radar device and considered reflectivity. Hydrometeors refer to liquid and frozen precipitation, but backscattering can also occur from large flocks of birds, insects, and other large airborne particles. Based on the density, size, and shape of the hydrometeors (e.g., spherical liquid vs. angular frozen crystals) and the polarization of the radar beam, the algorithms processing the radar signal can determine precipitation type and intensity.

RAINFALL AS ENERGY SPECTRUM

The wavelengths of radiation that are most commonly used for measuring precipitation are 3 cm (X-band), 5 cm (C-band), and 10 cm (S-band). National Weather Service (NWS) Weather Surveillance Radar 1988 Doppler (WSR-88D) can detect the radiation at various distances. Beam focusing algorithms are used to ensure that the beam penetrates a limited volume and distance and its signal-to-noise ratio is maximized. When radar beams are backscattered from intense precipitation, detection rises up to a 258-km radius from the radar unit, but reflectivity in weak to moderate precipitation usually limits detection to a 147-km radius.

WSR-88D Doppler radar stations were deployed in the 1990s to replace a network of non-Doppler radar units that were first deployed in the 1950s, after rapid advances in radar during WWII. The WSR-88D (also known as NEXRAD, for next generation weather radar) stations consist of a radar data acquisition unit (RDA) and data post-processing units. The RDA contains the antenna, pedestal, radome (a white spherical radar antenna cover), transmitter, receiver, and signal processor to transmit and then receive the microwave signal. The process of transmitting a signal, receiving and listening for a return signal, and then transmitting the next signal, takes place nearly 1300 times each second. For the 5-minute period to rotate 360° and survey precipitation, the WSR-88D transmits for only 0.6 seconds but receives for 4 minutes and 59.4 seconds to conduct surveillance of beam reflectivity.

Circular scans of 360° about the horizon by the WSR-88D referred to as volume coverage patterns (VCPs), are used to monitor the surrounding volume of the atmosphere. VCPs vary with weather forecasting needs, and there are currently two clear-air mode and two precipitation-mode VCPs. The differences between VCPs affect both the height and length of atmosphere sampled, which are inversely related such that scans that sample at greater heights will be limited to shorter ranges from the radar unit.

In both clear-air mode VCPs, the radar antenna transmits at five tilt angles, which are 0.5°, 1.5°, 2.5°, 3.5° and 4.5° (known as the 1st, 2nd, 3rd, 4th, and 5th tilt) above the horizon, completing a full VCP scan in 10 minutes (see Fig. 1). In both clear-air mode VCPs, two sweeps are taken at the 1st and 2nd tilt, the first sweep to monitor radar reflectivity and the second to monitor Doppler velocity, and a single sweep is taken for the 3rd to 5th tilt when reflectivity and velocity monitoring are combined. Distinguishing the two clear-air mode VCPs is the 3rd tilt, where one mode conducts two sweeps and the other mode one sweep, to monitor reflectivity and velocity. After the radar performs a full 360° revolution at each tilt angle, the radar has completed a full volume scan, and the radar processing algorithms can compute the precipitation rates. Each tilt has a limited range of detection from the radar, which is greatest at the 1st tilt and decreases with higher tilts. Precipitation VCPs begin tilts at 0.5° and end tilts at 19.5° to sample a greater volume of atmosphere. In one precipitation-mode VCP, a total of 14 tilts is sampled in 5 minutes (see Fig. 2); in the other, slower VCP, 9 tilts are scanned in 6 minutes (see Fig. 3).

Ground-based Doppler radar precipitation estimates are often overestimates by a factor of 2 due to their inability to scan the lower volume without ground interference. They often extend a prediction of upper level precipitation readings and do not account for evaporation in the lower 1 km of the atmosphere. Gauge measurements

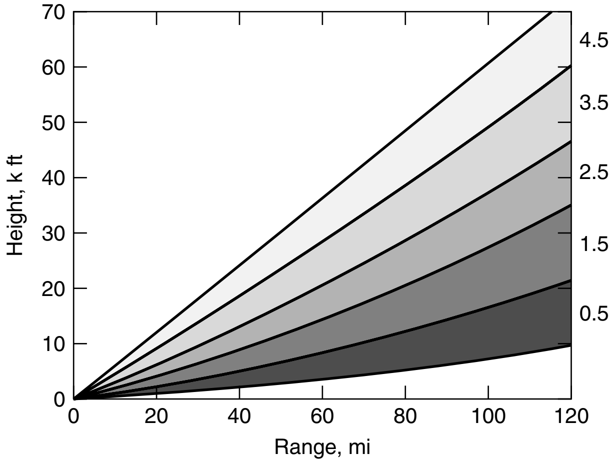

Figure 1. Clear-air mode VCP scan tilt and heights (thousand feet) for 0 to 120 mile ranges.

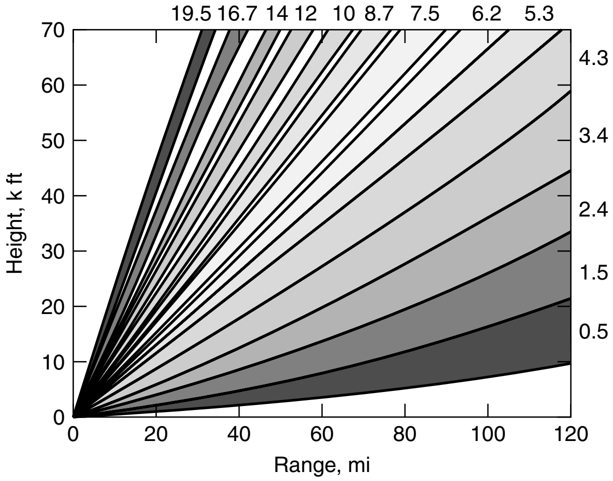

Figure 2. Precipitation-mode VCP scan tilt and heights (thousand feet) for 0 to 120 mile ranges in fast mode.

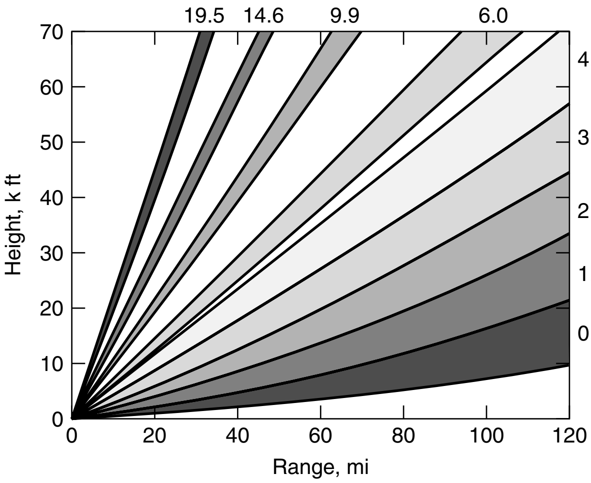

Figure 3. Precipitation-mode VCP scan tilt and heights (thousand feet) for 0 to 120 mile ranges in slow mode.

recorded at the ground may be used to correct some of this bias, and the adjusted radar estimates can provide better spatial estimates than traditional Thiessen polygon and other methods of interpolating point measurements. Extensive research on removing radar bias is ongoing.

Separating transmitting, attenuating, and receiving aspects of the radar is most helpful in understanding Doppler radar. The pulsed-Doppler radar is transmitted by coordinating oscillation and amplification. After the stabilized local oscillator (STALO) generates a nearly perfect sinusoidal continuous wave (cw) signal, which is modulated on and off, it is then amplified to create the powerful microwave signal. These pulses are phase coherent such that their interaction with a moving hydrometeor could displace the phase and allow for Doppler interpretation of hydrometeor movement path and velocity. The microwave beam is manipulated to have a fixed diameter, and an antenna is used to focus the radiation into a narrow angular region, or beam width, containing the peak radiation intensity.

Radar attenuation describes the power loss in the microwave beam due to absorption and scatter during its path through the atmosphere. The total power extracted from the wave is proportional to the combined absorbance and total-scatter cross section encountered and is determined by the highly sensitive radar receiving antennas.

The radar receiver detects the radar reflectivity factor, or Z, which is given units of $\mathrm{mm}^6\ \mathrm{m}^{-3}$, and is proportional to the sample volume of the radar, the number of hydrometeors within that volume, and the 6th power of the diameter of the hydrometeors. Determining the diameter of the hydrometeors is one of the most sensitive steps in determining rainfall rates, for there is often more than one diameter in the volume scanned. Much of the work in this area stems from observations made by Marshall and Palmer in 1948, determining the raindrop diameter for different raindrop size distributions. The Z factor is most commonly expressed as decibels Z, or dBZ, which is 10 times the $\log_{10}$ of Z.

Rainfall rates, R, are computed from the receiver measured Z factor using an empirical power law expressed as $R = \alpha Z^{\beta}$, where the α and β constants are determined from collecting actual rainfall data. For different climates, different values of α and β have been determined; values for α range from 0.013 to 0.028, and those for β range from 0.62 to 0.76. Currently, the NWS uses four different combinations of α and β to estimate rainfall rates for different weather systems. Methods for determining snowfall rates, which are expressed as S, are not as stable as for rainfall rates. Rainfall rates for WSR-88D radars associated with detected dBZ values are provided in Table 1. Note that most bird, insect, and dust detections are usually less than 30 dBZ.

Rainfall products are initially stored in binary HRAP units, which are part of a spherical coordinate system that records intensities. When HRAP units are transformed to a Cartesian system, typically presented at spatial scales of 1 to 4 km bins of average rainfall rates, for time periods per volumetric scan (about 5 minutely), 15 minutely, 1 hourly, 3 hourly, 6 hourly, and storm total precipitation. These rainfall rate products can be viewed on-line in spherical coordinates. They also can be downloaded and reconfigured or purchased from various vendors in the Cartesian coordinate system.

Products available from the WSR-88D radar units linked to the Internet provide “real-time” reflectivity images. These products are categorized as a base reflectivity image from the 0.5° tilt and a composite reflectivity image showing the greatest values sampled from all tilts. The base reflectivity maximum short-range distance provides a 227-km sample radius, and its maximum long-range distance is a 456-km sample radius; both have a spatial resolution at 1 km × 1 km grids. The composite reflectivity maximum short-range distance provides a 227-km sample radius at 2 km × 2 km grids, and the long-range distance provides a 419-km sample radius, but spatial resolution is at a 4 km × 4 km grid.

Algorithms process the data from the integrated volume scan and search for anomalous propagation (AP), such as backscatter from a nonmoving target such as the ground. One method of detecting AP is to look for an abrupt decrease in backscatter between the 1st and 2nd scan, which would indicate that the 1st scan captured surface terrain. Other methods may compare signal strength between different polarization angles or concurrently analyze strength with knowledge of the zero-degree isotherm, or radiosonde determined elevation above which precipitation should be frozen. Another algorithm

Table 1. Rainfall Rates

Reflectivity dBZ	Rain Rate in h^{-1}	Rain Rate cm h^{-1}
65	16.0	40.6
60	8.0	20.3
55	4.0	10.2
52	2.5	6.4
47	1.3	3.2
41	0.5	1.3
36	0.3	0.6
30	0.1	0.3
20	Trace	Trace

technique is to discriminate hail from rainfall or snow by capping the maximum dBZ at 50 or 53.

Radar measured rainfall is also observed from space by the Precipitation Radar instrument, owned by the Japanese, which rides aboard the Tropical Rainfall Measuring Mission (TRMM), a joint U.S. and Japanese satellite. This satellite, which has a low earth orbit of 350 km, was launched in November 1997 to measure precipitation in tropical areas (approximately 30°N and S of the equator) at a resolution of 4.3 km horizontal at 250 m vertical increments and a swath width of 220 km. It is sensitive to a rain rate of 0.5 mm h^{-1}.

Numerous private companies offer rainfall radar, but WSR-88D units are nationally deployed by the NWS, under the federal Department of Commerce and National Atmospheric and Oceanic Administration (NOAA), as well as the Department of Defense and the Federal Aviation Administration. The NWS-88D radar units are deployed in every state, except Connecticut, New Hampshire, and Rhode Island, and in the territories of Guam and Puerto Rico. Most states contain more than one unit; the NWS placed them so that their observed volumes would overlap and create complete coverage for the United States. Daily archives of NEXRAD data files can be downloaded on the Internet at: http://www.nws.noaa.gov/radfiles.html. Current NEXRAD observations are viewable at: http://weather.noaa.gov/radar/mosaic/DS.p19r0/ar.us.conus.shtml.

RAINFALL

James A. Smith

(from *The Handbook of Weather, Climate, and Water: Atmospheric Chemistry, Hydrology, and Societal Impacts*, Wiley 2003)

The capability to measure rainfall advanced dramatically in the last quarter of the twentieth century. The advances have been paced by remote-sensing technologies including both ground-based weather radar and satellite-borne instruments. The most dramatic developments have centered around the capability to monitor precipitation globally from satellite sensors. This measurement capability provides a variety of avenues for hydroclimatological analysis and forecasting. Advances in ground-based radar technologies and deployment of dense networks of rain gages has enhanced the ability to measure rainfall at short time scales (less than 1 h) and small spatial scales (less than 1 km). These time and space scales are often most relevant for water management applications. A brief summary of rainfall measurement and analysis capabilities is presented in the following three sections and organized by the three principal measurement technologies: rain gage, radar, and satellite.

RAIN GAGES

Networks of rain gages play a key role in hydrologic applications ranging from flood forecasting to design of high-hazard structures and water supply management. A wide variety of recording and nonrecording rain gages are used for hydrologic applications. Review and discussion of rain gage technologies are presented in the work by Sumner (1).

There exist several inherent sources of error that affect all types of rain gages. All rain gages suffer from errors due to modification of the wind field by the gage [see Robinson and Rodda (2) for detailed discussions]. The magnitude of errors depends on wind speed, siting characteristics, and type of precipitation (3–9). Rain gage measurement of rainfall is especially difficult in a variety of settings, including mountain ridges, forests, and water bodies. Measurement errors for snow are typically much larger than for rain and are generally in the form of catch deficiencies (3).

Rain gage networks serve as the basis for climatological assessments of precipitation that are used for a wide range of applications (see, e.g., 10). Three of the principal types of climatological analyses that are used for water management applications are illustrated in Figs. 1 to 3. Assessments of average rainfall conditions, in a variety of forms, are central to activities involving industrial, municipal, and agricultural water use. Mean annual precipitation is shown in Fig. 1 [see also Groisman and Legates (3) for a discussion of biases in rain gage analyses of mean precipitation]. Global assessments of continental precipitation have been developed from rain gage observations by Legates (11) [see also Legates and Wilmott (12)]. Precipitation frequency analysis plays a central role in engineering design problems, especially in urban areas (13). The 15-min, 100-year rainfall magnitude for the United States (14) is illustrated in Fig. 2. The network of gages that have the temporal resolution to provide short-term precipitation frequency analyses, such as those in Fig. 2, is far less dense than the rain gage network used to produce mean annual precipitation maps. Consequently, it is difficult to assess the true geographic variability of extreme rainfall rates. It is likely that geographic features, such as mountains and land–water boundaries, exert a pronounced influence on the frequency of extreme rainfall rates. The density of the network, however, is not adequate to resolve these geographic variations. Design of high-hazard structures, such as spillways on major dams, is determined through probable maximum precipitation (PMP) analyses (15,16). Rain gage data sets, in the form of storm catalogs, play a central role in PMP analyses. Storm catalogs for PMP analyses consist of gage observations from specific events. Consequently,

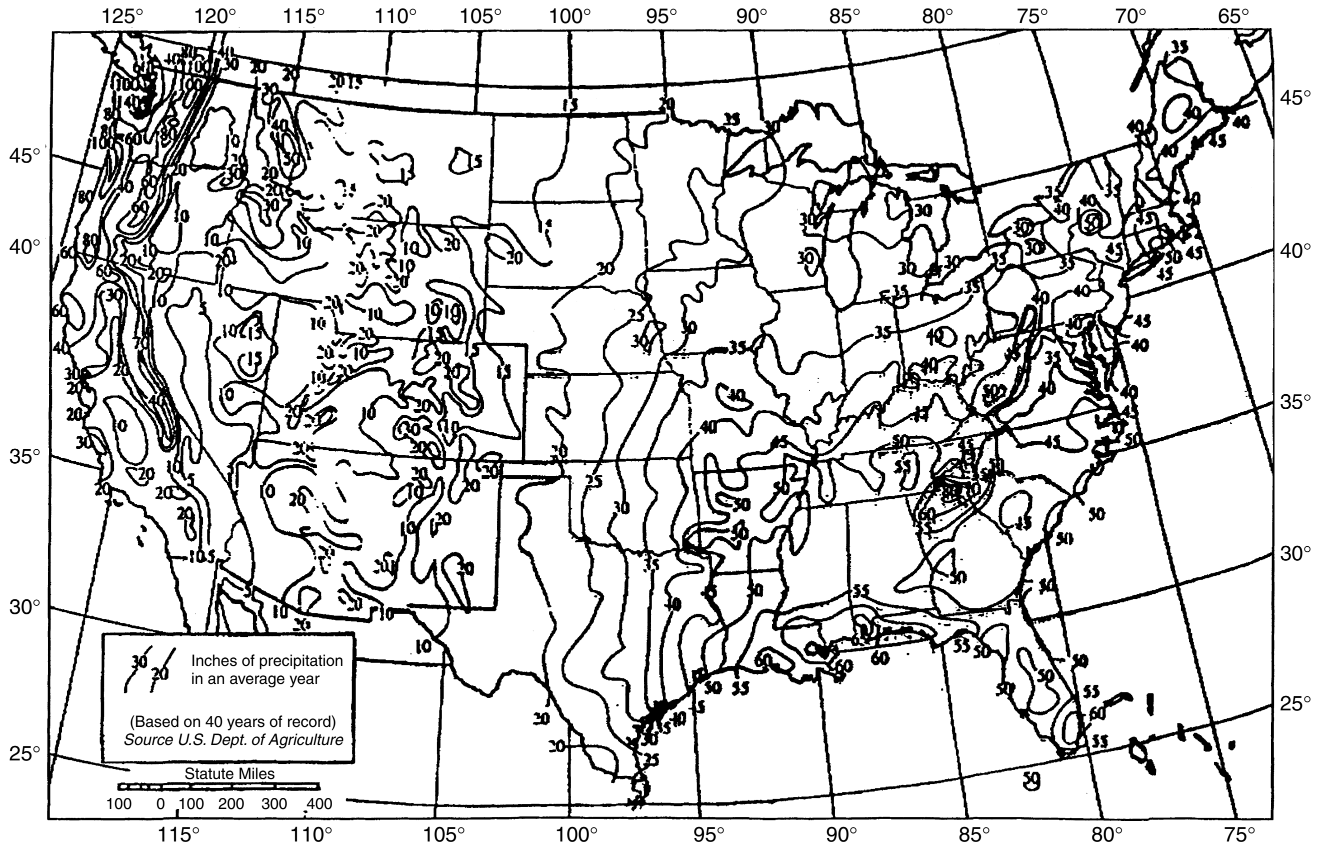

Figure 1. Mean annual precipitation (inches) for the United States from rain gage observations.

the density of gage observations in regions experiencing catastrophic rainfall is critical for PMP analyses. The 6-h, 200 mi^2 PMP for the eastern United States is shown in Fig. 3. The greatest uncertainties in PMP analyses are for small areas (less than 200 mi^2), short time periods (6 h and less), and for regions of complex terrain (17).

RADAR

Implementation of the NEXRAD (next-generation weather radar) system of WSR-88D (weather surveillance radar—1988 Doppler) radars has resulted in dramatic advances in rainfall measurement capabilities for the United States (18). Operational National Weather Service (NWS) rainfall products derived from WSR-88D observations provide rainfall analyses for the United States at 1-h time resolution and spatial resolution of approximately 4 km (19).

The hourly digital product (HDP) rainfall estimates are created by the WSR-88D radar product generator on a 131×131, 4-km grid centered at each radar site. The range over which rainfall products are constructed for each site is approximately 230 km. The algorithm used to construct this product (20) consists of the following steps: (1) quality control, including identification and elimination of anomalous propagation returns, (2) conversion of radar reflectivity factor to rainfall rate through a Z-R relationship, (3) correction for range effects, (4) aggregation of rainfall estimates to hourly, 4-km grid scale, and (5) bias correction using rain gage observations. The HDP product is the base rainfall product from the NEXRAD system. Detailed assessments of HDP algorithm performance are presented in Smith et al. (21) and Baeck and Smith (22) [see also Joss and Waldvogel (23), Wilson and Brandes (24), and Anagnostou and Krajewski (25)].

In a second stage of WSR-88D rainfall processing, multisensor precipitation analyses employ rain gage observations and the 4-km HDP rainfall fields in an optimal estimation framework developed by Krajewski (26) and Seo (27,28). These rainfall fields are subsequently composited into a regional mosaic. The regions that comprise the individual mosaics correspond to the watershed boundaries that delimit the NWS River Forecast Center areas of coverage. Algorithms used for mosaicking of multiple, overlapping radar coverages are described in Seo et al. (29). A national, hourly precipitation analysis is produced at the National Centers for Environmental Prediction (NCEP).

The national 4-km, hourly rainfall mosaic produced by NWS from rain gage and WSR-88D rainfall products will provide an important source of rainfall information for climatological analyses, especially as the observing period

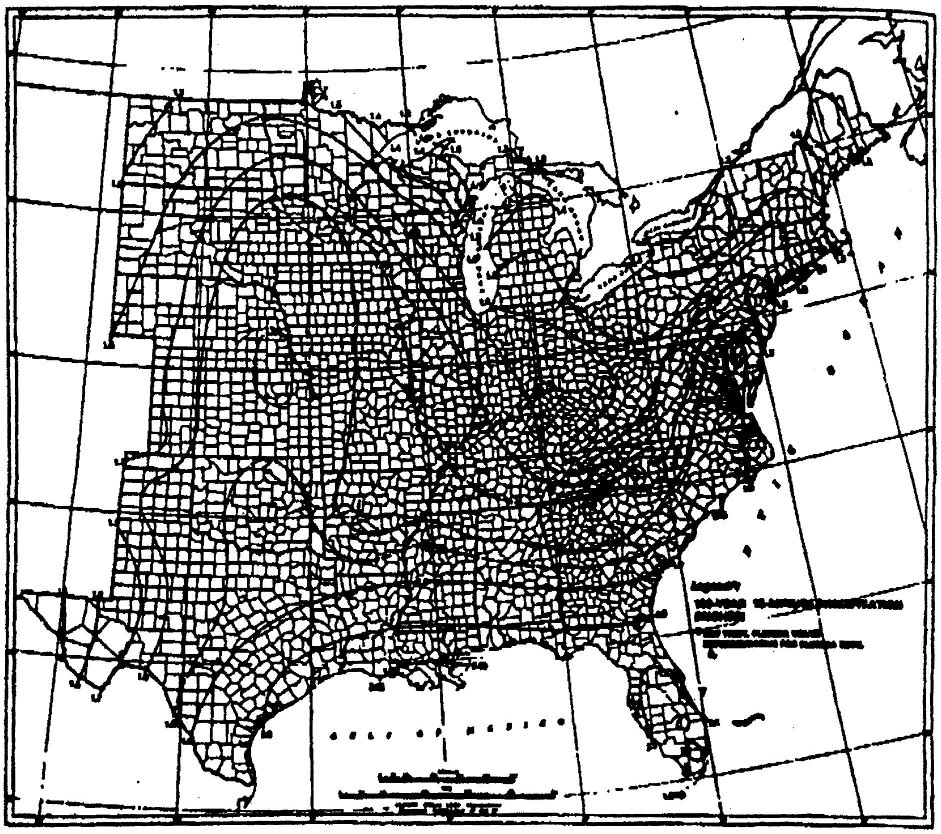

Figure 2. The 100-year, 15-min rainfall magnitudes (inches) for the United States east of the Rocky Mountains.

increases. Radar observations have not generally served as the basis for climatological analyses of rainfall [see, however, Baeck and Smith (30) for an exception]. Issues of bias in radar rainfall estimation must be addressed for radar-based rainfall databases to be most useful for climatological studies (21).

Radar polarimetric measurements (31–34), which utilize the capability of radar to transmit and receive electromagnetic radiation at alternating polarization, hold promise for providing significant improvements in rainfall estimates. Polarization measurements have been shown to be quite useful for quality control algorithms, including detection of bright band, hail, and AP [anomalous propagation (of radar waves, due to sharp gradients of water and air density)], as well as for algorithms for estimating rainfall rate (31,35). The NEXRAD network was designed for eventual implementation of polarization measurements by the WSR-88D.

Radar has provided a significant component of the observational basis for studying storms that produce extreme rainfall. Chappell (36) and Doswell et al. (37) summarize key elements of heavy rainfall producing storms with particular emphasis on storms that produce large point rainfall accumulations through small net storm motion [see also Maddox et al. (38)]. These storms have been termed quasi-stationary convective systems (36). Houze et al. (39) provide a detailed summary of radar-derived storm structure for severe thunderstorms in the central United States [see also Perica and Foufoula-Georgiou (40) and Steiner et al. (41)].

WSR-88D observations, and the rainfall products derived from these observations, have provided a new playing field for hydrologic application and science. Many hydrologic problems that were previously not possible to address due to an absence of information concerning rainfall, have been attacked from an observational perspective. Numerous examples can be drawn from flood hydrology. Figure. 5 illustrates a storm total rainfall analysis constructed for the rapidan storm of June 27, 1995 (42). More than 600 mm of rain fell on the east slope of the Virginia Blue Ridge during a 12-h period resulting in record unit discharge for the United States east of the Mississippi River and catastrophic landslides and debris flows. Fluvial and geomorphic impacts of the rapidan storm rival those described in the classic study by Hack and Goodlett (43) for the June 1949 storm in the Shenandoah Mountains. The chief difference between studies of the 1949 and 1995 storms is rainfall measurement at the 1-km horizontal scale and 6-min time scale for the 1995 storm that allows direct assessment of hydrologic processes.

SATELLITE

Satellite-borne instruments have proven useful for monitoring precipitating cloud system since the 1960s. Steady

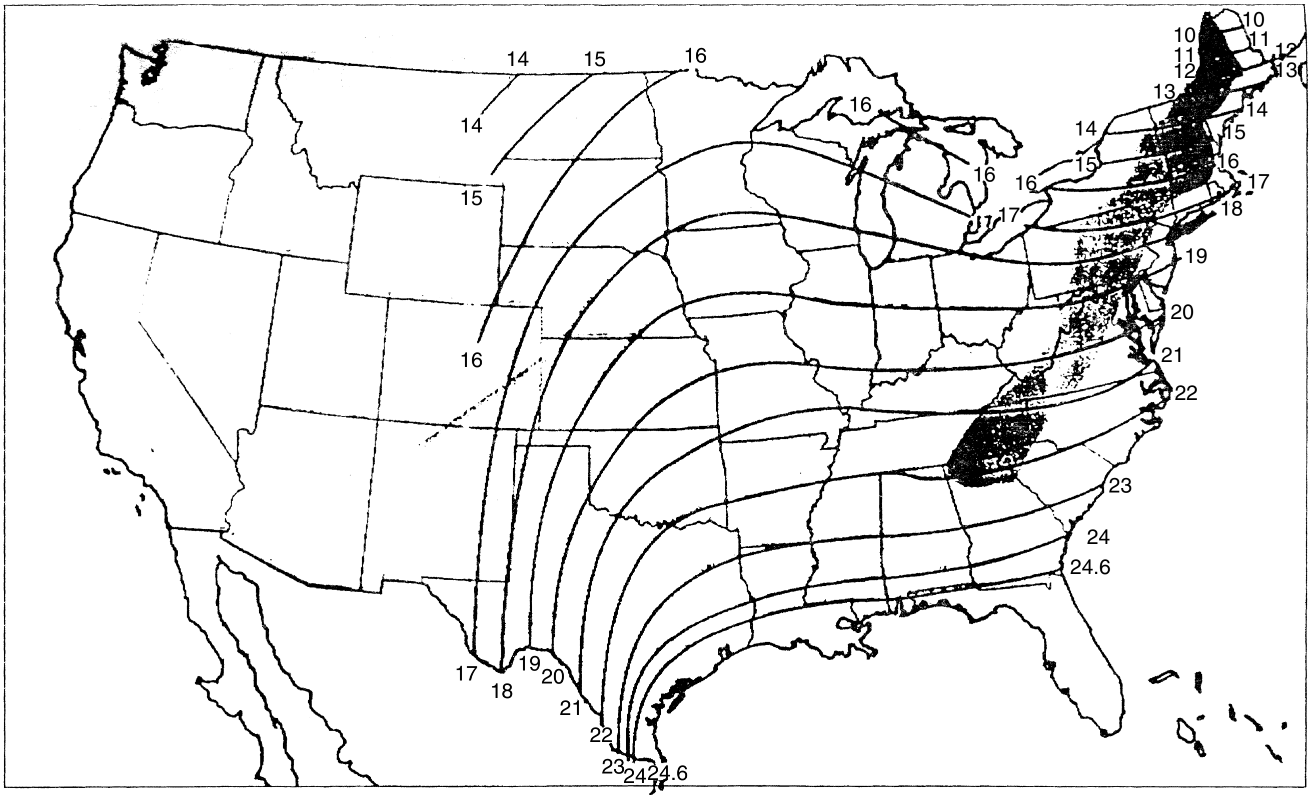

Figure 3. The 6-h, 200 mi^2 PMP magnitudes (inches) for the eastern United States.

progress has been made in developing algorithms for removing rainfall accumulations from passive satellite observations in the microwave (44,45) and infrared (46–48) portions of the electromagnetic spectrum. This progress is reflected in rapidly advancing capabilities for hydroclimatological analysis (49–53). Techniques for quantitative precipitation estimation from satellite sensors are reviewed below.

A geostationary, infrared-based satellite algorithm (46) has been developed and implemented for heavy rainfall measurement. This algorithm is specifically designed for deep, moist convective systems. Estimated precipitation rates are based on the cloud top temperature obtained from the 10.7-μm infrared channel. The empirical equations used to relate cloud top temperature and rainfall rate were calibrated from radar data sets consisting of observations from thunderstorm systems. A moisture correction factor obtained from the precipitable water and mean relative humidity is used to adjust the estimates for different moist environments. The technique of relating rain rate and cloud top temperature tends to overestimate the rain area in some cases and rain rate in others. The technique is also subject to underestimation of rain rates in warm cloud top environments and overestimation of cold top storms in strong wind shear environments.

The *Tropical Rainfall Measuring Mission* (*TRMM*) satellite (54) is designed to measure tropical precipitation and its variation. With the inclusion of a precipitation radar, TRMM provides the first opportunity to estimate the vertical profile of the latent heat that is released through condensation. The TRMM rainfall data will be particularly important for studies of the global hydrological cycle and for testing the ability of climate models to simulate climate accurately on the seasonal time scale.

The TRMM instruments for rainfall observation consist of a precipitation radar, a multifrequency microwave radiometer, and a visible and infrared (VIS/IR) radiometer. The precipitation radar provides measurements of the three-dimensional rainfall distribution over both land and ocean. The precipitation radar will permit the measurement of rain over land where passive microwave channels have difficulty. The horizontal resolution is approximately 4 km, the range resolution is 250 m, and the scanning swath width is 220 km. The multichannel microwave radiometer provides information on vertically integrated precipitation, its areal distribution, and its intensity. Rainfall analyses using the microwave radiometer are best suited for open ocean conditions. The visible infrared (IR) scanner provides high-resolution information on cloud coverage, type, and cloud top temperatures and serves as the link between these data and the long and virtually continuous coverage by the geosynchronous meteorological satellites. The instrument, with a swath width of 720 km, will provide cloud distributions by type and height and rain estimates from brightness temperatures at a horizontal resolution of approximately 2 km.

Satellite IR observations from geostationary satellites have been used extensively for assessing the climatology of extreme rainfall producing storms. An extensive

climatology has been developed for mesoscale convective complexes (55) based on IR-based assessments of cloud properties. Numerous studies have examined the links between mesoscale convective complexes (MCCs), and the more general category of mesoscale convective systems, and heavy rainfall [see Houze (56)].

RAINFALL AND RUNOFF

Theodore A. Endreny
SUNY-ESF
Syracuse, New York

Rainfall is generated by multiple weather patterns, summarized into frontal, orographic, and convective, that affect the duration and intensity of storm accumulation. Climate data analyses reveal regional and local trends in the seasonal and annual rainfall patterns of duration and intensity and have been reported in map and tabular form for durations of 5 minutes to 24 hours and a variety of return periods in Technical Papers 40 and 49 by the U.S. Weather Bureau and in HYDRO-35 by the National Weather Service. A large variation in rainfall spatial and temporal duration and intensity has been observed for large and small area, long and short time events, and a combined system of drop-size spectrometers, recording rain gauges, and microwave radar have helped to capture this detail nationally at the resolution of 5 minutely volume scans for 1 km^2 bins, aggregated to rain-gauge-corrected hourly totals at 4 km^2 bins. Internal warm and cold cloud precipitation dynamics, low-level evaporation of falling precipitation, and distinction between rain, sleet, freezing rain, and snow still provide technological challenges. Time series plots of rainfall are referred to as hyetographs, maps of equal rainfall amounts are known as isopleths, and National Weather Service NEXRAD Doppler radar gauge-corrected hourly 4 km^2 grid based rainfall maps are known as Stage III products. The spatial aggregation of rainfall point estimates from rain gauges is performed using surface fitting, weighting, and interpolation schemes, including the method of Thiessen polygons.

RAINFALL OBSERVATION AND ESTIMATION

Estimates of expected precipitation intensities, as a function of duration and return period (frequency), are referred to as intensity-depth-frequency (IDF) curves (see Fig. 1), and are computed using climatic precipitation data or regional coefficients, as found in such methods as HYDRO-35. Engineering analyses of the failure of various structures, such as drainage culverts and retention basins, are examined using the IDF curve for storms of regulated frequency and duration. The time of concentration, or the time for water to travel from its hydraulically most distant watershed point to the outlet, is used to design peak runoff concentration. Because the rainfall intensity diminishes with duration, the watershed will generate the greatest instantaneous volume of runoff for the time of concentration. Probable maximum precipitation (PMP) rates represent known and estimated regional maximum storm volumes for a given duration and are required inputs in the human safety analysis of critical infrastructure, such as nuclear power plants and large reservoirs and dams where significant loss of life is possible in cases of failure.

The temporal persistence or absence of sequential rainfall affects the earth's surface antecedent moisture and response to the current rainfall, as do surface slopes, ground cover, and roughness. Surface geologic, geographic, and biological features and controls on rainfall partition percentages and timing are relatively steady or predictable across time; surface antecedent moisture is ephemeral and has greater variability in partitioning between surface storage, groundwater recharge, and surface and subsurface runoff to rivers, lakes, and oceans. Antecedent moisture is categorized for the growing and dormant seasons, and in a Natural Resources Conservation Service (NRCS) method, antecedent moisture is a function of the previous 5-day precipitation totals. At the annual time step, however, soil moisture is relatively constant, absent periods of drought. As such, the fact that perennial, intermittent, and ephemeral streams drain most coastal areas indicates that rainfall exceeds evaporation and that runoff is a unique land feature. The atmosphere precipitates nearly 116,000 $\mathrm{km}^3\ \mathrm{yr}^{-1}$ over land surfaces, but only 44,700 $\mathrm{km}^3\ \mathrm{yr}^{-1}$ drains to the oceans in rivers, and only 2,200 $\mathrm{km}^3\ \mathrm{yr}^{-1}$ drains in groundwater. The difference is evaporated mostly from the land surface.

RAINFALL PARTITIONING AT THE LAND SURFACE

Landscape rather than plot analysis is the preferred method for predicting the partitioning of rainfall into runoff, which can travel as surface, unsaturated subsurface (through flow and interflow), and saturated subsurface flow toward the receiving water. Several theories on the partitioning and pathways of rainfall runoff exist, some of which are illustrated in Fig. 2, which isolate the interaction of rainfall and soil saturation conditions. In general, Hortonian overland flow expects infiltration to be exceeded uniformly in space and time and predicts an entire hillslope of overland runoff. This theory does not explain observed conditions in most areas, but it works reasonably well in many dry western U.S. states. Betson flow expects infiltration to have some spatial variation where it is exceeded by rainfall, and was derived from mathematical analysis and not located in the hillslope. In separate field studies by Hewlett and Dunne, this phenomenon of a dynamic spatial and temporal zone of runoff was observed and called the concept of variable source area (VSA). Whether this runoff originates as the result of rainfall rates exceeding infiltration, known as infiltration excess overland flow, or as the result of saturation from below, preventing infiltration, known as saturation excess overland flow, remains difficult to distinguish. In contrast, assuming that the system is a gaining stream where the terrestrial water table is above the streambed, then base flow is relatively constant for a storm runoff.

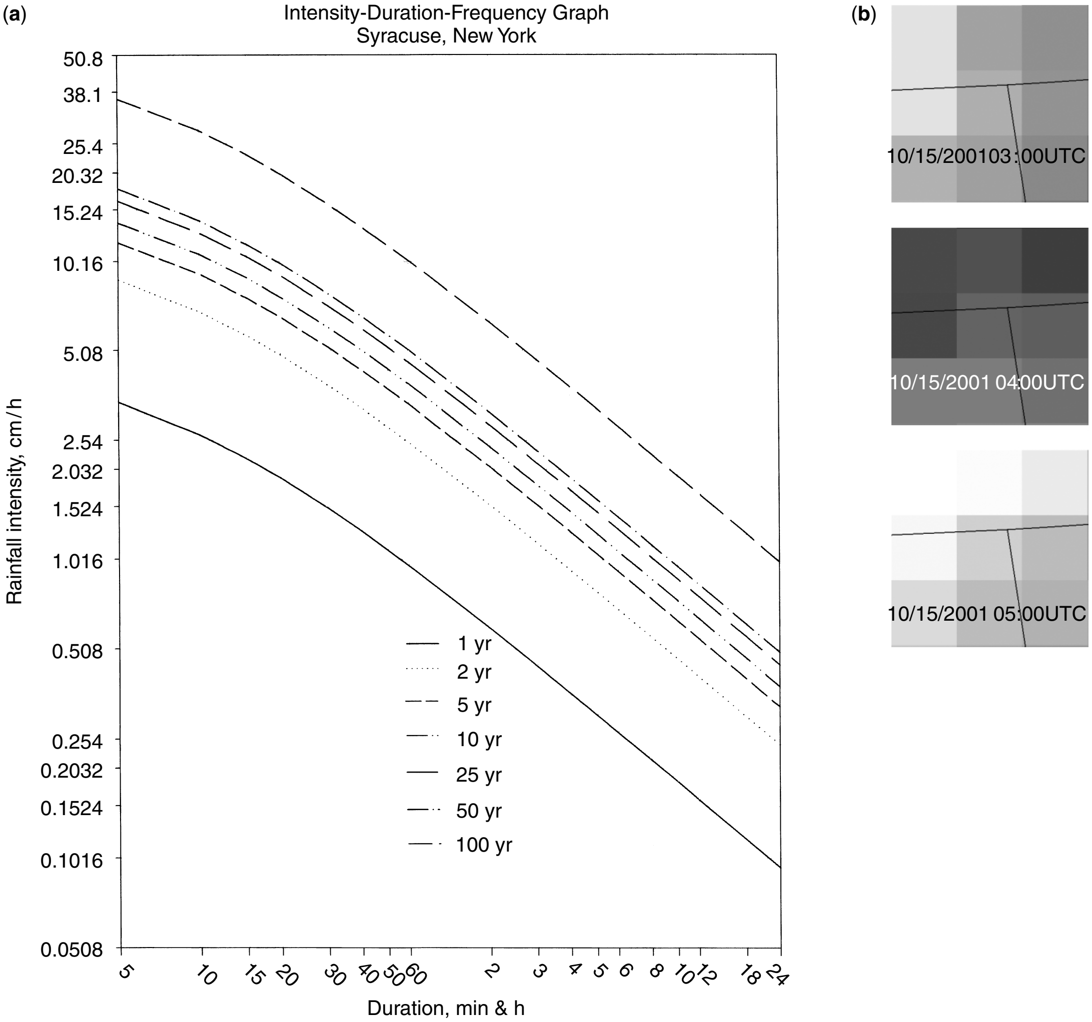

Figure 1. (**a**) The intensity–duration–frequency (IDF) curve for Syracuse, NY, where intensity decreases with duration, but increases with return period, or frequency; (**b**) Illustrations of space and time varying rainfall intensity, represented by 4km x 4km NEXRAD Stage III precipitation grids, where white indicates 0 mm/hour and dark gray indicates 14.5 mm/hour. The total area of 3 x 3 grids is 144 km^2, located at 45 degrees Latitude North by 74 Degrees Longitude West. The dark lines connect at the point where Franklin and Clinton County, New York border Ontario, Canada.

The distinction between infiltration excess and saturation excess has been examined theoretically, comparing observed precipitation rates, infiltration capacity rates, and hydraulic conductivity values, longer period (hourly) averaged precipitation rates seldom exceed infiltration capacity. Shorter period rates (5 minutely) of intense convective storms often do exceed soil infiltration capacity. In arid climates and agricultural areas where soils crust, infiltration is significantly retarded, and precipitation excess often generates runoff. In most other pervious areas, long-duration surface runoff is typically generated by saturation from below, where the local or perched water table has reached the surface. Observations that distinguish between these two events have been advanced using increased spatial and temporal remote sensing monitoring technologies of soil moisture and rainfall dynamics. As watershed rainfall runoff studies increasingly consider urban and suburban dynamics, a greater percentage of the watershed is paved, making the distinction of a runoff-generating mechanism a moot point.

RUNOFF OBSERVATION AND ESTIMATION

Runoff generated from rainfall can be expressed as a volume, a volume per time, as a depth per watershed area, or as a depth per watershed area per time. The ratio of the total runoff and total observed rainfall per time period gives the runoff ratio, which may be presented for climatological or storm periods and has an average U.S. value of 38%. Table 1 provides runoff ratio values for several global regions, and Table 2 provides values for several river basins, which range from 65 to 20%. It is apparent that not all rainfall is converted into storm runoff, and this was first quantified in the 1670s on the upper Seine River in France, but that significant percentages go toward recharging soils and groundwater supplies. The amount of rainfall that is converted into runoff is labeled the effective precipitation, which is an important distinction from observed (e.g., rain gauge measured) precipitation. The depth difference between observed and effective rainfall is explained by the filling by rainfall of a series of storages, including canopy interception, depression storage, detention storage, and soil moisture storage. Areas where observed precipitation is equal to effective, or in stream observed runoff, include rain on water and rain on impervious surfaces (e.g., pavement, rooftops, frozen soil) that are directly connected to the point of measured discharge.

Runoff in channels, or discharge, is measurable using a variety of techniques, including monitoring dilution of injected tracers; monitoring stage height per time for discharge calibrated control structures; monitoring total volumes of discharge per time; and monitoring depth integrated velocities with physical floats, impellers, and Doppler signals together with cross-sectional areas. A runoff time series follows a traditional trend of rising and falling discharge per time, known as a hydrograph. The hydrograph is often separated to distinguish different flow contributions, first delineating a steady volume of base flow or groundwater inflow mostly unaffected by storm dynamics and second, delineating the overlying pulse of event flow. The event flow is potentially separated into separate types of response by using tracers and mixing models, such as slow and fast from the through flow, interflow, pressure wave release, macropore or pipe flow, surface flow, and in-stream rainfall.

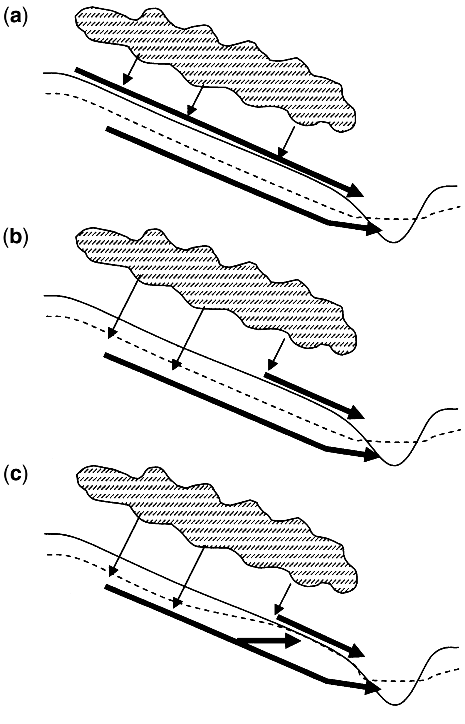

Figure 2. In all figures, the thin solid line is the hillslope surface, the dashed line is the watertable and stream surface, the hashed cloud is rain, the thin arrows are rainfall with or without infiltration, and the thick arrows are surface and subsurface runoff. (**a**) Hortonian concept for overland runoff; the entire hillslope contributes, and base flow is below the water table; (**b**) Betson concept of a with partial hillslope area contributions, but not derived from observations of variable areas; and (**c**) Dunne and Hewlett concept of a variable source area where the water table rises to the ground surface and generates overland runoff.

ENGINEERING VERSUS SCIENTIFIC METHODS

Discharge as total storm runoff, peak storm runoff, or storm time series runoff is estimated by using an equally wide array of methods, and each uses a specific method that first distinguishes the effective precipitation. The most common engineering approach to predicting storm total runoff is the curve number, or SCS, method that partitions observed rainfall into effective rainfall for 6 to 24 hour storms based on antecedent moisture, land cover type, management condition, and hydraulic soil type, which ranges from high infiltration A soils to poor infiltration D soils. The most common engineering approaches to predicting storm peak runoff are either by the curve number based TR-55 method or the runoff coefficient based rational method, which uses a land cover type runoff coefficient to convert observed rainfall intensity into an effective intensity. The most common engineering approach to predicting time series runoff is the unit hydrograph, which requires a user input of the effective rainfall across time, provides a transfer function known as a convolution integral technique to output volume per time discharge, and represents the observed rising and falling limbs of incrementally changing watershed contribution. Unit hydrographs are created for unit depth rainfall (e.g., 1 cm) of distinct duration and based on the principle that runoff response is linear and additive, are weighted by greater or lesser effective precipitation amounts. Empirical, synthetic, and geomorphic techniques exist to create unit hydrographs.

Alternative analytic approaches exist to partition observed rainfall into estimated runoff and, through validation studies on several watersheds, are increasingly demonstrated as accurate. These approaches are based on solving a series of equations for estimating interception volumes, filling detention, depression, and retention storages, partitioning soil infiltration volumes, and possibly accounting for evaporation rates, where initial estimates of storages are either input or acquired from model spin ups where evaporation is a controlling process. As the watershed size increases, effective values for observed precipitation and parameters for soil and plant processes present greater model input challenges. Distinctions between these mechanistic models include their representation of the watershed in space, as either distributed or lumped, and their simulation through time, as either storm or continuous. New modeling techniques are experimenting with parameter optimization through genetic algorithms that mutate and select the most robust parameter strings, and neural networks that seek optimal, but nonphysical, solutions that have best met the objective functions, which typically minimize differences between observed and predicted runoff. Popular rainfall runoff models include those used for operational forecasting

Table 1. Continental Average Estimated Runoff

Continent	Area km^2	Runoff mm yr^{-1}	Runoff Ratio %
Antarctica	14,100,000	28	83
Europe	10,000,000	375	43
Asia	44,100,000	420	40
South America	17,900,000	946	40
North America	24,100,000	403	38
Africa	29,800,000	582	16
Australia	7,600,000	420	6
Total Land	148,900,000	480	36

Table 2. Average Estimated Runoff Ratio for Major River Basins

Watershed by River Name	Continent [Nation(s)]	Basin Size km^2	Runoff Ratio %
Brahmaputra	Asia (Tibet/Bangladesh)	589,000	65
Irrawaddy	Asia (Burma)	431,000	60
Yangtzekiang	Asia (China)	1,970,000	50
Amazon	South America (six nations)	7,180,000	47
Orinoco	South America (Venezuela)	1,086,000	46

by the National Weather Service, such as the SAC-SMR (Sacramento Soil Moisture Accounting) or on those capturing governing topographic controls on generating runoff, such as TOPMODEL. A partial list of agency and research based surface water models is provided by the USGS Surface Water Modeling Clearinghouse website.

RUNOFF ROUTING

Explicit routing of runoff across the landscape, through a retention basin, and along a section of channel upstream of the gauging station may provide additional insighting time-based runoff estimates. In each case, routing has been examined using fully dynamic equations of energy and continuity, written in their complete form (e.g., St. Venant) or neglecting acceleration and pressure gradients (e.g., kinematic), solved using numerical methods of finite element and finite difference. Simpler solutions that still consider the effects of friction, such as the Darcy–Weisbach and Manning equations have been used to route flow across land, as have stand-alone continuity equations that simply push water from cell to cell at a given slope-based velocity. The algorithms used to partition flow in grid-based networks of the watershed terrain map (e.g., digital elevation map files with draped land cover) are varied, ranging from a single path to flow into a maximum of all eight neighboring lower cells. Routing across triangular irregular network grids and polygons is also used. Flow through a reservoir, known as level-pool routing, and along a channel (e.g., the Muskingum method), attenuates the inflow hydrograph based on increasing storage surface area and stage-discharge relationships and wave celerity and propagation rates, respectively. Both methods are presented in most hydraulic engineering handbooks.

SPECIAL TOPICS: WATER YEAR, RUNOFF QUANTITY AND RUNOFF QUALITY

Annual time series analysis of precipitation hyetographs and runoff hydrographs reveals trends that give rise to regional characterization of U.S. hydrologic zones. The hyetograph analysis considers rain and liquid equivalent snowfall. West of the 100th meridian, rainfall is typically less than 20 inches annually. California has increased precipitation during the winter when a Pacific blocking high moves northward; southwestern states have summer monsoon rains; central, midwestern, and southeastern states have increased precipitation during summer convective showers, and eastern states have rather steady annual precipitation. Runoff often follows separate trends, given the land surface seasonal function in partitioning rainfall. Snow accumulation in the winter often keeps winter runoff low; snowmelt in the spring and higher altitudes in the summer release a pulse of the largest stream flow volumes. Spring and summer vegetation growth creates soil moisture deficits that allow for larger soil storage of rainfall and reduced stream flow. The fall dieback of vegetation reduces evaporation rates, and the soil storage fills and remains filled, which increases stream flow. The annual rainfall–runoff cycle that leads to a renewal of soil moisture reserves and increased runoff has led to the creation of the water year, beginning on October 1. Anomalies to this pattern exist, and events such as warm rain on snow, which melts the pack in midwinter but does not infiltrate into the frozen soils, can create huge winter floods. Likewise, the global ocean and atmospheric patterns set in place by systems such as the El Niño southern oscillation can cause southeastern spring and summer droughts when there are usually heavy rains.

Special topics in runoff hydrology include flood and drought analysis as well as water quality, which are useful in human safety, infrastructure design, and environmental management. The Water Resources Council 1972 method continues to provide guidance on fitting annual maximum discharge observations onto a Type III Pearson distribution to forecast return interval floods that exceed observed record lengths. Although 10, 50, and 100 year events have significant discharge rates and therefore erosive power, channel patterns are shaped by flows of the more frequent 1.5 return intervals. Drought analysis is critical to sizing drinking water reservoirs and wastewater treatment discharge dilution plans and are typically based on 7-day, 10-year low flows, or for ungauged rivers, on regional relationships derived from similar streams that were gauged. Water quality has become more directly tied to rainfall runoff analysis after the successful control of many municipal and industrial point source pollution dischargers, leaving the nonpoint source (NPS) pollution from agricultural fields, commercial parking lots, urban streets, and residential lawns. NPS runoff from these sources, it has been observed, explains the large fraction of soil, nutrient, chemical, metal, organic, and bacterial loads entering the 40% of national waterways that are still noncompliant with Clean Water Act requirements for fishing and swimming access.

REMOTE SENSING DEFINED

Remote sensing is the science of observing and analyzing an area, object, or phenomenon based on data collected by sensors physically separated from the target. The sensors are mounted on platforms such as ground-based, airplane, or satellite platforms. Physical radiation transfer is the foundation for remote sensing. Typically, the observation is of radiation reflected or emitted from the object of interest. There are two types of remote sensing: active and passive. In active remote sensing, the object is illuminated by radiation of a known wavelength (or frequency); the backscatter from the object is recorded by the sensor. In passive remote sensing, the sensor records radiation generated from natural sources, such as the sun, or radiation emitted from the earth or atmosphere. Radiation that the sensor receives has a spectral response that reveals properties of the atmosphere and object of interest. By extending remote sensing applications to improve the spatial and temporal resolution of certain key water resource variables, scientists can better understand and quantify water resource processes.

METHODOLOGIES

Qualitative and quantitative approaches for analyzing remotely sensed data provide discrete and continuous information about an area. The qualitative approach separates observed spectral data into different classes and generates map-based images showing the spatial distribution of the classes. For example, if trying to map vegetation in an area that has certain known vegetation classes, the qualitative approach produces a map where every pixel is assigned a vegetation class or a 'no class.'

The quantitative approach provides numerical information about the area or phenomenon of interest. For example, by computing the normalized difference vegetation index (NDVI) using visible and near-infrared data and generating a map where a value is attached to every pixel, a map user has an idea how dense the vegetation is and where the denser areas lie.

For either of these approaches, several different classification methods can be used. All classification methods fall under two general categories: supervised classification and unsupervised classification. Supervised classification requires the scientist to collect data from the area of interest and assign these data to pixels within the image. Examples of supervised classification methods are the parallelepiped method and the minimum distance method. Examples of unsupervised classification are the chain method and the ISODATA method.

RESOLUTION AND SPECTRAL REGIONS

To determine the type of data required for a remote sensing application, scientists need to identify and quantify the key data characteristics of the phenomenon of interest. These characteristics may include the temporal resolution, spatial resolution, radiometric resolution, and spectral resolution. All four characteristics determine the platform, sensor, and capital necessary for the project.

The spatial resolution determines the minimal size of objects that can be seen from the sensor; the smaller the area covered, the higher the resolution. The temporal resolution is the time between data acquisitions across the

Table 1. Resolution Types and Potential Applications

Resolution Type	Resolution	Applications	Sensor Examples
Spatial	10–100 m	Local hydrological processes	ASAR; MSS
Spatial	1–5 km	Local meteorologic processes	AVHRR/2; MODIS; SSM/I; ERBE
Spatial	>25 km	Basin-wide studies; global studies	
Temporal	Every 30 min	Meteorologic studies	VHRR; VISSR
Temporal	2/day	Meteorologic studies	AVHRR
Temporal	Every 2 weeks	Land use	ETM+
Temporal	Once	Maps	

same area. The radiometric resolution is the sensitivity of a sensor to differences in signal strength as it records the incoming radiant flux. The radiometric resolution is often determined by the number of bits (6 bits, 8 bits, etc.), available for storing the data. The spectral resolution is the range of wavelengths detected by the selected sensor (1). Different wavelengths or frequencies can be used for different applications. For examples of different uses for different resolutions and spectral regions, see Tables 1 and 2.

Almost all spectral regions have been used for passive remote sensing, ranging from the visible (VIS), infrared (IR), and microwave (MW) regions (Table 3); however, active remote sensing has been limited to microwave regions. Each of these regions breaks down to smaller regions; some of these regions are more commonly used than others. For example, remote sensors will capture red, blue, and green within the visible region more often than purple/violet or yellow because of the way certain physical environments reflect these particular wavelengths. Within the IR region, near-infrared (NIR) and thermal-infrared (TIR) radiation react to or are emitted from certain components of the physical environment more than other wavelengths in that region. The bands of microwave radiation wavelengths and frequencies are denoted by the letters K-, W-, X-, C-, S-, and L-.

Table 2. Spectral Bands, Bandwidths, and Their Potential Applications[a]

Spectral Band	Bandwidth	Applications	Sensor Examples
Blue	0.45–0.50 μm	Water penetration, land use, vegetation characteristics, sediment	ETM+; ASTER; MISR; TM
Green	0.50–0.60 μm	Green reflectance of healthy vegetation	AATSR; ASTER; MISR; TM
Red	0.60–0.70 μm	Vegetation discrimination because of red chlorophyll absorption	AATSR; ASTER; AVHRR/2; MISR
Panchromatic	0.50–0.75 μm	Mapping, land use, stereo pairs	ASTER;
Near-infrared	0.75–0.90 μm	Biomass, crop identification, soil crop, land–water boundaries	AATSR; ASTER; AVHRR/2
Midinfrared	1.5–1.75 μm	Plant turgidity, droughts, clouds, snow-ice discrimination	AATSR
Thermal infrared	8–12.5 μm	Relative temperature, thermal discharges, vegetation classification, moisture studies, thermal inertia	AATSR; AVHRR/2
Microwave: Shortwave	0.1–5 cm	Snow cover, depth, vegetation water content	ALT Duel-frequency Radar Altimeter; MWR
Microwave: Long wave	5–24 cm	Melting snow, soil moisture, water–land boundaries, penetrate vegetation	SAR; AMI-SAR

[a] Compiled based on Reference 2, p. 11, Table 1.1.

Table 3. Wavelengths and Frequencies for VIS, IR, and MW

Region	Wavelength (λ)	Frequency (υ)
Visible: R,B,G	0.4–0.7 (μm)	750,000–428,571 GHz
Infrared: NIR, TIR	0.7–100 (μm)	428,571–3000 GHz
Microwave shortwave: K-, W-band	0.1–5 (cm)	300–6 GHz
Microwave long wave: X-, C-, S-, L-band	5–24 (cm)	6–1.25 GHz

Basic Terms and Equations

Basic terms and equations fundamental to the theory of remote sensing applications in water resources are given below. Wavelength, λ (m), is the length of the cycle of vibration, given as

$$\lambda = \frac{c}{v} \tag{1}$$

where c is the speed of light, approximated as 3×10^8 m/s, and v is the frequency of vibration (1/s). Note that the speed of light is adjusted for density differences between space and the earth's atmosphere. Calculation of brightness temperature (3), T_{B}, is based on the measured excitance, or vibration, from a narrow spectral band, as a function of emissivity, ε, and temperature, T:

$$T_{\mathrm{B}}(\lambda) = \varepsilon(\lambda)T \tag{2}$$

The terms backscatter (3), emission (3) and reflectance (3) refer to different types of energy received by a spaceborne sensor from the targeted area. Backscatter is the reflectance of microwave radiation from the target, defined by

$$\frac{P_{\mathrm{r}}}{P_{\mathrm{r}}} = \frac{\lambda^2 G_{\mathrm{t}} G_{\mathrm{r}}}{(4\pi)^3 R_{\mathrm{t}}^2 R_{\mathrm{r}}^2}\sigma \tag{3}$$

where P_{r} is the received power, P_{t} is the transmitted power, λ is the wavelength of the radar beam, G is the antenna gain, R is the distance (range) between target and antenna, and σ is the radar scattering cross section. Reflectance occurs when radiation bounces off the target and is redirected. Specular reflectance occurs when ~100% is redirected in the same direction, and diffuse reflectance occurs when 0% is redirected in the same direction. Reflectance is defined by

$$r_{\mathrm{s},\lambda} = \frac{\pi L_{\mathrm{s},\lambda}}{(E_{\mathrm{dir},\lambda} + E_{\mathrm{dif},\lambda})} \tag{4}$$

where $r_{\mathrm{s},\lambda}$ is the spectral surface reflectance, $L_{\mathrm{s},\lambda}$ is the reflected radiance at the surface, $E_{\mathrm{dir},\lambda}$ is the direct irradiance, and $E_{\mathrm{dif},\lambda}$ is the diffuse irradiance. Excitance (emission) is the radiation that comes from the earth's surface, such as heat, and is defined by

$$L_{\infty,\lambda} = L_{0,\lambda} t_\lambda(0,\infty) + \int_{z=0}^{z=\infty} L_{\mathrm{B},\lambda}[T(x)] \frac{\partial t_\lambda(z,\infty)}{\partial z} dz \tag{5}$$

where t_λ is the spectral transmissivity, $L_{\mathrm{B},\lambda}$ is the spectral blackbody radiance, $L_{0,\lambda}$ is the surface emitted radiance, and $L_{\infty,\lambda}$ is the upwelling radiance.

Water resource remote sensing applications covered in this article include evapotranspiration, flood mapping, precipitation, soil moisture, surface snow, waterbodies, and wetland detection. Each topic is discussed in detail, and basic algorithms are provided where possible. These algorithms, adapted from different situations, may have limitations, when applied to new situations. These limitations, noted and explained in the article, should be considered when applying the equations to different environments.

EVAPOTRANSPIRATION

Evaporation is the physical change of liquid water to a vapor. Transpiration is the evaporation of water from plant tissues into the atmosphere. Evapotranspiration (ET) is the combination of these two processes. Remote sensing of evapotranspiration remains an imperfect science in part because scientists are still largely unable to measure evapotranspiration directly. Scientists must rely on creating evapotranspiration algorithms and defining the variables within the algorithm using remote sensing. Even with these algorithms, scientists still require ground data for variables not determined through remote sensing methods (4).

The two spectral regions utilized for ET are VIS and IR (4). Scientists can analyze two types of ET, actual ET and potential ET, using different methods. Actual ET, the ET that occurs in any real situation, becomes more difficult to quantify in remote sensing, compared to potential ET(PET), the ET that occurs in when the soil/vegetated area has 100% soil moisture.

Currently, many algorithms exist to calculate ET. For this article, two equations were selected that calculate some idealized evaporation rates (potential and reference crop), and then different methods are explained for calculating actual ET. The first equation, developed by Priestley and Taylor (5), calculates the reference crop evaporation assuming that approximately 30% of the evaporation is driven by turbulent transfer. This equation depends upon remotely sensed thermal properties.

$$E_{\mathrm{rc}} = \alpha \frac{\Delta}{\Delta + \gamma}(R_{\mathrm{n}} - G) \tag{6}$$

where E is the evaporation rate for the reference crop; R_{n} is the net radiation; G is the ground heat flux; Δ is the slope of the vapor pressure versus temperature curve; and α is the empirical evaporation constant, determined as 1.26 or dependent on soil moisture (6,7).

The second equation, derived by Choudhury (8), calculates global potential evaporation. The data for this equation need to be collected from a variety of satellites that measure visible and thermal bands (4):

$$E_0 = \frac{\Delta R_{\mathrm{ni}} + \rho c_{\mathrm{p}} \dfrac{D}{c r_{\mathrm{e}}}}{\Delta + \gamma \dfrac{(r_{\mathrm{s}} + r_{\mathrm{h}})}{r_{\mathrm{e}}}} (\mathrm{mmd}^{-1}) \tag{7}$$

where Δ (hPa K^{-1}) is the differential of saturated vapor pressure with respect to temperature evaluated at air temperature T_{a} (K), γ (hPa K^{-1}) is the thermodynamic psychrometric constant, R_{ni} (mm d^{-1}) is the thermal net radiation, ρ is the density of air, c_{p} is the specific heat of air, D (hPa) is the vapor pressure deficit, r_{s}(s m^{-1}) is the surface resistance, r_{H} (s m^{-1}) is the aerodynamic resistance for heat transfer from a virtual source height where the canopy is at a reference level in the atmosphere, r_{e}(s m^{-1}) is the effective resistance to heat transfer obtained by putting the aerodynamic resistance r_{H} and the resistance to long-wave radiative transfer r_{R} in parallel, and c (mm d^{-1}) is the constant equal to the product of latent heat of evaporation and density of water.

The Choudhury (8) equation, based only on PET from grassy areas, needs to be adjusted before application to other types of land cover (9,10):

$$K_c = \frac{E_m}{E_0} \tag{8}$$

where K_c is the crop coefficient; E_m is the basic evaporation equation result with changes in albedo, aerodynamic effective resistance, and the minimum surface resistance relevant to the crop/landcover to be studied; and E_0 is the basic evaporation equation result.

To calculate actual evapotranspiration, scientists employ numerical models because of the complexity of the data requirements. One method, the integration of soil-vegetation-atmosphere-transfer (SVAT) models with planetary boundary layer (PBL) models, have the advantage of calculating ET from a higher altitude, thereby reducing surface spatial heterogeneity (4). Some problems to consider when tackling the calculation of actual evapotranspiration are the difficulty of validation and the inability to derive air humidity from remotely sensed data (4).

FLOOD MAPPING

Flood mapping is the process of delineating areas that may be flooded or have been flooded. Remote sensing flood mapping deals mostly with areas that have been flooded. The spectral regions used for this type of mapping are NIR (only for cloud-free conditions) and MW. NIR produces maps where the waterbodies are dark in contrast to surrounding soil and vegetation. Barber et al. (11) determined that C-HH data (active microwave data) also produced flood delineation maps collecting specular reflection, as long as the incident angles were greater than 45°. Active microwave sensors have an advantage over NIR sensors for flood mapping because they can penetrate clouds (12).

PRECIPITATION: RAINFALL AND SNOWFALL

The detection and estimation of precipitation can be either ground-based or space-based. All three spectral regions are used, VIS, IR, and MW, and each spectral region requires a different approach to calculating precipitation. Common instruments for ground-based rainfall and snowfall estimation are weather radars. These instruments take vertical measurements of snow/rainstorms and receive the backscattering from the individual drops or flakes. Spaceborne instruments include infrared and visible sensors (13).

For ground-based weather radars, the theoretical basis for rainfall estimation consists of the following equations (13,14):

$$Z = \int_0^\infty D^6 N_V(D)dD \tag{9}$$

$$R = 6\pi \times 10^{-4} \int_0^\infty D^3 v(D) N_V(D)dD \tag{10}$$

$$v(D) = cD^\gamma \tag{11}$$

where Z is the radar reflectivity factor, $N_V(D)\ dD$ is the drop size distribution per volume of air, D is the spherical raindrop diameter, R is the precipitation rate, $v(D)$ represents the functional relationship between the raindrop terminal fall speed in still air and the equivalent spherical raindrop diameter, $c = 3.778$ (if v is expressed in m s^{-1} and D in mm), and γ is 0.67. A limitation of Equation (9) is that raindrops are not round, they are oblate. To take this limitation into account, an adjustment is made in the original Z reflectivity equation where dual polarization is used. A limitation of this method is that single point measurements for the differential reflectivity may not properly represent rainfall at the land surface (13).

The relationship between the radar reflectivity factor, the radar properties, and backscatter is defined by the following equation (15):

$$\overline{P_r} = C\frac{|K|^2}{r^2}Z \tag{12}$$

where $\overline{P_r}$ is the mean power (W) received from raindrops at range r (km), C is the radar constant and $|K|^2$ is a coefficient related to the dielectric constant of water (~ 0.93). The limitations of this equation are that it holds for Rayleigh scattering theory, where targets are small compared to radar wavelength, perfect radar calibration is necessary, and attenuation is absent (14). The relationship between Z and R (sometimes denoted as S for snowfall), the precipitation rate, is the following:

$$Z = AR^B \tag{13}$$

where A and B are coefficients that vary with climatic and location characteristics but are independent of R (Table 4). This equation is theoretically based upon Eq. 14 and empirically based on numerical evidence (15). There are two methods for calculating A and B: regression analysis and parameterization using the raindrop size distribution (Eqs. 9–11) (14).

For snowfall, Z_e is considered instead of Z because of the physical differences between snowflakes and water drops (16):

$$Z_e = \frac{|K|_i{}^2}{|K|_W{}^2} \cdot Z \tag{14}$$

where Z_e is the radar reflectivity of snow/hail, $|K|_i{}^2$ is the dielectric constant for ice and $|K|_W{}^2$ is the dielectric constant for water. The 'correct' values for $|K|_i{}^2$ depend on the particle size selected (or determined). Some examples of selected particle sizes and their respective dielectrics can be found in Table 5. A typical value for the dielectric constant for water ($|K|_W{}^2$) is 0.93.

Two major physical differences exist between snow and rain that make Eq. 13 less accurate for snowfall. Upwelling of snow due to the snowflake density/size

Table 4. Empirical Constant Values and Respective Precipitation[a]

A	B	Precipitation Type	Reference
140	1.5	Drizzle	(19)
250	1.5	Widespread rain	(19)
200	1.6	Stratiform rain	(20)
31	1.71	Orographic rain	(21)
500	1.5	Thunderstorm rain	(19)
486	1.37	Thunderstorm rain	(22)

1780	2.21	Snowflakes	(24)
1050	2	Snowfall (X-Band)	(25)
229	1.09	Snowfall (X-Band)	(26)
427	1.09	Snowfall (X-Band)	(27)

[a] Adapted from Reference 13 pg 113, Table 6.2; $Z(\mathrm{mm}^6\ \mathrm{m}^{-3})$, $R(\mathrm{mm\ h}^{-1})$

Table 5. Snowfall Diameter Types and Respective Dielectric Constants $|K|_i^2$

Diameter Size/Type	Dielectric Constant Value
Melted deep diameters	0.208
Ice sphere diameters	0.176

and the inhomogeneity of snowflake type and density do not follow the basic assumptions required for the Z–R relationship and decrease its overall accuracy (17). However, Collier (13) states that with careful quality control and adjustment of radar measurements, snowfall estimations can be as accurate as rainfall up to 50 km from the radar site.

For infrared satellite measurements, two algorithms commonly used are the cloud indexing algorithm and the life history algorithm. There are also several modeling methods that use artificial neural networking (ANN) in combination with remote sensing data. Cloud indexing is based on the idea of a classification type where the brightness temperature of every pixel is calculated and compared to a threshold brightness temperature. The threshold brightness temperature represents the temperature below which a cloud pixel precipitates. The algorithm is adjusted using empirically derived constants. One of the major limitations of this algorithm is that it is relevant only to cumuliform clouds and precipitating clouds. It is not relevant to cold nonprecipitating clouds like cirrus. However, this adjustment can be overcome by using wavelengths of 10.8 and 12 μm to differentiate between the two types of clouds (18). Another major limitation is calibration and validation due to the lack of spatial and temporal correlation between rain gauges and the algorithm. Rain gauges are point measurements whereas the algorithm measures over space. An alternative to rain gauges for calibration/validation is ground-based radar, but it too has inaccuracies (13):

$$\mathrm{PI} = A_0 + \sum_i A_i\ S_i(\mathrm{TBB}_i) \tag{15}$$

where $\mathrm{TBB_i}$ is the Pixel brightness temperature, T_0 is the brightness temperature threshold that is determined empirically, A_0 is a constant that is determined empirically, A_i is a constant that is determined empirically, S is the surface area, which is a function of brightness temperature, and PI is the precipitation index.

The life history method takes into account the growth and decay of a particular cloud or storm, and rain rates are adjusted to the cloud's stage of growth. The variables and limitations of this equation are similar to those of the cloud indexing equation (13).

$$\mathrm{PI} = A_0 + A \cdot S(\mathrm{TBB}) + A' \frac{d}{dt} S(\mathrm{TBB}) \tag{16}$$

Modeling programs that use the IR spectral region, such as precipitation estimation from remotely sensed information using artificial neural networks (PERSIANN), are alternative methods of calculating rainfall and snowfall more precisely than the simple algorithms above.

The use of the passive MW spectral region in precipitation detection and estimation is a hot topic in research now and is producing very favorable results. Microwave estimation of precipitation is favorable because it measures precipitation more directly than IR, where the radiation is absorbed or scattered by the precipitation. The distinction between the two methods of estimation, absorption/emission and scattering, is important because both have limitations. Absorption/emission of microwave radiation by liquid water is relatively high and increases as frequency increases. This increase in emission drowns out signals of light precipitation. Scattering occurs when ice particles are in the lower parts of the cloud before the particles become liquid. However, the existence of ice particles must then be connected to the physical precipitation in some manner (13).

SOIL MOISTURE

Soil moisture is defined as the water retained in the soil after infiltration. The spectral regions used for remote sensing are MW and TIR. The spatial resolution for this work is very important, and is one of the reasons that the microwave region is preferentially used by hydrologists. The use of thermal infrared and passive microwave requires more algorithmic work compared to active microwave. Generally, soil moisture is measured by developing an algorithm that contains variables quantifiable through remote sensing analysis (28). For TIR, the following equations can be used:

$$\mathrm{DT_s} = T_\mathrm{s}(\mathrm{PM}) - T_\mathrm{s}(\mathrm{AM}) = f\left(\frac{1}{D}\right) \tag{17}$$

$$D = w \cdot Q_\mathrm{c} \cdot k \tag{18}$$

where $\mathrm{DT_s}$ is the diurnal temperature, the difference between the afternoon surface temperature $T_\mathrm{s}(\mathrm{PM})$ and the early morning surface temperature $T_\mathrm{s}(\mathrm{AM})$; D is the diurnal inertia; w is the day length; Q_c is the volumetric heat capacity, and k is the thermal capacity.

Based on this equation, a scientist would then develop a relationship between the temperature change and the soil moisture. The limitations of this equation are that it can be used only for bare soil. Clouds, surface topography, and local meteorologic conditions can decrease accuracy due to their absorption of thermal radiation. The penetration depth that can be considered is small because the thermal radiation is not penetrating but emanating (28).

Microwave soil moisture equations are based on dielectric constants or the emanation of microwaves from the soil surface. Passive microwave soil moisture calculations require the brightness temperature, ground emissivity, and the dielectric constant. Scientists will then use the final temperature brightness outcome to develop an empirical relationship to known soil moisture values (28,29):

$$T_{\mathrm{B}} = t(H) \cdot \lfloor rT_{\mathrm{sky}} + (1-r)T_{\mathrm{soil}} \rfloor + T_{\mathrm{atm}} \tag{19}$$

where T_{B} is the brightness temperature, $t(H)$ is the atmospheric transmissivity for a radiometer at height H above the soil, r is the smooth surface reflectivity, T_{soil} is the thermometric temperature of the T_{soil}, T_{atm} is the average thermometric temperature of the atmosphere, and T_{sky} is the contribution from the reflected sky brightness.

Active microwave soil moisture measurement has problems similar to passive, requiring an empirical development of a relationship between backscatter and soil moisture. The spatial resolution of active microwave sensors has an advantage over passive and thermal infrared sensors. Both types of microwave remote sensing can also be used for change detection (28). Some limitations to consider for microwave sensing are surface roughness and measurement depth. Surface roughness is spatially and temporally variable, which affects measurements on the watershed scale (12). Measurement depth is important for calculating the correct dielectric constant (28).

SURFACE SNOW

Surface snow is important as a source of freshwater for many areas. Scientists are interested in many characteristics of surface snow that will help them to estimate quantity and time to runoff. The most important characteristics are identification of extent, snow-covered area (SCA), depth, density, and snow water equivalent (SWE). Each of these characteristics requires different spectral data, and each can use different techniques during analysis.

Surface snow extent can be measured using VIS and MW from satellite platforms. The method employed for snow extent is detection. Each spectral region has advantages and limitations. The visible region usually has good resolution (depending upon the type of satellite) but cannot provide data at night and is not good for distinguishing between clouds and snow.

Passive microwaves (SSM/I) are limited to very large areas due to poor resolution (~25 km) and detect only dry snow. Passive microwave data are also hard to validate due to large pixel size. Active microwave data, such as SAR, can discriminate between wet and dry snow with a high resolution but have trouble with forested areas (30).

Surface snow water equivalent can be calculated using microwave and gamma radiation. The gamma radiation is detected by using an airplane platform, and microwaves are detected by using an airplane or satellite platform. The following equation was developed for gamma radiation calculation of SWE. When using gamma radiation to calculate SWE, soil moisture can attenuate the radiation, and this affects the accuracy (20,31).

$$\mathrm{SWE} = \frac{1}{A}\left(\ln\frac{C_0}{C} - \ln\frac{100+1.11M}{100+1.11M_0}\right) \tag{20}$$

where SWE (g/cm^2) is the snow water equivalent, C and C_0 are uncollided terrestrial gamma counts over snow and bare ground, M and M_0 are the percent soil moisture in snow covered and bare soil areas, and A (cm^2/g) is the radiation alternation coefficient in water.

The SWE based on passive microwave data is a function of brightness temperature and empirical constants. These constants allow the "moving" algorithm from location to location. When calculating SWE, the effect of vegetation on backscattering and emissions must be considered. Forested areas tend to decrease the accuracy of results. A major limitation of passive microwave snow detection and SWE estimation is that passive microwaves sensors cannot detect wet snow. Wet snow increases brightness temperatures much more than dry snow, thereby decreasing the accuracy of the original equation. Even slightly wet snow is hard to detect with passive microwaves.

Active microwaves, such as SAR, can detect wet snow but cannot distinguish dry snow from no-snow areas. This suggests that multiband methods have a future in SWE determination, but the sensor technology may not be available (20,32).

$$\mathrm{SWE} = A + B\left(\frac{T_{\mathrm{B}}(f_1) - T_{\mathrm{B}}(f_2)}{(f_2 - f_1)}\right) \tag{21}$$

where A is the offset of the regression of the brightness temperature difference, B is the slope of the regression of the brightness temperature difference, f_2 is the high scattering channel, commonly 37 GHz, f_1 is the low scattering channel, commonly 18 or 19 GHz, and SWE (mm) is the snow water equivalent.

WATERBODIES: DETECTION, COLOR, CLARITY, AND QUALITY

Remote sensing can be used to observe several different characteristics of waterbodies such as waterbody detection; waterbody perimeter calculation; and waterbody clarity, color, and quality. Waterbody detection is the process of determining the existence of water bodies within an area, whether they are ephemeral or permanent. The regions used for this type of detection are VIS, IR, and MW. IR is absorbed by water, so waterbodies show up as black areas on false colored IR images, and when using

VIS, radiation is reflected (12). Passive microwave emissions can be used to calculate the brightness temperature, and this allows distinguishing between water and floating ice. Open water has a lower brightness temperature (12).

Examples of satellite sensors and platforms for waterbody detection are SSM/I, Landsat TM, and NOAA AVHRR (LIC). A problem to consider with the spectral regions of VIS and IR is that VIS and IR are constrained by clouds. A general limitation to consider is that the area to be analyzed should exceed the spatial resolution by a factor of 10 (33).

To determine water quality, clarity, or color requires using the same spectral regions, VIS and IR, but with a different method of analysis. Using linear and nonlinear equations based on the radiance, reflectance, or energy of the radiation, scientists relate these to the parameter of interest. There are three approaches for creating this relationship: empirical, semiempirical, and analytical. The empirical methods use measured spectral properties and measured water quality parameters. The semiempirical methods use spectral/optical characteristics to approximate the appropriate wavelength for the water quality parameter. The analytical method uses optical properties of the water quality parameters to develop a model for the spectral quality of the water, and this model is introduced into an equation that relates the remote sensing data, the water quality parameters, and the optical parameters. Some examples of parameters that can be measured are suspended sediments, chlorophylls (algae), DOM (humus), oil, and temperature (Table 6) (34). An example of an empirical/semiempirical equation is

$$Y = A + BX \tag{22}$$

or

$$Y = AB^X \tag{23}$$

where Y is the measured radiance, reflectance, or energy; X is the water equality parameter of interest; A is the empirically derived constant; and B is an empirically derived constant (35). An example of an analytical equation is

$$R = r_{\mathrm{i}}\frac{b}{a+b} = r_i\omega_b \tag{24}$$

where R is the reflectance, r_{i} is the radiance to reflectance conversion, a is the absorption, b is the backscattering, and ω_{b} is the backscattering albedo (34,36).

WETLAND DETECTION

The detection of wetlands has become extremely important for environmental agencies as more and more shoreline areas become developed. The main difficulty in identifying wetlands is the submerged aquatic vegetation. This vegetation can make water detection difficult with VIS and near- or midinfrared. However, thermal infrared allows comparison between aquatic vegetation and terrestrial vegetation because the water/vegetation combination has higher thermal inertia compared to that of land (12). The major limitation of this spectral region is that when the surrounding area is supersaturated with water, the thermal infrared comparison is difficult (12). Another method is to use active microwave radar data, such as SAR, and a qualitative approach to distinguish plants from open water and land.

ADDITIONAL TOPICS

Topics not covered in this article, but remain important in the area of water resources and hydrology, are land cover mapping, area delineation, slope delineation, flood forecasting, bathometry, ice and glaciers, and permafrost. Land cover mapping was discussed briefly

Table 6. Water Quality Parameters and Spectral Bands

Water Quality Parameter	Spectral Region	Note
Suspended sediments	700–800 μm(38)	Other scientists have found that optimum wavelength depends on concentration(37).
Chlorophyll (algae)	0.69 μm (red edge)	Distinction between chlorophyll and suspended sediment is difficult given the spectral data available; however, one should concentrate on the relationship between chlorophyll-a and the red edge of the spectrum(34)
Temperature	10.4–12.5 μm	
Oils	8–14 μm	Most commonly used sensors are those that are placed on airborne platforms, e.g., planes, because immediate and constant coverage is required for an oil spill; however, Landsat TM can also be used for monitoring. Spatial resolution is very important for patches and windrows. Infrared thermal remote sensing is most important for cleanups; ultraviolet is important as well because thin layers of oil emit high ultraviolet radiation patterns; passive microwave is good because oil emits more microwaves than water, but spatial resolution is poor (34).

Satellites useful for Water Resources[a]

Variable	Satellite	Central Wavelength or Frequency Required for Observation	Resolution	Coverage
Snow-covered area (SCA)	NOAA	0.62, 10.80 μm	1 km	2 per day
	SPOT	0.59, 0.69, 0.89 μm	10–25 m	16 day[b]
	GOES	0.64 μm (visible)	2 km	2 per hour
Snow depth	Nimbus 7	37 GHz	30 km	2 per hour
	DMSP			
Snow water equivalent (SWE)	SSM/I			
	MOS-1, MSR	19.3 GHz, 37.0 GHz	25 km	2 per day
		23.0 GHz, 31 GHz	23–32 km	2 per day
	ERS-1,2	C-band(5.3 GHz)V V	30 km	35 days
Wet snow	RADARSAT	SAR C-BAND(5.3 GHz) H H SAR	8–25 m	16 days[c]
Surface temperature	NOAA	12.0 μm (band 4)	1 km	2 per day
	Landsat TM	12.5 μm (band 6)	80 m	16 days
Evapotranspiration	NOAA	0.62, 0.91, 10.80, 12.0 μm	1 km	2 per day
	GOES	0.64,11.5 μm	2–8 km	2 per hour
	Meteosat			
	GOES	0.65 μm (visible)		
Precipitation	TRMM	Infrared	3 km	2 per hour
	Landsat TM	0.52, 0.60, 0.96, 0.90, 1.75, 2.35, 12.5 μm	30 m	16 days
Land cover/land use and vegetation	Landsat	0.55, 0.65, 0.75, 0.9 μm	80 m	16 days
	MSS NOAA	0.62, 0.91 μm (visible)	1 km	2 per day
	SPOT	0.59, 0.69, 0.89 μm	10–25 m	16 day[b]

Soil Moisture	RADARSAT	C-band (5.3 GHz) H H	8–25 m	16 days[c]
Groundwater	Landsat	0.95 μm (band 7, near IR)	80 m	16 days
	SPOT			
	ERS-1,2	0.59, 0.69, 0.89, μm	10–25 m	16 days[b]
	Radarsat	C-band (5.3 GHz) V V	30 m	35 days
	Landsat TM	C-band (5.3 GHz) H H	8–25 m	16 days[c]
	Landsat	0.52, 0.60, 0.69, 0.90, 1.75, 2.35, 12.5 μm	30 m	16 days
Surface Water	MSS	0.55, 0.65, 0.75, 0.9 μm	80 m	16 days

[a] Compiled from Reference (12).

[b] Coverage frequency can be up to 2–3 days in northern latitudes using the off-nadir pointing capability of the satellite.

[c] Coverage frequency can be increased depending on incidence angle.

in the opening of this article. Terrain elevation analysis from imagery remotely obtained by stereopairs and interferometry provides the main method for area and slope delineation. Flood forecasting may occur by real-time monitoring of water surface elevations with light detection and ranging (LIDAR) or by simulation of soil moisture dynamics, land surface runoff, and river routing with remotely sensed inputs of vegetation, terrain, and precipitation.

CONCLUSION

There are several limitations of remote sensing of water resources to keep in mind while delineating a water resource application. The first limitation, that parameters are never measured directly, cannot be solved easily but rather calls for an increase in confidence in calibration and validation methods for the equation and the ability to select equations/algorithms or methods proper for the particular study (2). A lack of suitable algorithms for available data can also hinder studies. To a certain extent, remote sensing is new for water resources, so data required for specific algorithms may not be accessible. Calculating parameters such as evaporation may require expensive mapping programs that cannot be afforded by certain research institutes and universities. Finally, much of VIS and IR remote sensing depends on the weather, such as the presence of clouds, and other uncontrollable factors.

APPENDIX

Common Acronyms

AVHRR	Advanced very high resolution radiometer
DEM	Digital elevation model
EOS	Earth Observing System
ERS-1,2	European Resources Satellite 1,2
GIS	Geographic Information Systems
IR	Infrared radiation
NOAA	National Oceanic and Atmosphere Administration
NDVI	Normalized difference vegetation index
PBL	Planetary boundary layer model
RADARSAT	Radar satellite
SAR	Synthetic aperture radar
SPOT	Système Probatoire pour l'Observation de la Terre
SSM/I	Special sensor microwave imager

SWE	Snow water equivalent
TIR	Thermal infrared radiation
VIS	Visible radiation

ATMOSPHERIC SCIENTISTS

U.S. Department of Labor,
Bureau of Labor Statistics

SIGNIFICANT POINTS

- Almost 4 in 10 atmospheric scientists work for the Federal Government, which is the largest employer of such workers.
- A bachelor's degree in meteorology, or in a closely related field with courses in meteorology, is the minimum educational requirement; a master's degree is necessary for some positions, and a Ph.D. is required for most research positions.

NATURE OF THE WORK

Atmospheric science is the study of the atmosphere—the blanket of air covering the Earth. *Atmospheric scientists*, commonly called *meteorologists*, study the atmosphere's physical characteristics, motions, and processes, and the way in which it affects the rest of our environment. The best known application of this knowledge is in forecasting the weather. Aside from predicting the weather, scientists also attempt to identify and interpret climate trends, understand past weather, and analyze today's weather. However, weather information and meteorological research also are applied in air-pollution control, agriculture, forestry, air and sea transportation, defense, and the study of possible trends in the Earth's climate, such as global warming, droughts, or ozone depletion.

Atmospheric scientists who forecast the weather, known professionally as *operational meteorologists*, are the largest group of specialists. They study information on air pressure, temperature, humidity, and wind velocity; and apply physical and mathematical relationships to make short-range and long-range weather forecasts. Their data come from weather satellites, weather radars, sensors, and weather stations in many parts of the world. Meteorologists use sophisticated computer models of the world's atmosphere to make long-term, short-term, and local-area forecasts. More accurate instruments for measuring and observing weather conditions, as well as high-speed computers to process and analyze weather data, have revolutionized weather forecasting. Using satellite data, climate theory, and sophisticated computer models of the world's atmosphere, meteorologists can more effectively interpret the results of these models to make local-area weather predictions. These forecasts inform not only the general public, but also those who need accurate weather information for both economic and safety reasons, such as the shipping, air transportation, agriculture, fishing, forestry, and utilities industries.

The use of weather balloons, launched a few times a day to measure wind, temperature, and humidity in the upper atmosphere, is currently supplemented by sophisticated atmospheric monitoring equipment that transmits data as frequently as every few minutes. Doppler radar, for example, can detect airflow patterns in violent storm systems—allowing forecasters to better predict tornadoes and other hazardous winds, and to monitor the storms' direction and intensity. Combined radar and satellite observations allow meteorologists to predict flash floods.

Some atmospheric scientists work in research. *Physical meteorologists*, for example, study the atmosphere's chemical and physical properties; the transmission of light, sound, and radio waves; and the transfer of energy in the atmosphere. They also study factors affecting the formation of clouds, rain, and snow; the dispersal of air pollutants over urban areas; and other weather phenomena, such as the mechanics of severe storms. *Synoptic meteorologists* develop new tools for weather forecasting using computers and sophisticated mathematical models of atmospheric activity. *Climatologists* study climactic variations spanning hundreds or even millions of years. They also may collect, analyze, and interpret past records of wind, rainfall, sunshine, and temperature in specific areas or regions. Their studies are used to design buildings, plan heating and cooling systems, and aid in effective land use and agricultural production. Environmental problems, such as pollution and shortages of fresh water, have widened the scope of the meteorological profession. *Environmental meteorologists* study these problems and may evaluate and report on air quality for environmental impact statements. Other research meteorologists examine the most effective ways to control or diminish air pollution.

WORKING CONDITIONS

Most weather stations operate around the clock, 7 days a week. Jobs in such facilities usually involve night, weekend, and holiday work, often with rotating shifts. During weather emergencies, such as hurricanes, operational meteorologists may work overtime. Operational meteorologists also are often under pressure to meet forecast deadlines. Weather stations are found everywhere—at airports, in or near cities, and in isolated and remote areas. Some atmospheric scientists also spend time observing weather conditions and collecting data from aircraft. Weather forecasters who work for radio or television stations broadcast their reports from station studios, and may work evenings and weekends. Meteorologists in smaller weather offices often work alone; in larger ones, they work as part of a team. Meteorologists not involved in forecasting tasks work regular hours, usually in offices. Those who work for private consulting firms or for companies analyzing and monitoring emissions to improve air quality usually work with other scientists or engineers; fieldwork and travel may be common for these workers.

EMPLOYMENT

Atmospheric scientists held about 7,700 jobs in 2002. The Federal Government was the largest single employer

---

of civilian meteorologists, accounting for about 2,900. The National Oceanic and Atmospheric Administration (NOAA) employed most Federal meteorologists in National Weather Service stations throughout the Nation; the remainder of NOAA's meteorologists worked mainly in research and development or management. The U.S. Department of Defense employed several hundred civilian meteorologists. Others worked for professional, scientific, and technical services firms, including private weather consulting services; radio and television broadcasting; air carriers; and State government.

Although several hundred people teach atmospheric science and related courses in college and university departments of meteorology or atmospheric science, physics, earth science, or geophysics, these individuals are classified as college or university faculty, rather than atmospheric scientists. (See the statement on **postsecondary teachers** elsewhere in the *Handbook*.)

In addition to civilian meteorologists, hundreds of Armed Forces members are involved in forecasting and other meteorological work. (See the statement on **job opportunities in the Armed Forces** elsewhere in the *Handbook*.)

TRAINING, OTHER QUALIFICATIONS, AND ADVANCEMENT

A bachelor's degree in meteorology or atmospheric science, or in a closely related field with courses in meteorology, usually is the minimum educational requirement for an entry-level position as an atmospheric scientist.

The preferred educational requirement for entry-level meteorologists in the Federal Government is a bachelor's degree—not necessarily in meteorology—with at least 24 semester hours of meteorology courses, including 6 hours in the analysis and prediction of weather systems, 6 hours of atmospheric dynamics and thermodynamics, 3 hours of physical meteorology, and 2 hours of remote sensing of the atmosphere or instrumentation. Other required courses include 3 semester hours of ordinary differential equations, 6 hours of college physics, and at least 9 hours of courses appropriate for a physical science major—such as statistics, chemistry, physical oceanography, physical climatology, physical hydrology, radiative transfer, aeronomy, advanced thermodynamics, advanced electricity and magnetism, light and optics, and computer science. Sometimes, a combination of education and appropriate experience may be substituted for a degree.

Although positions in operational meteorology are available for those with only a bachelor's degree, obtaining a second bachelor's degree or a master's degree enhances employment opportunities and advancement potential. A master's degree usually is necessary for conducting applied research and development, and a Ph.D. is required for most basic research positions. Students planning on a career in research and development need not necessarily major in atmospheric science or meteorology as an undergraduate. In fact, a bachelor's degree in mathematics, physics, or engineering provides excellent preparation for graduate study in atmospheric science.

Because atmospheric science is a small field, relatively few colleges and universities offer degrees in meteorology or atmospheric science, although many departments of physics, earth science, geography, and geophysics offer atmospheric science and related courses. Prospective students should make certain that courses required by the National Weather Service and other employers are offered at the college they are considering. Computer science courses, additional meteorology courses, a strong background in mathematics and physics, and good communication skills are important to prospective employers. Many programs combine the study of meteorology with another field, such as agriculture, oceanography, engineering, or physics. For example, hydrometeorology is the blending of hydrology (the science of Earth's water) and meteorology, and is the field concerned with the effect of precipitation on the hydrologic cycle and the environment. Students who wish to become broadcast meteorologists for radio or television stations should develop excellent communication skills through courses in speech, journalism, and related fields. Those interested in air quality work should take courses in chemistry and supplement their technical training with coursework in policy or government affairs. Prospective meteorologists seeking opportunities at weather consulting firms should possess knowledge of business, statistics, and economics, as an increasing emphasis is being placed on long-range seasonal forecasting to assist businesses.

Beginning atmospheric scientists often do routine data collection, computation, or analysis, and some basic forecasting. Entry-level operational meteorologists in the Federal Government usually are placed in intern positions for training and experience. During this period, they learn about the Weather Service's forecasting equipment and procedures, and rotate to different offices to learn about various weather systems. After completing the training period, they are assigned a permanent duty station. Experienced meteorologists may advance to supervisory or administrative jobs, or may handle more complex forecasting jobs. After several years of experience, some meteorologists establish their own weather consulting services.

The American Meteorological Society offers professional certification of consulting meteorologists, administered by a Board of Certified Consulting Meteorologists. Applicants must meet formal education requirements (though not necessarily have a college degree), pass an examination to demonstrate thorough meteorological knowledge, have a minimum of 5 years of experience or a combination of experience plus an advanced degree, and provide character references from fellow professionals.

JOB OUTLOOK

Employment of atmospheric scientists is projected to increase about as fast as the average for all occupations through 2012. The National Weather Service has completed an extensive modernization of its weather forecasting equipment and finished all hiring of meteorologists needed to staff the upgraded stations. The Service has no plans to increase the number of weather stations or the number of meteorologists in existing stations. Employment of meteorologists in other Federal agencies is expected to remain stable.

On the other hand, job opportunities for atmospheric scientists in private industry are expected to be better than for those in the Federal Government over the 2002-12 period. As research leads to continuing improvements in weather forecasting, demand should grow for private weather consulting firms to provide more detailed information than has formerly been available, especially to weather-sensitive industries. Farmers, commodity investors, radio and television stations, and utilities, transportation, and construction firms can greatly benefit from additional weather information more closely targeted to their needs than the general information provided by the National Weather Service. Additionally, research on seasonal and other long-range forecasting is yielding positive results, which should spur demand for more atmospheric scientists to interpret these forecasts and advise weather-sensitive industries. However, because many customers for private weather services are in industries sensitive to fluctuations in the economy, the sales and growth of private weather services depend on the health of the economy.

There will continue to be demand for atmospheric scientists to analyze and monitor the dispersion of pollutants into the air to ensure compliance with Federal environmental regulations outlined in the Clean Air Act of 1990, but related employment increases are expected to be small. Opportunities in broadcasting are rare and highly competitive, making for very few job openings.

EARNINGS

Median annual earnings of atmospheric scientists in 2002 were $60,200. The middle 50 percent earned between $39,970 and $76,880. The lowest 10 percent earned less than $30,220, and the highest 10 percent earned more than $92,430.

The average salary for meteorologists in nonsupervisory, supervisory, and managerial positions employed by the Federal Government was about $74,528 in 2003. Meteorologists in the Federal Government with a bachelor's degree and no experience received a starting salary of $23,442 or $29,037, depending on their college grades. Those with a master's degree could start at $35,519 or $42,976; those with the Ph.D., at $51,508. Beginning salaries for all degree levels are slightly higher in areas of the country where the prevailing local pay level is higher.

RELATED OCCUPATIONS

Workers in other occupations concerned with the physical environment include **environmental scientists and geoscientists, physicists and astronomers, mathematicians**, and **civil, chemical**, and **environmental engineers**.

RAIN SIMULATORS

Joseph Holden
University of Leeds
Leeds, United Kingdom

Rain simulators have been extensively used in hydrological, pedological, and geomorphological problems (1−13). Simulators allow much greater control of the rainfall variable for experimental purposes and have been used in both field and laboratory applications (13). The amount, intensity, and duration of rain can be controlled, along with other parameters such as drop-size distribution and water chemistry, to varying degrees, depending on the system of application. Unlike a ring infiltrometer, the surface does not pond immediately but will only do so at some later stage, if the input is great enough. The time to ponding will depend on the application rate as well as on the hydraulic properties of the soil. Surface runoff can be collected to determine infiltration rates (by subtracting surface runoff rates from application rates) and erosion, either as a whole sample for smaller plots or in a subsampling strategy for larger plots.

TYPES OF RAINFALL SIMULATORS AND CHOICE OF APPROPRIATE EQUIPMENT

There is a range of simulator designs, and a database catalogue has been developed incorporating design information by the British Geomorphological Research Group (www.geog.le.ac.uk/bgrg). Some other designs are published in Costin and Gilmour (14); Romkens et al. (15); Bowyer-Bower and Burt (16); Esteves et al. (17); and Waddington and Devito (18). There are two rainfall simulator systems: spray nozzles (including rotating sprays) and drip-screens. Spray systems generally supply rainfall in pulses to the ground (14), and rotating sprays deliver rainfall across a large surface area although intensity usually decreases with distance from the rotating nozzle. The spray-type systems often provide rainfall at terminal velocities which approach that of natural rainfall. Drip systems use hypodermic syringes (15) or other drop formers across a fixed grid to produce rainfall across relatively small surface areas. The drop formers are often not raised high enough to allow representative terminal velocities, but they generally allow a constant rainfall rate whose drop sizes are more easily controlled than in the spray systems (16).

Various factors, including money, time available, the purpose of the experiment, and the local climatic conditions whose simulation is desired, influence the choice of simulator. Table 1 lists some of the factors of importance in choosing a type of rainfall simulator and the most suitable type of simulator for each factor. The amount of water used to provide rainfall at any given intensity is generally much less for a drip-screen design than for spray-type simulators (16). This may be crucially important in remote arid or semiarid areas. The use of a drip-type simulator generally means, however, that smaller plot areas will be used for analysis. Using appropriate pressure regulators, rain simulators in the field or laboratory can be attached to a mains water supply. It usual to control the amount and intensity of rain during a simulation by using a pressure regulator, but often a simple tap connected to a calibrated manometer board will suffice (16).

Table 1. Desirable Characteristics of a Rainfall Simulator

Desired Attribute	Best Suited Simulator
Easily transportable	Drip-type
Efficient use of water	Drip-type
Protection from the wind to increase accuracy of rainfall application volumes into selected plot	Drip-type
Reproduction of high intensity rainfall to reflect expected natural conditions	Spray-type
Reproduction of low intensity rainfall to reflect expected natural conditions	Drip-type
Long duration rainfall	Drip-type
Achievement of 'natural' terminal velocity	Spray-type
Control over drop-size distribution	Drip-type (but not very flexible)
Attainment of desired drop size relative to rainfall intensity (i.e., flexibility)	Spray-type
Accurate replication of rainfall parameters	Drip-type
Uniformity of rainfall across the whole plot	Drip-type
Large plot area	Spray-type
Adaptability to difficult terrain and vegetation	Spray-type

Drop-Size Distribution

Drops of a uniform size formed by a rain simulator do not represent those in natural rainfall. If the experiment requires simulating a natural drop-size distribution (19–21), then it is often necessary to have a wire mesh that scatters and breaks up drops into different sizes. For drip-type simulators, Bowyer-Bower and Burt (16) found that suspending a wire mesh below the drop former of 3 mm × 3 mm spacing and 1 mm diameter wire was suitable. Salles et al. (22) demonstrated that it is necessary to sample at least 10,000 drops to estimate the drop-size distribution from a rain simulator at an accuracy of 3% or less. Several methods are available for examining drop-size distribution, including light diffraction and filter paper collection. An economic and simple approach is to allow drops to fall into finely sieved flour and then to bake the pellets and sieve them through meshes of different diameters. Larger intensity rainfall is associated with larger raindrop size (21), but it is often difficult to replicate changing drop sizes as intensity is altered using rain simulators, although spray-type simulators are more flexible.

Achievement of Terminal Velocity and Energy Characteristics of the Rain

Where erosion or soil crusting processes are the focus of study, it is essential to know the kinetic energy of the raindrops produced by a rain simulator (23). Kinetic energy is crucial for soil detachment and transport. Natural rain normally falls from great heights by which time the droplets have achieved terminal velocity (maximum velocity in air—they cannot fall any faster because air resistance prevents any further acceleration due to gravity). Droplets that fall at terminal velocity have more kinetic energy than those falling from small heights. Larger drops require a greater height to reach their terminal velocity. Droplets of 1 mm in diameter require around 2.5 m, and droplets of 2 mm in diameter require around 6 m to reach terminal velocity. Thus, if a rainfall simulator is not positioned high enough, then the kinetic energy of the drops will be significantly less than that of natural rainfall. Knowledge of the drop size distribution is therefore important for determining the rain splash energy provided.

Spatial and Temporal Coverage of a Plot

For experiments that are concerned only with some aggregate or mean effect of simulated rain, then variations in rainfall delivery across a plot may be unimportant. Where rainfall simulation is being used to study small-scale processes that are themselves spatially variable (such as rill initiation), then knowledge of the simulator's inherent variability is vital (24). Rainfall delivery may be measured quite simply by placing a series of collectors across a trial plot and recording rainfall delivery to the ground across a range of rainfall intensities and durations. Many spray systems have greater intensity rains closer to the spray nozzle, and intensity declines as the distance from the nozzle increases.

Typical Measurements

Depending on the nature of the experiment, it is usually necessary to create a bounded plot when simulating rain. This is particularly important if a parameter of interest is infiltration. It is usual to bound the plot on three sides and then to collect the surface runoff from the unbounded fourth (downslope) side of the plot. The bounding prevents leakage out of the plot, so that more accurate estimates of infiltration rates can be made. Measurement of the surface runoff can indicate the infiltration rate within the plot, as long as the application rate is known: At steady state, Infiltration = Rainfall intensity—Surface Runoff. Units of length are used for the three variables in the equation, and so one must remember to divide the surface runoff volumes by the plot area. There will be a time lag in response so that in the early stages of the experiment when the soil surface is wetting and water is stored in detention pools, then the previous equation will not hold. The equation also ignores evaporation and storage on vegetation surfaces. If the interest is in infiltration rates, it is often necessary to run the experiment long enough to allow runoff rates to stabilize. Early in the experiment, runoff rates are likely to increase over time, but in theory should eventually stabilize if the rainfall intensity remains constant. It should then be possible to apply the theoretical infiltration curve of Philip (25) which is an exponential curve fitted through the first and last data point of the order of $I = A + Bt^{-0.5}$, where I = infiltration rate at time t and A and B are constants. This equation may be solved using simultaneous equations (i.e., equations at two different times) to allow constants A and B to be evaluated.

In practice, however, surface runoff from the plot on most slopes of interest will rarely stabilize completely because of surface ponding and episodic cut and fill of microtopographical features on the surface and the burst out of water followed by a period of pool refill and microchannel change (12). It may therefore be better to use a mean value across a sample of data points to estimate infiltration. If the rainfall intensity is lower than the infiltration rate into the surface of investigation, then it may be that no surface runoff is observed. If surface runoff is collected, it is also possible to collect sediment, solutes, and microorganisms moved by the runoff.

Typically, results are scaled up to the hillslope and sometimes the catchment scale. However, this should be done only with great caution. First, most hillslopes have a high natural heterogeneity such that plots may not be representative. Second, coupling of water, sediment, nutrients, or microorganisms within a plot may not be the same as on a hillslope. Sediment moved from the top to bottom of a plot, for example, may not move from the top to bottom of a hillslope during a real storm because there may be natural zones of deposition and erosion and larger hillslopes may not provide the good coupling seen in a plot-scale experiment.

Almost all field rainfall simulator experiments have collected runoff solely from the surface layer and have disregarded any lateral through-flow in deeper soil layers. However, using an appropriate apparatus, it is possible to investigate soil water flow mechanisms using a rain simulator by digging a pit at the lower end of the plot and collecting runoff from different layers of the subsurface (12). However, pit disturbance may change the local hydrologic gradients resulting in unwanted changes of the natural processes, particularly, if the layers of investigation are deep below the surface.

IMPORTANCE OF RAINFALL INTENSITY USED

Some rainfall simulators can reproduce natural rainfall typical of tropical storms across 50-m plots (e.g., Reference 17 reproduced 70 mm h^{-1} storms), whereas others can reproduce gentle rains typical of temperate parts of the world whose intensities are as low as 3 mm h^{-1} (12). The choice of rainfall intensity used in a simulation may be very important, and many hydrologic studies have ignored this issue. Most studies have simulated only one rainfall intensity. Some studies, however, found that as rainfall intensity is increased on a simulation plot, the steady infiltration rate also increases (12,26). This is very important and has major implications for conclusions drawn from experiments. There are likely to be physical reasons for this phenomenon, including increased ponding development on the soil surface as rain intensity is increased that leads to a greater hydraulic head that forces more water into the soil (27–29); increased ponding that results in dispersing and suspending soil crusts and surface particles, allowing pores to unblock; and most soil plots are nonuniform; some parts allow much more infiltration than others (30). Therefore, if rainfall intensity is increased, then proportionally more water may infiltrate into particular parts of a plot. This will result in an increased plot-averaged value of the infiltration rate. Thus, those experiments that have simulated unrealistic rainfall intensities (e.g., 150 mm h^{-1} in the British Isles where rainfall very rarely exceeds 12 mm h^{-1}) may have unrealistic results. The results from an intense rainfall simulation may assume that the infiltration capacity of the soil is 80 mm h^{-1}, for example, but if a more realistic intensity had been used, then the result may be an infiltration capacity of 6 mm h^{-1}. Thus, conclusions drawn about runoff production in soil water processes, irrigation, and erosion may be misleading, and care should be taken in choosing an appropriately representative range of rainfall intensities.

SNOW DENSITY

Pratap Singh
National Institute of Hydrology
Roorkee, , India

Density is one of the fundamental and important characteristics of snow. It is defined as the mass of snow per unit volume. To determine the density of snow, a core sample of snow is extracted from the accumulated snow on the ground using a snow sampler of known volume. The extracted snow sample is weighed and its mass is determined. The density of the sampled snow is determined by dividing the mass by the volume. The most common unit used for representing the density is g/cc or kg/m^3.

Freshly fallen snow is very light and has a very low density. The density of fresh snow varies from about 0.01 to 0.20 g/cc, but a rule of thumb often used for the average density of fresh snowfall is 0.1 g/cc when actual measurements are not made. Once snow accumulates on the ground and stays over time, the density of the snow increases. Metamorphic changes in snow, which involve readjustment of the shape and size of crystals, contribute to changes in the density of snow. Metamorphism also results from the compaction of snow caused by the pressure of overlying layers of snow and can also be accelerated by strong winds, warm temperatures, and intermittent melting of the snow cover. The density of snow changes significantly during the first 2–3 months when transformation of fresh snow into fine granular snow continues and recrystallization processes dominate. During a period of time, snow first transforms into firn, defined as snow that has survived for at least one melt season. When climatic conditions allow snow to remain

Table 1. Typical Densities of Snow in Different Forms[a]

Snow Type	Density g/cc
New snow at low temperature in calm air	0.01–0.03
New snow immediately after falling in calm air	0.05–0.07
Damp new snow	0.10–0.20
Settled snow	0.20–0.30
Depth hoar	0.20–0.30
Windpacked snow	0.35–0.40
Firn	0.40–0.65
Very wet snow and firn	0.70–0.80
Glacier ice	0.85–0.95

[a] Ref. 1.

for several years, it gradually transforms into glacier ice. Glacier ice is impermeable to air and water; some air is present only as bubbles. Glacier ice is the most compacted form of snow. It attains the maximum density at this stage, which is very close to the density of water, 1.0 g/cc. The density of snow at different stages is shown in Table 1.

To estimate the amount of water stored as snow in a basin, information on the density and depth of the snowpack is needed. Usually, such information is collected through snow surveys, which are organized to obtain the density and depth of snow at representative points in the basin. Snow density is determined for the total depth of snowpack because it varies with depth. The average density of a snowpack is determined by taking the average of the snow density obtained at different depth levels of the snowpack. The snow water equivalent at any point can be obtained by multiplying the snow density by the depth. In addition to the texture and wetness of snow, information on the density of snow near the surface is also required to ascertain the suitability of snow for skiing, which is one of the most important recreational activities in Europe and North America.

FLATTOP MOUNTAIN SNOTEL SNOWPACK: WATER YEAR 2004

Global Change Research
Program—U.S. Geological
Survey

These materials prepared by the Global Change Research Program—U.S. Geological Survey, Northern Rocky Mountain, Glacier Field Station. Dan Fagre, Program Coordinator, email: dan_fagre@usgs.gov. For more information, visit the Glacier Field Station—Global Change Research Program web site.

The Flattop Mountain SNOTEL (SNOw TELemetry) station is one of nearly 600 similar stations operated throughout the western United States by the Natural Resources Conservations Service (NRCS, U.S. Department of Agriculture). These stations measure and record Snow Water Equivalent (SWE), which is the weight of snow water equivalent to inches of water. Most SNOTEL sites also measure temperature and precipitation; many now measure snow depth as well. Various agencies and organizations use the data from the stations to forecast water availability, floods, and avalanche hazard.

The Flattop Mountain SNOTEL station has operated since October 1st, 1969. To help calculate water storage and availability during agricultural growing seasons, the data are compiled by water year; a water year runs from 1 October - 30 September. SWE records from the station extend for 33 water years (1970–2002). Precipitation records from the station start water year 1979, with temperature records starting water year 1983.

The Flattop Mountain SNOTEL station is located at approximately 6300 feet in elevation on Flattop Mountain, a high plateau between the Lewis and Livingston Ranges in Glacier National Park, Montana. The site is three air miles south of the Continental Divide. During the winter, complex combinations of weather and terrain determine snowfall at the site. Westerly weather systems predominate, bringing moisture from the Gulf of Alaska or Pacific Ocean. Less frequent northerly systems spill drier Arctic air through passes on the Continental Divide as they slide south along the Rocky Mountain Front. Flattop Mountain's position between the Livingston and Lewis Ranges amplifies the effects of these large-scale weather systems; the two ranges rise 2–4000 feet above the site and orographically wring moisture from both westerly and upslope easterly storms. Flattop Mountain is a useful indicator of snowfall throughout Glacier National Park because it is subject to the factors that influence conditions elsewhere in the park.

The graph below shows the current water year SWE at Flattop Mountain along with snow depth and average daily temp:

Since the last update of this webpage (May 10th), the snowpack at Flattop Mtn. SNOTEL station continued its annual melt. Conditions in May and early June have generally been wet, with average temperatures. The station recorded. 1" or more of precipitation on 27 of 44 days, for a total of 8.3" of precipitation, 5.2" of that

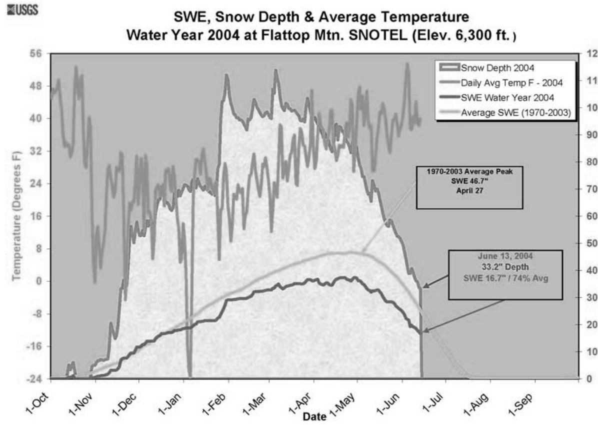
---

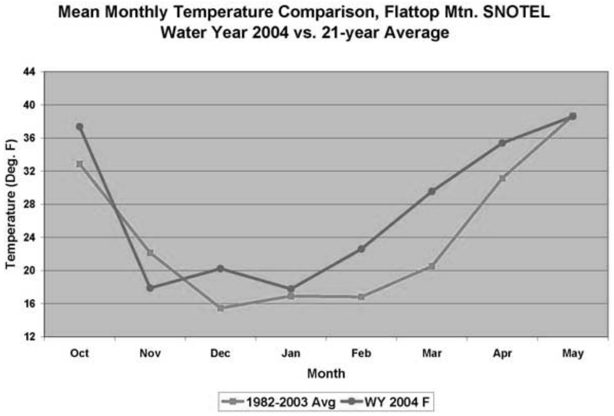
during May. Nearly all of that fell as rain; the station has measured just 1" of SWE gain in May and .5" in June. The highest one-day rainfall was .9" on May 28th, while the longest stretch of days with precipitation was May 25th–May 30th. It was followed by the longest period without precipitation, May 31st–June 4th. The precipitation of the past four weeks is common for this time of year; the station typically shows a secondary peak in precipitation known locally as the "June Monsoon."

The station recorded the warmest temperatures early in the month. After a mid-month winter storm, temperatures remained cool. Maximum and minimum temperatures for May were 16.7 C (60 F) on May 1st and -8 C (17.6 F) on May 12th. The highest mean daily temperature for the month was 8.2 C (47.8 F) on May 7th. The mean monthly temperature was 3.7 C (38.6 F), which is identical to the mean monthly temperature for May for the 21 years (1982–2003) that the station has recorded temperatures.

The average temperatures for the month ended a trend of above-average temperatures that dominated the winter. November has so far been the only month of the 2004 Water Year with mean temperatures below average. From December through April, mean monthly temperatures have remained above average, with December and January warmer than the mean (2.6 C/4.7 F and .5 C/1 F respectively), and February and March substantially warmer than average (3.2 C/5.8 F for February; 5 C/9 F for March). The difference between 2004 and the 21-year average narrowed in April and closed in May. The Mean Monthly Temperature Comparison Graph below shows this pattern. While the graph shows a relatively normal curve to the temperatures, the curve appears shifted a month forward. That is, early winter temperatures are typical mid-winter temperature, and late winter/early spring temperatures are typical of late spring. A. pdf version of this graph is available at Mean Monthly Temperature Graph.

The warm temperatures of the winter had a significant effect on the snowpack at the station. Despite a dry February, SWE gain for February-April was 15.9", which is average. The warm temperatures, however, have resulted in 7" of SWE loss in the same period, leaving the snowpack considerably below average when it peaked on April 20th, a week earlier than the 34-year average of April 27th. The SWE total was 37.4", or 81% of the 34-year average of 46.74". In addition to the 7" of SWE loss in March and April, the station lost 1.2" of SWE in October, for a total loss of 8.2"—nearly enough to make up the 9.3 inch deficit on April 20th. It's thus reasonable to conclude that the below average snowpack at Flattop Mtn. SNOTEL is primarily the result of warm temperatures rather than lack of precipitation. A graph showing the monthly SWE gain at Flattop Mountain SNOTEL is below; a. pdf version of the graph can be found at Monthly SWE 2004.

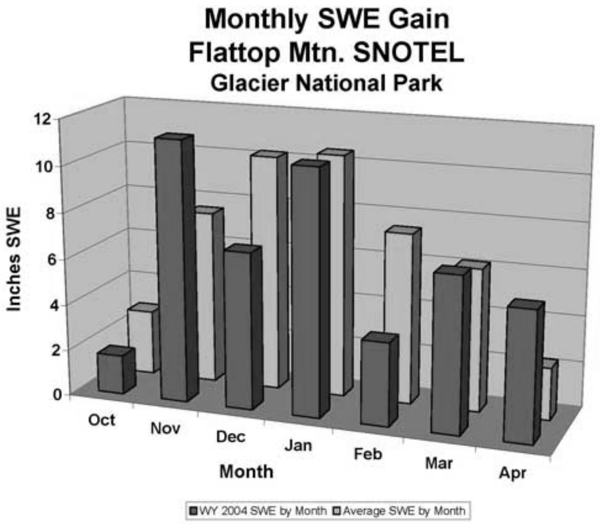


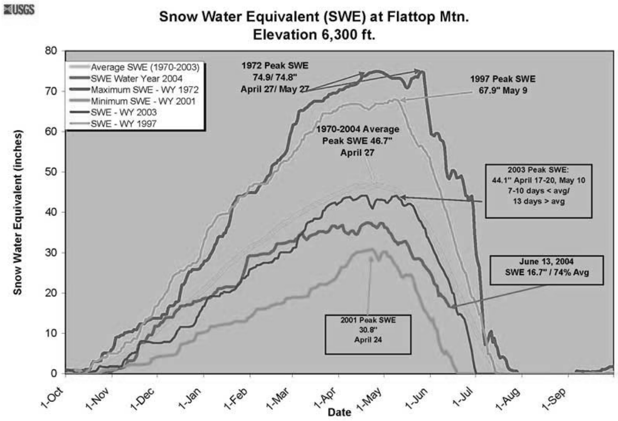


Since April 30th, the snow pillow at Flattop has recorded 22" of SWE loss and 1.5" of SWE gain. The station measured 13" of SWE loss and 1" of SWE gain in May. The greatest SWE loss occurred May 18th (1.1") and June 3rd (1.4"). As of midnight, June 14th, the SWE total at Flattop was 16.7", which represents 74% of the 34-year average of 25.3". Snow depth was 33". Despite the below-average SWE total, conditions at the station are well within the range of the past 34 water years. The maximum SWE recorded on this day (Julian Day 165) was 48.6" in 1974; the minimum was 0" in 1987, a 48.6" range. All told, there have been 12 years in the 34-year history of the station in which SWE total on this date was lower. The SWE total on this date last year was 22.6", with a snow depth of 44.5". A graph comparing SWE for significant water years is below.

A more detailed. PDF version of this graph is available for printing or viewing at SWE Comparison Graph.

In its June10th El Nino/ENSO Discussion, the National Weather Service Climate Prediction Center (CPC) reported that oceanic and atmospheric conditions In May throughout the Pacific Basin were typical of neutral phase of the El Nino Oscillation. The CPC reported that Sea Surface Temperature (SST) anomalies have been warmer than average in the western and central equatorial Pacific and cooler than average in the eastern equatorial Pacific. These anomalies have led to precipitation and wind speed gradients across the equatorial Pacific, with precipitation and wind speeds generally higher in the western portion of the equatorial Pacific. Forecasts of conditions for the next 3 months are split, with some models predicting neutral conditions and others El Nino conditions. The CPC concluded that ENSO-neutral conditions are more likely through August 2004, while noting that trends after that are uncertain.





For more information, see the climate prediction center's El Nino/ENSO Discussion.

Also available for viewing are graphs for Water Year 2003, Water Year 2002, Water Year 2001, Water Year 2000, and Water Year 1999.

For details on how snowpack affects the spring opening of Logan Pass, visit our **Spring Opening of the Going-to-the-Sun Road** web page (Logan Pass is located at 6646 feet elevation along the upper edge of the McDonald drainage, approximately 10 miles southeast of the Flattop Mountain SNOTEL station).

- For the most recent SNOTEL data, graphs, and maps of snow distribution visit the Montana NRCS - Snow, Water, and Climate Services Snow Products web page—they provide *snow depth!* data for the Flattop Mountain SNOTEL station under the Daily Products-Reports heading. Also, their detailed map of Montana SNOTEL sites is a great resource.

SNOW AND SNOWMELT

Pratap Singh
National Institute of Hydrology
Roorkee, India

Snow is a solid form of precipitation. The formation of snow crystals inside a cloud depends on the presence of ice nuclei, water vapor, motion of the cloud, and the temperature of the cloud. Snow crystals are formed when the cloud temperature is below freezing. These crystals experience diffusional, accretional, and aggregational growth inside the cloud. At temperatures greater than about $-5\,^{\circ}\mathrm{C}$, crystals usually stick together, and aggregation of ice crystals forms snowflakes. Snowflakes obtain their maximum size when the temperature of a cloud is near $0\,^{\circ}\mathrm{C}$. Aggregation of ice crystals ceases at temperatures below $-20\,^{\circ}\mathrm{C}$. Due to changes in the ambient condition of the cloud, the size and form of the crystals change when they descend through a cloud. In a typical cloud, a snowflake of 1 mm diameter can grow to 10 mm in about 20 minutes. Because of the irregular shapes of snowflakes, measurement of their linear dimensions is difficult. The maximum diameter of snowflakes may range from 0.1 mm to several centimeters.

Snow falls from the clouds mainly in the form of branched hexagonal crystals or stars. Other observed shapes include hexagonal rods, needles, and plates. Snowflakes have a large surface area and fall slowly compared with raindrops. Therefore, snowflakes scavenge more atmospheric aerosols than rain. Precipitation as snow occurs when the atmospheric temperature is near $0\,^{\circ}\mathrm{C}$ or less. Compared to rainfall, snowfall occurs more uniformly, but its distribution on the ground is highly influenced by wind. To obtain the water equivalent of snow, the actual depth of snow unaffected by wind and its density are needed.

Accumulation of snow on the ground leads to the development of a snowpack, which stores water in the form of snow. Depending upon climatic conditions, snow on the ground can stay for a period as long as several months. The global distribution of snow shows that a major portion of the Northern Hemisphere is covered by snow during winter. Snow has great scientific interest because of its practical importance and utility in many fields, especially, in water resources, climate, and winter sports. For many countries, such as the United States, Canada, India, China, Pakistan, Afghanistan, Russia, Nepal, and European countries, snowmelt runoff is a vital source of water for drinking, irrigation, and hydropower generation. Several important rivers, such as the Columbia River in the United States and Canada, the Rhine River in Europe, and the Indus River in Asia, get substantial contributions from snowmelt runoff. Melting snow provides more than 70% of the water supply for the western United States (1).

In general, snow starts melting in the spring when the temperature begins rising. The depth and extent of the snowpack is reduced due to snow melting, and water is released from the snowpack. Snowmelt runoff estimates are needed for forecasting seasonal water yields, river regulation, reservoir operation, determination of design floods, design of hydrologic and hydraulic structures, and planning flood control programs. The snowmelt is estimated either using the energy balance approach or the temperature index method. The energy balance method requires information on radiation energy, sensible and latent heat, energy transferred through rainfall onto the snow, and heat conduction from the ground to the snowpack. When all the components for an energy balance computation are known, the melt rate can be expressed as (2)

$$M = \frac{1000\,Q_m}{\rho_w L \beta} \tag{1}$$

where M is the depth of melt water (mm d^{-1}), Q_m is the net energy flux available for melting ($\mathrm{kJm^{-2}\,d^{-1}}$), L is the latent heat of fusion (333.5 kJ kg^{-1}), ρ_w is the density of water (1000 kg m^{-3}), and β is the thermal quality of the snow. The thermal quality of snow depends on the amount of free water content (generally 3–5%) and the temperature of the snowpack. Assuming $\beta = 0.97$ for a thermally ripened snowpack, Eq. 1 reduces to

$$M = 0.0031\,Q_m \tag{2}$$

Snowmelt follows an almost diurnal pattern of energy availability, and thus, it is possible to determine the diurnal variation in snowmelt by applying the diurnal distribution of energy received on the snow surface. The albedo, the most important parameter controlling the absorption of solar radiation, is very high for snow. For fresh snow, the albedo is about 0.80–0.90, suggesting that most of the short-wave radiation is reflected back to the atmosphere from the snow surface.

In the absence of detailed energy data for computing snowmelt, the temperature index method is considered the best substitute for the energy balance and is widely used. The air temperature, expressed as degree-days, is used for snowmelt computation. Temperatures are the most readily available data; therefore, the temperature index method is extensively used. The most common expression for estimating snowmelt using temperature is given as

$$M = D(T_i - T_b) \tag{3}$$

where M is the depth of melt water (mm d^{-1}) produced in unit time, D is the degree-day factor (mm $^\circ\mathrm{C}^{-1}$ d^{-1}), T_i is the index air temperature ($^\circ$C), and T_b is the base temperature (usually, $0\,^\circ$C). Daily mean temperature is most commonly used as an index of temperature for snowmelt. The degree-day factor is used to convert the degree-days to the depth of snowmelt. A wide range of degree-day factors (0.7–9.2 mm $^\circ\mathrm{C}^{-1}$ d^{-1}) has been reported in the literature. However, the majority of the reported values of the degree-day factor range from 3–5 mm $^\circ\mathrm{C}^{-1}$ d^{-1} (2). The degree-day factor is influenced by the physical properties of the snow and, therefore, changes with time. Usually, temperature data used for melt estimation are available at a few locations in a basin. These available temperatures can be interpolated/extrapolated to different altitudes using the temperature lapse rate (usually, 0.65 °C/100 m).

Snow melts on the upper surface of the snowpack exposed to the atmosphere. In some cases, a little melting is also possible from the lower surface of the snowpack due to ground heat transfer. Snow is a porous medium, and melt water generated on the surface percolates through the snowpack before appearing as runoff. In the beginning of the melt season, the upper part of the snowpack may be warm (0 °C), but the lower part may be cold (subfreezing). Under such conditions, melt water produced on the surface may freeze in the snowpack to raise the temperature to 0°C. Unless the whole snowpack is isothermal at 0°C, no melt runoff is produced.

SNOW SURVEYS

Pratap Singh
National Institute of Hydrology
Roorkee, India

The basic objective of conducting snow surveys is assessing the spatial distribution of the snow water equivalent accumulated in the basin at a specific time. The distribution of snow is affected by several factors, including topography, orientation, vegetation, and wind speed. During strong winds, the drifting and blowing of snow create a highly uneven spatial distribution of snow depth. Therefore, to account for uneven distribution of snow in a basin, snow surveys are needed. Snow surveys are primarily a field activity that include determining the depth and vertically integrated density. An estimate of the snow water equivalent at a site is computed by multiplying the snow depth by the density of the accumulated snow. Snow surveys are made at regular intervals during both accumulation and ablation periods. Snow surveys conducted just after winter are considered especially important because they provide information about the total snow water equivalent accumulated during the winter. Such information helps in assessing the water resource potential of the deposited snow and is used for forecasting the volume of water expected from snowmelt.

The distribution of the snow water equivalent is needed as input to snowmelt models used for predicting runoff. In addition to hydrologic applications, agricultural, transportation, and recreational activities also require such data (1).

To carry out snow surveys, first, a snow course is established in the basin. The snow course represents a preselected line of marked sampling points in the basin. It is selected by considering representative sites to provide a reliable index of the water stored as snow across the entire basin. Based on the topographical features of the basin, the length of the snow course and a suitable number of observations are chosen for snow surveying. Once the snow course is established in the basin, measurements are repeated every year on the same snow course. Each sampling point of a snow course is located by measuring its distance from a reference point marked on a map. In mountainous regions, snow is distributed much more unevenly and therefore, the length of a snow course is shorter, say, only a few hundred meters, compared to flat regions. Moreover, sampling points are closely located in mountainous areas. The average of the snow water equivalent at all sampling points on the snow course gives information on the availability of water in the basin in the form of snow. Depending on the area covered by surveying, surveys can be made by surveyors using snowshoes, skis, or snow vehicles.

The most common instruments used for snow surveying include a graduated tube that has a snow cutter fixed at its lower end and a balance for determining the weight of the snow sample. The extracted core is retained in the sampler, and the sampler plus core is weighed. The weight of the empty sampler is predetermined. Therefore, the difference in weight with and without the core gives the value of the snow water equivalent of the core. Some instruments, such as the spring balance, give a direct value of the snow water equivalent of a sample when it is weighed. Proper documentation of records is made after sampling the site. In addition to the depth, density, and snow water equivalent for each sampling site, the snow course number and details of site (latitude, longitude, and elevation), weather conditions, vegetation, etc., are also recorded. Such data help in interpreting data collected. The date and timing of the beginning and end of the snow surveys and name of the snow surveyor are also recorded. A complete set of information should be prepared in the desired format just after finishing snow surveys.

An alternative method used for surveying the snow is based on the detection of natural gamma radiation emitted from the ground surface. The gamma radiation flux near the ground originates primarily from natural radioisotopes in the soil. Potassium, uranium, and thallium in the soil are the main sources of radiation. Typically, more than 95% of the gamma radiation is emitted from the top 20 cm of soil. Snow on the ground attenuates the emission of natural gamma radiation from the earth's surface, and the magnitude of attenuation provides an estimate of the snow water equivalent. A greater water equivalent of the snow on the ground will provide a higher attenuation of radiation. Therefore, presnow or no-snow measurements of gamma radiation level are required along the traverse to be followed for surveying. This approach can be used for a ground survey as well as for an aerial survey by aircraft. In a ground survey, a hand carried detector provides a means for measuring the averaged water equivalent along the length of the snow course. The equipment includes a portable gamma-ray spectrometer that uses a small scintillation crystal to measure the rays across a wide spectrum. Recently, radars are also being used for estimating snow water equivalent in basins. Such a radar is installed on a small carrier attached to a snow scooter, that is driven over the snow following the snow course.

In aerial natural gamma radiation surveys, a gamma-ray sensor and a recording device are installed in a low-flying aircraft. Flying of aircraft along the predetermined line is very essential in this type of survey because a relatively small deviation from the flight line may introduce errors due to radiation from other types of rocks. Thus, the flight line must be selected very carefully, so that the aircraft can follow it from year to year. Such aerial surveys may be made at altitudes up to 300 m but are most accurate at the lowest altitude possible for the terrain because of significant atmospheric attenuation of the radiation. This approach is considered the most reliable for level terrain but can also be used for hilly areas where elevation differences up to 400 m can be surveyed. There are some advantages and disadvantages of this approach. The disadvantage is that the aerial survey can be used only to measure the water equivalent of 10 to 100 mm of show (2). The advantage of natural gamma radiation method is that manual observations of the depth, density, or snow water equivalent are not required and a larger area can be surveyed, in a short time.

INTRODUCTION

Periodicity analysis is a natural and integral part of meteorological studies on different timescales. Numerous studies have focused on the possible cyclicity of several meteorologic data and/or phenomena, such as wind velocities, atmospheric pressures, sunspots, hurricanes, and currents (1–4).

In numerous coastal areas, winter storms are common meteorologic phenomena characterized by wind measuring 10 or higher on the Beaufort scale (89 km per hour, 55 miles per hour). Storm periods are a significant problem for coastal managers; they cause considerable property damage to beach–nearshore profiles with tourist-economic uses, fisheries, harbors, private vacation homes, and public earthworks (5). Their effects may vary over successive sectors of the same coast with different hydrodynamic features (6,7). These events increase coastal erosion and move sands rapidly offshore, whereas lower energetic conditions may cause gradual beach accretion (8). Consequently, managers need tools (i.e., event periodicity, sediment transport, modeling approach) to evaluate the possible consequences (9–11).

In this article, we analyze some mathematical procedures used in time series analysis. These robust methods are applied to calculate an approach to critical storm periodicity on the southwestern Spanish coast.

THE STATISTICAL BASIS FOR CRITICAL STORM PERIOD ANALYSIS

Introduction: The Predicting Nature

Statistical techniques permit us to analyze the structure and behavior of natural phenomena, their relationships, and temporal evolution. In this last case, high variability levels appear in the time series analysis, and consequently some statistical approaches may be useful to study their periodicity. The following step is prediction, but sometimes it is not possible to reach this objective because of great variability in the variables that describe the nature of a reliable prediction or insufficient levels of correlation between both explanatory variables and objective variables.

Even though adequate levels of prediction cannot be reached, statistical methodology allows us to obtain useful conclusions on the natural phenomena under study. The analysis of a "storm period" is a particular case of this type of study. Prediction is difficult, but it is possible to reach conclusions about past behavior. To this end, time series and spectral analysis are especially useful.

Spectral Analysis

Spectral analysis is a set of statistical and mathematical methods for identifying hidden periodicities in a time series. Moreover, spectral analysis is concerned with estimating the spectrum over the whole range of frequencies (or their inverses, the time periods). These techniques are widely used in electrical engineering, physics, computer science, geology, and environmental sciences (12–15).

From a mathematical viewpoint, spectral analysis is a modification of Fourier analysis to suit it for stochastic rather than deterministic functions of time. Fourier analysis is oriented to approximate a function by a sum of sine and cosine terms that is called the Fourier series representation. We distinguish two classes of spectral techniques, univariate and bivariate.

Univariate Spectral Analysis. The Wiener–Khintchine theorem states that the variance of any stationary stochastic process can be expressed as the integral in the interval (0, p) of a function called the spectral density function (or spectrum); so a spike of this function identifies a frequency with an important contribution to the variance, and a periodicity is associated with that frequency. Basically, univariate spectral analysis computes an estimate of the spectrum from the Fourier series representation of the available time series, and a graphical representation, called a periodogram (Fig. 1), is used to identify possible spikes in the underlying spectral density function (16).

This method has been used to calculate the periodicity of the heart rate and locomotor activity of several organisms (17), orbital cyclicities in geologic sequences (18), and seismology (19). In meteorology, it may be applied to the relationships among wind and waves (20) and analysis of the periodicity and persistence of daily rainfalls (21).

Bivariate Spectral Analysis. When we try to identify periodic movements common to a pair of time series, we need bivariate spectral analysis techniques. The definition of a cross-spectrum lets us generalize the univariate spectrum of this situation, although its interpretation is not so clear. Several statistical measures can be computed from this cross-spectrum, but some controversy is associated with the selection of the one most appropriate. We can remark on one of these measures for its easy interpretation: coherence. It measures the square of the linear correlation between two time series at a given frequency. It takes values in [0,1], and the closer it is to one, the more closely related are the two process at that frequency, so identifying a common periodic term.

In meteorology, these techniques have been used in investigating tropospheric ozone formation and decomposition processes (22), correlation of sea levels and atmospheric variables (23), analysis of the interactions between biosphere and atmosphere (24), and monitoring present-day climatic conditions (25).

A CASE STUDY: THE RECENT STORM RECORD ON THE SOUTHWESTERN SPANISH COAST

Study Area

The Huelva coast (SW Spain) is composed of large sandy beaches (145 km long), interrupted only by estuarine mouths (Fig. 2: Guadiana, Piedras, Tinto-Odiel, and Guadalquivir). The littoral morphology of this area is linked mainly to a mesotidal regime (2 m mean range), medium wave energy, and the fluvial sedimentary inputs of the Guadiana (144 m^3/s) and Guadalquivir (185 m^3/s) Rivers, a littoral net sediment flow oriented toward the east (26–29).

This coast is heavily "defended" by modern protective groins, causing either total (Vila Real do Santo Antonio,

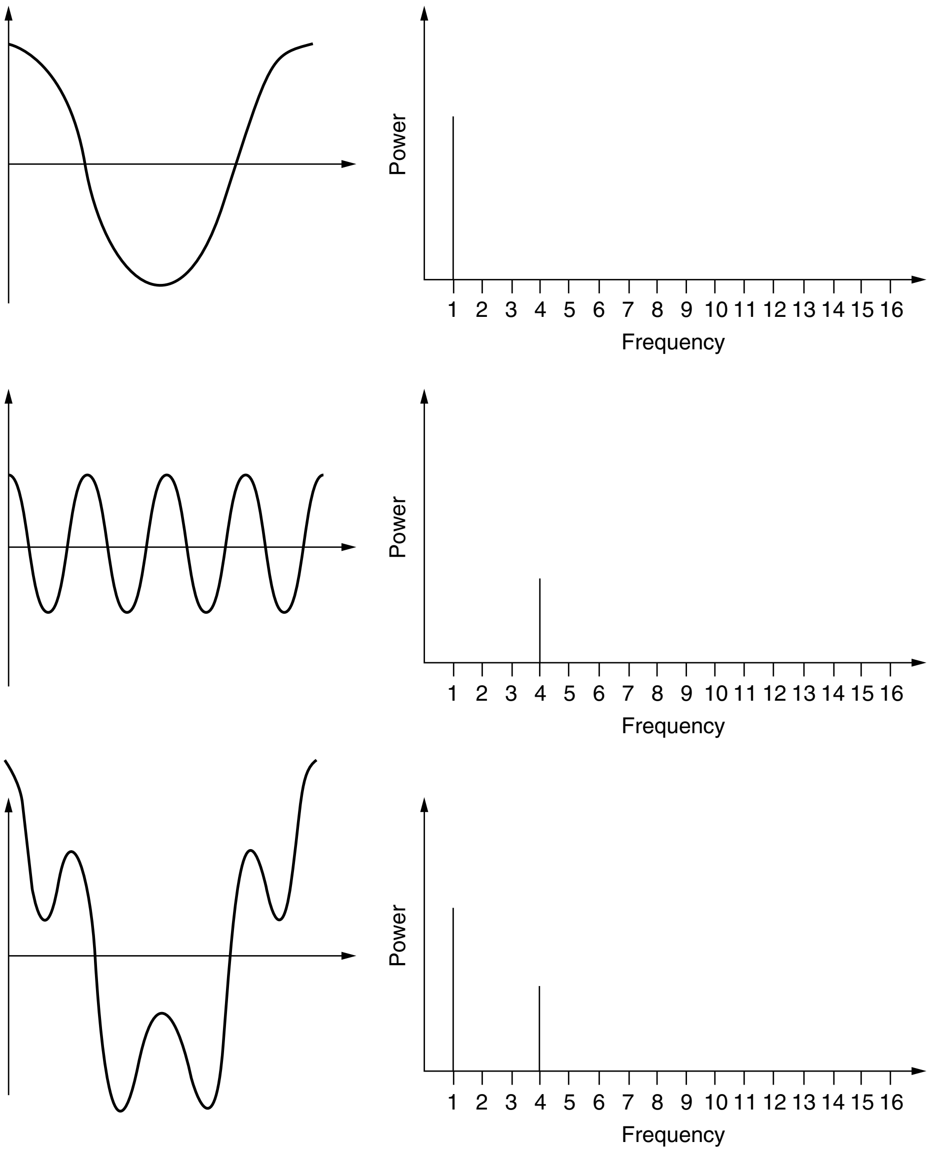

Figure 1. Fourier power spectra (right) resulting from various idealized data sets (left). Modified from Reference 15.

Huelva) or partial (Isla Cristina, Punta Umbria) obstacles to sedimentary transition. Consequently, two sedimentary units (Ayamonte-Punta Umbría and Mazagón-Doñana) may be delimited in this human-altered area, directly related to the effects of the main groins (30).

Each unit includes two different zones: (1) beaches affected by erosive processes (Ayamonte, Isla Cristina, La Antilla, Punta Umbría, Mazagón, Matalascañas) and (2) prograding spits (El Rompido, Doñana). These beaches constitute an important tourist area and are visited by more than 1 million people between May and September. This “sun and beach” tourism needs continuous management during the winter months due to periodic storm damage. The causes of this periodicity have not been studied but may be initially related to climate variables, such as the North Atlantic Oscillation Index (NAO; 31). The NAO is an index that represents the differences in atmospheric pressure at sea level between the Azores and Iceland (32). Positive values are associated with low cyclone activity in southern Europe and conversely (33).

The Winter Storm Record

The recent record (1956–1996) of critical storm periods was obtained from two daily journals (Odiel and ABC), wave heights were recovered from the Huelva harbour archives, and the wind speeds were supplied by the Spanish National Institute of Meteorology at the Huelva station (period 1961–1996). Data were normalized to standard scales (Fig. 3).

Between 1956 and 1996, eight winter storm periods on the southwestern Spanish coast were identified (Fig. 3, C): 1962–1963, 1969–1970, 1972–1973, 1978–1979, 1981–1982, 1987–1988, 1989–1990, and 1995–1996. In most cases, these high-energy periods are concentrated in December and January. An additional periodicity may be inferred in the fair weather conditions, the intervals separating two consecutive storm periods (5). After the

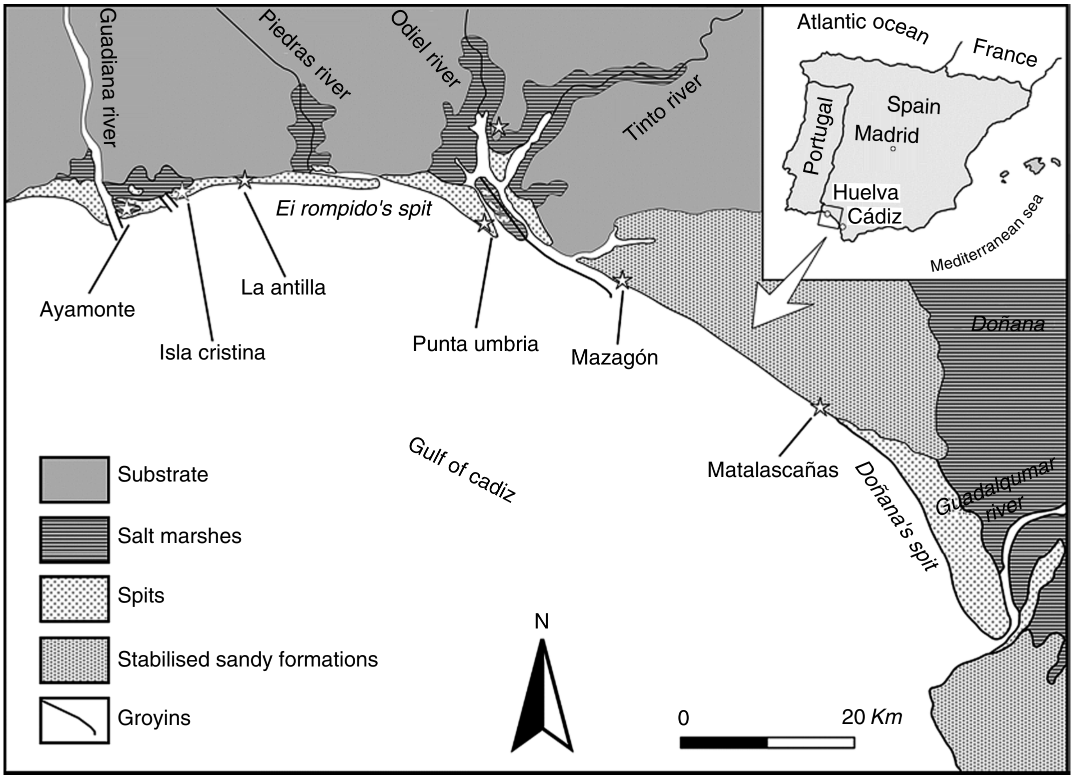

Figure 2. Location map, including the main tourist beaches, spits and groins. 1: Plio-Pleistocene substrate; 2: salt marshes; 3: spits; 4: stabilized sandy formations. Main groins. a: Vila Real do Santo Antonio; b: Huelva.

first storm period (1962–1963), a long interval (6–7 years) was found until the next period, followed by a shorter cycle (2–3 years).

An analysis of the storm features indicates a direct relation between the direction and speed of the prevailing winds and the causes of these events. In all cases, these winds come from the third quadrant at high to very high speed (Fig. 3: 8–12) on the Beaufort scale. Consequently, a more detailed study of the third quadrant velocities is needed to establish the periodicity of the storm wind.

Meteorologic Variables and Storm Periodicity

The application of the Fourier transformation to the time series of autumn–winter wind speeds permits us to distinguish two more probabilistic frequencies (Fig. 4a: 6–7 years and 9–10 years), which are also found in the storm series. In most cases, a 9-year poststorm period contains two storms (period 2 and period 3), situated at 6–7 and 9–10 years after period 1, respectively. This initial coincidence would indicate a possible statistical interrelationship between both variables, but the small record of recent storm periods permits only a first approximation.

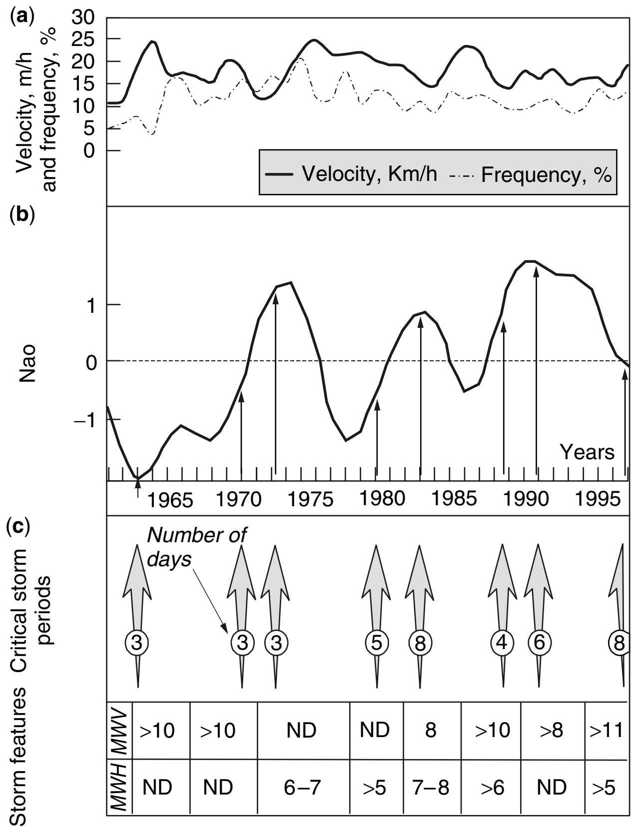
This hypothesis was tested in the period 1996–2000 by analyzing the new record of storm periods. A high-energy period (1998–1999) happened in agreement with the hypothetical storm sequence, which predicts new storms in 1995–1996 (period 2) and 1997–1998 (period 3) after 1989 (period 1). In this hypothetical 9-year sequence, the next storm period will be between 2004 and 2005, although a new positive date does not totally confirm the initial hypothesis. We will need 20–30 storm periods (a century, at least) for an adequate, statistical test of this correlation.

This possible periodicity may be related to cyclical changes of the cyclone regime, which are expressed in NAO values (Fig. 4a). In the analysis of the wind–NAO spectral series, the 3-year frequency shows the higher probabilities (Fig. 4b), indicating some degree of common behavior between these two variables.

This frequency agrees with the two main frequencies (6 and 9–10 years) obtained for the wind series. Moreover, an additional coincidence was found by contrasting the evolution of the NAO values and the storm record. Except for the 1989–1990 winter, the remaining storm periods were characterized by negative values of the NAO index, indicating a possible relation between storms and high cyclone phases. In the future, the NAO values collected during storm periods may even be positive due to the increasing tendency of this variable in the last decades.

ADDITIONAL MANAGEMENT IMPLICATIONS

A continuous, yearly study in 20–30 years will be interesting to contrast the first approach now presented to estimate the periodicity of critical storm periods



MWV	>10	>10	ND	ND	8	>10	>8	>11
MWH	ND	ND	6–7	>5	7–8	>6	ND	>5

Figure 3. (**a**) Velocity and frequency of the third quadrant winds (period 1961–1996); (**b**) NAO record; (**c**) Critical storm periods between 1960 and 1996, with the maximum wind velocities (MWV; Beaufort scale) and maximum wave heights (MWH, in meters). ND: No data.

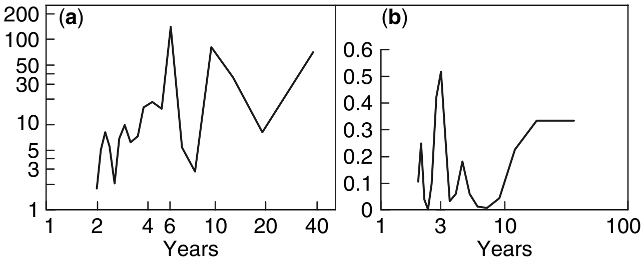


Figure 4. Periodicity diagram of the third quadrant wind speeds; Coherence values between NAO and wind speeds (X axis on log scale).

and its consequence more rigorously. Some additional investigations are necessary:

1. A short-term, periodic analysis of beach–nearshore profiles at the main beaches, with special attention to significant changes during these storms.
2. A first approach to long-term coastal development in examining the roles of waves, tides, storms, and sediments in coastal dynamics, as pointed out by Carter (34).
3. An evaluation of the sedimentary effects produced by the two main groins of the sector (Vila Real do Santo Antonio and Huelva), with indications of possible new emplacements and/or changes in their characteristics (mainly length and alignment).
4. Coastal strategies, including future redistribution of the littoral space (protection zones, demolition of shorefront residences, and relocation of both public infrastructures and private homes).

Taking into account the total damage occasioned by storms in the 1989–1999 period (probably up to $ 20 million), a moderate inversion ($2 million/year) may be very profitable in the next decade.

CONCLUSIONS

In the last 40 years (1956–1996), the analysis of storm periods suffered by the Huelva littoral (SW Spain) indicates a concentration in the winter months (December–January) and statistical behavior similar to third quadrant wind speeds. After the first storm period registered (1962–1963), two new high-energy periods were found in the following 10-year intervals: period 2, at 6 years and period 3, at 9–10 years. The first test of this hypothesis was positive in the 1997–2000 period.

This first approach holds out the prospect of a possible statistical prediction of critical storm periodicity in the next decades, in connection with new investigations into meteorologic changes, sedimentological studies, and coastal management strategies in this area.

SUBLIMATION

Edinara Adelaide Boss
Artur-Nogueira-SP, Brazil

CONCEPT

Sublimation occurs when the matter passes directly from the solid phase to the vapor phase, as is shown in Fig. 1. Examples include dry ice, how a frost-free refrigerator works, and naphthalene.

Sublimation is an endothermic process:

$$\Delta H_{\text{sublimation}} > 0$$

The heat required to change the phase of a pure substance is given by

$$Q = m \cdot L$$

where m is the mass of the pure substance and L is the latent heat.

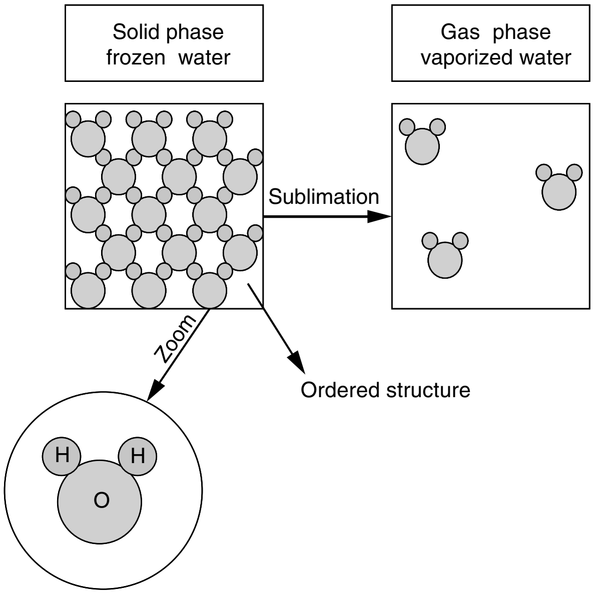

Figure 1. Water sublimation.

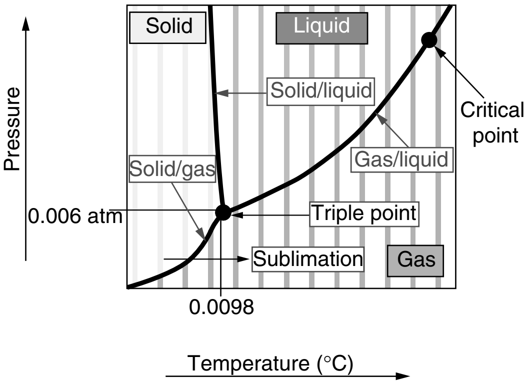

Figure 2. Phase diagram of pure water.

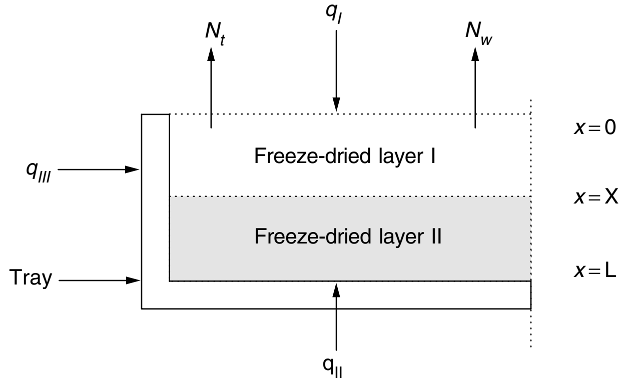

Figure 3. Diagram of a frozen material on a tray during freeze-drying. X is the position of the sublimation interface between the freeze-dried (layer I) and the frozen material (layer II).

The water latent heat for sublimation is 2.83×10^6 J/Kg.

Figure 2 presents the water phase diagram, which usually shows the pressure versus the temperature.

The diagram is divided into three areas, which represent the solid, liquid, and gaseous phases.

Triple point is a particular condition of temperature and pressure, which the three phases for a substance are in equilibrium.

Above the critical point, the liquid and gas phases are indistinguishable. The critical temperature is the minimum temperature for liquefaction of a gas using pressure. The critical pressure is the pressure required for liquefaction. The critical temperature of water is 374 °C, and the water critical pressure is 218 atm.

Sublimation phenomenon happens below the triple point in the water phase diagram. The sublimation curve is the line between the solid and gas phases.

At the triple point of the water phase diagram, the temperature is 0.0098 °C and the pressure is 0.006 atm.

APPLICATION

Freeze-drying is a process by which a water or aqueous substance is removed from a frozen material or frozen solution by sublimation. Figure 3 shows an example of a frozen solution in a freeze-drying tray.

Here q_{I}, q_{II}, and q_{III} are the heat, which can be supplied to the surface by conduction, convection, or radiation. N_{w} and N_{t} represent the mass flow of the water vapor and the total mass flow, respectively, in the dried layer.

This process involves the following three periods: freezing, primary drying, and secondary drying periods (1) as shown in Fig. 4.

A batch freeze-dryer is shown in Fig. 5. This equipment is composed of a stainless steel cylinder chamber with eight connectors for connection of the bottles. Above the cylinder chamber, a cover is built by transparent material. At the cylinder, there is a system with three trays. The vacuum pump localizes outside the freeze-dryer.

The freeze-drying process has a wide range of applications, including pharmaceutical products, foodstuffs (the organoleptic properties are important and have to be maintained), and other industrial byproducts (conservation of living microorganism, dehydration, or concentration of heat labile).

Another example of freeze-drying is the soluble coffee process, which produces a porous product by sublimation. This porous material is eager for water.

The performance of the overall freeze-drying process depends significantly on the freezing stage. The material to be processed is cooled to a temperature below the solidification. The shape of the pores, the pore size distribution, and the pore connectivity of the porous network of the dried layer formed by the sublimation of the frozen water during the primary drying stage depend on the ice crystals formed during the freezing stage.

The solvent is removed by sublimation under a vacuum pressure, and heat addition in the primary drying stage is carried out. A significant amount of the latent heat of sublimation is also kept when the water molecules sublime and enter the vapor phase. Because of this result, the temperature of the frozen product is reduced. Then it is necessary to supply heat to the product. The heat could be provided by conduction, convection, and/or radiation.

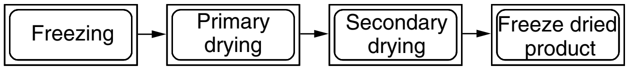

Figure 4. Freeze-drying periods.

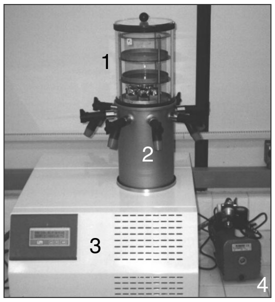

1. Glass camera with trays of inoxidable steel.

2. Manifold-exits of silicon and serpentine interns.

3. System of control of refrigeration and pressure.

4. Bomb of vacuous.

Figure 5. Freeze-drying equipment.

During the secondary drying stage the solvent is removed from the chamber and a small amount of sorbed water can be removed by desorption.

A dynamic mathematical model for the freeze-drying stages was proposed by Boss et al. (2). This model represents the process well.

The low temperature of the freeze-drying process and the low water activity resulting from this process minimize some reactions of degradation such as Maillard's reaction, protein denaturation, and enzymatic reaction (3). Color and flavor are important quality attributes in food, and the freeze-drying process preserves more of the pigments and reduces more of the transport rates than does the conventional drying processes. The hot air drying causes irreversible damages to the texture and incomplete rehydration. The freeze-drying process proposes good preservation of the original product characteristics and an increase in the stability of the product during the storage.

TRANSPIRATION

Koichi Miyashita
Okayama University
Kurashiki, Japan

Transpiration is the evaporation of water from the plant to the atmosphere. The moved water speed in a plant by the transpiration depends on a vapor pressure deficit that is the difference of a water vapor pressure between the atmosphere and the leaf surface. Two types of the transpiration exist. One is the stomatal transpiration through stomata, and the other is the cuticular transpiration through a cuticular. When the stomata open, the cuticular transpiration is much less than the stomatal transpiration. However, the cuticular transpiration may become large when the stomata are almost closed or when the leaf is cracked and damaged. Figure 1 shows that the water vapor in a stomatal aperture diffuses to the atmosphere through the stomata and the boundary layer of a leaf, in the case of the open stomata.

The transpiration rate from a leaf (Tr) can be generally expressed as

$$Tr = \frac{c_p \rho}{\gamma L} \frac{e_s - e_a}{r_s + r_a}$$

where C_p is the specific heat capacity, ρ is the density of air, γ is the psychrometer constant, L is the latent heat, e_s is the water vapor pressure of the stomatal aperture, e_a is the water vapor pressure of the atmosphere, r_s is the stomatal resistance, and r_a is the leaf boundary layer resistance that is effected by a leaf size and a shape.

The transpiration rate (Tr) is proportional to the difference ($e_s - e_a$) of a water vapor pressure between the stomata and the atmosphere. Usually, in the case of a plant with the water fully supplied, the water vapor pressure of the stomatal aperture is the saturated water vapor pressure at a leaf temperature. The more atmosphere dries, the more ($e_s - e_a$) become large. Then, the transpiration rate increases.

In general, the plant transpiration has the diurnal pattern. It is great in the daytime. On the other hand, the transpiration is small at the nighttime. In the daytime, the stomatal resistance (r_s) becomes small because of the opening of stomata, depending on photosynthesis activities by the solar radiation. Moreover, the exchange of a water vapor becomes active because of the increase of the wind speed on a leaf surface. Then, the leaf boundary layer resistance (r_a) decreases. Therefore, the transpiration rate (Tr) becomes large for the reason that the transpiration is inversely proportional to the sum total ($r_s + r_a$) of a stomatal resistance (r_s) and a leaf boundary layer resistance (r_a).

Meteorological factors significantly affect the transpiration. Several experimental results have been published about the relationships between the meteorological factors and the transpiration. Transpiration completely depends on the physiological activities as long as stomatal aperture does not change. However, the plant may regulate stomatal opening and transpiration. A temporary reduction of stomatal aperture is often caused by a decrease of light intensity, dry air, water deficit, high temperature, and toxic gases. Haseba (1) showed by a simulation analysis between meteorological factors and physiological activity that the transpiration rate increases with increasing a wind speed under a high air temperature, a low relative humidity, a low solar radiation, and a large stomatal conductance and that decreases in an adverse condition. He also showed that the transpiration may not change between two extreme conditions even if a wind speed increases.

The increase in a solar radiation and an air temperature makes the transpiration increase because the saturated water vapor pressure in the stomatal pore (e_s) increases by rising leaf temperature. On the other hand, the transpiration rate is inhibited as the relative humidity of the ambient air is great and the water vapor deficit decreases.

For example, transpiration is also influenced by deficit of the soil moisture. Transpiration does not change if the soil moisture slightly decreases. However, if the soil water content greatly decreases, to keep the water content plant regulate stomatal aperture decreases transpiration.

Transpiration is necessary for the growth of plants. The flow of water through the plant by transpiration increases the absorption of minerals from the soil. Changes in the water balance and the amount of water available in the soil

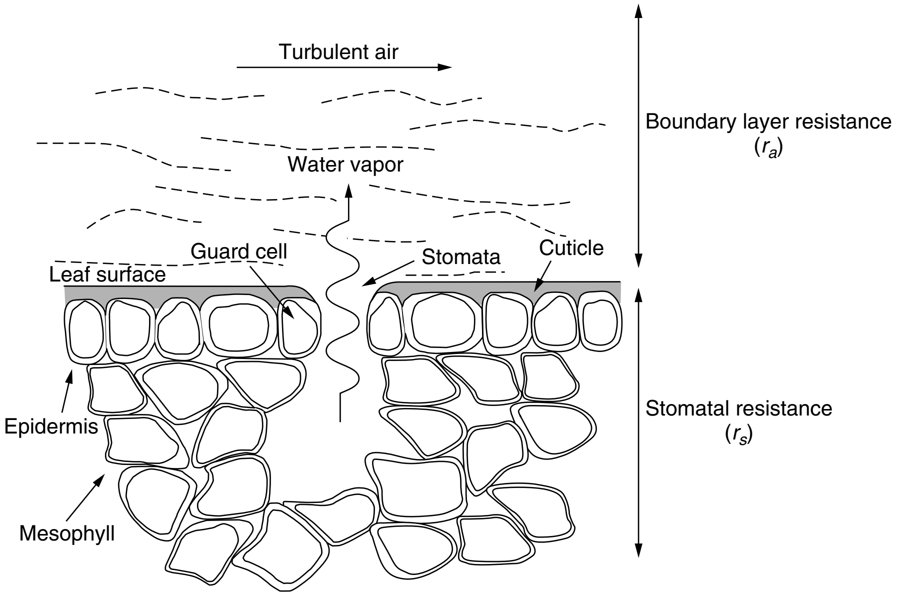

Figure 1. Conceptual diagram of the transpiration from a leaf in case of the open stomata. The curvilinear arrow is the flow of a water vapor from the stomatal aperture to the atmosphere.

can be crucial for plants. There is a rising concern that the worldwide water resources may be exhausted by global warming. Under the drought stresses, a plant does not only decrease the transpiration along with the decrease of stomatal conductance, but also it often may cause damage. Miyashita et al. (2) showed that the recovery level of transpiration in the kidney bean after drought stress gradually decreased as the periods of water stress.

The other effect of transpiration is to decrease the leaf temperature. In particular, the adjustability of a leaf temperature prevents too high of a temperature of a plant from the strong solar radiation. It is well known that the leaf temperatures are different among the plant species even if meteorological conditions are the same, which is mainly the difference of transpiration.

The differences (Ts-Ta) between leaf temperature (Ts) of worldwide barley cultivars (north America cvs, north African cvs, Chinese cvs, Ethiopian cvs, southwest Asiatic cvs, Japanese cvs, Korean cvs, Nepalese cvs, Turkish cvs, and European cvs) and ambient air temperatures (Ta) were measured under the same field (3). The temperature differences (Ts-Ta) of barley cultivars in the habitats with the cool meteorological phenomena such as Europe were large under high-temperature conditions. These show the differences of capability in the transpiration among the geographical varieties. Not only the plant species, but also the relationships between transpiration and the meteorological conditions at the places of origin are recognized.

For the plant canopy, such as a forest or an agricultural land, the transport of water vapor from the canopy to the atmosphere includes both the transpiration from plants and the evaporation from the wetted surfaces of plants and soils. Total of transpiration and evaporation is known and described as evapotranspiration. Transpiration of plant canopy is approximately proportional to the green mass, although the transpiration rate of individual leaves decreases with increasing leaf densities because of shielding of radiation and wind. Therefore, transpiration from the canopy is affected by development of the foliar mass. Canopy transpiration has the seasonal and diurnal patterns. Total annual and daily transpiration of stands of plant in various climatic regions, which are obtained from data of numerous authors, are summarized (4). Community transpiration of tropical rainforest is 1500 ~ 2000 mm/year, that of grain fields 400 ~ 500 mm/year and that of open vegetation in arid desert 0.01 ~ 0.4 mm/day. Under similar climatic conditions, forests with greater mass transpire more than grass lands, which in turn transpire more than heath. In addition to accurate observational data, the detailed simulation models, which include all basic hydrological parameters, are now available in calculation of stand transpiration. These quantitative data about transpiration of plant vegetations are important for forestry and landscape management, irrigation management, and prediction of climatic change.

As high CO_2 in the future decreases stomatal aperture (or stomatal conductance), transpiration may decrease if CO_2 increases and leaf temperature is constant. However, high leaf temperature at higher ambient temperature may partly counteract the expected suppression of transpiration. Despite higher leaf temperature, water-use efficiency (the ratio of photosynthesis to transpiration) increases at high CO_2 mainly because of increased photosynthesis (5).

MEASUREMENT OF TRANSPIRATION

Transpiration in the single leaf, the individual plant, and the canopy level measured by many methods is as follows: (1) The weighing method. The total weight of a plant with a pot is precisely measured at a constant time. The amount of a drop of a weight is comparable with the transpiration. As similar methods, there are the leaf cutting method for a single leaf and the lysimeter method for many plants. (2) The chamber method. The plant is covered by a transparent box with an inlet and an outlet port for the air flow. The humidity of an outlet port increases by the transpiration if an air flows. Transpiration rate can be calculated from the difference of an absolute humidity and an air flow rate. This method can be widely used for a single leaf, an individual plant, and a canopy. (3) The sapflow method. There is a transpiration stream within a plant vessel from a root to a leaf. It is in proportion to the increasing amount of a stem temperature when a stem is warmed by a constant quantity of heat. This method is used for plants (tomato, soybean, sugarcane, sweet potato, and etc) or trees. (4) Micrometeorological method. Evapotranspiration from a canopy is measured by a micrometeorological observation. Also, the Bowen ratio energy balance method, the aerodynamic method, the turbulent transport method, and so on are available.

WATERSPOUT

Arthur M. Holst
Philadelphia Water Department
Philadelphia, Pennsylvania

A funnel-shaped weather disturbance which exists over a body of water, a waterspout is often referred to as a tornado on water. This is accurate for one type of waterspout, the aptly named tornadic waterspout. It is somewhat inaccurate with regard to the much more common type of waterspout, the fair weather waterspout.

Tornadic waterspouts are tornadoes over water. These are stronger, larger, and faster than fair weather waterspouts. However, they do tend to form over land as true tornadoes before moving over water. Fair weather waterspouts form differently from tornadoes. Rather than developing downward, they begin at the surface, building up toward the sky.

For waterspouts to form, a series of things must occur. First, a small portion of air over the surface of water must become heated. As this warm air begins to rise, the cool air around it starts to form a small vortex of rotating air. This vortex of swirling air is carried upward by rising water vapor; waterspouts usually form over warm water because there is more water vapor present. Upon rising to an overhead cloud mass, the vortex forms a funnel cloud. At this point, a fair weather waterspout begins its five-stage life cycle.

The first stage of fair weather waterspout development involves the formation of a light spot on the surface of the water, which is surrounded by a darker area. The second stage is the formation of a spiral pattern on the surface around the dark spot. This spiral is colored lightly in some places and darkly in others. The third stage is when the funnel winds begin to pick up speed. The waterspout becomes more visible as sea spray is picked up from below.

This water swirls around the dark spot, known as a cascade. Like a hurricane, it appears to center around an eye. The fourth stage is the stage at which the waterspout is most powerful. Winds can be 60 mph or more. The funnel cloud can be hundreds or even thousands of feet high. Almost all the destruction caused by a waterspout occurs during this stage. The fifth and final stage is the decay of the waterspout. Often, rain begins to fall from the top of the waterspout. As these vortices require warm air to sustain themselves, the resulting downdraft of cool air speeds the process of dissipation of the waterspout. The entire life span of a fair weather waterspout is not often longer than 15 minutes.

Fair weather waterspouts can cause some damage, but it is always over water; they are rarely a threat upon reaching land. Tornadic waterspouts, however, are much more destructive. Their winds can exceed 150 miles per hour, they can last a half-hour or longer, and they are much more likely to appear during severe weather disturbances, such as tropical storms, tropical depressions, and hurricanes. These waterspouts can sink smaller ships and can cause extensive damage to sails and masts on larger ships. However, most waterspouts merely result in large amounts of rain.

UNITED STATES WEATHER BUREAU

Arthur M. Holst
Philadelphia Water Department
Philadelphia, Pennsylvania

From 1890–1970, the United States Weather Bureau provided various weather-related services to the nation. Weather analysis had been considered for hundreds of years, but real progress was not made until the nineteenth century, when techniques and technology began to make accurate and useful weather forecasting possible, the main purpose of the United States Weather Bureau, its predecessors, and its successor, the National Weather Service. The first national American weather service was initiated on February 9, 1870, when President Ulysses S. Grant signed into existence what was then known as The Division of Telegrams and Reports for the Benefit of Commerce. This service began in November 1870. It lasted until 1890, when it was renamed the United States Weather Bureau, and Congress reassigned it from the Department of War to the Department of Agriculture at the behest of President Benjamin Harrison. Then, in 1940, President Franklin Delano Roosevelt reassigned the Weather Bureau again, this time to its current home, the Department of Commerce. The United States Weather Bureau existed until 1970, when its name was again changed, this time by President Richard Nixon, to the National Weather Service, the name it is known by today.

During the 1800s and early 1900s, servicemen for the Weather Bureau often communicated by telegraph, sharing readings of atmospheric pressure, temperature, and the like. They also communicated with seafaring ships in this manner, receiving the first weather report from a ship in 1905. From 1898 to 1933, the Weather Bureau also used kites regularly to ascertain atmospheric conditions. As technology progressed, so did the tools used by the Weather Bureau. Starting in 1909, the Bureau began using weather balloons, a more versatile tool, for weather measurements. And in 1925, it began to use airplanes in Washington, DC., as a more precise tool. The Air Commerce Act of 1926 make the Bureau responsible for providing weather-related services to civil aviators.

Besides forecasting daily weather, the Bureau also made progress in forecasting, tracking, and predicting more specific types of inclement weather. In 1943, an airplane was flown into the eye of a hurricane for the first time, a technique that now provides for hurricane readings that could not otherwise be obtained. In 1948, members of the Air Weather Service issued the first official tornado warning. And in 1952, the Bureau launched a program to forecast and warn of severe locally thunderstorms.

Throughout the Bureau's 70 years of existence, the United States government also tried to incorporate it into an international network of weather forecasting. In 1951, the World Meteorological Organization was formed, and at its head was U.S. Weather Bureau President Francis W. Reichelderfer. Ten years later, President John F. Kennedy called for a worldwide weather forecasting system in his State of the Union address. This all came together in 1963, when the World Weather Watch was established. This program still ensures today the free exchange of data, analysis, and equipment among WMO members (including the NWS), allowing for better weather forecasting and more standardized methods and measurements.

WEATHER FORECASTING THROUGH THE AGES

NASA—Goddard Space Flight
Center

INTRODUCTION

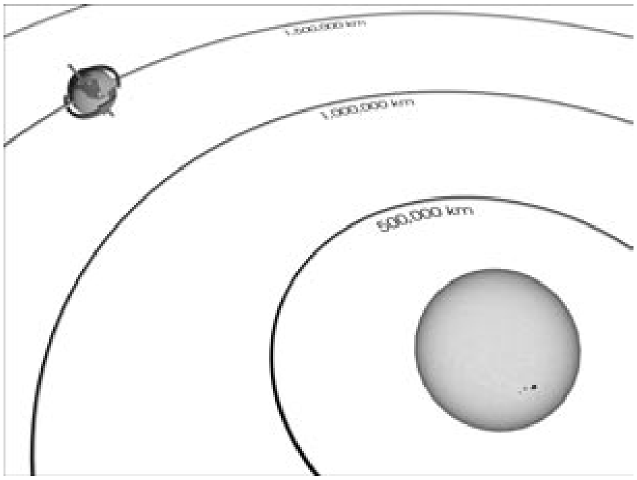
Imagine a rotating sphere that is 12,800 kilometers (8000 miles) in diameter, has a bumpy surface, is surrounded by a 40-kilometer-deep mixture of different gases whose concentrations vary both spatially and over time, and is heated, along with its surrounding gases, by a nuclear reactor 150 million kilometers (93 million miles) away. Imagine also that this sphere is revolving around the nuclear reactor and that some locations are heated more during one part of the revolution and others during another part of the revolution. And imagine that this mixture of gases continually receives inputs from the surface below, generally calmly but sometimes through violent and highly localized injections. Then, imagine that after watching the gaseous mixture, you are expected to predict its state at one location on the sphere one, two, or more days into the future. This is essentially the task encountered day by day by a weather forecaster (Ryan, Bulletin of the American Meteorological Society, 1982).

EARLY HISTORY

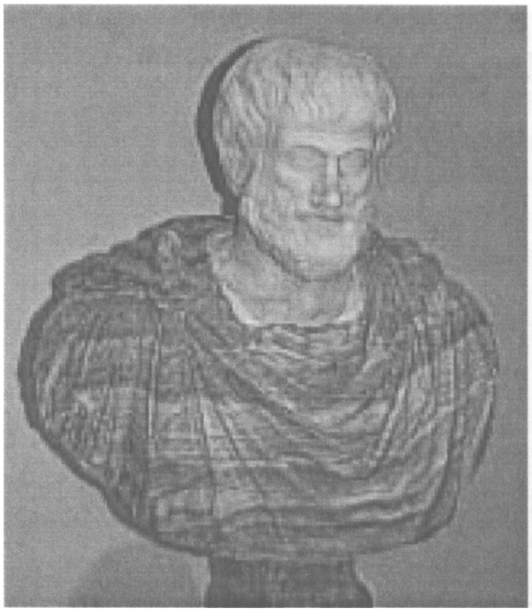
The art of weather forecasting began with early civilizations using reoccurring astronomical and meteorological events to help them monitor seasonal changes in the weather. Around 650 B.C., the Babylonians tried to predict short-term weather changes based on the appearance of clouds and optical phenomena such as haloes. By 300 B.C., Chinese astronomers had developed a calendar that divided the year into 24 festivals, each festival associated with a different type of weather.

Around 340 B.C., the Greek philosopher Aristotle wrote *Meteorologica*, a philosophical treatise that included theories about the formation of rain, clouds, hail, wind, thunder, lightning, and hurricanes. In addition, topics such as astronomy, geography and chemistry were also addressed. Aristotle made some remarkably acute observations concerning the weather, along with some significant errors, and his four-volume text was considered by many to be the authority on weather theory for almost 2000 years. Although many of Aristotle's claims were

---



Earth rotates on its axis once every 23 hours, 56 minutes, and completes one revolution around the sun every 365.25 days



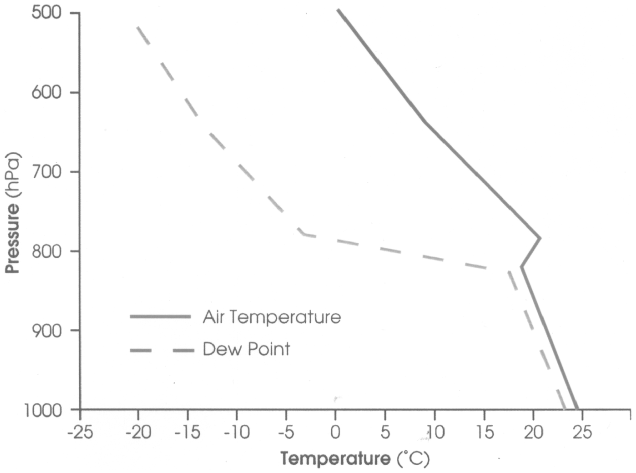
Aristotle, as sculpted by the Greek sculptor Lysippos

erroneous, it was not until about the 17th century that many of his ideas were overthrown.

Throughout the centuries, attempts have been made to produce forecasts based on weather lore and personal observations. However, by the end of the Renaissance, it had become increasingly evident that the speculations of the natural philosophers were inadequate and that greater knowledge was necessary to further our understanding of the atmosphere. In order to do this, instruments were needed to measure the properties of the atmosphere, such as moisture, temperature, and pressure. The first known design in western civilization for a hygrometer, an instrument to measure the humidity of air, was described by Nicholas Cusa (c. 1401–1464, German) in the mid-fifteenth century. Galileo Galilei (1564–1642, Italian) invented an early thermometer in 1592 or shortly thereafter; and Evangelista Torricelli (1608–1647, Italian) invented the barometer for measuring atmospheric pressure in 1643.

While these meteorological instruments were being refined during the seventeenth through nineteenth centuries, other related observational, theoretical, and technological developments also contributed to our knowledge of the atmosphere; and individuals at scattered locations began to make and record atmospheric measurements. The invention of the telegraph and the emergence of telegraph networks in the mid-nineteenth century allowed the routine transmission of weather observations to and from observers and compilers. Using these data, crude weather maps were drawn and surface wind patterns and storm systems could be identified and studied. Weather-observing stations began appearing all across the globe, eventually spawning the birth of synoptic weather forecasting, based on the compilation and analysis of many observations taken simultaneously over a wide area, in the 1860s.

With the formation of regional and global meteorological observation networks in the nineteenth and twentieth centuries, more data were becoming available for observation-based weather forecasting. A great stride in monitoring weather at high altitudes was made in the 1920s with the invention of the radiosonde. Small lightweight boxes equipped with weather instruments and a radio transmitter, radiosondes are carried high into the atmosphere by a hydrogen or helium-filled balloon that ascends to an altitude of about 30 kilometers before bursting. During the ascent, these instruments transmit temperature, moisture, and pressure data (called soundings) back to a ground station. There, the data are processed and made available for constructing weather maps or insertion into computer models for weather prediction. Today, radiosondes are launched every 12 hours from hundreds of ground stations all over the world.



A schematic sounding of air temperature and dewpoint derived from radiosonde data. This sample schematic sounding includes a temperature "inversion" (temperatures increasing with height) at about 800 hPa and reflects atmospheric conditions that frequently precede the development of severe thunderstorms and possibly tornadoes. [1 hectoPascal (hPa) = 1 millibar (mb).]

The North American network of upper air ground stations, each indicated by a three-letter station identifier. Radiosondes are launched and tracked from each location every twelve hours

TOWARDS NUMERICAL PREDICTION

Over the past few centuries, physical laws governing aspects of the atmosphere have been expressed and refined through mathematical equations. The idea of numerical weather forecasting—predicting the weather by solving mathematical equations—was formulated in 1904 by Vilhelm Bjerknes (1862–1951, Norwegian) and developed by British mathematician Lewis Fry Richardson (1881–1953, British). Despite the advances made by Richardson, it took him, working alone, several months to produce a wildly inaccurate six-hour forecast for an area near Munich, Germany. In fact, some of the changes predicted in Richardson's forecast could never occur under any known terrestrial conditions. Adding to the failure of this effort, a six-hour forecast is not particularly useful if it takes weeks to produce.

Courageously, Richardson reported his results in his book *Weather Prediction by Numerical Process*, published in 1922. In one of the chapters of this work, Richardson describes a scheme for predicting the weather before it actually happens, a scheme involving a roomful of people, each computing separate sections of the equations, and a system for transmitting the results as needed from one part of the room to another. Unfortunately, Richardson's estimated number of human calculators needed to keep pace with weather developments was 64,000, all located in one very large room.

Richardson's work highlighted the obvious fact that a large number of calculations had to be made very rapidly in order to produce a timely forecast. In the late 1940s, using one of the earliest modern computers, significant progress toward more practical numerical weather forecasts was made by a team of meteorologists and mathematicians at the Institute for Advanced Study (IAS) in Princeton, New Jersey. Mathematician John von Neumann (1903–1957, Hungarian-American) directed the construction of the computer and put together a team of scientists led by Jule Charney (1917–1981, American) to apply the computer to weather forecasting. Charney determined that the impracticality of Richardson's methods could be overcome by using the new computers and a revised set of equations, filtering out sound and gravity waves in order to simplify the calculations and focus on the phenomena of most importance to predicting the evolution of continent-scale weather systems. In April 1950, Charney's group made a series of successful 24-hour forecasts over North America, and by the mid-1950s, numerical forecasts were being made on a regular basis.

MODERN TOOLS OF THE TRADE

Modern technology, particularly computers and weather satellites, and the availability of data provided by coordinated meteorological observing networks, has resulted in enormous improvements in the accuracy of weather forecasting. Satellites, in particular, have given forecasters routine access to observations and data from remote areas of the globe. On April 1, 1960, the polar-orbiting satellite TIROS 1 (the first in the series of Television and Infrared Observation Satellites) was launched. Although the spacecraft operated for only 78 days, meteorologists worldwide were ecstatic over the pictures of the Earth and its cloud cover that TIROS relayed back to the ground.

Over the past 40 years, satellite sensor technology has advanced enormously. In addition to providing visual images, satellites can also provide data that allow calculation of atmospheric temperature and moisture profiles and other environmental variables. This is done using a variety of instruments, among them atmospheric

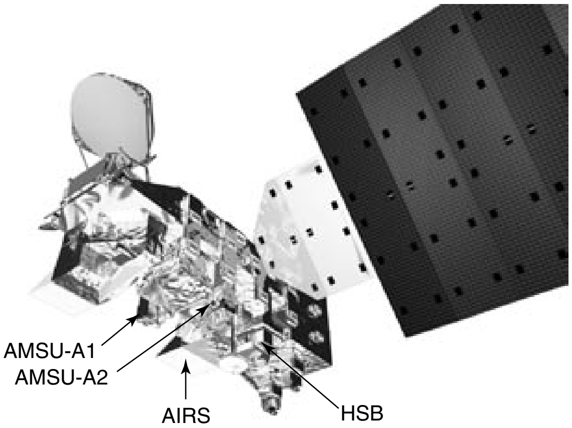
British mathematician Lewis Fry Richardson (1881–1953). (Photo credit: Bassano and Vandyk Studios.)

The first picture of Earth from a weather satellite, taken by the TIROS-1 satellite on April 1, 1960. Although primitive in comparison with the images we now receive from satellites, this first picture was a major advance

sounders, which measure quantities at various levels in atmospheric columns. The data retrieved from sounder measurements taken from a satellite can be made similar to radiosonde observations, with the major advantage that the satellite data are more complete spatially, filling in gaps between weather ground stations, which often are hundreds or even thousands of kilometers apart.

THE AQUA SPACECRAFT

In 2002, the Atmospheric Infrared Sounder (AIRS), the Advanced Microwave Sounding Unit (AMSU), and the Humidity Sounder for Brazil (HSB) were launched together on NASA's Earth Observing System (EOS) Aqua satellite, a satellite that also carries a Moderate-Resolution Imaging Spectroradiometer (MODIS), two Clouds and the Earth's Radiant Energy System (CERES) sensors, and an Advanced Microwave Scanning Radiometer for EOS (AMSR-E). The AIRS/AMSU/HSB sounding system provides the capability for determining atmospheric temperature and moisture more accurately than ever before from space-based measurements. These measurements provide to the National Oceanic and Atmospheric Administration (NOAA), the European Centre for Medium-Range Weather Forecasts (ECMWF), and the weather community at large for assimilation into operational numerical weather prediction models. It is expected that assimilation of global AIRS/AMSU/HSB data, complementing other operational observations, should lead to a substantial improvement in the accuracy of mid- and long-range weather forecasts.



The Aqua spacecraft, with pointers to the AMSU-A1, AMSU-A2, AIRS, and HSB instruments

The AIRS/AMSU/HSB instrument suite builds on the technical heritage of NOAA's High Resolution Infrared Sounder (HIRS) and Microwave Sounding Unit (MSU). The HIRS/MSU combination was the National Weather Service's (NWS's) operational weather sounding system for nearly twenty years, flying on numerous NOAA polar orbiting satellites. This system was enhanced in the late 1990s by the replacement of the four-channel MSU by a 20-channel AMSU, which includes Aqua's AMSU and HSB channels. Looking toward further improvements in weather forecasts, the NWS has set measurement requirements for temperature at an accuracy of 1 °C in layers 1 km thick and humidity at an accuracy of 20% in layers 2 km thick in the troposphere (the lower part of the atmosphere, where weather systems are of most relevance to human life and property). AIRS/AMSU/HSB will meet these requirements, allowing meteorologists to improve and extend their predictions and reduce the number of significant prediction mistakes, like failing to predict a major storm prior to a few hours before its arrival.

BENEFITS TO SOCIETY

The economic benefits of more accurate weather forecasts are immense. For example, a more accurate 24-hour forecast of heavy rain and thunderstorms along a cold front could allow airline dispatchers enough time to reroute their airplanes appropriately and thereby help alleviate costly delays. Being able to pinpoint a wintertime low temperature in Florida could be the deciding factor in whether orange grove farmers make the correct decision regarding deployment or non-deployment of freeze prevention methods to save their crops. Better information on wind patterns could aid the National Hurricane Center in producing a more accurate forecast of a hurricane's track and might enable a reasoned decision to be made regarding evacuating thousands of families out of Miami or Jacksonville. In military operations, there is a considerable historical record of instances when weather conditions have altered the course of battles, including examples when accurate forecasting has been a deciding factor in one side's victory.

Sample crops that could benefit from more accurate weather forecasts aiding farmers in selecting harvesting times and in protecting their crops from freezing temperatures

CLOSING

Only fifty years ago, weather forecasting was an art, derived from the inspired interpretation of data from a loose array of land-based observing stations, balloons, and aircraft. Since then it has evolved substantially, based on an array of satellite and other observations and sophisticated computer models simulating the atmosphere and sometimes additional elements of the Earth's climate system. All this has been made possible by advances in satellite technology, a sweeping acceleration in worldwide communications, and overwhelming increases in computing power. Aqua's AIRS/AMSU/HSB combination should further these advances, enabling more accurate predictions over longer periods.

OVERVIEW OF WEATHER SYSTEMS

John W. Nielsen-Gammon
(from *Handbook of Weather, Climate, and Water: Dynamics, Climate, Physical Meteorology, Weather Systems, and Measurements*, Wiley 2003)

INTRODUCTION

Meteorology is the only science in which it is common for a practitioner to appear every day on the evening news. Weather forecasting has immediate interest to people because it affects their day-to-day lives. The impact is great because weather itself changes from day to day. If weather were all good, or all bad, perhaps no one would notice—when's the last time you thought about the quality of the ground under your feet?

FOUNDATIONS OF WEATHER FORECASTING

The attempt to understand the weather is driven largely by the desire to be able to forecast the weather. However, the atmosphere is a complicated dynamical system, and an understanding of even the basic physical principles came only recently. Before that, scientists either attempted to understand the physical causes of weather events or recorded "weather signs," rules for weather forecasting. Because the physical understanding was incorrect, and most weather signs had no physical basis, neither approach was very successful. True progress in the study of the atmosphere that would lead to success in weather forecasting required a complete understanding of physical principles and a comprehensive set of observations of the atmosphere.

Aristotle's *Meteorologica*, written around 340 BC, was the leading book on meteorological principles in the Western world for two millenia. With his theories on the fundamental physical nature of the universe, Aristotle sought to explain a wide range of meteorological phenomena. For example, he argued that wind is caused by the hot, dry exhalation of the earth when struck by sunlight. A leading book on weather signs, *De Signis Tempestatum*, written by Aristotle's pupil Theophrastus, focused on such maxims as "A dog rolling on the ground is a sign of violent storm" and "Reddish sky at sunrise foretells rain." Since some of these maxims are still in use today, it appears that Theophrastus's work has outlived that of Aristotle.

Astronomers during the Middle Ages often argued that weather could be predicted by careful examination of the sky, clouds, and stars. This method of weather forecasting is sometimes successful, but it more closely resembled astrology than modern-day meteorology. Astrological forecasting schemes grew more advanced and intricate with time, while the scientific study of weather systems made little or no progress.

Scientific progress required basic observational data for describing weather systems. Only with good observations could theories be tested and the correct nature of the atmosphere be determined. The primary tools for observation of weather conditions are the thermometer (for temperature), the barometer (for air pressure), and the hygrometer (for humidity). Prior to and during the Middle Ages, these basic weather instruments did not exist. These instruments were invented in the sixteenth and seventeenth centuries and refined throughout the eighteenth century. The resulting observations of the atmosphere eventually established the basis for meteorological breakthroughs of the nineteenth and twentieth centuries.

Meanwhile, Isaac Newton had laid the foundation for the development of physical laws governing the motion of objects. The great mathematician Leonhard Euler of Germany, in 1755, rewrote those laws in a form that applied to a continuous fluid such as air or water. But Euler's laws were incomplete. They described how air can be neither created nor destroyed and how air accelerates (and wind blows) in response to forces acting on it. Missing from Euler's equations were the crucial relationship between temperature and pressure and the consequences of evaporation and condensation.

With the new instruments, the study of air became an experimental science. Through numerous laboratory experiments, scientists gradually discovered the fundamental physical laws governing the behavior of gases. In particular, the missing key relationship, the first law of thermodynamics, became known from experiments during the first half of the nineteenth century.

Now that the basic physical laws were known, a comprehensive set of observations of the atmosphere was necessary for further progress. Weather observations from a single careful observer were insufficient, but dozens of observations taken simultaneously across Europe or the United States gave a much clearer picture of the distribution of weather elements within a winter storm. Such "synoptic" observations were also used directly in weather forecasting. As rapid long-distance communication became possible through the telegraph, individual weather systems could be tracked and therefore forecasted. The coordinated observations that have taken place since the middle of the nineteenth century form the foundation of modern weather forecasting and our understanding of weather systems of all scales.

DEVELOPING AN UNDERSTANDING OF WEATHER SYSTEMS

Progress in understanding meteorology in the nineteenth century was largely based on thermodynamics. James Pollard Espy of the United States conducted a variety of laboratory experiments involving the condensation of water vapor in air. In 1841, based on his experiments and those of others, Espy correctly described the basic principle of thunderstorm formation: Condensation of water vapor within ascending air causes the air to become warmer than its surroundings and thus to continue rising. Espy went on to assert that the resulting lower pressure near the ground accounts for the low pressure observed in large-scale storm systems.

Espy's theory lay dormant until later in the nineteenth century, when the complete first law of thermodynamics was established. With this development, scientists were able to put Espy's theory of convection on a solid mathematical footing. Karl Theodor Reye of Germany, for example, determined the specific conditions under which such ascending air would be unstable. Their ideas form our understanding of the fundamental nature of individual thunderstorms to this day.

Espy also suggested that upward motion and the release of latent heat by evaporation might be the driving force for large weather systems. The widespread development of synoptic observations finally established that surface winds spiral inward toward a large-scale low-pressure system. The strong temperature contrasts within low-pressure systems suggested that the ascent would be driven, at least initially, by a current of warm air impinging on a current of cold air and rising. The rising air, and the resulting latent heating from condensation, would cause surface pressures to fall. This theory for the cause of low-pressure systems gained rapid acceptance for both theoretical and observational reasons in the 1870s.

A leading proponent of this thermal theory of cyclones was the American William Ferrel. Earlier, Ferrel had completed the application of Euler's equations to the atmosphere by formally including the effect of Earth's rotation as the Coriolis force. Ferrel also saw a clear analog to the role of equatorial convection in the general circulation, which drives ascent in the tropics and descent in the subtropics.

Unfortunately for its proponents, the thermal theory was wrong. Coordinated mountaintop observations in Europe, analyzed by Julius von Hann, showed that above the ground the centers of low-pressure systems were actually cooler than the centers of high-pressure systems. This observation illustrates the self-limiting nature of moist convection: The downward motion outside the convective cell causes warming of that surrounding air, so that eventually the instability is eliminated.

WEATHER AND ENERGY

The above discussion leads to a key question for the understanding of weather systems: How do weather systems grow and maintain themselves? As noted above, the basic dynamics of ordinary moist convection were well established, both conceptually and mathematically, by the end of the nineteenth century. Convection was also understood to be an important driver of the general circulation, or at least the tropical and subtropical circulation known as the Hadley cells.

By the turn of the century, the work of Hann and others showed that convection was not the energy source for extratropical cyclones, the midlatitude migratory low-pressure systems. Attention shifted from the role of latent heat release to the role of the large horizontal temperature gradients that were systematically observed within midlatitude low-pressure systems. In 1903, Max Margules, born in the Ukraine and working in Austria, calculated the amount of kinetic energy that could be obtained from the rising of hot air and the sinking of cold air in a low-pressure system. He found that the amount of energy that could be converted into kinetic energy was comparable to the actual amount of kinetic energy in a mature storm system. Margules had identified the correct energy source for extratropical cyclones. The process by which cyclones form and move was described by researchers working under Vilhelm Bjerknes in Bergen, Norway, shortly after World War I. Finally, a comprehensive theory by Jule Charney in 1947 explained that the structure and intensity of low-pressure systems was a consequence of the growth of unstable eddies on a large-scale horizontal temperature gradient.

Hurricanes did not have the prominent horizontal temperature variations found in midlatitude weather systems; indeed, many hurricanes seemed almost perfectly symmetrical. The prominence of convection throughout the hurricane, particularly within the eyewall, suggested that convection was fundamentally important in the development and maintenance of hurricanes. But how did the hurricane organize itself or maintain itself against large-scale subsidence within its environment? The currently accepted theory, published by Kerry Emanuel and Richard Rotunno in 1986 and 1987, relies on radiative cooling of the subsiding air at large distances from the hurricane. Emanuel also noted that as air spirals inward toward the eye it would become more unstable because it would be gaining heat and moisture from the sea surface at a progressively lower pressure.

Theories satisfactorily describing organized convection such as mesoscale convective systems and supercells also have been slow to develop. One reason for this is that no observing systems could accurately describe the structure of organized convection until the development of radar. Indeed, the term "mesoscale" was coined specifically to refer to in-between sizes (10 to 500 km) that were too large to be adequately observed at single locations and too small to be resolved by existing observing networks. The widespread use of weather radar in the 1950s helped fill the observation gap. The development of Doppler radar (for measuring winds within precipitating systems) for research purposes in the 1970s and as part of a national network in the 1990s helped even more. With comprehensive radar observations, it became clear that the long lifetime of organized convection was due to a storm keeping its updraft close to the leading edge of its cold, low-level outflow. The storm could then take advantage of the ascent caused by the cold air undercutting warm air without having its supply of warm air cut off completely. But even radar was not sufficient. The development of the first dynamical descriptions of supercells and squall lines in the 1980s, by Joseph Klemp, Richard Rotunno, Robert Wilhelmson, and Morris Weisman, relied upon numerical computer-generated simulations of the phenomena to provide an artificial data set unavailable from observations.

While the above discussion has focused on self-contained weather systems, certain "weather producers" may be thought of as byproducts of these weather systems. Many forms of severe weather, such as hail, lightning, and tornadoes, are essentially side effects of convection (organized or otherwise) but have little or no influence on the convection itself. Other mesoscale phenomena, such as sea breezes, upslope precipitation, and downslope windstorms, do not represent instabilities at all. Instead they are called "forced" weather phenomena because they are driven by such external features as solar heating gradients and topographic obstacles to the large-scale flow.

FORECASTING

The massive strides in weather forecasting during the past 50 years are due in large part to our growing understanding of the nature and dynamics of important weather systems. Forecasting of many phenomena has evolved from an exercise in extrapolation to specific predictions of the evolution of weather systems to computer simulations that accurately forecast the evolution of weather systems. Currently, the most skillful weather forecasts involve the prediction of large-scale extratropical weather systems.

One very important advance in our ability to forecast large-scale weather systems was the development of the omega equation, first presented in simplified form by Richard Sutcliffe in 1947. The omega equation is named after the Greek symbol that represents the change in pressure of an air parcel. In its original form, the omega equation is based upon a simplification of the equations of motion that assumes that all motions are large-scale and evolve slowly. When this approximation is made, it is possible to diagnose vertical motion entirely from large-scale pressure and temperature variations. Vertical motion is important for weather prediction because it is fundamentally related to clouds and precipitation, but large-scale vertical motion also can be used to infer the evolution of low-level and upper-level wind patterns. Vertical motion became the key to understanding the evolution of weather. In forecast offices, maps were designed and widely distributed that made it easy to look at the large-scale fields and diagnose vertical motion.

A second important advance was the development of numerical weather prediction, or NWP. NWP, discussed more extensively in the chapter by Kalnay in the dynamics part of this *Handbook*, has completely transformed the forecasting of large-scale weather systems. In the past, forecasters relied on their diagnosis of the current weather patterns to make forecasts. Nowadays, computers can make much more accurate forecasts than humans alone, and the best possible forecast is obtained by humans working with computer forecast output. The forecaster's task has become one of identifying likely errors in the model forecast, based on the forecaster's knowledge of systematic errors within the model, errors in the initial analysis, and computer forecast scenarios that run counter to experience.

In contrast to large-scale weather systems, individual convective storms are not directly simulated, nor accurately forecasted, by the numerical weather prediction models currently in use. Forecasting convective storms still relies heavily on extrapolation and a sound knowledge of what sorts of storms are likely to be produced by certain larger-scale weather conditions. The modern era of forecasting severe weather began in 1948, when two Air Force weather forecasters (Maj. Ernest Fawbush and Capt. Robert Miller) had responsibility for forecasting at Tinker Air Force Base near Oklahoma City. After a damaging tornado struck the base in 1948, the two meteorologists were given the task of identifying the days when tornadoes were likely to strike the base. We now know that forecasting the specific path of a tornado is essentially impossible, but when a similar low-pressure system evolved a few days later, the forecasters were compelled by the base commander to use a newly minted severe weather warning system to issue a forecast of a possible tornado at the base. Amazingly, the forecast came true, and preventive measures taken before the second tornado struck the base prevented considerable casualties to aircraft and personnel. This weather forecast, possibly the most serendipitous in the history of humankind, led directly to modern tools for diagnosing the likelihood of severe weather from large-scale conditions and laid the foundation for modern tornado forecasting.

CONCLUSION

This historical review has emphasized that progress in our understanding of the weather has required four ingredients: the need to understand the science of the atmosphere before one can hope to make accurate forecasts; a complete knowledge of the basic physical underpinnings of atmospheric behavior; observations adequate to test the theories and point the way toward new ones; and numerical models to provide simulations of the atmosphere more complete than any set of observations. The following chapters of this part of the *Handbook* discuss the current understanding of the weather phenomena discussed above, improvements in which have lead to vastly improved weather forecasts.

UNIT HYDROGRAPH THEORY

Vijay P. Singh
Louisiana State University
Baton Rouge, Louisiana

INTRODUCTION

In 1932, Sherman (1) developed the concept of the unit hydrograph (UH) for determining the surface or direct runoff hydrograph (DRH) from the effective rainfall hyetograph (ERH). The unit hydrograph, or simply unit graph, of a watershed is defined as the DRH resulting from one unit (1 inch or 1 centimeter) of effective rainfall (ER) that occurs uniformly across the watershed at a uniform rate during a unit period of time. This unit period is not necessarily equal to unity; it can be any finite period up to the time of concentration. This unit period of ER is the period for which the UH is determined for a watershed. As soon as this period changes, so does the UH for the watershed. This means that there can be as many UHs for a watershed as periods of ER. Often used are a 1-hour UH, 6-hour UH, 12-hour UH, or a 1-day UH. Here the duration of 1 hour, 6 hours, 12 hours, or 1 day is not the duration for which the UH occurs, but it is the duration of the ER for which the UH is derived. The ER is assumed constant during its duration D for which the UH is derived, so the effective rainfall intensity (ERI) is $1/D$.

Since its inception, the unit hydrograph concept has been widely applied in surface-water hydrology. The principle underlying the UH has considerable appeal and has, therefore, been applied to a wide range of problems in environmental and water resources. For example, Rendon-Herrero (2) employed the UH concept to derive unit sediment graphs. Williams (3) extended the same concept to derive instantaneous unit sediment graphs. Thomann (4) used it to derive water quality graphs, and Dooge (5) employed it for groundwater recharge. It has also been used by Snyder and Asmussen (6) for subsurface flow, by Venetis (7) for groundwater flow, by Singh et al. (8) for irrigation flow, and by Westestrom and Singh (9) for snowmelt runoff.

The objective of this chapter is to describe the unit hydrograph theory and illustrate its application to build hydrologic models in four select areas.

UNIT HYDROGRAPH THEORY

The fundamental premise of unit hydrograph theory is that the hydrologic system is linear and time invariant. Although the assumptions implied or made in the theory are, strictly speaking, seldom true, the theory, nevertheless, does yield reasonable results in practice. The theory is applicable to a wide range of problems in hydrology and water resources.

The unit hydrograph is based on these postulates: (1) For a given drainage basin, the duration of surface runoff is constant for all uniform-intensity storms of the same duration, regardless of differences in the total volume of surface runoff. (2) For a given drainage basin, if two uniform-intensity storms of the same length produce different total volumes of surface runoff, then the rates of surface runoff at corresponding times, after the beginning of the two storms, are in the same proportion to each other as their total volumes of surface runoff. (3) The time distribution of surface runoff from a given storm period is independent of concurrent runoff from antecedent storm periods.

Postulates 1 and 2 together make up the principle of proportionality. In other words, if the duration of the ER is fixed but its volume changes, then the duration of the ERH does not change, but its ordinates do in proportion to the volume of ER. The third postulate is the principle of superposition, which allows the decomposition of a complex ERH into rectangular blocks or pulses and then superimposing, on one another, hydrographs of these rectangular pulses, each of steady intensity, to obtain the total DRH.

As stated in the definition of the unit hydrograph, it is assumed that the ER is uniformly distributed within its duration. This means that the rainfall intensity is uniform throughout the watershed while rain falls. The other assumption is that it is uniformly distributed throughout the watershed. This means that uniform runoff occurs from all parts of the watershed. The ER is defined as that portion of rainfall that produces surface runoff, so all abstractions must be subtracted from rainfall, and for the ER to be uniform, the abstractions must be uniform throughout the watershed.

These postulates, together with the definition and the assumptions, constitute what is now referred to as the unit hydrograph theory. The theory fundamentally assumes that the watershed is linear and time invariant, that is, the DRH is derived from the ERH by a linear operation. Once the assumptions of linearity and time invariance are recognized, the theory can be applied to any linear, time-invariant system (10,11) and is not restricted only to computing the surface runoff hydrograph. For this reason, it has been employed to derive the unit sediment hydrograph, the unit pollutant graph, the unit groundwater hydrograph, and the unit interflow hydrograph, among others. Thus, in a generic sense, the behavior of a linear, time-invariant system that receives input and produces output can be described by the theory. By conservation of mass, the volume of input must be equal to the volume of output.

The dimensions of the UH can be expressed in two ways. First, if the UH is derived from the DRH due to an ER of specified duration whose depth is not unity, then the dimensions of UH ordinates will be equal to the dimensions of runoff divided by the dimension of the depth of ER. Runoff can, however, be expressed either in terms of discharge in volumetric rate units or specific discharge in volumetric rate per unit area or intensity units. Therefore, the dimensions of UH ordinates are either the dimensions of discharge per unit depth or the dimensions of discharge per unit area per unit depth. Let L denote the dimension of length and t the dimension of time. Then, the two forms of the dimensions of UH ordinates are (1) L^2/t and (2) $1/t$.

LIMITATIONS OF THE UNIT HYDROGRAPH THEORY

The unit hydrograph theory is only an approximation, and its postulates are not strictly valid. Nevertheless, it is a useful practical tool and is amenable to linear mathematics whose methods are simple and easily understood.

An ER of a specified duration seldom occurs uniformly across a watershed of reasonable size. Spatial variation generally becomes more pronounced as the watershed size increases. Rainstorms that produce intense rainfall usually do not extend across large areas. The nonuniform distribution of rainfall can cause variation in the hydrograph shape. However, errors in the UH due to nonuniformity in areal distribution can be minimized by decomposing the watershed into subwatersheds, each small enough to ensure approximately uniform areal distribution, by deriving the UH for each subwatershed, and then by appropriately combining these UHs to develop the UH for the entire watershed.

An ER seldom occurs uniformly, even for as short a duration as 5 minutes. However, the effect of temporal variation of rainfall intensity on the UH shape depends principally on the watershed size. For example, rainfall bursts lasting only a few minutes may produce well-defined peaks in the runoff hydrograph from small watersheds but may cause little change in the runoff hydrograph shape from large watersheds. The effect of temporal variation can be minimized by employing the instantaneous unit hydrograph (IUH).

All watersheds in nature are nonlinear; some are more linear, and some are less. They are linear only by assumption. If the hydrographs from storms of the same duration are compared, their ordinates are not in proportion to their corresponding runoff amounts. The peaks of the UHs for small rainfalls are usually lower than those for larger ones.

MATHEMATICAL REPRESENTATION

To avoid ambiguity in interpreting the UH, it must be emphasized that it corresponds to a particular duration of an ER and has a volume of one unit (i.e., 1 inch or 1 cm). Because the ER, it is assumed, occurs uniformly, its duration is sufficient to define its uniform intensity. This duration is referred to as the unit storm duration and may change from one application to another. Thus, for a given watershed, there can be a large number of UHs; each corresponds to a specific duration of ER.

Let an ERH of D-hour duration be denoted as

$$I(t) = I, 0 \le t \prec D; \quad I(t) = 0, \quad t \ge D \tag{1}$$

where I is a constant ER intensity (L/t), the D-hour UH is $h(D, t)$ and the resulting DRH is $Q(t)$. Then, applying the principle of proportionality, one obtains

$$Q(t) = h(D, t)I(t)D = h(D, t)ID \tag{2}$$

The quantity ID denotes the volume of ER. This equation states that the DRH is proportional to the ER volume. When, $ID = 1$, the DRH and UH are numerically the same.

Let an ERH be a complex hyetograph composed of an n number of pulses, each of duration D hours. Let the intensity of pulse j be $I_j, j = 1, 2, 3, \ldots, n$, and the DRH of pulse j be $Q_j(t)$. If the D-hour UH is $h(D, t)$, then the DRH due to the complex hyetograph can be expressed as

$$Q(t) = \sum_{j=1}^{n} Q_j[t - (j - 1)D] \tag{3}$$

Now, note that Q_1 starts at $t = 0$, Q_2 starts at $t - D$, and Q_j starts at $t - (j - 1)D$. The individual DRHs can be expressed as

$$\begin{aligned}
&Q_1(t) = h(D, t)I_1 D \\
&Q_2(t - D) = h(D, t - D)I_2 D, \qquad h(D, t - D) = 0, t \le D \\
&Q_3(t - 2D) = h(D, t - 2D)I_2 D, \quad h(D, t - 2D) = 0, t \le 2D \\
&\vdots \\
&Q_n[t - (n - 1)D] = h[D, t - (n - 1)D]I_n D \\
&\qquad\qquad\qquad\qquad h[D, t - (n - 1)D] = 0, t \le (n - 1)D
\end{aligned} \tag{4}$$

Thus, the DRH can be expressed as

$$Q(t) = \sum_{j=1}^{n} h[D, t - (j - 1)D]I_j D \tag{5}$$

The DRH at any time t is the result of the ERH pulses up to that time but not subsequent to it, so Equation 5 must be modified as

$$Q(t) = \sum_{j=1}^{t} h[D, t - (j - 1)D]DI_j D \tag{6}$$

For simplicity, time t can be taken as a discrete variable that takes on values at D time intervals.

The difficulty that develops from the dependence of the UH on the duration of D of the ER is circumvented by letting D tend to be instantaneous. The UH so obtained is called the instantaneous unit hydrograph (IUH). Thus, the IUH, $h(0, t) = h(t)$ is a hypothetical UH due to the ER whose duration tends to zero as a limit, but whose volume remains unity (say, 1 cm). Clearly, the IUH is independent of the duration of ER. Mathematically,

$$h(t) = h(0, t) = \lim_{D\to 0} h(D, t) \tag{7}$$

and

$$\delta(t) = \lim_{D\to 0} I(t, D)D \tag{8}$$

where $\delta(t)$ is the Dirac delta function at $t = 0$. Physically, this function can be thought of as a spike of infinitesimally small thickness and infinitely large height such that the area under the spike is 1. Therefore, Eq. 6 can be expressed as

$$Q(t) = \int_0^t h(t-\tau)I(\tau)d\tau, \quad h(\tau) = 0, \quad \tau \le 0 \tag{9}$$

Because mathematical operations are linear, Eq. 9 can also be written as

$$Q(t) = \int_0^t h(\tau)I(t-\tau)d\tau \tag{10}$$

where

$$h(t) \ge 0 \quad \text{for any } t \ge 0$$

$$\lim_{t\to\infty} h(t) = 0$$

and

$$\int_0^\infty h(s)ds = 1$$

Experimental evidence shows that

$$\int (t - \bar{t})h(t)dt \succ 0 \tag{11}$$

where $\bar{t}$ is the centroid of the IUH located at the t axis:

$$\bar{t} = \int_0^\infty th(t)dt \tag{12}$$

Equation 12 states that the IUH must be skewed to the right, that is, its peak must be to the left of the centroid, and a long tail extends to the right.

If the duration of the ER is indefinitely long and its intensity is one unit per unit of time (say, 1 cm/h), then the hydrograph so obtained is termed the summation hydrograph or S-hydrograph. This hydrograph assumes a deformed S-shape, and its ordinates ultimately approach the rate of ER in the limit or at the time of equilibrium. If the ERH is broken down into pulses each of duration D hours, then the SH will be obtained by superimposing the DRHs due to individual pulses. For this ERH, the SH, $U(t)$, is obtained from Eq. 6 as

$$U(t) = \sum_{j=1}^{t} h[D, t-(j-1)D]D = \sum_{j=1}^{t} Q[D, t-(j-1)D] \tag{13}$$

Clearly, if D tends to 0, $h[D, t-(j-1)D]$ tends to $h(t)$, the lower limit for summation will approach the origin, and

$$U(t) = \int_0^t h(s)ds \tag{14}$$

Now, the relations between IUH, UH, and SH can be derived. From the definitions of the UH and IUH, one can write

$$h(D, t) = \frac{1}{D}\int_{t-D}^{t} h(s)ds \tag{15}$$

Similarly, the relation between UH and SH can be expressed as

$$h(D, t) = \frac{1}{D}[U(t) - U(t-D)] \tag{16}$$

As D tends to 0,

$$h(t) = \frac{dU(t)}{dt} \tag{17}$$

It may be instructive to summarize that the three hydrographs—IUH, UH, and SH—are ascribed to three distinct characteristics of the effective rainfall—volume, duration, and intensity—as shown in Table 1:

Also note that the time to the peak of $h(D, t)$ can be determined by differentiating Eq. 16 with respect to t and equating the derivative to zero:

$$h(t) - h(t-D) = 0 \tag{18}$$

Equation 18 states that the peak of $h(D, t)$ occurs when the ordinate of the IUH is equal to the ordinate at D time units earlier. The SH attains its maximum value at a time equal to D hours less than the time base of the initial $h(D, t)$.

UNIT HYDROGRAPH MODELS

The unit hydrograph theory has been extensively applied to develop a range of hydrologic models in surface water hydrology, groundwater hydrology, and water quality hydrology. Four illustrative examples are presented.

Rainfall–Runoff Models

The unit hydrograph theory was developed for rainfall–runoff modeling and has been most extensively applied therein. There is a large range of UH-based models, including empirical, conceptual, and physically based (10). However, for economy of space, only a simple conceptual model will be presented to illustrate the power of the UH theory. To develop a conceptual model,

Table 1. Effective Rainfall Characteristics

Hydrograph	Volume	Duration	Intensity
IUH	Unity	Zero	Indefinite
UH	Unity	Finite	1/duration
SH	Indefinite	Indefinite	Unity

a watershed is represented by a network of linear elements, such as reservoirs and channels. This network can be defined using the laws of geomorphology or arbitrarily to mimic best the flow pattern in a watershed. Rainfall is reduced to effective rainfall by subtracting infiltration. Then, an instantaneous ER is routed through the network of reservoirs and/or channels to obtain the IUH of the watershed. By convoluting this IUH with the ERH, the DRH is obtained.

A linear reservoir can be defined by a linear relation between storage S and surface runoff Q as

$$S = KQ \tag{19}$$

where K is the residence time. The water balance of the reservoir can be expressed as

$$\frac{dS}{dt} = I(t) - Q(t) \tag{20}$$

where I is ER and t is time. Substituting Eq. 20 in Eq. 19 yields

$$\frac{dQ}{dt} + \frac{1}{K}Q = \frac{I}{K} \tag{21}$$

For an instantaneous $I(t)$, represented by $\delta(t)$, $Q(t)$ will reduce to $h(t)$. Therefore, Eq. 21 can be expressed as

$$\frac{dh}{dt} + \frac{1}{K}h = \frac{\delta(t)}{K} \tag{22}$$

For $h(0) = 0$, the solution of Eq. 22 is

$$h(t) = \frac{1}{K}\exp(-t/K) \tag{23}$$

If n linear reservoirs are arranged in series, then the IUH of this cascade is

$$h(t) = \frac{1}{K\Gamma(n)}\left(\frac{t}{k}\right)\exp\left(-\frac{t}{K}\right) \tag{24}$$

Equation 24 is a gamma function and is known as the Nash model (12).

A linear channel is defined by a linear rating curve or a linear relation between flow cross section $A(t)$ and discharge Q:

$$A = C(x)Q \tag{25}$$

where $C(x)$ is a constant at a channel section, varies with distance, and has the connotation of the inverse of the velocity; and x is the distance along the channel. The continuity equation for a channel in one-dimensional form can be written as

$$\frac{\partial Q}{\partial x} + \frac{\partial A}{\partial t} = 0 \tag{26}$$

Substituting Eq. 25 in Eq. 26 produces

$$\frac{\partial Q}{\partial x} + C(x)\frac{\partial Q}{\partial t} = 0 \tag{27}$$

The inflow to the channel is upstream and can be denoted as $Q(x_0, t)$. A linear channel simply translates the flow by the time equal to the travel time, T. Thus, the solution of Eq. 27 is

$$Q(x_1, t) = Q(x_0, t - T), \quad T = C(x_1 - x_0) \tag{28}$$

where x_1 denotes the downstream end of the channel reach. If the inflow is given by the delta function $\delta(t)$ at the upstream end of the channel, the IUH of the channel is

$$h(t) = \delta(t - T) \tag{29}$$

The linear reservoirs and linear channels can be arranged in a way that best represents the watershed. Dooge (13) employed a network of linear channels and reservoirs to represent the watershed. All operations are linear, so the IUH of the network can be derived with little difficulty. For any $I(t)$, the DRH can be determined by convolving the IUH with $I(t)$ as

$$Q(t) = \int_0^t h(t - \tau)I(\tau)d\tau \tag{30}$$

For practical purposes, Eq. 30 can also be expressed in discrete form.

Channel Flow Routing

Channel flow is routed by using either a systems-based approach or a hydraulic approach. The unit hydrograph theory is applicable to both approaches if they are linear. The systems-based approach based on the Muskingum method is the most popular. This method is comprised of Eq. 20 and a linear storage–discharge relation expressed as

$$S = k[wI + (1 - w)Q] \tag{31}$$

where S is the storage of water within the channel reach, I is the inflow rate, Q is the outflow, and w and k are routing parameters. For a delta function inflow, $\delta(t)$, the IUH of the Muskingum method is obtained by substituting Eq. 31 in Eq. 20 and solving the combined equation:

$$h(t) = -\frac{w}{1 - w}\delta(t) + \frac{1}{k(1 - w)^2}\exp\left[-\frac{t}{k(1 - w)}\right] \tag{32}$$

where $I(0)$ is $I(t)$ at $t = 0$. By convoluting Eq. 32 with $I(t)$, the outflow discharge $Q(t)$ can be obtained.

On the other hand, in a hydraulic approach, St. Venant equations are employed. The unit hydrograph theory has been applied to several linearized forms of these equations. One simple approximation is the kinematic diffusion approximation (14,15) expressed as

$$\left(gh_0 - \frac{u_0^2}{4}\right)\frac{\partial^2 Q}{\partial x^2} = 3gS_0\frac{\partial Q}{\partial x} + \frac{2gS_0}{u_0}\frac{\partial Q}{\partial t} \tag{33}$$

where h_0 is the flow depth at the reference discharge, u_0 is the velocity at the reference discharge, Q is the perturbation discharge around the reference discharge, g is the acceleration due to gravity, S_0 is the bed slope, x is the distance along the channel, and t is time. The reference discharge may correspond to steady uniform flow. For instantaneous flow at the upstream end of the channel reach, $\delta(t)$, the IUH of the channel reach described by Eq. 33 is

$$h(t) = \frac{x}{\sqrt{4\pi D t^2}} \exp\left[-\frac{(x-at)^2}{4Dt}\right] \tag{34}$$

where $a = 1.5\,u_0$, and

$$D = \frac{Q_0}{2S_0}\left(1 - \frac{F^2}{4}\right), \quad F = \frac{u_0}{\sqrt{gh_0}} \tag{35}$$

where F is the Froude number corresponding to the reference discharge and D is hydraulic diffusivity. By convoluting Eq. 34 with the upstream discharge, the outflow (or routed) discharge can be obtained.

Groundwater Flow

The unit hydrograph theory has been applied to model groundwater recharge, stream–aquifer interaction, aquifer response due to pumping, and a whole host of groundwater problems. Only the problem of stream–aquifer interaction will be discussed to illustrate an application of the unit hydrograph theory in groundwater hydrology. To that end, suppose that a seminifinite aquifer interacts with a stream. The aquifer is confined, homogeneous, and isotropic. The governing equation for one-dimensional flow can be written as

$$\frac{\partial^2 H(x,t)}{\partial x^2} = \frac{1}{D}\frac{\partial H(x,t)}{\partial t} \tag{36}$$

where H is the hydraulic head and D is the aquifer diffusivity equal to the ratio of transmissivity (T) to storativity S_c. The initial and boundary conditions can be written as

$$h(x, 0) = 0 \tag{37a}$$

$$h(0, t) = I(0, t) \tag{37b}$$

$$h(0, t) \to 0, \text{ as } x \to \infty \tag{37c}$$

The IUH of Eq. 36 can be obtained using the Laplace transform (16) as

$$h(x,t) = \frac{x}{2t}\left[\frac{S_c}{\pi t T}\right]^5 \exp\left[-\frac{S_c}{T}\frac{x^2}{4t}\right] \tag{38}$$

Equation 38, when convoluted with $I(0, t)$, will yield the aquifer response.

SEDIMENT TRANSPORT

Analogous to the IUH, in the instantaneous unit sediment graph (IUSG), h_S is defined as the distribution of sediment from an instantaneous burst of rainfall that produces one unit of runoff and is considered the product of the IUH and the sediment concentration distribution $C(t)$:

$$h_S(t) = h(t)C(t) \tag{39}$$

In the IUSG, $C(t)$, it is assumed, varies linearly with V_Q, the amount of effective rainfall or direct runoff. Analogous to the ERH, Chen and Kuo (17) defined the effective sediment erosion intensity per unit depth (e.g., foot) (ESEI), S_e. Then, similar to the surface runoff hydrograph given by Equation 6, the sediment discharge, Q_S, can be expressed as

$$Q_S(t) = \sum_{j=1}^{n} h_S[D, t-(j-1)D]D)S_e(t)D \tag{40}$$

where D is the time interval of each pulse. The dimensions of Q_S and h_S are FT^{-1} and T^{-1}, respectively. A value of 1 hour or less may be appropriate for D. Singh and Chen (18) established that the sediment yield, Y, and the direct runoff volume are related as

$$Y = aV_Q^b \tag{41}$$

where a and b are parameters. A similar relation exists between $Q(t)$ and $Q_S(t)$. As $Q(t)$ varies with ERI, so does $Q_S(t)$ with ESEI. In other words, the effective rainfall intensity or depth produces direct runoff; in turn, the direct runoff produces the direct sediment yield. Conceptually, therefore the ERI generates its counterpart ESEI which when combined with IUSG produces a sediment graph. The relation between $S_e(t)$ and the effective rainfall is of the same form as that between $Q_S(t)$ and $Q(t)$. The sum of S_e ordinates must equal Y as that of ER ordinates must equal V_Q.

CONCLUSIONS

The unit hydrograph theory is a powerful tool that is applicable to a wide range of problems in hydrology and environmental engineering. In practice, this theory is still routinely applied. Although most hydrologic and environmental systems are nonlinear, their linear part dominates in most cases. That is why this theory works so well.

WEATHER AND THE ATMOSPHERE

David P. Stern
Goddard Space Flight Center,
NASA

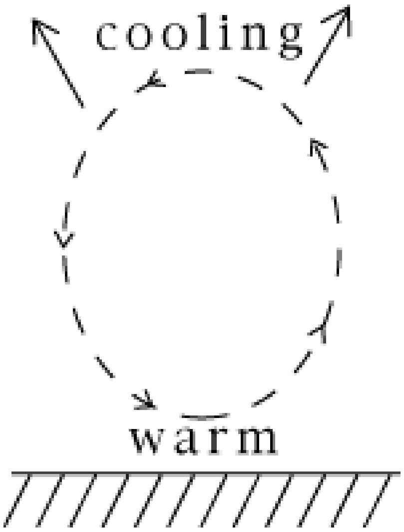
An optional extension of section (S-1) "Sunlight and the Earth." A more detailed (but qualitative) discussion of heat flow in the atmosphere and related weather processes, including the roles of buoyancy, convection and humidity.

> Around and around goes the wind, and from its circuits returns the wind.
>
> *Ecclesiastes, ch. 1, v.6*

PRESSURE AND CONVECTION

Let us start with the **flow of air.** Suppose a "parcel of air" is heated near the ground (by **conduction** of heat, the flow of heat due to direct contact). Heat makes it expand, it becomes less dense than the surrounding air and **buoyant,** and it rises like a hot-air balloon (or like a drop of oil in a bottle of water).

At the higher levels of the atmosphere, this warm bubble again gives up its heat (to other flows or perhaps to cold space), cools down, and other bubbles coming from below push it to the side, where it descends again. (diagram on the board). Such a circulating flow is called **convection.**



More generally, convection is any flow which

1. picks up heat at one place,
2. drops it at another, and
3. is driven by this transport of heat.

The important thing to remember when dealing with convective flows, is that the **higher** one is in the atmosphere, the lower are the **pressure and density** of the air. What compresses it is the **weight of air above it** which it must support. On top of Mt. Everest, less air is piled up on top and therefore the pressure is lower.

At ground level, the compressing weight of the atmosphere amounts to about 1 kilogram on each square centimeter. That pressure does not bother our bodies, because the air inside us is at the same pressure, and the fluids of the body (like blood) do not compress easily. For the same reason, fish have no problems with depth—even at a depth of 100 meters, with a pressure 11 times larger (10 kilogram water above each square centimeter, plus the weight of the atmosphere) they feel no discomfort.

> (Divers too can stand such pressure, provided the air they breathe is similarly compressed—except that the mixture must be changed, otherwise they may take in too much oxygen, and too much nitrogen is dissolved in their bloodstream.)

At an altitude of about 5 kilometers, only **half** the atmosphere is above us, the other half is below, so only the weight of half the atmosphere must be supported, and the pressure is reduced to one half.

By "Boyle's law" (named for Robert Boyle, 1627–91), the **density** is also reduced to one half (ignoring any variation in temperature). Rising an **additional** 5 kilometers, the pressure again falls by half, to 1/4 of what it was on the

---

ground, and at 15 kilometers, it is halved again to about 1/8. All this is approximate and depends on temperature, but the trend should be clear.

The cabin of a jetliner flying at 10 km must be sealed and pressurized, because passengers breathing air at 1/4 the sea-level density would be starved for oxygen and might lose consciousness. On the very rare occasions when a jetliner loses its pressure, masks connected to oxygen canisters drop down automatically, allowing the passengers to breathe normally while the pilot quickly descends to a lower altitude.

WEATHER

First, **a word of caution:** what follows below is **a very crude and simplified** picture of a much more complicated process. While the circulation in the drawing below resembles the one proposed by Hadley in 1735, the actual situation is much more involved.

(a) Local Weather

When the atmosphere is stable, the higher we go, the **cooler** the air is.

Air is **warmest** near the ground, which absorbs receives heat from sunlight. It is **coldest** above the level where jetliners fly, at 10–15 kilometers, the region from where it **radiates** most of its heat into space. That is why mountaintops are cold and the highest mountains have snow on their tops.

(Still higher layers may get quite hot again, by absorbing UV and "extreme UV," but they have little effect on what goes on below them).

How Exactly Does This Happen?

Suppose some "parcel of air" (dry air, for now—humidity is an additional factor, considered later) is heated by the ground and rises. Higher up the pressure is lower, so the air expands: but expansion **cools** it.

Similarly, if for some reason the parcel is blown down, is compressed again and **heated** by the compression. Such up-and-down motions happen all the time, and the net result is that when conditions are stable, the temperature drops at a **steady rate** as we go higher.

The motion of the rising parcel of air depends on its surroundings. It always cools by expansion—but is it still warmer than the still air around it? **If it is, it continues to rise; if not, it stops.** As will be seen, this is where the **humidity** of air has an important effect.

[On an ordinary day, direct heating by the ground only carries the air a few hundred meters, perhaps a kilometer, creating above the ground a "boundary layer" with many small convective flows. Large scale motions like thunderstorms usually occur higher up (see below).]

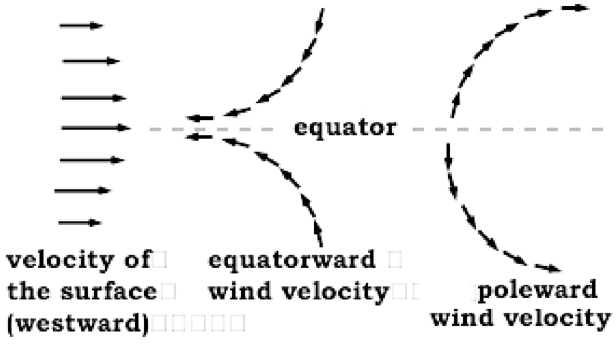
(b) Global Weather

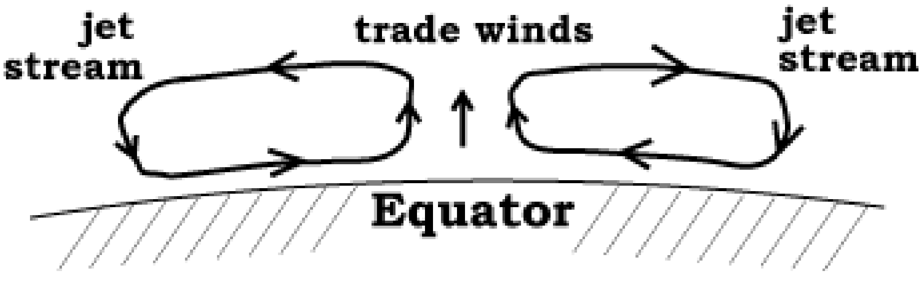
Convection also operates on a global scale. The greatest heating occurs near the equator, and air heated there **rises and flows poleward,** to cooler regions of the Earth.

The rotation of the Earth greatly modifies this flow, by the *Coriolis effect*, as explained below.

- At the equator the east-west motion of the air **matches** that of the equator.
- **Away** from the equator, however, the Earth's surface is **closer** to the rotation axis, the distance it covers in 24 hours is **smaller,** and so its west-to-east speed is **slower**. If the air moving **away** from the equator (right side of the drawing above) **persists** at its original west-to-east speed, it will **overtake** the local surface, making the predominant winds blow from **west to east** ("westerlies").
- The cooler air returns equatorward (middle part of the drawing above) at **lower** altitudes, completing the loop. If it **still** kept its original west-to-east speed, it would **again** match the local rotation of the equator.
- Actually, the air loses velocity to friction with the ground. Therefore, the time it returns to the equator, it **lags behind** the rotating ground, and the average wind is **easterly**.

In the age of sailing ships, sea-captains took advantage of this system. Sailing from Spain to America, they would





go closer to the equator, a more southern route that took advantage of the easterly “trade winds.” Sailing back home they would go further north and use the westerlies. The many Spanish wrecks off Florida, some containing quite rich cargo, were lost on this home voyage back to Spain, loaded with gold and silver from Mexico and South America.

Jetliners flying across the US cannot swing quite as far. However, when flying west to east, their pilots often exploit the fast core of the westerlies, known as the **jet stream** and flowing at high altitudes. Flying westward they try to avoid the jet stream.

WATER VAPOR

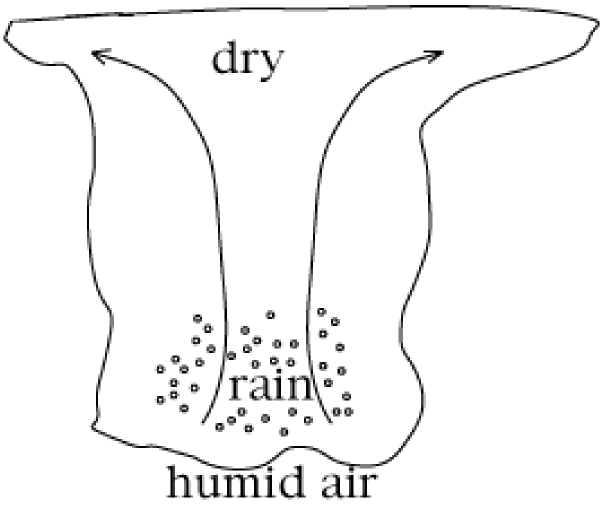
Instead of heating the Earth, sunlight can **evaporate water** from it—especially from the oceans, which cover most of the Earth’s surface. Humid air may be viewed as containing **additional energy**, invested by the Sun when its heat evaporated the water. While heat drives convection, humidity may **amplify** it.

Hot humid air is what drives thunderstorms, and a warm ocean surface is also the traditional birthplace of violent tropical storms, known as hurricanes in America and typhoons in Asia.

We look at two examples of humidity in action.

1. In a **thunderstorm**, hot humid air rises, as in ordinary convection. As it rises to regions of lower pressure, it cools by expanding. However, cold air cannot hold as much humidity as warm air, and the extra water is therefore squeezed out. In moderate convection it forms **clouds** (as in the second example below), but in a vigorous thunderstorm, there is too much of it and it turns into **rain**.

Giving up water **heats** the air, or rather, slows down its cooling, because the heat invested by the Sun in evaporating the water is now passed back to the air. As a result, the rising air is still warmer than the air layers around it, and it **continues to rise vigorously**. It squeezes out still more rain and forms the tall thunderstorm clouds, which pilots know well to avoid.



Thunderstorm convection

(In very vigorous thunderstorms, the “updrafts” of rising air may rise so quickly that they blow raindrops into the higher and colder sections of the cloud, where they **freeze,** producing **hail.** Some hailstones are picked up again and again, adding layers of ice on each upwards journey. That is how unusually big hailstones can form.)

2. On a hot clear day, many fluffy small **clouds** may form. A light plane flies across the land, and every time it comes under a cloud, the pilot feels that it is **bodily lifted.** What is happening?

—Here is the reason. The heating of the ground by the Sun has created many small convection currents rising upwards. Their air contains humidity, not enough for a serious thunderstorm, but enough to produce small clouds when droplets of water condense as the rising air cools.

The small clouds mark the top of the “boundary layer” near the ground, with many small circulating flows. Each cloud sits on top of a rising convection current, which lifts the airplane as it flies across it. Since “what goes up must come down” the pilot can also expect downdrafts between the clouds, where the air goes down again, as part of the circulating convection. Such up-and-down motions may make passengers on low-flying airplanes quite airsick!

Further Exploring. Strictly for those interested in history: the original 1896 article in which Svante Arrhenius proposed the greenhouse effect. Note that carbon dioxide was then called “carbonic acid.”

Tidbit. Who first wrote “**Everybody talks about the weather, but nobody does anything about it**”? Most would claim it was Mark Twain (just type the first 5 words into a search engine and see!), but it ain’t necessarily so. It looks like Twain’s style, but actually the words first appeared in an editorial in the Hartford (Conn.) Courant on 24 August 1897, written by **Charles Dudley Warner.**

Warner was a good friend of Twain, who himself had lived in Hartford for many years (he left before 1897). He was a newspaperman in Hartford and the two had collaborated on an 1873 book “The Gilded Age.” Warner is also remembered for other quotes, e.g., “Politics make strange bedfellows.”

Concerning the quote, see on the web http://www.m-w.com/wftw/99aug/082499.htm. and more about Charles Dudley Warner (and Twain) at http://courant.ctnow.com/projects/twain/warner.htm.

VAPOR PRESSURE

Naraine Persaud
Virginia Polytechnic Institute
and State University
Blacksburg, Virginia

Vapor pressure is the partial pressure exerted by the vapor of a substance in the gaseous phase of a closed heterogeneous system at equilibrium with condensed phases (i.e., solid or liquid) of the substance present in the system. It is the macroscopic measure of the tendency of the molecules of a given species in the condensed phases of the system to escape into the gaseous phase. A heterogeneous system means a mixture of two or more distinct, physically or chemically homogeneous phases. Mixture implies the phases are mechanically separable; distinct implies presence of unequivocally defined physical boundaries (interfaces) between phases; and homogeneous implies each phase is uniform throughout chemically and physically. The simplest possible conceptualization for a heterogeneous system is any closed two-phase system consisting of the solid or liquid of a pure substance in equilibrium with its vapor at a given temperature. In more complex heterogeneous systems, the condensed phases may be completely miscible or immiscible liquids, aqueous solutions, discontinuous liquid aerosols, or solid/liquid emulsions, and the vapors may be mixed with other vapors and gases present in the gaseous phase. Although the entire system is closed (permitting only energy transfer) with respect to its surroundings, the subsystems (phases) are open, permitting both energy and mass transfer between phases.

The equilibrium vapor pressure is of interest and importance in many applications encountered in water/atmospheric science and engineering such as quantifying water vapor pressure in the air above ice or liquid water, above an aqueous solution, and in the presence of curved air–water interfaces (menisci, bubbles, and droplets). Covering all these facets of vapor pressure would necessitate a discussion that far exceeds the limits of an encyclopedia article on vapor pressure. Our subsequent discussion will therefore focus on the fundamental relationships that can be universally applied to quantitatively describe and predict phase equilibrium in any closed heterogeneous system—in particular, a discussion of the Gibbs chemical potential and phase rule. We will then demonstrate applications of these principles to the simplest (and perhaps the most common) case of the vapor pressure in a two-phase system of a pure substance with specific reference to the solid/liquid/vapor system for pure water.

In a quintessential contribution to classical thermodynamics (entitled "On the equilibrium of heterogeneous substances") published between 1875 and 1876 in the *Transactions* of *the Connecticut Academy of Arts and Sciences*, Josiah Willard Gibbs (1839–1903) formulated seminal concepts governing equilibrium in *any* closed heterogeneous system (1,2). Specifically, Gibbs addressed reversible changes in the equilibrium state of closed heterogeneous systems at uniform temperature and pressure due to changes in the chemical composition or physical state of any of the phases through chemical reactions or mass transfer between phases.

From the first law of thermodynamics, for a reversible change in equilibrium state of a closed system, the differential change (gain) in the internal energy $dU = \delta q + \delta w$, where δq and δw represent the small amounts of the (positive) total heat or total work transferred into the system. Heat or work transferred out of the system is negative, implying a loss in U. The total work can be divided into any PV work (δw_{PV}) done on the system ($\delta w_{PV} = -P\,dV$ since dV is negative), and any (reversible) non-PV work done on the system ($\delta w_{\mathrm{n}PV}$). Since dS (entropy change) is defined as $\delta q/T$, then $\delta q = T\,dS$ and $dU = T\,dS - P\,dV + \delta w_{\mathrm{n}PV}$. In the absence of any external force fields and surface effects, Gibbs identified the non-PV work with changes in composition of each phase of the system. Gibbs therefore extended the internal energy function U for pure substances to include composition variables as $U(S, V, n_1, n_2, \ldots, n_c)$, where $n_1, n_2, \ldots, n_C$ represent the minimum number (C) of variables (termed as components) required to characterize the composition of a given phase j (of J phases), specified either as number of moles (n_i), mole fractions ($x_i = n_i/n_{\mathrm{total}}$), or mass fractions. Mathematically, the C variables represent the basis vectors of the compositional space of a phase, and $(n_1, n_2, \ldots, n_C)$ can be written as a compositional vector $\mathbf{n}_i$. Since dU is an exact differential, for the entire multiphase system, $dU = (\partial U/\partial S)_{V,ni}dS + (\partial U/\partial V)_{S,ni}dV + \sum_j \sum_i (\partial U/\partial n_i)_{S,V,\mathbf{n}_j}dn_i$, where the summation is over $j = 1, 2, \ldots, J$ phases and $i = 1, 2, \ldots, C$ components. Comparison to $dU = T\,dS - P\,dV + \delta w_{\mathrm{n}PV}$ implies $(\partial U/\partial S)_{V,ni} = T$, $(\partial U/\partial V)_{S,ni} = -P$, and $\sum_j \sum_i (\partial U/\partial n_i)_{S,V,\mathbf{n}_j}dn_i = \delta w_{\mathrm{n}PV}$.

The intensive partial molar internal energies $\partial U/\partial n_i$ are a measure of how much the internal energy of the system changes if one changed the ith species in any phase by a small amount (dn_i mole) while keeping the amounts of the other species (denoted as vector $\mathbf{n}_j$) together with S, V in the phase constant. For a given phase, Gibbs termed the intensive partial molar quantity ($\partial U/\partial n_i$) the chemical potential (function) of the ith component in the phase and denoted it as μ_i. For a given phase $\mu_i = f(S, V, \mathbf{n}_j)$ represents the slope of the $U(S, V, \mathbf{n}_j)$ space for that phase. Physically, the chemical potential represents the generalized force for defining energy (work) due to changes (displacements) in composition ($\mathbf{n}_j$) of any of the phases due to reaction or mass transfer. Since they represent partial molar quantities, μ_i values depend on the composition of the phase. Chemical potential gradients driving such non-PV work transfer between phases or between system and surroundings are analogous to temperature and pressure gradients that drive energy transfer as heat and PV work.

In order to transform the system coordinates from (S, V) to the more convenient and practical (P, T), one can apply a Legendre transformation on the basic $U(S, V)$ state function in order to eliminate S and V in favor of P and T. Gibbs applied the Legendre transformation to develop the state potential function $G = U + PV - TS$ defined on the five primitive thermodynamic state functions (internal energy U, pressure P, volume V, temperature T, and entropy S). The total differential of this function is $dG = d(U + PV - TS) = dU + P\,dV + V\,dP - T\,dS - S\,dT$. Substituting $dU = T\,dS - P\,dV + \delta w_{\mathrm{n}PV}$ gives $dG = -S\,dT + V\,dP + \delta w_{\mathrm{n}PV}$. Therefore, if some (reversible) process changes the system equilibrium state at constant temperature and pressure, $dG = \delta w_{\mathrm{n}PV}$ and $\int dG = \Delta G = w_{\mathrm{n}PV}$ represents the work exclusive of PV work that must be done on the system (or by the system if ΔG is negative) to achieve the change in equilibrium state. Gibbs termed the state function G as the free energy of the system. Since the state function H (enthalpy) was defined as $H = U + PV$, the free energy function is formally defined as $G = H - TS$, and is therefore alternatively called the free enthalpy. Since for any phase $dG \quad (P, T, \mathbf{n}_i) = (\partial G/\partial P)_{T,\mathbf{n}_i} dP + (\partial G/\partial T)_{P,\mathbf{n}_i} dT + \sum_i (\partial G/\partial n_i)_{P,T\mathbf{n}_j} dn_i$, then by comparison with the above total differentials dG and dU, $(\partial G/\partial P)_{T,\mathbf{n}_i} = V$, $(\partial G/\partial T)_{P,\mathbf{n}_i} = -S$, and $\mu_i = (\partial U/\partial n_i)_{S,V,\mathbf{n}_j} = (\partial G/\partial n_i)_{P,T,\mathbf{n}_j}$ for a given phase.

As the four extensive thermodynamic energy functions (i.e., $U, G, H,$ and A) present the same physical information in different coordinates, Legendre transformations made on $U(S,V,\mathbf{n}_i)$ can be used to develop the other two energy functions, enthalpy $H(S,\ P,\ \mathbf{n}_i)$ and Helmholtz free energy $A(T, V, \mathbf{n}_i)$. The partial molar values of these functions give equivalent definitions for $\mu_i = (\partial H/\partial n_i)_{S,P,\mathbf{n}_j} = (\partial A/\partial n_i)_{T,V,\mathbf{n}_j}$. In the case of a single pure substance $\mathbf{n}_j$ has only one element, and the value of μ for a given phase is simply the value of the state energy function divided by the moles of the pure substance comprising the phase.

Extensive thermodynamic equilibrium state functions (the four energy functions included) of the form $f(x_1, x_2, \ldots)$ are first-order homogeneous functions of degree one, meaning that $f(\lambda x_1, \lambda x_2, \ldots) = \lambda f(x_1, x_2, \ldots)$, where λ is an arbitrary constant scaling all *extensive* variables in the basis vector set $\mathbf{x}_i$. Applying Euler's theorem for first-order homogeneous functions in this case would give $f(x_1, x_2, \ldots) = \sum_i (\partial f/\partial x_i)\ x_i$. As an example, applying these concepts for the Gibbs energy function $G(T,\ P,\ \mathbf{n}_i)$ gives (since T and P are intensive variables), $G(T, P, \lambda\mathbf{n}_i) = \lambda G(T, P, \mathbf{n}_i)$ and by Euler's theorem $G(T, P, \mathbf{n}_i) = \sum_i n_i (\partial G/\partial n_i)_{P,T,\mathbf{n}_j} = \sum_i n_i \mu_i$. Therefore, $dG = \sum_i n_i d\mu_i + \sum_i \mu_i dn_i = V\,dP - S\,dT + \sum_i \mu_i dn_i$. Subtraction of these two expressions for dG gives $V\,dP - S\,dT + \sum_i n_i d\mu_i = 0$. This result is called the Gibbs–Duhem equation. Similar "Gibbs–Duhem" equations can be derived for any extensive state function of the form $f(x_1,\ x_2,\ \mathbf{n}_i)$ using Euler's theorem (although strictly this name refers to the Gibbs function). Such results are essential starting points in the analysis of solution/vapor systems.

For internal equilibrium (meaning nothing changes macroscopically) in any heterogeneous system, it is intuitive (albeit there are formal proofs) that the intensive state functions P, T, and μ_i (the chemical potential of each component) must be uniform throughout the system. Achieving uniformity of μ_i implies that mass transfers between phases occur such that the phase with the smaller chemical potential will grow at the expense of the phase with the larger chemical potential until equilibrium is achieved. At equilibrium since T, P, μ_i are fixed, the system cannot deliver non-PV work and therefore $dG = 0 = \sum_i \sum_j \mu_{ij} dn_{ij}$, where the summation is over $j = 1, 2, \ldots, J$ phases and $i = 1, 2, \ldots, C$ components.

Among thermodynamic intensive state functions, the chemical potential function $\mu(P, T, \mathbf{n}_i)$ serves as a powerful tool in analyzing processes (i.e., changes in equilibrium state) in heterogeneous systems of variable composition, especially those involving phase changes, chemical reactions, or electrochemical and surface phenomena. At equilibrium, $\mu(P, T, \mathbf{n}_i)$ defines a surface (sometimes called the Gibbs surface) representing all possible equilibrium states of the system. Each point on the Gibbs surface represents the minimum value of $G(P, T, \mathbf{n}_i)$ at a given T, P. From the relationships for $G(T, P, \mathbf{n}_i)$ in the preceding paragraphs, and Euler's condition for exactness, $(\partial\mu/\partial T)_{P,\mathbf{n}_i} = \partial/\partial n_i (\partial G/\partial T)_{P,\mathbf{n}_j} = -(\partial S/\partial n_i)_{P,\mathbf{n}_j} = -s$ (partial molar entropy) and similarly $(\partial\mu/\partial P)_{T,\mathbf{n}_i} = (\partial^2 G/\partial n_i\ \partial P)_{T,\mathbf{n}_j} = v$ (partial molar volume) for a given phase.

Gibbs also quantified the minimum number (D) of unconstrained intensive variables (such as T, P, μ_i) required to unambiguously define the equilibrium state of a closed heterogeneous system. Each such variable constituted one of D "internal degrees of freedom" of the system. As discussed above, components (C) are distinct chemical species that can be independently varied and whose total quantities are conserved; phases (J) are the coexisting mechanically separable, distinct, homogeneous subsystems.

Gibbs considered a system containing C components present in J phases designated $1, 2, 3, \ldots, J$. In each phase, in addition to P and T, there are $C - 1$ possible independent composition variables since the sum of the moles in that phase is fixed. The total *possible* number of degrees of freedom describing the system is therefore $2J + J(C - 1) = JC + J$. If the system is in a state of internal equilibrium, P, T, and μ_i are equal in all phases. These constitute restraints that reduce the total possible degrees of freedom. Equality of P and T in each phase provides $2(J - 1)$ restraints. Equality of μ_i in all phases imposes $J - 1$ restraints for each component (meaning that for the ith component one can write $J - 1$ equalities for that μ_i), and therefore $C(J - 1)$ restraints for C components. The difference between the potential degrees of freedom and the restraints gives the actual degrees of freedom of the system. This gives $D = JC + J - (2J - 2 + JC - C) = JC + J - 2J + 2 - JC + C = C - J + 2$. This result is the well-known Gibbs phase equilibrium rule and is universally applicable to all heterogeneous systems at equilibrium. D (sometimes called the variance) is the number of unconstrained variables, that is, intensive quantities that can be independently varied without changing the number of phases. It may be interesting to note that it is no coincidence that this result resembles Descartes's topological formula ($F = 2 + E - V$) relating the number of faces (F), edges (E), and vertices (V) of simple polyhedra. In this context, the phase rule characterizes the topology of the Gibbs surface for the phases at equilibrium.

The foregoing concepts and relationships are *sine qua non* to the understanding and quantifying of all heterogeneous phase equilibrium systems. As an example, let us consider the experimental phase equilibrium for a pure ice/liquid water/water vapor system. It can be represented as the locus of points in a vapor pressure (P in pascal) versus temperature (T in kelvin) coordinate plane representing states for which these phases are in equilibrium. Such a plot, termed a phase diagram, for water is shown in Fig. 1. There are three regions in the phase diagram corresponding to the three phases of water. The phase diagram shows three possible phase transitions liquid ↔ vapor (vaporization), solid (ice) ↔ liquid (fusion or melting), and solid (ice) ↔vapor (sublimation). Applying the phase rule to Fig. 1, all three phases can coexist at only one combination of P and T known as the triple point. At the triple point the system has no degree of freedom, implying that the triple point is unique for all pure substances. The two lines separating the vapor from the liquid and solid phases specify the pressure at which the vapor of the substance is in equilibrium with its liquid or solid phases at a given temperature. For example, along the sublimation line, ice and vapor can coexist in equilibrium. Along the phase equilibrium lines the system has one degree of freedom, and hence the vapor pressure is fixed if T is specified and vice versa. Since the equilibrium vapor pressure for a given system may be established at any temperature, and because vapor formation is endothermic, an increase in temperature will tend to shift the equilibrium state toward higher vapor pressure and vice versa. Therefore, vapor pressure is necessarily an increasing function of the temperature of the system. The temperature at which the vapor pressure exactly equals the atmospheric pressure ($1\ \text{atm} = 1.103 \times 10^5$ Pa) is called the normal boiling point of the substance (100 °C for water). Above the critical temperature (374 °C), it is not possible to produce condensation by increasing the pressure, and the system has two degrees of freedom (i.e., P and T). Similar phase diagrams exist for all pure substances except that the fusion line usually tilts to the right of the triple point. Water is one of few substances (another is bismuth) whose melting temperature is lowered as P increases so that its fusion line tilts to the left of the triple point.

For a single-component phase diagram (as in Fig. 1), application of the foregoing general equilibrium relationships are greatly simplified. A question of practical importance is: What is the relation $P(T)$ between vapor pressure (P) and T along the equilibrium sublimation and vaporization curves? Using subscript α to denote any of the condensed phases (solid, liquid) and the vapor phase as β, then at any point along the phase transition curves $\mu_\alpha = \mu_\beta$. Applying Taylor's theorem to expand μ_α (T, P) and μ_β (T, P) in the neighborhood of the same arbitrary point P_0, T_0 [i.e., about μ_α $(T_0, P_0) = \mu_\beta$ (T_0, P_0)] on the phase transition curve by one gets μ_α $(T_0 + dT, P_0 + dP) = \mu_\alpha$ $(T_0, P_0) + (\partial\mu_\alpha/\partial T)_P dT + (\partial\mu_\alpha/\partial P)_T dP \ldots$ equal to the similar expansion for μ_β (T, P) about μ_β (T_0, P_0). Equating the terms involving dP and dT in these expansions gives $dP/dT = -(\partial\mu_\alpha/\partial T - \partial\mu_\beta/\partial T)/(\partial\mu_\beta/\partial P - \partial\mu_\alpha/\partial P)$. As shown in a previous paragraph $(\partial\mu_\alpha/\partial T)_{P,n\beta} = -s_\alpha$ and $(\partial\mu_\alpha/\partial P)_{T,n\beta} = v_\alpha$, where s and v represent partial molar entropy and volume.

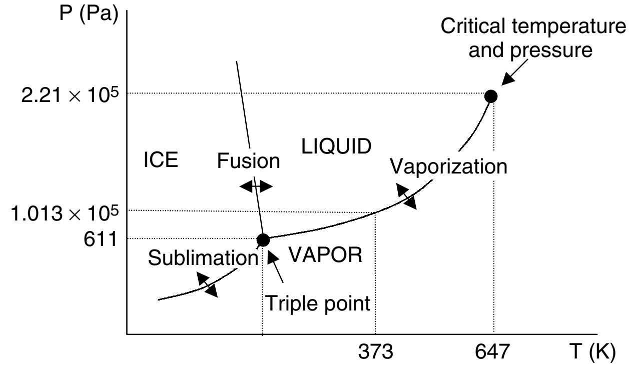


Figure 1.

However, in the special case of only one component, partial molar values of extensive state functions are the same as their molar values, and therefore $-s_\alpha = -S_\alpha$ and $v_\alpha = V_\alpha$, where S_α and V_α denote molar entropy and volume. $-S_\beta$ and V_β are similarly defined, and therefore $dP/dT = (S_\beta - S_\alpha)/(V_\beta - V_\alpha)$. This important general equation for the slope of the phase equilibrium line in phase diagrams for single-component systems was first proposed by French physicist and engineer Emile Clapeyron in 1834. As, by definition, $(S_\beta - S_\alpha) = (H_\beta - H_\alpha)/T$, then $dP/dT = (H_\beta - H_\alpha)/[T(V_\beta - V_\alpha)]$. By convention, extensive property changes (such as ΔS, ΔH, ΔG) for phase transition are taken such that their values are positive. Along the vaporization curve in Fig. 1, $\Delta H_{\text{vap}} = H_{\text{vap}} - H_{\text{liquid}}$ and $\Delta V_{\text{vap}} = V_{\text{vap}} - V_{\text{liquid}}$. Similarly, along the sublimation curve, $\Delta H_{\text{sub}} = H_{\text{vap}} - H_{\text{solid}}$ and $\Delta V_{\text{sub}} = V_{\text{vap}} - V_{\text{solid}}$.

The foregoing reasoning assumes that the gaseous phase consists only of the vapor. If, however, other gases are present (e.g., water vapor in air), this would increase the external pressure on the condensed phase and tend to increase mass transfer to the vapor phase. For this system, μ_α $(P)|_T = \mu_\beta$ $(P)|_T$ at equilibrium (for fixed T). Taylor's series expansion, described above, reduces to dP_α $(\partial\mu_\alpha/\partial P)_T = dP_\beta$ $(\partial\mu_\beta/\partial P)_T$ and therefore $dP_\alpha/dP_\beta = V_\beta/V_\alpha$, where V is the molar volume, P_β is the vapor pressure, and P_α is the total pressure exerted on the condensed phase. This assumes that the only effect of the other gases is increasing the total pressure on the condensed phase, meaning they behave as a closed subsystem with respect to the vapor phase. V_β (molar volume of the vapor phase) is usually $>> V_\alpha$ (molar volume of the condensed phase) and therefore V_α can be assumed constant. Assuming ideal behavior of the vapor phase, $V_\beta = RT/P_\beta$. Substitution and rearranging gives $dP_\beta/P_\beta = (V_\alpha dP_\alpha)/(RT)$. Integration between $(P_\beta)_1$ at $(P_\alpha)_1$ and $(P_\beta)_2$ at $(P_\alpha)_2$ gives $\ln[(P_\beta)_2/(P_\beta)_1] = [V_\alpha/RT][(P_\alpha)_2 - (P_\alpha)_1]$. For water, using $V_\alpha = 18\ \text{cm}^{-3} \cdot \text{mol}^{-1} = 1.8 \times 10^{-7}\ \text{m}^3 \cdot \text{mol}^{-1}$ at 277.16 K (4 °C), $R = 8.314\ \text{J}\cdot\text{mol}^{-1}\cdot\text{K}^{-1}$, and 1 atm ($1.013 \times 10^5$ Pa) change in external pressure, we find the right-hand side of the solution $= 0.000791$. This implies the ratio of the vapor pressures $= e^{0.000791} = 1.00079$ and therefore an increase in vapor pressure of 0.079%. This shows that the effect of the presence of other "inert" gases that increase the external pressure on the condensed phase is generally small and can be ignored for most cases of practical interest.

The Clapeyron equation can be integrated exactly if functions $(\Delta H)_{\text{tr}}(T, P)$ and $(\Delta V)_{\text{tr}}(T, P)$ can be defined. Here, the subscript tr denotes either solid/vapor or liquid/vapor transition. Such functions are usually semianalytical at best. They are often applicable over short ranges of T and P and therefore values for pure substances are usually presented as tables (3). These tabulations usually list H, S, and V for the pure phases as values per unit mass obtained by dividing the molar values by the molecular weight in appropriate mass units.

Reasonable approximations can be made if one assumes (1) $V_{\text{vap}} >> V_{\text{liquid}}$ or V_{solid}, (2) ΔH_{tr} is constant over the range of temperature of interest, and (3) the vapor behaves as an ideal gas. In this case, $v_{\text{vap}} = RT/P$, where v_{vap} is the specific volume of the vapor ($\text{m}^3{\cdot}\text{kg}^{-1}$) and R ($\text{J}{\cdot}\text{kg}^{-1}{\cdot}\text{K}^{-1}$) is the specific ideal gas constant ($R = 8.314\ \text{J}{\cdot}\text{mol}^{-1}{\cdot}\text{K}^{-1}$/molecular weight of the vapor in $\text{kg}{\cdot}\text{mol}^{-1}$). After some rearrangement, the Clapeyron equation becomes $dP/dT = d(\ln P)/d(1/T) = -(\Delta h)_{\text{tr}}/R$, where $(\Delta h)_{\text{tr}}$ is the specific enthalpy change ($\text{J}{\cdot}\text{kg}^{-1}$), that is, the latent heat for the phase transition. Integration of this approximation of the Clapeyron equation (called the Clausius–Clapeyron equation) between $P = P_1$ at $T = T_1$ and $P = P_2$ at $T = T_2$ gives $\ln(P_2/P_1) = (\Delta H_{\text{tr}}/R)\,(1/T_1 - 1/T_2)$. Indefinite integration gives $\ln P = [-(\Delta h)_{\text{tr}}/(RT)] + C$ (an integration constant). This implies that if observations of $\ln P$ are plotted versus $1/T$, the (negative) slope of the line multiplied by $(-R)$ gives an estimate of $(\Delta h)_{\text{tr}}$ over a short temperature range of interest. Discontinuities exist as the upper limit of the temperature range approaches the triple point or the critical temperature.

In practical applications over wider ranges of temperature, empirical equations are preferred (4). For water, the Goff–Gratch (5–7) and Magnus–Teten (8) equations for $P(T)$ are commonly used in the atmospheric sciences. The Goff–Gratch function for water is regarded as the standard (9) and is given by $P(T) = ke^{f(\theta)}$, where $\theta = 373.16/T$ and

$$f(\theta) = a\theta + b\ln(\theta) + ce^{d/\theta} + fe^{g\theta}$$

where P is in mb, T is in K, $k = 7.95357242 \times 10^{10}$, $a = -18.1973$, $b = 5.0281$, $c = -70242.1852$, $d = -26.1205$, $f = 58.0692$, and $g = -8.0395$.

The corresponding function for ice is $P(T) = ke^{f(\theta)}$, where $\theta = 273.16/T$ and

$$f(\theta) = a\theta + b\ln(\theta) + c/\theta$$

where P is in mb, T is in K, $k = 5.75185606 \times 10^{10}$, $a = -20.9470$, $b = -3.5665$, and $c = -2.0189$.

The Magnus–Teten function is $P(T) = ae^{f(T)}$ with $a = 6.1078$ (P at triple point) and $f(T) = c_1\ (T - 273.16)/(T - c_2)$, where P is in mb and T is in K. For water $c_1 = 17.2694$ and $c_2 = 35.86$. For ice $c_1 = 21.8746$ and $c_2 = 7.66$

Values of P at 10 °C = 283.16 K for water are 12.272 mb by the Goff–Gratch equation and 12.279 mb by the Magnus–Teten equation. Values of P at −10 °C = 263.16 K for ice are 2.597 by the Goff–Gratch equation. The corresponding value by the Magnus–Teten formula is 2.595 mb.

ADIABATIC COOLING

Naraine Persaud
Virginia Polytechnic Institute
and State University
Blacksburg, Virginia

When any closed gaseous system expands against an external pressure with no compensatory input of heat from its surroundings to offset the pressure–volume work done by the system, the expansion results in adiabatic cooling of the gas. The vice versa process results in adiabatic heating. The term adiabatic (from the Greek word meaning "not passing through") implies an idealized process and a perfectly insulated system. Real, imperfectly insulated systems would permit some compensatory heat flux. However, if the effect of such fluxes on the system temperature is small relative to the cooling effect, the expansion can be considered as adiabatic for practical purposes.

Adiabatic cooling and heating is the principal mechanism underlying the continual turbulent vertical mixing (autoconvection) in the earth's troposphere, that is, the lowest 9 km (polar regions) to 18 km (tropics) thick atmospheric layer comprising about 80% of the atmospheric mass where all weather processes occur. It is especially important in the planetary boundary layer (i.e., the lowest 1–2 km thick layer) where surface effects on vertical motions are more manifest. Cloud formation and precipitation, observed temperature decrease with height, and energy and mass transfers in the troposphere all depend on adiabatic cooling. This thermophysical process is therefore sine qua non to the continuity of the earth's hydrological cycle. The focus here is on the physics of adiabatic cooling in the troposphere and the resulting temperature decreases with elevation.

A global average of close to 30% of incoming solar short-wave radiation is absorbed at the earth's surface layers. The resulting increase in the temperature of these layers and heat transfer to the air is the most important driver for turbulent vertical convection and associated adiabatic cooling in the troposphere. The earth's atmosphere is a quasiuniform thermophysical system, meaning that pressure gradients rather than the pressure of the atmosphere as a whole can be defined. To facilitate the analysis of tropospheric adiabatic cooling, the concept of an air parcel is introduced. A parcel (or less commonly an eddy) is a discrete closed volume of tropospheric air with uniform properties that is small enough so that the pressure at any point is the same. This implies that, although each parcel has its own individual structure and evolution in time, the observed state and dynamics of tropospheric air is the net result of the motion of these parcels. Because of the many forces involved in such motions, applying Newton's second law to describe the hydrodynamics of these parcels in the earth's atmosphere would result in a complex set of three-dimensional vector differential equations in spherical coordinates. However, only the relatively simpler vertical component of the vector equations is required for analysis of adiabatic cooling. This component is dominated by the vertical pressure and gravitational forces (1).

In order to understand the interplay of these forces, consider a prizm-shaped, initially motionless parcel in a *dry* atmosphere air above the earth's surface as shown in Fig. 1.

It is assumed that tropospheric air is continuously stratified meaning pressure (P) and density (ρ_d) are continuous and decreasing functions of vertical height (z) above the surface. The subscript d refers to dry air. The volume of the prizm (V) is ($\Delta x\ \Delta y\ \Delta z$). The net force on the prizm is $-V\rho_d g$ (downward weight) + $(\Delta x\ \Delta y)(dP/dz)\ \Delta x$ (upward net pressure buoyancy force). Since the prizm is assumed static, the net force per unit mass (acceleration) = 0 and therefore $(1/\rho_d)\ dP/dz + g = 0$. This equation (termed the hydrostatic or aerostatic equation) states the necessary condition for vertical hydrostatic equilibrium in the troposphere, namely, that gravity must be balanced by the vertical component of the atmospheric pressure gradient force.

Any disturbance of this hydrostatic equilibrium would result in vertical motion of the parcel. In particular, if the density of the parcel (ρ_p) is different from that of the surrounding air (ρ_0), the parcel would accelerate. The buoyancy acceleration is $g[(\rho_0/\rho_p) - 1]$ and is positive (upward) if $\rho < \rho_0$ and vice versa (assuming the vertical pressure gradient force is fixed). Substituting $g = 9.81\ \mathrm{m{\cdot}s^{-2}}$, a 10% decrease in the density of the parcel would result in an acceleration of close to $1\ \mathrm{m{\cdot}s^{-2}}$. Such buoyancy accelerations are the direct result of temperature changes caused by heating (from surface or otherwise) of air parcels. Assuming dry air behaves as an ideal gas $\rho_d = P/R_dT$ [where R_d is the specific gas constant for dry air = $8.314\ \mathrm{J{\cdot}mol^{-1}{\cdot}K^{-1}}/0.289\ \mathrm{kg\ (mol\ dry\ air)^{-1}}$ and T is the absolute temperature (K)], the buoyancy acceleration can be written as $g[(T/T_0) - 1]$, where T and T_0 are the temperatures of the parcel and surrounding air at a given elevation.

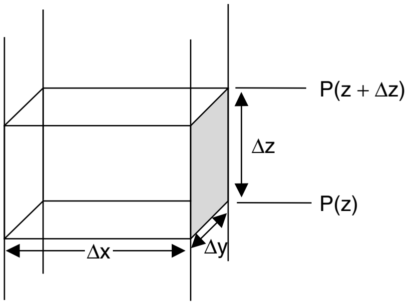

Figure 1. Schematic representation of a retarding basin.

For purposes of analysis of adiabatic cooling, an air parcel is considered as a perfectly insulated bubble of air submersed in the atmosphere, although in reality it could exchange heat with its surroundings. The thermal conductivity of dry air (k_{da} in $\mathrm{W{\cdot}m^{-1}{\cdot}K^{-1}}$ or $\mathrm{cal{\cdot}s^{-1}{\cdot}cm^{-1}{\cdot}K^{-1}}$) at 1-atm pressure is linearly related to temperature over the range 263–473 K. It increases from $0.023823\ \mathrm{W{\cdot}m^{-1}{\cdot}K^{-1}}$ ($0.0000568\ \mathrm{cal{\cdot}s^{-1}{\cdot}cm^{-1}{\cdot}K^{-1}}$) at 273.16 K by $0.0000712\ \mathrm{W{\cdot}m^{-1}{\cdot}K^{-1}}$ ($0.0019\ \mathrm{cal{\cdot}s^{-1}{\cdot}cm^{-1}{\cdot}K^{-1}}$) for each kelvin unit (or °C) change in temperature. The conductivity of moist air is always less than or equal to k_{da}, the difference widening in nonlinear manner with increasing temperature and increasing humidity. Upward acceleration and accompanying expansion of the parcel occur relatively quickly, and because of the low thermal conductivity values of moist air, any heat transfer to the parcel is negligible. This assumption makes possible analysis of the thermal physics of an ascending air parcel as an adiabatic cooling process.

From the integral form of the first law of thermodynamics, a change in internal energy (ΔU) of a parcel equals absorption (gain) or release (loss) of heat (q) minus mechanical work done *by* the parcel (loss) or work done *on* the parcel (gain). Assuming expansion/compression takes place reversibly (i.e., ideally balanced quasistatic equilibrium is always maintained during the process), the mechanical pressure–volume (PV) work done by the parcel against the external pressure (P) is given as $P(\Delta V)$, where ΔV is the volume change (positive for expansion). Thus, in general, $q = \Delta U + P(\Delta V)$. The ideal gas equation of state for unit mass of dry air is $PV = R_dT$. Assuming reversible adiabatic expansion (i.e., process is isentropic), $q = 0$ and $\Delta U = -P(\Delta V) = -R(\Delta T)$ for reversible adiabatic cooling of an ideal gas.

For dry air (a homogeneous gaseous mixture) U in general is a function of absolute temperature (T) and P. However, for an ideal gas, U is a function of T only as demonstrated by James Prescott Joule (1818–1889). Also, U is a state function implying that ΔU is the same for a given temperature change (ΔT) of the parcel, regardless of how ΔT was achieved. Two possibilities are discussed below, namely, changing T at constant volume or at constant pressure.

The specific heat of any substance is the heat input required to cause unit temperature change in unit mass of the substance. In general, specific heat is a function of temperature. The specific heat for gases at constant volume and constant pressure are defined as $C_v(T) = (dq/dT)|_v$ and $C_p(T) = dq/dT|_p$. From the first law, for dry air $C_v < C_p$ since "extra" heat is required at constant pressure for expansion work done against the surrounding pressure. Over tropospheric temperature ranges of practical importance, the specific heats for dry air (denoted as C_{vd} and C_{pd}) can be considered as constants.

Several important results follow from applying the first law to the analysis of adiabatic reversible cooling of a dry air parcel in a quasiuniform atmosphere assuming ideal behavior and constant C_{vd} and C_{pd}. Applying $\Delta U = q - P(\Delta V)$ to the heating of unit mass dry air through ΔT, at constant P, implies that $C_{pd}(\Delta T) - \Delta U = P(\Delta V) = R_d(\Delta T)$. But ideal behavior implies that ΔU can be taken as $C_{vd}(\Delta T)$, and therefore $C_{pd}(\Delta T) - C_{vd}(\Delta T) = R(\Delta T)$, which simplifies to $C_{pd} - C_{vd} = R_d$.

Taking the total differential of the equation of state for unit mass of dry air assuming ideal behavior (i.e., $PV = R_dT$) gives $V\,dP + P\,dV = R_d dT$ or $P\,dV = R_d dT - V\,dP$. Substituting this, together with $R_d = C_{pd} - C_{vd}$, and $dU = C_{vd}dT$ into the differential form of the first law (i.e., $\delta q = dU - P\,dV$) gives $\delta q = C_{vd}dT - V\,dP + (C_{pd} - C_{vd})dT = C_{pd}dT - V\,dP$. The result $\delta q = C_{pd}dT - V\,dP$ is in effect a restatement of the differential form of the first law for dry air.

For an adiabatic ideal gas process $\delta q = 0$ and $C_{pd}dT = V\,dP = [(R_dT)/P]dP$. Separating variables gives $d(\ln T) = (R_d/C_{pd})d(\ln P)$. Integrating between $P = P_0$ at $T = T_0$ and $P = P$ at $T = T$, and rearranging gives $T/T_0 = (P/P_0)^{R_dC_{pd}}$. This result is one of the three adiabatic ideal gas process P–V–T relationships known as Poisson equations (Siméon Denis Poisson, 1781–1840). It describes the quasistatic reversible adiabatic expansion for an ideal gas with constant specific heats from an initial temperature T_0 and pressure P_0 to a new temperature T and pressure P. Usually the ratio $\gamma_d = C_{pd}/C_{vd}$ is defined. Dividing $C_{pd} - C_{vd} = R_d$ by C_{pd} and rearranging gives $C_{pd} = (R_d\gamma_d)/(\gamma_d - 1) = R_d/\kappa_d$ with $\kappa_d = (\gamma_d - 1)/\gamma_d$. For dry air $R_d = 8.314\ \mathrm{J{\cdot}mol^{-1}{\cdot}K^{-1}}/0.029\ \mathrm{kg\ (mol\ dry\ air)^{-1}} = 286.7\ \mathrm{J{\cdot}kg^{-1}{\cdot}K^{-1}}$, $C_{pd} = 1004\ \mathrm{J{\cdot}kg^{-1}{\cdot}K^{-1}}$, and $\kappa_d = 0.286$.

The result $T/T_0 = (P/P_0)^{\kappa_d}$ can be solved for $T_0 = T(P/P_0)^{\kappa_d} = \theta_d$. This definition of θ_d with $P_0 = 1$ bar (1000 mb) is termed the potential temperature. It is the temperature that the parcel initially at T, P would assume when changed adiabatically to 1000 mb. From its definition, $\ln\theta = \ln T + \kappa_d\ [\ln P_0 - \ln P]$ and $d(\ln\theta) = d(\ln T) - \kappa_d\ \mathrm{d}(\ln P)$. Dividing $\delta q = C_{pd}dT - [(RT)/P]dP$ by $C_{pd}T$ gives $\delta q/C_{pd}T = d(\ln T) - \kappa_d d(\ln P)$ and therefore $d(\ln\theta_d) = \delta q/C_{pd}T$. As $\delta q = 0$ for an adiabatic process, $d(\ln\theta_d) = 0$, implying the potential temperature is a parameter that remains invariant during the adiabatic ascent of a parcel. As $T = (\theta_d/P_0)P^{0.286}$, plots of T versus $P^{0.286}$ for different θ_d result in a family of straight lines.

Using $\delta q = C_{pd}dT - V\,dP$ with $\delta q = 0$ for adiabatic cooling, gives $dT/dP = V/C_{pd} = 1/(\rho_d C_{pd})$ because V per unit mass (specific volume) is the reciprocal of the density (ρ_d). As shown above, for hydrostatic equilibrium $dP = -\rho_d g\,dz$. Substituting this result for dP in the previous equation gives $-dT/(\rho_d g\,dz) = 1/(\rho_d C_{pd})$ or $dT/dz = -g/C_{pd} = -(g\kappa_d)/R_d$. Writing this result as $C_{pd}dT = -g\,dz$ shows that adiabatic cooling can be interpreted physically as the dry air parcel trading its internal energy ($C_{pd}dT$) to bootstrap its ascent in the troposphere to acquire gravitational potential energy ($-g\,dz$). This interpretation is appropriate since as already discussed the atmosphere is a quasiuniform thermophysical system.

The temperature of an adiabatically cooled parcel of dry (ideally behaved) air ascending in a tropospheric air layer that is in vertical hydrostatic equilibrium therefore decreases linearly with altitude with slope $= -(g\kappa_d)/R_d$. This important theoretical result is known as the dry adiabatic lapse rate (DALR). For $\gamma_d = 1.4$, $\kappa_d = 0.286$, and together with $R_d = 286.7\ \mathrm{J{\cdot}kg^{-1}{\cdot}K^{-1}}$, $g = 9.81\ \mathrm{m{\cdot}s^{-2}}$, gives $dT/dz = 0.0098\ \mathrm{K{\cdot}m^{-1}}$. Assuming a layer of dry air in the troposphere is rapidly and perfectly mixed by vertical convection of a large number of air parcels rising and falling adiabatically, the temperature would be expected to decrease linearly by approximately 1 K (same as 1 °C) per 100 m change in elevation. The layer is isentropic (constant entropy with elevation) and therefore the potential temperature (θ_d) is constant.

The DALR is a theoretical value achievable only in a turbulent well-mixed layer of dry tropospheric air. However, real tropospheric air is always moist because a varying amount of water vapor is always present. To facilitate including this factor in analysis of the behavior of rising moist parcels, the water vapor and dry air are treated as distinct components of a (one-phase) ideal gas mixture. In this case, three independent variables are needed to define an equation of state for moist air, namely, two (usually P,T) of the P–V–T variables together with a (humidity) variable that measures the mass ratio of water vapor in the air. Among several possible measures of this ratio the specific humidity (r_q) is the one traditionally used. It is defined as the mass of water vapor per unit mass of moist air.

Consider a volume (V) of moist air of mass (m_m) = mass water vapor (m_v) + mass of dry air (m_d). The subscripts m, v, d denote properties associated with the moist mixture, vapor, and dry air, respectively. The density $\rho_m = m_m/V = m_v/V + m_d/V = \rho_v + \rho_d$ (i.e., the sum of the partial densities), and therefore specific humidity $(r_q) = \rho_v/\rho_m$. The total pressure P of the volume V of moist air at temperature T (K) would be equal to $P_v + P_d$ (i.e., the sum of the partial pressures). P_v is usually denoted as e, implying $P_d = P - e$. Using ideal gas relations, $e = \rho_v R_v T$ and $P - e = \rho_d R_d T$, where $R_v = R/M_v$, $R_d = R/M_d$ denote the specific gas constants for water vapor and dry air, $R = 8.314\ \mathrm{J{\cdot}mol^{-1}{\cdot}K^{-1}}$ is the universal gas constant, and M is molecular weight ($M_v = 0.018\ \mathrm{kg{\cdot}mol^{-1}}$ and $M_d = 0.029\ \mathrm{kg{\cdot}mol^{-1}}$). This gives $\rho_v = e/(R_vT) = (eM_{wv})/(RT)$ and $\rho_d = (P - e)/(R_dT)$ Dividing numerator and denominator of the right-hand side for ρ_v by M_d gives $\rho_v = (0.622\ e)/(R_dT)$, where $0.622 = M_v/M_d$ (usually denoted as ε), and R_d is the specific gas constant for dry air ($= 286.7\ \mathrm{J{\cdot}kg^{-1}{\cdot}K^{-1}}$). Summing ρ_v and ρ_d, rearranging algebraically, and simplifying gives $\rho_m = [P/(R_dT)]\{1 - [e\ (1 - \varepsilon)/P]\}$. This shows that density of moist air is slightly less than the density of dry air $[= P/(R_dT)]$ at a given pressure and temperature, a fact first noted by Sir Isaac Newton in 1717 in his book entitled *Optiks*. The value of the expression in curly brackets increases with decreasing P for a given e. Taking a maximum possible value of $e = 4500$ Pa at mean sea level with $P = 1$ atm $= 1.013 \times 10^5$ Pa, and $\varepsilon = 0.622$ gives $1 - [e\ (1-\varepsilon)/P] = 0.96$ and implies $\rho_m \approx \rho_d$. Using these results gives, after substituting and simplifying, $r_q = \rho_v/\rho_m = (\varepsilon e)/\{P - [(1-\varepsilon)e]\} \approx \varepsilon e/P$. The mixing ratio r_w defined as mass vapor per unit mass dry air in the mixture $= \rho_v/\rho_d = (\varepsilon e)/(P - e) \approx r_q$.

Eliminating e between ρ_v and ρ_d, rearranging algebraically, and simplifying gives the equation of state for moist air as $P(T, r_q) = \rho_m R_d T(1 + 0.61\ r_q)$. This is equivalent to the ideal gas equation for dry air with $T(r_q) = T(1 + 0.61\ r_q)$ or with $R_m = R_d(1 + 0.61\ r_q)$. In the former case, $T(r_q)$ is termed the virtual temperature (denoted as T_v) and the moist air equation of state is written as $P = \rho_m R_d T_v$. T_v is the temperature dry air would assume in order to have the same density as moist air with specified values of P, T, and r_q.

The specific heats C_{pm}, C_{vm} for moist air would also be functions of r_q. Partitioning the heat for a temperature change (ΔT) in mass (m_m) of moist air at a given r_q expanding at constant pressure gives $m_m C_{pm}(\Delta T) = m_v C_{pv}(\Delta T) + m_d C_{pd}(\Delta T)$. Dividing by $m_m(\Delta T)$ gives $C_{pm} = r_q C_{pv} + (1 - r_q)C_{pd}$ since r_q is by definition m_v/m_m and $m_d = m_m - m_v$. Similar reasoning gives $C_{vm} = r_q C_{vv} + (1 - r_q)C_{vd}$. Values given in the Smithsonian Meteorological Tables (2) are (in J·kg^{-1}·K^{-1}): $C_{pv} = 1846$, $C_{pd} = 1005$, $C_{vv} = 1386$, and $C_{vd} = 716$. Substituting these values and simplifying gives $C_{pm} = C_{pd}(1 + 0.84\ r_q)$ and $C_{vm} = C_{vd}(1 + 0.94\ r_q)$. From these $\gamma_m = C_{pm}/C_{vm} = \gamma[(1 + 0.84\ r_q)/(1 + 0.94\ r_q)]$, where $\gamma = C_{pd}/C_{vd} = 1.4$ is the ratio of the specific heats for dry air as described previously. Multiplying numerator and denominator of the term in square brackets by $(1 - 0.94\ r_q)$ and neglecting r_q raised to powers >1 gives $\gamma_m \approx \gamma(1 - 0.1\ r_q)$. Similarly, $\kappa_m = R_m/C_{pm} = [R_d(1 + 0.61 r_q)]/[C_{pd}(1 + 0.84\ r_q)]$. Multiplying numerator and denominator of the term in square brackets by $(1 - 0.84\ r_q)$ and neglecting r_q raised to power >1 gives $\kappa_m \approx \kappa_d(1 - 0.23\ r_q)$, where $\kappa_d = R_d/C_{pd}$.

γ_m is lower for moist air than dry air but does not affect the DALR appreciably as long as the air does not become saturated. For example, using the foregoing results gives the unsaturated moist adiabatic lapse rate (MALR) as $dT/dz = -(g\kappa_m)/R_m$, where $\kappa_m = (\gamma_m - 1)/\gamma_m$ and $R_m = R_d(1 + 0.61\ r_q)$. At 20 °C and 50% saturation the vapor pressure ≈ 1170 Pa. Using the equations for ρ_v and ρ_m with $R_d = 286.7$ J·kg^{-1}·K^{-1} and $P = 1.013 \times 10^5$, Pa gives $r_q = \rho_v/\rho_m = 0.0072$ kg vapor (kg moist air)$^{-1}$, $\gamma_m = 1.4 \times 0.999 = 1.399$, $\kappa_m = 0.285$, $R_m = 288.0$ J·kg^{-1}·K^{-1}, and MALR $= -0.0097$ K·m^{-1} compared with -0.0098 K·m^{-1} for the DALR. As was done for dry air, the potential temperature invariant for moist unsaturated air (θ_m) can be defined as $\theta_m = T[P/P_0]^{\kappa_m}$, where as discussed above, $\kappa_m \approx \kappa_d(1 - 0.23\ r_q)$ with $\kappa_d = R_d/C_{pd}$.

If a rising moist air parcel becomes cooled to the dew point, condensation occurs (if condensation nuclei are present). The elevation at which this occurs is called the lifting condensation level (LCL). The dew point temperature at the LCL (T_{dL}) is different than at the surface because, although $r_q(\approx \varepsilon e/P)$ remains the same, the vapor pressure decreases as the ascending parcel expands. The dew point (T_{d0}) at the surface depends on the observed ambient temperature (T) and relative humidity $= (e/e_s)|_T$ of the air. The relationship can be obtained using the Clausius–Clapeyron equation $de_s/e_s = (L\,dT)/(R_v T^2)$ for the slope of the equilibrium saturation vapor pressure (e_s) versus temperature curve, where L is the latent heat of vaporization and $R_v(= 461.8\ \mathrm{J \cdot kg^{-1} \cdot K^{-1}})$ is the specific gas constant for water vapor (3). L (J·kg^{-1}) is usually a weak function of temperature approximated as $L = 3.071 \times 10^6 - 2134\ T$ K. L is usually taken as a constant value $= 2.5 \times 10^6$ J·kg^{-1} corresponding to $T = 273$ K. Integrating the Clausius–Clapeyron equation between $e_s = e$ at T to $e_s = e_s$ at T_d gives (after substituting for L and R_v), $T - T_{d0} = -(1.845 \times 10^{-4} T)T_{d0} \ln[(e/e_s)_T]$. When required, reasonable estimates of $e_s(T)$ can be obtained by integrating the Clausius–Clapeyron equation on the half-open interval using the triple point of water ($e_s = 611$ Pa at $T = 273.13$ K) as the lower bound. After substituting numerical values for L and R_v, rearranging and simplifying the result is $\ln e_s(\text{in Pa}) = \ln 611 + [19.83 - (5417/T)]$.

The foregoing implies T_{dL} depends on the surface T_{d0} and on the dew point lapse rate (DPLR). Logarithmic differentiation of $r_{qs} = \varepsilon e_s/P$ gives $dr_{qs}/r_{qs} = de_s/e_s - dP/P = 0$ and therefore $de_s/e_s = dP/P$. Substituting the Clausius–Clapeyron equation for de_s/e_s and the aerostatic equation dP/P gives $L/[R_v(T_d)^2]\,dT_d = (-g/R_dT)dz$, where T_d is the dew point of the ascending parcel at elevation z and T is the corresponding air temperature, and $R_d \approx R_m$. Substituting numerical values $L = 2.5 \times 10^6$ K·kg^{-1}, $R_v = 461.8$ J·kg^{-1}·K^{-1}, $R_d = 286.7$ J·kg^{-1}·K^{-1}, and $g = 9.81$ m·s^{-1} gives dT_d/dz (in K·m^{-1}) $= -(T_d)^2/(0.158 \times 10^6)T$. The LCL occurs when T by cooling at the DALR $= T_d$ by cooling at the DPLR. Therefore, the LCL is obtained by solving $T_0 - 0.0098\,\text{LCL} = T_{d0} - [(T_d)^2/(0.158 \times 10^6 T)]$ LCL, where T_0 is the surface air temperature, which gives LCL $= (T_0 - T_{d0})/\{0.0098 - [(T_d)^2/(0.158 \times 10^6 T)]\}$. T_d and T are functions of elevation but in practice are considered equal to T_{d0} and T_0, respectively, in estimating the LCL. For example, given $T_0 = 20$ °C (293 K) and $T_{d0} = 1$ °C (274 K), the LCL $= 19/\{0.0098 - [(274)^2/(0.158 \times 10^6 \times 293)]\} = 2.323$ km. Alternatively, it has been shown that $[(T_d)^2/(0.158 \times 10^6 T)]$ ranges from about 1.7 to 1.9 K·km^{-1} (4). Using an average value of 1.8 K·km^{-1}, the LCL can be estimated as LCL (km) $= (T_0 - T_{d0})/8$. Using this alternate formula in the above example gives LCL $= 19/8 = 2.38$ km.

For ascent above the LCL, latent heat of condensation is released into the parcel, but the parcel remains saturated at the given temperature. A change $d(r_{qs})$ in r_{qs} (where the subscript s denotes saturation) would result in latent heat released into the parcel $= -L\,d(r_{qs})$, where L denotes the latent heat of vaporization. As was done previously, substitution of the hydrostatic equation $dP = -\rho_s g\,dz$ into the first law as $\delta q = C_{ps}dT - V\,dP$ gives (for unit mass) $\delta q = C_{ps}dT + g\,dz$. Since no water is lost from the parcel $\rho_s = \rho_m = P/R_mT$. Substituting $-Ld(r_{qs})$ for δq gives

$C_{ps}dT + g\,dz = -L\,d(r_q)$. Assuming almost all of the heat released by condensation goes to heating the dry air component in the parcel would imply $C_{ps} \approx C_{pd}$. Making the substitution, dividing throughout by $C_{pd}dz$, and rearranging gives $dT/dz = -(L/C_{pd})(dr_{qs}/dz) - g/C_{pd}$. This is the saturated adiabatic lapse rate (SALR). Since r_{qs} is a function of T and P, dividing its total differential (dr_{qs}) by dz gives $dr_{qs}/dz = [(\partial r_{qs}/\partial P)]_T(dP/dz) + [(\partial r_{qs}/\partial T)]_P(dT/dz)$. Substituting this result with $dP/dz = -\rho_m g$ into the SALR expression, rearranging, and simplifying gives

$$\text{SALR} = \frac{-g}{C_{pd}}\left(\frac{[1 - \rho_m L(\partial r_{qs}/\partial P)_T]}{[1 + (L/C_{pd})(\partial r_{qs}/\partial T)_P]}\right)$$

Differentiating $r_{qs} \approx \varepsilon e_s/P$, where $e_s(T)$ is the saturation vapor pressure gives $[(\partial r_{qs}/\partial P)]_T = -(\varepsilon e_s)/P^2$ and $[(\partial r_{qs}/\partial T)]_P = (\varepsilon/P)(de_s/dT)$. Assuming constant L and ideal gas behavior, the Clausius–Clapeyron equation (3) for the slope of the saturation vapor pressure versus temperature curve is $de_s/dT = Le_s/(R_vT^2)$, where R_v is the specific gas constant for water vapor. Substitution of these results together with $\rho_m \approx \rho_d = P/R_dT$ into the equation for the SALR and simplifying gives a more practical form as (4):

$$\text{SALR} = \frac{-g}{C_{pd}}\left(\frac{\left(1 + \dfrac{Lr_{qs}}{R_dT}\right)}{\left(1 + \dfrac{L^2r_{qs}}{C_{pd}R_vT^2}\right)}\right)$$

The value of (Lr_{qs}/R_dT) is usually small. In many applications this term is neglected, resulting in the simpler expression usually encountered in atmospheric science literature. The SALR represents the saturated lapse rate above the LCL. It is assumed that the system remains closed, that is, r_q remains the same (all the water and heat from condensation remains within the ascending parcel), and the ascent continues as a reversible saturated-adiabatic process. However, the system would no longer remain closed if (as may be expected) some or all of the water and heat from condensation at a given elevation is immediately released from the parcel. This would imply an irreversible and nonadiabatic process. However, the heat lost is small relative to the heat content of the parcel and the ascent in this case is termed as pseudoadiabatic (meaning "as if it were adiabatic"). The SALR given above is considered equal to the pseudoadiabatic rate for all practical purposes.

However, the SALR is considerably lower than the DALR $\approx$ MALR and is a function of temperature. The SALR is about 4 K·km^{-1} for humid air masses near the surface. It increases to about 9 K·km^{-1} as the humidity decreases with increasing elevation. An average value is about 5.4 K·km^{-1}. Like its counterparts θ_d and θ_m for dry and unsaturated air, the potential temperature invariant for saturated adiabatic ascent (θ_e termed the equivalent potential temperature) is defined as $d(\ln\theta_e) = \delta q/(C_{pd}T) = (-L\,dr_{qs})/(C_{pd}T) = -d[(Lr_{qs})/(C_{pd}T)]$. Integrating (on the half-open interval with lower bound $\theta_e = \theta_d$ at $r_{qs} = 0$) and exponentiating gives $\theta_e = \theta_d e^{[Lr_{qs}/(C_{pd}T)]}$. Physically, θ_e is the temperature attained if moist air at temperature T is expanded pseudoadiabatically, until all the water has condensed out and is removed from the parcel, and then is compressed adiabatically to the standard pressure of 1000 mb.

The theoretical lapse rates developed in the foregoing discussion serve as reference values for inferring tropospheric conditions from the observed environmental lapse rate (ELR) at a given location. Departures of the ELR from these reference lapse rates provide a measure of the stability (i.e., the autoconvective propensity or the tendency for vertical motions induced by density stratification) in a given layer of tropospheric air.

Below the LCL, when the ELR = DALR $\approx$ MALR (lapse rate is adiabatic) a rising parcel will always be at the same temperature as its surroundings. Therefore, it would have the same density and would neither tend to return nor continue its displacement. The stability of a tropospheric layer with these conditions prevailing is termed neutral. If the ELR < DALR (lapse rate is subadiabatic) an ascending parcel will quickly become colder (more dense) than the surrounding air and will return to its original position. The layer is termed absolutely stable. Stable air resists vertical movement. If the reverse is true and the ELR > DALR (lapse rate is superadiabatic) an ascending parcel will become warmer (less dense) than the surrounding air and will continue to rise. Except in the heated layer next to the surface, such instabilities do not persist since they are rapidly counteracted by vigorous autoconvection and vertical mixing as fast as they develop. In terms of θ_d, these stability conditions correspond to stable ($\theta_d < 0$), neutral ($\theta_d = 0$), and unstable ($\theta_d > 0$). In a similar manner, saturated air parcels will be stable, neutral, or unstable with respect to vertical displacements depending on whether the ELR is <, =, or > the SALR or θ_e <, =, or > 0.

The tropospheric lapse rate for the standard atmosphere (5) is $-6.5\,^\circ\text{C·km}^{-1}$. Parameters for the standard atmosphere have been specified by the International Civil Aeronautical Organization (ICAO) and are needed for standardization in aviation, aeronautics, and meterology. Using subscript *sa* to denote the standard atmosphere, solving $-0.0065\ \text{K}\cdot\text{m}^{-1} = -[g(\gamma_{sa} - 1)/(R_d\gamma_{sa})]$ for γ_{sa}, with $g = 9.81\ \text{m·s}^{-2}$ and $R_d = 286.7\ \text{J·kg}^{-1}\text{·K}^{-1}$, gives $\gamma_{sa} = 1.23$ compared to the value of $\gamma_d = 1.4$ for dry air. Other parameters for the standard atmosphere are surface temperature = 288.15 K, pressure = $101,325$ Pa, density = $1.225\ \text{kg·m}^{-3}$, and mean molecular weight = $28.964\ \text{g·mol}^{-1}$.

The standard lapse rate implies $T(z) = T_0 - \beta z$, where $T(z)$ is the temperature (K) at elevation z (m), T_0 is the surface temperature, and $\beta = 0.0065\ \text{K·m}^{-1}$. Assuming ideal gas behavior, substituting $T = T_0 - \beta z$ into the aerostatic equation $dP/dz = (-Pg/RT)dz$, separating variables, and integrating on a half-open interval with lower bound $P = P_0$ at $T = T_0$ gives, after some rearranging, $\beta z/T_0 = 1 - (P/P_0)^{R\beta/g}$. These relationships can be used to calculate P, T of tropospheric air for the standard atmosphere at any given elevation. As an example, for $z = 10$ km and $T_0 = 288.15$ K, $T = 288.15\ \text{K} - (0.0065\ \text{K}\cdot\text{m}^{-1} \times 10^4\text{m}) = 223.2$ K. Substituting $T_0 = 288.15$ K, $P_0 = 1.01325 \times 10^5$ Pa, $R = 286.7\ \text{J·kg}^{-1}\text{·K}^{-1}$, and $\beta = 0.0065\ \text{K·m}^{-1}$ gives P at 10 km and $P = 0.26$ atm with $T = 223$ K.

RAIN AND ROCKS: THE RECIPE FOR RIVER WATER CHEMISTRY

Mohammed Riajul Islam
University of Idaho
Moscow, Idaho

INTRODUCTION

The dissolved and suspended loads of most of the world's major rivers are dominated by weathering processes. Particularly, chemical weathering of rocks and soils is one of the essential processes in the geochemical cycling of elements in rivers (1,2) as well as in the continent–river–ocean system (3). The climatic factors such as moisture and temperature mainly affect the weathering processes (2,4). The most soluble ions that will end up in the ocean through rivers are released because of interactions between water and rocks at the earth's surface (5–7). Weathering's importance has led to a huge number of detailed geochemical studies on the world's major river systems, including the Ganges-Brahmaputra (3,8), other major Himalayan rivers (9,10), the Amazon (11), the Mackenzie (12), rivers of the Canadian Shield (5,12), the Congo (13–15), some large Chinese rivers (16,17), the Mississippi, Indus, and some other U.S. rivers (18,19), the Loire River in France (20), and the upper Niger river (21).

Aerosols are the primary source of chemical elements transported by rainwater (22), which are removed from the atmosphere by rainout or by washout. Atmospheric aerosols (sea salt, crustal dust, and biogenic aerosols) have been found as the major sources of dissolved species in river water (14,23,24). Dissolved components from rainwater come from those originating from sea salt aerosols; from those originating from terrestrial aerosols (soil dust, biological emissions); and from those originating from anthropogenic sources (industry, agriculture, burning of fossil fuels, etc.) (25).

Along with the geological characterization of the watershed, meteorological parameters are critically important in evaluating rainfall effects, as demonstrated by Grosbois et al. (20). These investigators have demonstrated, in accordance with Negrel and Roy (25), that the Loire River basin was characterized by its diversity of air-mass trajectories divided into four major origins: (1) westerly, which originates from the Atlantic (26); (2) northeasterly to northwesterly, which originates from the North Atlantic and North Sea and passes over Great Britain and the industrialized countries from France to Eastern Europe; (3) easterly, with a continental origin and a geochemical signature influenced by polluted countries and a large forested area; and (4) southeasterly to southwesterly, which originates in the Mediterranean Sea and is influenced by natural Saharan aerosols and pollution from Spain.

The radiogenic isotope ^{87}Sr is produced because of the radioactive decay of ^{87}Rb isotope. The existence of ^{87}Sr—which is often expressed as the ^{87}Sr/^{86}Sr ratio in a given geological material—is a function of its age and Rb/Sr ratio. As a result, Sr released by aerosols having different origins results in different ^{87}Sr/^{86}Sr ratios in rainwater. The Sr variations are caused mainly because of the mixture of different sources with different Sr isotope compositions (25). Sr isotope ratios in precipitation have been reported by a wide number of investigators from various parts of the world (27–30).

METHODOLOGY OF STUDYING ROCKS–RECHARGE INTERACTIONS AND RAINWATER CHEMISTRY

Geology of the Study Areas

Consideration of geology is crucial in assessing the link between river water chemistry and local bedrock geochemistry, as demonstrated by English et al. (31) in their Seti river studies in the Himalayan area, which receives high rainfall (32). Over 70% of the TDS in the Seti River is derived from carbonate weathering in the Tethyan sedimentary series/Greater Himalayan series and upper Nawakhot Group of the Lower Himalayan as bedrock and sediment control riverine TDS and Sr. The investigators also found certain rock types in the river bedload that have been derived from related bedrock because of weathering. Furthermore, tributary waters display unique characteristics directly related to the local geology (i.e., bedrocks, climate, hydrology, etc.). The river watersheds, tributaries, local rainfall, humidity, and temperature data must be considered for the study of rocks–recharge interactions as well as river water chemistry. Table 1 shows the effects of various local bedrocks on river water chemistry in different regions.

Sampling

Systematic sampling of precipitation (25), river and tributary waters, bedrock, and river bed sediments would identify geochemical controls on stream chemistry (3,9,10,20,31).

The dissolved elements in stream waters provide information on the source of the atmospheric contribution (36). The marine contribution decreases with increasing distance from the ocean, whereas terrestrial contributions become dominant. However, it is very difficult to identify different kinds of sources (e.g., terrestrial aerosols, anthropogenic aerosols), unless isotopes (e.g., ^{87}Sr/^{86}Sr)

[a] bdl, below detection limit.

are obtained from atmospheric contributions. The major and trace element data of sediments does provide clues to source area (37).

For rainwater collection, an automatic precipitation sampler is used (25). The basic requirements for the collector are automatic detection and collection of rainfall, dry fallout elimination, collection of frozen precipitation, and avoidance of sample contamination, particularly for trace element analysis.

Chemical Analysis: Rainwater

Rainwater is analyzed for conductivity, temperature, and pH—all determined on site. Electrical conductivity and water temperature are determined with a microprocessor conductivity meter. pH is measured with any standard pH meter. For major and trace elemental analyses, AAS, ICP-MS, and IC (ion chromatography) are used. Bicarbonate is analyzed by HCl titration and Gran's method (25).

Chemical separation and mass spectrometry procedures for Sr followed the standard method used at BRGM. Strontium is separated by using a cation exchange column (i.e., DOWEX AG50X8) with 2 *N* HCl as eluant. After chemical separation, one-fifth of each sample is analyzed using a Finnigan MAT 262 multiple collector mass spectrometer. The $^{87}Sr/^{86}Sr$ ratios are normalized to $^{86}Sr/^{88}Sr = 0.1194$.

Bedrock and river sediments can be analyzed for major and trace elements using XRF, ICP-MS, and AAS.

RESULTS AND INTERPRETATIONS

Meteorological data are taken generally from local meteorological offices. Average air mass trajectories and weather patterns enable one to identify air mass origins. For example, Negrel and Roy (25) demonstrated the limits of the four air-mass trajectories and four directions of the air-mass movements in the Massif Central area in France. Rainwater chemistry and Sr isotope values are determined for the evaluation of rainwater. The mean pH value of rainwater is 5.22 ± 0.65 (ranges 4.29–6.2) as determined in Massif Central, France (25), whereas the pH of pristine rainwater is moderately acidic with a theoretical value of 5.7 (4). Any higher values reported in France could be the result of dissolution of windblown dust with high $CaCO_3$ content. Rainwater often has a pH value below 5.7 because of the presence of H_2SO_4, weak organic acids, anthropogenic emission of H_2SO_4, and/or HNO_3. The concentrations of elements in rainwater vary greatly with the variation of sampling period (25). In France, the ion imbalance between cations and anions in rainwater is well studied (26,38,39). Significant temporal variation in $^{87}Sr/^{86}Sr$ ratios is also present (709198 to 0.713141) and is particularly associated with changes in seasons. Table 2 indicates the influence of meteorological and anthropogenic effects on rainwater chemistry.

Quantification of Marine and Terrestrial Contributions Using Concentration Data

A sodium (Na) reference (hereafter referred to as Y_{ref}) is used to determine sea salt (ss) and terrestrial contributions in rainwaters (rw) (46–48). To calculate the contribution of the sea salt component (ss) with seawater (sw) characteristics, the following equation is used:

$$X_{\text{ss}} = Y_{\text{ref}} x (X/Y)_{\text{sw}} \tag{1}$$

The contribution of the terrestrial component (t) is the difference between the total composition of rainwater (rw) and the sea salt (ss) contribution:

$$X_{\text{t}} = X_{\text{rw}} - X_{\text{ss}} \tag{2}$$

In calculating the contribution for a given element X, the main obstacle to resolve is the selection of the reference species (marine or terrestrial). An element to be used as a marine or terrestrial reference must be free from fractionation during aerosol formation, transportation, or deposition by rain impaction. In addition, the element must be absolutely of marine or terrestrial origin.

Table 2. Chemical Compositions of Representative Rainwater in Various Regions, μequiv/L

Regions (Ref.)	pH	Cl^-	$SO_4{}^{2-}$	$NO_3{}^-$	$NH_4{}^+$	Ca^{2+}	Mg^{2+}	Na^+	K^+
Buyukcekmece, Istanbul (mean) (40)	5.36	215.11	231.89	78.41	16.41	473.6	259.84	113.13	73.6
Patras, Greece (41)	5.16	114.3	46.1	19.4	16.3	98.5	30.4	90.2	6.6
Montseny, Spain (42)	6.4	28.4	46.1	20.1	22.9	57.5	4	9.8	22.3
Sardinia, Italy (43)	5.18	322	90	29	25	70	77	252	17
Silent Valley, India (mean) (44)	—	43	20	21	3	43	14	46	4
Morvan, France (45)	5.25	14.7	29.4	18.8	57	12.4	6.4	13.3	—

Generally, Na is used as a reference element for sea salt and Mg for coastal or marine rains (4). However, both Na and Mg contents in rainwater can be influenced by nonmarine inputs (48–50). Chlorine could be used as a reference if the Cl/Na ratios of rainwater do not differ from those of seawater (1.16 mol/mol) (4).

Calcium comes mainly from a natural terrestrial source, and a marine source may not be significant for K and Sr. Nitrate (NO_3) and SO_4 come mainly as a result of human activities (e.g., fuel combustion) (4). However, major element chemistry cannot characterize perfectly the various terrestrial end members. For this reason, Sr isotope compositions are used to get additional information regarding the different possible terrestrial sources and their respective proportions.

To determine the possible terrestrial inputs, Losno et al. (38) used the Al content in rainwater to determine Na from terrestrial input (t), according to the following equation:

$$Na_t = Al_{rw}(Na/Al)_t \tag{3}$$

Strontium Isotope Systematics

From the mixture of sea salt and terrestrial dust, the terrestrial isotope ratio $(^{87}Sr/^{86}Sr)_t$ in each rainwater sample can be calculated using Sr isotope systematics (30). The binary mixing equation for these two end members is demonstrated by

$$(^{87}Sr/^{86}Sr)_{rw} = \alpha(^{87}Sr/^{86}Sr)_{sw} + (1-\alpha)(^{87}Sr/^{86}Sr)_t \tag{4}$$

where $(^{87}Sr/^{86}Sr)_{rw}$ is the measured isotope ratio in rainwater, $(^{87}Sr/^{86}Sr)_{sw}$ is the isotope ratio of seawater (0.70917 ± 0.00001), $(^{87}Sr/^{86}Sr)_t$ is the crustal isotope ratio, and α is $Sr_{marine}/Sr_{terrestrial} + Sr_{marine}$ (determined in Eqs. 1–3).

Hence, we obtain

$$(^{87}Sr/^{86}Sr)_t = \{(^{87}Sr/^{86}Sr)_{rw} - \alpha(^{87}Sr/^{86}Sr)_{sw}\}/(1-\alpha) \tag{5}$$

The terrestrial ratios in the rain samples significantly vary, which is indicative of terrestrial aerosol heterogeneities because isotopic variations in the crustal source demonstrate the different terrestrial components with different isotope ratios in the mixture. The isotopic composition of Sr in dusts can be calculated by studying $^{87}Sr/^{86}Sr$ ratios of river water. For example, on a carbonate watershed, the river water's $^{87}Sr/^{86}Sr$ ratio is the same as that of the rocks (25).

Identification and Quantification of Natural and Anthropogenic Inputs in River Water

Attention must be given to the different contributions of the different end-member inputs to the total dissolved load, as any calculation of the export rate of chemical species (natural or anthropogenic origin) requires the quantification of each end member. This problem can be solved using a mass balance calculation.

In general, a mass balance equation for the budget can be expressed as follows (51,52):

$$\begin{aligned}&\text{rock weathering} + \text{atmospheric input}\\&\quad + \text{human activities input}\\&\qquad = \text{dissolved load} + \text{solid load}\end{aligned}$$

Determination of an output–input budget (53,54) and determination of element origins are required for the mass balance approach. The mass balance approach may evaluate the contribution of atmospheric inputs, anthropogenic impacts, and rock weathering processes.

Atmospheric Inputs Correction

Dissolved species in surface water may contain a significant amount of solutes from rainfall (51). The target of the atmospheric input correction is to quantify and subtract the portion of the elements carried by rainwater in the chemical composition of the river water. Knowledge of the chemical composition of the rainfall on the total watershed is required for the quantification of atmospheric input because of rainfall (24,51).

Classically (51), for any element Z in the river $[(Z)_r]$, correction of the atmospheric contribution to a river (r) is estimated by reference to the Cl concentration, called $(Cl)_{ref}$, multiplied by the Z/Cl ratios of rainwater (rw):

$$(Z)_{rw} = (Cl)_{ref} \cdot (Z/Cl)_{rw} \tag{6}$$

$$(Z)_{r,rw\ corrected} = (Z)_{initial\ r} - (Z)_{rw} \tag{7}$$

Atmospheric chloride ions originate from sea salt and human activities. Except for salt rock, Cl release because of rock weathering has not been demonstrated clearly (55). Moreover, through the hydrological cycle, Cl behaves conservatively (55), so it is used as a reference of atmospheric inputs in many unpolluted hydrosystems (3,56). However, chloride ions can also have an anthropogenic origin (57). For the mass balance equations, the number of Cl ions issued from rainwater, known as $(Cl)_{ref}$, has to be determined. The $(Cl)_{ref}$ is calculated with each mean weighted chloride content for the sampling spots multiplied by the concentration factor F of each region. The concentration effect of evapotranspiration is represented by the factor F and is related to total amount of rainwater P (in mm) and the evapotranspiration process E (in mm) by the equation

$$F = P/(P - E) \tag{8}$$

The general equation to calculate $(\mathrm{Cl})_{\mathrm{ref}}$ is

$$(\mathrm{Cl})_{\mathrm{ref}} = (\mathrm{Cl})_{\mathrm{SA}} \cdot 0.25 \cdot \mathrm{F}_{\mathrm{SA}} + (\mathrm{Cl})_{\mathrm{MC}} \cdot 0.75 \cdot \mathrm{F}_{\mathrm{MC}} \tag{9}$$

where $(\mathrm{Cl})_{\mathrm{SA}}$ and $(\mathrm{Cl})_{\mathrm{MC}}$ correspond to the weighted concentration of chloride in study areas.

The residual chloride $(\mathrm{Cl})_{\mathrm{res}}$ in the river is attributed only to human activities:

$$(\mathrm{Cl})_{\mathrm{res}} = (\mathrm{Cl})_{\mathrm{measured}} - (\mathrm{Cl})_{\mathrm{ref}} \tag{10}$$

Budgets of Human Activities

When the influence of rainwater is subtracted from the river water composition, the general mass balance equation indicates that the dissolved load carried out by the river results from rock weathering and human activities. It is needed to quantify the influence of anthropogenic inputs in order to evaluate the chemical weathering on the river watershed (20).

It is widely known that phosphorus and nitrogen forms and potassium and chloride ions are mainly derived from agricultural fertilizers, animal waste, and municipal and industrial sewage (58–60). These species are indicative of both population and agricultural impacts, whereas sulfates are bacterial oxidation products of some industrial products (61,62).

The contributions of the different end members to the dissolved load can be calculated using the estimation of chemical signature of the pure end members. For each chemical species, the contributions for the silicate (SIL), carbonate (CAR), and anthropogenic (ANT1, ANT2) end members are calculated for each sample of river water using the following equation, as demonstrated by Grosbois et al. (20):

$$[\mathrm{X}]_{\mathrm{riv}} = a[\mathrm{X}]_{\mathrm{SIL}} + b[\mathrm{X}]_{\mathrm{CAR}} + c[\mathrm{X}]_{\mathrm{ANT1}} + d[\mathrm{X}]_{\mathrm{ANT2}} \tag{11}$$

Conditionally, $a + b + c + d = 1$, where X represents the amounts (in μmol/L) of X in the SIL, CAR, ANT1, and ANT2 end members, and a, b, c, and d represent the proportions (%) of each end-member contribution.

Natural and Anthropogenic Export in the River Watershed

Using the mixing equation (Eq. 11), it is possible to determine natural and anthropogenic exports from the river watershed. The export rates ω (in t/d) because of rock weathering or anthropogenic additions can be calculated for each end member (SIL, CAR, ANT1, and ANT2) and for each hydrological period as follows:

$$\omega = \Sigma(\alpha[\mathrm{Ca}^{2+}] + \alpha[\mathrm{Mg}^{2+}] + \alpha[\mathrm{K}^{+}] + \alpha[\mathrm{Na}^{+}] + \alpha[\mathrm{HCO_3}^{-}] + \alpha[\mathrm{Si}]) \cdot W \tag{12}$$

where [X] is the concentration (g/L), W represents the discharge ($\mathrm{m^3/s}$) measured at the sampling points during the considered hydrological period, and α represents the proportion of an end member for the sample (20). The rock weathering and anthropogenic rates are calculated and ω results behave differently in accordance with the hydrological period.

Contribution of the Lithology

Comparing $^{87}\mathrm{Sr}/^{86}\mathrm{Sr}$ and elemental concentration ratios (e.g., Ca/Na, Mg/Na, and $\mathrm{HCO_3}$/Na) for the rivers draining different monolithological watersheds (i.e., silicate, carbonate, etc.), the respective contribution of each lithology can be deciphered (14,63). The following methodology can be used to correct all ratios for atmospheric input:

$$\mathrm{X}_{\mathrm{atm}} = \mathrm{Cl}_{\mathrm{r}}(\mathrm{X}/\mathrm{Cl})_{\mathrm{rw}}$$

where $\mathrm{X}_{\mathrm{atm}}$ is the percentage of element coming from the atmosphere, Cl_{r} is the chloride concentration in the river, and $(\mathrm{X}/\mathrm{Cl})_{\mathrm{rw}}$ is the ratio measured in the local rainwater (64).

CONCLUSIONS

Chemical weathering of rocks and soils is one of the essential processes in the geochemical cycling of elements in rivers. Although climatic factors such as moisture and temperature play a major role in releasing those elements, atmospheric aerosols have been identified as a major source of dissolved species in river water. Rainwater is significantly impacted by sea salt aerosols, terrestrial aerosols, and anthropogenic sources. For the study of rocks–recharge interactions as well as river water chemistry, the river watersheds, tributaries, local rainfall, humidity, and temperature must be considered. Furthermore, attention must be given to the different contributions of the different end-member inputs, either natural or anthropogenic, to the total dissolved load, as any calculation of the export rate of chemical species requires the quantification of each end member.

PHYSICS AND CHEMISTRY OF WATER

ACID RAIN AND SOCIETY

Paulette Middleton

(from *The Handbook of Weather, Climate, and Water: Atmospheric Chemistry, Hydrology, and Societal Impacts*, Wiley 2003)

INTRODUCTION

Acid rain is one of many manifestations of how actions of society can have adverse effects on human health and welfare. Now more than ever before, the breadth of socioeconomic as well as environmental impacts associated with air pollutants, connections among pollutant contributions to these many impacts, and the implications of these connections are being recognized for policy making and development of management strategies.

It can no longer be argued that it is very costly to mediate acid rain and related air quality concerns. Assessments are beginning to suggest that multiple benefits associated with addressing acid rain in combination with other issues outweigh the costs of control of key responsible pollutants. In addition, when innovative strategies, which include market trading and incentives for conservation and use of clean fuels, are initiated, the costs of pollutant management become even lower. As factors that are not easily quantified monetarily are considered more directly in assessments, the benefits become even greater.

Recent analyses show that the implementation of the acid-rain-related part of the 1990 Clean Air Act Amendments has resulted in reductions in acidity in the north-eastern United States. Improvements in acid-related impacts have also been suggested. However, projections of future conditions over the next 20 to 50 years suggest that, unless more dramatic steps are taken, the overall burden of harmful pollutants could continue to rise in general in different parts of the country. Dramatic reductions in sulfur oxides, the current main contributors to acidity, alone are probably not enough. Planned reductions in nitrogen oxides may or may not be adequate. Similarly, continued close monitoring, if not increased management, of volatile organic compounds and fine particulates, and reassessment of their importance to acid rain and related concerns will be important over the next few years.

Of course, all of these issues are part of the bigger international picture of energy, environment, and economy. While the United States may be more aggressively and wisely addressing acid rain and related issues here at home, the projections for future fossil fuel use worldwide must be considered for the sake of regional air quality as well as the global climate condition. Capital investment in cleaner technologies such as renewable energy and the promotion of conservation strategies worldwide could bring long-term environmental and economic benefits that far surpass the initial costs. The alternative, continued growth in fossil fuel usage in developing countries, could exacerbate air quality problems that already exist in many of these areas and, in the long term, could cause the same acid rain damages experienced in many parts of North America and western Europe. In addition, it would contribute to adverse long-term carbon-dioxide-induced climate change.

As a contribution to our understanding of the atmospheric pollution problem and our role in the solution, this chapter summarizes:

- Acid rain and its relationship with other major issues
- U.S. response to the acid rain issue
- Current assessment of progress on reducing the effects of acid rain
- Projections and speculation on the future of acid rain

ACID RAIN: THE PHENOMENON

The relationships between chemical emissions into the atmosphere and the effects of the chemicals on various ecosystems, human health, and materials are highly complex. Many harmful chemicals (i.e., air pollutants) chemically interact to form other pollutants, which are perhaps even more harmful than the originally emitted chemicals. The most prominent examples of these dangerous chemical products are acid rain, ozone, and aerosols. In addition, many air pollutants are thought to interact in a synergistic fashion to cause even more harm as a group rather than individually. An example of the possible synergism is the hypothesized impact of acid rain and ozone on forest ecosystems. Understanding the causes and effects of acid rain and related air quality issues has become an important mission of atmospheric scientists around the globe.

DEFINITION OF ACID RAIN

Acid rain is the general term used to describe the removal, by rainfall, of acidic pollutants from the atmosphere. Acids also can be removed by other forms of precipitation, such as snow or fog. Acid pollutants may also fall as dry particles or gases that form acids when later combined with moisture. The term *acid deposition* is used to include all the possible forms of acid pollutant removal from the atmosphere, but *acid rain* remains the popular term.

The majority of the deposited acids are nitric acid and sulfuric acid. In some of the more rural regions of the world, organic acids also are important. In very remote areas where the level of acid is low, the “natural background” acid is carbonic acid, which is associated with carbon dioxide in the air. The overall acidity of precipitation also depends on the basic (or alkaline) constituents of the precipitation. Major bases include ammonia and geologic materials, such as dust and fly ash.

Acidity is measured in terms of a pH scale, which is a measure of the log of the hydrogen ion concentration in the precipitation. The scale runs from 0 to 14 with 0 being very acidic and 14 being very alkaline. A midscale value of 7 is considered neutral. A change in 1 pH unit indicates 10-fold increase or decrease in acidity. Unpolluted rain water is considered to have a pH of about 5.6. This acidity is assumed to contain only carbonic acid. In the highly polluted eastern states of the United States., the average acidity of water has a pH between 4 and 5. Even in some remote areas of the world, pH values of 5.2 have been found. These acidity levels suggest that there is a long-range transport of nitrogen and sulfur chemicals.

SOURCES OF ACIDITY

Atmospheric acids mainly are produced in the air as a result of complex chemical reactions of the acid precursor gases. Direct emissions of acids such as sulfuric acid, hydrogen chloride, and hydrogen fluoride have been estimated but are not thought to play a significant role in the acidic deposition processes (1). Sources of the harmful chemical precursors affecting the acidity of deposited materials can be natural or human caused. The three pollutants of most concern in the acidic deposition process are sulfur dioxide (SO_2), nitrogen oxides (NO_x) and volatile organic compounds (VOCs). Fossil-fuel-based power plants and motor vehicles are the major sources of all of these acid precursor pollutants in industrialized areas of the world (2,3).

Sulfur gases are primarily emitted from point sources, involving the combustion of coal in particular. Natural sources of sulfur gases include sea spray, volcanoes, and biologic activity. These sources, however, are at least a factor of 10 *less* than the human-caused emission for major industrial areas such as the United States. Nitrogen gases also result primarily from human activities involving fossil-fuel-derived energy use related to transportation and utilities. Major natural sources include soils and lightning and are thought to make up a significant portion of the overall emission totals, more than has been estimated for the sulfur gases. Estimates of these levels, however, are uncertain (1). The VOCs that produce the organic acids and influence the chemistry producing sulfuric and nitric acids also come mainly from automobile use. However, for the VOCs, natural production from vegetation can be quite significant. In highly vegetated, low industrialized regions natural sources become the dominant producers of VOCs.

Estimates of alkaline particulate and ammonia emissions indicate that there is a high potential for acid neutralization in some parts of the United States. The estimates, however, are subject to a high degree of uncertainty (1). On a global scale, emissions of these important acid neutralizers are among the least well-known chemical emissions (2).

EFFECTS OF ACID RAIN

The effects of acid deposition are the subject of continuing controversy. The northeastern United States has experienced the worst reported impacts in the United States (1). Severe damages attributed to acid rain also have been documented for parts of western Europe (4).

The most sensitive systems to acid deposition are poorly buffered lakes and streams. Buffering capacity refers to the availability of alkaline minerals from soil or rocks to neutralize the acids. When minerals are dissolved in a lake, buffering is able to diminish acid effects. However, this buffering ability or alkalinity can be used up with additions of acidic pollutants. Low alkalinity lakes have the greatest potential for damage, since their neutralizing minerals can be quickly depleted.

Vegetation is exposed to wet acidic deposition through rain, snow, and by direct contact with low, acid-laden clouds. There is currently no widespread forest or crop damage in the United States related to these possible pathways. However, cloud acidity, together with a complex combination of other factors (e.g., ozone, soil acidification, climate) contribute to reduced cold tolerance in high-elevation spruce in the eastern United States and in Europe. This can contribute to damage to trees above cloud level during winters with particularly low temperatures.

Adverse effects on forests in other regions of the world are associated with ozone, as is the case with high-elevation pines in California, or they are closely related to localized soil nutrient deficiencies, as is the case with sugar maples in eastern Canada. Acidic deposition may increase leaching rates of important base cations, principally magnesium and calcium, in forest solids and may be a contributing factor in sugar maple decline in some areas.

Generally, controlled experiments on trees and crops have indicated that ozone, at concentrations near ambient levels, adversely affects forests and crops primarily by growth reduction. Other controlled experiments have demonstrated that normal levels of atmospheric sulfur and nitrogen deposition cause no negative direct effects. Some areas actually may benefit through nutrient enrichment by nitrogen and sulfur deposition.

Computer models project that continued acidic deposition could result in long-term deficiencies of nutrients in some soils. However, currently, there is no evidence to indicate that forest health in general is currently affected by nutrient deficiency or will be affected in the next half century.

Air pollution and acidic deposition contribute to the corrosion of metals and deterioration of stone in buildings, statues, and other cultural resources. Although air pollution is an important concern for cultural objects, the magnitude of its effect on construction materials has been difficult to assess. Many construction materials have protective coatings such as paints; therefore, maintenance and service of protective coatings have an important role in determining the ultimate impact of air pollutants. Paints may also be affected by ambient levels of air pollution.

Another related side effect of acid rain is visibility degradation. Fine particles in the atmosphere containing sulfate, nitrate, and other chemical constituents, which when deposited are associated with acid deposition, cause visibility degradation while in the air. These fine particles have been the major factor in the reduction of visibility in rural and urban areas in the eastern United States since the beginning of the century. In the U.S. West, visibility degradation is being reported in major urban areas and in national parks and wilderness areas.

Direct adverse effects of these pollutants on humans occur largely through the respiratory system. Sensitive populations with existing respiratory or cardiovascular problems, such as those with asthma, are especially susceptible. These effects have been mainly associated with the acid precursor gases and ozone. Studies of the effects of acidic aerosols, composed primarily of nitric acid, ammonium bisulfate, and sulfuric acid, are still relatively new. It has been found that on rare occasions acid levels approach 10 times the long-term mean levels for sulfuric acid. Although substantial uncertainty exists, the body of data raises concern that acidic aerosols alone, or in concert with other pollutants, may be contributing to health effects in exposed populations at current concentration levels.

Human health also can be affected indirectly by pollutants related to acid deposition. People who eat large amounts of fish from acidic lakes or streams may experience exposure to methylmercury in some regions of the country. Drinking water from acidic sources may contain significantly elevated levels of lead. It is unlikely, however, that exposure to humans by this pathway is important, except in isolated cases.

SOCIAL RESPONSE TO ACID RAIN

Historically, toxic effects have been observed in populations acutely exposed to high concentrations of air pollutants. As early as the Middle Ages in London prohibitions on coal burning were instituted in response to perceived health effects of mixtures of dust, soot, and fog. The industrial revolution brought the air pollution issue to the United States, where air quality management continued to be considered local in nature into the twentieth century.

The severity of air pollution impacts became very obvious during the London “killer fog” of 1952, when a mixture of particulates, sulfur dioxide, and acidic fog was associated with severe respiratory effects and approximately 4000 deaths. Emergence of air pollution as a public health issue in the 1950s, as a result of this and other deadly episodes, led to the development of federally funded research programs, culminating in the Clean Air Act and in the establishment of the Environmental Protection Agency (EPA) in 1970. These were major stimuli for the establishment of the U.S. National Ambient Air Quality Standards (NAAQS) that today restrict the atmospheric concentration of pollutants such as sulfur dioxide, nitrogen oxides, and ozone.

Other countries around the world have been developing institutional responses to the threat to human health of air pollution. Air pollution effects on the environment, however, had been slower to be recognized as a serious issue. Acid rain and its ecological effects were first documented in England at the end of the nineteenth century and became regional issues in northwestern Europe and the northeastern United States and eastern Canada only recently—in the late 1960s. During this period and into the 1970s, the mounting anecdotal evidence of the effects of acid rain on aquatic and terrestrial ecosystems launched acid rain as perhaps the first pollution threat to the environment to receive international attention.

The origins of the pressures to regulate acid rain in the United States were primarily twofold. First, Canada protested, lobbied, and publicized its contention that major environmental damage was occurring in its eastern provinces because of acid deposition, and that the major sources of acid precursors were in the United States Second, elected officials and citizens in the eastern and New England states echoed the same concerns, elevating the acid rain controversy to the level of a growing interregional conflict between receptor states and polluting states (5).

The U.S. responses to these concerns took the form of federal research and eventually control programs. The first step was the Acid Precipitation Act of 1980, which created the National Acid Precipitation Assessment Program (NAPAP). During its first 10 years, the research and periodic assessments conducted by NAPAP improved the understanding of the scientific processes and effects of acid deposition. The monitoring and research conducted in the 1980s and the subsequent integrated assessment completed in 1990 provided the scientific knowledge base for Title IV, the Acid Deposition Control Program, of the 1990 Clean Air Act Amendments.

Title IV is designed to reduce the adverse effects of acid deposition through the reductions in annual emissions of sulfur dioxide (SO_2) and nitrogen oxides (NO_x), the precursors to acid rain. Recognizing that the principal sources of acid rain precursors in the atmosphere are emissions from the combustion of fossil fuels, control measures were initiated to reduce emissions from electric utilities. However, rather than the traditional command-and-control approach to regulation, alternative methods of compliance were allowed. These methods included technological adaptation (e.g., scrubbers, higher-efficiency boilers), fuel-switching, and an innovative SO_2 emissions allowance trading program. This represented the first national effort to use market-based incentives to achieve environmental goals.

Due to the innovative nature of using market-based incentives for environmental regulation, Congress set up a mechanism for checking how well trading was working. As part of this activity, Congress asked NAPAP to assess the costs and economic impacts of the acid deposition control program as well as the effectiveness and benefits associated with the various human health and welfare effects. The effects included visibility, materials, and cultural resources damages and ecosystem effects. NAPAP was also asked to consider the deposition levels needed to protect sensitive ecosystems. The results of the assessment of Title IV are to be reported to Congress quadrennially, beginning with the 1996 Report to Congress (6).

CURRENT CONDITIONS

As of the completion of the first report to Congress, several observations have been made regarding the success of Title IV. It appears that the market-based approach has lowered compliance costs. Costs are lower than expected, probably due to a number of factors such as railroad deregulation, technological innovation, and lower operating costs for scrubbers. In addition, all affected utilities have fulfilled the compliance requirements of Title IV. In the first annual reconciliation of allowances and emissions, SO_2 allowances matched or exceeded SO_2 emissions. NO_x reductions have not been as dramatic. This is expected since mandates on NO_x reductions are not in place yet. However, NO_x emissions from all sources in 1995 were 1.5 million tons below 1980 levels. Utilities were responsible for 53% of that reduction.

Statistically significant reductions in acidity and sulfate in precipitation were reported at monitoring sites in the Midwest, mid-Atlantic, and northeastern United States. There is no real evidence of statistically significant decreases in nitrate concentration. Changes in aquatic ecosystems have not yet been detected. However, over the last 15 years, lakes and streams throughout many areas of the United States have experienced decreases in sulfate concentration in response to decreased emissions. While there is some evidence of recovery from acidification in New England, Adirondack lakes continue to acidify, suggesting that additional reductions may be needed in these areas (6).

Sulfur and nitrogen deposition has caused adverse impacts on certain sensitive forest ecosystems in the United States, with high-elevation spruce in the eastern United States being most sensitive. Other sensitive forests are apparently not experiencing the same effects in mortality and growth, at least for now, but some of the same processes appear to be slowly occurring.

The leaching of soil nutrients by continued acidic deposition is a gradual process that will eventually impact forest nutrition and growth in many areas. The recent reductions in sulfur should result in some small immediate improvements in sensitive forests, but large improvements will be slow to occur.

Reduced emissions of sulfur oxides are expected to reduce sulfate concentration and its contribution to haze. It is difficult to assess the extent to which recent reductions have contributed to changes in visibility over the past few years since meteorological and other factors determine the overall changes in visibility. Information is needed over the long term.

The recent reductions in SO_x and NO_x emissions are expected to reduce fine particulates and, as a result, lead to improved human health. It is suggested that reduced emissions will lead to a reduction in premature mortality from cardiovascular and respiratory causes and to a dramatic reduction in the number of asthma symptom days.

One difficulty in determining effects at this time is that many impacts have a response times that are longer than the few years since the passage of Title IV. Visibility and acute health effects can be detected on the order of hours to days. Episodic aquatic effects and soil and plant processes in the forest ecosystem respond on the order of days and weeks to months. Chronic human health, chronic aquatic effects, and forest health, on the other hand, indicate response times on the order of years to decades. Effects on forest solid nutrient reserves and effects on materials begin to show up on the order of decades to centuries. These latter effects are more on the order of climate change impacts response times.

The difference in response times, of course, makes an evaluation of actions taken in the early 1990s difficult to quantify. Improvements in health and visibility can serve as indicators of positive change. However, as already noted, even changes in visibility cannot be directly attributed to sulfate reductions alone, since other factors such as meteorological variability play a role in determining visibility changes especially in the humid part of the eastern United States.

KEEPING A BROAD BASIS OF ASSESSMENT AND ACTION

To review, acid deposition is an end product of a complex series of interactions among atmospheric chemical species emitted by both natural and human sources. For policy assessment purposes, the most important groups of chemical species are compounds containing sulfur and nitrogen compounds that are emitted from factories, power plants, and automobiles based on fossil-fuel combustion. In addition, volatile organic carbon compounds and fine particles play a role in modulating chemical processes and acidity. Some key compounds remain unchanged in the atmosphere and some are neutralized, but others are oxidized into more acidic forms through a complicated series of chemical, meteorological, physical, and biological interactions.

Decisions about the control of acid deposition must deal with the environmental impacts of estimated future emission levels as well as present levels. Projections depend on many complex and interacting socioeconomic factors. The predictability of how rapidly and to what extent fossil fuels will be replaced by clearer and safer fuels (society may change transportation and other energy use habits) and the inter-relationships among countries of the world becoming driving influences for these changes is highly uncertain. Given the demonstrated value of examining multiple causes and effects together, it will continue to be important to keep the base of assessment broad in spite of the uncertainties. The elements of such assessments are illustrated in Fig. 1.

On issues related to acid rain, other policy discussions going on throughout North America also illustrate the growing awareness of the interconnections, as well as the need to capitalize on the relationship in developing strategies for the future. For example, EPA, through the Federal Advisory Committee Act (FACA), is leading the development of combined ozone, particulate matter (aerosols), and regional haze implementation program rules and guidance. Other activities at the regional level, such as the Western Governors' Association (WGA) Air Quality Initiative, the Ozone Transport and Analysis Group (OTAG), the Southern Appalachian Mountain

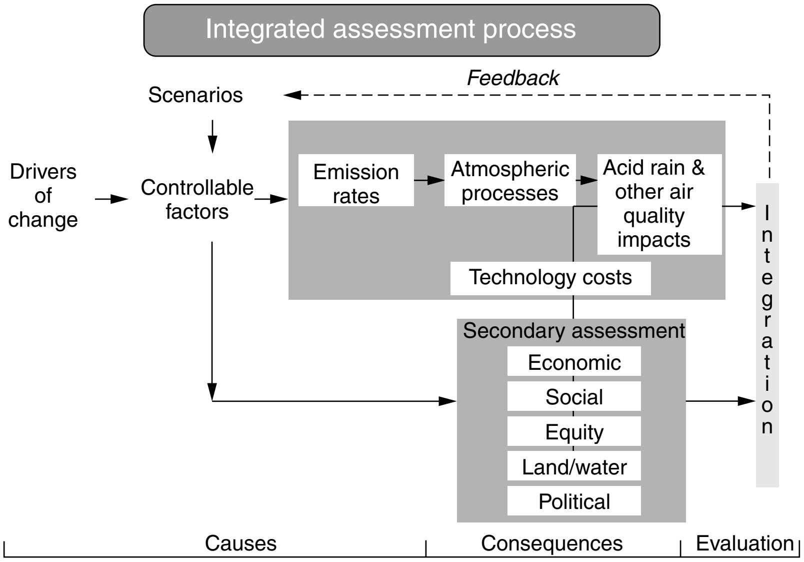

Figure 1. Important elements to consider in an assessment of acid rain in the context of other important environmental, energy, and economic concerns.

Initiative (SAMI), the Southern Oxidant Study (SOS), and the North American Research Strategy for Tropospheric Ozone (NARSTO), are addressing various science and policy issues associated with ozone, particulate matter, and regional haze.

On a continental scale, the Commission on Environmental Cooperation (CEC) is working on North American strategies for addressing transboundary concerns, which include ozone, particulate matter, regional haze, and acid rain along with other hazardous pollutants. Finally, on a much broader scale, the U.S. global climate change program is addressing regional climate assessment for areas throughout the United States. The regional air quality concerns addressed by FACA and the climate concerns to be considered in these discussions are closely linked through the development of aerosols that can influence climate on regional scales as well as produce other problems. On a larger policy implementation level, the two are linked through the development of energy strategies aimed at reducing greenhouse gas emissions and the emission of other more traditionally harmful air pollutants.

All of these programs and approaches share the same fundamental concerns. The role of natural or background processes and the role of chemical interactions in determining the levels of impacts in different regions continue to be fundamental overarching scientific questions. The implementation issues of emissions trading versus pollution prevention versus technological controls are also part of each aspect of the various debates. Assessments of trade-offs for any decisions made with respect to any of these issues must consider the less quantifiable, and sometimes more uncertain, impacts associated with heath, social impacts and values, equity, and related environmental concerns about water and soil quality as well as air. Given these strong interconnections, it is important to make the best use of research and policy-making resources across organizations addressing acid rain and related issues, where energy and the environment are key factors.

ADSORPTION CAPACITY OF ACTIVATED CARBON FOR WATER PURIFICATION

Carl L. Yaws
Prasad K. Narasimhan
Lamar University
Beaumont, Texas

Adsorption on activated carbon is an effective method for water purification. In this article, results for the adsorption capacity of activated carbon for removing organic chemicals from water are presented for a wide variety of substances—alcohols, ketones, aldehydes, acetates, benzenes, chloroalkanes, chloro-olefins, and bromoalkanes. The results use the adsorption capacity as a function of the adsorption potential of the chemical in the aqueous liquid. The correlation constants are displayed in an easy to use tabular format that is especially applicable to rapid engineering usage.

Correlation results and experimental data are in favorable agreement.

INTRODUCTION

Physical and thermodynamic data for organic chemicals are especially helpful to engineers and scientists in industry. In particular, capacity data for adsorption of organic chemicals on activated carbon is becoming increasingly important in engineering and environmental studies because of more and more stringent governmental regulations involving substances in water.

In this article, the objective is to provide results for the adsorption capacity of activated carbon for removing organic chemicals from water. Such results are usable in engineering and environmental studies. As an example of such usage, capacity data from the correlation are useful in the engineering design of carbon adsorption systems for water purification.

CORRELATION FOR ADSORPTION CAPACITY

Adsorption capacity was correlated as a function of adsorption potential (Polyani theory) of a chemical in the aqueous phase using the following equation:

$$\log Q = A + B\ T/V \log\,(x_s/x) \tag{1}$$

Q = adsorption capacity at equilibrium, g compound/100 g carbon
A and B = regression coefficients
T = temperature, K
V = molar volume of liquid, cm^3/mol
x_s = solubility in water, parts per million by weight, ppm(wt)
x = concentration in water, parts per million by weight, ppm(wt)

The coefficients (A and B) are given in Table 1 for a wide variety of organic chemicals in water—alcohols, ketones, aldehydes, acetates, benzenes, chloroalkanes, chloro-olefins, and bromoalkanes. The table also provides the representative formula and an example compound for the chemical families. The correlation should not be used for other chemical families.

The coefficients were determined from regression of available data. In preparing the correlation, a literature search was conducted to identify data source publications (1–10). The excellent compilations by Arbuckle (1); Sonthier, Crittenden, and Summer (2); and Speth (3,4) were used for adsorption capacity. The compilations by Howard and Meylan (5); Mackay, Shiu, and Ma (6); Verschueren (7); Yalkowsky (8); and Yaws (9) were used for water solubility. Liquid molar volume was ascertained from data compilations by Yaws (9,10). The publications were screened and copies of appropriate data were made. These data were then keyed into the computer to provide a database of adsorption capacity at different adsorption potentials in the aqueous phase. The database also served as a basis to check the accuracy of the correlation.

Graphs of adsorption capacity as a function of the adsorption potential are shown in Figs. 1–5, for the substances. The graphs discloses favorable agreement of correlation results and experimental data.

In general, experimental data available in the literature are very limited for the adsorption capacity of activated carbon for organic compounds in aqueous liquids at low concentrations (parts per million range). In view of the very limited experimental data, estimates in the tabulation should be considered rough approximations. Adsorption capacity is also complicated by differences in carbon, lots of carbon, source of water, and concentration ranges (4). If initial feasibility studies using the correlation are favorable, follow-up experimental determination of equilibrium adsorption capacity is recommended.

Examples

The correlations for water solubility are useful in engineering applications involving process wastewater. Examples are shown below.

Table 1. Adsorption Capacity of Activated Carbon—Aqueous System[a]

$\log_{10} Q = A + B\ T/V \log_{10}(x_s/x)$ ($Q - g$ of Compound/100 g of carbon, x − ppm(wt))

Chemical Family	A	B	Formula	Example Compound
Alcohols	1.7250	−0.1210	$C_nH_{2n+2}O$	1-Butanol
Ketones	1.7250	−0.1210	$C_nH_{2n}O$	Diethyl ketone
Aldehydes	1.7250	−0.1210	$C_nH_{2n}O$	Butyraldehyde
Acetates	1.7250	−0.1210	$C_nH_{2n}O_2$	Butyl acetate
Benzenes	1.8893	−0.1199	$C_{n+6}H_{2n+6}$	Ethyl benzene
Chloroalkanes	2.6021	−0.1931	$C_nH_{2n+2-x}Cl_x$	Chloroform
Chloro-olefins	2.2175	−0.1599	$C_nH_{2n-x}Cl_x$	Trichloroethylene
Bromoalkanes	3.0607	−0.1991	$C_nH_{2n+2-x}Br_x$	Bromoform

[a] F 400 Activated carbon, Calgon.
Q—adsorption capacity at equilibrium, g compound/100 g carbon.
x_s—solubility in water at 25 °C, parts per million by weight, ppm(wt).
x—concentration in water at 25 °C, parts per million by weight, ppm(wt).
T—temperature, K.
V—molar volume of liquid, cm^3/mole.
A and B—regression coefficients.

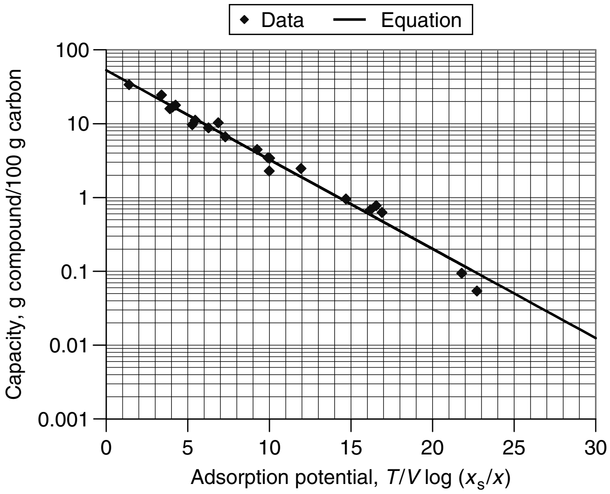

Figure 1. Adsorption capacity of activated carbon for organic oxygen chemicals (alcohols, ketones, aldehydes, and acetates) in water.

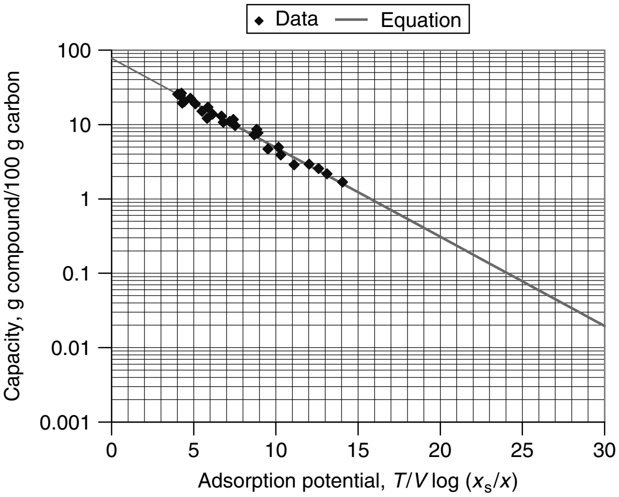

Figure 2. Adsorption capacity of activated carbon for benzenes in water.

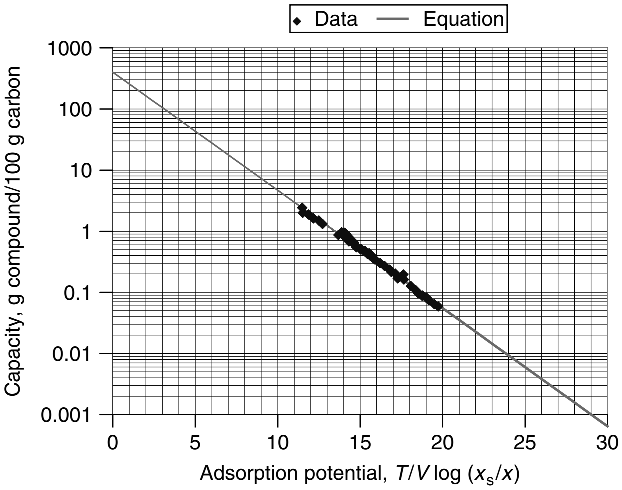

Figure 3. Adsorption capacity of activated carbon for chloroalkanes in water.

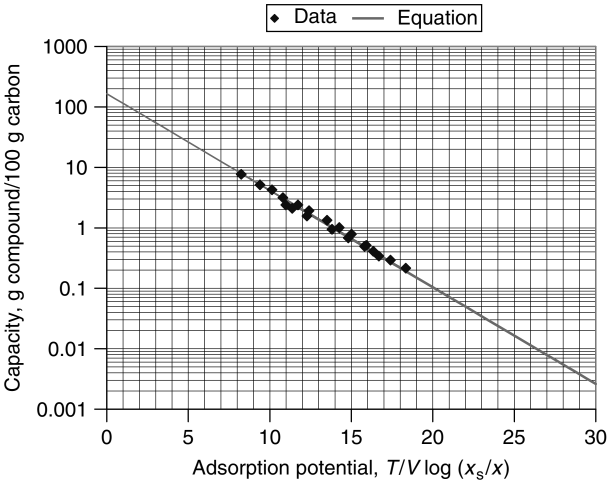

Figure 4. Adsorption capacity of activated carbon for chloro Olefins in water.

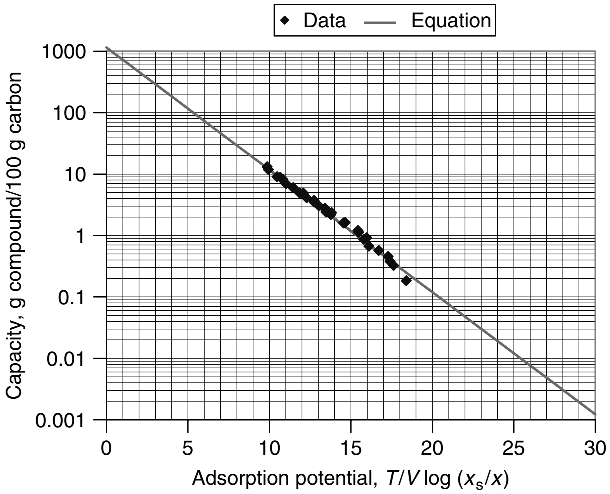

Figure 5. Adsorption capacity of activated carbon for bromoalkanes in water.

Example 1. A chemical spill of n-hexanol occurs in a body of water at ambient conditions. Additional data are

Concentration in water, ppm(wt)	96.31
Temperature, K	298.15
Molecular weight, g/mol	102.177
Liquid density, g/cm^3	0.816
Liquid molar volume, cm^3/mol	125.216
Solubility in water, ppm(wt)	5875

Estimate the adsorption capacity of activated carbon to purify the water.

The correlation for adsorption capacity may be used. Substitution of the coefficients for alcohols and above data in the correlation equation yields

$$\begin{aligned}\log_{10} Q &= 1.7250 - 0.1210 \\ &\quad \times [298.15/125.216 \log_{10}(5{,}875/96.31)] \\ &= 1.21063\end{aligned}$$

$$Q = 16.24 \text{ g } n\text{-hexanol}/100 \text{ g carbon.}$$

The calculated value and data compare favorably (16.24 vs. 17.79; deviation = 1.55/17.79 = 8.7%).

Example 2. A chemical spill of toluene occurs in a body of water at ambient conditions. Additional data are

Concentration in water, ppm(wt)	2.211
Temperature, K	298.15
Molecular weight, g/mol	92.141
Liquid density, g/cm^3	0.865
Liquid molar volume, cm^3/mol	106.521
Solubility in water, ppm(wt)	542.4

Estimate the adsorption capacity of activated carbon to purify the water.

The correlation for adsorption capacity may be used. Substitution of the coefficients for benzenes and the above data in the correlation equation yields

$$\begin{aligned}\log_{10} Q &= 1.8893 - 0.1199 \\ &\quad \times [298.15/106.521 \log_{10}(542.4/2.211)] \\ &= 1.0874 \\ Q &= 12.23 \text{ g toluene/100 g carbon}\end{aligned}$$

The calculated value and data compare favorably (16.23 vs. 12.96; deviation = 0.73/12.96 = 5.6%).

ADSORPTION OF ORGANIC COMPOUNDS

Suparna Mukherji
IIT Bombay
Powai, Mumbai, India

INTRODUCTION

Organic compounds in the aqueous phase have a strong tendency to interact with surfaces, which results in their immobilization on the surfaces and consequent removal from the aqueous phase. This tendency is particularly high for nonpolar hydrophobic organic compounds (HOCs) characterized by low aqueous solubility. In water treatment applications, low levels of HOC contamination of both natural and anthropogenic origin are effectively removed by passage through a bed packed with activated carbon. In the subsurface environment, organic compounds in groundwater have a strong tendency to associate with soil. Thus, in contaminated zones soils and sediments are heavily loaded with organic contaminants, and the loading on these natural geosorbents per unit mass is eventually significantly higher than the aqueous phase concentration. The desorption of sorbed contaminants from soil acts as a long-term source, contaminating groundwater over decades. The association of HOCs with soil is typically termed sorption, which is inclusive of both absorption (partitioning) and adsorption (interface accumulation) (1).

Although sorption is primarily considered to be a reversible process, it significantly affects the fate and transport of organic compounds (2). It affects transformation processes such as photolysis and biodegradation. Thus, sorbed compounds are not readily available to microorganisms even though they may be readily biodegradable from aqueous solution. Aside from the fraction of the organics that are irreversibly bound to the surfaces, through reactions such as polymerization reactions, the reversibly bound fraction can desorb back into aqueous solution. However, the rate of desorption varies with the degree of penetration into the surface sites on the solids. A part of the reversibly bound fraction desorbs rapidly, while the remaining desorbs at a very slow rate over an extended period of time. This is responsible for the hysteresis and aging phenomena often reported in the literature. Hysteresis implies that isotherms relating the loading of a compound on a sorbent to aqueous phase concentration at equilibrium obtained in adsorption studies are not valid for desorption. Aging is the phenomenon of slow desorption observed for sorbents that have been exposed to pollutants over a long period of time. Thus, desorption experiments in laboratory contaminated soil may not be representative of field contaminated soil.

EQUILIBRIUM CONSIDERATIONS IN SORPTION OF HYDROPHOBIC ORGANIC COMPOUNDS ON GEOSORBENTS

Adsorption Isotherms

The maximum loading of an organic compound on a sorbent (q_e, mg/g) is a function of the solution phase concentration (C_e, mg/L) at equilibrium. This relationship is defined for a constant temperature and is known as an isotherm. Since the characteristics of the geosorbents are highly variable, each geosorbent yields a unique isotherm that needs to be obtained experimentally. Isotherms are obtained by setting up multiple batch reactors (sealed bottles) in which a fixed volume of the aqueous phase (V, L) containing varying concentrations of the organic compound (C_o, mg/L) is exposed to a fixed mass of sorbent (M, g). Parallel control reactors without sorbent are also included to determine the system losses. The reactors are tumbled end over end until equilibrium is achieved, and the loading on the sorbent (q_e) is determined by liquid phase mass balance as shown in Eq. 1 (1):

$$q_e = \frac{(C_o - C_e)}{(M/V)} \tag{1}$$

Equation 2 indicates how q_e can be determined after loss correction; it assumes system losses are linearly related to C_e and yields a constant slope S, which is estimated using the controls (3):

$$q_e = \frac{[C_o - C_e(1 + S/V)]}{(M/V)} \tag{2}$$

The experimentally obtained isotherms are fitted to models, such that the model and its parameters indicate the nature of the relationship between q_e and C_e. Three models most commonly used for fitting sorption data are the linear model, the Langmuir model, and the Freundlich model. The model expression, parameters, and the linear transformation typically used for parameter estimation are provided in Table 1 (1).

The constant K_D in the linear model can be determined by one-parameter linear regression. The constants Q_a^o and b in the Langmuir model and the constants K_F and n in the Freundlich model can be determined by two-parameter linear regression by using appropriate data transformations. However, a direct estimation of model parameters by nonlinear regression, which can readily be performed using statistical packages, is more desirable since the transformations performed distort the error structure, thus violating a basic assumption inherent in least squares linear regression (4). The Langmuir model assumes monolayer sorption, reversible sorption, and equal energy sorption sites. It is linear at low concentrations and levels off at a high concentration and shows the characteristic shape depicted in Fig. 1. The Freundlich model is empirically derived and typically provides the best fit to data since it allows for multilayer sorption and heterogeneous sites with variable energies (1). The characteristic shape of this isotherm for various n values is demonstrated in Fig. 1. Low n values, significantly lower than unity, are indicative of greater heterogeneity in site energy distribution and more favorable sorption for low C_e values. The K_F value reflects the sorption capacity.

Sorption in Various Geosorbent Domains

Sorption of nonpolar organic compounds on geosorbents can occur in various domains that are distributed within

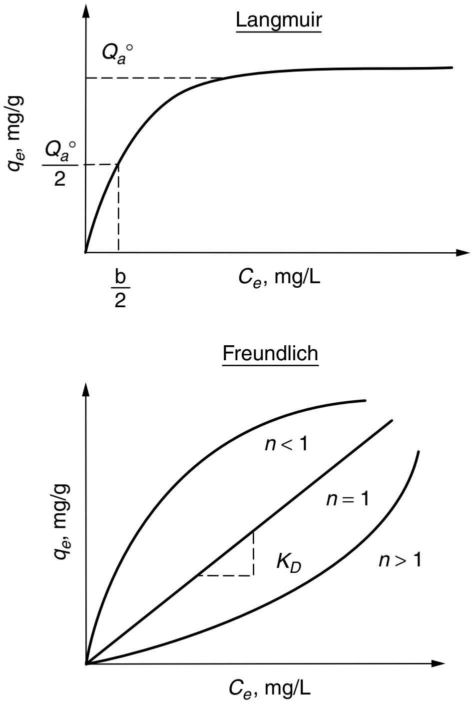

Figure 1. Characteristic shape of the Langmuir and Freundlich isotherm.

Table 1. Isotherm Models and Linear Transformations for Parameter Estimation

Model	Equation	Parameters	Linearization[a] ($y = a + mx$) and Parameter Estimation
Linear	$q_e = K_D C_e$ $K_D = f_{OC} K_{OC}$	K_D, distribution coefficient; f_{OC}, fraction organic carbon in sorbent; K_{OC}, organic carbon normalized coefficient	$a = 0, K_D = m$
Langmuir	$q_e = \dfrac{Q_a^o b C_e}{1 + bC_e}$	Q_a^o, monolayer sorption capacity; b, relates to sorption energetics	Reciprocal transform: $\dfrac{1}{q_e}$ versus $\dfrac{1}{C_e}$ $Q_a^o = 1/a; b = a/m$
Freundlich	$q_e = K_F C_e^n$	K_F, relates to sorption capacity; n, relates to sorption energetics	Log transform: $\log q_e$ versus $\log C_e$ $K_F = 10^a; n = m$

[a] Here a is the intercept and m is slope.

the geosorbent. Thus, the overall q_e is the sum total of q_e in the various domains. The domains have been conceptualized as the amorphous organic matter domain, the condensed organic matter domain, and the mineral domain. While organic matter is typically considered to be of natural origin, organic matter of anthropogenic origin can also exert a significant influence when present (5). Such organic matter includes nonaqueous phase liquids and combustion residues such as soot.

Sorption in Amorphous and Condensed Organic Matter Domains. It is well established that soil organic matter has a strong influence on the sorption of organic compounds and a linear correlation exists over a wide range of organic carbon content from about 0.1% to 20%. The distribution coefficient K_D for sorption of an organic compound on soil (assuming linear isotherm) can thus be normalized using the fraction organic carbon on a soil to yield the organic carbon normalized coefficient (K_{OC}). The K_{OC} value is strongly dependent on the organic compound of interest and correlates strongly with the octanol–water partition coefficient, K_{OW}, and the solubility S of the organic compounds. Linear correlations between log K_{OC} and log K_{OW} have been developed for specific groups of compounds as summarized in various reviews and handbooks (6,7). However, these values should be used as preliminary estimates.

It is well established that the linear model is often inadequate and the Freundlich model provides better fits to data, particularly when data is obtained over a wide C_e range. For phenanthrene sorption on various sorbents, Weber et al. (8) have demonstrated how the individually measured (single point) K_D and corresponding K_{OC} values vary as a function of C_e, when sorption is well characterized by the Freundlich isotherm. This has been attributed to the heterogeneity of sorption sites. The organic matter in the sorbent includes proteins, lignin, cellulose, and macromolecules that are altered over geologic time scales. This organic matter originates from organisms, such as microorganisms (algae and bacteria), zooplanktons and phytoplanktons, and vascular plants, depending on the depositional environment of the sorbents.

The linear model was originally proposed for sorption of organic compounds on various soils. Soil organic matter is proposed to be amorphous in nature and is often termed "soft" carbon, which is easily oxidized (e.g., humic and fulvic acids). Sorption of organics on soft carbon is like a partitioning phenomenon; that is, organic contaminants are distributed over the entire volume of soil organic matter. This is essentially a physisorption process characterized by low sorption energies. The K_{OC} values that are determined from correlations based on K_{OW} and aqueous solubility widely reported in the literature are only representative of sorption in the soft organic matter fraction.

As the organic matter gets aged by weathering processes over geologic time scales, indicated by a lowering in the O/C and H/C ratios, it gets more condensed, the degree of cross-linking increases, its aromaticity increases, and it becomes "hard" and insoluble (difficult to oxidize), for example, kerogen present in shales. Sorption on condensed organic matter is a true adsorption phenomenon, characterized by accumulation of organic compounds at the interface. The condensed organic matter has a significantly higher sorption capacity for organic compounds compared to the amorphous organic matter, and the sorption nonlinearity increases (characterized by decrease in Freundlich exponent n) with increase in the degree of condensation as diagenesis progresses. The sorption energies are also higher as in chemisorption processes. The distributed reactivity model proposed by Weber et al. (9) indicates that sorption in geosorbents is the sum total of sorption in the individual components; however, shale particles in a subsurface sand, rich in condensed organic carbon, were found to dominate the sorptive interactions. The failure of subsurface remediation technologies designed using linear isotherms have been attributed to increased nonlinearity.

Physisorption involving weak intermolecular forces is a reversible process. Thus, sorption on soft amorphous carbon typically present in soil is reversible. The adsorption isotherm and desorption isotherm are coincident and both are linear, as shown in Fig. 2. For sorption on hard condensed carbon such as kerogen, the adsorption and desorption isotherms are not coincident and significant hysteresis exists as demonstrated in Fig. 2. Moreover, both sorption and desorption are characterized by significant nonlinearity.

Sorption in Mineral Domain. The mineral surfaces exert greater influence on the sorption of polar organic compounds and the sorption is strongly dependent on the solution pH, pK_a values of the polar organic compound, and $\mathrm{pH_{PZC}}$ (point of zero charge of the sorbent). For nonpolar organic compounds, although the influence of organic matter content and nature dominates the sorptive interaction, mineral surfaces can also play a role, particularly when the organic matter content is less than

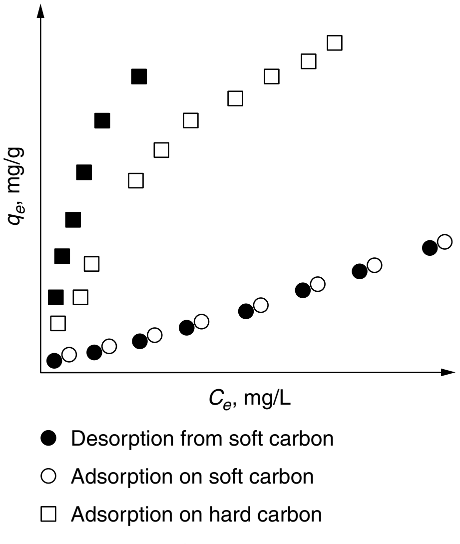

Figure 2. Adsorption and desorption isotherms on hard and soft carbon.

0.1–0.2%. Aquatic systems and subsurface environments are often characterized by low organic matter content. Moreover, the clay liners used in landfills can play a role in the retardation of organic compounds by virtue of sorptive interactions.

Sorption on minerals is dependent on the area of the mineral surface per unit mass of the sorbent. Area of the exposed mineral surface is higher when the organic carbon content is lower, since the natural organic matter competes with the organic compound for attaching on to the mineral surface. Thus, porous silica and the finer clay fraction exert a greater influence. Overall sorption also depends on the type of mineral surfaces that are present—clays (montmorillonite, kaolinite), silica, alumina, and iron oxide. Competition between sorption on natural organic matter and on mineral surfaces may depend on the proportion of swelling clays, the determining parameter being the ratio of clay surface area to the fraction of organic carbon. The interactions on mineral surfaces are typically due to van der Waals forces, that is, dipole–dipole, dipole–induced dipole, and hydrogen bonding interactions. Sometimes the interactions are stronger; chemisorption and clay colloid induced polymerization dominate sorption. Such specific binding of organics on the mineral surfaces may cause sorption to appear irreversible (7).

Factors Affecting Sorption Equilibrium

Factors other than geosorbent characteristics that affect sorption have been discussed elaborately by Schwarzenbach et al. (7). These include the following:

- *Temperature*: Adsorption is typically an exothermic process and K_D decreases with increasing temperature. Heat of adsorption associated with physisorption is typically a few hundred calories per degree per mole.
- *Nature of the Compound*: Within a group of organic compounds, K_D and K_{OC} increase as the aqueous solubility decreases and as the octanol–water partition coefficient K_{OW} increases. These linear free energy relationships have been widely utilized for obtaining preliminary estimates of the linear sorption coefficient.
- *Solution pH*: The effect of pH on the sorption of nonpolar organic compounds is not very significant. For ionizable organics the effect is significant.
- *Salinity*: As salinity increases, the aqueous solubility of organic compounds decreases; thus, K_D increases. However, typical levels of dissolved salts present in aquatic environments do not cause much impact.
- *Organic Colloids*: Colloids are macromolecules that remain in aqueous solution. Thus, in aqueous solution the organic compound is present as truly dissolved species and also as species associated with colloidal macromolecules. This causes an apparent lowering in the K_D values.

RATE CONSIDERATIONS IN SORPTION OF HYDROPHOBIC ORGANIC COMPOUNDS

The instantaneous local equilibrium assumption with respect to sorption processes is often made for modeling the transport of organic compounds through subsurface systems. These transport models assume that the sorption kinetics is so rapid that rate considerations can be ignored and that the sorption isotherm is linear (constant K_D). With these assumptions the net effect of sorption is manifested by a reduction in the advective velocity and dispersion coefficient by a constant factor, referred as the retardation factor (2). The retardation factor (R) can be estimated if K_D and porous media characteristics, such as the porosity (ε) and solid density (ρ_s) or bulk density (ρ_B), are known, as shown in Eq. 3:

$$R = 1 + \frac{\rho_B K_D}{\varepsilon} = 1 + \left(\frac{1-\varepsilon}{\varepsilon}\right)\rho_s K_D \tag{3}$$

However, the assumption of instantaneous equilibrium is typically a poor assumption and this often leads to failure of the models in predicting the experimentally observed fate and transport phenomenon. Nonequilibrium sorption can affect the transport of contaminants by causing effects such as early breakthrough, decrease in peak breakthrough concentration, and tailing/asymmetry in the concentration profile.

Sorption rates are typically slow at the intraparticle level. The various mechanisms implicated in slow sorption include (1,10) low film transfer coefficient (k_f) for mass transfer across the boundary layer separating the sorbent from the aqueous phase; slow diffusion through natural organic matter matrices along the sorbent surfaces due to low surface diffusion coefficient (D_S); and slow diffusion through tortuous nanopores due to low pore diffusion coefficient (D_p). However, the relative contribution of the various mechanisms is difficult to predict. The adsorption–desorption bond energies may also play a role in determining the process kinetics. High energy adsorption sites within the organic matter matrix and in the nanopores may be responsible for slow sorption kinetics. A conceptualization of factors affecting adsorption rates is illustrated in Fig. 3. Film transfer and intraparticle diffusion constitute resistances in series, and since intraparticle diffusion is typically slower, it has a dominant impact on the slow kinetics. The two intraparticle diffusion mechanisms—surface and pore diffusion—represent parallel mechanisms, and the faster of the two is thought to control overall mass transfer.

Typically, the sorption and desorption of organics on geosorbents is characterized by a rapid phase, followed by a slow phase—that is, it is bimodal. The magnitude of the slow fraction is quite significant. Pignatello and Xing (10) have effectively illustrated how slow sorption can affect the experimentally determined K_D values. With increasing contact time in equilibrium studies from short (1–3 days) to long (several months), the K_D was demonstrated to increase from 30% to tenfold for a range of organic compounds. The time to reach true equilibrium in batch systems may vary from 1 wk to several months.

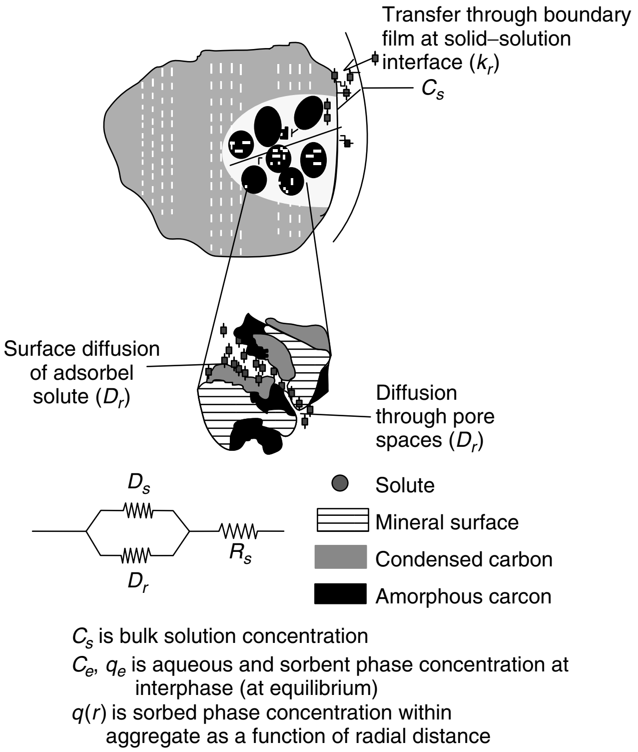

Figure 3. Rate considerations in sorption processes on a geosorbent.

Slow sorption leads to a chemical fraction that resists desorption. If sorption is allowed to occur over a long time period (aging), the contribution of slow sorption and a desorption resistant fraction increases; that is, the slow fraction following a rapid release may vary from 10% to 96% depending on aging time and the type of geosorbent. The desorption resistant fraction is persistent in natural environments and is also difficult to extract. Thus, for historically contaminated field samples, it is difficult to ensure complete recovery by the extraction techniques employed. Hatzinger and Alexander (11) effectively demonstrated how the biodegradation of phenanthrene and 4-nitrophenol was significantly reduced in aged soils.

Sorption–desorption kinetics is significantly affected by diffusion processes; however, Fickian diffusion alone cannot explain experimental and field-scale observations. It has been reported that the slow fraction is inversely dependent on the initial concentration. This is partly explained by isotherm nonlinearity (Freundlich exponent significantly lower than unity); however, it also appears that intraparticle retardation increases as the concentration within a particle declines. Moreover, sorption is reported to be kinetically hysteretic—the rate of filling the slow sites appears to be faster than the rate at which they are emptied, thus indicating an apparent irreversibility. Several researchers have used stochastic modeling for describing the slow sorption phenomenon on geosorbents; that is, the rate constants and diffusion coefficients are assumed to be distributed according to a statistical density function (e.g., two-parameter gamma distribution).

AGE DATING OLD GROUNDWATER

Gholam A. Kazemi
Shahrood University of
Technology
Shahrood, Iran

INTRODUCTION

First, two closely interrelated terms, groundwater age and groundwater residence time, need to be explained and differentiated. Groundwater age is the amount of time that has lapsed since the water molecule, whose age is of concern, was recharged into the system till this molecule is sampled for age-dating. Groundwater residence time is the time it takes for a single molecule of water to travel from the recharge area to the discharge area of the aquifer, the time interval between infiltrating into, and exfiltrating out of, the subsurface media. Groundwater age and residence time are comparable to the age and lifetime of a person, respectively.

Groundwater age and residence time are illustrated in Figs. 1a,1b. Note that some researchers mix up these two

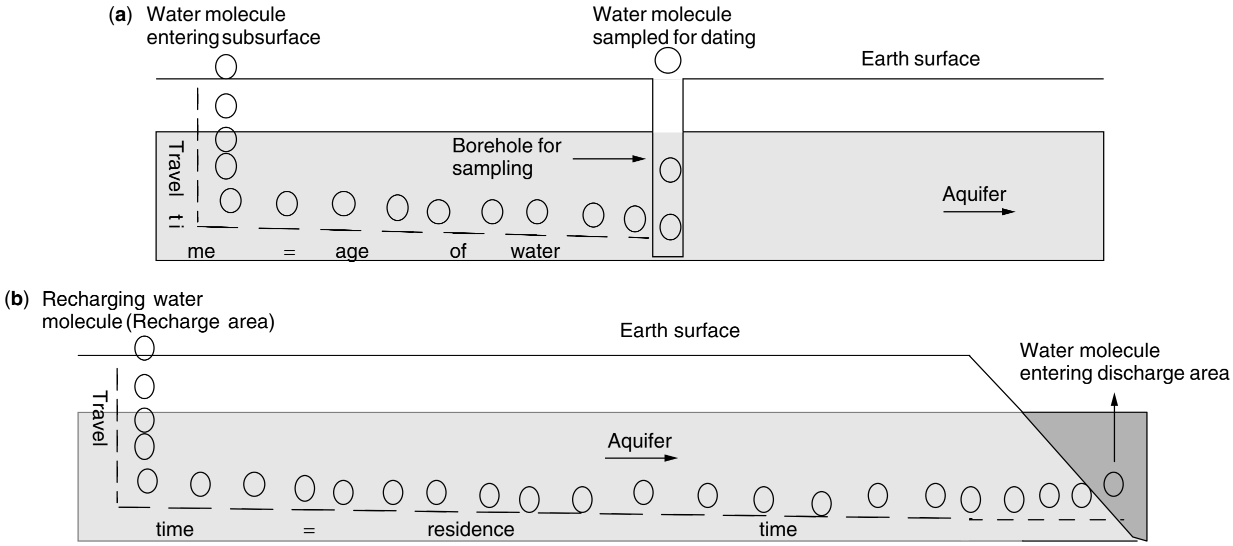

Figure 1. (**a**) Illustration of groundwater age (**b**) Illustration of groundwater residence time.

concepts and do not clearly differentiate between them. Mazor and Nativ (1, p. 219), for instance, refer to the age of groundwater as hydraulic age: "Hydraulic ages relate to travel time, the time needed for a volume of groundwater to move across a flow path Δl." Similarly, their definition of residence time "or isotopic age" is no different from the definition of "groundwater age" given by many other researchers. A number of workers use slightly different terms for groundwater age such as mean age, transit time, turnover time (2) or mean travel time (3). A recent useful discussion on groundwater age is that by Bethke and Johnson (4).

DISCUSSION

There is neither clear definition nor many citations of the term "old groundwaters" in the literature (in contrast to "young groundwaters"). Examples of limited available references include Coplen (5), Zhao et al. (6), Le Gal La Salle et al. (7), and Park et al. (8).

Old groundwaters may be defined as those that are too old to be dated using techniques like ^{3}H, CFCs, ^{85}Kr, ^{36}Cl/Cl and ^{3}H$-^{3}$He. These techniques are specifically applied to age-date young groundwater. Four methods have been in use for dating old groundwaters. In the order of the age range they can measure, these include (1) ^{39}Ar, (2) ^{14}C, (3) ^{36}Cl, and (4) ^{4}He. A brief description of each dating technique and example(s) from each method follow. Note that other less known/used methods such as ^{2}H, ^{18}O, ^{32}Si, and ^{81}Kr for dating old groundwater have received very little attention (9).

^{39}Ar

Argon-39 whose half-life is 239 years can be used to date groundwater ages that range from 200 to 1000 years (10). This method has not been used widely.

^{14}C

The ^{14}C method is the most extensively used method for dating old groundwater. ^{14}C, also known as radiocarbon, has a half-life of 5730 years; it can enter groundwater systems by various geochemical and biological processes. The concentration of ^{14}C in soil CO_2 is 100 pmc (percent modern carbon) in prenuclear bomb times (pre-1952) and up to 200 pmc (about 130 pmc, on average) in postbomb years (11). Once water reaches the saturated zone of an aquifer, it is isolated from the atmosphere, and its ^{14}C decays. ^{14}C measurement is useful for dating groundwater ranging in age from 200 to 50,000 years. Values of 90 pmc or more, indicate post-1952 water, and values less than 50 pmc indicates ages up to 50,000 years.

Examples

1. The age of palaeochannel groundwaters of Western Australia is estimated at 20,000 years (12).
2. The ages of groundwater in the upper part of the Mojave River Basin, California, USA, and in the regional aquifer close to the Mojave River were estimated at less than 2400 and 20,000 years, respectively (13).
3. Le Gal La Salle et al. (7) computed that the age of groundwater in the Iullemeden Basin (Niger) is older than 25,000 years.
4. The age of groundwater brines in the Dead Sea area, determined by Yechieli et al., was 9000 years (14).
5. Kazemi (15) calculated that the age of groundwater in various parts of the Buckinbah Creek Catchment, Eastern Australia, is between 970 and 13,000 years.

^{36}Cl

^{36}Cl, whose half-life is 301,000 years, is useful for dating very old groundwater. It is produced naturally in the deep subsurface through thermal neutron capture on the stable nuclide chlorine-35; at and near the land surface by spallation and neutron capture related to secondary cosmic particle bombardment; by cosmic particle interaction with atmospheric gases, particularly argon; and artificially through the activation of ^{35}Cl in sea water by the high flux of neutrons from testing of fusion devices in the western Pacific starting in late 1952 and extending through mid-1958 (16).

Rainfall dissolves atmospheric ^{36}Cl, and carries it to the subsurface where decays, and its initial value is reduced according to the following equation:

$$C = C_0 e^{\lambda t}$$

where C is the concentration of ^{36}Cl at any time t, C_0 is the initial concentration of ^{36}Cl, and λ is the decay constant of $2.25 \times 10^{-6} \alpha^{-1}$. The longer ^{36}Cl resides in the aquifer, the less is its concentration, and hence the older the ambient groundwater. The subsurface production of ^{36}Cl is not large enough to affect the age calculations (8). The age range of the ^{36}Cl method is from 50,000–1,200,000 years.

Example. The age of soil water in Southern Nevada, USA, was estimated at up to 120,000 years (17).

Limitation. If chlorinity of the water sample exceeds $\sim$75–150 mg/kg, the ^{36}Cl method cannot be used for groundwater dating (8). Note that the ratio of ^{36}Cl/Cl is used for dating young groundwater (18).

^{4}He

Helium accumulates in basin groundwater from radioactive decay of the uranium and thorium in the basin strata, as well as from any flux into the basin from the underlying crust and mantle (6). If the rate at which the *in situ* production and basal flux have supplied helium to flowing groundwater is known, then it is possible to calculate the length of time that the groundwater of known helium content has resided in the subsurface. The age range of this method is 10^4 to 10^8 years and due to semiquantitative nature of the method, it is referred to by some researchers as an age indicator rather than a dating method (11).

Example. Using this method, the age of the Baden region of Switzerland was estimated at several hundred thousand years (10).

AMMONIA

Robert M. Burgess
U.S. Environmental Protection
Agency
Narragansett, Rhode Island

Ammonia is a primary breakdown product of nitrogen-containing organic matter in aquatic environments. Because a great deal of organic matter and waste is introduced into the hydrologic cycle by natural and anthropogenic processes, ammonia can be found in aquatic environments, especially those exposed to large amounts of human or domestic animal wastes. Ammonia is also of great importance in understanding the global cycling of several key elements, including nitrogen and carbon. Ammonia is one of the compound uniquely critical to life which when not present in adequate amounts in aquatic environments can be associated with negative biological effects and when in excess can result in adverse ecological and toxic effects. When insufficient ammonia is available to plants, which assimilate ammonia to grow, they may experience metabolic problems due to nutrient limitations. Conversely, excess ammonia is commonly associated with eutrophic conditions in water bodies and toxicity to some organisms. Further, nitrous oxide (N_2O) a molecule involved in the environmental cycling of ammonia is considered a potential 'greenhouse gas' which can also destroy stratospheric ozone. Because of these adverse effects, ammonia is frequently considered a pollutant in aquatic systems.

BACKGROUND

The word 'ammonia' first came into chemical-related use in approximately 1799 and was derived from the Egyptian deity, Ammon. Ammonia referred to the gas emitted by camel excreta in the vicinity of temples honoring Ammon. The form of ammonia known as ammonium (NH_4^+) was named by the eminent Swedish chemist Berzelius in 1808.

Today, it is known that ammonia consists of one nitrogen atom and three hydrogen atoms (NH_3) and has a molecular weight of 17. Ammonia is formed from the bacterial decomposition of organic matter containing nitrogen. For example, the degradation of the simple organic molecule urea [$(NH_2)_2CO$] in water:

$$(NH_2)_2CO(l) + H_2O(l) \longrightarrow 2\ NH_3(g) + CO_2(g) \qquad (1)$$

results in the formation of the gases, un-ionized ammonia (NH_3) and carbon dioxide (CO_2). In the same way, complex organic molecules in industrial and municipal wastes and plant and animal matter also form NH_3 when degraded. In aqueous solution, ammonia exists in two forms as a function of pH, ionic strength, and temperature:

$$NH_4^+ + OH^- \longleftrightarrow NH_3 + H_2O \qquad (2)$$

Ionic strength and temperature influence ammonia speciation, but pH is the controlling variable. Consequently, with a base dissociation constant (pK_b) of 9.5, at a pH less than 9.5, most of the ammonia in solution is ionic ammonium (NH_4^+); at a pH greater than 9.5, the majority is NH_3. Consequently, in seawater and freshwater, the majority of ammonia is in the NH_4^+ form.

CYCLING

As noted above, ammonia is a key component of the greater global nitrogen cycle. As shown in Fig. 1, the fixation of nitrogen gas (N_2) forms NH_3, and the ammonification of organic nitrogen also results in forming ammonia. Ammonia is assimilated by plants and used to form organic nitrogen molecules, including amino acids, and then proteins. Conversely, ammonia can be formed by the ammonification of amino acids and proteins. Through nitrification, ammonia can also be oxidized to form nitrite (NO_2^-) which is further oxidized to form nitrate (NO_3^-). Nitrate is another nitrogen molecule that is assimilated by plants. Anaerobic conditions retard nitrification and cause an elevation of NH_3 concentrations. Denitrification of nitrite and nitrate results in forming N_2 and several nitrogen oxides, including N_2O, which completes the nitrogen cycle. Nitrification, denitrification, and ammonification are all reactions that occur abiotically but can also be moderated by bacteria. In nature, fixation requires microbial mediation. Synthetic fixation can be performed using the process developed by Haber and Bosch in 1910–1914 to produce fertilizer. Energetically, the path leading to the formation of organic nitrogen compounds is most favored compared to the reverse path resulting in nitrogen gas (Fig.1).

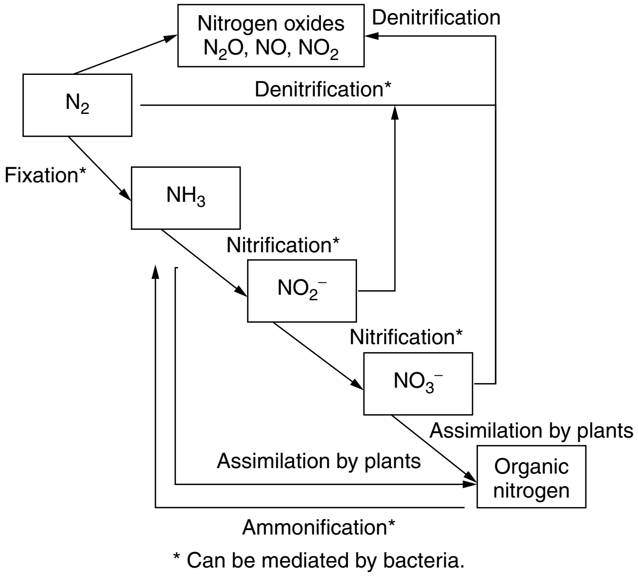

Figure 1. Nitrogen cycle.

Equation 1 gives an example of NH_3 formed by ammonification. The formation of NH_3 by fixation of N_2, as shown in Equation 3, is more complicated and involves linking the nitrogen cycle to the carbon cycle. In this reaction, a simple carbon molecule (CH_2O) is oxidized to form CO_2; the inclusion of N_2 and an exchange of hydrogen ions (H^+) and electrons (e^-) results in ammonium formation:

$$CH_2O(s) + H_2O(l) + N_2(g) + 8H^+ + 6e^- \longrightarrow CO_2(g) + 4H^+ + 4e^- + 2\ NH_4^+(l) \qquad (3)$$

Without the involvement of the carbon cycle, this reaction would not be thermodynamically favored, and N_2 fixation would not take place. Because Equation 3 is thermodynamically favored, microbes mediate the reaction and acquire energy.

SOURCES AND CONCENTRATIONS

Several studies have attempted to quantify ammonia sources and concentrations around the world. In these studies, the atmosphere is considered the ultimate sink for global ammonia, although, it should be noted, other studies speculate that the oceans are the ultimate sink. Primary sources of ammonia to the global environment from four different studies are listed in Table 1. Despite the different information used to assemble the table, the sources show remarkable similarity. The range of total ammonia released to the environment is 45 to 75 TgN yr^{-1}. Clearly, domesticated animals are the largest sources of ammonia globally, followed by soil, the oceans, and fertilizers. Lesser amounts of ammonia originate from biomass burning and human waste, and even lesser from fuel combustion and automobiles. The primary sources of ammonia are all systems containing bacteria that significantly enhance the nitrogen fixation and ammonification reactions discussed before.

As may be expected, concentrations of ammonia in aquatic systems vary based on sources and environmental conditions (Table 2).

Overlying fresh and marine waters that are well mixed, aerobic, and lack a direct source of ammonia maintain relatively low concentrations in the high parts per billion range ($\mu g\ L^{-1}$ or ppb); sediment interstitial waters, especially those that are anoxic, support elevated levels in the lower parts per million range ($mg\ L^{-1}$ or ppm). Sewage effluents and sludges can have extremely high concentrations of ammonia from human and animal waste. As a concentrated form of nitrogen-containing organic matter, sludge is potentially very elevated in concentrations of ammonia. Because of the elevated concentrations of ammonia in sewage effluents, waste treatment facilities frequently aerate the liquid to enhance nitrification and counter anaerobic conditions. Finally, rainwater can have elevated ammonia concentrations as a result of the diffusion of NH_3 into precipitation from the atmosphere.

Table 1. Sources of Ammonia in the Environment

Source	Amount, TgN yr^{-1a} Study 1	Study 2	Study 3	Study 4
Domestic animals	32	26	24.5	22
Ocean surface	13	—	7	8
Undisturbed soils	10	15	5.1	6

Table 2. Ammonia Concentrations in Aquatic Samples

Aquatic sample	Total Ammonia Concentration ($mg\ L^{-1}$)
Coastal marine waters	0.24–0.58
Freshwaters	<1.0
Marine sediment interstitial waters	1–11
Freshwater sediment interstitial waters	1–53
Sewage effluent	16–33
Sewage sludge	1000–2030[a] ($mg\ kg^{-1}$)
Rainwater	0.05–2.60[a]

[a] Expressed as NH_4^+.

EUTROPHICATION

Eutrophication is the process of enriching a water body with nutrients (see *Eutrophication*). In marine systems, nitrogen-containing compounds (e.g., NO_3^-, NH_3) most often cause eutrophic conditions, in freshwater systems, phosphorus-containing compounds are currently considered most important. In most instances of eutrophication, anthropogenic sources of nutrients, including fertilizers and domestic animals, are suspected as the causes. Consequently, eutrophication is considered a major environmental problem in areas where human populations are present. Eutrophication causes several adverse environmental effects. The first effect is the occurrence of large algal blooms. These blooms can reduce light penetration into the water throughout the system which may adversely affect other vegetative life. Next, the accumulation of decaying organic matter enhances the growth of bacteria which causes a decline in water column dissolved oxygen concentrations. The resulting anaerobic conditions can kill aquatic animals and foster an increase in ammonia concentrations in the water and adjacent sediments. Because anaerobic environments support the persistence of ammonia, it is frequently associated with eutrophic conditions. Thus, the presence of ammonia perpetuates the potential for eutrophic conditions to arise. Another adverse effect of eutrophication and elevated concentrations of ammonia is volatilization of NH_3 to the atmosphere followed by transport and deposition in other regions. The occurrence of eutrophication has many implications, including severe disruptions of ecological processes and potential ammonia-related toxicity to aquatic organisms.

TOXICITY

Ammonia toxicity to aquatic organisms is extremely well documented. Table 3 has a small collection of selected ammonia toxicity values. The toxicity of ammonia is dominated by the NH_3 form; NH_4^+ demonstrates little contribution to overall toxicity. Because the concentration of NH_3 is a direct function of solution pH, very frequently, the toxicity of total ammonia to organisms is observed to increase as pH increases. This trend is explained by the commensurate increase in NH_3 concentration as pH increases. Interestingly, the toxicity of NH_3 actually decreases as pH increases, indicating that NH_3 is less toxic at higher pHs.

Ammonia toxicity, as measured by effects on survival, tends to occur in the low parts per million concentration range, although this varies by species. Sublethal effects to

Table 3. Ammonia toxicity to aquatic organisms

Species	Medium	End Point	Toxicity Value[a] (mg/L)
Mysid shrimp (*Americamysis bahia*)	Marine	Mortality	2.82
Mysid shrimp (*Americamysis bahia*)	Marine	Sublethal	0.23
American lobster (*Homarus americanus*)	Marine	Mortality	2.21
Inland silverside (*Menidia beryllina*)	Marine	Survival	0.88
Inland silverside (*Menidia beryllina*)	Marine	Sublethal	0.06

Rainbow trout (*Oncorhynchus mykiss*)	Freshwater	Sublethal	0.02
Smallmouth bass (*Micropterus dolomieui*)	Freshwater	Mortality	1.01
Smallmouth bass (*Micropterus dolomieui*)	Freshwater	Sublethal	0.60

[a] Mortality values are LC_{50}s; sublethal values are EC_{50}s.

aquatic organisms, including effects on growth and reproduction, occur in the high parts per billion concentration range but also vary by species. In general, fish species in both fresh and marine waters are the most sensitive to ammonia, as compared to invertebrate species. For example, Table 3 shows that in marine waters, the inland silverside (a minnow) is approximately three times more sensitive to ammonia than the mysid shrimp, based on a survival end point. Similarly, in freshwater, the rainbow trout is about seven times more sensitive than a cladoceran (Table 3). These differences in sensitivity are also apparent based on sublethal effects; for example, sublethal effects in trout occur at concentrations 30 times lower than sublethal effects in a cladoceran (Table 3)! The extreme sensitivity of fish species to ammonia has significant implications for the aquaculture and fisheries industries with regard to ensuring that their wastes do not adversely affect their products.

Because nitrogen-containing organic matter accumulates in sedimentary aquatic environments, elevated concentrations of ammonia are often found in sediments. This is especially true in eutrophic settings enriched with anthropogenically derived nutrients. Consequently, concerns about ammonia toxicity are frequently focused on sediment-dwelling organisms and not the water column species in aquatic systems. Of course, if there is evidence that ammonia from point (e.g., sewage treatment plant) or nonpoint sources is being released into aquatic systems, ammonia toxicity may be expected.

ANALYSIS

The two most common ways to measure ammonia in aqueous solution are by spectrometry and ion-selective electrodes. Both methods function well in freshwater and seawater, including clean and polluted samples. The spectroscopic method involves a reaction between ammonia and phenol and sodium hypochlorite with sodium nitroprusside to form indophenol blue which is measured by spectrometry. A variation on this method substitutes sodium salicylate for the phenol, eliminating the production of *o*-chlorophenol, a toxic substance, and resulting in comparable sensitivity. In the ion-selective method, changes in the measured electrode potential are compared to a reference potential. These potentials are proportional to the amount of NH_3 in the sample solution allowing for a determination of ammonia concentration. Both methods have advantages and disadvantages. The spectrometric method is the more sensitive technique, detection limits are in the mid- to high parts per billion range, but it suffers from being a relatively slow method which uses somewhat hazardous reagents. The ion-selective method is relatively fast allowing analyses to be completed in minutes but is relatively insensitive; detection limits are in the upper parts per billion to lower parts per million range. Both methods also differ in terms of the form of ammonia measured. Spectrometric methods measure NH_4^+ whereas the ion-selective method measures NH_3. Given that the two forms of ammonia behave differently in the environment, it is important to understand which is being measured.

BERYLLIUM IN WATER

Jay Clausen
AMEC Earth and
Environmental, Inc.
Westford, Massachusetts

INTRODUCTION

Beryllium was discovered by Vauquelin in 1798 as an oxide in beryl and emeralds. The metal was isolated in 1828 by Bussy and Wohler but its use was limited until it was discovered that a mixture with copper produced an alloy six times stronger than steel (1). Beryllium is a Group 2 (IIA) element found naturally as a rare alkaline earth metal in the earth's crust and is the lightest metal. As a pure metal, beryllium has a steel gray color and is present in a variety of materials, such as coal, oil, rock, soil, and volcanic dust. It can be found concentrated in igneous intrusive rocks such as granites, specifically beryllium-rich pegmatite. Beryllium ions are small enough to substitute for silicon in igneous rocks. Beryllium is found in some 50 mineral species; the most important are beryl [$Be_3Al_2(SiO_3)_6$], bertrandite [$Be_4Si_2O_7(OH)_2$], chrysoberyl [$BeAl_2O_4$], and phenacite [Be_2SiO_4]. These minerals can be present at elevated concentrations in water due to the weathering of the host rock. Beryllium, however, does not dissolve readily under natural conditions. For this reason, precious forms of beryl, better known as either aquamarine (blue or blue-green) or emerald (green), can be found in nature.

In addition to its presence in its natural state, beryllium can also be redistributed into the environment through anthropogenic activities such as burning coal (2–4) and oil and disposal of metal manufacturing waste (5). Prior to the 1940s, there were few applications for beryllium. Specialized metal components requiring lightweight and strength have resulted in its increased usage during the last 60 years. Most of the beryllium ore that is mined is converted into alloys (mixtures of metals). Beryllium can be found in computer, aircraft, spacecraft, and automotive parts; gyroscopes; sports equipment; nuclear reactor reflectors; X-ray machines; mirrors; and other specialized engineering components.

Beryllium metal and its salts are extremely toxic. Inhalation of fine beryllium dust can result in the lung disease, berylliosis, also known as chronic beryllium disease, and possibly cancer (6–9). The U.S. Department of Health and Human Services lists beryllium as a Class A carcinogen (2). As a consequence, beryllium is typically included as one of several metals analyzed as part of environmental investigations.

Numerous analytical methods are available for analyzing beryllium: inductively coupled plasma-mass spectrometry (ICP-MS), optical emission spectrometry (ICP-OES), atomic absorption spectrometry (AAS), colorimetric, and fluorimetric methods (10,11). A detailed listing of the colorimetric methods can be found in Taylor et al. (12). The preferred method for soil and water analysis in the environmental business is ICP-MS following United

States Environmental Protection Agency (USEPA) methods 200.7 and 6010. The ICP-MS instrumentation has greater sensitivity and reduced interference from other metals, compared to other analytical methods. A typical reporting limit of beryllium in environmental investigations using the ICP-MS method is 5 ppb; typical method of detection limits for soil and water are 0.1 μg/kg and 0.7 μg/L, respectively. AAS is also an USEPA approved process following method 7090 or 7091. Due to beryllium's low concentration and subsequent interference with other metals in environmental samples, a number of separation and preconcentration methods have been developed using chelating agents, ion-exchange resins, sorbants, and surfactants.

CHEMISTRY

Most beryllium oxides and hydroxides have very low solubilities, although the chloride and sulfate oxides are very soluble. However, the chloride and sulfate oxides hydrolyze to relatively insoluble hydroxide species. Baes and Mesmer (13) found that beryllium hydroxide solubilities range from 0.9 to 100 μg/L in the pH range of 6 to 8.5. Iron, manganese, and zinc beryllium silicates are believed more soluble because they contain divalent sulfur, which can be easily oxidized (14).

The dominant dissolved species found under environmental conditions are Be^{2+}, $BeOH^{+}$, $Be(OH)_2$, and $Be(OH)_3{}^{-}$. Thermodynamic data for the dominant beryllium species are presented in Table 1.

Figure 1, a phase diagram for beryllium under normal temperatures and atmospheric conditions at a concentration of 90 μg/L, suggests the solid species of BeO dissolves to form Be^{2+} under acidic conditions. Increasing the concentration of beryllium in solution results in a shift of the BeO to the Be^{2+} transition zone at higher pH. However, this is contrary to known environmental conditions, whereby beryllium can form insoluble mineral species such as beryl, emerald, and bertrandite. Brookins (18) suggested that the discrepancy between thermodynamic calculations and reality may be attributable to the presence of metastable species, which affect the solubility of the various beryllium species.

Table 1. Thermodynamic Data for Beryllium

Species[a,b]	$\Delta G^0{}_f$, kcal/gfw[c]	Reference
Be (metal)	0	15
Be^{2+} (aq)	− 90.76	16
BeO (s)	−138.70	16

SOURCE MATERIAL

Beryllium is a widely distributed metal that has a crustal average of 3 ppm, and its average concentration is 5 ppm in granitic rock, according to Krauskopf (19). The weathering product of rock is typically a kaolinite or hydrolysate, which accumulates in the B-soil horizon. Hydrobiotite, a feldspar mineral, weathers to montmorillonite, which sorbs beryllium (20). Beryllium concentrations in soil often correlate with aluminum and magnesium levels because both metals can be involved in cation exchange reactions with montmorillonite minerals. Berg et al. (21) found a correlation between aluminum and beryllium in a study near an aluminum smelter. Similarly, a study by Asami and Kubota (22) found a weak correlation, 0.505 at a level of significance of 0.1% for n=113 samples, between beryllium and aluminum for soils collected from several different countries. An earlier study by Asami and Fukazawa (23) found a similar relationship for soils collected in Japan near a beryllium manufacturing facility.

A number of studies have been conducted to determine the range of beryllium concentrations in surficial soils (0.3 to 6 ppm) throughout the world (22,24–34). A study by Anderson et al. (35) of four eastern U.S. Piedmont soils suggested higher beryllium concentration ranges for surface soil of 6.3 to 13.3 and 7 to 30.5 mg/kg for deeper soils. However, the number of samples collected was very small and insufficient to develop statistically meaningful values. In a study in Germany, Grote et al. (25) found beryllium levels range from 0.05 to 1 mg/kg for rural soils and 1 to 2.5 mg/kg for urban soils. This study suggests that elevated levels of beryllium can be found as a result of anthropogenic activities.

Fishbein (36) reports beryllium can be found in coal at concentrations ranging from 0.1 to 1000 ppm and in oil at a concentration of 0.8 ppb. Data of beryllium concentration in different types of U.S. coal by weight are presented in USEPA (37) and summarized in Taylor et al. (12). Weathering of soil and rock and combustion of oil and coal can account for the presence of beryllium in water.

Surface Water

A number of studies have been conducted on surface waters such as lakes, rivers, and seawater (Table 2).

Table 2. Concentration of Beryllium in Various Waters

[a] NA: not available.
[b] ND: nondetectable.

In some cases, it appears that "finished water," treated drinking water, was analyzed. However, the studies in many cases do not indicate whether the original source of water was a river, lake, or groundwater. A number of studies also state that surface water was sampled but do not elaborate if this consisted of river or lake water.

A study of 59 surface water bodies and 15 rivers in the United States and Canada found a maximum beryllium concentration of 0.22 μg/L (41). However, the study did not specify which waterbodies were studied and whether raw or finished water was analyzed. Similarly, Kopp (44) analyzed 1577 surface water samples from the United States and found a concentration range of 0.01 to 1.22 μg/L and a mean of 0.19 μg/L. Griffitts et al. (45) reported a range of beryllium of 0.1 to 0.9 μg/L in eastern U.S. and Siberian surface waters. Soviet surface water rarely exceeded 0.1 μg/L, according to Grigor'yev (20).

In Hem's (48) review of several studies, it was concluded "that river waters normally can be expected to carry no more than a few tenths of a microgram per liter of beryllium in solution." However, elevated beryllium concentrations were found in streams where the beryllium-rich source rock was being attacked by acid rain (46). Skirivan et al. (43) suggest that the concentration of fluoride ions and pH significantly control beryllium concentrations in surface waters.

Studies by Skirivan et al. (46) and Burba et al. (49) suggest beryllium can be sorbed onto suspended organic matter. The work of Grigor'yev (20) found between 50 and 73% of the total beryllium in river water samples is associated with suspended solids, which supports the Burba et al. (49) findings. However, some streams at low pH contain dissolved beryllium. Upon discharge of low pH stream water into a higher pH pond, the mobile beryllium was scavenged from the water by solid species containing hydrated metal oxides (aluminum, iron, and manganese) residing on organic matter (43,46,50,51). At higher pH, the beryllium complexes of $BeOH^+$ and $Be(OH)_2$ form, which then can be adsorbed onto colloidal particles (52). Skirivan et al. (43) and Veseley et al. (46) found the highest beryllium concentrations in surface water were associated with low pH waters. At a pH less than 4, beryllium is principally found as the Be^{2+} cation (43,52).

Fishbein (36) found beryllium levels of 18 to 21 μg/L from effluent samples collected downgradient of power plants and metal manufacturing facilities, although the locations were not specified. This study suggests that elevated beryllium levels in surface water are a possibility near metal manufacturing facilities.

Groundwater

Very limited information is available on the concentration of beryllium in groundwater in the general literature. Data is likely to be available from environmental studies of potential contaminated sites; however, this information is not readily accessible.

No general regional baseline studies of beryllium in groundwater have been published in the peer-reviewed literature. However, Grigor'yev (20) studied groundwater from a granitic intrusive area and found levels range from 0.01 to 30 μg/L. Additionally, a study by Korkish et al. (11) was conducted with European bottled water, which likely originated as ground-fed spring water. The Korkish et al. (11) study found beryllium levels range from nondetectable to 2.25 μg/L. Burba et al. (49) present data on two mineral water samples collected in Germany, which

Table 3. Beryllium Groundwater Concentrations for Paducah, KY[a]

McNairy	deep	14	0.76	0.04–2.2

[a] Reference 53.

again presumably have a groundwater origin. A sample from Essen had a beryllium concentration of 9 μg/L, and a sample from Bad Pyrmont had a level of 55.8 μg/L.

To place the previous discussion in context, the US EPA maximum contaminant level (MCL) for beryllium is 4 μg/L. The MCL is the highest level of a contaminant that is allowed in drinking water and is an enforceable standard. The drinking water equivalent level (DWEL) for beryllium is 70 μg/L. A DWEL is a lifetime exposure concentration protective of adverse, noncancer health effects, which assumes that all exposure to a contaminant is from drinking water.

Several studies of potential contamination sites have been conducted where beryllium was one of several metals analyzed. One specific study focused on a beryllium manufacturing plant in India (34). This study found groundwater concentrations ranged from 0.001 to 0.002 μg/L, which suggests the beryllium levels represent background conditions.

Another detailed groundwater study (Table 3) was conducted at an uranium gaseous diffusion facility and included beryllium data for groundwater in a shallow unconfined system, a mid-depth confined aquifer, and a deep confined aquifer (53). The pH of this low ionic strength groundwater ranged from 5.3 to 7.9 and was oxidizing. No known source of beryllium existed at this facility, so the beryllium concentrations were likely representative of ambient background conditions.

CONCLUSION

The available information on the presence of beryllium in water samples is spotty, many of the studies lack specific information on type of water sample (lake, river, or groundwater), where, when, and why samples were collected. However, taken as a whole, the studies indicate that the presence of beryllium in water samples should be low at concentrations in the tenths to single ppb range. Beryllium water concentrations near landfills, metal manufacturing sites, coal regions, or locations of beryllium-enriched pegmatitic rock can have elevated levels, typically at the tens of ppb level. Higher beryllium water concentrations are limited by the low solubility of most mineral species.

DISSOLVED ORGANIC CARBON

Of the three words in the title of this entry, little explanation is needed for the last two. The first, however, needs some clarification. The term has traditionally been used to denote material that has been filtered through a certain type of standard membrane (0.45 μm nominal pore size). Material passing through the filter (filtrate) was termed the dissolved phase, and material retained by the filter (retentate) was termed the solid phase. This filtration step was performed for a number of reasons such as reduction in the complexity of the sample and partial sterilization of the filtrate due to the removal of microorganisms. The procedure is still widely used in the scientific and regulatory community. However, it has long been recognized as an inadequate definition because of the presence of colloidal carbon (1–1000 nm in size) and the artifacts inherent in filtration (1,2). The use of a single filtration step thus leads to results that are neither thermodynamically accurate nor biogeochemically relevant. There have been a number of theoretical and practical attempts to delimit the colloidal and dissolved phases. Now, the main practical delimiter is based on ultrafiltration using a nominal pore size of 1,000–10,000 daltons (ca 1 nm) (5). This is a more useful definition for understanding biogeochemical processes but remains entirely operational. In this article, the term 'dissolved' will be used in the wider sense to incorporate a fraction of the colloidal material.

The importance of dissolved organic carbon (DOC) lies in its role in the biogeochemical carbon cycle, as a necessary basis for aquatic microbial processes and in aquatic chemistry (6). Although the global burden of carbon is dominated by sediments (7), dissolved organic carbon is of obvious importance as carbon is the basis of life, an energy and nutrient source for microorganisms. DOC is also of significance in trace pollutant binding (and consequently in pollutant transport and bioavailability), in the charge and aggregation behavior of colloids, in weathering, in pH buffering, and in acid–base and redox chemistry of natural waters. It thus has a large and essential role in determining the chemical composition of natural waters. Although microbiological and chemical aspects are frequently taught and researched in isolation, it may be impossible to understand the composition and regulation of natural waters without simultaneously considering the microbiological and chemical processes because they are so closely interlinked (8). Any distinction between the two processes is therefore likely to be arbitrary and misleading.

The chemical structure of much of dissolved organic carbon is poorly understood because of its complexity, its variability over both space and time, and the ease with which its structure is changed by sampling and analytical procedures (1,9). As DOC is physicochemically diverse, a number of partially successful subclassifications have been used based on size, chemistry, and source. However, for most DOC, it is impossible to define either an exclusive structural or functional definition or classification system, as has been done for biochemical polymers. Here, we will discuss two types of DOC, humic substances and biologically produced chemicals. In addition, anthropogenic pollutants may also be important, for instance, in human and ecological health, although not in terms of total environmental loads of DOC.

Humic substances (HS) are often the dominant type of DOC, particularly in 'organic-rich' waters such as marshes and in dystrophic waters where microbial activity is limited. HS are a general class of complex, biogenic, macromolecular species. They are heterogeneous and polydisperse and do not have one single structure but exhibit a range of characteristic properties such as molar mass and charging behavior. It has been suggested that heterogeneity is their essential, defining characteristic (10). They are the products of biological decomposition. However, they differ from the biologically produced chemicals of the next section because they have undergone a substantial degree of chemical and biological degradation (humification), resulting in a kinetically stable product resistant to further degradation. They are defined operationally by the extraction system used to separate them from other components such as clays, oxides, and nonhumic organic material. It is important to realize that they are not defined either by structure or function because their structure is too complex and they have no clearly defined 'function' in the biochemical sense. HS are usually divided into three main groups based on their relative solubilities. It is hoped that these reflect to some extent the solubility of HS in the environment and properties such as solid:solution partitioning and transport. In any case, the division results in a simplification of the HS which has analytical advantages. The three fractions are

fulvic acid—soluble at all pHs.
humic acid—soluble at high pH, precipitated in acid (pH 2).
humin—insoluble in acid and base.

The extraction and fractionation scheme have been standardized by the International Humic Substances Society (IHSS). In general terms and considering their heterogeneity, fulvic acids and aquatic HS are more soluble, have a greater density of functional groups, carry a greater charge, and have a lower C:O ratio than humic acid or terrestrial HS, respectively. HS are important in a number of processes and have been much studied. Information has been collected on properties such as their acid–base, metal binding and redox chemistry, photochemistry, structure, functional group content, molar mass, and role as a nutrient. However, a fundamental, unanswered question relates to the extraction and fractionation scheme: To what extent are their properties significantly modified by the extraction system and therefore how are extracted HS different from 'natural' HS?

Biologically produced chemicals consist of a number of well-defined chemicals produced directly from microbial activity. These can further divided into (1) simple monomers and (2) more complex polymers. The monomers include amino acids and monosaccharides that are relatively simple compounds whose structure can be ascertained precisely. In the main, they are produced and consumed rapidly and thus have a short residence time (a few days), low concentration, and are of relatively minor importance. Their concentrations depend on the relative rate of supply and the rate of demand, both controlled primarily by microbial activity. The compounds may be 'free' or bound to humic substances. As for HS, their concentration and fraction of total DOC are variable, depending on the water type and season. More complex, biologically produced polymers, sometimes denoted as biopolymers, are less well studied than HS. However, they can have concentrations similar to HS and can make up 30–40% of total DOC, particularly in eutrophic waters. They consist primarily of proteins and polysaccharides from sources such as plant and microbial cell walls, exudates secreted by microbes, and internal cellular proteins and polysaccharides from microbes after cell lysis. It is possible that HS and biopolymers have differing roles in aquatic systems. For instance, it is well known that HS tends to stabilize colloids and particles and reduce aggregation. However, it is possible that the biopolymers tend to increase aggregation by bridging mechanisms (11) that have important consequences for the chemical and biological composition of natural waters.

In summary, DOC, including some colloidal OC, is clearly extremely important in biological and chemical activity and interactions in the environment. However, despite the progress made and the vast amount of research performed, many fundamental questions await answers.

The properties of water are of importance in many scientific disciplines such as chemistry, biology, geology, nanotechnology, and materials technology. Moreover, the adsorption of water on activated carbon (AC) is an important topic in many different areas of science and technology because water is the most common solvent in nature. The adsorption and phase behavior of polar fluids in carbon pores has been studied extensively, but our understanding of the adsorption of water on carbonaceous materials is still incomplete (1–4).

In recent years, a number of experimental and simulation studies of adsorption of water in pores have appeared in the literature. Some studies have assumed that the adsorption behavior of water in graphite pores is hydrophobic. Although principally hydrophobic adsorbents may contain significant numbers of adsorption centers that can interact with water, it is generally believed that the combination of weak carbon–water dispersive attractions and strong water–water associative interactions are responsible for the complex behavior of water confined in carbonaceous pores.

On the other hand, surface heterogeneity can be introduced by incorporating some polar groups on the surface and those active sites lead to enhanced water adsorption. The loss of water–water H-bonds in graphitic pores is compensated for by the ability of water molecules to form H-bonds with the surface sites in activated carbon pores; the result is a change in the molecular level adsorption phenomenon from capillary condensation in graphite pores to continuous pore filling in activated carbon pores. This leads to an important practical conclusion that water adsorption measurements can be used to determine the number of surface-active centers.

The next important problem is the structure of water adsorbed in pores. Some experimental X-ray diffraction (XRD) (5), differential scanning calorimetry (DSC) (6), dielectric relaxation spectroscopy (DRS) (6), and theoretical studies (6–8) showed the presence of a well-ordered structure of water adsorbed in the graphite micropores at ambient temperature. The adsorbed water has a more ordered structure than bulk liquid, but less than ice, and the structure of water molecules depends on the width of pores (5,8).

One of the most spectacular methods is calorimetry (2,9–22). Careful measurements of the energetic effects accompanying water adsorption on carbon blacks and carbons were studied by scientists from the so-called "Russian school of adsorption" in the 1950s (15,16) and the 1980s (17,18) and by others (9–11,13,14,19–22). Heats of adsorption of water indicate that adsorption is a strong function of surface chemistry. The primary high-energy sites have a significant influence on adsorption and the enthalpy of adsorption at low relative pressures. Three components can be delineated according to measured differential heats of adsorption: (1) chemical adsorption, (2) physical adsorption, and (3) condensation and/or micropore filling. From the point of view of the thermodynamic verification of theoretical models, the first is the most interesting and important. Chemisorption of water on carbons has been previously reported (2,9–11,17,20–22). Summing up, analysis of the experimental data points out that significant discrepancies exist between the role of specific surface groups (e.g., various types, location, density) and their energy of interaction with water molecules and a quantitative description of the isotherm over the entire relative pressure range that is universal for all carbons with low, medium, and high densities of surface groups.

Recently, knowledge of the water–carbon intermolecular interaction and adsorption of water in the microporous region of ACs has been greatly increased by quantum methods (QM) and molecular simulations. A natural starting point for computer simulations is the development of a model potential for the interaction between water and benzene (23,24). Although model potentials already exist for the water/benzene and water/graphite systems (3,23,25), the reliability of these models has not been widely tested. The chemistry and reaction mechanisms of adsorption, as well as of intercalation, are less known, and ab initio QM methods provide a way to examine these phenomena on the atomic level.

The existing water/graphite model potentials give binding energies for a single water monomer interacting with the surface ranging from −6.91 to −18.00 kJ/mol (25). There also exists an experimental value of −15.07 kJ/mol for the binding energy (26). However, these values seem somewhat low in the light of the most recent high-level ab initio results for the water–benzene system, for which the electronic binding energy has been estimated at −19.32 kJ/mol (27). A large basis set at MP2 level (second-order Mřller–Plesset perturbation theory) calculations on a series of fragment models up to $C_{96}H_{24}$ in size was used by Feller and Jordan (28) to estimate the electronic binding energy of an individual water molecule to single-layer graphite (−24.28 ± 1.67 kJ/mol). The interaction between water molecules and graphite structures was clearly stronger with the $C_{96}H_{24}$ model than for the smaller ones. The opposite result was observed for a smaller basis and the Hartree–Fock method (28). These calculations highlight the difficulty of approaching the complete basis set limit in extended systems, such as graphite, using traditional atom-centered basis sets. Feller and Jordan shown (29) that the estimated water–graphite binding energy is slightly larger than that for the interaction between two water molecules (−20.92 ± 0.42 kcal/mol) (30). At the same time, this interaction is significantly smaller than the average electronic binding energy of water monomers in bulk water, where the hydrogen bonding network involves each water molecule in (up to) four hydrogen bonds (30). Nonetheless, the estimated water–graphite interaction is sufficiently large to lead to the conclusion that in carbon, the interaction of water with the graphite walls plays a significant role in determining the structure of the confined water. On the other hand, in the water–benzene complex, the important attractive interactions are the dipole-quadrupole, dipole-induced dipole (induction), and dispersion contributions (23,24,27).

Ruuska and Pakkanen (28) investigated interactions between water molecules and one- and two-layer graphite using the ab initio Hartree–Fock (HF) method. Three one-layer models were used as a reference to investigate the influence of the adsorption site (on top, bridge, and hollow), the orientation of the water molecule, and the size of the model. Only minor differences were found in the three adsorption sites. The behavior of water molecules between two graphite planes was examined using the two-layer model. The coronene planes were moved from a distance of 9 to 3 Å, and the water molecule was placed in the middle of the layers. It is clear from results published by Ruuska and Pakkanen (28) that a water molecule requires relatively much space because it doubles the interlayer distance. Additionally, the features of the two-layer graphite with a water molecule between are similar to those of graphite intercalates.

A more complex problem considered by QM is the interaction of water with a graphite-like surface containing oxygenated hydrophilic groups. It is well known that adsorption is strongly dependent on the presence and arrangement of hydrophilic groups. Tarasevich and Aksenenko (31) used the semiempirical PM3 method to study the interaction of very few water molecules with a partially oxidized graphite surface. The main conclusion of this work is that the water molecules are adsorbed at the hydrophilic center (i.e., the carboxyl) with the formation of microclusters consisting (at initial coverages) of two to three molecules. In the light of these results, Tarasevich and Aksenenko (31) suggested that water adsorption measurements cannot be used to determine the number of active centers even at hydrophobic, and, far less, at hydrophilic surfaces, and methanol was recommended for this purpose.

Hamad and co-workers (32) reported the quantum chemical characterization of a hydrophilic site modeled by a carboxyl group attached to one of the carbon atoms in the graphite layer. They supply values of point charges at the

–COOH sites that have been used to derive a pair potential for the water-active site interaction. Picaud et al. (33) presented molecular dynamics simulations based on a classical potential issued from QM calculations (30) to provide a view of the dynamics and the structure of a water layer on a model surface that consists of a planar graphitic layer plus different numbers of active carboxylic sites. The results of these simulations show that the –COOH groups act as strong trapping sites for a few water molecules that then become nucleation centers for other water molecules that form larger aggregates tied to the –COOH.

The strong effect of PACs on water adsorption was indicated on the basis of the computer simulations (3,8,33–45). The adsorption of water molecules on a hydrophobic surface has been investigated (8,34,35,38–41,44). On the other hand, several types of polar oxygen-containing sites [e.g., carboxyl (42) carbonyl (34,42,43), and hydroxyl (37,42) groups or H-sites (40)] were placed on the surface of carbon with different densities and local distributions to determine the influence of each of these factors on the adsorption of water. Computer simulation models are still being developed and more and more complicated systems have been analyzed. To provide a realistic pore representation and a description of water adsorption, recently, Thompson and Gubbins (3,43,45) suggested the application of a model based on reverse Monte Carlo. In this model, surface sites have been added at random points on the edges of graphene microcrystals possessing random sizes and structures. The major drawback to advanced numerical calculations is the computing power and time needed to simulate isotherms. Therefore, uncomplicated analytic approaches are often favored to simplify consideration and cut down significantly the computation time, for instance, so-called local isotherms obtained from computer simulation are described by a theoretical model [for example, proposed by Talu and Meunier (46)] (37).

Muller and Gubbins (36) showed, that for nonactivated carbon slit pores almost no adsorption occurs until a sharp vertical rise in the adsorption curve is seen and the pore fills suddenly (i.e., capillary condensation occurs). If the surface is doped by active sites, the adsorption isotherm changes drastically, strong bonds are formed between these sites and water molecules, and these adsorbed molecules become nucleation sites for other water molecules to adhere. Thus, these results confirm the role of primary surface sites in the enhancement of water adsorption. Furthermore, Jorge et al. (42) showed that the local distribution of primary sites (carboxyl, hydroxyl, and carbonyl) has a strong effect on the low-pressure part of the adsorption isotherm, whereas the overall site density affects mainly the vapor–liquid phase transition. The type of oxygen-containing group was not of critical importance because more complex groups can effectively be represented by simpler sites. On the other hand, McCallum et al. (37) proposed two alternative mechanisms for water adsorption onto activated carbon walls due to surface sites regularly arranged or a random array (the same site density in both cases was assumed). Five stages are observed from the analysis of both types of simulated adsorption isotherms. Moreover, their behavior is similar to experimental ones.

The theory describing the mechanism of water adsorption on carbonaceous materials proposed by Dubinin and Serpinsky (DS) (1,3,16,47) is probably the most famous. Although the fundamentals of this model were developed 50 years ago, it is still widely used mainly due to its simplicity. Dubinin et al. (16) introduced a phenomenological model of adsorption of water molecules on energy privileged sites which act as primary adsorption centers for water on a predominantly hydrophobic carbon surface. On the other hand, water molecules adsorbed on these sites produce new centers (called elsewhere secondary ones) for further adsorption and cluster formation. Note that the hyperbolic behavior of this equation leads to an infinite adsorbed water concentration at higher pressures. It is well known that the DS model describes well only the data measured on nonporous surfaces and on strongly hydrophobic carbons. The next main limitation is the assumption of unlimited adsorption space. Therefore, the original DS equation has been improved by Dubinin et al. (47), Barton et al. (48–50), and others (10,11,51–55) by taking into consideration new functions describing a decrease in the number of secondary adsorption sites.

On the other hand, it is well known that the simplest method leading to an increase in the affinity of a carbon surface for water vapor is, for example, oxidation of this surface. In such a case, a more hydrophilic surface chemical composition leads to a rise in adsorption, especially in the initial range of the water isotherm (an increase in the enthalpy of adsorption and enthalpy of immersion in water are observed simultaneously (2,9–11,15,17,19–21,56)). For hydrophilic surfaces, DS-like equations (1,3,10,11,51–55) are insufficient and, for example, the D'Arcy and Watt (DW) adsorption isotherm can be applied (57) (however, some attempts to improve the DS model to correct the description of this type of experimental data were recently proposed by Gauden and Terzyk (52,53)). In the original DW model, it is assumed that sorption of water takes place independently on strongly (high-energy) binding primary sites (which are hydrophilic groups) and to a less extent on weakly (low-energy) binding primary sites (located elsewhere on the carbon surface). Moreover, the term describing multilayer adsorption on the so-called secondary centers (which need not be completely occupied before monolayer formation) is assumed in the D'Arcy and Watt isotherm. As shown by Evans et al. (58,59) and others (1,10,11,60,61), the DW equation satisfactorily describes water adsorption data on different adsorbents (not only on carbons). Note that in the opinion of Barton and co-workers (59), as well as in the opinion of the authors of the current study (54,55), it appears that D'Arcy and Watt's isotherm contains some inconsistencies. A serious flaw in this simple treatment is the assumption that Langmuir and the original DS isotherms describe the adsorption of water molecules on the adsorbent independently (i.e., they are connected with various centers). Moreover, the further disadvantage of this model is an unsatisfactory description of experimental adsorption data at higher pressures and enthalpy of adsorption data (10,11,51,54,55) due to the assumption of one kind of surface center on the carbon surface. Therefore, we recently generalized the original D'Arcy and Watt equation taking into account the influence of the concentration of the surface primary sites on the amount of the secondary ones (54,55). Next, we assumed that the adsorbent has regions of heterogeneity on the molecular level (i.e., the various functional groups and/or defects on the surface of the adsorbent). Moreover, water molecules can adsorb on all types of high-energy primary sites obeying the Langmuir isotherm. Summing up, the multisite generalized D'Arcy and Watt (MSGDW) model was proposed (54,55). It can be noticed that finite adsorption space is taken into account by the term $(1 - ka^n)$. From the analysis of the isotherm generated as well as the enthalpy plots, it is seen that these curves are similar to those measured using adsorption calorimetry (10,11,18,20,54,55,63,65), especially at low coverages.

Note that the theories proposed by Dubinin, Serpinsky and D'Arcy and Watt do not give information on the dimensions of adsorbed water clusters (however, it is obvious that their sizes are confined to the available adsorption space). On the other hand, it is well known that water molecules in the bulk state form dimers (64); however, the number of dimerized molecules is not significant at room temperature and standard pressure. In a hydrophobic micropore, water molecules are expected to be more dimerized due to the compressed condition there. In narrow pores, the dimers grow to a greater cluster, which has been used to model the elemental structure of water (1,8,44,65). On the other hand, the pore width is limited, and so the size of the clusters is restricted by the finite pore dimension. Iiyama et al. (66) stated that water forms clusters containing at least five water molecules per cluster.

Different authors, for example, Do and Do (67) and Neitsch et al. (68), applied the above mentioned fundamental information about the size of water clusters to develop new water adsorption models. As a result, the model proposed by Do and Do (67) is based on the growth of a water cluster around surface functional groups, the creation of a pentamer, and penetration of these clusters into the micropore (they remain in the fine pores if they have sufficiently high dispersion energy). Note that the Do and Do model can be considered a so called "hybrid" (similarly to the DW and MSGDW equations) in which the first term describes adsorption on primary sites (it is a BET-type) and the second term refers to desorption from the secondary sites and the adsorption of the pentamer into the micropores (so the equation describes a micropore filling mechanism). Neitsch et al. (68) modified this model. They assumed that the size of the water clusters (pentameter in the original Do and Do model) is the best fitting parameter.

Another well-known model describing water adsorption was proposed by Talu and Meunier (46). Their theoretical isotherm equation assumed the following mechanism of adsorption of water molecules: at low pressures, the behavior of the system is controlled by vertical interactions of a molecule to the surface and the molecules are adsorbed on active sites. At intermediate coverages where the inflection point occurs, the adsorbed molecules form clusters via hydrogen bonding. At high surface coverages where the plateau is observed, the adsorption is limited by micropore filling.

Malakhov and Volkov (69) proposed a cooperative multimolecular adsorption theory describing adsorption of alcohols on glassy polymers. This model was successfully adopted by Rutherford to water adsorption on activated carbons (70). In this theory, the movement of adsorbate molecules to a single adsorption site is taken into account. The cooperative influence is induced by the adsorbed molecule (primary stage) which promotes the entry of other molecules to adjacent centers. In the secondary stage, the model considers a unit triad where a central adsorption site promotes adsorption on either side of the central site. Additionally, secondary centers are defined as side associates forming from the primary surface sites and hence allowing the formation of dimers, trimers, and more complicated clusters. Summing up, the cooperative multimolecular adsorption theory is based on the assuming the existence of one kind of primary and three kinds of secondary centers. However, this theory is not valid to describe adsorption at high relative pressures (70).

Several predictive models have been proposed (in our opinion the most important are mentioned above). Unfortunately, none of them satisfactorily describe the isotherms and the corresponding differential heat of adsorption over the whole pressure range. Moreover, some fundamental aspects are not taken into account in the theoretical considerations: the role of specific surface groups (e.g., various type, location, density), their interaction with water molecules, and the structure of water confined in pores.

THE EFFECT OF CARBON SURFACE CHEMICAL COMPOSITION ON THE MECHANISM OF PHENOL ADSORPTION FROM AQUEOUS SOLUTIONS

Experimental studies of solute adsorption from dilute solutions, especially from aqueous dilute solutions, are carried out in many laboratories, yet the theoretical foundations of this phenomenon are still insufficiently solved (1). Adsorption of phenols on carbons is an important subject especially due to ecological aspects. Therefore, an enormous number of papers has been published in this field. The most important reviews dealing with this problem were recently published by Radovic and co-workers (2) and by Moreno - Castilla (3). The authors consider the changes in the surface chemistry of carbons with changes in pH, and discuss different mechanisms of adsorption proposed in the literature.

The main regularities associated with adsorption of phenol on carbons are as follows (2):

- (usually observed) a decrease in adsorption with a rise in surface acidity (as measured by Boehm titration) and with surface oxidation, problems in determining real equilibrium;
- chemisorption is inhibited by the presence of oxygen surface complexes; therefore, the sites responsible for phenol chemisorption are carbon sites of the active surface area, that is, oxygen free sites located at the edges of graphene layers whereas physisorption occurs all over the surface;
- irreversible adsorption is caused by oxidative coupling in the presence of molecular oxygen.

The authors mentioned pointed out the importance of the papers by Coughlin and Ezra (4) who found that adsorption of phenol decreases after oxidation of carbon, and they suggested that surface oxygen complexes increase the affinity of water to carbon and, therefore, solvent molecules can effectively block some micropores. Magne and Walker (5) suggested that phenol adsorbs by physisorption and chemisorption, but they did not define the mechanism of adsorption. Mattson and co-workers (6), Kipling (7), and Puri (8) emphasized the important role of surface carbonyls (the interaction of the π electrons of the benzene ring with the partial positive charge of the carbonyl carbon atom) in the adsorption of phenol and benzene. Coughlin and Ezra (4) suggested that oxygen chemisorbed on carbon appears to influence phenol adsorption only at low concentrations, when the molecules are thought to be adsorbed parallel to the surface due to nonpolar forces operating over the entire phenol molecules. At higher concentrations, phenol molecules are probably adsorbed in the vertical or "end-on" position due to intramolecular interaction with the hydroxyl groups directed away from the carbon surface. Under these conditions, surface oxygen has little influence on phenol adsorption. They also suggested that the decrease in phenol adsorption after oxidation can be caused by the removal of electrons from the π electron system of the basal planes as a result of oxygen chemisorption. They pointed out that adsorption of phenol takes place between the phenol aromatic ring and the π electron system of carbon basal planes.

In their paper, Radovic et al. (2) pointed out the two possible factors influencing the mechanisms of phenol adsorption on carbons. Citing the paper of Coughlin and Ezra (4) and Mattson and co-workers (9), they concluded that the mechanism of phenol adsorption is determined by so-called "$\pi-\pi$ interactions" and "donor–acceptor complex" formation. The first mechanism assumes that oxygen atoms bound to the carbon reduce the π electron density and weaken the dispersion forces between phenol π electrons ring and the π electrons of carbons. Second, one postulates that the adsorption mechanism is based on the formation of donor–acceptor complexes between the surface carbonyl groups (electron donors) and the aromatic rings of phenol acting as the acceptor and the decrease in phenol adsorption after carbon oxidation can be due to the oxidation of surface carbonyls (9).

The energetics of phenol adsorption was studied by Kiselev and co-workers (10) who considered the effect of the substitution of the benzene ring on the enthalpy of phenol adsorption on graphitized carbon black at "zero" coverage. They showed that the substitution of hydrogen for an OH group in the benzene ring increases the potential energy of interaction of the phenol molecule with the surface of graphitized carbon by about 15 kJ/mole and the substitution for an NH_2 group by about 14 kJ/mole.

The study by Jankowska and co-workers (11) paid attention to the role of basic groups in phenol adsorption, showing that they play a dominant role in this process. They also pointed out that the rise in the ratio of the immersion heat of carbon in benzene to the immersion heat in water leads to a rise in phenol adsorption. For that reason, their study is of extreme importance from the point of view of the adsorption mechanism of phenol on carbons. The authors concluded that phenol adsorption is limited by the micropore volume of the carbons, and the actual position beneath this limit is determined by their acid–base characteristics. The study by these authors performed with Koganovski (12) also pointed out that in the range of low equilibrium concentrations, the pore volume of carbon and also the ratio of acidic/basic group concentration determine phenol adsorption. The larger this ratio, the lower the adsorption. The results of Koganovski and co-workers were also confirmed in the paper by Tarasevich and Rak (13) showing that the modification of coal leading to the introduction of basic surface sites favors the adsorption of weak acid in micropores. There was also Speculation about the role of surface functionalities in phenol adsorption on carbons at infinite dilution. Biniak and co-workers (14) studied the isotherms of phenol adsorption on different carbons, and the main attention was paid to the correlation between the value of adsorbability and acidic properties of carbon surface; however, a linear relationship between these two values was possible only if it was assumed that the acidic groups diminish phenol adsorbability with different contributions. They also pointed out that moderately and slightly acidic groups are the most important ones influencing the mechanism of phenol adsorption on carbons.

Zawadzki (15), applying FTIR spectroscopy, showed that oxidation of the carbon surface does not always lead to a decrease in phenol adsorption. Contrary to others, he showed that phenol uptake increases after oxidation. He explained his results by showing that surface oxidation increases the binding energy between phenol and the carbon surface. The interaction with the surface is partially a specific one and occurs with the participation of π electrons of the adsorbed molecules. The main role is played by hydrogen bonds between phenol and surface oxides. Therefore, he concluded that the effect of the competition between water and phenol in the adsorption on surface-active sites is negligible and cannot result in a decrease in phenol adsorption after oxidation by nitric acid.

Calleja and co-workers (16) compared the different models of diffusion showing that the pore diffusion and linear models describe the kinetic adsorption curves of phenol on carbons satisfactorily. The study by Halhouli and co-workers (17) is one rarely met in the literature, where the effect of temperature on phenol adsorption was studied. They showed that the decrease in pH has no effect on the adsorption capacity of charcoal (unspecified by them) and the rise in the temperature increases the adsorption of phenol.
